We have previously shown that peripheral (i.p.) administration of selective antagonists of the dopamine (DA) receptor subtypes inhibits the positive reinforcing effects of sham-fed sucrose in rats, i.e. sweet taste reward. Here, we compared the effects of equimolar treatment with the D-1 antagonist SCH 23390 and the D-2 antagonist raclopride when given centrally (i.c.v.) or i.p. on 30-min sham intakes of a 10% sucrose solution. Male Sprague-Dawley rats (n=6) were chronically implanted with a lateral ventricular cannula and a gastric fistula. Rats were tested after a 4.75 h food deprivation and 15-min after an i.p. injection (2 $ml\text{-}kg^{-1}$) and i.c.v. infusion (10 $ul\text{-}kg^{-1}$). Baseline intakes were 36 $\pm$ 1 ml/30 min. We found that both receptor antagonists were significantly more potent when given i.c.v. than i.p. For D-1 receptors, doses of SCH 23390 which produced complete and partial significant suppressions when infused i.c.v. had no effect when injected i.p. For D-2 receptors, raclopride was clearly more potent i.c.v. than i.p.; its ID_{50} i.c.v. was subthreshold i.p. These data provide further evidence that central D-1 and D-2 receptor mechanisms mediate sweet taste reward. The neuroanatomical loci of the critical D-1 and D-2 sites remain to be determined.

SUCROSE RESPONSIVENESS PREDICTS THE ONSET OF OBESITY: RELATION TO HYPOTHALAMIC α-NORADRENERGIC SYSTEM. J. A. Grinker, M. Jhanwar-Uniyal, W. D. Block*, M. Darwish* and S. F. Leibowitz. Univ. MI., Ann Arbor, MI 48109 and Rockefeller Univ., NY., NY. 10021.

Chronic administration of norepinephrine into the paraventricular (PVN) and ventromedial (VMN) nuclei increases daily carbohydrate ingestion and body weight gain, while decreasing energy expenditure. The present study aimed to: 1) Categorize rats on the basis of their natural sensory responsiveness to sucrose and determine its relationship to the development of dietary induced obesity; and 2) Relate this sucrose responsiveness and dietary induced obesity to α-noradrenergic receptors in discrete hypothalamic areas.

Male Sprague-Dawley rats on lab chow were tested for sensory responses during acute presentations of sucrose solutions. High and low sensory responsiveness was defined on the basis of slope of regression of solute consumed to concentration. In a 2nd experiment rats received either lab chow or high fat diet (lab chow + 30% wt/wt crisco) for 6 weeks. Six hypothalamic sites, PVN, medial preoptic area, dorsomedial nucleus, VMN, perifornical lateral hypothalamus and arcuate nucleus and median eminence, were micropunched. Standard radioligand binding technique, using the α_2-noradrenergic receptor agonist [3H] p-aminoclonidine (2 nM) and α_1-noradrenergic receptor antagonist [3H] prazosin (0.5 nM) were employed. Results demonstrate: 1) High sucrose responders became obese on high fat diet. 2) High sucrose responsiveness is associated with a small decrease in α_1- and α_2-receptors in the PVN. 3) Density of PVN α_2-receptors is higher in dietary induced obese rats. These results suggests that PVN α-noradrenergic receptors may be involved in development of obesity.

GALANIN INCREASES EXTRACELLULAR NOREPINEPHRINE IN THE PARAVENTRICULAR HYPOTHALAMUS AS MEASURED BY MICRODIALYSIS. S.E. Kyrkouli, B.G. Stanley and S.F. Leibowitz, The Rockefeller Univ., NY.

Galanin (GAL), a neuropeptide which coexists with norepinephrine (NE), specifically stimulates food intake when injected into the paraventricular hypothalamus (PVN) of satiated rats. Evidence suggests that GAL may act by modulating the release of endogenous NE in the PVN.

To test this, GAL (1.0 μg) was injected into the PVN of satiated rats. Using a small, removable microdialysis probe, consecutive samples of dialysate (40 μl/20 min) were collected for 80 min before and 120 min postinjection. Extracellular levels of NE and of the DA and 5-HT metabolites, DOPAC and 5-HIAA, were measured by HPLC-EC. Galanin reliably increased extracellular NE from 3.0 to 7.2 pg ($p<0.01$, by ANOVA). This effect occured within 20 min after the injection and lasted for about 80 min. There was no change in the other metabolites measured. Preliminary experiments with NPY revealed no increase in extracellular NE. These effects, consistent with previous findings, support the view that GAL specifically releases NE in the PVN and suggest that this peptide may stimulate feeding by acting through endogenous NE release.

249.10

DEFENSIVE BURYING OF FLAVORS PAIRED WITH LITHIUM BUT NOT AMPHETAMINE. L.A. Parker. Dept. of Psychology, Sam Houston State University, Huntsville, TX 77341.

Although rats demonstrated avoidance of both lithium- and amphetamine-paired flavored solutions, only lithium-paired flavors elicited a defensive burying response. On each of three conditioning trials, rats were presented with milk solution which was immediately followed by an injection of 127.2 mg/kg LiCl, 3 mg/kg d-amphetamine or 9 mg/kg d-amphetamine in the CS+ groups or by an injection of physiological saline in the CSc groups. One week after the final conditioning trial, the rats were tested for both conditioned avoidance of the flavored solution (CTA) and for defensive burying of the spout of the bottle containing the flavored solution. The amount consumed of milk and water and the change in the height of the bedding material at the point at which the spout entered the chamber were measured at hourly intervals over a seven hr test period. The results support the contention based upon our prior work that lithium-based, but not amphetamine-based, CTAs are mediated by a palatability shift.

249.11

HEAD FIXATION DURING ROTATION INHIBITS FORMATION OF MOTION-INDUCED CONDITIONED FOOD AVERSION IN SQUIRREL MONKEYS. C.R. Wilpizeski and L.D. Lowry*. Dept. of Otolaryngology, Jefferson Med. Col., Philadelphia, PA 19107.

Head fixation is known to inhibit motion-induced vomiting. Because conditioned food aversion (CFA) appears to be another facet of motion sickness, it is hypothesized that immobilization also prevents development of CFA. Squirrel monkeys were exposed for 2 hours per day for 5 consecutive days to each of the following conditions: (1) head fixation without horizontal rotation, (2) fixation during 30 rpm rotation, (3) rotation while nonrestrained. Banana intake was quantified immediately before each daily session. When permitted free movement during continuous rotation, subjects exhibited frequent emesis and a significant daily decrease in banana intake (CFA). On the other hand, when fixed, with or without rotation, neither emesis nor CFA occurred. If the development of CFA is presumed to signify the presence of motion-induced nausea or malaise, then head fixation prevents subjective symptoms as well as objective signs of motion sickness.

249.12

TASTE AVERSION OR HYPERRESPONSIVENESS TO PALATABILITY FOLLOWING AREA POSTREMA LESIONS? Naomi Tomoyasu and Nancy J. Kenney. Dept. of Psychology, Univ. of Washington Seattle, WA 98195.

Area-postrema-lesioned (APX) rats overingest novel, palatable foods. To assess whether the novelty or the palatability of foods underlies such overingestion, 6 APX and 7 sham-lesioned (CONT) rats were fed a palatable AIN diet for the first 8 days after ablation Six APX and 7 CONT rats were fed pelleted chow during this period. For the next 2 days, all rats were offered both AIN and milk adulterated with .05% quinine (choice days).

On the 1st choice day, pellet-fed APX and CONT rats and AIN-fed CONT rats did not differ in food choice consuming 60-86 Kcal AIN and 7-13 Kcal quinine-milk. APX rats which were fed AIN after ablation took only 15 ± 10 Kcal AIN but ingested 37 ± 14 Kcal quinine-milk. On the 2nd choice day, quinine-milk intake of the AIN-fed APX rats decreased to 29 ± 9 Kcal and those of the remaining groups increased to 18-25 Kcal. AIN intakes of AIN-fed APX rats remained low (21 ± 10 Kcal) compared with those of the other groups (61-80 Kcal).

If the novelty of foods is equal, palatability has similar effects on food choice of APX and CONT rats. Ingestion of a food following APX results in an aversion to that food such that APX rats will ingest an unpalatable novel food more readily than a palatable food available since ablation.

CHOLINERGIC, GLUTAMATERGIC, GABAERGIC AND NORADRENERGIC TRANSMISSION IN THE ROSTRAL VENTROLATERAL MEDULLA (RVL) OF NORMOTENSIVE WISTAR KYOTO RATS (WKY) AND SPONTANEOUSLY HYPERTENSIVE RATS (SHR). W.H. Cline*, A.M. May*, L.L. Stephenson*, C.R. Kelley* and S.P. Arneric (Sponsor: T.J-F. Lee), Dept. Pharmacol., Southern IL Univ. Sch. Med., Springfield, IL

We sought to determine whether alterations in the pattern of neurotransmission within the RVL, the presumed tonic vasomotor center, may contribute to the initiation of hypertension in SHR. Male WKY and SHR were studied at 4-6 weeks when systolic blood pressure did not differ between the two groups (WKY: 142±2; SHR: 149±3 mmHg; p>0.05, N=15). In micropunches of the RVL (1.5 mm dia. x 0.5 mm thick), at the level of the C_1 adrenaline cell group, release of endogenous glutamate (Glu), gamma-aminobutyric acid (GABA) and ^{3}H-acetylcholine (^{3}H-ACh) were measured in vitro; while turnover of norepinephrine (NE) following metryosine (250 mg/kg, i.p.) was measured in vivo. Spontaneous and K^+ (55mM)-evoked release of Glu, GABA and ^{3}H-ACh did not differ between WKY and SHR (p>0.05, N=4); nor did NE content (WKY: 11.8±2.9; SHR: 14.4±10.6 ng/mg prot.) or NE turnover (WKY: 1.2±0.9; SHR: 1.2±1.3 ng/mg prot./hr). CONCLUSION: Initiation of hypertension in SHR does not appear to be the result of derangements in neurotransmission within the RVL related to the sympathoexcitatory transmitters Glu and ACh or the sympathoinhibitory transmitters GABA and NE. (Support: American Heart Assn., IL Affiliate, to S.P.A and W.H.C).

250.2

BLUNTED PRESSOR RESPONSIVENESS TO QUINPIROLE, A DA D2 AGONIST, IN CONSCIOUS DOCA/NaCl HYPERTENSIVE RATS IS RELATED TO ANP RELEASE. Y.F. Chen, H. Jin*, R. Paul*, S. Nagahama* and S. Oparil. Hypertension Program, University of Alabama at Birmingham, AL 35294.

The selective dopamine (DA) D2 agonist quinpirole (QUI) causes an acute centrally mediated pressor response in conscious normotensive rats that is blunted in the DOCA/NaCl model. To examine the hypothesis that the blunted pressor response to QUI in DOCA/NaCl rats is due to enhanced atrial natriuretic peptide (ANP) release, plasma ANP and max pressor response (ΔMAP) to QUI were measured in 4 wk DOCA/NaCl (MAP=165±3 mmHg) and control rats (MAP=110±1 mmHg) after QUI (1 mg/kg, i.v.) administration with or without pretreatment of domperidone (DOM, 2.5 mg/kg, i.v.), a peripherally acting DA D2 antagonist. Results (mean ±SEM):

	ANP (pg/ml)			ΔMAP (mmHg)	
	Basal	QUI	QUI+DOM	QUI	QUI+DOM
Control	117±16	260±59*	103±14	22±2	32±3
DOCA/NaCl	260±32Δ	501±52*Δ	273±47Δ	10±2Δ	33±5

Δp<0.05 compared to control; *p<0.05 compared to basal, n=8-10. In addition, replacement with exogenous ANP (1 μg/kg, i.v.) attenuated the pressor response to QUI in DOM pretreated DOCA/NaCl and control rats. These data indicate that peripheral DA D2 receptors modulate ANP secretion in the rat and support the hypothesis that the blunted pressor response to QUI in DOCA/NaCl rats is related to enhanced ANP release.

250.3

BETA-2 ADRENOCEPTOR MEDIATED VASODILATION IN THE HYPERTENSIVE RAT. R.F. Kirby, C.H. Woodworth, & A.K. Johnson. Depts. of Psychology and Pharmacology and the Cardiovascular Center, University of Iowa.

Activation of peripheral beta-adrenoceptors by circulating epinephrine produces vasodilation in the skeletal muscle vasculature of the rat. We have previously found that blockade of beta-2 adrenoceptors during an acute stressor leads to enhanced pressor responses in the borderline hypertensive rat (BHR) but is without effect in the normotensive Wistar-Kyoto (WKY). The enhanced pressor response of the BHR appears to be a trait inherited from the spontaneously hypertensive rat (SHR) which also exhibits exaggerated pressor responses to acute stress following beta-2 adrenoceptor antagonism. These results suggested that the vasculature of BHR and SHR may be more sensitive to the vasodilatory effects of circulating epinephrine. However, in the present study SKY, BHR, and SHR showed equivalent depressor responses to direct beta-2 adrenoceptor activation with graded doses of salbutamol. The results indicate that differential release of adrenomedullary epinephrine during acute stress may occur among the three strains producing greater activation of beta-2 adrenoceptors that mediate vasodilation.

DEPRESSOR EFFECT OF ANGIOTENSIN II IN THE BRAINSTEM OF RENAL HYPERTENSIVE RATS. R, Mosqueda-Garcia, C.J. Tseng*, M. Appalsamy*, D. Robertson*. Div. Clinical Pharmacology, Vanderbilt University, Nashville, TN 37232.

Angiotensin II (AII) is a potent vasoconstrictor. Central or peripheral administration of AII increases BP, more pronounced in spontaneously hypertensive (SHR) than in normotensive rats. In this study we investigated the sensitivity of renal hypertensive rats to AII administration into the area postrema (AP) and in the nucleus of the solitary tract (NTS).

Two kidneys one clip renal hypertensive Sprague-Dawley rats (renal-HTN), sham-operated normotensive (NT) and (SHR) were anesthetized with urethane and placed in a stereotaxic frame. The dorsal surface of the medulla was exposed for intra-AP and NTS administration of AII (5, 20 and 200 ng) and adenosine (615 ng). Administration of 200 ng of AII into the AP increased BP and HR in NT rats (+13±5 mmHg; +10±4 b/m) and in SHR (+18±2 mmHg; +20±2 b/m). In contrast, in renal-HTN rats the same dose of AII decreased BP and HR (-59±5 mmHg, -73±9 b/m). The smaller doses of AII also decreased cardiovascular parameters in this group of rats, whereas pressor responses were observed in the other groups of rats. Similarly, in the NTS, AII was depressor in the renal hypertensive rats and pressor in the other two groups. In contrast, intra-AP or NTS adenosine elicited similar qualitative depressor effects in the 3 groups of rats, with the renal-HTN rats the most sensitive and the SHR the least sensitive. These results indicate that in the development of renal hypertension central structures change not only the sensitivity but also the type of final cardiovascular response to AII.

GABAergic NEURONS AND OPIATE RECEPTORS ARE INVOLVED IN INITIATION OF GENETIC HYPERTENSION. Bang H. Hwang. Terre Haute Ctr. for Medical Education, Indiana Univ. Sch. of Med., Terre Haute, IN 47809.

Spontaneously hypertensive (SHR) rats and Wistar-Kyoto (WKY) rats were used. The μ and δ oplate receptor binding, as well as GABAergic terminal density in the brainstem were evaluated. Blood pressure was determined by tail-cuff method. The μ and δ oplate receptor binding was studied by using ^{125}I-FK33824, and ^{125}I-enkephalin plus morphiceptin respectively. GABAergic terminals were revealed by immunocytochemistry using antibody to glutamic acid decarboxylase (GAD). This study showed that μ receptors were increased in the nucleus tractus solitarius (NTS), dorsal motor nucleus of the vagus, and spinal trigeminal nucleus at the pre-hypertensive stage (3 weeks of age) of SHR rats, but not at the well-established hypertensive stage (11 weeks of age). In contrast, δ opiate receptors were decreased at the pre-hypertensive stage. GAD-positive GABAergic terminals were reduced in the NTS of SHR rats at the pre-hypertensive stage, but not at the hypertensive stage. Collectively, this study provides evidence to support that GABAergic neurons and opiate receptors may play important roles in initiating hypertension seen in SHR rats, but are not closely associated with the maintenance of hypertension. (supported by NIH grant NS25087).

250.6

CONTRIBUTION OF PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS (PVH) TO THE MAINTENANCE OF TWO-KIDNEY ONE-CLIP (2K1C) RENAL HYPERTENSION. T.X. Zhang* and J. Ciriello (SPON: J.P. Girvin). Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

We have previously shown that PVH is involved in the hypertensive process in several different experimental models of hypertension. The present study was done to investigate the contribution of PVH neurons to the maintenance of the elevated arterial pressure (AP) in the 2K1C model of renal hypertension. Rats were randomly assigned to two groups: in one group a 0.2 mm diameter clip was placed on the left renal artery and in the other group the artery was exposed but not clipped. Thirty days later the hypertensive 2K1C and the normotensive sham-clipped animals were divided into two additional groups: one group received bilateral electrolytic lesions of PVH and the other sham-PVH lesions. In the sham-clipped rats PVH lesions did not alter AP. However, AP in the 2K1C-PVH lesioned rats (120 $\pm$ 7 mmHg) was significantly reduced, compared to 2K1C-sham-PVH lesioned animals (167 $\pm$ 8 mmHg), to a level not different from sham-clipped rats that received PVH lesions (118 $\pm$ 3 mmHg) or sham-PVH lesions (124 $\pm$ 5 mmHg). AP remained approximately 52 mmHg lower in the 2K1C-PVH lesioned group then in the 2K1C sham-PVH lesioned group throughout the study. These data suggest that renal hypertension is dependent on the integrity of PVH neurons. (Supported by HSFO).

250.7

AFFERENT RENAL NERVE (ARN) STIMULATION ALTERS PLASMA LEVELS OF VASOPRESSIN AND OXYTOCIN IN THE AWAKE RAT. J.K. Simon*, J. Ciriello and N.W. Kasting (SPON: T.E. Feasby). Dept. of Physiology, Univ. of Western Ontario, London, Canada and Dept. of Physiology, Univ. of British Columbia, Vancouver, Canada.

We have recently shown that stimulation of ARN in the cat increases plasma levels of arginine vasopressin (AVP) and in the rat excites putative neurosecretory AVP cells in the hypothalamus. The present study was done to obtain direct evidence for changes in plasma levels of AVP and oxytocin (OXY) in the conscious rat during electrical stimulation (5 min, 10s pulse train, 40 Hz, 5 ms pulse duration, 500 μA) of the left ARN using bipolar cuff electrodes. Rats were instrumented with arterial and venous cannulae for the recording of pressure and removal of blood samples for assay of AVP and OXY by radioimmunoassay, respectively. Blood samples were taken 1 hr prior to and at the end of the 5 min ARN stimulation period. ARN stimulation elicited a pressor response (8$\pm$2mmHg) and significantly elevated plasma levels of AVP from 0.65$\pm$0.28 pg/ml to 2.00$\pm$0.48 pg/ml and of OXY from 6.36$\pm$1.34 pg/ml to 12.88$\pm$3.24 pg/ml. These data demonstrate that in the conscious rat afferent inputs from the kidney contribute to reflex pathways that alter the release of the neurohypophyseal peptides AVP and OXY to influence circulatory and body fluid homeostasis. (Supported by HSFO).

250.8

EFFERENT CONNECTIONS OF THE MEDIAN PREOPTIC NUCLEUS (MnPO) IN THE RAT. S. Roder* and J. Ciriello (SPON: J.D. Cook). Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

The MnPO has been implicated in cardiovascular and body fluid regulation. However, the efferent connections of the MnPO have not been adequately mapped. This study was done to investigate the distribution of fibers originating in MnPO using the anterograde transport of the tracer Phaseolus vulgaris leucoagglutinin (PHA-L). PHA-L was iontophoresed into MnPO and after a survival period of 7-12 days, transverse sections of the forebrain and brainstem were processed immunohistochemically for the demonstration of PHA-L containing fibers and terminals. Cells within the injection site containing PHA-L were observed in the dorsal portion of MnPO. In the forebrain these cells were observed to give rise to axons projecting to the medial and lateral septum, vertical limb of the n. of the diagonal band of Broca, medial preoptic n., supraoptic n., subfornical organ, paraventricular n., lateral and posterior hypothalamic n., and medial habenular n. In the brainstem, fibers and terminals were observed in the central grey, dorsal tegmental n. and in the dorsal, median and pontis raphe n. These data have provided evidence for the anatomical substrate by which MnPO can influence circulatory and body fluid regulatory mechanisms. (Supported by HSFO).

250.9

NUCLEUS MEDIANUS (NM) LESIONS ALTER THE DRINKING RESPONSE TO ANGIOTENSIN II (ANG II) INJECTED INTO THE SUBFORNICAL ORGAN (SFO). M.B. Gutman*, D.L. Jones and J. Ciriello (SPON: G.G. Ferguson). Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

It is known that ANG II acts at SFO to elicit increases in arterial pressure (AP), drinking and vasopressin secretion and that SFO projects directly to NM. To investigate the role of NM in the AP and drinking responses to ANG II injected into SFO or intravenously studies were done in awake unrestrained rats. Microinjection of ANG II into SFO elicited drinking (7.9 $\pm$ 0.8 ml in 15 min) and pressor (15 $\pm$ 1 mmHg) responses. Intravenous infusion of ANG II elicited a pressor response (36 $\pm$ 3 mmHg) but not a drinking response. Lesion of cells in the dorsal NM (dNM) with kainic acid resulted in a significant attenuation of the drinking but not the pressor response to ANG II injected into SFO (8.3 $\pm$ 0.8 ml in 15 min pre-lesion and, 1.9 $\pm$ 1.4 ml in 15 min post-lesion). Injection of the vehicle into dNM and kainate lesions of structures adjacent to dNM had no effect on the pressor or drinking responses. Similarly there was no effect of these lesions on the pressor response to ANG II injected intravenously. These data indicate that cells in dNM are part of a forebrain neural circuit that mediate the drinking but not the pressor response to ANG II acting at SFO. (Supported by HSFO).

250.10

EFFERENT PATHWAYS FOR SYMPATHETIC RESPONSES FROM INSULAR CORTEX. D.F.Cechetto, V.C.Hachinski, S.J.Chen *. Robarts Research Inst./Dept.of Physiology, U.of Western Ontario, London, Ont. N6A 5K8.

Insular cortex (IC) stimulation elicits a number of autonomic responses. The IC projects directly to subcortical sites, including the lateral hypothalamic area (LHA), the parabrachial nucleus (PB) and the nucleus of the solitary tract (NTS), which in turn project to sympathetic preganglionic areas. To determine which sites mediate the sympathetic responses originating from the IC, sympathetic nerve discharge (SND) responses resulting from IC stimulation were recorded before and after synaptic block with cobalt (COB) injections in the LHA, PB or NTS. Blood pressure, heart rate and multi-unit SND from the renal nerve were continuously monitored in 31 rats anesthetized with a-chloralose or urethane. Single pulse IC stimulation (200 uA, 1.0 ms) elicited an early increase and two later decreases in SND in chloralose-anesthesized animals, while urethane-anesthesized animals did not exhibit the initial increase. Ipsilateral COB injections (500 nl) into LHA significantly attenuated all SND responses elicited by IC stimulation. COB into the ipsilateral PB did not affect the SND responses. Ipsilateral COB injections into the NTS (500 nl) significantly enhanced the initial increase in SND. Bilateral COB injections into the LHA or NTS did not significantly attenuate or enhance the SND changes compared to ipsilateral injections only. These results suggest that the LHA is a necessary component of the descending pathway for sympathetic responses originating in the IC, while synaptic blockade in the NTS enhances sympathetic excitation elicited from IC.

250.11

FEAR-INDUCED CHANGES IN PLASMA CATECHOLAMINES AND CORONARY HEMODYNAMIC FUNCTION. Richard L. Verrier and Fernando A. Moya-Huff. Cardiovascular Laboratories, Harvard School of Public Health, Boston, MA 02115.

We have demonstrated that provocation of an angerlike state in dogs produces significant elevations in plasma norepinephrine (NE) levels with only moderate alterations in epinephrine (E) concentration. These changes are accompanied by increases in heart rate (HR), systemic blood pressure (BP), and coronary blood flow (CBF) (Circulation 75:249, 1987). The goal of this study was to model the fear state and to characterize the attendant neurohumoral and hemodynamic responses. Five dogs were instrumented for determining ECG, BP, and left circumflex CBF. Fear was induced by having an aggressive animal challenge the test subject's access to food. This paradigm elicited intimidation behavior as evidenced by cowering, ear retraction and somatic tremor. (Means ± SEM; *p<0.05).

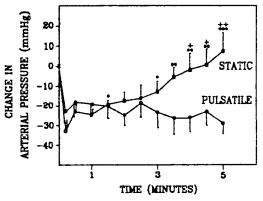
	Control	Fear	% Change
HR (bpm)	96±4	132±5*	38
BP (mmHg)	96±4	119±8*	24
CBF (ml/min)	27±6	40±11*	48
NE (pg/ml)	245±24	378±53*	54
E (pg/ml)	187±33	328±48*	75

Thus, the fearlike state elicited significant hemodynamic changes and a prevalent increase in plasma E over NE. The neurohumoral response is distinct from that produced by anger, wherein NE is dominant.

250.12

RAPID RESETTING OF THE REFLEX RESPONSES TO STATIC AND PULSATILE PRESSURES AT THE ARTERIAL BARORECEPTORS IN CONSCIOUS DOGS. D. Mendelowitz* and A.M. Scher* (SPON:F.R. Robinson, Jr.). Univ. of Washington, Seattle, WA. 98195

Rapid resetting of the baroreceptors occurs within 5 minutes. The reflex from these receptors, (the baroreflex) has been shown to reset in some studies, but not in others. In many studies in which resetting was observed the baroreceptors were exposed to static pressure. In all studies in which resetting did not occur pressure remained pulsatile. This study tests the hypothesis that static pressures elicit transient responses and pulsatile pressures evoke sustained baroreflex responses. One baroreceptor region, the right carotid sinus, was surgically prepared for reversible isolation in 6 dogs with all other arterial baroreceptors denervated. Sinus pressure was changed from control levels to either an a) elevated static or b) elevated pulsatile pressure for five minutes. The elevated static pressure caused an initial decrease in arterial pressure which decayed rapidly, -32.7±5.5 mmHg initial, +7.6±8.9 mmHg at five minutes, p<.005. In contrast with elevated pulsatile pressure the responses were sustained throughout the sinus pressure change, -23.2±5.3 mmHg initial, -29.0±4.8 mmHg at five minutes, p>.4. Thus pulsatile pressures may prevent the resetting that occurs with static pressures at the baroreceptor and/or within the central nervous system.



BLOOD/BRAIN/NERVE BARRIER I

251.1

HOW SIGNIFICANT IS THE BLOOD-BRAIN BARRIER? M. Tangoren*, R. Broadwell, E. Moriyama*, C. Oliver*, and A. Wolf* (SPON: M. Salcman). Div. Neurosurgery, Univ. MD Sch. Med., Balto., MD 21201 and NIDR, NIH, Bethesda, MD

We reported previously that labeling of CNS pericytes with blood-borne tracer protein in the mouse was attributed to the absence of a cellular barrier at the level of the meninges (J. Comp. Neurol. 251: 260, 1986). Blood-borne HRP escapes fenestrated vessels in the dura mater, presumably passes extracellularly through the arachnoid mater, reaches the pial surface for entry to the perivascular clefts, and eventually is endocytosed by pericytes throughout the CNS. Conversely, blood borne lectin-HRP fails to enter the CNS of mouse and rat by this extracellular route, due to lectin-binding occluding open junctions in the arachnoid mater, but does undergo adsorptive transcytosis through the BBB (PNAS 85: 632,1988). We now report that the meninges of the rat are not a barrier to blood-borne HRP and perhaps peptides. A series of rats was injected intravenously or into the carotid artery with 0.5-1ml of 40-250mg of native HRP/saline or with 0.67-1ml of transferrin-HRP (1-7mg/ml); post-injection times were 10mins-2hrs. At 10mins. the macromolecules were endocytosed by cerebral endothelia with no evidence for transcytosis through the BBB; however, cerebral pericytes were labeled with HRP reaction product at 1hr. Reaction product of native HRP was evident on the pial surface and within the Virchow-Robbins spaces at 10mins. Perfusion-fixation of the brain at 10mins but not after 30mins resulted in extravasations of HRP throughout the forebrain. The results in the rat suggest that, as in the mouse, blood-borne proteins, peptides (i.e., transferrin, insulin) and other molecules may circumvent the BBB by way of the meninges for entry to the CNS and that perfusion-fixation of the CNS may rupture tight junctional complexes between endothelial cells. Similar studies in the primate are in progress. Supported by NINCDS grant 18030.

251.2

HOMING TO THE CNS OF ^{14}C-LABELED MYELIN BASIC PROTEIN (MBP) REACTIVE LYMPHOCYTES MEDIATING ADOPTIVELY-TRANSFERRED EAE. A.H. Cross*, B. Cannella* and C.S. Raine, Dept. of Pathology, Albert Einstein Coll. of Med., Bronx, NY 10461.

Experimental allergic encephalomyelitis (EAE) in SJL/J mice is well-characterized pathologically in its acute and chronic forms and is known to be mediated by T cells of helper phenotype. The present study analyzed the CNS homing, distribution and ultimate fate of labeled effector cells in EAE induced by adoptive transfer. LNC blasts from syngeneic SJL/J donors immunized 10 d previously with MBP were labeled with ^{14}C-thymidine after 3 d stimulation in vitro with MBP. Recipients developed an illness indistinguishable from that induced by unlabeled cells. At day 8, ^{14}C cells were noted in perivascular (pv) cuffs in the spinal cord and cerebrum. During chronic phases, ^{14}C cells were still present in pv cuffs, representing <5% of cuff cells. During relapses, ^{14}C cells were again limited to pv infiltrations in CNS areas which correlated with new signs. In comparison to acute illness, ^{14}C cells at relapse were fewer. Despite extensive inflammatory infiltration into CNS parenchyma, ^{14}C, MBP-specific cells were confined to the immediate pv cuff.

In view of very small numbers of specific cells being apparently sufficient for extensive disease and their restriction to pv areas, we speculate that the ^{14}C, MBP-immune lymphocytes orchestrate the influx of other cells that mediate demyelination. [Supported by NMSS FG-749-A-1 and NS 08952]

ANTIBODY INFLUX FROM BLOOD TO CSF IN CSF-IMMUNIZED RATS. H.F.Cserr, M.J. DePasquale*, and P. Knopf*. Physiology and Biophysics, Brown University, Providence, RI 02912.

We have previously demonstrated that the ratio of antibody titers, CSF/serum, to human serum albumin (HSA) is elevated following HSA injection into a lateral cerebral ventricle, as compared to intramuscular injection in Sprague-Dawley rats. We have now investigated the possibility that antibody transport from blood to CSF contributes to the elevated CSF antibody titers in CSF-immunized animals. Rat anti-HSA serum was infused i.v. for 180 minutes, using a schedule which yielded a step-increase in serum anti-HSA titer. CSF was withdrawn from the cisterna magna, without a change in pressure, at a rate of 2 µl/min. Experiments were conducted in non-immunized, control rats and in rats previously immunized via CSF with up to 3 doses of 100 µg HSA. CSF albumin, CSF total protein, and changes in CSF and serum anti-HSA titers were measured. CSF albumin (25+4, n=17) and total protein (79+5, n=26) remained unchanged and in the normal range in all animals, indicating that brain barrier function was normal. In the control group, Δ CSF/Δ serum titer ratios for anti-HSA ranged from 1/7600 to <1/26,000 and, in 15 of 21 of the CSF-immunized rats, from 1/5,700 to <1/38,000. In contrast, 6 of the CSF-immunized rats showed elevated titer ratios, ranging from 1/350 to 1/3,000. Results are consistent with facilitated antibody transport from blood to CSF in 30% of the rats immunized by HSA injection into CSF. Supported by PHS NS11050.

TRACER STUDIES OF PERIVASCULAR SPACES SURROUNDING BLOOD VESSELS ON THE SURFACE OF THE RAT BRAIN. T. Ichimura* and H.F. Cserr. (SPON: K. Chapman). Physiology & Biophysics, Brown U., Providence, RI 02912.

Recent studies suggest that blood vessels on the brain surface are surrounded by a perivascular space (PVS), which is continuous with the perivascular (or Virchow Robin) space within the parenchyma (e.g. Am. J. Physiol., 246:F835 1984). We have examined relationships of the surface PVS to the parenchymal PVS and general subarachnoid space (SAS) in Sprague Dawley rats. Anatomical tracers (India ink, or 1% Evans blue and 5% albumin in saline) were injected over 15-30 min using a glass micropipet through the intact dura into a PVS, the overlying SAS, brain tissue (1 µl), or cisterna magna (30 µl). Tracer distribution was followed for up to 90 min, by direct observation and in unfixed, lyophilized or fixed sections. After 30 min, tracers injected into the PVS of surface vessels distributed preferentially within surface and parenchymal PVSs, but also leaked into SAS. After 60 min, tracer injected into any of the four injection sites distributed widely, appearing in and around PVSs of the circle of Willis (CW) and in the SAS along the olfactory tract. This indicates that PVSs around parenchymal and surface vessels, including the CW, are continuous and in open communication, but that they are not entirely separated from the general SAS. Tracer movement within the PVS is not unidirectional, possibly reflecting the mixing action of the vascular pulse. Supported by NIH grant NS-11050.

ELECTROLYTE MOVEMENT IN RAT RETINA STUDIED BY ION MICROSCROPY M.S. Burns* (SPON: R. Joy). Dept. Ophthal. Univ. California, Davis, CA 95616

The retinal pigment epithelium (RPE)/choriocapillaris (CC) complex forms the outer blood-retinal barrier (BRB) and the retinal vessel endothelial cells form the inner BRB. The relative movement of electrolytes across these barriers was studied using secondary ion mass spectrometry equipped with a digital image analysis system. Long-Evans rats were perfused for 5 minutes prior to sacrifice with normal Ringer's solution containing Na and K, or with Ringer's in which Li was substituted for Na and Rb for K. Freeze-drying techniques were used for sample preparation to preserve microlocalization of diffusible ions. Selected areas of retina were analyzed quantitatively.

There was no difference in electrolyte content between the central and peripheral retina and there was no difference in Na and K content with either normal or Li/Rb perfusion, indicating that Li and Rb were acting as tracers. No barrier to Na (Li) movement was apparent in the choroid to sclera pathway, but Li did not leave the inner retinal vessels, despite a high local intravascular Li concentration. Li moved from the CC into the retina and formed a gradient across the retina. High endogenous content of Rb was found in these retinae. In regions with selective loss of the RPE cells, Li and Rb freely entered the neural retina, but Na and K levels were unchanged. These data show the importance of the RPE in controlling retinal electrolyte content, but also indicate that inner retinal homeostatic mechanisms maintain Na and K levels in the absence of RPE.

C-FRAGMENT OF TETANUS TOXIN: A NONTOXIC CARRIER FOR DELIVERY OF PROTEINS INTO THE CENTRAL NERVOUS SYSTEM. P.S. Fishman*, J.M. Savitt*, and D.A. Farrand* (SPON: N. Bass). VA Res.Labs, Dept. of Neurology, Univ. of Maryland, Sch. of Med.,Baltimore, MD 21201.

Tetanus toxin and its atoxic carboxyl terminus fragment (C-fragment) bind avidly to receptors concentrated at synapses, and are readily internalized by neurons through endocytosis. Previous investigators have been successful in using C-fragment as a vector to enhance internalization of other proteins by neurons in tissue culture, and by neurons innervating a local injection site. We have previously demonstrated the systemically administered C-fragment is internalized by all neuronal types with processes outside the blood-brain barrier (particularly motorneurons). We now have shown that proteins coupled to C-fragment are internalized from a systemic source in a similar distribution. Horseradish peroxidase (HRP) was covalently linked to C-fragment using the periodate activiation procedure of Nakane and Kawoi. Mice were injected by intraperitoneal, intravenous,and intramuscular routes with O.2 - 2 mgm of C-fragment-HRP conjugate. Animals were sacrificed at 1-5 days after injection and nervous sytem tissue analyzed with HRP histochemistry. Intense labeling of motorneurons was seen in all animals. Peroxidase activity was also observed in sensory ganglion cells, preganglionic autonomic neurons and neurons of several hypothalamic nuclei. Minimal labeling of neurons in a similar distribution was seen after injection of free HRP in excess of 50 times the injected HRP content of C-fragment-HRP conjugates. All animals remained well until the time of sacrifice. C-fragment-HRP conjugates are polymeric with molecular weights in excess of 500 kD. Conjugates containing C-fragment; HRP; and a third protein have also been synthesized using the same procedure. We are currently examining these conjugates as a means of enhancing the delivery of proteins of choice into the CNS. (Supported by the Veterans Administration.)

BLOOD-TO-BRAIN TRANSPORT OF MPTP. N.J. Riachi*, J.C. LaManna, and S.I. Harik Dept. of Neurology, CWRU, Cleveland, Ohio 44106

Systemic MPTP causes acute Parkinsonism in man and other primates. With intracarotid administration, even very small amounts of MPTP produce neurotoxicity. To investigate the blood-brain barrier transport characteristics of MPTP, we used the indicator-fractionation method with a bolus injection of [^{3}H]MPTP and [^{14}C]butanol into the right atrium of anesthetized adult male Wistar rats. The animals were decapitated at intervals ranging from 20 sec to 30 min after the bolus injection. Regional brain samples and the anterior tongue were obtained immediately after decapitation for dual isotope counting. Like butanol, MPTP was almost completely extracted by the brain on the first pass. However, while butanol was rapidly washed out as a function of time, MPTP and/or its products were trapped in the brain. The relative ^{3}H to ^{14}C extraction ratio thus increased from ~ 1 at 20 sec to ~ 12 by 30 min. The tongue failed to concentrate MPTP or its metabolites like the brain, with the ratio of ^{3}H to ^{14}C not exceeding 2 by 30 min. Metabolism of MPTP into polar compounds, less likely to cross biological membranes, may explain its retention by neural tissue. The exact site at which MPTP is trapped within the brain remains unknown. Supported by USPHS grant HL-35617.

CEREBRAL IRON UPTAKE IN THE YOUNG RAT. A.J. Dwork*, M. Durkin*, M. Osman*, N.J. Willson* and A.I. Barkai* (SPON: R.R. Goodman). NYS Psychiatric Inst., NY, NY 10032.

In the rat, iron acquired by the brain early in postnatal life undergoes little subsequent exchange with peripheral stores, and a deficiency of dietary iron at this time leads to an irreparable deficit in cerebral iron. The current study examines the extent of cerebral uptake and the neuroanatomic distribution of iron absorbed at various ages. Two-, 4-, or 6-week-old rats were injected i.p. with a trace dose of $^{59}FeCl_3$ and were sacrificed after various intervals (up to age 8 weeks) by cardiac perfusion. At the time of sacrifice, radioactivity was determined in blood, serum, and the left half of the brain; the right half was sectioned for autoradiography. When the injection was made at 2 weeks of age, brain radioactivity remained constant from the second postinjection day. However, the distribution of radioactivity became gradually more discrete to resemble that of ferric iron in the brain of the adult rat. The ratio of brain/blood radioactivity rose gradually, due to a loss of blood radioactivity, and showed the same 1.6-fold increase between 2 and 4 weeks postinjection for rats injected at age 2 or 4 weeks. The brain/blood ratio 2 weeks postinjection for rats injected at 4 or 6 weeks of age was 25% that for rats injected at age 2 weeks, indicating an active but diminished uptake by the brain at the later ages. Serum radioactivity was 4% that of blood 1 day postinjection and low enough thereafter to be explained by microscopic contamination with hemoglobin, suggesting that intracerebral rearrangement, rather than exchange between brain and blood, accounts for the changes in distribution.

ENDONEURIAL CAPILLARY PA TO ALBUMIN IN SCIATIC NERVES OF RATS MAINTAINED ON A LEAD DIET. A. Weerasuriya*, G. L. Curran*, and J. F. Poduslo. (SPON: J. W. McLaren) Membrane Biochem. Lab., Depts. Neuro. & Biochem./Molec. Biol., Mayo Fdn., Rochester, MN 55905

The permeability coefficient-surface area product (PA) of endoneurial capillaries in rat sciatic nerve to radiolabeled rat serum albumin (RSA) was examined in rats maintained on 4% lead carbonate and their corresponding pair-fed controls. Circulation time for the i.v. injected ^{125}I-RSA bolus was 60 min and 2 min for ^{131}I-RSA (residual endoneurial vascular volume indicator). After 5 weeks of the lead diet, there was no significant difference between the PA of lead fed rats and that of their pair-fed controls, even though their blood lead levels were in excess of 1.8 µg/ml. At 6 weeks, the PA in lead fed rats was 50% more than that of the pair-fed controls and by 8 and 10 weeks the PA of lead fed rats was more than double of that in the pair-fed controls. The above results are in accordance with previously observed increases of blood nerve barrier permeability in the initial stages of lead neuropathy. Furthermore, these results show that the i.v. bolus injection technique can be used to assess small changes in endoneurial capillary PA to large protein molecules in other models of experimental neuropathy. GALACTOSEMIA AND ALDOSE REDUCTASE INHIBITOR: EFFECT ON BLOOD-NERVE BARRIER PERMEABILITY AND WATER CONTENT OF THE RAT PERIPHERAL NERVE. K.C.Wadhwani, L.E. Caspers-Velu*, V.A. Murphy, Q.R. Smith, P. Kador*, and S.I. Rapoport. Lab of Neurosciences, NIA, NIH, Bethesda, MD 20892.

Galactosemia causes peripheral neuropathy such as nerve edema. It is not known, however, whether the permeability of the blood-nerve barrier (BNB) is altered in galactosemic animals. We, therefore, determined and compared the permeability-surface area product (PA) for sucrose at the BNB, using an i.v. bolus injection technique (Ohno et al, Am J Physiol, 235:H299, 1978), and the water content of the sciatic nerve in rats fed a normal diet, a 50% galactose diet or a diet containing both galactose and aldose reductase inhibitors (Statil, 0.04% or Alcon 1576, 0.0008%), for a period of 9-11 months. The PA at the blood-brain barrier (BBB) was also determined for comparison. Mean (±SEM) PA's ($\times 10^{-5}$ ml/s.g wet wt, n=7) at the BNB and BBB in control rats were 1.8±0.2 and 1.1±0.1, respectively. Values in a galactose-fed or galactose+aldose reductase inhibitor-fed animals did not differ from control animals ($p > 0.05$). Water content (% wet wt, n=6-8) in the nerve, however, increased significantly in galactosemic rats compared to control rats (76±1 vs 66±1) ($p < 0.01$). Aldose reductase inhibitors reduced water content to control values (Statil: 69±1; Alcon 1576:67±1). Our results show that galactosemia does not alter BNB permeability but leads to nerve edema, which can be prevented by aldose reductase inhibitors.

NOVEL INTERCELLULAR JUNCTIONS IN INVERTEBRATE CNS. N.J. Lane (SPON: P.D. Evans). AFRC Research Unit, Dept of Zoology, Downing Street, Cambridge, CB2 3EJ, UK.

The peripheral glial cells that surround the CNS in certain groups of primitive arthropods are characterised by unusual junctions. In centipedes and millipedes, (Myriapoda), these glial cells are associated by filamentous "linkers" which produce a reduction, but not an occlusion, of the intercellular cleft. Exogenous tracers, such as HRP or La^{+++}, are unable to penetrate beyond these glial clefts, however. This suggests the existence of an extracellular matrix "barrier" in conjunction with the linkers. These linker junctions are interposed between conventional gap junctions. In freeze-fracture replicas, loosely aggregated gap junctional connexon plaques fracture onto the E face, together with linear alignments of intramembranous particles and furrows; P face ridges complementary to the EF furrows also occur, but it is not clear how the linkers connect into the intramembranous structures, if at all. These structural modifications, or linker junctions, are quite distinct from the conventional tight or septate junctions found between the outer glial cells in more highly evolved arthropods such as the insects and arachnids, and appear to represent a new category of intercellular junction.

SYNAPTIC STRUCTURE AND FUNCTION II

252.1

A LINK BETWEEN ACIDIFICATION AND MEMBRANE CYCLING IN THE TERMINALS OF FROG RETINAL PHOTORECEPTORS. D. Sulzer* and E.Holtzman. Dept. of Biol.Sci., Columbia U., NY 10027

The presynaptic terminals of photoreceptors in Rana pipiens retinas maintained in oxygenated Ringers accumulate the weak-base vital dyes, Neutral Red and Acridine Orange. Dye accumulation is prevented by inhibitors of glycolysis (IAA) and of respiratory metabolism (KCN, DNP). By analogy to observations on non-neuronal cells, we infer that the terminals, or compartments within them, maintain a pH that is low relative to the extracellular milieu. Other "weak bases", including ammonium chloride, benzylamine and tributylamine, can block the uptake of the dyes; these bases are expected to raise the pH within acidified structures. Photoreceptor terminals in retinas exposed to ammonium chloride exhibit alterations in the exocytic-endocytic cycling of synaptic vesicles: Membrane retrieved by endocytosis accumulates in large vacuoles which subsequently can regenerate synaptic vesicles when the ammonium chloride is removed. Vacuolation is made more pronounced by depolarizing the cells with a high potassium medium. The vacuoles appear to be recycling compartments which become enlarged as an osmotic consequence of the low pH-dependent accumulation of ammonium ions within them. Thus, these observations suggest that membrane cycling in the photoreceptor terminals can proceed by way of intermediate compartments with low pH, perhaps comparable to "endosomes". Supported by NEI grant EY03168.

252.2

BRAIN SYNAPTIC VESICLES CONTAIN A SPECIFIC LIPID KINASE ACTIVITY. S.M. Bajjaleh*, T.F.J. Martin* and E. Floor. (SPON: A. Clark). Neurosciences Training Progam and the Departments of Zoology and Anatomy, University of Wisconsin, Madison, WI 53706.

Using highly purified brain synaptic vesicles (Floor et al, J. Neurochem. 50: 1588, 1988), we have identified a lipid kinase activity that is apparently specific to synaptic vesicles.

Membrane fractions at each stage of purification were incubated with [32]P-ATP, extracted under neutral conditions and analyzed by thin layer chromatography (TLC). Two lipid kinase activities were seen. One is a diacylglycerol kinase activity which is found in all membrane fractions. The other activity, specific to synaptic vesicles, produces a phosphorylated lipid that migrates with brain ceramide phosphates in three different TLC systems. Calcium, magnesium and the cationic antibiotic neomycin stimulate this activity.

A mixed micelle assay was used to determine the identity and distribution of the substrate for the synaptic vesicle- specific lipid kinase. Results from these experiments indicate that: 1) brain ceramides are phosphorylated by synaptic, but not by non-synaptic vesicle microsomes, supporting the notion that the synaptic vesicle-specific kinase activity is a ceramide kinase; 2) lipids extracted from non-synaptic vesicle fractions contain the kinase substrate, suggesting that it is the kinase activity, and not the substrate, that is specific to synaptic vesicles.

We are currently investigating the identity and regulation of this kinase, its substrate(s) and substrate producing enzymes.

Supported by NIH grants DK 25861 and NS 24890.

252.3

APLYSIA SYNAPTIC VESICLES CONTAIN SYNAPTOPHYSIN AND ARE ENRICHED IN G PROTEIN. G.J. Chin, S.S. Vogel, A.M. Elste*, and J.H. Schwartz. Howard Hughes Medical Inst., Columbia University, New York, NY 10032.

Synaptophysin, an integral membrane glycoprotein (M_r 38,000), is a major component of mammalian synaptic vesicles. Western blot analysis using an anti-synaptophysin monoclonal antibody (SY38) revealed that a single immunoreactive polypeptide (M_r 29,000) is present in *Aplysia* nervous tissue and greatly enriched in synaptosomes. Immunoreactivity was localized mainly to varicosities and neurites in cryostat sections of paraformaldehyde-fixed ganglia. Fractions containing synaptic vesicles and synaptic plasma membrane were prepared by hypotonic lysis and differential centrifugation. Electron microscopy revealed that the 200,000 x g pellet (SV fraction) consists of lucent and dense-cored vesicles with 50-150 nm diameter; numerous elongated, empty sacs were found in the 16,000 x g pellet (SPM fraction). The enrichments of synaptophysin relative to the synaptosome fraction were 10-fold in the SV fraction and 0.43-fold in SPM. For 5'-nucleotidase, a plasma membrane marker enzyme, the enrichments were 0.74-fold in SV and 2.0-fold in SPM. We conclude that synaptophysin is specifically associated with *Aplysia* synaptic vesicles. Surprisingly, as determined using an affinity-purified polyclonal antiserum (A569AP, kindly donated by S.M. Mumby, U. of Texas) directed against the α subunit of bovine brain G proteins, *Aplysia* Goα (M_r 41,000) was enriched in both the SV and SPM fractions as compared to the synaptosome fraction. Association of Go with intracellular vesicles is supported by the observations that the *Aplysia* pertussis-toxin substrate (M_r 41,000) is also enriched in the SV fraction and that squid axoplasm contains a membrane-bound pertussis-toxin substrate (M_r 41,000; Vogel *et al.*, These Abstracts). We speculate that G protein, like synaptophysin, is specifically associated with synaptic vesicles and may regulate fusion of synaptic vesicles with plasma membrane.

252.4

Immunolocalization of Different Molecular Forms of Acetylcholinesterase by Light and Electron Microscopy. S.N. Abramson, T. Deerinck*, P. Taylor*, and M. Ellisman. Depts. of Pharmacology and Neurosciences, UCSD, La Jolla, CA 92093.

Acetylcholinesterase (AChE) occurs in several structural forms, including a hydrophobic dimer (5.6 S) and an asymmetric oligomer (17 S). These species are thought to be differentially distributed, however, antibodies selective to each species have been difficult to obtain. Knowledge of the amino acid sequences of these forms in *Torpedo californica* has allowed us to generate polyclonal antibodies that are selective for a unique sequence in the catalytic subunits of the 17 S form, and high resolution immunolabeling of cryosections of electric organ has allowed us to determine the differential distribution of AChE forms with respect to synaptic specializations. Several antibody probes were used, including: 1) rabbit polyclonal antibodies that selectively recognize the catalytic subunits of the 17 S form; 2) a mouse monoclonal antibody that selectively recognizes a structural component of the 17 S form; 3) rabbit polyclonal antibodies that recognize the catalytic subunits of both forms; and 4) a mouse monoclonal antibody that recognizes the catalytic subunits of both forms. The sensitivity and specificity of these and other antibodies were determined by western blot, ELISA, and immunoprecipitation assays. Initial immunofluorescent localization revealed that the 17 S form was concentrated near the synaptic cleft, while the 5.6 S form was more evenly distributed over the innervated face of the electrocyte. This was confirmed by a combination of cryoultramicrotomy and immunogold labeling, with conventional and high-voltage electron microscopy. The 5.6 S form was associated with the nerve terminal and the innervated membrane of the electrocyte, while the 17 S form was found mainly in patches at the synaptic appositions.

252.5

RELATIONSHIP BETWEEN SYNAPTIC NOISE AND TEMPERATURE IN FORMAL NEURONS. H. Korn and Y. Burnod*. Lab. Neurobiologie Cellulaire, INSERM, Institut Pasteur, Paris.

The possible influence of synaptic noise on the output of a real neuron, i.e. the Mauthner cell, was investigated and compared with the effect postulated for temperature which is the maximum slope of the sigmoidal input-output function in formal neurons. Probability distributions of quanta released by a population of 42 inhibitory cells, with known binomial release parameters, were reconstructed under different firing rates of the network. The uncertainty of output resulting from this noise was calculated for given excitatory input signals on the basis of the cumulative functions of inhibitory events overcoming these signals. The performance of a system subjected to such fluctuations follows a sigmoidal shape, with a "temperature" which is proportional to the mean number of inhibitory quanta constituting noise. When excitatory and inhibitory quanta occur simultaneously, temperature decreases with the presynaptic firing rate (as does the probability of release). However, during more common situations of asynchrony, the overlap of postsynaptic responses produces a net increase of temperature as the number of active cells and their frequency of discharge increase. Thus, temperature is controlled by presynaptic activity, a notion which could be included in formal models.

252.6

COMPARISIONS BETWEEN COMPUTATIONAL OPERATIONS GENERATED BY ACTIVE RESPONSES IN DENDRITIC BRANCHES AND SPINES, USING SABER. G.M. Shepherd, N.T. Carnevale+, and T.B. Woolf. Sect. Neuroanat., Yale Univ. Sch. of Med., New Haven, CT 06510 and +Depts of Neurol. and Neurobio. and Behvr., SUNY, Stony Brook, NY 11794.

Previous studies of the computational abilities of a dendritic branch demonstrated that active properties in spine heads can lead to the generation of logic operations. We have extended those results by comparing the relative effectiveness of different distributions of active membrane within the branch.

We have used a new analog circuit simulator (Flach et al. Soc. Neurosci. Abs. (1987) p.159) called SABER (Analogy, Inc). Its advantages include: entering nonlinear equations directly; creating hierarchial components so that users can directly input anatomical and physiological details; exploring compartmental values or conductance changes using batch files; and a plotting package supporting output comparisons from different runs.

A prototypical stretch of a spiny dendritic tree was modeled. The four spine heads were 1um by 1um with 0.1um by 1um spine necks. The trunk was 700 um in total length with the spines distributed at 250um (2), 300um (1) and 350um (1) from the most apical end. In previous work an AND gate was simulated by 1 nS excitatory synaptic conductance changes in the two most apical spine heads. When active membrane of the same amount and density was placed at the base of these voltage-gated spines, 2 nS was necessary for the AND operation. As the same number of channels was distributed over more dendritic membrane (lowering the density) the efficacy fell further, at first gradually, and then rapidly, to a point where logic operations were no longer possible. The results further indicated that action potentials generated at either branch or spine locations could appear similar when recorded nearer the soma.

MODELS OF LOCAL ELECTRICAL INTERACTIONS WITHIN SPINY DENDRITES OF GRANULE CELLS IN MOUSE OLFACTORY BULB. T.B. Woolf, G.M. Shepherd, C.A. Greer. Sections of Neuroanatomy and Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510

Olfactory bulb granule cells participate in reciprocal dendrodendritic synapses with mitral and tufted cells. The granule cell components of these synapses are restricted to heads of dendritic spines. We wished to test the postulate that local spread of current within granule cell dendritic trees is capable of activating synaptic output from these spines.

We have made detailed reconstructions of spiny dendrites using camera lucida and through focus light photomicrographs (mag=5000X) of Golgi-Kopsch impregnated mouse granule cells. Measurements consisted of the length and diameter of all dendritic processes, spine necks, and spine heads. Measurements were made to within 0.2um, although below about 1 um light diffraction limited this accuracy. We then used an analog circuit simulator (SABER; Analogy, Inc.) to model the effects of transient conductance increases in spine heads and the subsequent passive spread of depolarization in the remainder of the dendritic tree.

The influence of a conductance change of 1 nS in a particular spine head tended to be restricted to a limited subset of the total available spines. The size and organization of these subsets were determined not only by the input conductance but also by the complex interaction of position, closeness of other spines, and spine dimensions. Consequently, markedly different morphologies can correspond to a similar functional subset. Preliminary data were also obtained on the effects of non-linear and temporal interactions between spines. Collectively, the results support the notion that, in the absence of active properties, subsets of granule cell spines may act as spatially restricted processing units.

TRAUMA I

253.1

THE COINCIDENCE OF HEAD AND CERVICAL SPINE INJURY. D.B.Michael, D.R.Guyot*, and W.R.Darmody*. Depts. of Neurosurgery and Radiology, Wayne St. Univ. Sch. of Medicine, Detroit, MI 48201.

The association of head and cervical spine injury has long been recognized. Reports of the coincidence of these injuries in the literature range from 1.2-19%. This study was undertaken to determine the coincidence and examine the mechanisms of head and cervical spine injuries at a major trauma hospital.

All cases of cervical spine injury (CSI) and head injury (HI) admitted to The Detroit Receiving Hospital during 1987 were identified using the hospital computer data bank and spine unit log book. There were 359 admissions for HI including concussion, skull fracture, and intracranial hemorrhage. There were 92 admissions for CSI including complete or incomplete neurologic syndromes with or without fractures.There were 22 patients with both HI & CSI (both). Thus the coincidence of primary CSI with HI (both/CSI) is 24% while the coincidence of primary HI with CSI (both/HI) is 6%.Mechanism of injury will be demonstrated with appropriate imaging studies.

Our study supports the view that all seriously head injured patients be treated as though a concomitant cervical spine injury is present until proven otherwise. Further, it shows nearly 1/4 of patients with cervical spine injury have also suffered a head injury. This coincidence may be an important consideration in the rehabilitation of such injured patients.

253.2

GFAP-LIKE IMMUNOREACTIVITY IN DAMAGED NEURONS AFTER SPINAL CORD INJURY. D.J. Gower, C.R. Hollman* and M. Tytell. Neurosurg. Section, Univ. Oklahoma, Oklahoma City, OK and Anatomy Dept, Wake Forest Univ. Medical Center, Winston-Salem, NC.

Glial fibrillary acidic protein (GFAP), a cytoskeletal component of the astrocyte, increases dramatically in amount concommitant with astrocyte hypertrophy after CNS injury. This study examined changes in localization of GFAP immunoreactivity after spinal cord injury.

Pentobarbital-anesthetized adult male rats underwent a single-level thoracic laminectomy. A 50 gm/cm concussive spinal cord injury was induced and the cords collected 0, 24, 48, 72, 96, 120, and 144 hrs later. The tissue was fixed by microwave irradiation in Carnoy's solution, paraffin embedded and sectioned at 7 µm. The GFAP was detected using a mouse anti-GFAP monoclonal antibody (1:500 dilution, Chemicon), followed by a rat-absorbed anti-mouse antibody (1:50) and the Vector Co. Elite ABC kit for HRP.

Within 24 hrs of injury, glia in the penumbra around the injury demonstrated typical thickening and lengthening of processes which precedes formation of a glial scar. Concurrently, a small percentage of the retraction balls of damaged axons in the white matter were highly positive for GFAP immunoreactivity. At later times more of these became immunoreactive, as well as portions of axons at a distance from the injury and occasional neurons.

These observations may reflect either the endocytosis by damaged axons of GFAP released from damaged astrocytes or an injury-induced alteration of a neuronal cytoskeletal protein producing an epitope similar to GFAP.

253.3

DIMETHYL SULFOXIDE AND MECLOFENOXANE MAY ATTENUATE NEUROLOGICAL DYSFUNCTION AFTER CLOSED IMPACT INJURY TO THE SPINAL CORD. L.Bunegin,* M.S.Albin and J.Martinez*. Dept. of Anesthesiology, Univ. Tx. Hlth. Sci. Cntr., San Antonio, TX 78284 and Dept. Pathology (Neuropath). Univ. Pgh. Sch. Med., Pittsburgh, PA.

In this study we evaluate the effects of dimethyl sulfoxide (DMSO), a free radical scavenger, and meclofenoxane (MEFOX) an antioxidant-enzyme sitmulator, on acute closed impact injury to the spinal cord. Fifteen (15) barrier raised anesthetized cats were assigned to either the control group (Group 1, placebo five animals), DMSO (Group 2, five animals, 2.5 grams daily), and MEFOX (Group 3, five animals, 50 mg daily). Spinal cord injury was produced by firing a missile impacting on an impounder resting within the confines of an electronic collar seated on the T_9-T_{10} interspace using a force at or greater than 0.8 x 10^7 dynes/kg. Previous data from our laboratory has indicated that 0.8 x 10^7 dynes/kg is the threshold force to produce irreversible paraplegia. Functional evaluation was carried out daily during the subsequent 4 weeks using a Recovery Index Score (RIS) in which the ability to run, move and climb were tested. A score of 16 indicates normal function and a score of 3 indicated paraplegia. The neurobehavioral changes found in each group were analyzed for statistical significance using paired t test with alpha splitting. All control animals were at 7.0 or lower in the RIS (mean 4.6±0.9 SEM). All animals in the DMSO group showed a good level of functional recovery (mean 12.4±1.2 SEM), while the MEFOX group demonstrated paraplegia in 2 and excellent scores in 3 for a mean of 10.6±2.8 SEM. There was no significant statistical differences between the impact forces used in all 3 groups. On the other hand, there was statistical significance in the RIS Scores ($p<0.05$) between DMSO against control and MEFOX against control. We noted no statistical differences between DMSO and MEFOX in the Recovery Index. It appears that significant functional recovery occurred after acute closed impact injury of the spinal cord using DMSO and MEFOX. Supported by a grant from the Moody Foundation, Galveston, Texas.

NMDA ANTAGONISTS ATTENUATE TRAUMATIC NEURONAL INJURY IN AN IN VITRO MODEL. E.S. Tecoma, M.P. Goldberg, H. Monyer, D.W. Choi. Stanford Univ. Med. Sch., Stanford, CA, 94305.

Recent evidence implicates excitatory amino acid neurotoxicity in the pathogenesis of traumatic CNS injury (Faden AI and Simon RP, Soc. Neurosci. Abstr. 13: 1031). We tested the hypothesis that NMDA antagonists might reduce neuronal loss in a novel cell culture model of traumatic injury.

Dissociated cortical cell cultures were prepared from E14 - E17 fetal mice, and maintained in 15 mm wells for 2 - 3 wks in vitro; neurons formed a network on top of a confluent glia monolayer. After transfer into a defined bathing medium, the cell layer was mechanically disrupted by applying a linear scratch with a sterile pipette tip, producing a 2 mm wide tear down to bare plastic. Within 1 - 2 mm of the margin of this tear, there was widespread acute swelling of neuronal cell bodies, followed by neuronal degeneration over the following day. In contrast, in cultures to which the NMDA antagonist dextrorphan (DX) (100 μM) was added prior to this traumatic insult, there was a marked reduction of neuronal swelling and subsequent death in this marginal area (mean severely injured area, defined by dense trypan blue staining of neuronal debris, in 5 consecutive microscopic fields: control 4.21 +/- 0.46 mm^2 (SEM, n = 4), DX treated 0.44 +/- 0.19 mm^2 (n = 4) , $p < 0.001$).

AUTORADIOGRAPHIC AND MICROSPHERE STUDIES OF CEREBRAL BLOOD FLOW AFTER TRAUMATIC BRAIN INJURY. D.S. DeWitt,* X-Q Yuan,* R.L. Hayes, B.G. Lyeth, L.W. Jenkins, D.S. Prough* (SPON: J. Butterworth), Dept. of Anesthesia, Bowman Gray School of Medicine, Winston-Salem, NC 27103; Division of Neurosurgery, Medical College of VA., Richmond, VA 23298.

Cerebral blood flow (CBF) was studied in rats after fluid percussion injury using the autoradiographic iodo-antipyrine (IAP) or the radioactive microsphere techniques. Rats were prepared for trauma under barbiturate anesthesia (Dixon, et al, J Neurosurg 67:110-119, 1987). Twenty-four hours later, rats were anesthetized with halothane (1%) and surgically prepared for CBF measurements. Anesthesia was decreased to 0.5% in 70% N_2O in both groups and, in one group, CBF was measured 25 minutes after injury (2.3 atm., n=6) or sham-injury (n=6) using IAP. In the other group, microspheres were injected prior to and at two of the following four times (T): 5, 15, 30, 60 minutes after injury (2.5 atm., n=17) or sham-injury (n=20).

After trauma, CBF decreased in all regions studied using IAP, including frontal, parietal and occipital cortices, caudate, basal forebrain, hippocampus, midbrain, and inf. colliculus (figure). In the sham-injured microsphere rats, CBF increased at all time points, probably due to halothane anesthesia. After trauma, MS hemispheric CBF was 14%, 26%, 37% and 45% of pre-trauma values at T5, T15, T30, and T60, respectively. These studies demonstrated that traumatic brain injury resulted in significant decreases in CBF in rats.

PERCUSSIVE INJURY TO THE RAT SPINAL CORD: A MODEL OF AXONAL DAMAGE. D.D. Rigamonti, H. Mena*, J.B. Long, A. Martinez-Arizala, R. A. King*, J. W. Holaday. Walter Reed Army Institute of Research and Armed Forces Institute of Pathology, Washington, D.C. 20307-5100

In an attempt to reproduce the conditions associated with human spinal cord trauma, we developed a novel technique to induce a closed spinal cord injury. Anesthesized, unoperated male Sprague-Dawley rats were secured and suspended from a stereotaxic head holder of a percussion instrument. The impacting device was aligned with the T1 vertebral spinous process and a pneumatically driven metal plunger contacted the animal without fracturing the vertebrae. Animals exhibited hindlimb paralysis after injury and neurologic, hemodynamic and morphologic changes at varied post-injury intervals were evaluated. Anesthetized rats were perfused through the heart with formalin, the spinal cords removed and sections stained with H&E, Nissl, Kluver-Barrera, and Bielschowsky techniques. The lesion, confined to the site of impact, involved the white matter in a diffused manner primarily in the ventral and ventrolateral funiculi with axonal swelling and loss, vacuolation and minimal cellular reaction. There was minimal central gray matter necrosis and cavitation although some neurons exhibited central chromatolysis. Small hemorrhages with hemosiderin pigment deposition and mild gliosis were found in the dorsal horns.

253.7

REGIONAL CEREBRAL BLOOD FLOW (rCBF) RESPONSIVENESS TO HYPOXIA AND HYPERCAPNIA BEFORE AND AFTER BRAIN MISSILE WOUNDING (BMW) IN ANESTHETIZED, PARALYZED CATS. D. Torbati, M.E. Carey*, J.F. Davidson* and J.B. Farrell*. Dept. of Neurosurg. Louisiana State University Medical Center, 1542 Tulane Ave. New Orleans, LA 70112.

The reactivity of rCBF to hypoxia and hypercapnia was measured in 16 brain structures by radioactive microspheres. The rCBF was measured during normoxia and hypoxia (n=7; P_aO_2=55 torr) and during normocapnia and hypercapnia (n=7; $P_a^2CO_2$=60 torr) both before and after BMW. Right cerebral hemisphere was wounded by a 2mm, 31 mg steel sphere penetrating an intact cranium (280 m/s; 1.4 J.). Before BMW, total CBF increased by 75% during hypoxia and by 99% during hypercapnia. After BMW, while total CBF was reduced by 30%, hypoxia and hypercapnia produced no increase in blood flow. Moreover, rCBF reactivity to hypoxia and hypercapnia was reversed in 5/16 structures. During hypoxia the wounded gray and white matter showed the highest decrease in blood flow (-19 and -27% respectively). This inverse reactivity was greater during post-BMW hypercapnia, reaching -37 and -40% in wounded gray and white matter. These data strongly suggest that CBF autoregulatory mechanisms responding to hypoxia and hypercapnia were impaired after BMW. Thus, BMW-induced hypoventilation and/or transient apnea leading to hypoxemia and hypercapnia are detrimental to post-BMW recovery. Supported by contract No. DAMD17-86-C-6098, LAIR, USMRDC.

253.8

THE EFFECT OF SERUM HYPERGLYCEMIA ON THE PHENOMENON OF INCREASED POST-TRAUMATIC ISCHEMIC VULNERABILITY. L.W. Jenkins, K. Moszynski*, B.G. Lyeth, L.P. Miller, W. Lewelt*, D.S. DeWitt*, A. Allen*, T.J. Majewski*, G.L. Clifton*, H.F. Young*, R.L. Hayes, Richard Roland Reynolds Neurosurgical Research Laboratories, Med. Col. of Virginia, Richmond, VA 23298.

Previous studies in fasted rats subjected to a sublethal mechanical injury followed 1 or 24 hours later by a normally sublethal ischemic insult have documented an increased post-traumatic ischemic vulnerability. This is evidenced by bilateral hippocampal CA1 pyramidal death which can be attenuated by combined muscarinic and NMDA receptor antagonists. The present study examines the effect of serum hyperglycemia on this phenomenon. Overt neuronal death was evaluated after identical combined injury and various post-injury survival in rats with pre-injury serum glucose levels of above 400 mg%. Hyperglycemic rats developed status epilepticus and died within 24 hours post-injury. Compared to fasted rats given the same combined insult the pattern of neuronal death was expanded in hyperglycemic rats to additional brain regions demonstrating high glutamate and cholinergic receptor binding. Based upon such spatial relationships, receptor mediated pathology may also be involved in the hyperglycemic exacerbation of neuronal injury following trauma and secondary ischemia. Supported by NIH Grant NS 19950.

THE EFFECT OF AN APPLIED DIRECT CURRENT FIELD ON FUNCTIONAL AND ANATOMICAL RECOVERY AFTER ACUTE EXPERIMENTAL SPINAL CORD INJURY M.G. Fehlings C.H. Tator and R.D. Linden Div. of Neurosurgery and Playfair Neuroscience Unit, University of Toronto

Recent evidence indicates that direct current (DC) stimulation promotes recovery after acute spinal cord injury in mammals. In this study, the effect of DC field polarity was studied in 30 adult rats. After 53 g clip compression injury of the cord at T1, the rats were randomly and blindly allocated to one of three groups (n=10): one group underwent DC stimulation (14 uA) with the cathode distal to the injury site (normal polarity); a second underwent DC stimulation with the cathode proximal to the lesion (reversed polarity); a third group received sham (0 uA) stimulators. Clinical neurological function was assessed weekly by the inclined plane technique. At 8 weeks after injury, motor and somatosensory evoked potentials (MEP and SSEP) were recorded and horseradish peroxidase (HRP) was introduced into the cord at T6. The total number of HRP-labelled cells was counted in the brain stem and motor cortex and a computer-assisted morphometric analysis of axons at the injury site was performed.

The inclined plane scores ($p<0.0001$), MEP amplitude ($p<0.02$), counts of HRP-labelled neurons ($p<0.0001$), and axon counts at the injury site ($p<0.01$) were significantly greater in the group treated with a normal polarity DC field than in the sham or reversed polarity groups. These data confirm that DC fields produce functional neurological and anatomical recovery in rats with acute cord injuries and show, for the first time in mammals, that the mechanism of action of DC stimulation is critically dependent on field polarity.

253.10

TRAUMATICALLY INDUCED DEAFFERENTATION AND REORGANIZATION IN THE LATERAL VESTIBULAR NUCLEUS OF CAT. D.E. Erb* and J.T. Povlishock. Department of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA. 23298.

Previous investigations have demonstrated that diffuse axonal injury (DAI) is a consistent finding in traumatically brain-injured man and animals. As such DAI also triggers diffuse deafferentation with sparing of related fiber systems, this situation provides a unique opportunity to assess the potential for posttraumatic neuronal reorganization and regeneration. To explore this issue we examined synaptic terminal loss and recovery in the lateral vestibular nucleus, known to undergo traumatic deafferentation. This nucleus offered a further advantage in that it possesses a relatively homogeneous neurotransmitter population. Specifically, we have examined moderately, traumatically brain-injured cats, at 2-211 days postinjury. In this study we employed both LM and EM immunocytochemistry for detection of Gabaergic terminals within the lateral vestibular nucleus. Through such an approach we again confirmed the association of traumatic brain injury with DAI, particularly within the vestibular complex where the lateral vestibular nucleus appeared most susceptible to axonal damage, associated with reactive axonal swelling, Wallerain degeneration and terminal loss. Such terminal loss was related to the focal loss of immunoreactive punctae. Following this loss of immunoreactivity preliminary analysis suggests a return of Gabaergic terminals in an "adaptive fashion". The source of such terminals is unknown, however, they are assumed to originate from related intact axons. The relation of these phenomena to both the morbidity and recovery seen in brain-injured humans will be discussed. This research was supported by grant NS 20193.

GENE STRUCTURE AND FUNCTION II

ACTIVE-SITE-DIRECTED INHIBITION OF Ca^{++}/CaM-DEPENDENT KINASE II (CK-II) BY A BIFUNCTIONAL CALMODULIN-BINDING PEPTIDE. P. Kelly, R. Weinberger* and M. N. Waxham*, Dept. of Neurobiol. and Anat., and Neurology, Univ. of Tex. Med. Sch., Houston TX 77225.

Recent recombinant DNA and synthetic peptide studies have shown that the calmodulin (CaM)-binding domains of CK-II reside between two consensus phosphorylation sequences, RQET and RNFS at its N- and C-terminus, respectively. CK-II activity is initially dependent on Ca^{++}/CaM, however, following autophosphorylation its activity becomes independent of Ca^{++}/CaM. Recent studies suggest that the autophosphorylation of a Thr residue accompanies the generation of Ca^{++}/CaM-independent kinase activity. We report here that a synthetic peptide containing the CaM-binding domain and consensus phosphorylation sequence at its N-terminus contains bifunctional inhibitory properties. The peptide acts as a potent antagonist of Ca^{++}/CaM-dependent activation of CK-II by competing for Ca^{++}/CaM. More importantly, this peptide inhibits (IC_{50}= 2.5 um) synapsin I phosphorylation and continued autophosphorylation of Ca^{++}/CaM-independent CK-II. A second peptide, identical to the one just described but lacking the Arg of the N-terminal consensus phosphorylation site did not inhibit Ca^{++}/CaM-independent CK-II activity. These results suggest that the phosphorylation sequence just N-terminal to the CaM-binding domain of CK-II can bind to or near the enzyme's active site and inhibit activity. We suggest that this active-site-directed inhibitory domain naturally resides in the active site of Ca^{++}/CaM-dependent CK-II. Furthermore, binding of Ca^{++}/CaM and subsequent autophosphorylation of this N-terminal phosphorylation sequence may cause disinhibition of the active site thus facilitating kinase activation and substrate phosphorylation.

NEURON SPECIFIC EXPRESSION OF BACTERIAL β-GALACTOSIDASE UNDER THE REGULATION OF THE MOUSE THY-1.2 PROMOTER IN TRANSGENIC MICE. K. A. Kelley* and K. Herrup (SPON: S. Zaremba). The Mount Sinai School of Medicine, New York, NY 10029 and E.K. Shriver Center, Waltham, MA 02254.

In an attempt to produce a novel neuronal marker in transgenic mice, the bacterial β-galactosidase gene was fused to 5'-flanking sequences from the mouse Thy-1.2 gene. Five transgenic mice were produced and their offspring were subsequently examined for the presence of transgene mRNA. Expression was observed in only two of the five lines, and was restricted to the CNS. Although the endogenous mouse Thy-1 gene is expressed in thymus as well as brain, expression of the Thy-1/β-galactosidase transgene was never detected in the thymus. These results suggest that the regulatory sequences which are necessary for neuronal or thymic expression of the endogenous Thy-1 gene may be discrete elements. The Thy-1 regulatory sequences that were used for this study were sufficient to direct neuronal expression; however, transcription appears to be integration dependent since only two of the five lines express the transgene. This suggests that the Thy-1 sequences may contain a weak neuron-specific promoter/enhancer. The bacterial protein was easily detected in many types of neurons throughout the CNS, with particularly high levels observed in neurons of area CA2 of the hippocampus, the septal nucleus and large neurons of most cranial nerve nuclei. Expression of this heterologous protein in the PNS is currently under investigation. The presence of bacterial β-galactosidase in the CNS of mice provides a novel marker to examine the lineages of various neurons during the development of the CNS.

HOMOLOGUES OF RAT BC1 RNA ARE EXPRESSED IN MICE AND MEN. Henri Tiedge*, Katarina Eisinger*, Robert T. Fremeau, and Jürgen Brosius. Center for Neurobiology and Behavior, Columbia University CPS, 722 W 168th St., New York, NY 10032.

We have previously shown that neural BC1 RNA is heterogeneously expressed in the rat central and peripheral nervous system. This small, non-messenger RNA is comprised of three domains: (1) the 5' ID element which includes an internal RNA polymerase III promoter, (2) a central A-rich region, and (3) a 3' unique sequence. If BC1 RNA serves a specific function in the mammalian nervous system we would anticipate that it is conserved in evolution. Thus we have used probes complementary to the 3' most 60 nucleotides of rat BC1 RNA to analyze expression of BC1 homologues in species other than rat.

We now report that in addition to other rodents such as mouse and hamster, a BC1 homologue is also expressed in human nervous tissue. Furthermore, when the rat probe was used to localize the murine homologue by hybridization *in situ* to mouse brain sections, a high degree of conservation of the overall expression pattern was observed between mouse and rat, again suggesting a functional role for BC1 RNA. Specifically, high levels of expression were observed in the mouse cerebral cortex, thalamic and hypothalamic nuclei, the zonal and superficial gray layer of the superior colliculus, the central gray, and the amygdaloid complex. Only background labelling was observed in white matter areas such as the corpus callosum, the anterior commissure, and the optic nerve. The putative human BC1 homologue was detected in cerebral cortex by Northern blot analysis at low stringency. This RNA-species is barely detectable in non-neural human organs such as lung or kidney. Like rat BC1 RNA, the human brain homologue cofractionates with the poly-A fraction on an oligo-(dT) column. The human and murine BC1 homologues are currently being cloned, and sequence analysis should reveal the degree of homology with rat BC1 RNA.

MOLECULAR CLONE OF A RAT BRAIN cDNA HOMOLOGOUS WITH THE *raf/mil* FAMILY OF PROTO-ONCOGENES. R.M. Lewis. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh, Sch. of Medicine, Pittsburgh, PA 15261.

Proto-oncogenes are believed to be normally occurring genes which are involved in regulating cell growth or differentiation. When altered, these genes (now referred to as oncogenes) are capable of causing malignant transformation. Oncogenes are frequently associated with cell lines and tumors of neuronal origin. The expression of oncogenes also appears to be regulated during normal neuronal development. The *raf* oncogene is among the oncogenes which recently have been identified.

The cDNA clone XRAF1 was obtained while screening a rat brain cDNA expression library with antibodies specific for neuronal proteins. XRAF1 had a high degree of homology with a portion of the nucleotide sequence for the human c-*raf*-1 gene. The nucleotide sequence of XRAF1 was not homologous to *pks*, another *raf*-related gene. Unlike *raf* and *pks*, the derived peptide sequence of XRAF1 did not appear to code for any known serine/threonine protein kinases. The XRAF1 mRNA was detected as a single species of ~2.9 kb on Northern blots of rat brain poly A^+ RNA. Probes generated from XRAF1 bound to specific restriction fragments of rat, mouse, and human genomic DNA on Southern blots. The ontogeny and tissue specificity of the mRNA for XRAF1 is currently under investigation.

Supported by IN-58Z from the ACS and NIH RR05416-25.

DETECTION OF ANTI-MBP RNA IN MYELIN DEFICIENT MUTANT MICE. H. Okano*, K. Ikenaka* and K. Mikoshiba*. (SPON:Y. Oda). Institute for Protein Research. Osaka Univ., Suita, Osaka 565, Japan.

A hereditary dysmyelinating mutation, named myelin deficient (mld), is characterized by hypomyelination in the central nervous system and the reduced myelin basic protein (MBP) gene expression. In mld, the MBP gene was duplicated and its reduced expression was mainly determined by the level of mRNA. The reduced mRNA level was not attributed to the defect of the promoter region, as promoter activities of 1.3 kb 5'-flanking regions from respective genes of mld measured by cell-free transcription assay and transfection studies were indistinguishable from that of the control MBP gene. Chromosomal mapping by in situ hybridization suggested that the duplicated MBP genes were located closely to each other at the distal part of chromosome 18. Exon 3 was present in an inverted orientation 10 kb upstream of the 5' end of the gene-2. Recently, Popko et al. (Neuron in press) demonstrated that the MBP gene is duplicated tandemly in mld, and exon 3 to 7 of the upstream copy is inverted. We detected antisense RNA complementary to exons 3 and 7, which correspond to the inverted segment. This abnormal transcript was also shown to elongate through the inverted segment to reach the transcription initiation site of the downstream gene.

254.6

MORPHOMETRIC ANALYSIS OF MYELIN IN THE OPTIC NERVE OF TRANSGENIC SHIVERER MICE H.D. Shine, C. Readhead*, B. Popko*, L. Hood* and R. L. Sidman. Ctr. for Biotech., Baylor College of Med., The Woodlands, TX 77381; Depts. of Neurosci., Children's Hospital and Neuropath., Harvard Medical School, Boston, MA, 02115; Div. of Biol., Calif. Inst. of Tech., Pasadena, CA 91125.

The mutation Shiverer (shi) is a large deletion in the Myelin Basic Protein (MBP) gene. Homozygotes (shi/shi) have no MBP, have severely hypomyelinated CNS, shiver, convulse, and die at 4-5 months. The MBP gene was introduced into the shi germline by microinjecting the cloned gene into fertilized eggs. Homozygous transgenic mice (shi/shi;MBP^1/MBP^1) had approximately 25% of normal amounts of MBP mRNA and protein and did not shiver, convulse or die early. A detailed morphometric analysis of the myelin structure in optic nerve of normal, shi, Myelin Deficient (mld, an allele to shi), and transgenic mice was performed using computer assisted quantitative methods at the electronmicroscopic level. As the amount of MBP mRNA increases the percentage of myelinated axons increases and myelin thickness increases. Axons with larger calibre are myelinated before smaller calibre axons.

A DIVERSE POPULATION OF NEURAL ADHESION MOLECULE TRANSCRIPTS IS GENERATED BY ALTERNATIVE SPLICING D. Barthels[1]*, M.-J. Santoni[2]*, G. Vopper[1]*, C. Goridis[2]* and W. Wille[1]. [1]Institut für Genetik der Universität zu Köln, D-5000 Köln 41, F.R.G. and [2]Centre d'Immunology INSERM-CNRS, F-13288 Marseille Cedex 9, France

The name 'neural cell adhesion molecule' (NCAM) refers to a class of cell surface glycoproteins which play a role in developmental and adult processes of cell-cell contact formation and maintenance. Three major isoforms NCAM-180, -140, & -120 have been identified in the mouse. All three isoforms are encoded by a single gene with a length of more than 80kb. At least four mRNA species are detected in rodents, of which the 7.4 kb transcript encodes NCAM-180, the 6.7 kb mRNA NCAM-140, and the 2.9 & 5.2 kb species code for NCAM-120. The two latter mRNA only differ by the length of their 3'-non-coding region.

The three isoforms have very similar N-terminal (extracellular) domains and differ mainly by the size of their transmembrane and cytoplasmic regions. While NCAM-180 & -140 contain membrane spanning domains, NCAM-120 lacks a transmembrane segment and is anchored to the membrane by lipids.

We isolated and analyzed the complete cDNA sequences of all transcripts encoding the three NCAM isoforms and established the splice pattern on the genomic and cDNA level leading to the major NCAM proteins. Here we report data which demonstrate that in addition to alternative splice sites in the codin region for the cytoplasmic domain at least two more alternative splice sites, a & π, exist in the coding region for the extracellular domains which are involved in posttranslational modification generating a much more complex NCAM family than anticipated.

254.8

EXPRESSION OF TRANSFECTED GENES BY DIFFERENTIATED, POSTMITOTIC NEURONS AND PHOTORECEPTORS IN CULTURE. **Marc Werner*, Paul Lieberman*, Steven Madreperla* and Ruben Adler, The Wilmer Institute and Department of Pharmacology, The Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD.**

Using purified cultures of chick embryo retina neurons and photoreceptors (Prog. Ret. Res., 6:1-27), we have investigated whether gene transfection techniques, which are frequently used with dividing cells, are equally applicable to postmitotic, differentiated cells. Marker genes for chloramphenicol-acetyltransferase (CAT) or β-galactosidase (β-gal) were driven by either a Rous sarcoma virus or a cytomegalovirus promoter. Cultured cells were exposed to DNA for 18-48 hrs in cultured medium plus a transfection solution containing Na_2HPO_4 and $CaCl_2$, and returned to normal medium for up to 30 hr. β-gal histochemistry and a autoradiographic CAT assay showed that up to 15% of the neurons and photoreceptors expressed these genes with efficiencies depending on DNA concentration and length of transfection. When compared to control cultures, calcium phosphate-treated cultures showed relatively similar cell numbers, modest (10-30%) decreases in aspartate uptake and choline acetyltransferase activity, and approximately 60% decrease in GABA uptake. Thus, although different metabolic activities are selectively affected by the transfection treatment, it is possible to obtain expression of genes transfected into primary, postmitotic cells such as neurons and photoreceptors.

254.9

MOLECULAR CLONING AND SEQUENCE ANALYSIS OF cDNAs FOR A UNIQUE GFAP FROM THE GOLDFISH VISUAL PATHWAY. S. Giordano*, E. Glasgow*, P. Tesser*, N. Schechter. Departments of Psychiatry and Biochemistry, SUNY, Stony Brook, New York 11794.

We have characterized cDNA clones corresponding to a glial fibrillary acid protein (GFAP) expressed in goldfish optic nerves. A comparison of its amino acid sequence with those of intermediate filaments (IFs) from higher vertebrates reveal highly conserved and unique regions, for this protein. The goldfish proteins ON_3 and ON_4 are synthesized in glial cells associated with the optic nerve. Biochemical data and immunohistochemical localization studies suggested that ON_3 and ON_4 correspond to a unique GFAP.

A lambda gt11 expression library prepared from optic nerve total RNA was screened with anti-ON_3/ON_4 polyclonal antisera. Ten positive clones between 1.5 and 2Kb in length were characterized and appear to be derived from the same mRNA species. Evidence that we have cloned a cDNA for ON_3/ON_4 comes from in vitro transcription and hybrid select experiments. These clones have been subcloned into an MI3mp18 vector and sequenced.

All IF proteins contain a highly conserved 40K core region. Sequence data from our clones reveals the presence of this 40K core. The carboxy region of the core in these clones matches exactly the amino acid sequence for that region in most other IFs. In the less conserved amino end of the core, the ON_3 amino acid sequence more closely resembles that of vimentin than mammalian GFAP. The diversity of IF proteins is generated by variable regions on either side of the core, which may be involved in cell specific functions of IF proteins. The amino acid sequence in the carboxy terminal region of ON_3 does not resemble the amino acid sequence for other known IF proteins. In addition, the ON_3 carboxy variable region contains a sequence rich in Ser, Gly, and Tyr. This sequence is repeated at least four times and may represent phosphorylation sites. Supported by EY05212 to N.S.

STRUCTURE, NGF-INDUCIBILITY AND NEURON-SPECIFIC EXPRESSION OF THE RAT SCG10 GENE ENCODING A NOVEL 22kD PROTEIN: THE 5' UPSTREAM REGION CONTAINS NEURON-SPECIFIC TRANSCRIPTIONAL SIGNALS. N.Mori*, C.W.Wuenschell, R.Stein*†, and D.J. Anderson*. Div. of Biology, Calif. Inst. of Technology, Pasadena, CA 91125, and †Tel Aviv Univ., Tel Aviv, Israel.

We have sequenced a rat cDNA, SCG10, originally isolated as a marker for neuronal derivatives of the neural crest. It encodes a novel 22kD protein. Structural features suggest the protein may function in mediating membrane-cytoskeletal interactions, possibly related to neurite extension. The rat SCG10 gene contains at least five exons and spans 40kb of DNA. Primer extension and S1-mapping studies show multiple transcriptional start sites and identify a putative promoter. To study the transcriptional regulatory region, sequences upstream of the SCG10 gene were fused to the bacterial CAT gene. In DNA-mediated transfer experiments using various cell lines and in transgenic mice, expression of a construct bearing 4kb of SCG10 upstream sequence (pCAT37) was largely restricted to neuronal cells. However, a 0.5kb SCG10 upstream-CAT construct (pCAT4) was expressed in all cell lines and tissues studied except melanoma cells. The pCAT37 was also inducible by NGF in PC12 cells, while pCAT4 was not. These data suggest that the 4kb upstream sequence includes necessary and sufficient information for NGF responsiveness and neuron-specific expression of the SCG10 gene.

TRANSFECTION OF NEURONS WITH A DEFECTIVE HSV-1 VECTOR AND EXPRESSION OF *B*-GALACTOSIDASE. A.I. Geller, A. Freese, J.F. Gusella*, and X.O. Breakefield, Lab. Of Neurogenetics, Mass. Gen. Hosp., Boston, MA

We are developing HSV-1 virus vectors to deliver genes into neurons in vitro and in vivo. This approach offers the potential to perform gene therapy on neuronal disease, and to modify neuronal physiology in vivo to study learning and memory. pHSVlac, a 8.1 kb defective HSV-1 vector, contains a transcription unit that places the E. coli Lac Z gene, which encodes a *B*-galactosidase, under the control of the HSV-1 immediate early 4/5 promoter. pHSVlac was packaged into HSV-1 virus particles using temperature sensitive (ts) mutants of HSV-1 as helper virus. Virus was grown at the permissive temperature of 31C. Infection of cells at the restrictive temperature of 37C results in expression of *B*-galactosidase without cell death. Expression of *B*-galactosidase following infection with pHSVlac has been observed in mitotic cells: CV1 monkey fibroblasts, LM tk^- mouse fibroblasts, N1E-115 mouse adrenergic neuroblastomas, NS-20Y mouse cholinergic neuroblastomas, PC12 rat pheochromocytomas, AtT-20 mouse pituicytes, GH 4 rat pituicytes, SK-N-BE(2) human neuroblastomas, and in nonmitotic cells: PC12 cells differentiated with NGF, and N1E-115 cells differentiated with dibutyryl cAMP. Expression also occurs in neurons in primary culture from superior cervical ganglia, dorsal root ganglia, spinal cord, cerebellum, thalamus, striatum, hippocampus, occipital cortex, temporal cortex, and frontal cortex. pHSVlac is stably maintained, and *B*-galactosidase is stably expressed for at least two weeks in differentiated PC12 cells, differentiated N1E-115 cells, and sensory neurons. HSV-1 ts mutants have been shown to establish a latent infection following injection into the mouse cerebral cortex. These results form a foundation for using HSV-1 vectors to deliver genes into neurons in adult animals. The Lac Z gene in pHSVlac can be replaced with genes whose products affect neuronal physiology, including components of second messenger systems and neurotransmitter metabolism.

THE OLFACTORY MARKER PROTEIN GENE IS NON-CLASSICAL. E. Danciger* and F.L. Margolis. (SPON: R. Wurzburger) Roche Inst. Molec. Biol., Nutley, N.J. 07110.

Genomic DNA encoding rat olfactory marker protein (OMP) was isolated from a charon 4A lambda phage library using OMP-cDNA as a probe. A 10 Kb EcoRI fragment (λ-OMP) was subcloned into Bluescript plasmid. A restriction map was constructed. Upon hybridization to OMP cDNA a 2.6 Kb HindIII-SacI fragment was found to contain the entire cDNA information. Southern blot of rat genomic DNA, digested with EcoRI, XbaI and BamHI was hybridized to OMP-cDNA. The bands obtained agreed with the restriction map of λOMP. Bands that hybridized less intensely were also seen. These related fragments remain to be investigated. The HindIII-SacI fragment was subcloned into M13Mp18 and sequenced by the Sanger method. Deletions were generated to provide a series of overlapping clones. The sequence obtained was co-linear with the cDNA. To look for the promoter, 860 bp upstream of the ATG translation start site, was sequenced by the Sanger method using synthetic primers and double stranded DNA. Primer extension studies with an 18-mer synthetic primer complimentary to the 5'end of the coding region indicated the transcription start site. Beyond the start site, no TATA or CAAT boxes were found. The OMP gene, seems to lack introns and to be missing typical promoter boxes. We intend to use the genomic upstream region to study promoter activity and specificity.

MOLECULAR AND IMMUNOLOGICAL CHARACTERIZATION OF GLYCOPROTEINS OF THE POSTSYNAPTIC DENSITY. B. Ni, J.W. Gurd and I.R. Brown. Departments of Zoology and Biochemistry, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada M1C 1A4.

We have previously identified three high molecular weight glycoproteins (gp180, gp116 and gp110) which are concentrated in postsynaptic densities (PSDs) purified from the mammalian brain (Gurd, Can. J. Biochem., 58, 941-951, 1980). In order to further characterize these glycoproteins, antibodies were raised by intrasplenic immunization of rabbits with protein blots of gp180 and gp116 purified from rat PSDs. Immunoblots against whole brain homogenates demonstrated that the antibodies raised against gp180 recognized a prominent protein of app. Mr 65K and a minor species of app. Mr 180K whereas the antibodies against gp116 reacted with a protein of app. Mr of 116K. Both antisera detected immunoreactive species in adult rat brain but not in liver, spleen or kidney. In both cases the immunogens were enriched in synaptic glycoprotein fractions and were highly concentrated in isolated PSDs. The concentrations of the proteins recognized by both antisera changed during early postnatal development at a time when synapses are actively being formed. The antisera have been utilized to screen a rat brain gt11 expression library. (Supported by grants from NSERC to I.B. and MRC to J.G.)

254.14

CHARACTERIZATION OF cDNA CLONES ENCODING PUTATIVE SYNAPTIC GLYCOPROTEINS. I.G. Johnston, T. Paladino, J.W. Gurd and I.R. Brown. Departments of Zoology and Biochemistry, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada M1C 1A4.

Glycoproteins are important components of the mammalian synapse. We have previously reported the isolation of clones from a rat brain cDNA expression library based on immunoreactivity with a mixed polyclonal antibody raised against synaptic glycoproteins (Johnston et al., Soc. Neurosci. Abstr. 13:561, 1987). Briefly, mice were injected with concanavalin A-binding glycoproteins isolated from bovine synaptic junctions and the resultant antiserum used to screen the library. Clones recognizing two messages have been isolated in this fashion. The clone designated SC1 recognizes a 3.2 kb message which is expressed at high levels in brain and much lower levels in muscle and lung. It is absent in liver and spleen. Interestingly, DNA sequence data reveal extensive homology with the collagen-binding protein osteonectin. The clone designated SC2 recognizes a 1.3 kb message which is abundant in brain and is expressed at lower levels in all other tissues examined. In situ hybridization reveals a neuronal pattern of expression for both clones although glial expression is also observed for SC2. Efforts are currently underway to establish the subcellular location of proteins encoded by SC1 and SC2. (Supported by grants from NSERC to I.B. and MRC to J.G.)

HYPERSENSITIVE SITES AND CHROMATIN ORGANIZATION OF GENES EXPRESSED IN CORTICAL NEURONS. T.R. Ivanov and I.R. Brown. Department of Zoology, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada, M1C 1A4.

Nuclei purified from cortical neurons of the adult mammalian brain exhibit an atypically short nucleosomal repeat length of approximately 165-170 base pairs whereas glial and liver nuclei possess nucleosomal repeat lengths of 200 base pairs. This unique chromatin conformation appears during the first week of postnatal development in mouse, rat and rabbit, concomitant with an increase in overall DNase I sensitivity of total cortical neuronal chromatin. Within this relatively uncoiled, 'short repeat' chromatin, hierarchies of DNase I sensitivity exist reflecting genes which are active (i.e., neurofilament and neuron-specific enolase) or inactive (i.e., albumin) in neuronal cells. Developmental studies reveal the presence of three DNase I hypersensitive sites associated with the 68 kDa neurofilament gene and at least one hypersensitive site associated with the neuron-specific enolase gene. Availability of a mouse genomic neurofilament probe (Lewis and Cowan, 1986, Mol. Cell. Biol. 6: 1529-1534) allows for the mapping of the neurofilament gene hypersensitive sites. (Supported by grants from NSERC).

EXPRESSION OF A NOVEL TRANSCRIPT OF THE MOUSE MBP GENE A. Campagnoni, S. Newman*, K. Kitamura*, and C. Campagnoni* UCLA School of Medicine, Los Angeles, CA 90024.

An MBP cDNA with an usually long 5'-UT region was isolated from a mouse brain cDNA library. The sequence of the clone indicated that it corresponded to a full-length 14 K MBP mRNA plus an additional ∿350 bp upstream of the CAP site thought to represent the 5' end of all MBP mRNAs. The 350 bp sequence is encoded by two genomic regions, one of which is immediately upstream of exon 1 of the mouse MBP gene, and the other of which is more than 25 kb upstream of exon 1. A probe specific for the unique 5'-UT region was prepared and used to examine the expression of this transcript in the developing mouse brain. The probe hybridized to two bands of ∿2.7 and ∿5.4 kb on Northern blots. The developmental expression of these mRNAs was unlike that of the major MBP mRNAs, with greatest expression occurring much earlier than that of the transcripts expressed from the "normal" promoter. The 2.7 kb band was missing from Northern blots of mRNA isolated from shiverer mice, which contain a deletion of exons 3-7 of the MBP gene. These results indicate that the clone corresponds to the 2.7 kb mRNA and that the gene encoding the 5.4 kb mRNA lies outside the genomic piece deleted in shiverer, but shares genomic regions in common with the MBP gene. The data also suggest that the MBP gene is more complex than previously thought and that there exists a subpopulation of MBP mRNAs, under separate developmental regulation, that arises from a previously unsuspected transcription start site.

ALLELIC HYPOMYELINATION MUTATIONS jp AND jp^{msd} INTERACT DIFFERENTLY WITH qk. S. Billings-Gagliardi, J.-B. Gow*, and M.K. Wolf. Dept. Cell Biol., U.Mass. Med. Sch., Worcester, MA 01655.

Individual mice whose genomes contain both CNS hypomyelination mutations quaking (qk/qk) and myelin synthesis deficiency ($Tajp^{msd}/Y$) (abbreviation: $qk*jp^{msd}$) have been bred. The morphology of their optic nerves, posterior columns, and cerebellar white matter is indistinguishable from that of animals with genotypes qk/qk or qk/qk*Ta+/Y (qk*Ta control for effects of Ta marker). In P20 optic nerve the proportion of axons myelinated relative to wild type is 25% qk; 24% $qk*jp^{msd}$; 22% qk*Ta. All three phenotypes are characterized by axons and oligodendrocyte processes associated with whorls of myelin-like membranes, inappropriate myelin targeting, and macrophages. Myelin sheaths are thin but compacted. Thus in $qk*jp^{msd}$ the distinctive morphology of jp^{msd} appears completely suppressed by qk, although the shorter lifespan of jp^{msd} is not. By contrast, the allelic double mutant qk*jp has about half as many myelinated axons as $qk*jp^{msd}$ with thicker, more regularly formed sheaths grouped in clusters. This morphology is truly intermediate between qk and jp. We had previously found that shi suppresses jp more completely than jp^{msd}; now we show that qk suppresses jp^{msd} more completely than jp! Grant support: NINCDS (Javits Award).

PROTEOLIPID PROTEIN (PLP) GENE EXPRESSION AND PROMOTOR ACTIVITY IN C6 GLIOBLASTOMA AND CULTURED SCHWANN CELLS. K.-A. Nave, G. Weinmaster*, C. Lai*, and G. Lemke.
Molecular Neurobiology Lab, The Salk Institute, La Jolla, CA 92037.

PLP is the major structural protein in central nervous system myelin, and has recently also been detected in Schwann cells of the peripheral nerve, where it appears not to be incorporated into the myelin sheath (Puckett, C. et al., J. Neurosci. Res.,18: 511, 1987). In order to functionally define the PLP promotor and to test its tissue specificity, we have isolated the rat PLP gene and constructed a plasmid in which 1200 basepairs of DNA upstream of the PLP transcription start site are linked to the bacterial chloramphenicol acetyltransferase (CAT) reporter gene. Calcium phosphate mediated DNA transfection showed that the PLP promotor region was active in the C6 glioblastoma cell line as well as in NIH3T3 and rat2 fibroblasts. C2C12 myoblastoma and B78H1 melanoma cells did not respond to the PLP promotor. In C6 cells CAT activity was about 5 fold higher when the transiently transfected cells were allowed to grow into stationary phase.
Using a full length rat PLP cDNA (p27) as a probe, Northern blot analyses confirmed transcription of the PLP gene in rat sciatic nerve and in cultures of primary rat Schwann cells. Forskolin, which stimulates the cAMP dependent expression of the P0 and MBP mRNAs in Schwann cells, also increases the steady state level of PLP mRNA. This suggests that genes encoding the major myelin proteins are coordinately regulated in Schwann cells. The PLP promotor region will be used to direct the expression of foreign genes into myelinating glial cells *in vivo*.

STRUCTURE OF THE GENE ENCODING DROSOPHILA TYROSINE HYDROXYLASE. W. S. Neckameyer.* (SPON: T. Tully). Dept. of Biology, Brandeis University, Waltham MA 02254.

Tyrosine hydroxylase (TH) catalyzes the rate-limiting step in the sysnthesis of catecholamines. Since catecholamines are believed to modulate many behaviors in both vertebrates and invertebrates, it would be interesting to compare TH regulation in diverse species.

cDNA homologues to rat TH were isolated from Drosophila third instar- and head-specific libraries using a probe (gift of D. Chikaraishi) derived from the conserved 3' coding sequence of the rat gene. The longest cDNA clone, λcDTH.2, contains 90 bp of 5' noncoding, 1525 bp of coding sequence, 1605 bp of 3' noncoding and a 60 nucleotide poly(A) tail. Recently, Drosophila genomic TH clones have been obtained. The genomic clone λgDTH.1 contains all sequences corresponding to λcDTH.2. It is therefore believed that λgDTH.1 contains the entire coding sequence for the enzyme, as well as up to 4 kb of 5' upstream sequences.

Similar to the rat and human TH genes, Drosophila TH is single-copy and spans approximately 8 kb. Preliminary sequence analysis of λgDTH.1 indicates that none of the 5' intron/exon junctions are conserved between the mammalian hydroxylases and the Drosophila gene, but that at least one junction within the 3' end of the genes is conserved. Complete genomic analysis of Drosophila TH is in progress.

FIRING PATTERNS OF PHASE-SPANNING GENIOHYOID MOTOR UNITS (MU) IN CATS. E. van Lunteren and T.E. Dick. Department of Medicine, Case Western Reserve University and University Hospitals, Cleveland, OH 44106.

The geniohyoid, an upper airway dilating muscle, is supplied by the hypoglossal nerve, and is phasically active with respiration. To compare its neural regulation during inspiration (I) and expiration (E), electrical activity was recorded from 23 MU which were active during both phases of the respiratory cycle in anesthetized tracheostomized cats. The relative duration of I activity (92 ± 2% Ti) was significantly longer than the relative duration of E activity (68 ± 5% Te; $P < 0.00001$). Furthermore the mean frequency of I firing was significantly higher than the mean frequency of E firing (23.5 ± 1.6 versus 15.7 ± 1.3 impulses/second; $P < 0.00001$), and the number of impulses per I exceeded the number of impulses per E (16 ± 2 versus 10 ± 1; $P < 0.0001$). The influence of volume-related vagal afferents was tested by occluding the airway at end-expiration. MU activity during I was significantly increased in relative duration ($P < 0.02$), firing frequency ($P < 0.001$) and number of impulses ($P < 0.0001$), whereas MU activity during E was significantly decreased in relative duration ($P < 0.00002$), firing frequency ($P < 0.001$) and number of impulses ($P < 0.0001$). These results suggest that during unobstructed breathing the firing intensity of phase-spanning geniohyoid MU during I exceeds that during E, and that lung-volume related afferents inhibit I but stimulate E activity of geniohyoid MU. NIH HL-38701, HL-01600.

CHOLINERGIC RETICULAR MECHANISMS CAUSE STATE-DEPENDENT HYPOTONIA IN UPPER AIRWAY MUSCLES. R. Lydic, H.A. Baghdoyan, K. Gilbert* and C.W. Zwillich*. Pulmonary Div., Penn. State Univ. College of Med. Hershey, PA 17033.

Microinjection of the cholinergic agonist carbachol into the medial pontine reticular formation (mPFR) of intact, unanesthetized cats produces a state (D-CARB) which is similar to rapid eye movement (REM) sleep. Since D-CARB and REM sleep are both characterized by postural muscle atonia, this study is using the D-CARB model to evaluate the hypothesis that cholinergic mechanisms also mediate state-dependent changes in upper airway muscle tone. To date, over 30 microinjections have been made into 6 mPFR sites in 4 cats. EMG recordings were made from the posterior cricoarytenoid (PCA) muscles in the larynx. Analysis of PCA EMG activity for 200 breaths before and 200 breaths at 4 min after carbachol revealed that every drug injection produced significant decreases in PCA EMG activity. During D-CARB, inspiratory (I) PCA activity was 44.5% of PCA I activity during waking (W) ($p<0.001$). Expiratory PCA activity declined from 37% to 14.5% of IW PCA values ($p<0.001$). The direction and magnitude of these changes parallel the PCA hypotonia of physiological REM sleep. Since these carbachol-induced effects are blocked by centrally administered atropine, these data specify for the first time that cholinergic reticular mechanisms can causally mediate state-dependent hypotonia in the upper airway.

RESPONSE OF CERVICAL INSPIRATORY NEURONS TO INTERCOSTAL NERVE AFFERENT STIMULATION. R. Shannon, Y.M. Hernandez* and B.G. Lindsey. Dept. Physiol. & Biophysics, Col. Med., Univ. South Florida, Tampa, FL 33612.

Experiments were conducted to determine if intercostal nerve afferents have intersegmental effects on inspiratory (I) neurons located in the cervical spinal cord (C1-C2). We compared the latencies of response of extracellularly recorded evoked unit activity in the dorsal caudal medulla, cervical I-cell activity, and phrenic (C5) efferent activity (PA) to electrical stimulation of internal intercostal nerve afferents (IINAs). Studies were performed on 8 anesthetized (Dial), thoracotomized, paralyzed, ventilated cats. Stimulation of low threshold T5,6 IINAs which reduces PA only by inhibition of medullary I-cells (i.e., disfacilitation), resulted in a decrease in cervical I-cell (19) activity at approximately the same time (3/19) or after 16/19) the decrease in PA; PA decreased after medullary evoked activity. Stimulation of low threshold T9,10 IINAs which excites PA through intersegmental pathways, resulted in an increase in cervical I-cell activity (6/12 cells) at approximately the same time (4/6) or after (2/6) the increase in PA; evoked activity in the medulla occurred at approximately the same time as the increase in PA. These results suggest that: a) intercostal nerve afferents (e.g., from tendon organs) do not inhibit cervical I-cells through intersegmental pathways, and b) lower intercostal afferents excite cervical I-cells intersegmentally. (NIH Grant HL17715)

Phrenic Afferent Fibers (PAFs) Excite Cervical Spinothalamic Tract (STT) Neurons in the Monkey. **D.C. Bolser, S.F. Hobbs, M.J. Chandler and R.D. Foreman. Dept. of Physiol. and Biophys., OUHSC, Okla. City, OK 73190.**

Pain associated with diseases of the diaphragm, such as diaphragmatic pleuritis, can be referred to the shoulder. The neurophysiological basis for this pain referral is unknown. Referred visceral pain can be explained by excitatory convergence of visceral and somatic afferent input onto the same STT neurons. This theory of referred visceral pain also may be applicable to the diaphragm, a somatic organ. We hypothesized that STT neurons in the cervical spinal cord are excited by stimulation of somatic fields in the shoulder and proximal forelimb and by activation of PAFs. Six monkeys (Macaca fascicularis) were anesthetized with chloralose and paralyzed with pancuronium. Extracellular single unit activity was recorded from the left grey matter of the C5-C8 spinal cord. All cells were antidromically activated from the ventroposterolateral nucleus of the thalamus and had excitatory somatic fields in the left shoulder and/or proximal forelimb. Electrical stimulation of the left phrenic nerve just rostral to the diaphragm (2-34 V, 20 Hz, 0.1 ms pulse) increased the activity of 13/16 neurons. Three neurons were unaffected. We conclude that activation of PAFs can increase the activity of cervical STT neurons that have excitatory somatic fields in the shoulder and forelimb. This excitatory convergence can explain referral of pain to the shoulder in diseases involving the diaphragm. (Supported by NIH grants HL22732, HL07930, NS08150 and the American Heart Assoc.).

GRAVITATIONAL REPRESENTATION OF RESPIRATORY NEURON ASSEMBLIES B.G. Lindsey, R. Shannon, and G.L. Gerstein. Dept. Physiol., Univ. S. Florida, Tampa, FL 33612 and Dept. Physiol., Univ. Penn. Philadelphia, PA 19104.

We have used the gravity method (J. Neurosci. 5:881) to assess the cooperative behavior of respiratory modulated medullary neurons in raphe nuclei and lateral respiratory groups. Twelve sets of 5-9 simultaneously recorded neurons from 8 anesthetized (Dial), paralyzed, bilaterally vagotomized, artificially ventilated cats were studied. Neurons were represented as particles that acquire charges as a function of the cells' activities. 1) Rates of particle aggregation a) were related to interaction strengths derived from cross-correlograms, and b) varied with time. 2) Putative shared inputs and excitatory interactions were more readily detected than inhibitory interactions. 3) Some midline neurons exhibited multiple concurrent associations with both midline cells and the lateral groups. Cross-correlation analysis of midline neurons recorded in n. raphe obscurus or at the pontine-medullary border revealed joint increases in activity that resulted in symmetrical and asymmetrical correlogram peaks spanning up to 100 ms. These preliminary results establish that midline neurons may be elements of spatially distributed neural assemblies, suggest fluctuations in the relationships among some cells, and confirm conclusions about the method derived from network simulations. Supported by NS19814, SDF-0013, and ONR N00014-87-K-0766.

INHIBITION OF MEDULLARY EXPIRATORY NEURONS IN THE CAT BY RETROFACIAL INSPIRATORY NEURONS. P.M. Lalley, K.Anders*, D.Ballantyne‡ A.M. Bischoff*, and D.W. Richter. I. Institute of Physiology, Univ. Heidelberg, D6900 Heidelberg,FRG

The discharge of expiratory neurons in the caudal medulla is terminated by decrementing waves of IPSP's during inspiration (I) and post-inspiration(PI). We wished to determine if I neurons near the retrofacial nucleus (RFN) are involved in the depression of caudal expiratory (CE) neurons. RFNI and CE neurons were recorded from. Comparisons were made between the discharge patterns of RFNI neurons and the membrane potential profiles (MPP's) of CE neurons. Spike - triggered averaging (STA) of IPSP's in CE neurons by RFNI firing was used to detect synaptic connectivity. Of 51 RFNI neurons, 46 had incrementing discharges, 6 had plateau and 3 had decremental patterns;thus most patterns did not match the MPP's of CE neurons. However, a later wave of IPSP's was often seen, accompanied by increased RFNI firing frequency. STA of 30 pairs revealed IPSP's with latencies and shape indicies which were not consistent with a monosynaptic connection; at least one inhibitory neuron may be interposed between RFNI and CE neurons. We conclude that RFNI neurons inhibit CE neurons throughout I, in concert with other types of medullary I neurons. The inhibition by RFNI neurons is relatively moderate , but is augmented at times during late inspiration, leading to a second wave of IPSP's in CE neurons.

THE NUCLEUS RAPHE MAGNUS: A SITE FOR PRODUCTION OF ACUTE RESPIRATORY FAILURE IN THE RAT. M.K. Carruth*, A.A. Fowler*, G.R. Leichnetz, D.J.Mayer (SPON: D. Bossut). Departments of Anatomy, Medicine and Physiology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

Acute respiratory failure was produced in rats by injection of the excitotoxin, ibotenic acid into the nucleus raphe magnus (NRM). Pulmonary arterial pressure, blood gas tensions, systemic arterial pressure, core body temperature, lung water, and bronchoalveolar lavage fluid (BALF) protein levels were monitored and compared to controls. NRM injection produced a dramatic rise in pulmonary arterial pressure (128%), acute hypoxia ($p < 0.01$), metabolic acidosis ($p < 0.01$), and a widened arterial to alveolar oxygen gradient in the absence of a rise in systemic arterial pressure. Following injection we also observed a significant decrease in core body temperature ($p < 0.01$). There was no significant change in pCO2 levels, lung water, or BALF protein content compared to controls.

This is the first study suggesting that NRM participates either directly or indirectly in neural regulation of pulmonary arterial tone. Electrolytic lesioning of this nucleus does not produce similar respiratory effects. We suggest that prolonged excitation of the NRM, not death of constituent neurons, produces rapid onset of pulmonary failure. We further conclude that pulmonary arterial hypertension with profound ventilation/perfusion mismatching is responsible for the hypoxemia which results following neural excitation of the NRM.

255.8

DISCHARGE DEPENDENCIES OF PERIAQUEDUCTAL GREY (PAG) NEURONS TO THE RESPIRATORY CYCLE DURING SLEEP-WAKING STATES. H Ni*, J Zhang, RR Terreberry and RM Harper. Dept of Anatomy & Brain Res Inst, UCLA, Los Angeles, CA 90024.

The PAG projects to brainstem structures regulating respiratory patterning, especially the n. tractus solitarius, and rostral ventrolateral medulla including the n. ambiguus, and receives projections from rostral limbic structures that can alter respiratory patterning. Since the PAG could modulate descending influences on respiratory patterning, particularly during different states, we examined PAG neuronal discharges in cats during sleep and waking. In 6 cats chronically instrumented with microelectrodes in the PAG and diaphragmatic leads, we correlated tonic PAG neuronal discharge with T(tot) and determined phasic discharge dependencies with the respiratory cycle in waking (AW), quiet sleep (QS) and active sleep (REM) states. Of 38 cells recorded in the PAG, 10 showed a tonic discharge correlation and 8 showed a breath-by-breath dependency to the respiratory cycle. The greatest number of tonic relationships (5) were observed during AW, followed by REM and QS. Breath-by-breath correlations were observed equally in AW and QS, but less often in REM. These results suggest that a subset of PAG cells discharge with aspects of the respiratory cycle, and that these discharge correlations are state related. The PAG may mediate these state-related differences, or PAG cell discharges may be altered by descending state-related influences. Supported by HL-22418-10

NUCLEUS RETICULARIS GIGANTOCELLULARIS MEDIATES RESPIRATORY INHIBITION DURING TRANSIENT HYPERTENSION. RW Stremel*, CA Richard, KW Lemmons* and TG Waldrop* (SPON: JP Porter). Depts of Physiology & Biophysics, Univ of Louisville, Louisville, KY 40292 & Univ of Illinois, Urbana, IL 61801.

Activation of cell bodies within the nucleus reticularis gigantocellularis (NGC) causes inhibition of tidal volume and ventilatory frequency. Since the NGC is known to receive baroreceptor information, we hypothesized that this same inhibitory mechanism is responsible for the suppression of ventilation during transient hypertension (TH). In anesthetized cats, respiration was quantified by either C5 phrenic recording or pneumotachographic integration. Phenylephrine (PE) was injected IV (5-40 µg in saline) before and after either electrolytic or chemical (0.1 µg/ml kainic acid in 500 nl saline) NGC lesion. The inhibition of breathing (e.g., apnea) during TH was significantly reduced by bilateral NGC lesion; TH induced by PE caused frequency to be significantly reduced before lesion while after lesion frequency was only minimumly influenced. Normalizing the breath frequency response as change per mm Hg pressure change provides the same result. Indices of tidal volume indicated similar suppression due to TH while lesion has less effect on the inhibition of this variable. The NGC appears to be critically involved, particularly for frequency changes, in the inhibition of breathing during transient hypertension. Supported by Kentucky Heart Association.

AGE DIFFERENCES IN RESPONSES OF RAT BRAINSTEM RESPIRATORY CHEMOSENSORY NEURONS. Pan Y.*, Whittaker*, J.A., Bernard D.G., and Trouth C.O. Dept. Physiol, Coll. Med. Howard Univ., Washington, D.C. 20059 (SPON: J.A. Holloway).

Central respiratory chemosensitivity has been ascribed to neurons in 3 areas (rostral, intermediate, caudal) located within the marginal glial layer of the ventral medullary surface (VMS). This study examines the hypothesis that the superficial brainstem chemosensory mechanism, might from a functional point of view, not be fully developed at birth. In 3 age groups (newborn 1-4 days, young pups 5-11 days, and adult over 6 months) of spontaneously breathing rats, neuronal activity in the caudal zone (Area L) on the VMS was studied for responsiveness to increased inspired CO_2 and decreased inspired O_2. Units were also tested for responsiveness to other modalities of sensation such as touch, pressure, joint manipulation and temperature. In young and adult rats, increased inspired CO_2 (5% CO_2) increased the firing rate of chemosensitive neurons, and increased respiratory frequency. In newborns the response was slight; 1 and 2 day old rats were least sensitive to CO_2 stimulus. Decreased inspired O_2 (12 % O_2) increased neuronal activity in newborns and young pups, whereas no significant change was noted in the adult. These results suggest (1) central CO_2 chemoreceptor mechanism might not be fully developed functionally at birth (2) a central hypoxic drive to respiration appears to be mediated via the central chemoreceptor elements in newborns. (Supported by MBRS-2-S06-RR-08016-16).

BRAINSTEM NEURONS DEVELOP AT DIFFERENT RATES IN EARLY LIFE: IN-VITRO ELECTROPHYSIOLOGIC STUDIES. G.G. Haddad and P.A. Getting. Dept. of Pediatrics, Columbia Univ., New York, NY, and Dept. of Physiology, Univ. of Iowa, Iowa City, IA 52242.

We have previously shown that the electrophysiologic properties of neurons in the ventral region of the Nucleus Tractus Solitarius (NTS) develop postnatally. In order to determine whether the cellular properties of other neuronal groups involved in cardiorespiratory control mature postnatally, we studied dorsal vagal (DMNX) and Hypoglossal (HYP) motoneurons in newborn (3-12d) and adult rats. Transverse, in vitro brainstem slices were used for intracellular recording. DMNX neurons of both the adult (n=24) and newborn (n=20) displayed profound spike frequency adaptation (SFA) with steady-state to peak firing frequency ratios of 0.31 and 0.37 respectively. In addition, both adult and newborn DMNX cells exhibited delayed excitation (DE) which was manifested as a delay between the onset of depolarization and the first spike. HYP neurons of both the adult and newborn showed much less SFA (steady-state to peak ratio = 0.6-0.9) than DMNX cells but no DE was observed. The major difference between newborn and adult DMNX or HYP neurons was a higher input resistance and longer time constant for the newborn cells.

We conclude that besides differences in passive properties that can be attributed to soma size, the electrophysiologic properties of DMNX and HYP neurons mature early suggesting that the developmental schedule of DMNX or HYP neurons is different from that of NTS neurons.

ROLE OF OPIOID PEPTIDES IN LUNG DEVELOPMENT: EFFECTS OF CNS BETA-ENDORPHIN (BE) ON ORNITHINE DECARBOXYLASE (ODC) ACTIVITY AND ON DNA SYNTHESIS. N.L. Greer*, J.V. Bartolome* and S.M. Schanberg* (SPON: F. Menitti). Dept. Pharmacol., Duke Univ., Durham, N.C. 27710.

It is well established that neonatal lung maturation is controlled by various hormones including catecholamines and insulin. Accumulated evidence indicates that endogenous opioids may also have an important role in lung development. Premature infants of narcotic addicts rarely show Respiratory Distress Syndrome. Naloxone, an opiate antagonist, retards lung maturation. The specific opioid(s) involved and its mechanism of action is unknown. Recent studies suggest BE may participate in this process. Fetal and postnatal levels of BE are elevated in neonates of opiate exposed mothers. We have reported that CNS BE alters basal ODC activity as well as its responsivity to trophic factors in liver and heart. ODC is the rate-limiting enzyme in the synthesis of the polyamines which regulate nucleic acid and protein syntheses. The present study examined the effects of postnatal BE on basal lung ODC activity and lung DNA synthesis as well as lung ODC responsivity to insulin and isoproterenol.

Central BE markedly lowered lung ODC activity in the neonatal rat. ODC inhibition had clear developmental consequences as indicated by significant reductions in DNA synthesis. In addition, BE treatment suppressed lung ODC responsivity to insulin and isoproterenol in an age-selective manner. These findings strongly support a modulatory role for CNS BE in neonatal lung development. (Supported by grants: NIH R01-NS25738 and NIH 5R01-MH13688)

NEUROENDOCRINE CONTROLS: PITUITARY III

256.1

EVIDENCE FOR INHIBIN β-CHAIN LIKE-PEPTIDE MEDIATION OF SUCKLING-INDUCED OXYTOCIN SECRETION. P.M. Plotsky, P.E. Sawchenko, and W. Vale. The Salk Institute, La Jolla, CA, 92037.

The recently identified inhibin-β-subunit immunopositive projection, ascending from the nucleus of the solitary tract (NTS) to oxytocin-immunoreactive (irOT) magnocellular perikarya of the paraventricular (mPVN) and supraoptic (SON) nuclei, may represent an important regulatory pathway for parturition- and suckling-induced irOT secretion. This hypothesis was tested in several rat models. First, we were able to demonstrate a 2.0-fold ($p < 0.001$) elevation of irOT in the systemic circulation following bilateral microinfusion of inhibin β-chain homodimer into the mPVN of urethane-anesthetized male rats (36 fmoles/1 µl per side infused over 15 min). Conversely, infusion of carrier or inhibin α-subunit peptide was without effect. Second, activation of endogenous inhibin β-subunit containing pathways via electrical stimulation of the NTS (100 µA, 1 msec duration paired pulses, 1 Hz) in intact or 6-OHDA treated (2 µg/1 µl bilaterally into mPVN 5 days earlier) rats also resulted in elevation of systemic irOT levels. Finally, bilateral mPVN microinfusion of antiserum to the inhibin β_A-subunit attenuated both suckling-induced increases in intramammary pressure and irOT secretion anesthetized dams on day 10-12 of lactation; infusion of carrier was without effect. These observations provide strong support for the hypothesis that the NTS-to-mPVN inhibin β-chain peptide-containing projection represents a physiologically significant afferent system mediating the milk ejection reflex. EVIDENCE FOR INVOLVEMENT OF AN ADRENAL CATECHOLAMINE IN THE β-ADRENERGIC INHIBITION OF OXYTOCIN RELEASE IN LACTATING RATS. S.-L. Song*, C.E. Grosvenor, and W.R. Crowley. Departments of Physiology & Biophysics and of Pharmacology, University of Tennessee College of Medicine, Memphis, TN 38163.

Adrenergic systems exert both excitatory (α-adrenoceptors) and inhibitory (β-adrenoceptors) influences on oxytocin (OT) release. Because suckling also releases epinephrine from the adrenal medulla, the present experiments tested whether adrenal catecholamines participate in the adrenergic regulation of OT release during lactation. In two experiments, adrenal demedullation in midlactation did not alter the basal plasma levels of OT, but markedly enhanced the suckling-induced release of OT. OT release in response to suckling in both sham and adrenal demedullated rats was blocked by stimulation of β-adrenergic receptors with isoproterenol. Blockade of β-adrenergic receptors with propranolol prevented the inhibitory action of isoproterenol and when given alone, mimicked the effect of demedullation to enhance suckling-induced OT release. Stimulation of α-adrenergic receptors with phenylephrine did not affect OT release, but blockade of α-receptors with phentolamine blocked release of OT by suckling. These findings support the concept that stimulation of β-adrenergic receptors inhibits OT secretion and suggest that this may be due to an action of an adrenal catecholamine, which may act centrally and/or at the neurohypophysis.

SUPRAOPTIC VASOPRESSIN CELL EXCITATION FOLLOWING SOLITARY NUCLEUS STIMULATION IS MEDIATED VIA THE A1 NORADRENALINE CELL GROUP. Trevor A. Day and John R. Sibbald*, Department of Physiology, University of Otago Medical School, Dunedin, New Zealand.

Nucleus tractus solitarius (NTS) stimulation excites supraoptic (SON) vasopressin (AVP) cells via a catecholaminergic projection. Although a direct NTS input to SON involving A2 noradrenaline (NA) cells exists, this projection is sparse, suggesting the possibility that NTS effects on AVP cells are relayed through the A1 NA cell group. This possibility is consistent with evidence that NTS projects to the A1 region, and that A1 stimulation excites SON AVP cells.

SON cells recorded in pentobarbital anaesthetized rats were classified as AVP-secreting on the basis of activity patterns and responses to baroreceptor activation. Medial NTS stimulation excited 82% (latency 51+/- 1 ms) and A1 region stimulation 77% (38 +/- 1 ms) of putative AVP cells tested (n=83). Most NTS responsive units (90%) were excited by A1 stimulation. Bilateral A1 lesions, or contralateral A1 lesions combined with ipsilateral GABA injection (100 nl, 0.75 M), abolished NTS stimulation effects on AVP cells.

The present data suggest that, despite a direct projection to SON from NTS, visceral afferent information reaching the brain via NTS influences SON AVP cells indirectly, through the A1 NA cell group.

RESPONSES OF NEUROSECRETORY NEURONS IN THE RAT PARAVENTRICULAR NUCLEUS TO FASTIGIAL NUCLEUS STIMULATION STUDIED BY INTRACELLULAR RECORDINGS. T. Katafuchi* and K. Koizumi. (SPON: C.M. Brooks) Department of Physiology, SUNY, Health Science Center at Brooklyn, Brooklyn NY 11203

It has been reported that the fastigial nucleus of the cerebellum (FN) is involved in the regulation of the sympathetic nervous system and vasopressin release in relation to the orthostatic reflex. However, the influence of the FN on secretion of vasopressin is still controversial. In the present study, responses of neurons in the paraventricular nucleus (PVN) of the hypothalamus to electrical stimulation of the FN were examined by extracellular and intracellular recordings in anesthetized rats. About one half of spontaneously firing PVN neurosecretory cells identified by the pituitary stalk stimulation responded to contralateral FN stimulation (0.1-0.3mA, 0.2 ms, 1Hz), of which 70% were inhibited after a short latency. Intracellular recordings of neurosecretory neurons in the PVN showed that the membrane resistance was about 30 MΩ and FN stimulation evoked IPSPs. Most of them were considered to be monosynaptically evoked, since their latencies were constant when FN stimulus intensity was changed. Polysynaptic IPSPs and EPSPs were also observed. These results suggest close functional connections between the PVN and the FN which may contribute to hypothalamic modulation of autonomic and neuroendocrine systems.

HYPERTONIC SALINE IS AN EFFECTIVE STIMULUS FOR ALTERING SPINAL CORD OXYTOCIN AND VASOPRESSIN IN SHR. D. Lukic*, J. Vrba* and J. Haldar Department of Biological Sciences, St. John's University, Jamaica, NY 11439

Recently we have demonstrated that immobilization stress (Brain Res. In Press) as well as hypertonic saline stress (Neurosc. Abst. #186.4, 1987) alter Oxytocin (OT) and Vasopressin (VP) content of the spinal cord in Long Evans (LE) rats. Since spontaneously hypertensive rats (SHR) are known to be particularly sensitive to some stressors, this study was conducted with three groups of 12 weeks old male SHR. Rats were decapitated 15 mins. after an ip injection of either isotonic (0.85%, 20ml/kg) or hypertonic saline (1M, 20ml/kg). Untreated rats served as control. OT and VP content of cervical, thoracic, and lumbosacral cord segments of all three groups of rats were determined by RIA in sep-pak extracted sample. Our results demonstrate 1) hypertonic saline increases OT content but decreases VP content of the spinal cord 2) isotonic saline decreases primarily VP content of the spinal cord. 3) changes observed for either hormone are similar throughout the cord 4) saline-induced effect is more pronounced in the SHR than in LE. In conclusion, these data suggest that extrahypothalamic neuropeptide of SHR respond differently to stress.

VASOPRESSIN AND OXYTOCIN RELEASE IN RESPONSE TO HYPOTONICITY. C.Yagil* and C. D. Sladek. University of Rochester School of Medicine, Rochester, NY 14642.

Vasopressin (VP) release in vivo and from cultured explants of the hypothalamo- neurohypophyseal system (HNS) is inhibited by decreases in osmolality (OSM). In the current study, we utilized HNS explants to examine the time course of the response to a decrease in OSM and the effect of the rate of decrease on VP and oxytocin (OT) release. HNS explants were perifused at 2.1ml/hr. Basal OSM was 301-306mosm/kg H20. A 15mOsm decrease in OSM was achieved by decreasing the concentration of NaCl in the medium over a 2 hour period (2% rate of decrease) or a 1 hour period (5% rate of decrease). Both 2% and 5% rates of decrease in OSM significantly inhibited VP release (75±8% and 88±4% of basal respectively, $p<0.025$; n=4 and n=7 resp.) and OT release (66±10% and 89±4% of basal resp., $p<0.05$). During the 2% rate of decrease, inhibition of VP and OT release was evident 30-40 minutes after initiation of the decrease when OSM was reduced by 4-5mOsm. During the 5% rate of decrease, a significant reduction in VP and OT release was observed in the first 10-20 minutes of hypotonicity corresponding to a 3-5 mOsm reduction in OSM. These data do not provide evidence of rate sensitivity in the inhibition of VP and OT release by a decrease in OSM, in contrast to our previous demonstration that the response to an increase in OSM is rate sensitive. During both the 2% and the 5% rate of decrease, inhibition of hormone release was present only during the portion of the pulse which corresponded to 10 mosm reduction in OSM. This was followed by an increase in VP and OT release which exceeded basal release (2%: 131±4% of VP basal release, $p<0.01$ and 169±8% of OT basal,$p<0.025$. 5%: 127±14 of VP, $p<0.025$ and 151±25%, $p<0.05$ of OT). This rebound phenomenon was previously observed when OSM was returned to basal levels after a period of hypertonicity. The mechanisms underlying the rebound hormone release remain to be elucidated. OXYTOCIN IS NATRIURETIC AT PHYSIOLOGICAL PLASMA CONCENTRATIONS. J.G. Verbalis, M. Mangione* and E. M. Stricker. Departments of Medicine and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

Oxytocin (OT) is known to stimulate natriuresis at high plasma levels. We examined the potential physiological effects of lower plasma OT levels by infusing graded doses of OT subcutaneously in adult male rats maintained on sodium-deficient (NaD) diet. Our results demonstrated a clear dose-related increase in urinary Na+ excretion during the initial day of OT infusion (**p< 0.01 compared to 0 dose):

OT Infusion Rate (mU/h)	Plasma OT (uU/ml)	Urinary Na+ (uEq/24h)
0 (n = 14)	2.1 ± 0.3	195 ± 21
1.0 (n = 15)	2.7 ± 0.7	194 ± 21
5.0 (n = 12)	6.4 ± 0.9**	618 ± 100**
10.0 (n = 20)	6.7 ± 0.9**	927 ± 86**
50.0 (n = 11)	39.5 ± 5.3**	1102 ± 100**

The minimal plasma OT levels associated with significant increases in natriuresis (5-10 uU/ml) were well within the range of physiological OT secretion in rats in response to stimuli such as dehydration and food intake. However, the OT-induced natriuresis was not sustained during subsequent days on NaD diet, suggesting that this effect can be overridden by opposing antinatriuretic factors such as aldosterone. These results are consistent with the hypothesis that peripherally and centrally secreted OT act in concert in rats to promote sodium excretion and to inhibit sodium appetite.

REGIONAL ANALYSIS OF VASOPRESSIN mRNA BY IN SITU HYBRIDIZATION IN WATER DEPRIVED RATS **R.B. Meeker, R.S. Greenwood and J.N. Hayward, Dept of Neurology and Neurobiology Curriculum, University of North Carolina, Chapel Hill, NC 27599**

A method was developed for semi-quantitative regional and single cell analysis of vasopressin (VP) mRNA transcription in the magnocellular neuroendocrine system in response to water deprivation. A 26-mer oligonucleotide probe to VP mRNA was 3' end labeled to a specific activity of 1-3 X 10^7 CPM/ug with ^{125}I-dCTP using deoxynucleotide terminal transferase. The probe was hybridized to 20 um sections of 4% paraformaldehyde perfused rat brain. These sections were then coated with NTB-2 emulsion, exposed for 2-5 days at 4° C, developed and counterstained with acridine orange. Silver grain densities were analyzed over fluorescent cells utilizing an image analysis system (Bioquant IV). Each magnocellular neuroendocrine region showed an increase in probe hybridization in response to three days of water deprivation. The increase in hybridized probe within the supraoptic nucleus (SON) was twice that of the paraventricular nucleus (PVN) and 56% greater than the nucleus circularis complex (NC). Analysis of single cells within each of these regions, however, revealed substantial heterogeneity in the hybridization signal. Labeled cells within the SON fell within a single population, whereas, two populations of cells were observed within the PVN and NC. This diversity of mRNA expression may represent different functional categories of vasopressin magnocellular neurons.

INHIBITORY EFFECTS OF κ-AGONISTS ON SUPRAOPTIC NEURONS IN HYPOTHALAMIC SLICE PREPARATIONS. H. Yamashita[1], K. Inenaga[1*], H. Kannan[1], S. Uesugi[1*], K. Nakao[2*] and H. Imura[2*]. [1]Dept. of Physiol., Occup. & Environ. Health, Sch. of Med., Kitakyushu & [2]Dept. of Med., Univ. of Kyoto, Kyoto Japan

Existence of opioide peptides in the hypothalamic supraoptic nucleus(SON) suggests functional importance on the neural activity. Recently it has been observed that a κ-agonist, Leumorphin (LM), administered cerebroventricularly inhibited release of vasopressin in the plasma. This inhibitory mechanism, however, is not known. To clarify the mechanism, intra and extracellular recordings were made from rat SON neurons in the slice preparations. LM decreased the spontaneous neural activities in a half of both phasic and non-phasic SON neurons with dose-related manner. The threshold was about 10^{-8}M. Another κ-agonist, dynorphin inhibited both phasic and non-phasic neurons as LM did. The κ-agonist-induced inhibition was suppressed by κ-antagonist, MR2266. LM decreased excitatory post-synaptic potentials with membrane hyperpolarization and a small increase of membrane resistance. Morphine, μ-agonist, and DADLE, δ-agonist, inhibited non-phasic neurons more preferentially than phasic neurons. From these results, we suggest that κ-agonists inhibit presynaptically the neural activities of both vasopressin and oxytocin secreting neurons.

INTRAVENOUS VASOPRESSIN INFUSION INCREASES PLASMA CORTISOL CONCENTRATION IN DEXAMETHASONE-TREATED, CONSCIOUS DOGS. V.L. Brooks* and L.J. Blakemore*. (SPON: L. Pubols) Dept. of Physiology, Oregon Hlth Sci Univ., Portland, OR 97201.

Although vasopressin (AVP) is considered a major stimulator of ACTH secretion, we recently found that AVP infusion decreases plasma ACTH concentration (ACTH), and only transiently increases plasma cortisol concentration (CS) in dogs. To determine if AVP causes an early undetected increase in ACTH that mediates the initial increase in CS, dogs (n=5) were pretreated with dexamethasone (DEX; 4 mg S.C.), to inhibit endogenous ACTH release, 135 min before the start of a 90 min AVP (1 $ng \cdot kg^{-1} \cdot min^{-1}$) infusion. In DEX-treated dogs, AVP infusion did not increase CS (5 ± 1 to 4 ± 1 ng/ml; $p > 0.10$), suggesting that ACTH is necessary for the CS rise. ACTH can enhance the direct adrenal effect of factors that increase CS. Therefore, it was then determined whether AVP increases CS in dogs that were pretreated with DEX and a dose of α1-24 ACTH (0.3 $ng \cdot kg^{-1} \cdot min^{-1}$) that clamped ACTH and CS at basal levels (DEX+0.3 ACTH), or a dose of ACTH (0.5 $ng \cdot kg^{-1} \cdot min^{-1}$) that elevated ACTH and CS (DEX+0.5 ACTH). In DEX+0.3 ACTH dogs, AVP infusion produced a sustained increase in CS from 22 ± 3 to 49 ± 8 ng/ml ($p < 0.001$). In DEX+0.5 ACTH dogs, AVP infusion produced a similar increase in CS (from 32 ± 6 to 61 ± 10 ng/ml; $p < 0.001$). These results suggest that AVP can increase CS independently of an increase in ACTH, but that normal basal ACTH is required for this effect. Supported by UPS HL35872 and AHA, OR affiliate.

SUCKLING DOES NOT AFFECT GASTRIC MOTILITY IN RATS. D.L. Helmreich, E. Thiels, J.G. Verbalis, E.M. Stricker. Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

After rats are given LiCl or cholecystokinin (CCK) ip, pituitary oxytocin (OT) secretion (reflecting magnocellular activity in hypothalamic paraventricular nucleus (PVN)) is highly correlated with decreases in gastric motility (reflecting parvocellular PVN activity). We now report the effects on gastric motility of suckling, another known stimulus of OT secretion. Gastric motility, measured in 11 lactating rats 8-14 days postpartum, was 94 ± 14% (M ± SE) of baseline values when the pups were attached but no milk ejections occurred, and 97 ± 13% of baseline values during the milk ejections. Gastric motility during suckling and milk ejection also was not altered by pretreatment with naloxone (2.5 mg/kg), which enhances OT secretion and inhibits gastric motility in rats after injection of LiCl or CCK (Flanagan et al., Soc. Neurosci. Abstr., 1988). Moreover, suckling and milk ejection did not influence the decrease in gastric motility caused by CCK in rats. These results demonstrate that suckling does not affect gastric motility in rats, and thus it appears to be a stimulus that selectively activates magnocellular rather than parvocellular neurons in PVN. EFFECTS OF VASOPRESSIN OR OCYTOCIN ANTISERUM ON ANTERIOR PITUITARY HORMONE SECRETION IN THE RAT.

C.F. Franci*, J. Anselmo-Franci*, G. P. Kozlowski and S.M. McCann, Department of Physiology, UT Southwestern Medical Center, Dallas, Texas 75235 and *Department of Physiology, Medical School of Ribeirao Preto-USP, 14049-Riberao Preto, SP-Brazil.

Adult female Sprague-Dawley rats were used for experiments 5 weeks after ovariectomy. Stainless steel cannulae were implanted into the third ventricle and silastic cannulae were introduced into the external jugular 1 week and 24 hours before the experiment, respectively. Blood samples were collected immediately before (time 0) and 15,30,60,120 and 180 min or 1,2,3,4,5,6 and 24 hours (h) after intracerebroventricular microinjection (i.c.v.m.) of normal rabbit serum (NRS), vasopressin antiserum (AB-VP) or oxytocin antiserum (AB-OT). There was no difference in the plasma LH, FSH, PRL and TSH between control groups (NRS) and groups submitted to the i.c.v.m. of AB-VP or AB-OT. Plasma GH was not changed with i.c.v.m. of AB-VP but increased significantly by 1-24 h after i.c.v.m. of AB-OT. Thus, endogenous oxytocin (OT) may play a role in the control of GH release by stimulating somatostatin secretion or inhibiting CRF secretion or by both actions. Surprisingly, a previous study showed that i.c.v.m. of OT increased GH release. However, the i.c.v.m. of OT could have blocked the action of endogenous OT by ultra short loop negative feedback. Elimination of ultra short loop feedback of OT by the AB-OT could explain why i.c.v.m. of AB-OT could have the same effects on GH secretion as i.c.v.m. of OT.

ULTRA-RAPID FREEZE TECHNIQUES ACHIEVE SUPERIOR ULTRASTRUCTURAL PRESERVATION AND SPECIFIC IMMUNOGOLD LABELING IN RAT NEURAL LOBE. W.E. Armstrong, M. Tian* and J. Reger* (SPON: R. Stiles). Dept. of Anat. Neurobiol., Univ. Tenn., Memphis, The Health Science Center, Memphis, TN 38163.

Ultra-rapid freeze fixation provides a theoretical means of more accurately preserving molecular structure. With the eventual goal of describing relatively fast morphological events which might accompany secretion of vasopressin and oxytocin, we rapidly froze freshly dissected neural lobes on a Med-Vac device, then freeze-substituted with acetone and osmium prior to plastic embedding and conventional electron microscopy. Post-embedding immunogold techniques were used to localize neurophysin (antibody kindly provided by A. Robinson).

Excellent ultrastructural preservation was consistently observed from the point of initial freezing to a depth of 15 μm. Neurosecretory terminals and their associated dense core granules, clear vesicles, mitochondria, microtubules and other tubular structures were clearly resolved. In thinner sections, immunogold labeling of dense core granules for neurophysin was achieved without etching the plastic or removing the osmium, thus allowing retention of well preserved ultrastructure. As ultra-rapid freeze fixation of neural lobes is useful in describing normal ultrastructure and hormone distribution, it offers a preferred means of identifying morphological changes associated with neurosecretory events.

GALANIN CONCENTRATIONS IN THE MEDIAN EMINENCE (ME) AND ANTERIOR PITUITARY ARE INFLUENCED BY THYROID STATUS. S.C. Hooi* J.I. Koenig, S.M. Gabriel and J.B. Martin. Department of Neurology, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

Galanin (GAL) is a 29 amino acid peptide implicated in neuroendocrine regulation. In order to determine if GAL has a role in the regulation of TSH secretion, we studied the effects of both chemical and surgical thyroidectomy on GAL concentrations in the hypothalamus and anterior pituitary (AP). Adult male rats were thyroidectomised either chemically using 5-propyl-2-thiouracil (PTU) or surgically. T4 replacement in PTU treatment and T4 treatment in control rats were achieved by daily sc T4 injections for 3 weeks. PTU treatment significantly decreased GAL concentration 39% in the ME and 67% in the AP. The effects of PTU treatment in both regions were reversed by daily T4 injections. However, T4 injections alone did not influence GAL concentrations in control animals. Similarly, surgical thyroidectomy significantly decreased GAL concentrations in the ME and AP by 54% and 64% respectively. No significant changes were seen in the rest of the hypothalamus. This study demonstrates that GAL concentrations in the ME and AP are responsive to changes in thyroid status of the animal and suggests that GAL may be involved in thyroid hormone regulation.

256.15

NEUROENDOCRINE REGULATION OF GALANIN IN RAT HYPOTHALAMUS AND PITUITARY. S.M. Gabriel, J.I. Koenig, S.C. Hooi*, D.M. Maiter*, L.M. Kaplan, J.B. Martin. Departments of Neurology and Medicine, Massachusetts General Hospital, Boston MA 02114. Galanin is a 29-amino acid peptide present in brain and peripheral tissues. We have studied galanin-like immunoreactivity (Gal-IR) in the hypothalamus and pituitary gland under a variety of biologic circumstances by radioimmunoassay. Gal-IR is affected in a tissue-specific manner by several endocrine and autonomic stimuli. Anterior pituitary (AP) gland Gal-IR is modulated by reproductive endocrine treatments and is under the potent stimulatory influence of estrogen. Thyroid hormone and adrenal steroids are also necessary for the maintenance of normal AP levels of Gal-IR. High concentrations of prolactin and GH in plasma exert an inhibitory influence on AP intrinsic Gal-IR. Two nerve terminal beds, the median eminence and the neurointermediate lobe, contain high concentrations of Gal-IR. In these sites, Gal-IR is under the permissive influence of thyroid hormone. In addition, these tissues respond provocatively to alterations in fluid balance. These studies indicate that multiple neuroendocrine inputs influence Gal-IR in the hypothalamus and pituitary gland.

256.16

NEONATAL MONOSODIUM GLUTAMATE (MSG) TREATMENT CAUSES A CHRONIC REDUCTION OF VASOACTIVE INTESTINAL PEPTIDE (VIP) LEVELS IN THE ANTERIOR PITUITARY OF RATS. P.N. Riskind, S.C. Hooi*, J. I. Koenig and J. Audet-Arnold*. Neurology Service, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

VIP is a putative prolactin (PRL)-releasing factor which is found in high concentration in both the hypothalamus and anterior pituitary gland. It has not been clearly established whether pituitary VIP is synthesized locally within the gland or sequestered from the portal blood after hypothalamic secretion. As a first step in evaluating the hypothalamic contribution to pituitary VIP *in situ* we have evaluated the effect of chronic neurotoxic lesions of the hypothalamus with MSG. This treatment is known to result in an 80-90% loss of neurons in the arcuate nucleus of the hypothalamus without damage to axons of passage. In adult male rats, MSG-treatment reduced anterior pituitary VIP content from 178 $\pm$ 45 pg/gland to less than 20 pg/gland, and decreased VIP concentration from 220 $\pm$ 52 pg/mg protein to less than 90 pg/mg protein, but did not change medial basal hypothalamic VIP content. These results indicate that the hypothalamus normally has a stimulatory effect upon anterior pituitary VIP levels, and suggest that releasing factors or neurotransmitters contained in the arcuate nucleus may participate in this phenomenon. It is not possible to exclude a hypothalamic source of pituitary VIP from these studies.

256.17

CO-LOCALIZATION OF TYROSINE HYDROXLASE (TH) AND SEROTONIN (5-HT) IMMUNOREACTIVITY IN RAT PITUITARY INNERVATION. L.C. Saland, J.A. Wallace, A. Samora*, L. Gutierrez* and M. Williams*. Dept. of Anatomy, Univ. of New Mexico Sch. Medicine, Albuquerque. NM 87131.

Fibers containing catecholamines, 5-HT, gamma aminobutyric acid (GABA) as well as a variety of peptides have been demonstrated within the neural and intermediate lobes with immunostaining methods. Recently, GABA and TH have been co-localized with EM in pituitary nerves. We have compared fiber staining patterns in neurointermediate lobes (NILS) for TH and 5-HT on adjacent sections, which suggested that both substances might co-exist in specific fiber locations (Saland et al, '87, Soc. Neurosci. Abst. 13:418). Here, we demonstrate co-localization of TH and 5-HT fibers, using immunofluorescence. Adult male Sprague-Dawley rats were ether anesthetized, perfused with buffered 4% paraformaldehyde, and the pituitaries prepared for paraffin sectioning. Sections were consecutively incubated with sheep anti-TH, donkey anti-sheep IgG-FITC, then rabbit anti-5-HT and goat anti-rabbit IgG-TRITC. Co-localization of staining was observed in areas of both lobes, especially along border zones. No staining was observed if the inappropriate 2° fluorescent antibody (Ab) was matched with either 1° Ab alone, or if the 1° Ab was omitted. These findings suggest that multiple classic neurotransmitters co-exist in nerve fibers to regulate NIL endocrine secretion. Supported by NIH NS 21256, RR 08139 (LS) and NSF BNS-8511079 (JW).

256.18

NEUROPEPTIDE Y POTENTIATES EXCITATORY ACTIONS OF NORADRENALINE ON SUPRAOPTIC NEUROSECRETORY CELLS. B.K.J. Wilson*, J.R. Sibbald* and T.A. Day (SPON: R.J. Harvey), Department of Physiology, University of Otago Medical School, Dunedin, New Zealand.

Supraoptic (SON) vasopressin (AVP) cells receive an excitatory input from the A1 noradrenaline (NA) cell group. In addition to NA, however, A1 neurons also contain neuropeptide Y (NPY), and application of either substance excites SON AVP cells examined in vivo. In the present experiments we have used an in vitro preparation in order to more accurately determine the dose responsiveness of SON cells to NA and NPY, and to examine possible interactions between these two substances.

Using rat hypothalamic slices, extracellular recordings were obtained from spontaneously active SON cells. Bath application of NA (10^{-6} - 10^{-3} M) elicited dose dependent increases in cell discharge, phasically discharging units displaying marginally greater responsiveness than non-phasic units. Bath applications of NPY ($10^{-7}$and 10^{-6}M) also increased SON cell discharge rates and additionally produced a 40-60% increase in the excitatory effects of low concentrations of NA (10^{-5}M).

These data are consistent with the possibility that NPY released from A1 NA cells acts on SON AVP cells to both mimic and potentiate the actions of NA.

256.19

DISTRIBUTION OF LAMININ IN THE MURINE PITUITARY GLAND. R.F. Payette*, M.D. Gershon, E.A. Nunez* (SPON: C. Noback). Dept. of Anatomy and Cell Biology, Columbia Univ., College of P & S, New York, N.Y. 10032.

Previous studies have demonstrated immunological heterogeneity among the secretory granules of gonadotrophs. All adult male gonadotroph granules contain luteinizing (β-LH) hormone, but only 43% of the granules contain follicle stimulating hormone (β-FSH) and 9% have serotonin (5-HT) immunoreactivity. Moreover, β-FSH and 5-HT immunoreactivities do not co-exist in the same secretory granule (Anat. Rec. 219: 1987). In the present study, the localization of the extracellular matrix glycoprotein, laminin, was investigated in the adult murine pituitary gland and compared with that of 5-HT. EM immunocytochemistry was employed with 3 different laminin antisera, applied to aldehyde-fixed sections embedded in L.R. White. Immunoblots confirmed that laminin was the only immunoreactive protein in the adult murine pituitary gland. Sites of binding of primary antisera to laminin were identified with affinity-purified secondary antisera coupled to 20 nm colloidal gold particles. The patterns of immunostaining by the 3 antisera raised against laminin were compared and found to be identical. Laminin immunoreactivity was found extracellularly only in formed basal laminae in all three lobes of the pituitary. Laminin immunoreactivity was found intracellularly in gonadotrophs but in no other endocrine or non-endocrine cells of the anterior lobe. Within gonadotrophs, only secretory granules were labeled. The majority of secretory granules (64%; n=1089) contained laminin immunoreactivity in all gonadotrophs examined. None of the laminin-immunoreactive granules of gonadotrophs contained 5-HT, and none of the 5-HT-immunoreactive granules contained laminin. No intracellular laminin immunoreactivity was detected in the intermediate or neural lobes of the pituitary. These observations confirm that the secretory granules of gonadotrophs are heterogeneous. All granules contain β-LH, but a subset also contains laminin and another non-overlapping subset also contains 5-HT. Supported by NIH grants AM19743 and NS12969.

COMPUTER 3D RECONSTRUCTION OF MEDIAN EMINENCE MICRO-CAPILLARIES. L.S. Hibbard, B.J. Dovey-Hartman* and R.B. Page. The Pennsylvania State University College of Medicine, Hershey, PA 17033.

The microvasculature of the median eminence (ME) of the hypothalamus modulates communication between the brain and the pituitary. To understand the structural details of that functional relationship, we have developed computer 3D reconstruction (3DR) methods to observe microcapillary modules and attendant cellular detail from transmission electron micrographs (TEM).

Currently, a survey 3DR is underway to map capillaries in a block of ME tissue from low magnification (100X) TEM images. New feature extraction and alignment techniques have been developed to supplement those reported previously (Hibbard, et al., Comput. Biol. Med., 16:411, 1986). Capillary lumen edges are extracted by algorithms based on pixel neighborhood gray level variance, and the images were aligned by alternate stages of translation and rotation refinement using Fourier crosscorrelation (Hibbard, et al., Science, 236:1641, 1987). This low magnification 3DR will survey the largest capillaries in a 100-micron tissue block to guide the choice of features to be re-imaged at higher magnification (1650X) in the same tissue sections. The high magnification 3DR will seek to place cellular details onto a capillary network mapped at low magnification. (Support: NSF BNS-8506479 and NIH NS15926.)

PREPARATION OF PURIFIED BASAL FOREBRAIN CHOLINERGIC NEURONS FROM THE DEVELOPING RAT. A. Fine and P.J. Richardson*. Dept. Physiology & Biophysics, Dalhousie Univ. Med. School, Halifax, NS, Canada B3H 4H7, and *Dept. Clin. Biochemistry, Univ. Cambridge Clinical School, Cambridge U.K.

The extrinsic cholinergic innervation of much of the neocortex and hippocampus arises from cell bodies in several basal forebrain nuclei. Transplantion and tisssue culture of "cholinergic" neurons from these heterogeneous regions have inevitably been impure and problematic; for such studies, it would be useful to be able to purify the cholinergic cells. We have developed gentle immunoaffinity methods for purification of cholinergic neurons from developing rat brain, using solid-phase immunoadsorbants and cholinergic cell surface-specific antibodies. These methods are effective, simple, inexpensive, and less damaging than FACS methods. Using polyclonal sheep antiserum to the cholinergic cell membrane-specific ganglioside Chol-I, with an anti-sheep IgG-derivatized cellulose immunoadsorbant, we have achieved 20- to 25-fold enrichment (as determined by ChAT/LDH and AChE/LDH enzyme activity ratios) of viable cholinergic cells, dissociated by papain proteolysis from the basal forebrain of 20-35 day old rats, with yields of >100,000 cholinergic cells, representing approximately 1% of the total initial cells. Using monoclonal mouse antibodies to NGF receptor with anti-mouse IgG-derivatized magnetizable microspheres, we have achieved 6-fold enrichment of viable cholinergic cells from 18-day rat fetuses. These methods should be useful for purification of other cell types by substitution of appropriate primary antibodies. Transplantation studies and studies of gene expression using these purified cells are underway.

EXOGENOUS CHOLINE INDEPENDENT AND INTRACELLULAR CHLORIDE DEPENDENT ACETYLCHOLINE SYNTHESIS IN THE RAT BASAL FOREBRAIN SLICES. T. Suzuki* and K. Kawashima. Department of Pharmacology, Kyoritsu College of Pharmacy, Tokyo 105, Japan.

Acetylcholine (ACh) content of basal forebrain slices (including the basal nucleus of Meynert) of the male Wistar rat (8- to 10-weeks-old) under various incubation conditions was determined by radioimmunoassay. ACh content of slices incubated with artificial cerebrospinal fluid (ACSF) was elevated significantly during incubation with time and reached to the plateau level by 60 min incubation. The increase in the ACh content was not affected by the exogenous choline supply. After preincubation with high-K^+ ACSF (30 mM, 30 min) which depletes releasable ACh and choline in the nerve, subsequent incubation with and without exogenous choline supply caused the same degree of increase in ACh content. Incubation with low-Cl^- ACSF (4.8 mM Cl^-, 142 mM I^- or CH_3COO^-) did not affect the ACh synthesis. However, preincubation with high-K^+ and low-Cl^- ACSF diminished subsequent increase in ACh content. These findings suggest that some portion of the ACh synthesis is independent on extracellular choline, but is dependent on intracellular Cl^-.

RELEASE OF ENDOGENOUS ACETYLCHOLINE (ACh) FROM THE RAT MEDIAL SEPTUM/VERTICAL LIMB (ms/vdB) OF THE DIAGONAL BAND. R.H. Metcalf*, R.J. Boegman, R.J. Riopelle & S.K. Ludwin. Departments of Pharmacology and Toxicology, Medicine, and Pathology, Queen's University, Kingston, Ontario, K7L 3N6.

In the present study, K^+-stimulated release of endogenous ACh from tissue slices prepared from the ms/vdB of adult rat brain was determined by gas chromatography - mass spectrometry (GC-MS). Choline acetyltransferase(ChAT) activity in the ms/vdB region was 150.21 ± 11.25 nmoles ACh formed/mg protein/hr (n=5). Multipolar neurons approximately 20-30 μm in diameter stained intensely with ChAT monoclonal antibody. The basal release of ACh in the ms/vdB was 0.14 ± 0.02 nmoles/g wet wt/min on the right side and 0.16 ± 0.03 nmoles/g wet wt/min on the left side. Upon 35 mM K^+ depolarization, this release increased to 3.73 ± 0.19 nmoles/g wet wt/min on the right side and 3.83 ± 0.16 nmoles/g wet wt/min on the left side. Neither basal nor K^+-induced ACh release differed significantly between hemispheres ($p > 0.05$, n=6). Omission of Ca^{2+} resulted in a 91% decrease in ACh release in the presence of 35 mM K^+. ACh release in the presence of 4 μM atropine resulted in a 48.22 ± 4.76 (n=4) increase in release above that seen in the absence of atropine. These results indicate that depolarization-induced ACh release, which is Ca^{2+}-dependent and atropine-sensitive, can be demonstrated in tissue sections prepared from the ms/vdB of rat brain. MEDIAL HYPOTHALAMIC AFFERENTS TO FOREBRAIN CHOLINERGIC PROJECTION NEURONS. W.E.Cullinan and L. Zaborszky Neuroscience Program and Dept. of Otolaryngology, Univ. of Virginia School of Medicine, Charlottesville, VA 22908

The distribution of medial hypothalamic projections to forebrain areas containing cholinergic neurons was examined in the rat using the anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L) in combination with choline acetyltransferase (ChAT) immunocytochemistry. For the simultaneous detection of PHA-L fibers and ChAT neurons, the avidin-biotin peroxidase (ABC) technique was utilized with either the nickel-enhanced DAB/DAB (Hsu and Soban,1982) or BDHC/DAB (Levey et al., 1986) method.

Discrete iontophoretic PHA-L injections were delivered to the medial preoptic area, anterior hypothalamic area, paraventricular hypothalamic nucleus, and the ventromedial hypothalamic nucleus. PHA-L labeled fibers and terminals were found in varying amounts approximating ChAT labeled cell bodies and dendrites in the lateral part of the vertical limb of the diagonal band nucleus, medial portion of the horizontal limb of the diagonal band nucleus, bed nucleus of the stria terminalis, sublenticular substantia innominata, peripallidal region, and nucleus ansa lenticularis. The density and distribution of these afferents in relation to the cholinergic projection neurons was dependent upon the location of injected sites. Electron microscopic analyses are underway to determine synaptic contact. Supported by USPHS Grant NS 23945, 17743.

LAMINAR TERMINATION PATTERN OF EFFERENTS OF THE NUCLEUS BASALIS OF MEYNERT. M.L. Voytko, C.A. Kitt and D.L.Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182.

The major pathways by which neurons in the nucleus basalis of Meynert (nbM) project to targets in the telencephalon were delineated recently using a combination of choline acetyltransferase and autoradiography [Kitt et al., Brain Res. 406:192, 1987]. However, laminar and regional patterns of nbM efferent projections have not been characterized fully. In order to address this issue, electrophysiologically guided, stereotaxically placed injections (1-2.5 μl) of [^{3}H] amino acids were made into the nbM of three rhesus monkeys. Projections to the temporal pole were examined because it is one of the few cortical regions that shares a reciprocal relationship with the nbM. Autoradiographic studies revealed labeled fibers exiting the nbM laterally and entering the white matter of the temporal lobe, within fasicles of the temporal stem, before terminating within superficial cortical layers of the temporal pole. There is heavier labeling along the medial aspect of the temporal pole in one animal, suggesting regional specificity in nbM projections to this cortical region. The distribution pattern of nbM efferents to temporal pole suggests that the nbM may be involved in modifying associative functions of this polysensory cortical area, which has been implicated in learning and memory [Voytko, Behav. Brain Res. 22:25, 1986].

IMMUNOCYTOCHEMICAL VISUALIZATION OF CHOLINERGIC FIBERS IN MONKEY NEOCORTEX: ENHANCED VISUALIZATION USING SILVER NITRATE. C.A. Kitt, A.I. Levey, D.P. Friedman†, L.C. Walker, V.E. Koliatsos, L.S. Raskin*, and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182 and †Neuropsychology Lab., NIMH, Bethesda, MD 20892 and Div. Preclinical Research, NIDA, Rockville, MD 20857.

Acetylcholinesterase (AChE) has been used to visualize putative cholinergic fibers and cell bodies in the nervous system, but AChE is not a specific cholinergic marker. The development of anti-choline acetyltransferase (ChAT) monoclonal antibodies allowed detection of cholinergic somata in monkey forebrain and brainstem; however, ChAT-positive axons and terminals within cortical and/or subcortical structures have proved difficult to image. To address this issue, rhesus monkeys were anesthetized deeply with sodium pentobarbital and perfused quickly with 2% paraformaldehyde, followed by sucrose in PO_4. Frozen sections were processed for ChAT peroxidase-antiperoxidase immunocytochemistry and intensified with silver nitrate, according to a modification of the Fontana-Masson method [Masson, Am. J. Pathol. 4:181, 1928]. ChAT-positive fibers and cell bodies had a black "Golgi"-like appearance. Within premotor cortex, a distinct laminar pattern of ChAT-positive fibers are seen: layers II and V had dense bands; labeled fibers in layers I and IV were sparse.

257.7

COMPARATIVE LAMINAR DISTRIBUTIONS OF CHOLINERGIC FIBERS AND RECEPTORS IN MONKEY PREMOTOR CORTEX. D.P. Friedman[1,3], A.E. Levey[4], J.B. O'Neill[1], P.B.S. Clarke[2], D.L. Price[4], and C.A. Kitt[4]. Lab Neuropsychology[1] & Biol Psychiatry Section[2], NIMH, Bethesda, MD 20892, Div Preclinical Res[3], NIDA, Rockville, MD 20857, Neuropath Lab[4], Johns Hopkins Medical School, Baltimore, MD 21205.

The distribution of fibers stained for ChAT was compared to the distributions of muscarinic (M) and nicotinic (N) cholinergic receptors in rhesus monkey cortex. Cholinergic fibers were revealed using a monoclonal antibody raised against ChAT as described in the accompanying abstract (Kitt et al). ^{3}H QNB and ^{3}H nicotine were used to reveal M and N binding sites as described previously (O'Neill et al., Soc Neurosci Abs 11:0153, 1985). All animals were deeply anesthetized with barbiturate before perfusion or brain removal.

ChAT positive fibers were seen in all cortical layers but were densest in layer II and the upper part of layer V. They were least dense in layer IIIb. Fibers stained for AChe were similarly distributed. M receptors were distributed in two bands. A dense band was seen in layers I-IIIa and a second, less dense band was seen in layers V-VI. Layer IIIb was largely unlabeled. N receptors were only seen in the lower part of layer IIIa.

Despite the overlap of high densitites of ChAT positivity and M receptors, neither the receptor nor the fiber distributions could predict the other.

GLUTAMIC ACID DECARBOXYLASE mRNA IN NEURONS OF THE PRIMATE NUCLEUS BASALIS OF MEYNERT. L.C. Walker, D.L. Price, and W.S. Young III§. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182. §Lab. of Cell Biology, NIMH, Bethesda, MD 20892.

The primate basal forebrain magnocellular complex (BFMC), which includes the nucleus basalis of Meynert (nbM) and nucleus of the diagonal band of Broca, has been defined by the presence of large cholinergic neurons. In the rat, a significant population of neurons in the BFMC contain the inhibitory transmitter γ-aminobutyric acid (GABA) as determined by immunocytochemical detection of glutamic acid decarboxylase (GAD) [Brashear et al., Neurosci. 17:439, 1986]. However, GABAergic neurons have not yet been reported in the BFMC of primates. Therefore, we used in situ hybridization to localize putative GAD-producing cells in the nbM of a 21-year old female rhesus monkey (Macaca mulatta). A [^{35}S]-labeled synthetic DNA probe to bases 1982-2029 of human GAD mRNA was hybridized [Young et al., Proc. Natl. Acad. Sci. USA 83:9827, 1986] to 20-µm thick coronal sections through the anterior nbM. Emulsion-coated slides were exposed for four months, developed, and counterstained. Hybridization was present in many small- to medium-sized neurons, as well as some large neurons, scattered throughout the anterior nbM. These data suggest that some neurons of the primate nbM may use GABA as a neurotransmitter. The authors thank Drs. Y. Kobayashi and A.J. Tobin for providing information on the human GAD sequence.

IBOTENIC ACID LESIONS OF THE SUBSTANTIA INNOMINATA AND MEDIAL SEPTUM RETARD AMYGDALOID KINDLING. D.P. Carey, D.J. Stewart and D.P. Cain, Depts. of Clin. Neuro. Sci. and Psychology, University of Western Ontario, London, Ontario, CANADA.

Cholinergic agonists facilitate and cholinergic antagonists retard but do not prevent the development of amygdaloid kindling. The amygdala receives cholinergic inputs from both the substantia innominata (SI) and medial septum (MS). The role of these inputs in amygdaloid kindling was studied after ibotenic acid lesions of both the SI and MS in the rat.

Combined SI and MS lesions significantly retarded the rate of amygdaloid kindling. Lesioned rats took a mean of 16.7 (plus or minus 2.1) after discharges (ADs) to reach a stage 5 fully kindled seizure. Control rats required 9.9 (plus or minus 0.5) ADs to reach a stage 5 seizure. Cell loss was evident in the SI and MS and acetylcholinesterase staining was decreased relative to controls in the basolateral amygdala of the ibotenic acid treated rats. The data support previous pharmacological studies implicating cholinergic mechanisms in kindling. These data also suggest that the basal forebrain cholinergic system may be involved in the developmemt of amygdaloid kindling.

SINGLE NEURONS IN THE MAGNOCELLULAR BASAL FOREBRAIN AND MESOPONTINE TEGMENTUM PROJECT TO BOTH RETICULAR THALAMIC NUCLEUS AND CORTEX: A DOUBLE RETROGRADE STUDY IN THE RAT. A. Jourdain, K. Semba and H.C. Fibiger. Div. Neurol. Sci., Univ. of British Columbia, Vancouver, B.C., Canada, V6T-1W5.

Both magnocellular basal forebrain (MBF) and mesopontine tegmentum (MPT) provide a cholinergic input to the reticular thalamic nucleus (RTN) and cerebral cortex (CX). We have examined the degree to which single neurons in the MBF and MPT have axons that diverge to innervate both the RTN and CX using a double retrograde technique. Each rat received a unilateral injection of fluoro-gold (FG) in the RTN followed by 6-9 ipsilateral cortical injections of propidium iodide (PI) or true blue (TB). The results indicate that the MBF and MPT contain individual neurons that innervate both the RNT and CX. In the MBF, double labeled cells (15-20% of total FG labeled cells) were mainly localized in the caudal part of the MBF, particularly in the nucleus basalis magnocellularis. In the MPT, double labeled cells (10-15% of total FG cells) were primarily observed in the region of the pedunculopontine tegmental nucleus.

The present data may be relevant in light of the proposed role of cholinergic transmission in regulating arousal and sleep in that some MBF and MPT neurons appear to modulate RTN and CX activity simultaneously.

CHOLINERGIC INNERVATION OF DEEP CEREBELLAR NUCLEI IN RAT ORIGINATES FROM THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS. T.L. Dellovade*, L.J. Martin*, V.E. Koliatsos, and D.L. Price. SPON: (T.C. Hain). Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182.

Although reports suggest that acetylcholine may be a transmitter within the mammalian cerebellum, cholinergic neurons have not been visualized intrinsic to cerebellum, and extrinsic sources of cholinergic innervation have not been identified. Cholinergic projections to cerebellum were examined by combining retrograde tracing with choline acetyltransferase (ChAT) immunocytochemistry. The fluorescent dye Fluoro Gold was injected into deep cerebellar nuclei (DCN) and cerebellar cortex (CC). Retrogradely labeled neurons were identified bilaterally in the pedunculopontine tegmental nucleus (PPN) following DCN but not after CC injections. Texas Red-ChAT immunofluorescence revealed that ca. 40% of the total number of PPN neurons projecting to DCN were cholinergic. Although label was present in cuneate, pontine, reticulotegmental, vestibular, olivary, and red nuclei, forebrain cholinergic groups were not labeled. After the anterograde tracer Phaseolus vulgaris leukoagglutinin was iontophoresed into PPN, terminals were observed in DCN, particularly in lateral and interpositus nuclei. These findings indicate that the PPN, a recipient of basal ganglia efferents, projects to DCN and may interrelate basal ganglia and cerebellar circuits and that the PPN provides a source of cholinergic innervation to thalamus and cerebellum.

257.12

TIME OF ORIGIN OF CHOLINERGIC NEURONS IN THE MESOPONTINE TEGMENTUM OF THE RAT. Kazue Semba and Hans C. Fibiger. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5 Canada.

The neurogenesis of cholinergic neurons in the magnocellular basal forebrain has been shown to occur from embryonic day (E) 12 to 16 in a caudal to rostral manner (Semba & Fibiger,'88). In the present study, the timing of neurogenesis of cholinergic neurons in the mesopontine tegmentum was examined. Timed pregnant rats were injected with tritiated thymidine, and the brains of their progeny as young adults were processed for immunohistochemistry for choline acetyltransferase, serotonin, tyrosine hydroxylase, or dopamine-β-hydroxylase followed by autoradiography. The data indicated that cholinergic neurons in the pedunculopontine tegmental nucleus and the laterodorsal tegmental nucleus become postmitotic mostly on E12 and 13. This paralleled the neurogenesis of serotonergic neurons in the dorsal and median raphe nuclei, whereas the noradrenergic neurons in the locus ceruleus underwent final mitosis about one day earlier, on E11-12. These results indicate earlier completion of cholinergic neurogenesis in the mesopontine tegmentum as compared to the magnocellular basal forebrain, and, in combination with previous studies, suggest the presence of a caudal to rostral gradient in the neurogenesis of cholinergic and aminergic projection neurons in the brain. (Supported by the MRC)

257.13

AFFERENT CONNECTIONS OF THE PEDUNCULOPONTINE AND LATERODORSAL TEGMENTAL NUCLEI IN THE RAT. Hans C. Fibiger and Kazue Semba. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5 Canada.

The cholinergic neurons in the mesopontine tegmentum have been shown to innervate various structures of the forebrain as well as the brainstem. To obtain a better understanding of the organization and function of the mesopontine cholinergic system, afferents to two subregions of the mesopontine tegmentum, i.e., the pedunculopontine (PPT) and the laterodorsal (LDT) tegmental nuclei, were investigated using standard anatomical techniques. The results indicate that both PPT and LDT receive heavy projections from the reticular formation throughout the brainstem, the midbrain central gray, and the lateral hypothalamus. Less heavy projections arise in the central nucleus of the amygdala, somatosensory relay nuclei in the medulla, the dorsal horn of the spinal cord (to the PPT), lateral habenula, and medial prefrontal cortex (to the LDT), as well as the dorsal raphe nucleus and zona incerta (to both PPT and LDT). In addition, bilateral and rostrocaudal interconnections appear to exist between the PPT and LDT. These anatomical data are consistent with the concept that the cholinergic neurons in the mesopontine tegmentum are involved in the regulation of behavioral states and sensorimotor functions. (Supported by the MRC)

DEVELOPMENT OF BRAIN CHOLINERGIC SYSTEMS. L.L. Butcher, E. Gould*, T.W. Farris, N.J. Woolf, Dept. of Psychology, UCLA, L.A., CA.90024.

Several biochemical reports indicate that brain cholinergic systems differentiate in the postnatal period. To better understand such developmental phenomena, ChAT immunohistochemistry, AChE pharmacohistochemistry and Golgi impregnation were performed on brains from postnatal rat pups. Light microscopic analysis revealed that cholinergic forebrain neurons undergo cell body hypertrophy and subsequent shrinkage during the third and fourth postnatal week, respectively. The number of dendrites and degree of dendritic branching on Golgi-impregnated basal forebrain neurons correlated positively with cell body size. Cholinergic neurons of the pontomesencephalic tegmental complex undergo a similar developmental pattern but at an earlier period than cholinergic neurons of the forebrain. Cholinergic neurons of cranial nerve nuclei do not undergo cell body hypertrophy and shrinkage during postnatal development but, rather, steadily increase in size through the fifth postnatal week. As cell body size increases, numbers of dendrites and degree of dendritic branching also increases. These findings suggest that brain cholinergic neurons undergo patterns of postnatal development specific to certain brain regions yet, for each group, cell body size increase correlates with increased number of dendrites and dendritic branching. Cell body size decreases are accompanied by pruning of dendrites and branches. (NS 10928)

257.15

BASAL FOREBRAIN NEURONS ARE SENSITIVE TO THYROID HORMONES. E. Gould*, T.W. Farris, C. Lee* and L.L. Butcher, Dept. of Psychology, UCLA, L.A., CA 90024.

To determine the effects of thyroid hormones on the development of basal forebrain cholinergic neurons, brains from hyperthyroid, hypothyroid and euthyroid rat pups were examined from the neonatal period through adulthood. Brain tissue from each group of rats was processed for ChAT immunohistochemistry and Golgi impregnation and quantitatively analyzed via light microscopy. Hypothyroid treatment resulted in ChAT+ basal forebrain neurons which were significantly smaller and less immunoreactive than untreated controls. Hypothyroid treatment also revealed Golgi-impregnated basal forebrain neurons with stunted dendrites and significantly less dendritic branching. Hyperthyroid treatment resulted in ChAT+ basal forebrain neurons which undergo cell body hypertrophy at an earlier period than untreated controls. Excess thyroid hormone also resulted in fine filopodia extending off Golgi-impregnated basal forebrain somata and dendrites. These findings suggest that thyroid hormones stimulate cell body hypertrophy and extension of dendritic processes on cholinergic basal forebrain neurons. It is of particular interest that morphological profiles seen in the basal forebrain of hyperthyroid animals were similar to regenerative dendritic changes and increased cell body sizes reported in the same neuronal population of Alzheimer's disease brains (Arendt et al., 1986). (NS 10928)

BIOCHEMICAL AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT II

258.1

IDENTIFICATION AND CHARACTERIZATION OF CALCIUM-DEPENDENT, ZINC-INHIBITED METALLOPROTEASES IN NEONATAL AND ADULT RAT BRAIN. R. B. Nelson and R. Siman, Neuroscience Group, The DuPont Company, Wilmington, DE 19898.

We investigated brain protease activities separated on substrate-containing polyacrylamide gels, with particular interest in calcium-sensitive proteases. We have identified three calcium-dependent proteases in rat brain which become active at micromolar and millimolar calcium concentrations. In contrast to the calcium-dependent neutral thiol proteases (calpains), all three activities appear to be metalloproteases on the basis of their inhibitor profiles. The three metalloproteases were designated MP-92, MP-70, and MP-65 on the basis of apparent molecular weights in kilodaltons. MP-70, the major activity detected, required 25-50 μM calcium for activity and was maximally stimulated at 1-5 mM added calcium. It was predominantly soluble and showed much higher activity in 7-day neonate forebrain than adult forebrain. MP-65 was similar to MP-70 in distribution, but had a magnitude greater sensitivity to calcium. MP-92, which had an intermediate calcium-sensitivity, contrasted with MP-65 and MP-70 due to its predominance in particulate fractions of adult brain. All three activities were: 1) inhibited by low levels of zinc (but not magnesium or manganese) even in the presence of 50-fold greater calcium; and 2) detectable in particulate fractions after detergent extraction of membrane, indicating a possible association with cytoskeletal or other structural proteins. The present results identify a new class of calcium-dependent brain proteases of potential importance in calcium-regulated neuronal functions. By analogy with their function in peripheral tissues, these enzymes may alter neuronal morphology by degrading intracellular and extracellular structural proteins.

258.2

EFFECT OF CALCIUM ON GLUCOSE TRANSPORT IN RAT BRAIN GLIAL CELLS. L.M. Roeder*, J.T. Tildon* and I.B. Hopkins*. (SPON: J. Krikorian) Dept. Ped., Univ. of MD Sch. of Med., Baltimore, MD 21201.

The signal transduction systems involved in the regulation of glucose transport in neural cells have not been fully delineated. There is evidence that the glucose transporter is phosphorylated under the influence of a variety of agents. Since calcium (Ca^{++}) plays a role in membrane-associated phosphorylation reactions, experiments were carried out to determine whether Ca^{++} influenced the transport of 2-deoxyglucose (2DG) in glial cells cultured from neonatal rat brain. Cells were maintained in MEM with 10% FBS and the net uptake of ^{3}H-2DG measured as previously described (J. Neurochem. 45:1653, 1985). The rate of transport of 2DG (1mM) in these cells (28-29 days in culture) was stimulated by addition of calcium in a concentration-dependent manner, reaching 62% above control (no Ca^{++}) with 2mM Ca^{++}. The addition of dBcAMP (0.25mM from day 14 to 29) increased the uptake of 2DG under conditions with no added Ca^{++}; addition of Ca^{++} also produced a dose-dependent enhancement in these dBcAMP-treated cells. These results indicate that the glucose transport system in brain glial cells is stimulated by Ca^{++} and this effect is still present after net glucose uptake is increased as a result of dBcAMP treatment. Furthermore, the data are consistent with Ca^{++}-mediated phosphorylation as part of glucose transport regulation in neural cells. (NICHD-16596)

258.3

DEVELOPMENT OF BASAL GANGLIA-SPECIFIC PHOSPHOPROTEINS IN REAGGREGATE CULTURES OF THE MOUSE CAUDATOPUTAMEN. N.L. Rosen, I.A. Shalaby, J.-A. Girault*, A. Horiuchi,* H.H. Hemmings, Jr., and P. Greengard. The Rockefeller University, New York, NY 10021. We have been investigating the ontogeny of the basal ganglia-specific phosphoproteins that are substrates for cyclic AMP-dependent protein kinase: DARPP-32, ARPP-21 and ARPP-16. Measured with a quantitative western blot, these phosphoproteins increased in concentration in the mouse caudatoputamen (CP) during the first three postnatal weeks concurrently with tyrosine hydroxylase [a marker of dopaminergic innervation from the substantia nigra (SN)]. ARPP-19, closely related to ARPP-16 in structure, but more generally distributed in the CNS, did not undergo this ontogenetic increase in the CP. To investigate the influence of innervation from the SN and other regions of the brain, we have grown cells from the fetal mouse CP in reaggregate culture for 4 weeks. In reaggregate culture the phosphoproteins underwent a time dependent increase in concentration that mirrored the in vivo development. Co-culturing CP with SN did not stimulate the synthesis of DARPP-32 or ARPP-16. Co-culturing with cortex, thalamus, or mesencephalic tectum did not stimulate the synthesis of DARPP-32. It appears that the basal ganglia specific phosphoproteins develop in a manner which is independent of the innervation from brain regions extrinsic to the CP. 258.4

DEVELOPMENTAL CHANGES IN NEURONAL CALMODULIN-BINDING PROTEINS J.W. Polli,* R.L. Kincaid,* and M.L. Billingsley. Hershey Medical Center, Penn State Univ. Herhsey, PA, 17033 and Section on Immunology, NIAAA, Rockville, MD 20852.

Developmental changes in calmodulin-dependent phosphodiesterase (PDE), calcineurin (CN) and other rat brain calmodulin binding proteins (CaM-BPs) were analysed. Cytosolic and synaptosomal preparations from embryonic day 6 (E6) through adult exhibited rapid postnatal increases in expression of CaM-BPs. Several CaM-BPs were expressed only during development. One embryonic protein was an isoform of CN which differed from adult CN in molecular weight and isoelectric point. Another embryonic protein was a putative isoform of PDE; it had immunoreactivity against affinity purified anti-PDE but exhibited an Mr of 75 KDa. This PDE isoform was found on day E6, and was absent by postnatal day 7; the 60 KDa "adult" PDE was expressed from E17 onward. Immunocytochemistry indicated developmental expression of this PDE isoform; hippocampal CA3 cells and hypoglossal nucleus exhibited PDE immunoreactivity only in embryonic brain while other regions (neocortex) exhibited no immunoreactivity at this time. A NOVEL PROCEDURE TO ILLUSTRATE KINETIC CHARACTERISTICS OF Ca^{2+} UPTAKE BY RAT BRAIN MITOCHONDRIA: DEVELOPMENTAL CHANGES AND REGIONAL DIFFERENCES. J.R. Jensen, G. Lynch and M. Baudry. Dept. of Psychobiology, and Center for the Neurobiology of Learning and Memory, Univ. of Calif., Irvine, CA 92717.

We have previously reported that spermine, an organic polyamine, stimulates mitochondrial Ca^{2+} uptake by allosterically activating the Ca^{2+} uniporter; cooperativity of uptake is decreased and the affinity for Ca^{2+} is increased in the presence of spermine. Analysis of mitochondrial Ca^{2+} uptake kinetics indicated the cooperativity of uptake is greatest in mitochondria isolated from developing telencephalon, lower in adult telencephalon, and lower still in adult non-telencephalic mitochondria. Correspondingly, spermine stimulation of mitochondrial Ca^{2+} uptake is greatest in developing telencephalon, lower in adult telencephalon and lowest in adult non-telencephalic brain regions.

In the present experiments, isolated brain mitochondria were subjected to repetitive low Ca^{2+} additions, closely spaced in time, and the extramitochondrial Ca^{2+} concentration ($[Ca^{2+}]_e$) measured by a Ca^{2+}-selective electrode. With these procedures, differences in kinetic parameters of Ca^{2+} uptake were markedly more apparent than with traditional methods of assessing mitochondrial Ca^{2+} buffering by utilizing the measurement of $[Ca^{2+}]_e$. The differences found were consistent with the results of the $^{45}Ca^{2+}$ uptake kinetics cited above.

In summary, we present a new method that amplifies the changes in $[Ca^{2+}]_e$ as a result of temporal summation and thus enables the detection of more subtle differences in mitochondrial Ca^{2+} buffering characteristics. Furthermore it might also reflect better the *in situ* properties of mitochondria, as Ca^{2+} is added in a presumably more physiological fashion. We use these methods to illustrate developmental changes and regional differences that suggest important differences in intracellular Ca^{2+} regulation during development and between telencephalic and non-telencephalic brain regions.

CHANGES IN LAMINAR DISTRIBUTION OF ORNITHINE DECARBOXYLASE DURING DEVELOPMENT OF THE CEREBELLAR CORTEX. L. Schweitzer, I.V. Nadler and T.A. Slotkin. Departments of Anatomy and Pharmacology, Duke University, Durham, NC 27710.

Ornithine decarboxylase (ODC) is the first enzyme in the biosynthesis of the polyamines, which control macromolecular synthesis during cellular development. Polyamines appear to play a critical role in the development of the cerebellar cortex, since postnatal treatment with the specific irreversible ODC inhibitor alpha-difluoromethylornithine (DFMO), arrests cell division and migration in this region. To determine whether the distribution of ODC within the developing cerebellar cortex correlates with specific maturational events, tritiated-DFMO, a specific marker for ODC activity, was localized autoradiographically in 3 to 13 day old rats. The density of autoradiographic grains within the cerebellar cortex as a whole paralleled the postnatal rise and fall of biochemically-determined ODC activity. Superimposed on this pattern was a selective laminar distribution of label which indicated specific association of ODC with cell replication, as shown by preferential labeling of the superficial (mitotic) zone of the external granule cell layer. In addition, ODC activity was temporally associated with regions in which post-mitotic cells were undergoing migration, axonogenesis and dendritic elongation, as shown by the patterns obtained in the deep layers. In contrast, there was no evidence for an association between ODC activity and synaptogenesis, gliogenesis or myelination. These results support the view that the ODC/polyamine system play an important role in both mitotic and post-mitotic events within the nervous system. Supported by HD-09713 and NS-20162.

VITAMIN K STIMULATION OF BRAIN SULFATIDE SYNTHESIS AND SULFOTRANSFERASE ACTIVITY. Meir Lev and K.S. Sundaram* CUNY Medical School, New York, NY 10031.

We have shown that the synthesis of sphingolipids in brain and other organs of young mice is inhibited by L-cycloserine and warfarin. Warfarin, the vitamin K antagonist, primarily affects sulfatide synthesis. 16 day old mice, treated with Na warfarin for 10 days showed a reduction of c. 20% in 3-ketodihydrosphingosine synthase activity; a reduction of 40% in sulfatide levels ($p<0.005$) whereas levels of other glycosphingolipids and sphingomyelin were minimally affected. To investigate the increase in sulfatide inhibition, cerebroside sulfotransferase (EC 2.8.2.11) activity was assayed and showed a 45% reduction. Aquamephyton administration to warfarin-treated mice resulted in a >50% increase in [^{35}S] incorporation into sulfatides and a recovery in sulfotransferase activity. Mice, fed a normal diet, which were treated with aquamephyton or menadione for 1 week showed a significant increase in brain sulfotransferase activity (70% and 100% respectively). These results demonstrate a major role for vitamin K in the biosynthesis of sulfatides and possibly other sphingolipids in the very young brain. Supported by NSF grant BNS 85-0395.

ONTOGENY OF RAT BRAIN PCP AND SIGMA RECEPTORS. G.A. Paleos, Z.W. Yang, AND J. C. Byrd. Developmental Neurobiology Program, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213.

Phencyclidine (PCP) binds principally to two CNS receptors - the PCP receptor, and the Sigma receptor. We have investigated the ontogeny of these two receptors in Sprague-Dawley rats using the selective radioligands [^{3}H]TCP and [^{3}H] (+) PPP. PCP receptors are present at prenatal (PrN) day 2 (B_{max} = 0.35 pmol/mg) and increase steadily after birth, reaching adult levels by PoN 28 (B_{max} = 1.82 pmol/mg). In contrast, Sigma receptor levels are highest on PrN day 2 (B_{max} = 2.0 pmol/mg), and decrease to adult levels by PoN 28 (B_{max} = 0.6 pmol/mg). The K_d of [^{3}H]TCP remains constant during development (9 nM), while the K_d of [^{3}H] (+) PPP declines from 49 nM (PoN day 1) to 27 nM (PoN 28). On PoN 6, the pharmacology of the PCP receptor is esentially equivalent to that of the adult (e.g. IC_{50}(+)NANM = 157 nM; (-)NANM = 292 nM). Sigma receptor pharmacology on PoN 6 also appears similar to that of the adult receptor (e.g. IC_{50} (+)NANM = 223 nM; (-) NANM = 2089 nM).

DIFFERENTIAL EFFECTS OF PERINATAL EXPOSURE TO DIAZEPAM ON THE TWO SUBTYPES OF BDZ RECEPTORS. B.Frieder and V.E.Grimm* Center of Neurosciences and Behavioural Research,The Weizmann Institute, Rehovot,ISRAEL,76100.

Rats were exposed to diazepam in the last prenatal and the first postnatal weeks of life.The drug was given in a dose of 15mg/kg per day in the drinking water of the pregnant and lactating mothers.Binding of H3-flunitrazepam was measured in the presence and in the absence of 1ul of CL-218872 in various brain regions of the offspring at 20 and 90 days of age.The rsults showed that perinatal exposure to DZP did not affect binding to BDZ_2(specific binding non displaced by CL218-872).Binding to BDZ_1 (binding displaced by CL-218872) was affected only in the cerebellum. In females there was a significant decrease(by 20%) in this binding.In males the binding to BDZ_1 was increased by 16%,but this increase was found only at 20 days of age.At 100 days of age, the animals were injected by 5mg/kg of DZP ip.After this injection,the females exposed perinatally to vehicle showed hyperactivity in an open field. This hyperactivity was abolished in the females exposed perinatally to DZP.In males there was an opposite effect,but it was less significant.Time to sedation was not affected by perinatal DZP.

CYTOSOLIC ESTROGEN RECEPTOR LEVELS IN THE BRAIN OF MALE AND FEMALE FETAL RHESUS MONKEYS. S.A. Sholl and K.L. Kim*. Wisconsin Regional Primate Research Center, Univ. of Wisconsin, Madison, WI 53715.

We have measured estrogen receptor (ER) levels in brain tissue cytosol from Day 100 and Day 160 (posconception) fetal rhesus monkeys (4-5/group). The brain regions which were examined included medial basal hypothalamus (MBH), amygdala (AMG), cerebral cortex (CTX) and cerebellum (CB). Tissues were dissected and homogenized as previously described (S.A.Sholl and S.M. Pomerantz, *Endocrinology* 119:1625,1986). Cytosol was passed through a microcolumn of Lipidex 1000 to remove interfering lipids and incubated with ^{3}H-moxestrol (4 nM) in the presence or absence of 500 nM moxestrol. Incubations were carried out for 24 hr. at 4°C, and free and bound ligand separated by Sephadex LH-20 gel filtration. In one case (Day 160 male fetus), saturation analysis yielded an estimate of apparent K_a of 2.2 x 10^9 M^{-1} and indicated that maximal specific binding was achieved at a ligand concentration of less than 4 nM. There was no sex difference at either stage of development (ANOVA). A significant tissue effect ($P < 0.001$) and an age x tissue interaction ($P=0.005$) were noted, however. These differences could be explained by significantly higher ER levels in the MBH of older fetuses than in any other tissue-age group (4 vs 1-3 fmoles/mg protein). The AMG of younger fetuses also contained significantly higher ER levels than the CB of older ones. These studies revealed that the ER is present during brain development. Thus any estrogens derived from the aromatization of circulating fetal androgens could potentially exert an influence upon brain differentiation, particularly upon the MBH and AMG. The lack of any definitive sex difference suggests that the availability of ER receptor sites is not determined by the hormonal milieu. (Supported by NIH Grant HD-18865 to SAS.)

ONTOGENETIC PROFILE OF (^{3}H)NITROBENZYLTHIOINOSINE AND (^{3}H) DIPYRIDAMOLE BINDING SITES IN GUINEA PIG BRAIN. J.Deckert, P.F.Morgan, J.L.Daval*, T.Nakajima* and P.J.Marangos. Unit on Neurochemistry, BPB, NIMH, Bethesda, Md. 20892.

The ontogeny of adenosine uptake sites has recently been described in rat brain using (^{3}H)Nitrobenzlthioinosine ((^{3}H)NBI) as a radioligand probe (Geiger, J.D., Brain Res. 436:265, 1987 and Morgan P.F. et al., J.Neurochem. 49:852, 1987). In guinea pig brain heterogeneity of adenosine uptake sites has been proposed based on the additional use of (^{3}H)Dipyridamole ((^{3}H)DPR) as a probe (Deckert, J. et al., Arch. Pharmacol. 335:660, 1987).

A differential ontogenetic profile for (^{3}H)NBI and (^{3}H) DPR binding sites was now observed in guinea pig cerebral cortex. (^{3}H)NBI binding was highest around E50 and decreased by 50% until P28 while (^{3}H)DPR binding continuously increased by 25% from E40 to P28. Accordingly, (^{3}H)NBI labeled as many sites as (^{3}H)DPR at E44 while at P28 (^{3}H)DPR labeled double as many sites and NBI inhibited a greater part of (^{3}H)DPR binding at E44 than at P28.

These findings suggest that the NBI-insensitive part of (^{3}H)DPR binding sites develops later during ontogeny than the NBI-sensitive one and (^{3}H)NBI binding sites themselves in guinea pig cerebral cortex.

258.12

LOCALIZATION OF ADENOSINE AND ADENOSINE A_1 RECEPTORS IN THE DEVELOPING CHICK RETINA AND IN PURIFIED RETINAL CELL CULTURES. (Spon: A.M. Suburo) R. Paes de Carvalho*, K.M. Braas, S.H. Snyder & R. Adler. The Wilmer Institute and Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Neurotransmitters appear to play important roles as developmental signals in the CNS. For example, adenosine (ADO) has been shown to modulate dopamine-induced cAMP increases in the embryonic chick retina via A_1 receptors. The functional significance of this developmentally-regulated interaction cannot be adequately studied in intact tissues, and requires preparations of isolated cells in which these properties are expressed. Purified cultures of chick embryo retinal neurons and photoreceptors appear to have several of the desired features. Thus, although in post-hatched retinas in vivo ADO immunoreactivity was restricted to the ganglion cell layer, in embryonic retinas it is also apparent in inner and outer nuclear layers, but not on the plexiform layers. Similarly, in 5 day cultures ADO was observed in the cell bodies of 30% of the cells among neurons and photoreceptors, but not on nerve fibers. The cultured cells also showed an uptake mechanism for ADO that could be blocked by dipyridamole. Experiments are now in progress to determine whether A_1 receptors, localized in the plexiform layers in vivo, can also be detected in the cultures, which appear as a useful model for studying the role of adenosine in retinal cell differentiation.

AN ANALYSIS OF CHOLESTEROL AND CEREBROSIDE IN DEVELOPING RAT BRAIN, SPINAL CORD, AND SCIATIC NERVE. N. Mann* and W.E.Edmonston, Jr. Colgate University, Hamilton, NY 13446.

Brains, spinal cords and sciatic nerves of 14, 21, 28 and 35 day old Long Evans rats were assayed for cholesterol and cerebroside content. Brain and spinal cord cholesterol increased significantly from 14 to 21 days, significantly decreased to 28 days, and significantly increased again to 35 days. Sciatic nerve cholesterol also increased significantly from 14 to 21 days, but significantly decreased thereafter. There were no significant changes in brain and spinal cord cerebroside during the period tested, but sciatic nerve cerebroaide significantly decreased after 28 days. The relationship of these measures to CNS regeneration is discussed.

258.14

EXPRESSION OF C-SRC$^+$ mRNA BY GANGLION AND AMACRINE CELLS OF CHICK NEURAL RETINA REVEALED BY IN SITU HYBRIDIZATION. C.A. Ingraham and P.F. Maness. Dept. of Biochem., UNC Sch. of Med., Chapel Hill, NC 27514.

One form of the c-src proto-oncogene product ($pp60^{c-src}$) is expressed in the central nervous system and contains a 6 amino acid insert as a consequence of alternative mRNA splicing. To identify cells expressing this form, we have carried out in situ hybridization in embryonic chick neural retina using an ^{125}I-labeled oligonucleotide probe complementary to the specific sequence. Grains were observed over ganglion and amacrine neuronal cell bodies. Few grains were observed over the ganglion fiber layer, and inner and outer plexiform layers, which contain primarily neuritic processes, or over undifferentiated, proliferating precursors. In control hybridizations with a non-specific oligomer as probe, little signal was detected. Expression of the c-src$^+$ mRNA occurs when these neuronal cells have ceased mitosis and are undergoing terminal differentiation and neurite extension.

A DEVELOPMENTALLY REGULATED NUCLEAR ANTIGEN IN NEURAL CELLS.
K. Schilling* and Ch. Pilgrim* (SPON: European Neuroscience Association). Abt. Anat. u. Zellbiol. d. Universitaet, D-7900 Ulm, FRG

We investigated expression of a nuclear antigen recognized by a monoclonal antibody (SMI 31) to phosphorylated neurofilaments (NF) in developing brain tissue.

Nuclear staining elicited by SMI 31 could be observed in brain tissue from fetal rats and was especially pronounced in those cells presumed to be in an early postmitotic phase but was absent in adult rat brain. In primary dissociated cultures of fetal rat brain, antibody SMI 31 elicited nuclear staining in both, neuronal and glial cells. Nuclear staining was also seen in C6 glioma and PC-12 cells.

Extracts of the above cells were subject to western blotting. Antibody SMI 31 recognized, besides NF, four additional proteins with apparent molecular weights of 35, 37, 52/54 and 250 KD. These were exclusively found in developing cells, but not in adult tissue. Neuronal differentiation, as indicated by quantitative increases of neuron-specific enolase, synaptophysin (p38), and NF, resulted in a decreased expression of these proteins. This was paralleled by a decreased nuclear staining in immunocytochemical preparations.

A search of protein data banks for proteins sharing the epitope recognized by antibody SMI 31 did not yield any protein of known nuclear localization that show the solubility properties and/or the same molecular weights of the additional proteins recognized by antibody SMI 31 in embryonic tissue. We conclude that we have come across hitherto unknown nuclear proteins that, in neural cells, are developmentally regulated.

ALZHEIMER'S DISEASE: AMYLOID

259.1

BRAIN AMYLOID PRECURSORS IN DOWN SYNDROME (DS)
G. Giaccone‡[1] F. Tagliavini‡[1] C. Bouras‡[2] B. Frangione‡[3] and O. Bugiani‡[1] (SPON: V. Olgiati). [1] Istituto Besta, Milano, Italy, [2] IUPG, Genève, CH, [3] NY University, New York.

Patients with DS invariably develop Alzheimer changes. We studied frontal and temporal samples of 5 DS patients aged 6,12,39,46,55, by means of silver salts, Congo red, thioflavine S and immunohistochemistry with an antiserum to a 28 residue peptide homologous to the NH_2 terminal region of β-protein (anti-SP28). Patients aged 6 and 12 did not show Alzheimer changes. In the 39 ys patient, senile plaques (SP), neurofibrillary tangles (NFT) and congophilic angiopathy (CA) were absent, but anti-SP28 revealed several cortical deposits of immunoreactive material, lacking the tintorial and optical properties of amyloid. Similar deposits and a few SP, not CA or NFT, were found in the 46 ys patient and, with many SP, NFT and CA, in the patient aged 55. Noncongophilic anti-SP28 immunoreactive deposits might consist of β-protein not yet in β-pleated sheet conformation. The presence of noncongophilic anti-SP28 immunoreactive deposits in the brain of the 39 ys DS patient without any other Alzheimer change suggests that they represent the earliest step of β-protein deposition in Alzheimer disease and related conditions.

259.2

STUDIES ON THE LOCALIZATION OF THE ALZHEIMER AMYLOID PRECURSOR PROTEIN USING SYNTHETIC PEPTIDE IMMUNOCYTOCHEMISTRY.
J.R. Currie, M. Barcikowska, D.L. Miller, P. Mehta, K.S. Kim, and H.M. Wisniewski. New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314.

Three different cDNA sequences provide the only clues so far to the possible structure of the Aging-Alzheimer-Amyloid-Precursor protein (AAAP). Polyclonal and monoclonal antibodies raised against 7 subsequences of the Kang et al. 695 aa sequence have been used on tissue sections (Vector ABC method) from the CNS and other autopsied organs from young, old, and Alzheimer disease cases as well as from rat and monkey tissues and on some cell lines in an attempt to localize the cells which produce and/or process the putative AAAP. The various antibodies did not all label the same cell type or extracellular structure. Following several different pretreatments, multiple structures were still labeled by the antibodies. The labeled CNS elements included: some astrocytes and microglia; vascular media and adventitia; perivascular areas in subpial, cortical, ependymal and white matter regions; amyloid plaques and cores; large neurons and their processes; and synaptic arborizations. The distribution of the labeling often suggests that different, but related, adhesive proteins are being labeled in the various cell types. Other alternately spliced products (containing the beta-peptide sequence) having different functions may also exist.

259.3

cDNA CLONING OF DIFFERENT BETA AMYLOID PEPTIDE PRECURSORS IN ALZHEIMER'S DISEASE.
J.N. Octave*, F. de Sauvage*, A.F. Macq* and J.M. Maloteaux* (SPON: C.G. Veraart). Lab. Neurochimie, Université Catholique de Louvain, B-1200 Brussels.

A cDNA library from a 54 years old patient with anatomopathological confirmed Alzheimer's disease (AD) has been constructed, and different clones coding for the beta amyloid peptide precursor (BAPP) have been isolated. From the sequence of the cDNA clones, different BAPP are expressed in the cerebral cortex of that patient. First, we have isolated BAPP cDNA clones which are identical to those found in the fetal brain (Kang et al., Nature, 325:733, 1987). Second, we have observed that some BAPP mRNA use a different polyadenylation site in the 3' non coding sequence. Third, we have isolated BAPP mRNAs which contain domains homologous to serine proteinase inhibitors either reported by Ponte et al. and Tanzi et al. or by Kitaguchi et al. (Nature, 331:525-532, 1988).

These results confirm that in AD, different RNA species coding for the BAPP can be obtained by alternative splicing of a single transcriptional unit. The expression of the different BAPP mRNA are being studied in AD as compared to control brains.

259.4

STUDIES OF β-AMYLOID PRECURSOR GENE EXPRESSION IN BRAINS OF AGED MONKEYS.
E.H. Koo, D. Goldgaber†*, S.S. Sisodia*, M.D. Applegate*, D.C. Gajdusek§, and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182. †NIH, Bethesda, MD 20892. §CNS Studies Lab., NINCDS, Bethesda, MD 20892.

Nonhuman primates provide a useful model for studying the age-associated deposition of amyloid (antigenetically similar to that occurring in humans) within plaques and blood vessels. Quantitative in situ hubridization with a cDNA probe from the region encoding the β-amyloid peptide of the precursor (APP) gene was used to map the distribution of APP mRNA transcript in four regions of brain (frontal, temporal/hippocampus, occipital cortices, and cerebellum) in rhesus monkeys (15-24 years of age). mRNA transcripts of the APP gene were most abundant within large pyramidal neurons of monkey cortex, but significant levels were also detected in neurons of other regions, including cerebellum. With aging, levels of mRNA in regions vulnerable to the deposition of amyloid (frontal and temporal cortices) were not altered relative to regions not susceptible to the formation of plaques (occipital cortex and cerebellum). In this setting, the pattern of APP expression was not altered with age and did not correlate with the development of plaques. Recent reports suggest the existence of alternative mRNA transcripts of the APP gene, and studies in progress will compare the patterns of expression of other transcripts in brains of nonhuman primates.

259.5

EXPRESSION OF AMYLOID-ß-PROTEIN PRECURSOR (APP) mRNA TRANSCRIPTS IN DOWN SYNDROME AND ALZHEIMER'S DISEASE. #Gerald A. Higgins, Linda B. Dawes and Rachael L. Neve. #Univ. Rochester Med. Ctr., Rochester, NY 14642 and Children's Hospital, Boston, MA 02115.

Amyloid deposition in neuritic plaques and the cerebrovasculature, occur both in Alzheimer's disease, and in older patients with Down syndrome. As part of a larger effort to characterize the relationship between neuronal pathology and APP gene expression in the human central nervous system, we have used *in situ* hybridization and northern blotting to study the expression of different APP mRNA transcripts in the human central nervous system, in Down syndrome, and in Alzheimer's disease. Recent studies show that at least 3 different APP mRNAs are generated from the human APP gene: a 695 amino acid precursor (APP-695), and 2 forms which contain an inserted protease inhibitor domain (APP-751 and APP-770). For these studies, we have used synthetic oligonucleotide probes to discriminate APP-695, APP-751 and APP-770 mRNA transcripts.

In situ hybridization shows that all 3 APP mRNAs have a similar distribution in the normal aged human hippocampal formation and neocortex. Similarly, *in situ* hybridization shows that both APP-695 and APP-751 have similar regional and cellular patterns of distribution in brains from patients with Down syndrome and Alzheimer's disease. However, RNA blotting studies of three Down syndrome brains (10 months, 37 years and 40 years of age) shows changes in the relative expression of APP mRNAs in Down syndrome versus normal aged brain. For example, in association areas of neocortex, levels of APP-695 mRNA appears to be decreased in aged Down syndrome compared to normal. In addition, in the hippocampal formation and caudate-putamen of aged Down syndrome brain, the abundance of APP-751 mRNA is markedly greater than that of APP-695 mRNA when compared to the normal adult brain or to young Down syndrome CNS.

259.6

EXPRESSION OF THE ALZHEIMER AMYLOID PRECURSOR PROTEIN IN THE BRAIN. W.R. Rodriguez*, R.L. Neve, D. Schenk*, D. Davis*, L.I. Benowitz (SPON: J. Gilbert). Harvard Medical School, Boston, MA 02115; Athena Neurosciences, Inc., San Carlos, CA 94070.

We examined Alzheimer amyloid precursor protein (APP) immunoreactivity in adult human brain using two different polyclonal antisera raised against amino acids 479-497 and 687-695 of the amyloid precursor, respectively. The most prominent feature of the immunoreactivity in the neocortex was intense staining of pyramidal cell bodies in cortical layers III and V. The antisera did not stain cortical white matter, with the exception of occasional, exceptionally dark axonal staining in motor and premotor cortex. In addition to the somatic staining, a prominent band of immunoreactivity was observed in layer II of most cortical areas examined. This staining sometimes appeared to overlie neuronal somata, but often appeared to be distributed diffusely in the neuropil and may correspond to the terminals of APP-positive intracortical neurons in layer II. A lower density of punctate staining was seen in the neuropil of cortical layers III-V, and was also present throughout the grey matter in the caudate nucleus, and in the hippocampus. Within the hippocampus, both antisera decorated cell bodies of granule cells in the dentate gyrus and pyramidal cells in Ammon's horn. In addition, a dense, diffuse staining was displayed in the molecular layer of the dentate gyrus. (HD18658, NINCDS NS25830)

259.7

REGULATION OF THE ALZHEIMER AMYLOID PRECURSOR RNA IN PRIMARY CELL CULTURE. L.R. Dawes, M.P. Mattson, S.B. Kater, R.L. Neve. The Children's Hospital, Boston, MA 02115 and Colorado State University, Fort Collins, CO 80523.

Recent work has demonstrated the presence of two forms of the Alzheimer amyloid precursor protein (APP) RNA. We have constructed molecular probes that distinguish between these two RNAs. The culture paradigm provides a means of characterizing the response of APP RNAs to environmental cues, relative to other genes. We have used our differential probes to show that both forms of APP message are expressed in dissociated cell culture of E18 rat hippocampal neurons. We have observed a decrease in the expression of both APP transcripts in the presence of kainate. This may be relevant to previous work, which has shown that glutamate prunes the dendritic tree of cultured hippocampal neurons. We have also observed a differential response of the two APP mRNAs to potassium-induced depolarization.

The pathology of Alzheimer's disease preferentially involves the cholinergic system. Further work, therefore, involves culture of rat post-mitotic sympathetic neurons which remain plastic with regard to transmitter phenotype. Culture conditions may be manipulated to cause these neurons to differentiate. Levels of APP expression will be monitored upon cholinergic differentiation.

Supported by NIH grant HD18658.

259.8

AMYLOID PROTEIN PRECURSOR GENE EXPRESSION IN TANGLE-BEARING NEURONS OF ALZHEIMER'S DISEASE. T. Golde*, M. Palmert*, R. Repasky*, M. Usiak*, L. Younkin, and S. Younkin. Institute of Pathology, Case Western Reserve University, Cleveland, OH 44106.

We are correlating the changes in amyloid protein precursor (APP) mRNA that we have observed in Alzheimer's disease with other changes that occur in this disorder. To evaluate APP mRNA levels in neurons undergoing neurofibrillary degeneration, we analyzed APP mRNA separately in tangle-bearing and tangle-free neurons. In the nucleus basalis of Meynert (where, in earlier studies, we observed a two-fold increase in total APP mRNA due to an increase in APP mRNA lacking the Kunitz protease inhibitor (KPI) domain) the probes for both total and KPI-containing APP mRNA consistently produced fewer specific grains over the tangle-bearing neurons than over the tangle-free neurons. In the subiculum (where we observed no changes in total or KPI-containing APP mRNA) both the probe for total APP mRNA and the probe for KPI-containing APP mRNA produced the same number of specific grains over tangle-bearing and tangle-free neurons. We are currently analyzing our cases to determine if the changes that we have observed in APP mRNAs are correlated (1) with changes in other relevant mRNAs (e.g. tau, ubiquitin) or (2) with the severity of neuronal loss, the extent of senile plaque or neurofibrillary tangle formation, or the degree of amyloid deposition. In addition, we are pursuing our observations on APP mRNAs using junctional probes capable of recognizing individual APP mRNAs. (Supported by USPHS grants AG06656, MH43444, and a grant from the state of Ohio.)

259.9

THE ß-AMYLOID PRECURSOR PROTEIN OF ALZHEIMER'S DISEASE (AD) OCCURS AS A GROUP OF 110-135 kD MEMBRANE-ASSOCIATED PROTEINS IN BRAIN AND NON-NEURAL TISSUES. D. Selkoe, M.B. Podlisny*, E. Vickers*, A. Reynolds*, L. Fritz, and T. Oltersdorf*., Harvard Medical School, Brigham & Women's Hospital, Boston, MA 02115, and Athena Neurosciences, San Carlos, CA 94070.

Cerebral deposition of filaments composed of ß-amyloid protein (ßAP) is a constant feature of AD. Since the gene encoding the ßAP precursor (ßAPP) appears unaltered in AD, changes in posttranslational processing may underlie accelerated ßAP deposition in AD. Detection of the native precursor in mammalian tissues has not been reported. Using 2 antibodies to the predicted C-terminus, we have identified the precursor in brain and non-neural tissues as a group of 110-135 kD proteins found in membrane-rich subcellular fractions. These proteins are distributed throughout the brain, abundant in fetal brain and detected in non-neural tissues containing ßAPP mRNA. Similar proteins occur in bovine and rat brain and cultured human HL-60 and HeLa cells. Confirmation that the immunodetected tissue proteins are forms of ßAPP was obtained when mouse L cells and human 293 cells transfected with full-length ßAPP cDNAs showed increased expression of 110-135 kD proteins. Both C-terminal antibodies label some amyloid plaques in AD brain. Thus, the ßAPP molecule exists in tissue as a heterogeneous group of membrane-associated ~120 kD proteins. Detection of the C-terminus within plaques suggests that proteolysis of ßAPP into insoluble filaments occurs locally in cortical regions developing amyloid in AD.

259.10

DISTRIBUTION IN RAT OF THE PRECURSOR PROTEIN FOR ß-AMYLOID. L.G. Davis, J.P. Card, C.M. Reid*, R.A. Lampe*, R. Meade* and R.W. Manning*. Medical Products Dept., E.I. Dupont de Nemours & Co., Inc., Wilmington, DE 19898.

The isolation and sequencing of the core peptide (ß-amyloid) found in the plaques of patients with Alzheimer's disease has allowed the identification of a cDNA corresponding to the precursor protein. Using a human cDNA clone for the amyloid precursor, we have identified homologous mRNAs (ca. 3.8kb) in eight species. We have determined the distribution of this mRNA in seven brain regions and twelve organs obtained from rodents. This mRNA is abundantly expressed in all brain regions and detectable in most tissues. Interestingly, a prominent, second mRNA species (ca. 2.3kb) has also been identified in non-neuronal tissues.

Synthetic peptides based on the sequence of the human precursor were used to raise polyclonal antibodies for immunohistochemical localization of the amyloid protein in rat brain. These data demonstrate that the amyloid precursor protein is consistently found in discrete cell groups throughout the neuraxis. Most prominent among these areas are the olfactory bulb, the medial septum and diagonal band of Broca, the cortex and cerebellum. Amyloid-like immunoreactivity also surrounds blood vessels in a number of areas of the CNS. Preliminary electron microscopic analysis has demonstrated that the perivascular immunoreactivity is concentrated in glial processes while that in the remainder of the CNS is found in both neurons and glia.

259.11

AMYLOID MESSENGER RNA IN THE ALZHEIMER FRONTAL CORTEX. INTRANEURONAL LEVELS, RELATIONSHIP TO CELL SIZE AND LAMINAR DISTRIBUTION. W.-G. Chou*, R.E. Majocha*, F. M. Benes, B. Tate-Ostroff, S. Rehman*, M. Stoler*, B.S.Zain*, and C.A. Marotta. Harvard Med. Sch., Mass. General Hosp., Boston, MA 02114; McLean Hosp., Belmont, MA 02178; U. Rochester Med. Ctr., Rochester, NY 14642.

cDNA containing the A4 region (Zain, et al., P.N.A.S. 85:929, 1988) was subcloned into the pGEM plasmid and both anti-sense and sense probes were labeled with tritium. The probes were hybridized to AD frontal cortices containing varying levels of immunologically demonstrable amyloid. The mRNA was present at similar levels in all cortical layers except the first where it was less abundant. In layers III and V of a case distinguished by large numbers of amyloid deposits, mRNA was higher per layer, per neuron and per unit area of each neuron, relative to controls. We have previously shown that amyloid deposits detected by anti-A4 antibodies exhibit a laminar-specific pattern (Majocha, et al, P.N.A.S., in press). The lack of a parallel distribution of amyloid mRNA and amyloid protein deposits according to individual layers implicates factors other than, or in addition to, neuronal levels of mRNA as probably contributing to amyloid deposition. IMMUNOCYTOCHEMICAL DEMONSTRATION OF DIFFERENTIAL LOCALIZATION OF ALZHEIMER AMYLOID PRECURSOR PROTEIN SUBDOMAINS: A4 vs. A NON-A4 REGION. R.E. Majocha*, B. Tate-Ostroff and C.A. Marotta (SPON: R.A. Nixon), Harvard Med. Sch., Massachusetts General Hosp., Boston, MA 02114; Mailman Res. Ctr., McLean Hosp., Belmont, MA 02178.

To gain insight into the processing of the amyloid precursor protein (APP), we examined the distribution of A4 and pre-A4 epitopes. Monoclonal (mab) and affinity-purified polyclonal (pab) antibodies were prepared to a pre-A4 site, with a unique sequence, considered to be in the extracellular domain. Mabs and pabs to the A4 site were previously characterized (Benes, et al., P.N.A.S., in press). In the Alzheimer's Disease (AD) prefrontal cortex and hippocampus, the A4 antigen was selectively localized to neuritic plaques. By contrast, high concentrations of pre-A4 immunoreactive product were found over neuronal cell bodies. In addition some non-cellular punctate deposition was observed. Neurologically normal control brains were devoid of A4 immunoreactivity. However, both controls and AD cases stained with pre-A4 antibodies were similar. The differential distributions of APP epitopes imply either processing events and/or a membrane orientation that are unique to the AD brain. Supported by AG02126, American Health Assistance Found. and Familial Alzheimer's Disease Res. Found.

ELEVATED EXPRESSION OF A SPECIFIC AMYLOID-ß-PROTEIN (APP) mRNA TRANSCRIPT IN THE BEHAVORIALLY-IMPAIRED AGED RAT. George A. Oyler[1], Fred H. Gage[2], Karen Chen[2], and Gerald A. Higgins[3], [1]Hershey Medical College, Hershey, PA 17033, [2] U.C.S.D., La Jolla, CA 92093, and [3]Univ. Rochester Med. Ctr., Rochester, NY 14642.

The behavorially-impaired aged rat may be a model system in which to study cellular and molecular changes which underly learning and memory deficits associated with the aging process. Cholinergic and NGF-receptor containing neuronal populations of the basal telencephalon, which send widespread projections to the neocortex and hippocampal formation, have been shown to undergo atrophy during aging of the rat CNS. In order to better understand the molecular basis of such changes, we have examined the expression of: (1) alternate transcripts of the amyloid-ß-protein precursor (APP) gene, (2) nerve growth factor receptor mRNA and protein, and (3) choline acetyl transferase (Chat) mRNA and protein, in young, aged, and behavorially-impaired aged Sprague-Dawley rats.

In situ hybridization and RNA blotting have revealed striking increases in the expression of a specific APP mRNA transcript in the aged rat. Levels of APP-751 mRNA, which encodes an amyloid precursor containing an inserted protease inhibitor domain, is elevated at least 3-4 fold in the basal telencephalon of aged rats. Increases in the abundance of this mRNA were observed in the striatum, nucleus basalis, diagonal band, ventral pallidum and medial septum using *in situ* hybridization with APP transcript-specific probes. In contrast, preliminary studies suggest that NGF-receptor mRNA levels are not significantly altered in aged animals. Thus, it appears that increases in a specific form of APP mRNA may be correlated with neuronal atrophy which occurs during the aging process.

RELATIONSHIP BETWEEN CALPAIN AND AMYLOID PLAQUES IN ALZHEIMER'S DISEASE. J.E. Wu*+, L.S. Perlmutter, M.Baudry+, G. Lynch+, and H.C. Chui* (SPON: B. Newman). Dept. of Neurology, Univ. So. Calif., Los Angeles, CA 90033 and CNLM+, Univ. of Calif., Irvine, CA 92717.

Alzheimer's Disease is a degenerative illness resulting in a progressive loss of cognitive ability. Characteristic lesions include senile plaques and neurofibrillary tangles, both of which contain abnormal accumulations of cytoskeletal proteins. Many of these are substrates of calpain, a calcium-activated neutral protease, which is implicated in muscle, myelin, and axon cytoskeleton degeneration. In fact, a calpain inhibitor, aluminum, has been colocalized with tangles and plaques. The relationship between calpain localization and amyloid plaques was studied. Postmortem brain tissue from controls and Alzheimer's patients were immunocytochemically labelled with an antibody against calpain then counterstained with thioflavine S (marker for amyloid). Brodmann's area 17 was analyzed for colocalization of amyloid and calpain immunostaining. The percentage of amyloid-positive plaques that was associated with calpain immunoreactivity was positively related to plaque and tangle densities, but not to a measure of clinical severity. Control tissue was devoid of amyloid. These data suggest that calpain may be involved in plaque formation and/or maintenance. (AG-07127 and French Foundation to LSP; AG-05142).

AMYLOID P COMPONENT IN DEMENTIA. D. Saperia, L.S. Perlmutter, J. Athanikar*, H.C. Chui*. Dept. of Neurology, University of Southern Calif., Los Angeles, CA 90033.

To examine components of senile plaques, correlative light and electron microscopic (LM,EM) localization of amyloid P component (APC) was performed. APC is found in serum, binds to amyloid fibrils in a calcium-dependent manner, and has recently been localized to the pathologic lesions of Alzheimer disease (AD). A polyclonal antibody (Dako) was used on tissue from patients with dementing diseases (classic/mixed AD, vascular dementia). Tissue was immersion fixed in mixed aldehydes and immunolabelled for APC with avidin-biotin-peroxidase. Sections were processed for both LM and EM. LM - a spectrum of patterns of APC immunoreactivity (APC-I) was seen: Non-AD samples had more prominent capillary staining; some also had plaque-like accumulations of APC-I. ADs also had these accumulations, as well as attenuation of capillary staining with concomitant labelling of neurofibrillary tangles (NFT). Decreased vascular staining appeared to be associated with increased NFT staining. EM - endothelial cytoplasm was stained in patients who displayed LM vascular APC-I. In all subjects, extracellular APC-I was seen near stained arterioles. This APC-I displayed an apparent affinity for myelinated axons, suggesting that APC may be involved in alterations in the neuropil in AD and non-AD brains. (AG-07127 & French Fdn to LSP; AG-05142).

ALTERATION OF BASEMENT MEMBRANE COMPONENTS IN DEMENTIA. J. Athanikar*, L.S. Perlmutter, D.Saperia, H.C. Chui* (SPON: L.Weiner). Dept. of Neurology, University of Southern California, Los Angeles, CA 90033.

Thickened and redundant basement membrane (BM) is seen in several diseases including Alzheimer (AD). Immunoelectron microscopy was used to localize 2 BM components in AD: Collagen type IV (CIV) spans the BM width providing mechanical support; heparan sulfate proteoglycan (HSPG) lines either side of the BM aiding filtration. Autopsy tissue was immersion fixed in mixed aldehydes, immunolabelled (avidin-biotin-peroxidase) with commercially available antibodies (Chemicon), and prepared for electron microscopy. As expected, the BMs were thickened, with vacuole-like holes and redundancies. CIV immunoreactivity (CIV-I) was deposited along the entire width of both normal and thickened BM in all patients. The holes appeared to be caused by dissection within the CIV domain rather than reduplication of the entire BM. HSPG immunoreactivity (HSPG-I) clearly labelled both the inner and outer BM surfaces in most patients. One severely demented AD patient, however, consistently lacked HSPG-I at the endothelial surface of the BM, which may be related to the reported presence of circulating HSPG antibodies in some AD patients. These abnormalities in CIV and HSPG suggest that alterations in both components may be involved in BM pathologies. (AG-07127 & French Fdn to LSP; AG-05142)

259.17

BASEMENT MEMBRANE PATHOLOGY IN DEMENTIA. L.S. Perlmutter, J. Athanikar*, C. Zarow*, H.C. Chui*. Dept. of Neurology, University Southern Calif., Los Angeles, CA 90033.

The vascular basement membrane (BM) participates in the blood-brain barrier. Thickened and redundant BM is seen in several diseases including Alzheimer's (AD). Quantitative electron microscopy (EM) was employed to accurately describe this pathology. Autopsy tissue from 4 AD and 4 non-AD (vascular dementia, supranuclear palsy, alcoholic) patients was immersion fixed and prepared for EM. Small blood vessels were photographed (3-10 per patient). The full extent of the BM on the micrographs was measured by computerized image analysis to determine the inside (I) and outside (O) perimeters as well as the area (A) of the BM. Two variables were computed: O/I (increased ratio seen with either thickenings or redundancies), and A/I (thickened BM results in a higher ratio, while redundancies of BM yield a lower ratio). Both measures discriminated between AD and non-AD patients. O/I: AD mean (±sd)=1.40 ± 0.1, non-AD mean=1.19 ± 0.1; A/I: AD mean= 0.52 ± 0.1, non-AD=0.36 ± 0.1. ADs scored consistently high on both measures. The one alcoholic patient had a thickened, but not reduplicated BM, perhaps indicative of alcoholic encephalopathy. Thus, these quantitative techniques discriminate between various BM pathologies and confirm a high incidence of overall BM pathology in AD. (AG-07127 & French Fdn to LSP; AG-05142)

ION CHANNELS: LIGAND-GATED I

260.1

FUNCTIONAL PROPERTIES AND DEVELOPMENTAL REGULATION OF NICOTINIC ACETYLCHOLINE RECEPTORS IN CHICK SYMPATHETIC NEURONS. B.L. Moss, S.M. Schuetze and L.W. Role§. Dept. Biol. Sci., Columbia Univ., NY, NY 10027, §Dept. Anat. & Cell Biol. and Ctr. Neurobiol. & Behav., Columbia Univ. P & S. NY, NY 10032.

We have examined the channel properties of neuronal nicotinic acetylcholine receptors (AChRs) by recording single-channel currents of cultured sympathetic neurons isolated from the lumbar chain ganglia of chick embryos. To address the role of synapse formation in the regulation of these properties, we removed ganglia before the onset of innervation (ED 8-10) and during the first major wave of synaptogenesis (ED 16-21).

In ED 10 neurons acetylcholine activates three distinct channel amplitude classes, S, M and L, in both cell-attached and outside-out patches. These classes can be distinguished from one another by both slope conductance and mean burst duration. The slope conductances are: S ≈ 20 pS, M ≈ 34 pS and L ≈ 50 pS. The burst distribution of S is fit with two exponentials with time constants of 1 ms and 8 ms (23°C). The burst distributions of M and L are singly exponential with time constants of 6 ms and 3 ms respectively. The three amplitude classes also differ in the frequency with which they occur in cell-attached patches; S and M are the predominant classes.

Our preliminary experiments indicate three developmental changes in channel properties in neurons removed from ED 16-17 animals. In addition to S, M and L, a new channel amplitude class (denoted XL) appears. This new class is also specifically activated by ACh in that in outside-out patches, XL openings are observed only during the application of ACh and in cell-attached patches, the frequency of XL openings increases with increasing ACh concentration. A second change in channel properties is a change in the relative frequency with which the classes occur in patches. In ED 16-17 neurons, M and L are the predominant classes. Finally, the fraction of patches with just one amplitude class increases from ≈11% at ED 10 to ≈ 55% at ED 16-17.

260.2

PHARMACOLOGICAL ANTAGONISM OF ACH AND ATP RECEPTOR-CHANNELS IN RAT CULTURED PARASYMPATHETIC NEURONS. L.A. Fieber* and D.J. Adams* (SPON: P. Strang). Dept. of Pharmacology, Univ. of Miami Sch. of Med., Miami, FL 33101

Acetylcholine- (ACh) and adenosine triphosphate- (ATP) activated responses were investigated in cultured cardiac neurons dissociated from neonatal rat parasympathetic cardiac ganglia. Ionic currents evoked by pressure application of the agonists were obtained using the whole-cell configuration of the patch clamp technique. The current-voltage relationships obtained with a pipette solution containing 140 mM CsCl, 5 mM BAPTA, 2 mM MgATP and 5 mM Cs-HEPES (pH 7.2) were similar for the two agonists, exhibiting marked inward rectification, and a reversal potential of approximately 0 mV. The nicotinic receptor antagonists hexamethonium, d-tubocurarine and mecamylamine inhibited the ACh-evoked response in cardiac neurons, but the P_{2y} purinergic receptor antagonist α,β-methylene ATP had no effect. Block of the ACh-induced current by hexamethonium (50 μM) and d-tubocurarine (2 μM) was voltage dependent whereas block by mecamylamine (3 μM) was voltage independent. ATP-activated whole cell currents were inhibited in a voltage independent manner during bath perfusion of α,β-methylene ATP (10 μM) and were unaffected by d-tubocurarine and 8-phenyltheophylline. This suggests that P_{2y} receptors mediate the ATP response. Bath application of ACh (10 μM) failed to inhibit the ATP-induced current. These data indicate that the action of ACh and ATP are mediated via distinct populations of receptor-channels.

260.3

THE NUCLEOTIDE SEQUENCE AND DEDUCED AMINO ACID SEQUENCE OF RAT NON ALPHA 2 K.E. Isenberg and G. Meyer Washington University School of Medicine, St. Louis, MO 63110

We report the nucleotide sequence and complete deduced amino acid sequence of a new member of the nicotinic acetylcholine receptor (nAChR) gene family. The 2500 bp clone was isolated by screening (3 X 10^5 recombinants) a rat superior cervical ganglion cDNA library (provided by J.P. Merlie) with an oligonucleotide that hybridizes to muscle nAChR subunits. Sequencing was performed by the dideoxy chain-termination method.

The novel clone lacks the pair of extracellular cysteine residues characteristic of acetylcholine binding (alpha) nAChR subunits. Although similar to the previously reported non-alpha nAChR subunit, the amino acid sequence is particularly different in a proposed second cytoplasmic loop. The deduced amino acid sequence suggests that the subunit could function as a non-acetylcholine binding subunit in a ligand gated ion channel.

260.4

PHOTOAFFINITY LABELING OF THE TORPEDO NICOTINIC ACETYLCHOLINE RECEPTOR BY THE NONCOMPETITIVE ANTAGONIST [^{3}H]-TETRACAINE. R.E. Middleton* and J.B. Cohen. Dept. of Anatomy and Neurobiology, Washington University, St. Louis, MO. 63110.

[^{3}H]-Tetracaine ([^{3}H]-Tet) binds to the noncompetitive antagonist site on the Torpedo acetylcholine receptor (AchR) with high affinity (K_d=1 μM) unless AchR is desensitized by agonist when K_d=30 μM. We have studied the photoincorporation of [^{3}H]-Tet into polypeptides of Torpedo postsynaptic membranes by SDS-PAGE. Irradiation at 302 nm resulted in specific labeling of each AchR subunit, i.e. photoincorporation was blocked by noncompetitive antagonists but not by α-bungarotoxin. Histrionicotoxin inhibited up to 90% of the subunit labeling with IC_{50}=2 μM. [^{3}H]-Tet photoincorporation was also inhibited by agonists, but this inhibition was blocked by α-bungarotoxin. Specific labeling was insensitive to the aqueous scavenger glutathione (50 mM). The extent of specific labeling varied with the [^{3}H]-Tet concentration (K=2 μM) and for each subunit the maximal specific incorporation was equivalent to 1-2% of the total subunit protein. The specific photoincorporation into the α-subunit has been localized to a S. aureus V8 protease fragment which begins at Ser-173 and contains the predicted membrane spanning regions M1, M2, and M3. The observed labeling pattern will be compared to affinity labeling by desensitizing non-competitive antagonists. (Supported in part by NS 19522 and a Markey Foundation fellowship to R.E.M.)

260.5

THE C-TERMINUS OF THE TORPEDO ACETYLCHOLINE RECEPTOR δ SUBUNIT IS EXTRACELLULAR. **M. DiPaola,* C. Czajkowski,* M. Bodkin,* and A. Karlin. Depts. Biochem. and Molec. Biophys., and Neurol., Columbia U., New York, NY 10032.**

Both even and odd numbers of membrane crossings of the AChR subunits ($\alpha_2\beta\gamma\delta$) have been supported by theory and experiment. An even number corresponds to an extracellular location of the subunit-C-termini; an odd number, with a cytoplasmic location. Torpedo AChR is a dimer in native membrane, disulfide-crosslinked between δ subunits. We found that this disulfide is readily reduced in sealed right-side-out (RSO) native membrane vesicles by the relatively impermeant reducing agents, glutathione and 2-mercaptoethansulfonate (cf. McCrea et al. (1987) EMBO J., 6, 3619-3626; Dunn et al. (1986) BBRC 139, 830-837). Far less reduction of δS-Sδ is obtained in sealed inside-out (ISO) vesicles. We have also identified the half-cystinyl residue forming δS-Sδ. We alkylated the accessible free SHs of the AChR dimer in Triton X-100 solution , mildly reduced the dimer to monomer, alkylated the newly formed SHs with ^{3}H-NEM, isolated the δ subunit, cleaved it with CNBr, and separated the fragments by reverse-phase HPLC. ^{3}H-NEM was incorporated into only one fragment, which we identified both by amino acid analysis and by sequencing as the C-terminal CNBr fragment. We also isolated a homodimer of this fragment from CNBr-cleaved unreduced δS-Sδ. The one Cys residue in this fragment is in the penultimate position of the δ sequence. Thus, the dimer is crosslinked via δ Cys 500 (cf. Popot and Changeux (1984) Physiol. Rev. 64, 1162-1239), and the C-terminus of δ and presumably of the other subunits is extracellular. 260.6

EFFECTS OF ORGANOPHOSPHORUS ANTICHOLINESTERASES ON NICOTINIC ION CHANNELS AT ADULT MOUSE MUSCLE ENDPLATES. JEH Tattersall*.(SPON: L.D. LEAKE). Biology Division, Chemical Defence Establishment, Porton Down, Salisbury, Wiltshire SP4 OJQ, UK.

Organophosphorus esters such as diisopropylfluorophosphate and VX have been shown to have direct actions on acetylcholine-activated ion channels at amphibian endplates (Albuquerque,E.X., Deshpande,S.S., Kawabuchi,M., Aracava,Y., Idriss,M., Rickett,D.L. and Boyne,A.F., Fundamen. Appl. Toxicol., 5:S182-S203, 1985). The present study investigated the effects of these compounds on mammalian endplate channels.

Flexor digitorum brevis muscles from adult Porton strain mice were dissociated according to the method of Henderson,L.P., Lechleiter,J.D. and Brehm,P. (J.Gen. Physiol., 89:999-1014, 1987). Single endplate channels were recorded in the cell-attached configuration, using patch pipettes filled either with acetylcholine (ACh, 100-300nM) alone, or with ACh and an organophosphate (1-500μM). Data were analyzed using a microcomputer to determine open and closed lifetimes and single channel conductances.

The results demonstrated that organophosphorus anticholinesterases can indeed have direct effects on mammalian nicotinic endplate channels, such as blocking open channels and reducing single channel conductance.

260.7

NON-COMPETITIVE ANTAGONISTS ACTING AT BRAIN PRESYNAPTIC NICOTINIC RECEPTORS: EVIDENCE FOR A CONSERVED ION CHANNEL. S. Wonnacott, J. Irons*, G.G. Lunt, & E.X. Albuquerque. (SPON: R. Sjodin). Biochemistry Dept., Univ. Bath, Bath BA2 7AY U.K. & Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

Structural diversity of neuronal nicotinic acetylcholine receptors (nAChR) is evident at the gene level and this is manifest by at least two classes of nicotinic ligand binding sites in vertebrate brain. Using nicotine-stimulated transmitter release from perfused synaptosomes we have characterized presynaptic nAChR in rat striatum and hippocampus. These functional nAChR best correlate with high affinity [^{3}H]nicotine binding sites. We have now investigated the action of non-competitive antagonists on nicotine-evoked [^{3}H]GABA release from hippocampus, to explore the molecular mechanism of the presynaptic nAChR. In agreement with previous results (FEBS Lett. 212:292, 1987), the nicotinic channel blocker perhydrohistrionicotoxin (10 μM) inhibited the action of nicotine. Phencyclidine (PCP; 10 μM) was also effective in this system. PCP blocks the channel of the endplate and central nervous system (Ramoa and Albuquerque, this meeting). MK801, another non-competitive antagonist at NMDA receptors, also reversibly inhibited nicotine-evoked [^{3}H]GABA release. Antagonism by MK801 increased on repetitive stimulation. These agents did not affect K^+-stimulated release and they did not inhibit radioligand binding to brain membranes. Thus the presynaptic nAChR may operate via an ionophore that is not only similar to that of the muscle nAChR but also related to the NMDA receptor ion channel. This is in accord with the proposal that ligand-gated ion channels, although pharmacologically distinct at the level of their agonist binding site, are members of a highly conserved "super family". 260.8

NON-OXIME BISPYRIDINIUM COMPOUND SAD-128 ALTERS THE KINETICS OF ACh-ACTIVATED CHANNELS. **M. Alkondon* and E.X. Albuquerque.** (Spon:Dr.N.Brookes) Dept. Pharmacol. & Exper. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

Endplate current (EPC) measurements from frog sartorius muscles in presence of 1,1'-oxybis (methylene)bis 4-(1,1,dimethylethyl)pyridinium dichloride (SAD-128) revealed a nonlinear I-V relationship and a biphasic decay. Using the frog interosseal muscle fibers for patch clamp recordings under cell attached configuration, the kinetics were analysed in detail. SAD-128 (1-40 μM) produced a concentration-dependent reduction in the mean channel open time of ACh (100 -200 nM)-activated channel currents without affecting their conductance. The square wave-like current pulses which appear under control condition were interrupted by many flickers forming bursts of many openings and closings in presence of the drug. Membrane hyperpolarization accelerated the reduction of mean open time but increased the duration of the closed times inside the bursts. The reciprocal of the mean open time followed a linear increase at low concentration range of SAD-128 (1-10 μM), but increased with a parabolic function at higher concentrations (10-40 μM). SAD-128 also reduced the mean total open time of the burst. A simple sequential scheme of channel block does not explain most of the effects of SAD-128. Additional pathways and/or a change in rate constants are needed in the above model to account for the channel blocking effects of SAD-128. (Support: U.S. Army Med. Res. & Devel. Com. Contract. DAMD17-84-C-4219).

260.9

EFFECTS OF PHILANTHUS TOXIN (PTX) ON THE NICOTINIC ACETYLCHOLINE RECEPTOR (nAChR). R. Rozental*, G.T. Scoble*, S. Sherby*, A.T. Eldefrawi, M.E. Eldefrawi* and E.X. Albuquerque. Dept. Pharmacol. & Exp. Ther., Univ. of MD Sch. of Med., Balto, MD, 21201.

PTX is the major neurotoxin present in the venom of the wasp *Philanthus triangulum*. PTX (80 μM) blocked the indirectly elicited twitch of frog sartorius muscle; these effects were reversed upon washing. PTX (20 μM) depressed the peak EPC amplitude (from 0.3 to 0.13 μA at -100 mV) in a voltage-dependent manner, and reduced the linearity of the I-V relationship. The decay time constant of the EPC was shortened, with marked loss of voltage sensitivity at negative membrane potentials. Using cell-attached patch clamp technique of frog interosseal muscle fibers, PTX caused a voltage- and concentration-dependent shortening of burst and channel lifetime of currents activated by ACh. In addition, PTX reduced and blocked the frequency of channel opening at hyperpolarized holding potentials. PTX competitively displaced the specific binding of [^{3}H]H$_{12}$HTX to activated but not to resting *Torpedo* nAChR. PTX also inhibited binding of [^{125}I]α-bungarotoxin to *Torpedo* nAChR, suggesting that PTX binds to the ACh recognition site as well as to the high affinity noncompetitive site associated with the ion channel. The results suggest that PTX interacts with the nAChR as a competitive and a non-competitive open channel blocker. (Support: US Army Med. Res. & Dev. Comm. Cont. DAMD17-84-C-4219 and NIH Grants NS25296 & ES02594.)

260.10

THIOCHOLINE IS AN AGONIST OF THE NICOTINIC ACETYLCHOLINE RECEPTOR. G. Amitai & S. Chapman*, Dept. of Pharmacology, IIBR, P.O. Box 19 Ness Ziona, Israel.

Thiocholine (TCh) mediates the opening of the acetylcholine receptor (AChR) channel in BC3H-1 muscle cells. The functional response of AChR was determined by agonist-mediated $^{22}Na^+$ influx in intact cells under depolarizing conditions. The K_{act} values obtained for TCh and carbamylcholine (Carb) were: 80 and 38μM, and n_H values were 1.3 and 2.7, respectively, implying that TCh interacts by a non-cooperative mechanism. TCh activity was inhibited competitively by d-tubocurarine (IC50=0.25μM, n_H=1.1) suggesting that TCh activates the channel via the agonist/antagonist site. The K_{des} values obtained from the desensitization state-function for TCh and Carb were: 19 and 63 μM, and n_H=0.8 and 1.9, respectively, indicating a non-cooperative mechanism for TCh-induced desensitization. The recovery from TCh-induced desensitized state was 90% of the original response ($\tau_{1/2}$=15 sec). Agonist activity was not induced by dimethylamino ethanethiol, diisoprpyl-amino ethanethiol, mercaptoethanol or choline. Thus, both TCh-elicited activation and desensitization are unrelated to its reductive capability. In addition, the agonist action of organophosphates which release TCh by hydrolysis (e.g. phospholine iodide) should be evaluated with caution. (Supported by USAMRDC, DAMD17-84-C-4016).

260.11

MUSCARINIC AGONISTS DEPRESS CA^{2+}-SENSITIVE CURRENT IN HIPPOCAMPAL PYRAMIDAL NEURONS. K.L. Zbicz and F.F. Weight. Lab. Physiologic and Pharmacologic Studies, NIAAA, Rockville, MD. 20852.

Outward membrane currents in hippocampal CA3 pyramidal neurons were studied using the single microelectrode voltage clamp technique. Neurons were impaled with microelectrodes (15-25 MΩ) containing a CsCl or Cs_2SO_4 solution. Cs^+-loading selectively reduced outward currents elicited by depolarizing voltage steps, allowing visualization of an initial large inward current and a slowly developing outward current which had characteristics of a Ca^{2+}-dependent K^+ current. This slow current was blocked or reduced by Ca^{2+}-channel blockers Co^{2+}(1-3 mM) and Mn^{2+}(2-4 mM), lowered extracellular Ca^{2+}, and by TEA($\geq$10 mM), but was insensitive to 4-AP (200 μM). The slow outward current was also greatly reduced by application of Ba^{2+}(0.2-1.0 mM).

Application of the cholinergic agonists carbacol or muscarine (10-25 μM) significantly reduced the slow Ca^{2+}-sensitive outward current. Application of these drugs also reduced the amplitude of the initial inward current. When the slow outward current was abolished by exposing the neurons to a 0 Ca^{2+} solution containing Mn^{2+}, subsequent application of muscarine did not reduce depolarization activated currents. These results indicate that in hippocampal pyramidal neurons, cholinergic effects are based, at least in part, by effects on Ca^{2+}-dependent outward current. The observed reduction in this current may be secondary to depression of inward Ca^{2+} current.

260.12

A CALCIUM CONDUCTANCE IS INDUCED IN HIPPOCAMPAL PYRAMIDAL CELLS BY MUSCARINIC RECEPTOR ACTIVATION. R.D. Blitzer, O. Gil*, and E.M. Landau. Dept. of Psychiatry, Bronx VA Medical Center, Bronx, NY 10468

Muscarinic agonists depolarize hippocampal pyramidal cells, due at least in part to the blockade of a number of K+ conductances. We have been interested in the possible activation of Ca++ conductances in these neurons by cholinergic stimulation, and have therefore examined the membrane effects of muscarinic agonists in the presence of external Ba++ ions.

Guinea pig hippocampal slices were superfused with artificial CSF and maintained at room temperature or at 31° C. Pyramidal cells from region CA1 were single-electrode voltage-clamped (sampling freq.: 2-6 kHz; holding potential between -70 and -80 mV), and drugs were applied in a medium containing 1-4 mM Ba++ and 0.5 μM TTX. In nearly all cells tested (95/97), carbachol (10 μM) induced a rapid inward current associated with an increase in conductance. This current inactivated within 3 min despite continued carbachol exposure, the period of desensitization lasting 10-20 min. The size of the current depended upon Ba++ concentration (1 mM: 147±34 pA, n=15; 4 mM: 213±17 pA, n=81), and the current was blocked by pirenzepine (0.1 μM) and by external Cd++ (200 μM) and Mg++ (8-10 mM). Oxotremorine (10 μM) only weakly induced the Ba++ current, and antagonized the carbachol effect.

We conclude that M-1 receptor stimulation is linked to the activation of a calcium conductance in pyramidal cells, perhaps through effects on the PI system. This conductance may underlie the calcium-dependent component of muscarinic depolarization reported recently by Alger and McCarren [*Soc. Neurosci. Abstr.*, **13**, 1005 (1987)]. In addition, this conductance may represent an important link between cholinergic activity and memory. Supported by NIH Grant 5-P50-AG05138-02.

Ca-ACTIVATED K-CHANNEL IN RAT NEUROHYPOPHYSIAL NERVE TERMINALS. P.J. Thorn* and J.R. Lemos. Worcester Foundation for Experimental Biology, Shrewsbury, MA

Nerve endings from the rat neurohypophysis were dissected free from pars intermedia and dissociated by homogenization. The isolated terminals release oxytocin and vasopressin in response to membrane depolarization in a Ca^{2+} dependent manner (Cazalis, et al., 1987, J. Physiol. 390:5). It is possible, using patch-clamp techniques, to directly analyze membrane ionic currents, including Ca^{2+} channels (Lemos and Nowycky, 1987, Soc.Neurosc. 13:793), and their influence on secretion using this preparation.

We have observed several types of cation channels in these isolated nerve endings. One has the characteristics of a maxi-Ca^{2+} activated K^+ channel, hypothesized to exist in the intact neurohypophysis (Parsons, et al, 1986, Bioph.J. 51:428). Reversal potentials in assymetrical salt gradients indicate that it is a cation channel which is more selective for K^+ than for Na^+ ($P_{K/Na}$=9:1). In symmetrical KCl the open probability increases with depolarizing voltages and with $[Ca^{2+}]_{in}$ >1 uM. This activation is very steep between 1 and 3 uM $[Ca^{2+}]_{in}$. The slope conductance of the Ca^{2+} activated K^+ channel is about 240 pS in symmetrical 150 mM KCl and appears to be affected by intracellular Na^+. This and other cation channels in the terminal membrane are being further characterized.

SINGLE QUININE-SENSITIVE K^+ CHANNELS ACTIVATED BY D_2 DOPAMINE RECEPTORS IN RAT CORPUS STRIATUM. Jonathan E. Freedman and Forrest F. Weight. Section of Electrophysiology, Laboratory of Physiologic and Pharmacologic Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

We have studied the actions of dopamine and antipsychotic drugs at the single channel level, using an enzymatic and mechanical method to acutely dissociate neurons suitable for patch-clamp recording from the corpus striatum (caudate and putamen) of young adult rats (*Proc. Natl. Acad. Sci. USA*, **85**: 3618, 1988). In cell-attached recordings, single channel openings were observed in the presence of dopamine or of quinpirole (a D_2 receptor agonist), but not in the presence of SKF-38393 (a D_1 agonist) or in the absence of drugs. Haloperidol and the D_2 antagonist spiperone were potent antagonists, whereas the D_1 antagonist SCH-23390 was less potent. The channel conductance was about 85 pS in the presence of 140 mM KCl, and the reversal potential varied with the extracellular K^+ concentration as predicted by the Nernst equation, suggesting the opening of single K^+ channels following D_2 dopamine receptor activation.

Quinine (which is known to block various K^+ and other ion channels at 1 μM to 1 mM, and is less toxic than many other channel blockers) potently inhibited D_2-activated channel openings. There was a partial blockade with as little as 5-10 nM quinine, and almost no channel current was observed at 100 nM. Concentrations exceeding 100 nM are known to be attained in human brain at clinical (ie, antimalarial) dosages of quinine. Why extrapyramidal signs, which are characteristic of D_2 receptor blockade, are not prominent quinine side effects is an interesting and unanswered question.

5-HT-INDUCED CURRENTS IN NCB-20 AND N1E-115 CELL LINES. T.G. Hales*, J.J. Lambert* and J.A. Peters*. (SPON: S.M. Bunt). Dept. of Pharmacology & Clinical Pharmacology, Ninewells Med. Sch., Dundee Univ., DD1 9SY. Scotland. UK.

Neuronal clonal cell lines are useful model systems for the study of neurotransmitter receptor function. Here clonal lines N1E-115 and NCB-20 were used to investigate the molecular properties of the 5-HT_3 receptor (e.g. Neijt, H.C. et al, Eur J. Pharmac., 127: 271, 1986).

Locally applied 5-HT (10μM) induced inward currents on 70% of NCB-20 cells (n=221) voltage-clamped at -60 mV. The response reversed in sign at 0mV ($[Na^+]_o = [Cs^+]_i$). Such currents were suppressed by the 5-HT_3 antagonists GR 38032F (1 nM) and ICS 205-930 (0.3 nM), but were unaffected by the 5-HT_2 antagonist ketanserin (1μM), the mixed "5-HT_1-like"/ 5-HT_2 antagonist methysergide (1μM), or the 5-HT uptake blocker citalopram (1μM).

On isolated outside-out membrane patches from N1E-115 cells (holding potential = -60 mV), 5-HT evoked inward currents of -1 to -20pA, which were reversibly suppressed by GR 38032F (1nM). In common with whole cell currents, the response of the isolated patch demonstrated desensitization and reversed in sign at 0mV. Despite the high resolution of these recordings, discrete single channel events were not discernible during such currents. Qualitatively similar results were obtained on membrane patches from NCB-20 cells. It is possible that 5-HT evokes a channel of small conductance in these cells.

260.16

GABA RECEPTOR cDNAs EXPRESSED IN TRANSFECTED CELLS AND STUDIED BY PATCH-CLAMP AND BINDING ASSAY D. Pritchett*, P. Schofield*, H. Sontheimer*, S. Ymer*, H. Kettenmann*, and P. Seeburg* (SPON: B. Shivers). ZMBH and Dept. of Neurobiology U. Heidelberg, D6900 Heidelberg, FRG.

GABA receptor chloride ion channels were expressed in human cell lines by DNA-mediated transfection. Four different (30% identity) cDNAs encoded GABA A receptor polypeptides; ligand-gated chloride channels expressed in transfected cells were characterized using the whole cell patch-clamp mode. Ligand and ion selectivity was observed even in single subunit homo-oligomeric receptors formed in cells transfected singly with any individual GABA cDNA. GABA receptor subunit cDNAs produced GABA- and muscimol-gated, bicuculline- and picrotoxin-sensitive channels; GABA had no effect on untransfected or vector transfected cells and glycine had no effect on GABA subunit cDNA transfected cells. Pentobarbitol potentiated only the GABA responses including the GABA homo-oligomeric channels. In filter binding assays, α+β transfected cell membranes had 3H muscimol and 35S TBPS binding sites; the addition of the γ cDNA produced a receptor, showing 3H flunitrazepam binding. This expression system offers the opportunity to assess how structural differences alter channel properties and, ultimately, information processing in the CNS. This system is also less labor intensive and seasonally variable than the oocyte expression system. In addition, stable cell lines can be produced for evaluating the therapeutic potential of channel-active drugs.

260.17

DIAZEPAM DOES NOT ALTER THE GATING KINETICS OF GABA RECEPTOR CHANNELS. C.J. Rogers, R.E. Twyman and R.L. Macdonald. Dept of Neurology, University of Michigan, Ann Arbor, MI, 48104.

We have reported previously that diazepam (DZ) increased the frequency of GABA receptor channel currents (Soc Neurosci Abst 12:669,1986). We now report the effects of DZ on the gating kinetics of the GABA receptor channel.

Dissociated fetal mouse spinal cord neurons were cultured for 3-6 weeks prior to use. The recording pipette and bathing media were Hepes buffered and had equal Cl^- concentrations. GABA (2 uM) with or without DZ (20 or 100 nM) was applied to the patch by pressure ejection from blunt micropipettes. When DZ was studied, it was added to the bathing medium. Strychnine was added to all solutions to block glycine receptor currents. Outsideout patches were voltage clamped at the potassium equilibrium potential (-75 mV). Currents were digitized at 8 KHz with a 1 KHz 8-pole Bessel filter and analyzed using a 50 percent threshold for channel detection.

GABA receptor channels opened to at least two conductance states (27 and 19 pS). Gating kinetics of the larger, more frequent 27 pS channel were analysed. DZ (20 or 100 nM) produced a concentration-dependent increase in the frequency of GABA-gated currents. Frequency distributions (F(O)s) of open durations of GABA receptor currents were fit with three exponential functions, suggesting that the GABA receptor channel opened into at least three different open states. After addition of DZ, the F(O) of GABA receptor currents was unchanged. DZ did not alter the time constants or relative areas of the exponential functions. Thus, DZ did not alter the gating kinetics of the GABA receptor channel but increased chloride current by increasing the frequency of channel opening.

260.18

GABA MAIN STATE AND GLYCINE SUBSTATE RECEPTOR CHANNELS HAVE SIMILAR GATING KINETICS - ADDITIONAL SUPPORT FOR A RECEPTOR SUPERFAMILY R.E. Twyman, C.J. Rogers and R.L. Macdonald. Dept of Neurology, University of Michigan, Ann Arbor, MI, 48104.

GABA and glycine (Gly) receptor channels have been shown to have significant sequence homology in their subunit peptides and to open to the same conductance states. The structural holomogy of the receptors suggests that GABA and Gly receptor channels may also have similar gating kinetics. To evaluate this, we recorded single channel currents from outside-out patches obtained from 2-5 week old mouse spinal cord neurons grown in cell culture.

Bathing and intrapipette recording medium consisted of a HEPES-buffered, symmetrical chloride solution. Patches were clamped at the potassium equilibrium potential (-75 mV). Pressure ejection micropipettes were used to apply GABA (1 uM) or Gly (1 uM). Responses were digitized at 20 kHz with a 2 kHz 8 pole Bessel filter and analyzed by computer.

GABA and Gly receptor channels both opened to at least 3 conductance states (19, 27 and 44 pS). The main states for GABA and Gly were 27 and 44 pS, respectively. Since the GABA receptor channel only opened rarely to the 44 pS state, the gating properties of the 27 pS states of the receptor channels were compared. The frequency distributions of open durations (F(O)s) for the 27 pS states were similar. The F(O)s for the 27 pS states were fit with 4 exponential functions whose time constants and relative areas were not significantly different. These results suggest that the gating domains of the 27 pS GABA and Gly receptor channels are similar, consistent with membership in a receptor superfamily.

ETHANOL ENHANCES A COMPONENT OF GABA-GATED CHLORIDE CHANNEL CURRENTS IN RAT DORSAL ROOT GANGLION NEURONS. M. Nishio* and T. Narahashi (SPON: E.M. Silinsky). Department of Pharmacology, Northwestern University Medical School, Chicago, IL 60611.

Behavioral and electrophysiological studies suggest that the effects of ethanol on CNS are mediated at least in part through interactions with GABA receptor-channel complex. A recent study has shown that GABA-induced ^{36}Cl influx in cultured spinal cord neurons is greatly enhanced by a low concentration (10 mM) of ethanol (Ticku, Brain Res. Bull., 17, 123, 1986). However, the effect of ethanol on the GABA-gated chloride channel current is yet to be determined. Membrane currents in response to bath application of GABA were recorded from primary cultured neurons of rat dorsal root ganglia using the whole cell patch clamp technique. The external and internal solutions were designed to isolate the chloride current. GABA produced an inward current which was composed of a transient peak and a sustained current. Both components were blocked by bicuculline. Ethanol at concentrations of 3 to 100 mM enhanced the initial peak component of the GABA-induced chloride current in a dose-dependent manner without affecting the sustained component. The maximum increase in the current amplitude was approximately 30%. This action appears to contribute to the depressant effect of ethanol on CNS (supported by NIH grant NS14144).

PROPERTIES OF SINGLE CAPSAICIN-ACTIVATED CHANNELS. C.A. FORBES* and S. BEVAN* (SPON: K. Valentino) Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN, U.K.

Capsaicin is the pungent agent present in the hot Capsicum pepper. It has a specific excitatory action on mammalian polymodal nociceptive neurones. We have shown in whole cell voltage clamp recordings from cultured primary sensory neurones from the dorsal root ganglia of adult or neonatal rats that capsaicin, at sub-micromolar concentrations, causes an increase in the membrane conductance. This results in membrane currents which can be carried by sodium, potassium, caesium, calcium, and possibly other cations (Bevan and Forbes, 1988, J.Physiol. 398 28P).

We have now made recordings in cell-free outside-out membrane patches of single channel currents flowing through membrane channels activated by capsaicin. The channels have a conductance of 25-30pS at -80mV, but the single channel conductance is not linearly related to holding potential, being around 70pS at +40mV. We attribute this to the presence of calcium ions in the medium bathing the external face of the membrane, since in bathing medium containing no added calcium ions much of the non-linearity is lost. We therefore suggest that calcium can permeate the capsaicin-activated channels, but that it does so less well than other cations such as sodium, and hence brings about a reduction in the observed single channel conductance.

ION CHANNELS: CHLORIDE AND OTHER

261.1

A DELAYED COMPONENT OF THE CALCIUM-DEPENDENT CHLORIDE CURRENT IN XENOPUS OOCYTES INJECTED WITH BRAIN MESSENGER RNA. B. Gillo,* T.M. Moriarity,* S. Sealfon,* J. Roberts* and E. Landau (SPON J. Eisenman). Depts. of Psychiatry and Pharmacology and the Fishberg Molecular Neurobiology Center of the Mt. Sinai School of Medicine and the Bronx VA Medical Center, New York, NY

When the membrane potential in oocytes injected with brain RNA was jumped to +10 mV, two peaks of outward chloride current were observed (Tout 1 and Tout 2) with average latencies of 90±10 ms (n=31) and 710±55 ms (n=31) respectively. Both currents had similar time constants of decay and similar amplitudes. Only Tout 1 was found in native oocytes and its amplitude was much smaller than that seen in RNA-injected oocytes. Tout 1 was more sensitive than Tout 2 to changes in extracellular calcium but only Tout 2 was enhanced by exposing the oocytes to serotonin (0.5-2 nM) or phorbol myristate acetate (10 nM). Injecting the oocytes with barium (300-400 pmol) blocked Tout 2 but not Tout 1. It is concluded that the brain RNA induces a novel calcium-induced calcium release mechanism in oocytes which can be regulated by transmitter via the the phosphatidylinositol second messenger system.

CHLORIDE CURRENTS GENERATED BY INJECTION OF ETHANOL INTO XENOPUS OOCYTES. K.A. Wafford* R.A. Harris and T.V. Dunwiddie, Dept. of Pharmacology, Univ. of Colo. Hlth. Sci. Cntr., and V.A. Medical Center, Denver, CO 80262

Xenopus oocytes possess a common receptor-channel coupling system for a number of different receptors. Native muscarinic receptors, and also those expressed from rat brain mRNA, including 5-HT, glutamate, noradrenalin and recently neurotensin and substance K, couple to this system (Parker et al., Proc. Roy. Soc. B, 231:37, 1987). These receptors activate calcium-dependent chloride channels by releasing calcium from intracellular stores via inositol phosphate formation (Nomura et al., Mol. Brain Res., 2:113, 1987). Injection of IP_3 also elicits a calcium-dependent chloride current (Parker & Miledi, Proc. Roy. Soc. B, 228:307, 1986). Ethanol has recently been shown to directly release calcium from intracellular stores in mouse brain synaptosomal preparations (Daniell et al., Mol. Pharm., 32:831, 1987). Ethanol and IP_3 also release microsomal calcium but from different pools (Daniell, pers. comm.). Defolliculated oocytes were perfused with modified Ringer's media (OR-2). Ethanol was pressure-injected into the oocytes, intracellular concentration determined by measuring the drop diameter with various injection times. Currents were recorded under voltage-clamp conditions and drugs were applied by perfusion. Injection of ethanol elicited a dose-dependent inward current consisting of a fast and slow component similar to that produced by IP_3. The EC_{50} of the slow response was 56 ± 10mM (n=4). The current reversed at approximately -20mV, close to the equilibrium potential for chloride in oocytes and this reversal potential shifted in a positive direction in the absence of extracellular chloride. The response was also reduced in the presence of the chloride ion transport inhibitors, SITS (1mM) and DIDS (500uM). Perfused ethanol gave similar responses. These results show that ethanol elicits a chloride current similar to that produced by IP_3 and many receptors expressed in the oocyte membrane. Previous work suggests that this may be due to ethanol-induced release of calcium from intracellular stores which in turn opens calcium-dependent chloride channels in the membrane.

EFFECTS OF INHIBITORY AMINO ACIDS ON CHLORIDE INFLUX IN ADULT AND DEVELOPING MOUSE BRAIN. Pirjo Kontro, E.R. Korpi and S.S. Oja. Department of Biomedical Sciences, University of Tampere and Research Laboratories, State Alcohol Company (Alko Ltd.), Helsinki, Finland.

The effects of inhibitory amino acids on the chloride influx through the chloride channel associated with the GABA receptor were investigated with brain homogenates from adult and 3-day-old mice. The homogenates from different brain regions were incubated for 2 s at room temperature in Krebs-Ringer-Hepes-glucose medium, pH 7.5, with radioactive chloride. GABA increased the chloride influx dose-dependently, the stimulation being maximal, about 3-fold, at 0.1 mM GABA in both adult and developing cerebral cortex. The GABA stimulation was lowest, about 1.3-fold, in the adult brain stem. Taurine, β-alanine and hypotaurine also enhanced the chloride fluxes, but their effects were more pronounced only at millimolar concentrations in both adult and immature brain tissue. Glycine had no marked effects on the chloride fluxes in homogenates from either the brain stem or higher brain regions. Picrotoxin, bicuculline and strychnine did not affect the basal chloride flux but blocked the GABA-, taurine-, β-alanine- and hypotaurine-stimulated fluxes in all brain regions studied. Moreover, taurine at millimolar concentrations inhibited the GABA-stimulated fluxes. The results show that, besides GABA, also other inhibitory amino acids can interfere with the function of chloride channels.

EVIDENCE FOR A LARGE CONDUCTANCE CHLORIDE CHANNEL IN CULTURED GLOMUS CELLS OF THE RAT CAROTID BODY. A. Stea* and C.A. Nurse. Dept. of Biology, McMaster University, Hamilton, Ontario, L8S 4K1.

In order to understand chemosensory mechanisms in the carotid body we are studying the physiology of cultured (parenchymal) glomus cells using the patch clamp technique. We report on the presence of a large conductance chloride channel (ca. 300 pS) in inside-out patches of glomus cells. In symmetrical 140 mM NaCl solutions the single channel I-V relation reversed at 0 mV (see Fig. open circles) and was hardly affected when the bath contained 70 mM NaCl: 70 mM choline Cl (open squares). Replacing half of the Cl^- in the bath by the impermeant anion glutamate resulted in a shift in the reversal potential to ca. +18 mV (V_p; closed circles), the predicted value for E_{Cl}. This finding together with the demonstration that these cells contain carbonic anhydrase (see accompanying abstract, Nurse et al.) raises the possibility that intracellular and probably extracellular pH regulation may be an important function of glomus cells. Other ion channels in these cells are presently being characterized. Supported by the Heart and Stroke Foundation of Ontario.

DEVELOPMENT OF NEURONAL EXCITABILITY: A DECREASE IN CALCIUM-ACTIVATED CHLORIDE CONDUCTANCE OF EMBRYONIC SPINAL NEURONS IN CULTURE. N. Hussy*(SPON: G.L.Harris). Dept of Neurosci., UCSD, La Jolla.

Voltage-dependent calcium, sodium and potassium conductances have previously been shown to change as *Xenopus* spinal neurons differentiate *in vitro*. However intracellularly recorded action potentials are always long in duration and Ca-dependent in the absence of external Na and the presence of TEA, to block K channels. Their enhancement by the reduction of external chloride and the dependence of this effect upon external calcium indicates the presence of a calcium-activated chloride conductance. This conductance is found in 75% of the neurons.

At one day in culture replacement of 90% of the external Cl with methane sulfonate caused a nearly 5 fold increase in action potential duration without altering its amplitude. When external Ca was reduced from 10 to 1 mM, replacement of Cl now caused an increase in both amplitude and duration of the smaller action potential. In experiments performed on cells after 6 to 9 hrs in culture, Cl substitution induced a nearly 20 fold increase in action potential duration. Reduction of extracellular calcium resulted in greater increases in amplitude and duration of the impulse than observed at one day in culture. In all cases, removal of external calcium abolished these action potentials.

The Ca-activated Cl conductance appears to undergo at least a 2 fold decrease during the first day in culture, when the developmental increase in potassium conductance is taken into account. This conductance will normally act to repolarize cells. However since it activates only slowly, it may not be involved in the action potential but in modulation of electrical activity. The ionic dependence, kinetics and pharmacology of this conductance are presently being studied with whole cell patch clamp recordings. Supported by NIH NS15918.

261.6

CHARACTERIZATION OF PROTON CURRENTS IN PERFUSED SNAIL NEURONS Y. Suen* & L. Byerly (Spon: George J. Augustine). Neurobiology Section, USC, Los Angeles, CA 90089-0371.

Internal-perfusion voltage-clamp and patch clamp techniques were used to study proton currents in neurons of the snail Lymnaea stagnalis. In whole cells the voltage-activated outward H^+ current density was typically 15 nA/nfd (range: 4.2-29.0 nA/nfd) measured at +40 mV with $[K^+]_i$=0 and pH_i=5.9, while the prolonged, voltage-activated K^+ current was typically 38 nA/nfd (range: 9.5-61.9 nA/nfd) measured at +40 mV with $[K^+]_i$=74 mM and pH_i=7.3. In inside-out patch studies, these currents were found to be distributed differently. While all patches had K^+ currents (2-35 pA at +30 mV) only 3 out of 30 patches studied had H^+ currents. The patch H^+ currents recorded, 5-21 pA in amplitude, exhibited little noise, suggesting that the unitary H^+ current is very small. The relative ability of various extracellular divalent cations to block the H^+ current was found to be Zn=Cu>Ni>Cd>Co>Mn>Mg=Ca=Ba. Thus, 100 μM Zn^{2+} helps to isolate Ca^{2+} currents from H^+ current. The Q_{10} of the H^+ current magnitude was 2.1, while that of the prolonged K^+ current was 1.4. All of these results demonstrate that H^+ current flow through distinct channel from those of the prolonged K^+ currents, even though these currents have similar voltage-dependence and kinetics.

COMPUTER ANALYSIS OF ION-SELECTIVE MICROELECTRODE RESPONSES: CALIBRATION AND RECORDING. A.W. Barolet, R. Andrews* and M.E. Morris. Playfair Neuroscience Unit and Departments of Anaesthesia and Pharmacology, University of Toronto, Toronto M5S 1A1.

A user-logical command-driven program, written in 'C' has been developed for the rapid and accurate analysis of both on- and off-line calibration and experimental data recorded with ion-selective microelectrodes. Required hardware includes an IBM-PC or compatible system with hard disc and graphics adaptor, parallel printer or serial plotter for graphics. Special features are (i) non-linear least squares fit of curves to data, (ii) optional selection and use of activity coefficients, (iii) calculation of selectivity coefficients using fixed interference or separate solution methods, (iv) conversion of voltage or length data to ion activity/concentration and correction for drift. Electrodes are calibrated in a stationary position in the recording bath or with a simple polyethylene flow-through chamber. Solutions with various concentrations of the ion to be measured are selected manually or by computer from one of six reservoirs by means of a controller circuit with relays and voltage-activated valves. Gravity flow of $\leq$ 4 ml/min to the calibration chamber is via an 8-way connector and monitored with a flowmeter.

262.1

CHARACTERIZATION OF CALCIUM CURRENTS IN RELAY NEURONS ISOLATED FROM MAMMALIAN THALAMUS.

J.R. Huguenard, D.A. Coulter, and D.A. Prince. Department of Neurology, Stanford University Medical Center, Stanford, CA 94305.

The transfer properties of the thalamo-cortical relay neurons (RNs), which control the flow of information from the periphery to the neocortex, are critically dependent on a prominent low threshold calcium spike (LTS, Llinas & Jahnsen, *Nature* 297:406, 1982). We examined the Ca currents underlying the LTS in neurons isolated from the ventrobasal (VB) complex of the thalamus in guinea pig and rat. This is the first detailed study of the various components of Ca current in mammalian thalamic neurons.

VB neurons were isolated by the method of Kay and Wong (*J. Neurosci. Meth.* 16:227, 1986), and putative RNs (somatic diameter > 10 um) were selected for study. Ca currents were isolated with appropriate intracellular and extracellular solutions, and were recorded by whole cell clamp. RNs have 3 types of Ca currents, T, N, and L, all of which are similar to the Ca currents recorded in dorsal root ganglion (DRG) neurons (Nowycky, *et al.*, *Nature* 316:440, 1985). In contrast to DRG cells, RNs are characterized by a much larger transient (T) current (up to 1 nA) that was often larger than the maximal L current, while the N component was always either small or absent. The large proportion of T current in RNs compared to DRGs may account for some of the functional differences between these two neuronal types. The high threshold and low threshold components were selectively susceptible to blockade by Cd (20uM) and Ni (100 uM), respectively. The T component showed threshold activation around -70 mV, peak activation near -30 mV, and steady state inactivation was half complete near -90 mV. We conclude that the properties of T-current in RNs are perfectly suited to produce LTSs: T-current is large, transient, activated at relatively low threshold, steady state inactivated near rest, and inactivation is removed by hyperpolarization.

Supported by NIH grants NS06477 and NS 12151.

262.2

ANTICONVULSANTS DEPRESS CALCIUM SPIKES AND CALCIUM CURRENTS OF MAMMALIAN THALAMIC NEURONS IN VITRO.

D.A. Coulter, J.R. Huguenard, and D.A. Prince. Dept. of Neurology, Stanford University Medical Center, Stanford, CA 94305

Thalamic neurons are known to play a role in the generation of normal and abnormal thalamocortical rhythms, including spike-wave disharges characteristic of petit mal seizures. Low-threshold calcium spikes (LTS) in thalamic neurons are thought to be of primary importance in the generation of normal thalamocortical rhythms, such as sleep spindles. Therefore, we postulated that the thalamic LTS might also be important in the generation of abnormal thalamocortical rhythms, such as spike-wave discharges, and further that anti-petit mal agents might act, at least in part, to reduce this conductance as a mechanism of action.

Intracellular recordings from guinea-pig thalamic slices demonstrated that ethosuximide (ES) and dimethadione (DMD), anti-petit mal drugs, reduced LTSs in thalamic relay cells, resulting in changes in rhythmic firing properties. Whole-cell voltage-clamp recordings from dissociated guinea-pig or rat thalamic neurons revealed at least two distinct calcium currents, based on voltage-dependence and kinetics of activation, inactivation, and deinactivation (Huguenard et al, this volume). ES and DMD reversibly reduced the low- and high-threshold calcium currents (L- and HTCCs) in a dose-dependent manner, at concentrations equal to clinical free serum levels. ES reduced the LTCC to a greater extent than the HTCC, while DMD was less specific for the LTCC. Succinimide, the inactive structural analogue of ES, had no such effect at equivalent concentrations. Valproic acid had only small effects on the LTCC. Phenobarbital reduced the L- and HTCC, while carbamazepine and phenytoin had no effect on these currents at clinically relevant concentrations. These data suggest that reduction of calcium currents in thalamic neurons may be a potential mechanism of action of anticonvulsants effective in petit mal. Supported by NIH grants NS06477, NS12151 and NS07280.

PHORBOL ESTER INCREASES CA^{++} CURRENT IN APLYSIA SENSORY NEURONS. O. Braha, M. Klein* and E.R. Kandel, Ctr. for Neurobiol. & Behav., HHMI, Columbia Univ., New York, NY 10032

Phorbol dibutyrate (PDBu), an activator of protein kinase C (PKC), facilitates the connection between sensory and motor neurons in cultured neurons of Aplysia (Hochner et al., Soc. Neurosci. Abstr., 1986, 12:1340). We have examined the effects of PDBu on the Ca^{++} current of sensory neurons in the absence of external Na^{+}, and with K^{+} currents blocked by extracellular K^{+}-channel antagonists (tetraethylammonium, 3,4-diamino-pyridine) and by intracellular injection of Cs^{+}. Voltage-clamp steps from a holding potential of -50 mV to +10 mV elicit inward currents that are increased by 20-100 nM PDBu, while the alpha isomer of PDBu, which does not activate PKC, has no effect. The increase in current produced by PDBu occurs with either Ca^{++} or Ba^{++} as the charge carrier. It shows a bell-shaped voltage dependence with a peak around +10 mV, a shape that is characteristic of Ca^{++}-dependent currents, and is blocked by the Ca^{++} channel antagonist Cd^{++} (0.1 mM). The current increased by PDBu resembles the slowly inactivating, nifedipine-sensitive, Ca^{++} current described in these cells by Edmonds, Kandel and Klein (Soc. Neurosci. Abstr., 1987, 13:792). We do not yet know how this current is related to the Ca^{++} current induced by phorbol esters in bag cells of Aplysia (Strong et al., Nature, 1987, 325:714-717).

262.4

SOMATOSTATIN INHIBITS CALCIUM CURRENTS IN AN ENRICHED POPULATION OF NORMAL ANTERIOR PITUITARY CELLS. I.Nussinovitch* (SPON: M. Schramm) Department of Physiology, Hebrew University-Hadassah Medical School, P.O.Box 1172, Jerusalem 91010, Israel

Somatostatin is known as the physiological inhibitor of growth hormone secretion from the anterior pituitary gland. Recently, it has been reported that somatostatin inhibits a voltage-gated calcium current in a pituitary cell line (Luini et al, J.Neurosci., 6:3128, 1986). The present study shows that somatostatin inhibits a voltage-gated calcium current in rat somatotrophs (an enriched population). Calcium currents were recorded in the whole-cell configuration of the patch-clamp technique, usually in response to a depolarizing step from a holding potential of -80mV to 0mV. Bath solution contained: NaCl 130 mM, KCl 5 mM, $CaCl_2$ 10mM, $MgCl_2$ 1 mM, glucose 10 mM, Hepes 10 mM and TTX 3 µM. Intracellular solution contained: CsCl 140 mM, $MgCl_2$ 2mM, EGTA 11 mM, Hepes 10mM, ATP 2mM, GTP 80 µM. After a control period of recording, somatostatin (61 nM) was applied to the cell by diffusion from a pipette placed near the surface of the cell. In 7 out of the 8 cells exposed to somatostatin calcium currents were reduced by 30-60%. The onset of the inhibition exerted by somatostatin was rapid (seconds) and recovery was completed usually less than 60 seconds after removing the diffusion pipette from the cell. In 5 cells with similar results somatostatin was applied repeatedly (at least 3 times). This inhibitory effect of somatostatin may be the underlying mechanism for the inhibition of growth hormone secretion. This work was supported by a Kohn fellowship and by the U.S.-Israel Binational grant No. 86-00198.

SINGLE L-TYPE CALCIUM CHANNELS IN DORSAL ROOT GANGLION NEURONS CAN BE MODULATED BY NOREPINEPHRINE. C.S. Anderson* and K. Dunlap. Department of Physiology, Tufts Medical School, Boston, MA 02111.

Norepinephrine-induced modulation of macroscopic calcium current in embryonic chick dorsal root ganglion neurons has been well-described. Results of Nowycky et al. (Nature, 316:440,1985) illustrate that at least three types of voltage-dependent calcium current can be recorded from these cells and descriminated both at the macroscopic and single channel level. Which of these is (are) a target for modulation by the transmitters? On the basis of macroscopic currents alone, we have suggested that the L-type calcium channel is one target for modulation by norepinephrine, but definitive support for this idea requires single channel recordings. Here we report that, in cell-attached patch recordings, Bay K 8644-sensitive L-type channels (ca. 25 pS) could be recorded following depolarization and were subject to modulation by norepinephrine applied to the extrapatch membrane. The modulation was associated with an increase in the number of null sweeps and a decrease in the overall number of single channel events detected following stimulation. These results support the idea that L-type calcium channels are modulated by norepinephrine and underscore the notion that the mechanism of the modulation involves the activation of a second messenger pathway. Future experiments will address whether the other types of calcium channel recorded from these cells also undergo transmitter-induced modulation.

2-CHLOROADENOSINE SELECTIVELY REDUCES THE N-CALCIUM CURRENT OF MOUSE DORSAL ROOT GANGLION NEURONS IN A PERTUSSIS TOXIN-SENSITIVE MANNER. T. Ryan-Jastrow, R.A. Gross and R.L. Macdonald. Dept. of Neurology, Univ. Michigan, Ann Arbor, MI 48104

Adenosine and its analogues shorten calcium-dependent action potential (CAP) duration and reduce calcium (Ca) current in mouse dorsal root ganglion (DRG) neurons (Macdonald *et al.*, J Physiol 370:75, 1986). The effect of an adenosine analogue, 2-chloroadenosine (CADO), on the three types of Ca current (T, L, and N) in mouse DRG neurons was studied. The involvement of a G-protein in the regulation of the effect of CADO on CAP duration and Ca current was studied using pertussis toxin (PT).

Intracellular recordings were made with micropipettes filled with 3M KAc (CAP) or 3M CsCl (voltage clamp). Recording media (pH=7.35) contained (in mM): Tris, 13; NaCl (CAP) or choline-Cl, 67; KCl, 5; TEA, 5 (CAP) or 100; $CaCl_2$, 2.0; glucose, 5.6; $MgCl_2$, 0.8. A single electrode voltage clamp was used that switched at 8-12 kHz with a 70-30% cycle. Voltage steps were generated and currents stored using a microcomputer. CADO was applied by pressure ejection from blunt-tipped micropipettes. Three Ca current components were recorded, the transient low-threshold, transient high-threshold and slowly-inactivating high-threshold currents (T,N,L).

CADO reduced CAP duration (10-80 %) but did not affect isolated T- or L-Ca current. In combined N- and L-Ca current, CADO produced a 14-57 % reduction (n=22) in the peak current with little change in the late current, suggestive of a selective decrease in N-Ca current. Pretreatment of cultures with PT (100 ng/ml) for 16 hours blocked the reduction of CAP duration and N-Ca current by CADO.

NEUROPEPTIDE Y AND PHORBOL ESTERS REDUCE THE N-TYPE CALCIUM CURRENT OF ADULT RAT NODOSE NEURONS BY DIFFERENT MECHANISMS. J.W.Wiley, R.A.Gross, N. Fox & R.L.Macdonald, Depts. Internal Medicine (JWW) and Neurology, Univ. Michigan, Ann Arbor, MI 48104, USA.

Neuropeptide Y (NPY) serves as an inhibitory neuroregulatory peptide in the central and peripheral nervous systems. We tested whether NPY reduces calcium (Ca) current via GTP binding (G) proteins. Ca currents were obtained from acutely dissociated adult rat nodose neurons using the single electrode voltage-clamp technique. Recording medium contained choline, and the recording micropipette contained cesium to permit recording of Ca currents. Three calcium current components were identified using 5mM Ca as the charge carrier. The transient low-threshold, transient high-threshold and slowly-inactivating high-threshold currents (T,N,L, respectively) differed in their voltage ranges of activation and inactivation, and their sensitivities to Ca-channel blockers. Drugs were applied from blunt-tipped micropipettes. NPY selectively reduced N-current 12 +/- 4 to 52 +/- 8% (1nM-1uM, respectively) in 47% (36/77) of neurons. The effect of NPY was voltage-independent and blocked by pertussis toxin (PTX), an inactivator of some G-proteins. Phorbol esters, activators of protein kinase C, have been shown to reduce Ca current in primary afferent neurons by a PTX-sensitive mechanism (Gross & Macdonald, Neurosci Lett., in press). Phorbol ester (PDBu-500 nM) selectively reduced the N-current 24 +/- 6% (n=6). This effect was present only at holding potentials positive to -70 mV and was blocked by pretreatment with 100 ng/ml PTX for 12-24 hr. Thus, the effects of both NPY and phorbol esters were blocked by PTX. The action of NPY was, however, voltage-independent while that of phorbol ester was voltage-dependent, suggesting different mechanisms of action on the N-channel. Supported by an AGA grant to JWW, NIH-NS01019 to RAG and NS19692 to RLM.

262.8

ACTIVATION OF A-KINASE REDUCES THE N-TYPE CALCIUM CURRENT IN MOUSE SENSORY NEURONS BY ENHANCING INACTIVATION. R.A. Gross and R. L. Macdonald, Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104, USA

Forskolin (FOR), 8-Br-cyclic AMP (8-Br), and cholera toxin (CTX) were used to study the effect of the cyclic AMP/A-kinase system on calcium currents in mouse dorsal root ganglion (DRG) neurons. Activation of A-kinase has been shown to increase Ca currents in invertebrate neurons and in vertebrate cardiac cells. In contrast, FOR and 8-Br reduced Ca current in mouse DRG neurons (Gross and Macdonald, Neurosci. Lett., in press).

Intracellular recordings were made with micropipettes filled with 3M CsCl (20-30 MOhm). Recording medium (pH=7.35) contained (in mM): Tris, 13; choline-Cl, 67; KCl, 5; TEA, 100; $CaCl_2$, 2.0; glucose, 5.6; $MgCl_2$, 0.8. A single electrode voltage clamp was used that switched at 8-12 kHz with a 70-30% cycle. Voltage steps were generated and currents were stored (digitized at 2-6 kHz) using a microcomputer. Drugs were applied by pressure ejection from blunt-tipped micropipettes. Three Ca current components were recorded, the transient low-threshold, transient high-threshold and slowly-inactivating high-threshold currents (T,N,L). They had different voltage ranges of activation and inactivation, and different sensitivities to Ca channel blockers.

None of the compounds affected the isolated T current. FOR, 8-Br and CTX reduced the peak but not the late current of combined N and L currents, but only when applied at holding potentials positive to -75 mV. Multi-exponential curve-fitting showed this to be a selective effect on the N current component. FOR also hastened current inactivation at depolarized potentials, and increased steady-state inactivation. These results suggest that activation of A-kinase selectively reduced N current by enhancing inactivation.

β-ADRENOCEPTOR MODULATION OF CALCIUM CHANNELS IN ACUTELY EXPOSED CA3 PYRAMIDAL NEURONS OF ADULT GUINEA PIG HIPPOCAMPUS. *R.E. Fisher*, R. Gray and D. Johnston* (SPON: H.F. Epstein). Prog. in Neurosci., Baylor College of Medicine, Houston, TX 77030

The induction of long-term potentiation (LTP) appears to require a post-synaptic calcium influx. Unlike at the Schaffer collateral to CA1 synapse, LTP at the hippocampal mossy fiber to CA3 synapse is not blocked by NMDA receptor antagonists. We are exploring the possibility that, in CA3 neurons, voltage-dependent calcium channels provide the necessary calcium influx. This is suggested by the findings that β-adrenoceptor agonists 1) enhance LTP at the mossy fiber synapse (Hopkins and Johnston, *J. Neurophysiol.* 59:667, 1988) and 2) enhance calcium channel activity in dentate granule cells (Gray and Johnston, *Nature* 327:620, 1987). In the present experiments, calcium channels in adult CA3 pyramidal cells were studied using patch clamp techniques applied to the acutely exposed hippocampal neuron preparation of Gray and Johnston (*J. Neurophysiol.* 54:134, 1985). Barium currents in cell attached patches revealed the presence of at least three distinct calcium channel conductances: 9, 14, and 26 pS. From a holding potential of -80 mV, the 14 pS channel showed significant activity during steps positive to -20 mV. The activity of this channel was enhanced by the β-adrenergic agonist isoproterenol, applied by pressure pipette (10 μM in pipette, avg 420% increase during steps from -80mV to either -10, 0, or +10 mV, n=7). Control applications of bath saline did not significantly affect channel activity (n=4). The 9 pS channel began to activate slightly during steps to -40 or -30 mV, and strongly during steps positive to -20 mV. It was largely inactivated by holding at -40 mV. Isoproterenol did not appear to affect the activity of this channel (n=2). The largest channel showed significant activation during steps from a holding potential of -40 mV to command potentials more positive than 0 mV. Its modulation has not yet been examined. These results support the hypothesis that at least one type of postsynaptic, voltage-dependent calcium channel may be involved in the neuromodulation and induction of LTP in CA3 neurons. REGULATION OF CALCIUM CURRENTS IN A SMOOTH MUSCLE DERIVED CELL LINE. T. N. Marks*, G.R. Dubyak*, and S. W. Jones. (Spon: E.F. Nemeth). Dept. of Physiol. and Biophys. Case Western Reserve Univ., Cleveland, OH 44106.

We have studied the regulation of calcium currents in the A7r5 cell line by applying techniques of electrophysiology, fluorometry, and radioimmunoassay (RIA). When cells were voltage clamped in the whole-cell configuration with near normal intra- and extracellular solutions, a current resembling the 'L' type Ca^{2+} current was dominant. With Ba^{2+} (10 mM) as the charge carrier, peak inward currents of -300 pA were typically recorded at test potentials between 0 and +20 mV. Forskolin (30 μM) or the β-adrenergic agonist isoproterenol (1 μM) increased peak currents an average of -x2. Confluent monolayers of cells loaded with the Ca^{2+} sensitive fluorescent indicator, fura-2, were apparently electrically coupled and showed spontaneous transient Ca^{2+} elevations. Bath application of isoproterenol or forskolin increased the frequency and magnitude of the transient elevations. Dihydropyridine Ca^{2+} channel agonists increased spike activity in a like manner, whereas antagonists abolished transient rises. Both isoproterenol and forskolin acted to raise cAMP in these cells as determined by RIA, suggesting that regulation of the Ca^{2+} current is mediated by cAMP dependent protein kinase.

SYNAPTICALLY RELEASED DOPAMINE INHIBITS CALCIUM CHANNELS. P.J. Williams, B.A. MacVicar and Q.J. Pittman, Neuroscience Research Group, University of Calgary, Calgary, Alberta T2N 4N1 Canada.

Dopamine (DA) inhibits spontaneous electrical activity and hormone release from melanotrophs of the pituitary intermediate lobe (IL). To test whether synaptically released DA directly inhibits Ca^{++} channels intracellular recordings were obtained from cells of the intact IL using electrodes containing K^+ channel blockers (.5MCs Acetate, 30mM TEA) and a sodium channel blocker (1mM QX-222). Voltage clamp studies showed 3 types of Ca^{++} current corresponding to T, N, & L types which were abolished by Co^{++} and Cd^{++}. Stimulation of the pituitary stalk (in the presence of Bicuculline (.1mM) to block GABAergic synapses) reduced all three currents (n=18) although the relative percent inhibition varied from cell to cell. These effects were mimicked by Quinpyrrole (50 μM,n=5) a DA D-2 agonist and were abolished by Domperidone (1 μM, n=3) a D-2 antagonist. Experiments were carried out to assess the role of G-proteins in this inhibition. In cells impaled with electrodes containing GTPγS, a Gi/Go activator, Ca^{++} currents were reduced and neither stalk stimulation nor Quinpyrrole caused a further reduction in current amplitude. We conclude that, in the cells of the IL, synaptic activation of the D2 receptor results in inhibition of Ca^{++} currents by a mechanism involving G-proteins in an intermediate step.

CHRONIC DEPOLARIZATION REDUCES Ca^{2+} CURRENT DENSITY IN CULTURED RAT MYENTERIC NEURONS. J.L. Franklin* and A.L. Willard. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599

We are interested in the role of Ca^{2+} influx through voltage-gated channels during neuronal development and have been investigating the influence of electrical activity on long term changes in Ca^{2+} currents.

Myenteric neurons dissociated from the small intestines of newborn rats were grown in culture medium containing either 5 or 25 mM K^+ (Nishi & Willard, 1985). The 25 mM K^+ causes a sustained 20-25 mV depolarization of the neurons. Whole cell patch clamp experiments were performed using 20 mM Ba^{2+} as the charge carrier. Current density was normalized to membrane capacitance. Na^+ and K^+ currents were eliminated by replacing them with impermeant ions.

A Ba^{2+} current with both rapidly (τ = 25-60 msec) and very slowly (τ > 450 msec) inactivating components was evoked by steps to potentials positive to -20 mV from holding potential negative to -70 mV. For a step to 0 mV from a holding potential of -90 mV, the mean density of the transient peak current was 76 ± 29 pA/pF for 17 neurons grown in 5 mM K^+. The mean density at 300 msec after the onset of the step was 57 ± 27 pA/pF. In 22 chronically depolarized neurons, the peak current was reduced 59% to 31 ± 20 pA/pF and the sustained portion of the current was reduced 54% to 26 ± 18 pA/pF (p .001 in each case). Work is in progress to determine if the decrease is due to a decreased number of Ca^{2+} channels. Support: NIH NS24362.

DIFFERENTIAL ROLE OF Ca++ CHANNELS IN THE RELEASE OF ^{3}H-ACh AND ITS MODULATION. D.B.Gray and G. Pilar. Dept. Physiol. & Neurobiol., Univ. Connecticut, 75 N. Eagleville Rd., Storrs, CT 06268.

We have shown that ^{3}H-ACh release can be evoked by 55mM KCl from intact ciliary ganglion (CG) nerve terminals on both isolated iris and choroid muscle in chick eye. We have also shown that somatostatin (SS) (Epstein, M. & J. Dahl, Soc. Neurosci. Abstr., 13: 683, 1987) is endogenous and inhibits this release in choroid but not in iris (Gray, D. & G. Pilar, Soc. Neurosci. Abstr., 13: 790, 1987). We are now interested in the nature of the voltage-sensitive Ca++ channels responsible for ACh release. Two types of channels, N and L, have been proposed for this function and can be differentiated with dihydropyridine (DHP) agents specific for L channels in either agonist or antagonist fashion. Nifedipine, a DHP Ca++ antagonist, even at 10μM, has no effect on 55mM KCl-evoked ^{3}H-ACh release from CG terminals in either iris or choroid. Similarly, Bay K 8644 a DHP agonist, cannot evoke ^{3}H-ACh release in normal Tyrodes from terminals in either iris or choroid, but inhibits the K+-evoked ^{3}H-ACh release by over 50% ($p < 0.5$) in the first 6 min. Adding Bay K 8644 to the iris preparation did not significantly affect K+-evoked ^{3}H-ACh release. These studies suggest that L channels do not directly regulate ACh release from terminals of CG neurons but may activate release of a neuromodulatory peptide such as SS from CG terminals in the choroid. SENSORY SYSTEMS: AUDITORY SYSTEMS IV

263.1

THE EFFECTS OF NOISE ON TEMPORAL PARAMETERS IN AUDITORY NERVE FIBERS OF E. COQUI. R. Dunia and P.M. Narins. Dept. of Biology and Brain Research Institute, Univ. of Calif., Los Angeles, CA 90024.

E. coqui is an arboreal frog found in the rainforests of Puerto Rico. Behavioral studies indicate that E. coqui has adaptations to facilitate communication in its noisy environment (>95 dB SPL), and these adaptations suggest a high degree of temporal resolution.

We used two distinct paradigms to measure the minimum and maximum integration times (MinIT and MaxIT, respectively) of auditory nerve fibers. We measured MinIT by the synchrony of the fibers to SAM noise, and the effect of varying the noise spectrum level. Results from 113 fibers reveal that mid-frequency fibers (0.5<CF<1.8 kHz) have shorter MinIT than low-frequency fibers (CF<0.5 kHz) or high-frequency fibers (CF>1.8 kHz). MinIT decreased as noise level increased, consistent with decreased spectral resolution as noise levels increase.

We measured MaxIT by the shift in rate threshold with increased tone burst duration, and the effect of continuous noise (20-50 dB SPL) on MaxIT. Low-frequency fibers had longer MaxIT (270 ms) than high-frequency fibers (230 ms) or mid-frequency fibers (210 ms); continuous noise increased the MaxIT in 88% of the fibers tested. We conclude that much of the temporal integration in the anuran auditory system is already encoded in the fibers by the spike rate and does not require central processing. (Supported by NIH grant NS19725 to PMN).

263.2

RATE-INTENSITY RELATIONS IN SINGLE AUDITORY NERVE FIBERS OF THE MONGOLIAN GERBIL. K.K. Ohlemiller and S.M. Echteler. Auditory Physiology Laboratory and Department of Neurobiology and Physiology. Northwestern University, Evanston, IL 60208.

We have examined the relation of characteristic frequency (CF) and spontaneous firing rate (SR) to rate-intensity parameters of single auditory nerve fibers in the gerbil in order to permit comparison with other species.

Most of our data comprise steady-state firing rates (>20 msec after stimulus onset) in response to CF tonebursts. Sound levels ranging from -20 to 100 dB SPL are presented in pseudorandom order in 2 dB steps. The functions obtained are fit using a least-squares method to a variation of the model of Winslow and Sachs (J. Neurophysiol. 57:1002-21, 1987). Maximum firing rate (R_{max}) and slope at $R_{max}/2$ are derived from fitted curves.

Out of more than 100 rate-intensity curves obtained from fibers with CFs of .5 to 20 kHz, only 5 are nonmonotonic. The most prominent correlate of slope and R_{max} is CF; slope and R_{max} are greater for high CFs than for low. The distributions of these parameters show an abrupt rise near 4 kHz. Changing the stimulus frequency from CF to 1 kHz (a frequency where phase locking is pronounced) does not systematically alter slope (Schmiedt and Zwislocki, J. Neurophysiol. 43:1390-1405, 1980) or R_{max}. This suggests that the apparent CF-dependence is not related to neural phase locking. Slope is correlated secondarily with SR; low-SR fibers (SR<2 sp/sec) with thresholds above 20 dB (15 of 22 low-SR fibers) tend toward lower slopes than other fibers of similar CF (Ohlemiller and Echteler, Neurosci. Abstr., 1987). R_{max} values often could not be assigned to these fibers because most of them (11 of 15) are only partially saturated at 100 dB. We will also discuss the influence of data-collection paradigm on observed slope, R_{max}, and monotonicity.

SINGLE-UNIT RESPONSES IN COCHLEAR NUCLEUS TO ELECTRICAL STIMULATION OF THE COCHLEA WITH BIPHASIC PULSES OF VARIABLE SHAPE. J.A. Wiler*, B.M. Clopton*, and M.A. Mikhail* (SPON: B. Pfingst). Kresge Hearing Research Institute, U. of Mich., Ann Arbor, MI 48109.

Electrical stimulation of cochlear axons and other sensory afferents with multiple electrodes is often requisite for prosthetic applications. Bipolar, pulsatile stimulation multiplexed across electrodes reduces crosstalk and provides many alternatives for encoding. Optimality for such pulses has not been established due to a lack of knowledge about their stimulation efficiency and its limitations on encoding strategies. We presented an extensive range of charge-balanced, square-wave pulse shapes to the guinea pig cochlea as constant-current waveforms. Their duration per phase was 20 to 900 usec and included initially positive and initially negative phases, some sets of stimulus pulses containing more than 180 pulse shapes. Spike counts for many single units in the ventral cochlear nucleus were increased by 100 times or more for specific pulse shapes as compared to less effective ones, and latencies, having minimal values of about 1.2 msec, also differed greatly. Usually a brief initial phase followed by a longer second phase produced the greatest spike counts, and in many instances more than one duration of the second phase was effective. The more effective polarity of the first phase was specific to a unit but about equally distributed between positive and negative for closely spaced bipolar electrodes. Minimal latencies were not necessarily associated with the pulse shapes producing maximal spike counts. Implications for encoding strategies follow from these results and reasonable assumptions about how information is represented in neuronal populations. (Supported by NIH Grant NS21440)

INTRACELLULAR RECORDINGS FROM DORSAL COCHLEAR NUCLEUS NEURONS IN VITRO. P.B. Manis* (SPON: P.F. Worley) Depts. of Oto.-HNS, Neuroscience, and Center for Hearing Sciences, Johns Hopkins Univ., Baltimore, MD 21205.

Neurons of the dorsal cochlear nucleus (DCN) respond to acoustic stimuli with discharge patterns significantly different than those of the auditory nerve fibers which innervate the nucleus. In order to clarify the physiological processes underlying these transformations, intracellular recordings were made in a brain slice preparation of the guinea pig DCN. Recordings were made from 36 cells; of these 16 meet the criteria (Vm<-50 mV, AP>45 mV) for acceptable recordings. These cells had a mean input resistance of 29.3 MΩ (N=12), and mean membrane time constant of 5.1 msec. Spike trains were regular (15/16 cells) one cell exhibited complex spikes. In 4 cells the membrane potential response to hyperpolarizing current pulses exhibited a sag suggestive of anomalous rectification. Seven of 8 cells injected with Lucifer Yellow were identified as pyramidal cells; the other cell was similar to the vertical cell type.

Paired shocks to the parallel fibers produce a burst of spikes from the cell in response to the second stimulus. Although the spike burst can be blocked by hyperpolarization of the cell, a small active potential remains in response to the second stimulus. This suggests the presence of a membrane conductance remote to the recording site which can facilitate the generation of spike bursts. (Supported by SNF BNS0867273 and NIH NS25065.)

263.5

RESPONSE PROPERTIES OF COCHLEAR NUCLEUS NEURONS IN YOUNG AND MIDDLE-AGED C57BL/6J MICE WITH PRESBYCUSIS. J.F. Willott, K. Parham, and K.P. Hunter*. Dept. Psychology, Northern Illinois Univ., DeKalb, IL 60115.

Extracellular recordings were obtained from the cochlear nucleus (CN) of anesthetized aging C57 mice using tone- and noise-burst stimuli. All typical CN response types (re: post-stimulus time histograms) were observed in middle-aged C57 mice (up to 15-mo.) with sensorineural impairment; however, there was a decline in the percentage of dorsal CN (DCN) units demonstrating inhibition and in ventral CN (VCN) units showing "chopper" or "on" responses.

Age-related decreases were observed in both the DCN and VCN for units' best frequencies (re: threshold or maximum discharge rates), upper frequency range, overall frequency range of response areas, sharpness of tuning, and threshold sensitivity for tones and noise. Changes in the latter three parameters were more pronounced in the VCN.

Synaptic and Membrane Properties Shape Response Patterns of Neurons in the Gerbil Cochlear Nucleus. J. Feng*, E.-M. Ostapoff, S. Kuwada, and D.K. Morest. Dept. of Anatomy and Ctr. for Neurological Sciences, University of Connecticut Health Ctr., Farmington, CT 06032.

Neurons in the cochlear nucleus differ in their discharge pattern to tonal stimuli. Are these patterns shaped by different membrane properties or by synaptic circuitry? We made intracellular recordings from cochlear nucleus neurons and compared the responses to tones and to depolarizing current. Neurons that fired regularly to tones were of two types: sustained and transient choppers. Both types showed a sustained regular discharge to current, indicating that the regularity of firing for these neurons is an intrinsic property. Some transient choppers showed tone-evoked hyperpolarizations, which may have caused the transient nature of the chopping pattern. Neurons that fired irregularly to tones were of several types. Primary-like neurons fired irregularly to current, again suggesting intrinsic factors, albeit different from those seen in choppers. In contrast, other neurons that responded with an irregular discharge to tones fired regularly to current. A circuit with feedback inhibition is consistent with such a response profile. In sum, a neuron's response pattern may be determined by its membrane properties and its synaptic inputs.

263.7

SEGREGATION OF SPONTANEOUS ACTIVITY IN AUDITORY NERVE INPUT TO THE COCHLEAR NUCLEUS: ENDBULBS OF HELD AND THEIR CONVERGENCE ONTO THE SAME SPHERICAL BUSHY CELL. S.Sento and D.K.Ryugo[1]. Dept. Public Health and Environ. Sci., Tokyo Med. and Dent. Univ., Tokyo, Japan and [1]Dept. Otolaryngol. and Neurosci., Johns Hopkins Univ., Sch. of Med., Baltimore, MD 21205.

Type I spiral ganglion neurons can be divided into two general groups based on their spontaneous activity (SR) and morphological properties (Liberman, Science, 216:1239, '82; Fekete et al., J.Comp.Neurolo.,229:432, '84). All axons of such neurons give rise to a terminal endbulb of Held, and when the form factor(FF), silhouette area divided by silhouette perimeter, is applied to an endbulb, a value is produced that reliably indicates the parent fiber's SR (Benson et al., Neurosci.Abst., 12:1266, '86). In this study, we applied the FF to endbulbs converging onto the same spherical bushy cell in order to investigate how segregation of SR might be expressed in the cochlear nucleus.

Eighteen pairs of endbulbs of Held from 4 cats were labeled following extracellular injections of horseradish peroxidase into the auditory nerve (AN). On the basis of intracellular labeling data, FFs greater or less than 0.52 indicated high (>18 s/s) or low (≤18 s/s) SR, respectively. Fourteen pairs had FFs typical of high SR fibers and 3 pairs had FFs typical of low SR fibers; only 1 pair straddled the line (0.50 and 0.53). The FF ratio of all pairs was close to 1 despite an individual FF range of 0.27-0.83. These data indicate that AN input remains segregated at the level of spherical bushy cells with respect to spontaneous activity.

263.8

ROC ANALYSIS OF AVERAGE FIRING RATES OF COCHLEAR NUCLEUS NEURONS IN THE GERBIL. W.P. Shofner and R.H. Dye*. Parmly Hearing Institute, Loyola Univ., Chicago, IL 60626.

The cochlear nucleus (CN) contains several subsystems where neural information in the auditory nerve can be degraded, preserved or enhanced. We present preliminary results from experiments designed to quantify the information in the average firing rates of CN units. Single unit responses to BF tones were recorded from the CN of anesthetized gerbils with 3M NaCl micropipettes. Based on interval histograms, units were classified as regular or irregular. Regular units were generally characterized as choppers; irregular units included primary-like, on-L and transient choppers. Receiver operating characteristic (ROC) curves were generated from empirical spike count distributions, and the area under the ROC curve (P(A)) was computed. For a given difference in the means of two spike count distributions, regular units typically give larger P(A) values than do some irregular units. Among irregular units, primary-like with a notch and on-L units give large P(A) values than do primary-like units. The results suggest that rate information may be enhanced in certain subsystems of the CN.

263.9

"FORWARD MASKING" OF SINGLE NEURONS IN THE COCHLEAR NUCLEUS: EFFECT OF MASKER FREQUENCY F.A. Boettcher*, R.J. Salvi, and S.S. Saunders*. Hearing Research Lab, SUNY-Buffalo, Buffalo, NY, 14214.

Forward masking is a psychophysical phenomenon in which the detectability of a brief probe signal is reduced by a stimulus which precedes the probe in time. The neural analogue of forward masking is the reduction in neural firing rate due to preceding stimulation. The purpose of this project was to determine how different types of neurons in the cochlear nucleus respond to a brief probe tone at the unit's characteristic frequency (CF) when the probe is preceded by a masking tone having a frequency above, below, or at the unit's CF. In general, if the masker excites the unit, neural firing to the probe is reduced compared to the unmasked condition. The degree of reduction varies with the firing rate of the unit to the masker. If the masker inhibits the unit, either enhanced or suppressed response to the probe is observed. The effect varies with the duration of the inhibition and the temporal separation of masker and probe. If the masker does not excite or inhibit the unit, no effect on the probe is observed.

263.10

RESPONSE LATENCIES OF FM UNITS IN THE INFERIOR COLLICULUS OF THE RAT. X.Y. Chen*, P.W.F. Poon*, Y.M. Cheung, and J.C. Hwang. Dept. Physiology, Univ. Hong Kong, Sassoon Road, Hong Kong

Knowledge of the response latency of the various types of frequency modulated (FM) cells is important for the understanding of feature extraction of complex sounds. Response latency to FM tones in 164 inferior collicular (IC) units of anaesthetised rats was estimated using linear regression methods based on PSTH to tones linearly modulated at different rates. Units were classified as either bi-directional (49%) or uni-directional (51%) based on their directional selectivity to tone sweeps. Results showed that uni-directional units respond to FM sounds with delays significantly longer than those of the bi-directional units (difference 3.1 ms, $p<0.01$).

We have provided evidence to support that in the IC of the rat, uni-directional cells, when compared with bi-directional cells, are activated by the FM tones through a longer synaptic linkage or via a slowly conducting pathway.

INTERACTIONS OF AUDITORY NERVE FIBERS AND VENTRAL COCHLEAR NUCLEUS CELLS STUDIED WITH CROSS-CORRELATION. E.D. Young and M.B. Sachs. Center for Hearing Sciences, The Johns Hopkins University, Baltimore, MD 21209.

We have computed cross-correlograms (CCGs) between the spike trains of simultaneously-isolated auditory nerve (AN) fibers and cells in ventral cochlear nucleus (VCN). CCGs were computed from spontaneous activity or from steady activity driven by long-duration (50 s.) tones or noise. An excitatory peak (EP), consistent with a monosynaptic excitatory connection, is observed in the CCGs of 32/179 AN-VCN pairs examined with spontaneous activity or tone-driven activity. EPs are observed only when the best frequencies of the two units differ by less than 15%; BFs differ by less than 5% for 65% of correlated pairs. The EPs are small, indicating that 10% or fewer of the spikes in the VCN unit are attributable to spikes in the AN fiber. EPs are largest for spontaneous activity and for sound levels near threshold and decline monotonically as sound level increases. Surprisingly, results for primarylike units are essentially the same as for choppers. Large EPs appropriate for AN end-bulb terminals on bushy cells have not been observed.

EPs are observed in 36/125 pairs studied with noise stimuli. In 7 cases, EPs are seen with noise but not with tones or spontaneous activity, whereas EPs are always seen with noise stimuli if an EP is seen with tones or spontaneous activity (8 cases). The implications of these results for input/output processing in VCN will be discussed. (Supported by NIH grant NS12524).

EFFECTS OF OFF-BF TONES ON RATE AND REGULARITY OF COCHLEAR NUCLEUS CHOPPER UNITS. C.C. Blackburn* and M.B. Sachs, Dept. of Biomedical Engineering and Center for Hearing Sciences, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

We are studying the effects of off-best frequency (off-BF) input on the responses of chopper units in the anteroventral cochlear nucleus (AVCN) of nembutal-anesthetized cats. Chopper units, recorded from stellate cells in the AVCN, fire in a regular manner in response to a BF tone. Responses of single units to tones and two-tone combinations were recorded, and the mean inter-spike interval and its regularity were computed as a function of time through the response (Young, E.D. et al. (1988) J. Neurophys. in press). The effects of off-BF input on the response patterns of choppers include rate suppression but reveal other changes which are more complex. Two generalizations may be made. First, off-BF inhibition (measured as rate suppression) tends to be weak in regular choppers (ChS) and stronger in irregular choppers (ChT). Second, the time course of the changes in rate and regularity that these units undergo can be dramatically affected by off-BF input. Changes in the temporal adaptation patterns of chopper unit responses, which have been recorded in both ChS and ChT units, cannot be accounted for on the basis of changes in sustained firing rate, suggesting that the mechanism is not simply two-tone suppression at the level of the auditory nerve fiber input. 263.13

ONTOGENY OF GABA ACTIONS WITHIN THE CAUDAL COCHLEAR NUCLEI OF KITTENS. E.J. Walsh, J. Fitzakerley and J. McGee*. (SPON: H. Konrad). Depts. of Surgery and Pharmacol., Southern Illinois Univ. Sch. of Med., Springfield, IL 62794-9230.

Responses to acoustic and microionophoretic GABA stimulation of neurons within the caudal cochlear nucleus were studied during postnatal development using extracellular recording techniques. GABA application reduced acoustically-evoked as well as spontaneous discharge rates in a dose-dependent manner at all ages studied, generally abolishing discharge activity at sufficiently high doses (currents). Dose-response curves generated during acoustic stimulation (roughly 20 dB sensation level, SL) were sigmoidal at all ages studied. Although discharge rates produced using equal sensation level stimuli increased with age, effective dose ranges (computed as the difference between currents required to produce 90% and 10% of the acoustically-evoked discharge rate) were smaller for neurons recorded from kittens younger than 10 days than those computed for adults. The application of GABA at doses producing a 50% reduction in the discharge rate evoked by acoustic stimulation at 20 dB SL, produced constant discharge rate decrements across much of the acoustic intensity range in most neurons recorded from animals older than 11 postnatal days. In younger kittens, GABA-induced effects on discharge rate were more pronounced, by as much as 5 times, at high sensation levels compared to low SLs (i.e., rate/intensity curves obtained in the presence of GABA were shallower than control curves and thresholds were higher during GABA application in young animals compared to adults). The influence of GABA on temporal response profiles and the time course over which GABA exerts its effects will also be considered for different cell types. (Supported by NIH grant NS21171).

263.14

SENSITIVITIES OF CELLS IN THE ANTEROVENTRAL COCHLEAR NUCLEUS OF CAT TO DISCHARGE PATTERNS ACROSS THE POPULATION OF AUDITORY NERVE FIBERS. L. H. Carney, Depts. of Neurophysiology and Electrical & Computer Engineering, University of Wisconsin-Madison, Madison, WI 53706.

Different types of cells in the anteroventral cochlear nucleus (AVCN) receive characteristically different forms of convergent input from the auditory nerve. The different forms of convergence should produce varying degrees of sensitivity to the temporal discharge patterns across the population of auditory nerve fibers in response to complex stimuli. This hypothesis can be tested by inserting a smooth transition into the phase spectrum of a complex stimulus, while leaving the magnitude spectrum unchanged, so that systematic time shifts are introduced between the responses of auditory nerve fibers with different characteristic frequencies (CFs). Responses to such stimuli were recorded from primary-like (PL) and primary-like-with-notch (PLn) cells, which probably receive from one or two to a few primary inputs with large somatic terminals, as well as choppers, which probably receive a large number of converging primary inputs ending in small terminals on both dendrites and soma. Responses of PLn cells are affected by the introduction of a phase transition; they show different sensitivities, as measured by threshold and rate, to stimuli with different phase transitions. This change in sensitivity suggests that PLn cells receive convergent input from fibers with different CFs and that the temporal pattern of discharges across these inputs is important in determining the responses of these cells. The change in sensitivity of PLn cells as a function of these systematic manipulations of the stimulus spectrum is consistent with a simple coincidence model, which is also compatible with several aspects of their responses to other stimuli, such as tones, clicks, and noise. Some PL cells and choppers also have responses which are affected by manipulations of the phase spectrum, suggesting some degree of sensitivity to the temporal pattern of their inputs.

263.15

ENHANCEMENT OF PHASE-LOCKING TO LOW FREQUENCY TONES IN SOME CELLS OF THE VENTRAL COCHLEAR NUCLEUS OF THE CAT. T.C.T. Yin, L.H. Carney, P.X. Joris*, and P.H. Smith. Dept. of Neurophysiology, Univ. of Wisconsin Medical School, Madison, WI 53706

It is generally believed that the synchronization of auditory nerve fibers to low frequency (<3-4 kHz) tones is relayed by the bushy cells in the ventral cochlear nucleus (VCN) with little or no change, i.e., that the synchronization coefficient of phase-locked responses in the VCN can be as high as in the nerve, but no higher. We report here evidence that a significant proportion of low-frequency (<1.2 kHz) VCN cells can have maximal sync coefficients that are between 0.9 and 1.0, greater than that ever seen in 8th nerve fibers of comparable characteristic frequencies (CFs). Recordings were made in the VCN or from axons of VCN cells in the trapezoid body of barbiturate anesthetized cats. We examined rate-level responses using short (25 msec) tone bursts at CF (as determined by a threshold tuning curve) over different SPLs. Sync coefficients were computed from period histograms contructed over the last 15 msec of the duration of the stimulus in order to avoid the large onset response that sometimes occurs out of phase with the sustained response. Such increases in the sync coefficient can be modeled by requiring coincidence and convergence of 8th nerve inputs on some VCN cells, for example, the small spherical and globular bushy cells.

263.16

RECEPTIVE FIELD PROPERTIES OF INTERNEURONS IN THE DORSAL COCHLEAR NUCLEUS. G.A. Spirou* and E.D. Young (SPON: David K. Ryugo). Dept. of Biomedical Engineering and Center for Hearing Sciences, Johns Hopkins University Baltimore, MD 21205.

We have measured the receptive fields of type II interneurons in the dorsal cochlear nucleus (DCN) of decerebrate cats. These units are responsible for a significant part of the inhibition of DCN principal cells. The interneurons have no spontaneous rate, so the effects of inhibitory sounds must be measured against a simultaneous excitatory sound. This two-tone paradigm reveals asymmetric sideband inhibition which is deepest adjacent to the excitatory tuning curve. Sideband inhibition is active in some units at levels as low as the excitatory threshold. This is consistent with the lack of response of these units to broadband stimuli even at very low levels. A reduction in rate is evident at levels as low as 3 dB SPL, indicating that inhibitory mechanisms, rather than 2-tone suppression, are the important determinants of this response at low sound levels. (Supported by NINDCS NS07283.)

263.17

EFFECTS OF INHIBITORY AMINO ACID NEUROTRANSMITTERS ON ONE POPULATION OF VENTRAL COCHLEAR NUCLEUS NEURONS.

D.M. Caspary, S.D. Yuscius*, B.A. Lawhorn*, and P.G. Finlayson.
Depts. of Pharmacology and Surgery, Southern Illinois University School of Medicine, Springfield, Il. 62794-9230.

Neurochemical, neuropharmacological, and morphological studies suggest roles for GABA and glycine in the processing of acoustic information in the ventral cochlear nucleus (VCN). VCN neurons have primarily been described as displaying excitation in response to tonal acoustic stimuli. However, inhibitory sidebands (Martin and Dixon, '83), near threshold suppression of spontaneous activity, and electrically evoked ipsp's have been described (Wu and Oertel, '86). This study examined VCN neurons displaying "phase-locked" temporal responses at CF and presumed to be bushy cells. Forty-four neurons displaying "phase-locked" temporal response patterns were localized to the anterior or interstitial VCN. When responses to CF tones were compared with responses to broadband noise, 14 neurons displayed rate-intensity functions with similar slopes while 30 neurons showed noise/tone slope differences. Twenty-six neurons displaying "phase-locked" responses were examined during iontophoretic application of GABA and glycine and the receptor antagonists bicuculline and strychnine. Both antagonists could selectively alter rate-intensity functions to broadband noise. Application of bicuculline and strychnine resulted in both near-CF and off-CF changes in response area. Efficacy of GABA and glycine were compared. These findings suggest that GABA and glycine receptors are present on VCN bushy cells and may function to shape selected portions of response areas. (Supported by NINCDS grant NS15640)

263.18

RESPONSE PROPERTIES OF SINGLE AUDITORY NEURONS IN THE DORSAL MEDULLARY NUCLEUS OF THE FROG.

J.C. Hall* and A.S. Feng. Dept. Physiol. & Biophys. Univ. of Illinois, Urbana, IL 61801.

The frog dorsal medullary nucleus (DMN), a homolog of the mammalian cochlear nucleus, is an obligatory synapse for auditory fibers of peripheral origin and the first site for the central processing of acoustic signals. We have studied the role of the DMN in the processing of complex sounds, particularly those serving a communicative function.

In this study, we characterized the discharge pattern of single neurons in the frog's DMN to "simple" stimuli consisting of tone bursts of different frequency and intensity. Neurons were further characterized on the basis of their spontaneous firing rate, best excitatory frequency, sharpness of tuning (Q_{10} dB), and firing threshold. Previously, we recognized two response types in the DMN, phasic and tonic. We now report a third type, pauser, so named because its discharge pattern resembled that of the pauser neurons found in the mammalian cochlear nucleus. We also identified four distinct classes of tonic units based upon differences in the shape of their post stimulus time and interspike interval histograms, average discharge rate to tone bursts, and tuning. The response properties of DMN neurons resembled those of VIIIth nerve fibers in many respects; but, several differences, particularly with respect to the diversity of response types, were noted. These differences provide an additional basis for our previous observation that DMN neurons are more selective for specific features of complex sounds than primary auditory nerve fibers.

RESPONSE CHARACTERISTICS OF FROG SUPERIOR OLIVARY NEURONS TO AMPLITUDE-MODULATED (AM) ACOUSTIC STIMULI.

S. Chang*, C. J. Condon*, and A. S. Feng. (SPON: T. G. Weyand). Department of Physiology and Biophysics and The Neural and Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

We investigated the responses of single units in the superior olivary nucleus (SON) of the leopard frog to AM signals and determined their selectivity to various temporal parameters (AM rate, rise-fall time, duration). Pulsatile and sinusoidal amplitude modulated stimuli were presented at rates of 5-300 Hz in order to describe the modulation transfer function (MTF) of individual neurons. The MTFs were measured with respect to mean spike rate and the synchronization coefficient (SC) to the phase of the modulation cycle of the AM stimulus. The spike rate and synchronization MTFs were used to define temporal filtering characteristics; the later further indicated the ability of a unit to act as an envelope detector.

On the basis of synchronization MTFs, SON neurons displayed two filtering characteristics: low-pass and all-pass. All-pass units gave constant synchronization with wide ranges of SC, while low-pass units maintained high SCs at low modulation rates (<60 Hz) that decreased with higher rates of modulation. However, with respect to mean spike rate, the MTFs of SON neurons exhibited a greater variation in temporal selectivity. In addition to low- and all-pass transfer functions, high-pass, band-pass, and band-suppression response types were also observed. These functions were often related to response selectivity to other temporal parameters. These results suggest that SON neurons play an important role in auditory processing; they perform extensive computations on the rate of AM as well as other temporal parameters.

263.20

PROPERTIES OF THE AUDITORY PERIOLIVARY NUCLEI.

M.N. Semple*, L.M. Kitzes*, G.W. Huntley and W.B. Warr (SPON: R. Blanks). Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717, & Boys Town Institute for Communicative Disorders in Children, Omaha, NE 68131.

In the mongolian gerbil, *Meriones unguiculatus*, as in most species, the periolivary nuclei (PON) of the superior oilvary complex (SOC) are somewhat poorly defined histologically. However, the lateral (LNTB) and ventral (VNTB) nuclei of the trapezoid body, the dorsal periolivary nucleus (DMPO) and the superior parolivary nucleus (SPN) can be distinguished in nissl or protargol stained material. The gerbil appears intermediate between other rodents and the cat in having both a rodent-like SPN and a cat-like DMPO. Anterograde and retrograde tracing showed that the major afferent and efferent connections of gerbil SOC are comparable with those seen in cat.

Single-unit recording in the primary auditory nuclei of SOC revealed response properties consistent with previous studies in cat: units in the medial nucleus of the trapezoid body (MNTB) typically discharged in a primary-like fashion and often displayed a prominent pre-potential; chopper patterns were commonly observed in the lateral superior olive; units in all primary SOC nuclei had short initial discharge latencies. In PON, however, response properties were frequently very different. Some units, whose tuning curves were often broad, responded at long latencies — usually in a build-up fashion. Spontaneous activity of some units was inhibited during the stimulus and often the silent period was followed by rebound excitation after stimulus offset. A third class of response was characterized by a strong preference for broadband noise; discharging transiently to tonal stimuli, but in a secure, sustained manner to noise. In LNTB, units responding at long latency were found intermingled with units sharply-tuned to ipsilateral tones and responding with short-latency, primary-like patterns. Intra-axonal injection of HRP revealed the existence of some quite distinctive axon terminals in PON: in LNTB, for example, a calycine terminal clasping the soma, and a large *en passant* contact.

RESPONSE SELECTIVITY OF NEURONS IN THE FROG TORUS SEMICIRCULARIS TO TEMPORAL COMPONENTS OF AMPLITUDE-MODULATED ACOUSTIC STIMULI.

D.M. Gooler, J.C. Hall* and A.S. Feng. Dept. of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

The responses of single units in the torus semicircularis (TS) of the leopard frog were examined for selectivity to the temporal parameters of acoustic stimuli associated with amplitude-modulated (AM) sounds. Sinusoidal, pulsatile, and square-wave AM stimuli were presented and the modulation transfer function (MTF) of individual neurons were calculated for AM rates of 5-400 Hz (or pulses per second). The MTFs were measured with respect to mean spike rate and the synchronization coefficient (SC) to the phase of the modulation cycle of the AM stimulus. The response functions to other temporal parameters (duration, rate of rise, duty cycle) were also derived in order to determine the response selectivity to these attributes.

The spike-rate response of single toral neurons to AM rate, signal duration and rate of amplitude change exhibited various filter functions: low, high, band or all pass. The response selectivity of neurons to these varying parameters was often tightly related to one another. For instance, the selectivity to the AM rate of sinusoidally AM signals could in some cases be attributed to a selectivity to the modulation rate itself, or the rate of rise, or duration. 264.2

ONTOGENY OF EXCITATORY AND INHIBITORY AMINO ACID LEVELS IN THE INFERIOR COLLICULUS OF RATS.

J. McGee*. (SPON: E.J. Walsh) Dept. of Pharmacol., Southern Illinois Univ. Sch. of Med., Springfield, IL 62794-9230.

Levels of excitatory (aspartic and glutamic acids and glutamine) and inhibitory (GABA, glycine and taurine) amino acids in the inferior colliculi (IC) of developing rats were determined using high performance liquid chromatography with electrochemical detection. Amino acid levels ranged between 14% and 32% of their adult values at birth, except for taurine which exceeded adult levels by 223% at birth. Generally, amino acid levels increased monotonically between birth and the end of the first postnatal month, exhibiting a 3- to 7-fold increase when levels were determined per colliculus. Aspartic acid levels increased beyond postnatal day 30, gradually acquiring adultlike values. Taurine levels, on the other hand, increased during the first 11 postnatal days and subsequently declined along an exponential time course achieving adultlike values by the end of the second postnatal month. Developmental trends were more complex when amino acid levels were considered in terms of tissue weight. Taurine levels remained constant during the first 11 postnatal days and declined to achieve adult values by the 35th day. Other amino acid levels increased sigmoidally to roughly the 18th postnatal day and declined thereafter to achieve adultlike values by the end of the first month. Aspartic acid levels displayed a second growth phase ending near the 60th postnatal day. Thus, the magnitude and rate of change in content of amino acids in the IC varied greatly over the course of postnatal development. These results will be considered in light of morphological and physiological aspects of maturation of the IC. (This investigation was supported in part by NIH grants NS15640, NS21171 and NSF grant BNS8646563).

COCHLEAR WHOLE-NERVE RESPONSES ALTERED BY ELECTRICAL STIMULATION OF THE INFERIOR COLLICULUS. David F. Dolan* and Alfred L. Nuttall. Kresge Hearing Research Institute, Univ. of Mich. Med. Sch., Ann Arbor, MI 48109.

The traditional method to achieve electrical activation of the efferent system to the cochlea is by stimulation of the crossed olivocochlear bundle (COCB) at the floor of the 4th ventrical. This is thought to excite fibers derived from cells which are located in and/or around the medial superior olivary complix (SOC). These cells are referred to as the "medial" portion of the efferent system and then send their axons primarily to the outer hair cells in the cochlea. There is currently little information about the descending neural input to these cells or to the cells that comprise the "lateral" portion of the efferent system which ends primarily on afferent dendrites from the inner hair cells.

We will show that electrical stimulation of the inferior colliculus produces similar, but not equivalent, effects on the whole-nerve response (CAP) as electrical stimulation of the COCB. CAP magnitude is reduced (equivalent to 10-20db attenuation) and latency increased most for low-level acoustic signals. The effects of electrical stimulation are abolished by the administration of strychnine.

The differences in the effects on the CAP between the two means of activation of the efferent system will be discussed in terms of the lateral and medial portions of the efferent system.

264.4

DYNAMIC PROPERTIES OF THE MAPS IN AUDITORY FOREBRAIN CENTERS OF A SONGBIRD. U. Haeusler*and H.J. Leppelsack. Inst.Zool.TU Muenchen 8046 Garching FRG

We introduce a new method of measuring functional maps in brain areas of awake animals. This method is based on multiunit recordings which are collected automatically under computer control. The response measure is the spike count as compared to spontaneous activity. Spatial resolution is determined by the chosen distance between recording points and the catchment area of the glass coated platinum electrodes. It is about 100 µm. Maps are plotted as iso-response lines or as dot density, and illustrate the distribution of response strength within a given time interval.Thus, the temporal development of a response cluster within a brain center can be investigated. Different stimuli can be used at the same recording point and maps of different parameter distributions may be compared within one individual brain.
Investigations of the tonotopicity of auditory centers in the caudal telencephalon of the starling confirm former results which showed that the tonotopic gradient is arranged dorsoventrally. The new results, however show an unexpected variety of functional subunits which change their shape during the course of constant stimulis. In addition, the centers of response can be observe to move along the tonotopic gradient. These changes can take place within only a few milliseconds.

264.5

DYNAMIC RANGE OF TONE LEVEL CODE IN RAT AUDITORY CORTEX D.P.Phillips and J.B.Kelly. Dept. Psychology, Carleton University, Ottawa, Ontario, Canada

The behavioral intensity dynamic range in hearing is about 100 dB wide. We investigated the fashion(s) in which the cortical neural representation of tone level exhibits a comparable dynamic range. We did so by obtaining spike rate-vs-tone level functions from single cortical neurons in anesthetized albino rats. Stimuli were 110-ms characteristic frequency tone pulses presented to the contralateral ear.

Most neurons had monotonic rate-level functions that tended towards firing rate saturation at high tone levels. The dynamic ranges of these functions were commonly 10 to 35 dB in breadth, though the distribution extended to at least 65 dB. Nonmonotonic rate responses were scarce, and were less well-developed than those seen in cats and primates. Neurons tuned to a single tone frequency in single cerebral hemispheres had thresholds that varied over a 50 dB range. The collective amplitude dynamic range expressed even by small such populations spanned 80 dB or more. These observations provide an estimate of the minimum population dynamic range of the rat's acoustic cortex. They suggest that this dynamic range may be comparable to the behavioral one, and that it resides in the firing rates of the relevant neurons.

CHOLINERGIC AGENTS MODIFY FREQUENCY RESPONSE FUNCTIONS OF SINGLE NEURONS IN AUDITORY CORTEX. T.M. McKenna, J.H. Ashe and N. M. Weinberger. Ctr. Neurobiology of Learning and Memory, Univ. California, Irvine, CA. 92717

Previously we have shown that cholinergic agonists modify spontaneous and evoked discharges to single tones in auditory cortex of unanesthetized cat (McKenna et al, Synapse, 1988, 2:54-68). Recent observations indicate that the cholinergic agonist methacholine (MCh,10-20 mM) and anticholinesterases eserine (0.2-0.4M) and soman (20mM) modify the frequency response function of these neurons. These agents, applied via multibarrel micropipettes (pressure ejection or iontophoresis) produce frequency specific modification in discharge rate of neurons tested with isointensity sequences of pure tone frequencies (1.0-30.0 kHz, 40-80db). These frequency specific changes were often accompanied by a shift in the frequency producing the maximum tone response and/or bandwidth changes. One aspect of shifts was decrease of response at the prior best frequency with increase at an adjacent frequency. As classical conditioning rapidly induces frequency-specific alterations of frequency response functions in auditory cortex (Diamond and Weinberger, Brain Res., 1986, 372:357-360), the current observations suggest that intrinsic cholinergic mechanisms may play a role in this phenomenon. Supported by DAMD 17-85-C-5072 to NMW.

ACETYLCHOLINE PRODUCES FREQUENCY-SPECIFIC RECEPTIVE FIELD ALTERATIONS IN CAT AUDITORY CORTEX THAT ARE BLOCKED BY ATROPINE. R. Metherate, K.C. Wong* and N.M. Weinberger; Center for the Neurobiology of Learning and Memory; University of California, Irvine

Cholinergic agents may affect auditory perception and sensory processing by modifying neuronal receptive fields. Previous work showed that single neuron responses to pure tones were modified by acetylcholine (ACh) administered iontophoretically in cat auditory cortex, and that this treatment could change a cell's frequency receptive field (FRF). The present study shows that the most common effect is a decrease in responsiveness that is restricted to the paired frequency.

Multibarrel micropipettes inserted into the auditory cortex of barbiturate anesthetized cats contained ACh chloride (1M), sodium glutamate (.5M), atropine sulphate (25mM) and NaCl (1M). A neuron's FRF was determined upon initial isolation, then ACh was paired with a repeated, non-best frequency tone. Following this, 45/90 neurons displayed altered receptive fields, and in 24 cases the FRF changes were highly specific to the paired frequency. Atropine selectively blocked the effects of ACh on single tone responses and frequency-specific FRF changes, suggesting that the effects of ACh are mediated via muscarinic ACh receptors.

INHIBITORY EFFECTS OF ACETYLCHOLINE ON TONE ELICITED SINGLE UNIT RESPONSES IN RAT AUDITORY CORTEX. H. K. Rucker. Department of Physiology and the Neuroscience Group, Meharry Medical College, Nashville, TN 37208.

The effect of iontophoretically applied acetylcholine (ACh) and atropine on single unit responses to near best-frequency tone bursts was studied in the auditory cortex of urethane anesthetized rats. These studies were undertaken to ascertain the cholinergic effect on response gain in the rat auditory cortex. Neuronal activity was recorded with glass multi-pipettes and 500ms peri-stimulus time histograms (PSTH) constructed for isolated units in response to 50 tone bursts (100ms, threshold +10 dB). In a sample of 48 units, fifteen percent (n=7) exhibited response attenuation (compared to drug-free PSTH) by 20-38% during ACh application. Paradoxically, these units concurrently increased control period discharge rate and glutamate excitatory responses were also facilitated by ACh. These latter ACh effects were consistently antagonized by atropine whereas the response attenuation was generally enhanced. A presynaptic role relevant to ACh mediated inhibition is suggested. TOPOGRAPHIC ORGANIZATION OF BINAURAL NEURONS IN THE PRIMARY AUDITORY CORTEX OF THE FERRET. P.W. Judge, and J.B. Kelly. (SPON: David Gardner). Laboratory for Sensory Neuroscience, Dept. of Psychology, Carleton University, Ottawa, Ontario, Canada K1S 5E6.

Microelectrodes were used to map binaural responses in the primary auditory cortex of nine barbiturate-anesthetized ferrets. Gated pure tones were delivered independently to the two ears through a sealed speaker system and sensitivity to binaural intensity was determined at various sound pressure levels. Units within AI exhibited binaural response properties which were similar in most respects to those found in the cat's primary auditory cortex. The binaural neurons tended to be grouped together on the basis of their binaural response properties. Along the length of each isofrequency contour, areas of binaural summation (EE/F) alternated systematically with areas of binaural suppression (EO/I). A third major binaural response type, first noted by Reale and Kettner (1986), combined the properties of EE/F and EO/I units. These cells exhibited summation when the contralateral intensity was near threshold and the inter-aural intensity was small, but were suppressed at higher ipsilateral intensities. Seventy-four percent of these 'mixed' units were located between areas of EE/F and EO/I cells. The mixed responses appeared to mark the transition between summative and suppressive responses both by virtue of the location, and the duality of binaural response properties. Monaural and binaural thresholds obtained from units located within narrow-bandwidth isofrequency contours were examined statistically. Preliminary evidence suggests that monaural thresholds vary as a function of distance along an isofrequency contour.

264.10

THE MEANING OF STIMULUS DEPENDENT CHANGES IN CROSS CORRELATION BETWEEN NEURONAL SPIKE TRAINS. P.H. Bedenbaugh*, G.L. Gerstein, K.H. Boven* and A.M.H.J. Aertsen* (SPON: M. Bloom). Depts. of Physiol. and Bioeng., U. of Penna., Philadelphia PA 19104 and MPI for Biol. Cybernetics, Tuebingen, West Germany.

Several labs have observed dynamic changes in raw and corrected cross correlograms of two simultaneously recorded spike trains in the presence of different stimuli, even when their pst histograms and spike counts are similar. This suggests that the apparent functional connection between two neurons can vary on the time scale of hundreds of milliseconds. We want to know how to interpret these results in terms of changes in neuronal organization: do the differences in cross correlation reflect changes in the synaptic strengths of connections between the cells or some emergent property of the assemblies to which they belong ? To answer this question we are simulating networks on the order of 100 neurons using a computer program based on SYSTM22 described by MacGregor (1987, Academic Press). This program simulates the neurons as four state variable non-linear systems whose properties are determined by specifying conductances, thresholds and time constants. Preliminary results for simulated neurons with fixed strength of synaptic connections indicate that if the spike counts elicited by different stimuli are close, then the stimulus modulation corrected cross correlogram is constant. When the spike counts are different, the corrected cross correlogram varies with stimulus, especially when the connectivity is highly convergent. Recent work offers a better correction for cross correlograms when stimulus related non-stationarities are present (Gerstein and Aertsen, this meeting). Supported by System Development Foundation SDF 0013 and by ONR N00014-K-0766 to GLG.

264.11

RAPID STIMULUS-MODULATION OF "EFFECTIVE CONNECTIVITY" BETWEEN TWO NEURONS. G.L. Gerstein, A. Aertsen, Dept. of Physiology, U. of Pennsylvania, Philadelphia PA 19104 and MPI for Biological Cybernetics, Tuebingen, West Germany.

Cross-correlation of two simultaneously recorded spike trains, with appropriate correction for the modulations of each firing rate by the stimulus, has been used to evaluate an "effective connectivity" between the two neurons. Does this quantity in turn show stimulus-locked modulation? We have developed new procedures to quantify and properly normalize the classical Joint Peri-Stimulus-Time Scatter Diagram (Gerstein and Perkel 1972). These allow separation of the "raw" correlation into time-varying components caused by direct stimulus modulations of the single neuron firing rates and those caused by various types of interaction between the two neurons. Application of the new procedures to spike trains from a neural simulator shows detection of fast stimulus-locked modulation of the "effective connectivity" even when this is masked by strong direct stimulus modulations of the individual firing rates. Application of the new procedures to real spike trains from several different preparations shows that fast stimulus-locked modulations of "effective connectivity" also occur for real neurons. This observation suggests that the organization among a group of neurons can be rapidly time-varying, on the scale of a stimulus presentation. Such changes may represent successive stages of the computation of stimulus information. Known mechanisms like pre-synaptic inhibition and/or interneurons can account for these modulations of interaction among neurons. However, it does seem that the usual concept of neurons with static interconnections of fixed or only very slowly changing value (during learning), is no longer appropriate. Supported by System Development Foundation SDF 0013 and ONR N00014-K-0766.

REGENERATION: GENERAL I

265.1

REGENERATIVE ORGANIZATION AFTER MANDIBULAR NERVE SECTION AND REPAIR. J. Zuniga*, A. Hegtvedt*, J. Pate*, W. Maixner (SPON: G. Essick). Dental Research Center, Univ. NC, Chapel Hill, NC 27599.

Two-stage double-label (DL) methods were used to determine whether the regeneration of adult trigeminal segments following mandibular nerve section and surgical repair is associated with regeneration or collateral sprouting of first-order neurons.

Twelve ganglia from 6 male adult Sprague-Dawley rats were analyzed following: 1) injection of 1 ul of 4% Fast Blue (FB) into the mandibular nerve; 2) transection and repair; 3) injection of 1 ul of 4% Diamidino Yellow (DY) distal to the repair 30, 60 and 90 days after repair. Following fixation, trigeminal ganglia were removed, cut serially (20 um) in longitudinal sections and examined using fluorescent microscopic techniques. The results were compared with data obtained from 12 ganglia of sham operated and positive (no repair) controls.

The total number (FB, DY & DL) of labeled neurons did not differ between groups. The DL neurons were confined to the mandibular segment and the number of DL neurons was the same for sham operated and operated groups at 90 days. The number of DY neurons (collaterals) was not different from sham control.

This study demonstrated that sectioning and immediate repair of the mandibular nerve results in the regeneration of fibers whose cell bodies are confined to the mandibular segment. There was no evidence of collateral sprouting at the level of first-order neurons. NIDR grant DE0827201A1.

NEONATAL TRANSECTION OF THE RAT'S INFRAORBITAL NERVE INCREASES THE PERCENTAGE OF SUBSTANCE P-POSITIVE GANGLION CELLS THAT REGENERATE AXONS INTO THIS TRIGEMINAL BRANCH. H.L. Enfiejian, N.L. Chiaia and R.W. Rhoades (SPON: R. Wazirí). Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Neonatal transection of the rat's infraorbital nerve (ION) results in an expansion of the laminar distribution of substance P-like immunoreactivity in the medullary dorsal horn by the time the animal reaches adulthood (Rhoades, R.W. et al. J. Neurosci., in press). In the present study, we combined retrograde tracing and immunocytochemistry to determine whether this change was associated with an increase in the percentage of substance P (SP) positive ganglion cells that projected into the regenerate ION. In the normal trigeminal (V) ganglion (N=8), 11.6 $\pm$ 3.2% of the cells retrogradely labelled by application of true blue to the ION were also immunoreactive for SP. In ganglia ipsilateral to the regenerate ION, this value was 18.5 $\pm$ 4.7% ($p<0.001$). We also compared the SP content of normal ganglia and ganglia ipsilateral to the regenerate ION by means of radioimmunoassay in 10 rats. The normal V ganglion contained an average of 3,454 pg SP/mg protein. In the ganglion ipsilateral to the lesion, this value was 5,469 pg/mg ($p<0.01$). Supported by BNS 85-17537 and DE 07734.

265.3

MORPHOLOGICAL RESPONSES OF DORSAL ROOT GANGLION NEURONS CONTRALATERAL TO CRUSH LESIONS OF THE SCIATIC NERVE. M.R. Wells and U. Vaidya. Neurochemistry Research, Veterans Admin. Hosp. Washington, D.C. 20422.

Responses of analogous neurons contralateral to those injured by a peripheral nerve lesion have been observed, but not well characterized. The present study examined the time course of morphological responses of L5 dorsal root ganglion neurons contralateral to a sciatic nerve crush. Male, Wistar-Furth rats (n=2/time) received a unilateral crush of the sciatic nerve at the level of the sciatic notch. At 1,2,3,4,5, 7,8,9, 11,14, and 30 days after injury, animals were perfused with fixative, both L5 ganglia embedded in plastic and sectioned. Camera lucida drawings were made of 70 neurons from each ganglia. Soma, nuclear and nucleolar area were measured and eccentricity of the nucleus examined. The response of the injured side has been described in prior studies. Compared to measurements obtained from normal animals, the uninjured side showed significant alterations characterized by a transient increase in most parameters from 3 to 7 days after surgery. Changes in nuclear and nucleolar area corresponded to increases in synthesis suggested by prior studies. A group of sham operated animals which had received a dorsal midline incision and retraction of musculature from the T2 spinal vertebrae also exhibited a response of L5 ganglion morphological parameters. A similar group of animals receiving anesthesia alone did not show a response. The experiments suggested that a significant contralateral alteration in morphological parameters occurs after unilateral sciatic nerve section. At least one component of this reaction appears to be a nonspecific response to surgical trauma. Supported by the Veterans Administration

265.4

REGENERATION OF SENSORY NEURONS AFTER SCIATIC NERVE TRANSECTION AND ENTUBULATION REPAIR. F. Langone*, J.C. Bittencourt* and C.F. Da Silva.
Department of Anatomy, Institute of Biomedical Science, University of São Paulo, São Paulo, Brazil.

A quantitative study on dorsal root ganglion (DRG) neuron number and sizes after peripheral nerve transection and tubulation repair is presented. Ten adult C57BL/6J mice received sciatic nerve transections at mid-thigh level and proximal and distal nerve stumps were sutured into a 6 mm polyethylene tube, to give a nerve gap distance of 4 mm. After 12 weeks, the distal nerve stump was cut and exposed to an HRP solution. After an additional 3 days, animals were perfused with fixative and the L3-L5 DRG were removed on the operated side. The DRG were then either serially frozen sectioned (4 animals) or processed as whole-mounts (6 animals) and reacted with TMB. The total number of labeled cells was counted using the serial sections and cell sizes (areas) were measured by selecting 200 cells/animal in the whole-mount preparations. Aditional 10 animals were used to estimate the number and sizes of DRG neurons of origin of mouse sciatic nerve. The results showed that the regenerating DRG cells represented only about 40% of normal DRG cell counts (1707±139 X 4211±96). On the other hand, the measurements showed that the total cell size range was similar for both operated and control animals, with no preferential loss of small neurons. One possible explanation for these findings is that peripheral nerve transection may result in a non-selective death of primary sensory neurons, decreasing the potential for sensory axon regeneration.

DO LUMBAR DORSAL ROOT GANGLION CELLS SURVIVE NEONATAL DORSAL COLUMN AXOTOMY? S.P. Lahr* and D.J. Stelzner. Dept. of Anatomy & Cell Biol., SUNY Health Sci. Ctr., Syracuse, NY 13210.

Ascending dorsal column (DC) axons do not grow around a cervical spinal overhemisection (cutting the dorsal funiculus bilaterally) made in newborn rats (Lahr and Stelzner, Neurosci. Abst. 13:750). Since the DC projection can be labeled shortly after birth in its normal target, the gracile nucleus (Lahr and Stelzner, Anat. Rec. 220:56A), one possible reason for lack of DC growth after neonatal overhemisection is death of axotomized dorsal root ganglion (DRG) cells. To investigate this possibility Fast Blue (3%, 0.1 µl) was injected into the gracile nucleus of newborn rats. Two days later some of these rats received a cervical spinal overhemisection injury and were allowed to survive for postinjection periods of 10 (n=4) and 22 (n=4) days. Frozen sections from L4 and L5 DRG were examined and the percentage of labeled cells was determined and compared to unlesioned animals with postinjection periods of 3 (n=4), 10 (n=4), and 22 (n=4) days.

Cell counts reveal no sign of DRG cell loss after newborn DC axotomy. Approximately 20% of L4 and L5 DRG cells are labeled at 3 and 10 days postinjection with or without spinal injury. At 22 days postinjection a smaller percentage of cells is labeled but the percentage is the same for both lesioned and unlesioned groups. Supported by NIH Grant NS 14096 (D.J.S.).

CELLULAR DEBRIS STIMULATES CNS SCAR FORMATION. G. Rodziewicz*, J. Rudge*, G. Smith*, J. Silver (SPON: R. Hardy). Neuroscience Center, CWRU Medical School, Cleveland, Ohio 44106.

The role of cellular debris in scar formation was studied in a bilaterally symmetric model of minimal scar formation.

Adult rats had bilateral frontal craniectomies and bilateral implantation of 8 u pore-size nitrocellulose filters. On the experimental side, the implants were transplanted from neonatal rat forebrains to the adult rat brains under a variety of conditions. Contralaterally the cell-free controls were implanted. Fourteen days later, the rats were killed and the forebrains were prepared for TEM and immunohistochemistry (laminin and GFAP).

In many areas of the control implants, basement membrane and collagen were absent, and astrocyte processes grew into the pores of the filter. Myelinated axons ran in close proximity to these implants. Around the debris-coated experimental implants, there was uniform scar formation, with collagen and phagocytes present in basement membrane, surrounded by layers of astrocytes.

Persistent phagocytes marked the areas of scar formation. Our experiment suggests that cellular debris enhances scar formation in this type of CNS wound.

CHLOROQUIN INHIBITS REACTIVE GLIOSIS IN VIVO. G. Spurr and M. Politis,(R.Pellegrino, spon.) Orth. Surg., U.B.C., Vancouver, V5Z 4H4

A number of studies in recent years suggest a link between activation of the immune system and reactive gliosis. In the present study, chloroquin, an antimalarial agent with action that include diminishing interleukin 1 secretion, was tested for its ability to inhibit reactive glial changes in traumatized rat optic nerve.

Right optic nerves were crushed behind the eyeball and animals given daily i.p. injection of either drug (chloroquin at 6 or 20mg/kg BW supplimented with 0.01 mg/kg BW colchicine) or saline. Animals were sacrificed at 9 and 14 d.p.o. and post-traumatic changes assessed in 1 micron toluidine-blue-stained cross-sections obtained 2 mm distal to the crush site. The following were blindly quantitated: (a) number glial nuclei, (b) percent cross-sectional area occupied by glial cytoplasm, and (c) number of intact myelin sheaths.

The extent of glial hyperplasia and hypertrophy in high-dose drug-treated rats was less than 50% of that in saline-treated animals at both time points. A significant delay in clearance of myelin debris was also indicated. No inhibition of gliosis was seen in low-dose drug rats.

Results suggest feasibility of using chloroquin to decrease reactive gliosis after CNS trauma.

DETECTION OF GROWTH CONES FOLLOWING NERVE CRUSH WITH THE VIBRATING PROBE AND ELECTRON MICROSCOPY. J.M. Kerns, Anatomy Dept., Rush Medical College, Chicago, IL. 60612

Regenerating axons proceed as a front into the distal segment of a lesioned nerve. The vibrating probe of Freeman was tested as a detector of actively growing axonal sprouts at the lesion site and the distal front. Rat sciatic nerves were given crush lesions under Nembutal anesthesia and aseptic surgery. After 7 days the current densities were measured in situ with the probe and represented as vectors on a video image of the nerve. Peaks were found at the lesion site and 14mm distally. They were eliminated following exposure to verapamil, a calcium channel blocker. The nerves were then fixed for electron microscopy and examined at five selected regions. Growth cone profiles were present at the peaks, while the "silent" regions displayed the following morphology: proximal to the lesion site were normal axons; in the "valley" between the peaks were degenerated and regenerating axons associated with Schwann cells; in the segment beyond the distal peak were degenerated axons and empty Schwann cell tubes. This study demonstrates that axonal growth cones are associated with regions of a regenerating nerve that exhibit an endogenous Ca^{+2} current. Clinical application for human nerve injuries is suggested.

EARLY CHANGES IN THE DISTRIBUTION OF FREE CALCIUM IN TRANSECTED LAMPREY SPINAL AXONS. Alan F. Strautman* and Kenneth R. Robinson*, (SPON: J. Strong), Department of Biological Sciences, Purdue University, West Lafayette, Indiana 47907.

An increase in intracellular free calcium concentration ($[Ca^{2+}]_i$) has been implicated in the degeneration of transected axons. We used fura-2 to measure the $[Ca^{2+}]_i$ in the last few mm of the proximal segments of transected axons in the larval sea lamprey spinal cord (Petromyzon marinus). There is a spatially graded increase in $[Ca^{2+}]_i$ that is complete within minutes; at 0.5 mm from the cut end the $[Ca^{2+}]_i$ is 14 times greater than basal levels and at two mm, it is three times greater. Superimposed on this initial change is a moving front of calcium that progresses up the axon, reaching 1.6 mm from the cut end in three hours. In thes regions, $[Ca^{2+}]_i$ exceeds what can be reliably measured with fura-2 (10 μM). One day after transection, $[Ca^{2+}]_i$ returns to precut levels except in the distal 300 μm indicating that the high levels of $[Ca^{2+}]_i$ do not result in the immediate destruction of the axon.

265.10

A PARTIAL CELL BODY REACTION TO AXOTOMY IN SYMPATHETIC B CELLS OF COLD-ACCLIMATIZED BULLFROGS. M.E.M. Kelly*, M.A. Bisby, A.G.M. Bulloch & K. Lukowiak. (Spon:R. Carlsen) Med. Physiology, Univ of Calgary, Calgary, Alta.

Axotomy of B-cells decreases amplitude and duration of action potential (AP) after-hyperpolarization (AHP), and increases AP duration. After regeneration, only AHP duration recovers (Kelly et al, J. Neurobiol. in press). We have now axotomized B-cells in frogs acclimatized to 15°C. At 15°C motor and sensory axons fail to regenerate, with an absence of most morphological and physical manifestations of the cell body response (CBR) (Carlsen et al, 1982, Brain Res. 234:11). The usual changes in AHP amplitude, AP duration, and sprouting from the initial segment occurred, albeit with a slower time-course. However, no significant changes occurred in AHP duration. Thus 15°C frogs respond to axotomy with only a partial CBR. To determine the site of the cold blockade of the CBR, we warmed the frogs to 21°C for one week following axotomy, before returning them to the cold. The usual reduction in AHP duration still occurred. We also took frogs from the cold 4 weeks after axotomy and placed them in the warm. One week later, the reduction in AHP duration had occurred. Thus, cold does not prevent cellular recognition of the axotomy signal or interfere with the expression of the response initiated in the warm, but interrupts a step between receipt of signal and expression of response, and can be reversed by rewarming.

265.11

PLASTICITY OF DORSAL ROOT GABA SENSITIVITY DURING PERIPHERAL AXON INJURY AND REGENERATION. R. B. Bhisitkul*, T. R. Gordon, J. D. Kocsis and S. G. Waxman. Dept. of Neurology, Yale Univ. Med. Sch., New Haven, CT 06510.

Axotomy of the sciatic nerve leads to a decrease in GABA sensitivity of L4 and L5 dorsal root axons. To examine the mechanisms of this alteration, unilateral tight ligatures were placed on sciatic nerves of adult Wistar rats for 4 weeks, then released to allow 3-4 weeks of regeneration. Isolated dorsal root segments excluding cell body and terminal regions were studied in a modified sucrose gap chamber to measure changes in membrane potential and input resistance. After 4 weeks ligation, the dorsal root depolarization elicited by GABA was reduced to approximately 60% of controls, and the effect of GABA on input resistance was diminished by about 40%. These decrements were reversed following release of the ligature; the GABA-induced depolarization was restored to approximately 75% of controls, and input resistance changes were about 10% less than controls. These effects were not accompanied by changes in compound action potential amplitude. The results suggest that dorsal root GABA receptor function is modulated by remote axon disruption, and that some component of the local regenerative environment may be involved in the restoration of axonal GABA sensitivity.

REGENERATION: FUNCTIONAL RECOVERY

266.1

DEVELOPMENT AND RECOVERY OF COMMAND FUNCTION BY THE PONTINE LOCOMOTOR REGION IN THE LAMPREY. L. Margolin* and J. Ayers. (*Spon: Norman Boissé*). Dept. of Biology and Marine Science Center, Northeastern University, East Point, Nahant, MA 01908.

Previous work has shown that swimming can be elicited by focal electrical stimulation of locomotor command systems in the rhombencephalon of larval lampreys that have behaviorally recovered from full spinal cord transection. This result had not been obtained in adults (Soc. Neurosci. Abstr.11:589). HRP studies (Swain and Ayers, this volume) have demonstrated that regeneration of a cell group *corresponding to the pontine locomotor region (PLR) (J. Neurophysiol.40:284)* was highly correlated with behavioral recovery. We stimulated the PLR in unoperated control and recovered larvae and adults and compared its effects with those evoked by rhombencephalic stimulation.

Two preparations were utilized: 1) *In situ*, the anterior quarter of the body was pinned down, allowing the caudal regions to behave freely and the brain exposed for electrical microstimulation. Movements were quantified by analysis of curvature (Science 221:1312). 2) The specimen was reduced to an isolated neuraxis for *in vitro* stimulation. Stimulus-evoked activity was recorded from ventral roots caudal to the lesion.

Focal stimulation of the PLR in larvae evoked swimming with normal timing and curvature in controls and normal curvature but slower timing in recovered specimens. In normal adults,the PLR evoked behavior was shower, less regular and of greatly reduced curvature when compared to the rhombencephalic effects. Behavior in PLR-stimulated recovered adults is similar to that found in recovered adults that were stimulated in the rhombencephalic locomotor command system. Rhythmic electrical activity was recorded in ventral roots several (~20) body segments posterior to the lesion upon focal stimulation of the PLR in recovered adults. We conclude that the PLR makes a major contribution to behavioral recovery in larvae but is only partially responsible in recovered adults.

266.2

ROLE OF CORTICO- AND SUBCORTICOSPINAL PATHWAYS IN THE RECOVERY OF FORELIMB MOVEMENTS FOLLOWING NEONATAL SPINAL HEMISECTION IN MONKEYS. S.S. Cheema, M. Galea* and I. Darian-Smith. Dept. of Anatomy, Melbourne University, Victoria 3052, Australia.

Infant monkeys with hemisection of the upper cervical spinal cord recover from most but not all the deficits involving movements of the hand and arm (Caine et al., *Neurosci. Letts. Suppl.*, 30:S53, 1988). We have investigated the alterations in cortico- and *subcorticospinal pathways in juvenile monkeys, following* neonatal lesions of the cord, when recovery of movement is maximal.

WGA-HRP injections into the sensorimotor cortex of the normal newborn monkey showed strong anterograde labeling of axons and terminals in the thalamus but sparse labeling in the brainstem and cervical spinal cord. After injections of fluorescent dyes into the spinal dorsolateral funiculus, the pattern of retrogradely labeled somas in the normal sensorimotor cortex was almost adult-like. These findings suggest that in the normal neonate the corticospinal terminations are poorly developed although the axons are already present in the spinal dorsolateral funiculus (Kuypers, H.G.J.M., *Science*, 138:678, 1962). After the cord lesion, there is a uniform drastic reduction of retrogradely labeled neurons in the ipsi- and contralateral sensorimotor fields which contrasts with a claim that an increase in the ipsilateral corticospinal component occurs in adult monkeys after spinal cord hemisections (Aoki et al., *Neurosci. Res.*, 3:617, 1986).

The reduction in corticospinal connections which result after neonatal spinal hemisection suggests that subcorticospinal pathways may play an important role in the recovery of limb movements.

266.3

REGENERATION AND FUNCTIONAL RECOVERY FOLLOWING CERVICAL AND THORACIC TRANSECTION OF THE SPINAL CORD OF BULLFROG TADPOLES. P.R. BRENNER* and D.J. STEHOUWER. Dept. of Psychology, Univ. of Florida, Gainesville, FL 32611.

Previous studies suggest that there is greater behavioral recovery following cervical transection than following thoracic transection of the spinal cord of larval amphibians. The present study was conducted to determine whether this difference in behavioral recovery could be attributed to differences in anatomical restitution of the spinal cord. Bullfrog tadpoles (Rana catesbeiana) were transected either cervically or midthoracically and allowed to recover for five weeks. Horseradish peroxidase crystals were inserted into the spinal cord caudal to the transection site four weeks post operatively. Despite abortive regeneration exhibited by many tadpoles, others produced large numbers of axons that crossed the transection site. Comparison of cervically and thoracically transected tadpoles showed that the amount of growth across the transection site varied little with the level of transection. However, retrograde labelling revealed many cell bodies in the brainstem of cervically, but not thoracically, transected tadpoles. This difference in the source of axons is thought to underlie the greater behavioral recovery found in cervically transected tadpoles. Supported by PHS grant NS 24442 to DJS.

266.4

REGENERATED RETINO-COLLICULAR SYNAPSES EIGHTEEN MONTHS AFTER SUBSTITUTION OF THE OPTIC NERVE BY A PERIPHERAL NERVE GRAFT IN ADULT RATS. G.M. Bray, M. Vidal-Sanz*, and A.J. Aguayo. (SPON: M. Rasminsky). Neurosciences Unit, The Montreal General Hospital and McGill Unversity, Montréal, Québec, H3G 1A4, Canada.

When the optic nerve (ON) was transected and the eye and the midbrain were linked by peripheral nerve (PN) grafts for 2 months, retinal ganglion cell (RGC) axons regenerated along the grafts and formed synapses in the superior colliculus (SC) of adult Sprague-Dawley rats (Vidal-Sanz et al., J.Neurosci., 7: 2894, 1987). The aim of the present study was to determine if these regenerated synapses would persist for longer periods of time. Thus, 18 months after graft placement, ^{3}H-proline-leucine was injected into the PN-grafted eye to label the terminals of regenerated RGC axons by anterograde transport. Examined by light and EM autoradiography, two types of labelled profile were observed within the SC neuropil near the end of the PN grafts: 1) Axons, some of which were ensheathed by CNS myelin, indicating that certain oligodendroglial cells in the tectum retain their capacity to respond to the regenerating axons and reform myelin sheaths; 2) Axon terminals forming asymmetric (Gray type II) synaptic contacts with dendrites. These results suggest that regenerated RGC axons in adult rats may maintain synaptic contacts in the SC for long periods of time.

266.5

TERMINAL ARBORIZATION AND SYNAPSE FORMATION BY REGENERATING RETINAL AXONS DIRECTED ALONG PERIPHERAL NERVE GRAFTS TO THE SUPERIOR COLLICULUS OF ADULT HAMSTERS. D.A. Carter,* G.M. Bray, and A.J. Aguayo. Neurosciences Unit, The Montreal General Hospital and McGill University, Montréal, Québec, Canada, H3G 1A4.

The retina and the superior colliculus (SC) were joined by a peripheral nerve (PN) graft after optic nerve (ON) transection in adult hamsters. Two-4 months later, the terminals of axons regenerating from the retina were labelled by anterograde transport of HRP. The ultrastructural features of the regenerated RGC terminals were compared with the retino-collicular terminals of control animals. The regenerated RGC terminals, observed in the neuropil of the superficial SC within 0.5 mm of the ends of the grafts, showed the densely-packed, spherical synaptic vesicles and mitochondria typical of the terminals of intact RGCs. Although some regenerated RGC terminals were larger than normal, most resembled the HRP-labelled RGC terminals seen in control animals in terms of: the proportions that showed well-differentiated synaptic specializations; the predominance of synaptic specializations of asymmetric type; and the proportions of contacts with dendritic profiles that contained vesicles. These results suggest that most regenerating RGC axons that re-enter the SC of these adult hamsters undergo pre- and post-synaptic differentiations that resemble those of normal retino-collicular synapses.

266.6

DEVELOPMENT OF A CORTICAL MAP OF THE HAND AFTER NERVE INJURY AND REGENERATION IN NEONATAL MACAQUE MONKEYS. J.T. Wall, J.H. Kaas, C.G. Cusick, S.L. Florence, P.E. Garraghty, M.F. Huerta, and M.A. Sesma. Department of Psychology, Vanderbilt University, Nashville, TN 37240.

Macaque monkeys were raised from the first 1-2 weeks after birth with an injured (transected and ligated) or regenerated (transected and repaired) median nerve to the hand. Maps of cutaneous tactile inputs in cortical area 3b of these monkeys were made with neurophysiological techniques 2-3 years after birth, and compared to maps from normal monkeys. Following injury, a persisting denervated zone is produced peripherally on the hand; however, an organized, but topographically abnormal representation of hand zones innervated by the 2 remaining nerves develops in cortex. Following regeneration, a map reflecting innervation by all 3 hand nerves is formed. Although indications of abnormal convergence/divergence are seen, normal topographical features (e.g. receptive fields, digit representation locations) are also apparent. Primate sensory systems undergo developmental changes during the first weeks and months after birth; however, it is not known whether a combination of peripheral regeneration and neonatal mechanisms of central change (e.g. exuberance, competition, segregation, etc.) can lead to postnatal formation of a normal map. The current findings suggest neonatal regeneration and developmental mechanisms are sufficient for at least a partial recovery of normal cortical features. (Grants NS21105 and NS16446).

266.7

ANATOMICAL AND FUNCTIONAL REGENERATION OF FIBER TRACTS IN THE NEONATAL RAT SPINAL CORD. A.A. Alfaro* and V.R. Holets (SPON: Å. Seiger). Dept. of Neurological Surgery, Univ. of Miami, Miami, FL 33136.

The neonatal rat spinal cord is immature at birth, with descending pathways developing during the first 2 post- natal weeks. Complete transection of the spinal cord at the T10 spinal cord level was done in 2-, 4-, 5-, 6-, 8-, 10-, 12-, 14- and 21-day old rats. The cut ends of the spinal cord remained opposed following the transection. Age-matched, sham-operated animals received a laminectomy, but no spinal cord lesion.

Animals lesioned at 2 to 21 postnatal days exhibited a >90% functional deficit during the first 2 weeks post-lesion using a modification of the system of Gale et al. (Exp. Neurol. 88:123-134,1985). Significant recovery was observed in the rats lesioned at 2 to 6 postnatal days from 2 weeks to 60 days post-lesion, with a recovery to <30% functional deficit. Neonates lesioned at 8 to 21 postnatal days did not show any functional recovery during this time. Immunohistochemical and retrograde axonal studies revealed significant growth of monoamine and peptidergic pathways from brainstem and hypothalamic nuclei, and from the red nucleus and the cerebral cortex through the lesion site and into the distal spinal cord segments. These results suggest that the neonatal spinal cord allows for regeneration of descending pathways during a narrow window of time during the first postnatal week. Funded by The Miami Project.

266.8

FUNCTIONAL RECOVERY AFTER LINGUAL NERVE INJURIES IN CATS. P.P. Robinson* (SPON: J. Stephens). Depts. of Physiology & Oral Surgery, Birmingham Univ. Med. School, B15 2TJ, U.K.

The recovery of gustatory, thermosensitive, mechanosensitive, vasomotor and secretomotor fibres in the combined trunk of the chorda tympani and lingual nerves has been investigated following nerve injury. Under anaesthesia the nerve was either crushed (4 cats) or sectioned (3 cats) unilaterally and recovery allowed for 12 weeks. Recordings made from 52 single units in the chorda tympani after nerve crush revealed that the proportions of gustatory, thermosensitive and mechanosensitive units were similar to those of controls but the units had slower conduction velocities, responded less vigorously and to a narrower range of stimuli. Recordings made from 46 units in the chorda tympani after nerve section revealed very few gustatory or thermosensitive units, the majority being purely mechanosensitive. The decrease in conduction velocity was greater than after nerve crush. Electrical stimulation of efferent vasodilator fibres in both the chorda tympani and lingual nerves, evoked a temperature rise on the dorsal surface of the tongue. This effect was completely restored after nerve crush but was significantly smaller after nerve section. The flow rate of saliva from the submandibular salivary gland was not significantly changed after nerve crush but was significantly smaller after nerve section. There was no evidence for functional reinnervation by inappropriate fibre types. Supported by the MRC (U.K.).

267.1

SYNAPTIC BOUTON CHANGES FOLLOWING CRUSH INJURY OF THE FACIAL NERVE. S.K. Jacob and T.E. Durica, Anatomy Dept., Rush Medical College, Chicago, IL 60612.

This study examines the short-term changes in axosomatic synaptic bouton contacts on facial motor neurons following crush injury of the facial nerve. Comparisons are made to results following axotomy (cut and removal of a segment) of the facial nerve. Adult hamsters underwent a crush of the right facial nerve; brains were processed for routine ultrastructural examination at 5 days postoperative (dpo). Following either injury the neurons exhibited a morphology typical of the chromatolytic response. At the perimeter of some injured neurons were many thin astrocytic processes. A quantitative study assayed the percent coverage of somal profile by synaptic boutons in normal, 5dpo crush, and 5dpo axotomy. Normal facial motoneurons have 30% of the soma contacted by synaptic boutons. Both injuries result in significant decreases in bouton contacts: 5dpo crush = 13% coverage and 5dpo axotomy = 8% coverage. The mean number of synaptic boutons/neuronal profile was compared: normal= 15 contacts, 5dpo crush = 9 contacts and 5dpo axotomy = 6 contacts. The less severe response seen after crush injury might reflect the fact that these neurons can regrow axons and return to normal function; while axotomy, which prevents axon regrowth, causes a greater response.

267.2

CHANGES IN SYNAPTIC BOUTONS AFTER AXOTOMY OF THE VAGUS AND HYPOGLOSSAL NERVES IN THE ADULT HAMSTER. T.E. Durica and S.K. Jacob, Anatomy Department, Rush Medical College, Chicago, IL 60612.

This study examined the short term changes in axosomatic synaptic bouton contacts on vagal and hypoglossal motoneurons after axotomy. The right vagus and hypoglossal nerves of adult hamsters were cut and at 5 days postoperative (dpo) the brainstems were processed for routine ultrastructural examination. These motoneurons exhibited a typical chromatolytic response to axotomy. The Bioquant System IV was used for measurement and data analysis. A quantitative study assayed the percent coverage of somal profiles by synaptic boutons on normal and axotomized neurons. After axotomy for both neuronal populations there is a decrease in percent coverage. For vagal neurons: normal = 14%; axotomy = 3%; for hypoglossal neurons: normal = 30%; axotomy = 18%. There was also an accompanying decrease in the mean number of synaptic boutons per neuronal profile. For vagal neurons: normal = 6; axotomy = 1; for hypoglossal neurons: normal = 18; axotomy = 14. These changes which are most dramatic for vagal neurons might be expected because long term studies have shown that these neurons do not survive axotomy.

DEVELOPMENTAL PLASTICITY OF THE OPOSSUM'S RUBROSPINAL TRACT-REGENERATION OR NEW GROWTH? X.M. Xu, R.R. Pindzola and G.F. Martin. Department of Anatomy and Neuroscience Program, The Ohio State University College of Medicine, Columbus, Ohio 43210.

We have shown previously that rubral axons can grow around a lesion of their spinal pathway in the developing opossum, but it is not clear whether they are the ones originally cut or later growing ones. In an initial attempt to address that issue, we tried to determine whether any rubral neurons survive axotomy during the early part of their critical period for plasticity. If not, rubrospinal plasticity must be a result of new growth, not regeneration of cut axons. In these experiments pouch-young opossums of the appropriate age were anesthetized so that Fast-Blue (FB) could be injected into the thoracic cord. Three to four days later they were reanesthetized and the rubrospinal tract was cut 3 segments rostral to the injection. The animals were retained for approximately 1 month after the lesion before being anesthetized and sacrificed by perfusion. In all cases, rubral neurons were labeled contralateral to the lesion but their number varied depending on the size of the injection. Our results indicate that at least some rubrospinal neurons survive axotomy suggesting that true regeneration may have occured. It is possible, of course, that the labeled neurons survived the lesion, but their axons did not grow around it. Additional experiments will have to address that issue. (Supported by NS-25095).

EFFECTS OF CLAW REMOVAL AND REGENERATION ON THE GANGLIONIC NERVE AND NEUROPIL OF MALE FIDDLER CRABS. J.I. Mayes* & C.K. Govind, Scarborough College, University of Toronto, Scarborough, Ont. M1C 1A4, Canada.

The paired dimorphic, major and minor, claws in male fiddler crabs, Uca pugnax, have a corresponding asymmetric nervous system. In a crab with pristine claws, the number of sensory axons in the nerves of the major side of the claw ganglion was 3x greater than on the minor side. The neuropil, however, had a higher density of nerve terminals (1.4x) and synaptic contacts (1.8x) on the minor side compared to the major side. In a crab with a newly regenerated major claw, the number of axons in the major claw nerves was only 1.8x greater than in the minor side. Since this ratio is smaller than that seen in a crab with pristine claws, it suggests that the regenerated claw has fewer axons. In this same animal, the density of terminals and synapses is higher (1.2x) in the minor side neuropil compared to the major side, although the difference is not as great as in the pristine condition, suggesting a slight increase in the number of these elements, or a decrease in the size of terminals, on the major side. The major side also shows degenerating profiles in the nerves and neuropil soon after the claw has been removed and even after it has regenerated, indicating a remodeling of the ganglion each time a claw is lost and regenerated. GROWTH AND ELECTRICAL COUPLING OF REGENERATING NEURITES FROM SEVERED AND ROTATED GIANT FIBERS IN THE EARTHWORM. A.W. Lyckman and G.D. Bittner. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

The ventral nerve cord (VNC) of the earthworm contains two lateral giant fibers (LGFs) and one median giant fiber (MGF). Lucifer yellow injections show that severed giant fibers grow neurites across the lesion site within several weeks after transection. In addition, if a segment of the VNC is doubly cut, removed and replaced after rotating 0-180° in the dorsoventral plane (DV-rotation), neurites regenerate across the lesion sites.

At all post-operative periods from 2 weeks to 9 months in both VNC-transections and DV-rotations, conduction of action potentials across the lesion site correctly restores the normal functional connections between severed giant fibers, *i.e.*, severed MGFs and LGFs reconnect appropriately. However, conduction of action potentials across the lesion site is much more easily fatigued by high frequency stimulation than action potential conduction in the unoperated VNC. Through-conducting MGFs or LGFs are electrically coupled with coupling ratios up to 0.5, a lower coupling ratio than is found in intact giant fibers (1.0).

Data from these and other studies is being used to better understand cellular mechanisms which contribute to the regeneration of specific and appropriate connections between these giant interneurons.

Supported by TATP grant from Texas.

TEMPORAL PARAMETERS OF OLFACTORY NEURONS DEGENERATION AND REGENERATION. L.M. Alves*, P.P.C. Graziadei and A.G. Monti Graziadei (Spon. J.S. Elam). Department of Biological Sciences, Florida State Univ., Tallahassee, FL 32306-3050.

Axotomy of the fila olfactoria in adult rats results in degeneration followed by regeneration of the olfactory sensory neurons with functional recovery. In this study we wanted to investigate the temporal parameters of this phenomenon using the olfactory marker protein (OMP) as a marker. Axotomy was performed at the intracranial level of the lamina cribrosa. Survival times ranged from 1 to 45 days. The rats were anesthetized, perfused with Bouin and embedded in paraffin. Serial sections were cut in the horizontal plane and stained with hematoxylin and immunohistochemically for OMP. Two days after surgery all the OMP-positive perikarya had disappeared from the olfactory neuroepithelium. Their reappearance began after twelve days and from the 35th day the number of perikarya in the epithelium was comparable to control values. In the olfactory bulb, OMP was observed in the glomeruli up to eight days after surgery. After this time, the glomeruli remained negative up to 20-23 days postoperative survival time, when few isolated OMP-positive axons started to enter into the glomeruli. Control level of OMP-positivity in the olfactory bulb was reached after 45-50 days. The disappearance of OMP from the epithelium and from the olfactory bulb did not parallel the morphological changes previously described and the significance of these results will be discussed. (Supported by NIH grant NS 20699).

AN AUTORADIOGRAPHIC TIME STUDY OF HEALING AND REGENERATION IN FULLY DIFFERENTIATED XENOPUS RETINAS. L. Wunsh* and C.F. Ide. Dept. of Biology, Tulane University, New Orleans, LA 70118.

In previous studies, removal of the temporal 2/3 of the fully differentiated Xenopus eye (stages 38-48) resulted in restoration of an intact eye. In addition, these eyes formed pattern duplicated projections to the midbrain optic tectum. To determine the role of healing and cell division during regeneration in these progressively older larval animals, tritiated thymidine labeling patterns were analyzed. Nasal one-third sized eye fragments made at stages 46 through 48 were injected either one day, one week, or one month post-surgery. All animals were fixed one day post-injection. At all stages, healing involved dedifferentiation of pigmented retinal epithelial cells stretching across the lens and closing the wound. Heavy label was localized in the ventral retina in a neuroepithelium internal to the extended pigmented retinal epithelium. These results correspond to previous label pattern studies done on undifferentiated stage 32 eye fragments. Thus, in both undifferentiated and differentiated retinal fragments, movements from the eye's ventral region and associated local cell division correlate with pattern duplication of the retino-tectal projection. **Supported by NSF Grant PCM-8316142.**

HAIR CELL REGENERATION FOLLOWING EXPERIMENTALLY INDUCED HAIR CELL DEATH IN THE LATERAL LINE SYSTEM OF THE AXOLOTL SALAMANDER (AMBYSTOMA MEXICANUM). K.J. Balak* and J.T. Corwin. Békésy Lab. of Neurobiology, Univ. of Hawaii, Honolulu, HI 96822.

The sensory hair cells of the lateral line system of the axolotl were specifically stained with the fluorescent mitochondrial dye 2-(4-dimethylaminostyryl)-N-ethyl pyridinium iodide (DASPEI). We have used this cell-type specific staining to kill the sensory hair cells of an individual neuromast organ by exposing the stained hair cells to intense UV irradiation for 1-2 hours. After UV irradiation the neuromast organ was devoid of sensory hair cells and consisted of a single layer of supporting cells as observed by differential interference contrast microscopy and fluorescence microscopy of DASPEI stained cells. Within 2 to 5 days of hair cell depletion new hair cells were observed by DIC and uptake of DASPEI. The tritiated thymidine technique was used to determine if the new hair cells arose from the progeny of proliferating supporting cells. A neuromast organ was depleted of hair cells using DASPEI and UV irradiation. The axolotl was given tritiated thymidine intraperitoneally and periodically examined for the appearance of new hair cells. The tissue was processed for autoradiography. The regenerated sensory hair cells were labeled with tritiated thymidine indicating that these cells arose through cell division from the remaining supporting cell population in the absence of differentiated hair cells. We conclude that the sensory hair cells arose from supporting cell progeny following hair cell death. (Supported by a Deafness Research Foundation Grant to KJB and grants from NINCDS to JTC.)

CELL BEHAVIOR DURING HEALING OF HALF-EYE FRAGMENTS OF THE EMBRYONIC MOUSE. C. D. Claypool*, C. F. Ide, and K. Muneoka*. Dept. of Biology, Tulane University, New Orleans, LA 70118.

We have begun to investigate the effects of surgical ablations of the neural retina prior to differentiation during embryonic stages of the mouse. Developing neural retina tissue was removed from mouse embryos on embryonic day (E) 14 and 15, using *ex utero* surgery techniques (Muneoka, et al., 1986, J. Exp. Zool., 239: 289-293). Approximately one-half of the developing eye was removed without disturbing the lens. No attempt was made to surgically close the wound. The mice were allowed to develop to E19 (term), and were then analyzed histologically.

The developing mouse retina at the time of surgery is a thin, undifferentiated neuroepithelium. An optic stalk and forming cornea and lens are present. Half-eye ablate embryos fixed immediately post-surgery showed the cornea pulled back almost to the eyelid flexure, with a gaping opening between the cut edges of neuroepithelium. By E19, the unoperated eye showed a thick neuroepithelium with a definite ganglion cell layer, an optic nerve head, and differentiated cornea, whereas operated eyes left to heal until day 19 showed a neuroepithelium somewhat reduced in thickness, with no evidence of differentiated ganglion cells. Healing involved the formation of a thin layer of cells emanating from the cut edge and stretching around the lens. The ciliary margin in the undamaged region of the fragment appeared intact.

Healing modes appeared similar to those seen in late stage amphibian embryos in which similar cell behavior correlates with extra cell division and, over time, restoration of a full sized eye. **Supported by NSF PCM-8316142, HD 23921, HD 20662, and a gift from the Monsanto Company.**

UNEQUAL PROBABILITIES OF REGENERATION AMONG LAMPREY RETICULOSPINAL NEURONS. R.S. Croop*, J.A. Snedeker* and M.E. Selzer. (Spon: S. Shuman). Dept. Neurology and David Mahoney Inst. of Neurol. Sci., Univ. of Pa. Sch. of Med., Phila., PA. 19104-4283.

Regeneration of reticulospinal axons in the sea lamprey (P. marinus) shows an increase in latency as the transection site is moved more distal to the cell body. Half of all axotomized neurons regenerate a neurite that extends at least 2.5 mm past the scar. In order to determine whether different cell groups have different regenerative abilities, the reticulospinal cells were subdivided into 13 groups and the regeneration of each determined by retrograde transport of HRP across a previous transection. Analysis of variance demonstrated that two of the groups, one of which contained the Mauthner and the bulbar Muller cells, had significantly greater probability of neuritic regeneration than the rest.

For transections at the level of the 7th gill, maximal probability of regeneration was seen at 95 days, declining thereafter in all cell groups. More caudal lesions were associated with longer delays for peak regeneration.

(NIH grants NS14837 and NS25581).

267.11

AXONS IN REGENERATED LIZARD TAIL ARE PRIMARILY OF LOCAL ORIGIN. M.T. Duffy*, B.M. Davis and S.B. Simpson Jr. Dept. of Biological Sciences, Univ. of Illinois at Chicago, Chicago, Il., 60680.

Transection or autotomy of the lizard (*Anolis carolinensis*) tail results in regeneration of a new tail with concomitant regeneration of CNS axons. Electron microscopic analysis shows the regenerate spinal cord white matter consists of an average of 2,000 axons (R = 1,720 - 2,346 ; n = 6).

HRP labeling of a normal midback spinal cord shows lumbar projections from many brainstem nuclei (Rub, Rs, Ras, Rm, Vest, Rai and Ri; X=1,384; n=5). HRP labeling of axons from normal tail cord(X=388 cells) shows the same brainstem distribution while HRP labeling in mature regenerate tail cord(X=49; n=19) shows fewer cells but a similar distribution. Interestingly, there is an absence of a rubrospinal projection to the regenerate tail. If, however, HRP is placed in the normal cord 1-2 mm rostral to the regenerate cord the distribution and number of cells is identical to normal tail. This suggests that the paucity of regenerated bulbospinal projections (including the absence of rubrospinal) is not due to retraction and/or degeneration.

Since the number of regenerating bulbospinal axons cannot account for the number of axons seen in the regenerate tail cord, the majority of their origins must be elsewhere. EM analysis following transection of the spinal cord at all levels more than 1 segment rostral to the regenerate cord revealed no reduction in number of regenerated axons. Transection of the spinal cord one segment rostral to the regenerate produced a significant reduction (>50%) in the number of regenerated axons. This suggests that the majority of regenerated fibers have their origin within one segment of the regenerate cord. These origins must be either local circuit spinal neurons or primary sensory cells of the dorsal root ganglia. (Supported by NS24162 to SBS).

TIME COURSE OF SALAMANDER SPINAL CORD REGENERATION: BEHAVIORAL AND ANATOMICAL ANALYSIS. B.M. Davis, J. Ayers, L. Koran*, J. Carlson*, and S.B. Simpson, JR. Dept. of Biological Science, Univ. of Illinois at Chicago, Chicago, IL 60680.

Five groups (10 animals/group) of salamanders received complete low thoracic transections. All animals received a second transection 10mm caudal to the first transection 2,4,6,8 or 12 wks following the initial lesion. A pledget of HRP was inserted at the site of the second transection to labeled any descending axons which had grown10m past the first transection. Just prior to the second transection each animal was filmed to record the animals abiltiy to walk and swim. In addition, the animals in the 12wk group were filmed every 2wks following the initial lesion. These films were used to score the recovery of function and for future kinematic analysis of ambulatory and swimming behaviors in regenerated salamanders. The earliest return of coordinated swimming and walking behavior was seen 4 weeks (2/20 animals) following transection but most animals (13/27) did not demonstrate coordinated behavior until week 6-8 weeks following transection. Examination of the site of the intial lesion and analysis of the films suggests that animals that did not demonstrate behavioral recovery by week 6-8 had ceased to regenerate. This suggests that there is a critical period during which regeneration must take place if it is to be successful. All animals which exhibited spontaneous coordinated locomotion contained HRP labeled neurons in the medullary reticular formation. Other spinally projecting nuclei (e.g., red nucleus, vestibular nuclei) were not consistently labeled in animals exhibiting coordinated locomotion. (Supported by NS 24162 to SBS).

REGENERATING CGRP-IMMUNOREACTIVE DORSAL ROOT GANGLION (DRG) AXONS FORM TERMINALS IN TRANSPLANTS OF FETAL SPINAL CORD. Y. Itoh* and A.Tessler. VA Medical Center and Medical College of Pennsylvania, Philadelphia, PA 19129.

We have previously shown that the cut central axons of adult DRG neurons regenerate into transplants of embryonic spinal cord and that some of these elongating axons are immunoreactive for calcitonin gene-related peptide (CGRP). In the present study we used electron microscopic (EM) immunocytochemistry to compare the morphology of CGRP-immunoreactive axons regenerating into transplants with CGRP-labeled axons in normal dorsal horn.

Adult Sprague-Dawley rats received transplants of E14 or E15 spinal cord at the lumbar enlargement, and adjacent dorsal roots were cut and juxtaposed to the grafts. After 6 weeks to 3 months CGRP immunoreactivity was visualized both at the LM and EM levels. CGRP-labeled fibers arborized extensively within the transplants, and CGRP-immunoreactive axon terminals were seen. Most of these axons were unmyelinated and therefore resembled CGRP-labeled axons in normal dorsal horn. These results indicate that the axons of CGRP-containing DRG neurons which regenerate into transplants resemble those found in normal dorsal horn and form terminals within the transplants. Supported by the VA Medical Research Service, NIH grant NS 24707, and USAMRDC grant 51930002.

PERIKARYAL CHANGES IN SPINAL MOTOR NEURONS GIVING RISE TO LONG-TERM REGENERATED AXONS. C.M. Bowe and C.Y. Yu*, Section of Neurobiology, Brown University, Providence, RI 02912

Morphological and physiological abnormalities are reported in regenerated mammalian axons examined one year following sciatic nerve crush injury. In the present study, histological properties of rat motor neurons giving rise to regenerated axons were examined 14-16 months following unilateral sciatic nerve crush at 1-3 months of age and were compared to those of cells contralateral to the crush or in comparable cord segments from age-matched control rats. Regenerated and control sciatic motor neurons were identified by retrograde labelling with horseradish peroxidase applied to sciatic nerves distal to the site of crush. Many of the experimental motor neurons were enlarged and had thickened dendritic processes compared to control cells. Mean cell area ipsilateral to the crush lesions was larger than that determined for control cells (p-value <.001) despite representation of all control cell areas in the regenerated population. These data indicate that persistent or progressive morphological changes occur in regenerated mammalian motor neurons following simple crush injury.

267.15

REGENERATION OF DESCENDING PATHWAYS AFTER SPINAL CORD TRAUMA IN THE RED-EARED TURTLE. D. Santini* and R.H. Browner (SPON: D. Marbey). Dept. of Anatomy, NY Med. Coll., Valhalla, NY 10595.

Turtles were anesthetized with Brevital Sodium and maintained with oxygen, halothane, and nitrous oxide. The spinal cord was exposed at the caudal end of the first vertebral scute, the dura mater incised, and the spinal cord cut or crushed with a microscissor. The wound was rinsed and dental cement closed the bony opening. Turtles survived for the 15-, 30-, 45-, and 60-days with at least 2 animals/group. Four to 6 days before final survival time the spinal cord was exposed and cut at the caudal end of the 2nd vertebral scute. A gelfoam plug of HRP type VI (30%) was placed in the cut. The wound was washed and closed. At the survival times turtles were killed with Nembutal and transcardiaclly perfused with Reptilian Ringers, fixed and processed for HRP. Transverse sagittal frozen sections (45 µm) were made through the brains spinal cords, respectively. Alternate sections were stained with Cresyl Violet. The 30-, 45-, and 60-day survivors showed HRP product in the upper cervical spinal cord, nucleus raphe inferior, vestibular nuclei, and reticular nuclei. Supported by the Culpeper Found and NYMC Biomed Grant.

Regeneration of the Pontine Locomotor Region in the Sea Lamprey G. P. Swain* and J. Ayers.. Dept. of Biology and Marine Science Center, Northeastern University, East Point, Nahant, MA 01908.

The descending reticulospinal system in ammocoete, metamorphosing, and transformed sea lampreys was described using the HRP backfill technique (Soc. Neurosci. Abstr.12:318). The spinal cords of larvae and adults were completely transected at 25% of body length and in control specimens HRP-soaked GelFoam pledgets were inserted into the lesions. The HRP- implanted specimens were maintained ten to fifteen days for HRP transport. The HRP was developed using the Hanker-Yates method and whole mounts of the brains were made on glass slides. The HRP filled cells were segmented into 13 bilateral regions based on natural clusterings and quantified. A sample of HRP- filled normal brains (n = 60) serve as the control population for our regeneration experiments.

Regenerating specimens were allowed to recover to behavioral criteria. The recovery of swimming behavior may occur in as little as 50 days, depending upon the temperature at which the animals are held (Soc. Neurosci. Abstr.12:1574). At various times after the animals had recovered function a second transection was made distal to the initial regenerated lesion and an HRP-soaked pledget was inserted and processed as described above.

The extent of regeneration of particular cells or cell groups is quite variable with two exceptions: at least some cells in the anterior ischmic region (which probably correspond to the pontine locomotor region (PLR) cells described in cats, J. Neurophysiol 40:284) and the posterior cells of the bulbar region have regenerated in all recovered animals. Examination of regenerated cords of different recovery times indicates that regeneration of these neurons occurs continuously for periods of up to 15 months. As the process continues the proportion of cells which regenerate to the second lesion increasingly resembles that of the controls.

The majority of experimental animals (n=60) were backfilled from a second lesion made approximately 5 mm distal to the regenerated lesion. A number of animals (n=15) were backfilled from 3.0 cm distal to the lesion. These animals demonstrate that the same principle operates for long-distance regenerated axons: the longer the animal is allowed to recover, the more normal the descending projections become.

Supported by NSF Grant BNS-8406880.

267.17

ONE CLASS OF CENTRIFUGAL FIBERS TO THE RETINA IN CICHLID FISH DOES NOT REGENERATE. Anne C. Rusoff. Dept. of Biology, Montana State Univ., Bozeman, MT 59717.

The fish optic nerve is known for its ability to regenerate. One factor often implicated in this ability is the continued addition of ganglion cells to the retina into adulthood. The presence of factors which enable precursor cells to continue dividing into adulthood may facilitate regeneration, or it may be permitted because the system retains specific developmental mechanisms to enable new axons to find the tectum.

The fish optic nerve also contains centrifugal axons. In the cichlid fish Herotilapia multispinosa axons from the nucleus olfactoretinalis (NOR) project to the retina (as do axons from some diencephalic nuclei). Unlike the ganglion cells, all the centrifugally projecting cells in the NOR are born early. I have used this system to examine the requirements for regeneration.

One optic nerve of 6 month old fish was crushed. The presence of centrifugal fibers to the retina was assayed using an antibody to FMRFamide. (Some of the centrifugally projecting cells in the NOR stain with this antibody.) The NOR on both the normal and experimental sides of the brain stained intensely. Axons were visible entering both optic tracts. However, no FMRFamide + axons were visible entering the retina or in the normal terminal zone of efferents in the inner plexiform layer. This suggests that regeneration in the optic nerve is limited to axons from cell populations which are dividing. (EY06495.)

AXOTOMY OF RETINAL AXONS CAUSES GANGLION CELL DEATH IN YOUNG LARVAE OF ZEBRAFISH

C. Kuschel and C. A. O. Stuermer, Friedrich-Miescher-Laboratorium der Max-Planck-Gesellschaft, Tübingen, FRG

Ganglion cells in the visual system of adult fish regenerate their axons after axotomy and reestablish appropriate connections with the tectum. Whether ganglion cells possess this ability at all developmental stages was investigated using zebrafish of various ages.

In zebrafish embryos retinal axons have formed connections with their retinotopic target sites in the tectum at 72 h post fertilization (Stuermer 1988). The optic nerves were sectioned (ONS) in fish of 7 d and 1, 2 and 6 months of age. 10 to 20 d after ONS HRP was applied to the retina to label the regenerating axons in the optic nerve and tectum.

The nerves and tecta of the fish with nerve cuts at 1, 2 and 6 months exhibited HRP labeled regenerated axons in high density. However, labeled axons were absent from the nerves and tecta of fish with nerve cuts at 7 d, even after survival periods of 20 d.

Examinations of serial transverse sections (4 µm) of the fish's head revealed that most of the ganglion cells of the 7 d ONS larvae had degenerated except for those at the peripheral margin. At the periphery cells are added continuously during the ongoing growth of the fish's eye. In the 1, 2 and 6 months ONS fish all ganglion cells were well preserved. As typical for ganglion cells with regenerating axons, they were larger than controls.

Thus, in contrast to juvenile and adult fish, retinal ganglion cells in larval fish die after injury of their axons. This suggests that ganglion cells change their properties with progress in development.

267.19

DEGENERATION AND REGENERATION OF RAT OPTIC NERVE FIBERS FOLLOWING AXOTOMY: EFFECTS OF NGF. C. Comelli*[1], G. Carmignoto*[1] and L. Maffei*[2] (SPON: G. Calderini). [1]Fidia Neurobiological Research Laboratories, Abano Terme, Italy and [2]Institute of Neurophysiology, CNR, Pisa, Italy.

Intraocular repetitive injections of NGF are effective on the survival of rat retinal ganglion cells after section of the optic nerve. Here we report that NGF has also an influence on the processes of degeneration and regeneration at the level of optic nerve fibers. Experiments were performed in adult rats 7 weeks after intracranial bilateral transection of the optic nerves. Animals received intraocular repetitive injections of NGF (3 μg/injection) into the right eye and cytochrome c into the left eye. Ultrathin sections were collected from both optic nerves every 500 μm starting from the site of the transection. Results show that a) the NGF treated optic nerves have much more numerous myelinated fibers with respect to controls; b) the NGF treated optic nerves show different stages of degeneration and regeneration at any distance from the globe. The degeneration in the NGF treated eye seems slowed down and regeneration, as evaluated by the presence of unmyelinated fibers, accelerated. The bundles of unmyelinated fibers show features similar to those observed in the regenerating optic nerve of lower vertebrates. Myelinated fibers are found in sections as distant as 5.0; 5.5; 6.0; 6.5 mm from the globe. At these levels no fibers were detected in the controls.

DRUGS OF ABUSE II

268.1

IN VIVO MICRODIALYSIS STUDY OF DA FUNCTION IN THE RAT NUCLEUS ACCUMBENS DURING ACUTE AND REPEATED COCAINE SELF-ADMINISTRATION. F. Weiss, Y.L. Hurd*, G.F. Koob, N.-E. Anden* and U. Ungerstedt*. Res. Inst. of Scripps Clinic, La Jolla, CA 92037, Dept. of Pharmacology Karolinska Institute, Box 60 400, S104 01, Stockholm, Sweden.

Previous research suggests that dopamine (DA) in the nucleus accumbens (NAS) is critical in both cocaine (COC) reward and dependence. We sought to further examine the role of mesolimbic DA in COC reward using the in vivo microdialysis method in awake, drug self-administering rats. Extracellular levels of DA and its metabolites were monitored in dialysate collected from the NAS during 3 h self-administration (SA) sessions in "acute" (first-) or "subchronic" (10th SA session) drug conditions. After completion of microdialysis, COC effects on DA synthesis (DOPA accumulation) were estimated from tissue homogenates of NAS, anterior (AS) and posterior striatum (PS). DA and metabolites in the dialysate of "acute" rats were markedly elevated and rose to 250% of control levels by the end of the SA session. In contrast, DA and metabolite levels in "subchronic" rats were indistinguishable from those of naive, saline-treated rats. COC treatments did not alter DOPA accumulation in any of the brain regions sampled. DA tissue levels in the AS of "subchronic" rats were increased 50% over those of "acute" animals; no such differences were found in the NAS or PS. These results suggest that extracellular DA levels in the NAS decline with repeated COC administration in the absence of changes in DA synthesis or reductions in intracellular DA concentrations. The results may also provide a neurochemical basis for anecdotal reports of profound tolerance to COC's euphoric effects after one exposure in man.

268.2

COCAINE: AN IN VIVO MICRODIALYSIS STUDY OF ITS PHARMACOKINETIC PROPERTY IN AWAKE SELF-ADMINISTERING AND ANAESTHESIZED RATS. Y.L. Hurd*, J. Kehr*, F. Weiss, G.F. Koob, and U. Ungerstedt* (SPON: E. Stein). Karolinska Institute, Pharmacology Dept., Box 60 400, S-104 01, Stockholm, Sweden.

Cocaine (COC), a highly addictive agent with major social problems, has been widely investigated and suggested to have potent action on the dopaminergic system in the nucleus accumbens (NAS) and striatum (STR) In this study the pharmacokinetic property of COC was tested by in vivo microdialysis in halothane-anesthetized and in freely moving rats during self-administration (SA). Microdialysis not only allows measurement of endogenous neurochemicals in the extracellular space of discrete brain regions, but also exogenous compounds such as COC. Following an acute intravenous (iv) injection, COC was detected within the first 10 min perfusate in the NAS, STR and blood. The response pattern of the actual level of COC in the NAS and striatum after this injection was consistent with the characteristic DA response pattern induced by this drug. Since in vivo microdialysis makes it possible to monitor the neurochemical consequence during SA of drugs, the extracellular level of cocaine in the NAS of rats during 3h "acute" (first) and "subchronic" (10th SA) COC SA sessions was also analyzed. The role of excitatory and inhibitory amino acids on neurotransmission after COC SA was also studied.

268.3

MONOAMINE INCREASE BY COCAINE AND PROCAINE IN THE NUCLEUS ACCUMBENS: A MICRODIALYSIS STUDY. L. Hernandez and B. G. Hoebel, Dept. Psychol. Princeton Univ., Princeton, NJ 08544

We showed previously that cocaine delivered locally into the nucleus accumbens can increase extracellular dopamine [1]. Like cocaine, procaine can induce mood changes in humans and is self-administered by monkeys. It has a molecular structure similar to cocaine, and both are local anesthetics. Therefore, cocaine and procaine were infused through a microdialysis probe in the nucleus accumbens to compare their actions. In Exp. 1, cocaine microinjections (20 ug/0.5 ul) significantly increased extracellular dopamine, norepinephrine and serotonin. The effect on dopamine and serotonin was seven times greater than on norepinephrine. DOPAC decreased while 5-HIAA and HVA were not affected. In Exp. 2, equimolar solutions of cocaine and procaine were compared; but to avoid local mechanical trauma, they were infused by reverse microdialysis. The infusion was 50 ug of drug in 20 ul of perfusate to produce an estimated 5 ug diffusing into accumbens tissue during 20 min. Both drugs increased dopamine significantly, but cocaine was 2.4 times more potent than procaine. These results suggest (1) that the actions of cocaine in the nucleus accumbens might be mainly due to dopamine and serotonin increase, (2) that cocaine and procaine act directly on monoaminergic terminals in the nucleus accumbens to increase extracellular dopamine, and (3) that mood changes and addiction with procaine are partly due to its cocaine-like effect on the dopamine terminals in the nucleus accumbens.

COCAINE STUDIES ON DOPAMINE RELEASE IN NUCLEUS ACCUMBENS WITH IN VIVO ELECTROCHEMISTRY. II. SEROTONIN RELEASE STUDIES. F.T. Phelan* and P.A. Broderick. Dept. of Pharmacology, City Univ. of New York Med. Sch., and Depts. of Biol. & Psych., CCNY, New York, NY 10031. (Rm. J-910)

Preclinical studies indicate that cocaine euphoria may be mediated by mesolimbic dopaminergic pathways. Yet, euphoria is not blocked in cocaine abusers treated with neuroleptics (Gawin, F.H. Psychopharmacol. 90:142, 1986). To understand this phenomenon, in vivo electrochemical studies of dopamine release in nucleus accumbens were carried out before and after administration of cocaine to chloral hydrate anesthetized male, Sprague-Dawley rats (250-350g). Stearate indicator electrodes were stereotaxically implanted in nucleus accumbens; Ag/AgCl reference electrodes and stainless steel auxiliary electrodes were placed in contact with dura. Careful attention was paid to the animals' well being. Cocaine hydrochloride (20 mg/kg SC and IP) decreased accumbens dopamine release. The alterations in brain reward dopaminergic mesolimbic neuronal circuitry suggest that directionality of released dopamine may not be the critical step linking neurophysiology with euphoric behavior. Preliminary data show that serotonin release may be simultaneously decreased. This is important because terminal serotonergic neurons are destroyed by designer drugs of abuse. Sponsored by DHHS, PHS Grant #2-SO7-RR07132, PSC/CUNY Award #667234 and Upjohn Award #775755 to P.A. Broderick.

268.5

IN VIVO ELECTROCHEMICAL STUDIES OF MESOLIMBIC DOPAMINE RELEASE AFTER MORPHINE IN THE ANESTHETIZED AND FREELY MOVING RAT. P.A. Broderick. (SPON: L. Mitchell) Dept. of Pharmacology, City Univ. of New York Med. Sch., and Depts. of Biol. & Psych. CCNY, New York, NY 10031. J-910

The effect of morphine on dopamine release from nucleus accumbens was studied in chloral hydrate anesthetized and freely moving male, Sprague-Dawley rats (250-350g) in order to elucidate brain reward mechanisms in mesolimbic neuronal circuitry. In vivo electrochemical studies of nucleus accumbens dopamine release were carried out before and after the administration of morphine (5mg/kg SC and IP). Stearate indicator electrodes were stereotaxically implanted in nucleus accumbens; Ag/AgCl reference and stainless steel auxiliary electrodes were placed in contact with dura. Careful attention was paid to the animals' well being. A slow onset decrease in accumbens dopamine release was seen after morphine was administrated to the freely moving rat; no change occurred in the anesthetized rat. Homovanillic acid increased and serotonin virtually remained unchanged in the freely moving rat after morphine administration. The data contrasts opioid effects on brain reward circuitry in the anesthetized vis-á-vis the freely moving rat and provides insight into release mechanisms of addicting drugs. Sponsored by DHHS, PHS Grant #2-SO7-RR07132, PSC/CUNY Award #667234 and Upjohn Award #775755.

THE DOPAMINERGIC THRESHOLD OF COCAINE REWARD MEASURED BY IN VIVO MICRODIALYSIS. H.O. Pettit, L.C. Nicolaysen* and J. B. Justice Jr.; Department of Chemistry; Emory University; Atlanta, Georgia 30322

Extracellular dopamine (DA) concentrations in the nucleus accumbens were measured following intravenous administration of cocaine. Results from anesthetized animals indicate that the DA concentration increases in a dose dependent manner following a single infusion of cocaine. Data obtained from both anesthetized and behaving animals indicate that DA concentrations can increase and stabilize in a schedule dependent manner when cocaine is administered repeatedly in 15, 5 and 2.5 minute intervals. When animals self-administer cocaine or when cocaine is administered by an experimenter in regular intervals, DA concentrations stabilize at a level substantially above the basal level. The data and pharmacokinetic calculations indicate that the DA concentration increases for a short period following each infusion. It then falls to a "reward threshold" at which point the animal again self-administers the drug. Animals may regulate self-administration responding for cocaine in order to maintain DA levels above this threshold, yet titrate responding so that levels are maintained below a higher threshold. Results indicate a dopaminergic window of reward in the nucleus accumbens.

GENDER AND ESTROUS CYCLE AFFECT COCAINE SELF-ADMINISTRATION ON A PROGRESSIVE RATIO SCHEDULE. S.A.L. Bennett*, D.C.S. Roberts and G.J. Vickers*. Department of Psychology, Carleton University, Ottawa, Canada, K1S 5B6

Although it has been demonstrated that many of the behavioural responses to psychomotor stimulants are sex dependent and hormonally sensitive, no studies have examined the possibility that gender and the estrous cycle interact with drug reinforcement. The present experiment assessed the effect of these variables on two aspects of cocaine self-administration behaviour in the Wistar rat: the rate of cocaine intake on a fixed ratio one (FR1) schedule and the "breakpoint" on a progressive ratio (PR) schedule.

On a FR1 schedule, the lever-press response in rats permanently implanted with jugular cannulae resulted in a single intravenous injection of cocaine HCL (0.5mg/0.1ml/4s delivery). On a PR schedule the response requirements for the reception of a single injection of cocaine escalated logarithmically. Behavioural extinction was defined as the failure to earn an injection over an one hour period. The "breakpoint" was defined as the final ratio the rat completed prior to behavioural extinction.

On a PR schedule, the "breakpoints" of female rats were significantly elevated during estrus compared to other stages of the cycle. The effect of gender was evident in the finding that female rats displayed higher "breakpoints" than their male counterparts Measuring the rate of drug intake on a FR1 schedule failed to detect the influence of gender and the estrous cycle on cocaine self-administration. The results reveal that the PR method is capable of detecting the profound effect of gender and the estrous cycle on cocaine self-administration.

INCREASED MOTIVATION TO SELF-ADMINISTER INTRAVENOUS COCAINE FOLLOWING 5,7-DYHYDROXYTRYPTAMINE LESIONS OF THE MEDIAL FOREBRAIN BUNDLE IN THE RAT. E.A. Loh and D.C.S. Roberts, Dept. of Psych., Carleton Univ., Ottawa, Canada, K1S 5B6.

Both lesion and pharmacological evidence suggests that cocaine achieves its reinforcing action by inhibiting the reuptake of dopamine into terminals within the mesolimbic system. While cocaine also has an action at the serotonin reuptake site, it is not clear whether this property is directly involved in cocaine reward. The present study was designed to evalute whether depletions of forebrain serotonin would affect intravenous cocaine self-administration behavior in rats. Male rats were trained to self-administer cocaine on a progressive ratio schedule in which the first lever response of the daily session resulted in a drug infusion (0.5 mg/kg) while each subsequent injection required progressively more responses. The final ratio of responses per infusion at which self-administration behavior extinguished was defined as the "break-point". After baseline breakpoints were established, rats were injectioned stereotaxically with 5,7-DHT into the MFB (following desipramine pretreatment), then tested daily for 2-3 weeks. Control animals received vehicle injections. Animals in the 5,7-DHT group showed a marked increase in breakpoints. This suggests that the action of cocaine on serotonin terminals may be aversive, and that the depletion of forebrain serotonin results in a significant increase in the rewarding action of cocaine.

DELAYED INCREASE IN AMPHETAMINE-INDUCED RELEASE OF DOPAMINE FROM STRIATUM FOLLOWING REPEATED COCAINE ADMINISTRATION. N.R. Zahniser, J. Peris, P. Curella and L.P. Dwoskin, Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

Persistent behavioral sensitization involving the nigrostriatal dopaminergic pathway can be observed following a single dose of cocaine and is augmented following repeated administration. Another persistent change we have observed following treatment of rats with a single injection of cocaine (10 mg/kg; i.p.) is increased amphetamine-stimulated release of [^{3}H]dopamine ([^{3}H]DA) from striatal slices (Peris and Zahniser, Pharmacol. Biochem. Behav. 27:533-535, 1987). This 30-50% increase lasts at least two weeks. To test whether changes in striatal amphetamine-induced [^{3}H]DA release parallel behavioral changes and are augmented following repeated administration of cocaine, groups of male rats were injected once daily for 8 days with either saline or cocaine (10 mg/kg, i.p.). Cocaine-induced sensitization was confirmed by comparing the stereotypic behavior on the first and eighth day of treatment. Release from striatal slices preloaded with [^{3}H]DA was stimulated with amphetamine (2, 6 or 20 μM; 2.5 min) or 300 electrical pulses (5 Hz) and was measured 1, 3 or 7 days after the last injection. Surprisingly, the dose-response curves for amphetamine-induced release from the rats withdrawn from cocaine for 1 or 3 days were identical to those from the saline-treated rats. However, following the 7 days of withdrawal, a significant 20-30% increase in [^{3}H]DA release was observed at each dose of amphetamine tested. These results were similar to those previously observed 1-14 days after a single injection of cocaine. Release evoked by electrical stimulation was similar for control and treatment groups (4.5-5% total tissue tritium). These results demonstrate that at relatively short times after the cessation of repeated cocaine administration, there are no observable changes in amphetamine-induced [^{3}H]DA release; we hypothesize that short-term changes in DA autoreceptors obscure the augmentation of release. A longer withdrawal period is needed in order to observe the augmentation. Like sensitization, the lasting increase in amphetamine-induced [^{3}H]DA release is associated with increased dopaminergic transmission. Supported by USPHS DA04216.

COCAINE: BEHAVIORAL SENSITIZATION AND THE SEROTONIN SYNDROME. K. A. Cunningham. Dept Pharmacology/Toxicology, Univ Texas Medical Branch, Galveston, Tx 77550

Repeated cocaine treatment results in a progressive enhancement of cocaine-induced behaviors and increases the sensitivity of 5-HT neurons to cocaine (Cunningham et al., S N Abst 13: 1651, 1987). The aim of the present study is to analyze whether the 5-HT syndrome induced by 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) is altered in cocaine-sensitized rats; the "5-HT syndrome" is thought to be a result of direct or indirect stimulation of 5-HT-1 receptors. To this end, adult male rats were treated (ip) with cocaine (15 mg/kg) or saline (1 ml/kg) 2X/day for 7 days. On the last injection, behavioral sensitization was expressed in cocaine- (6.8 $\pm$ .3) but not saline-treated rats (2.4 $\pm$ .3; $p<.01$; Kilbey-Ellinwood scale). Twenty-four hours after the last injection, the behavioral response to 5-MeODMT (1-4 mg/kg) was scored every 5 min for 30 min. In preliminary experiments, the dose of 5-MeODMT which produced the 5-HT syndrome in 50% of rats (ED50) was reduced in cocaine- (1.3 mg/kg) as compared to saline-treated rats (2.3 mg/kg), although the duration of the 5-HT syndrome appeared unchanged (5-12 rats/group). These studies suggest that cocaine treatment which results in behavioral sensitization is possibly associated with modifications of receptors which mediate the 5-HT syndrome. Studies are underway to replicate and extend these initial findings. Supported by DHHS RR07205.

COMPARISON AND CONTRAST OF ADDICTIVE AGENTS ON CNS STRUCTURES. I: COCAINE AND MORPHINE EFFECTS FOLLOWING MICROIONTOPHORESIS INTO CAUDATE, NUCLEUS ACCUMBENS AND MEDIAL PREFRONTAL CORTEX. J.-T. Qiao, R.C. Wiggins, P.M. Dougherty* and N. Dafny (SPON: A.H. Lockwood). Dept. of Neurobiology and Anatomy, The Univ. of Texas Medical School at Houston, 77225.

Cocaine and morphine have greatly different acute effects upon behavior. However, these agents both share the characteristic of rapidly inducing a state of dependence. The objective of this study was to investigate the effects of both these agents following microiontophoretic application upon the single neurons of brain regions implicated in the establishment of this phenomenon. Urethane-anesthetized male Sprague-Dawley rats were used. An array of 5 micropipettes were used for drug injections. A total of 50 neurons were studied from these brain areas. In the majority of the cells, cocaine depressed neuronal activity, while morphine elicited excitation from the same cells. Three receptor antagonists (sulpiride, naloxone and methysergide) demonstrated that cocaine effects were reversed only by sulpiride, and those of morphine were reversed only by naloxone. Thus, for these brain regions, these two agents appear to have distinct mechanisms of action.

268.12

COMPARISON AND CONTRAST OF ADDICTIVE AGENTS ON CNS STRUCTURES. II: COCAINE AND MORPHINE EFFECTS ON HABENULA AND THE PARAFASICULUS THALAMI. R.C. Wiggins, J.-T. Qiao, P.M. Dougherty* and N. Dafny Dept. Neurobiol. & Anat., The Univ. of Texas Medical School at Houston, 77225.

Cocaine has quickly become the most abused drug in the USA, replacing opiates such as morphine. As a part of our effort to determine if cocaine and opiates induce a state of dependence through similar means, we have undertaken an investigation of the effects of these agents in several brain regions following microiontophoretic application. Sprague-Dawley rats anesthetized with urethane and mounted in a stereotaxic frame were used. An array of 5 micropipettes were used for drug injection; 63 units were recorded. The agents were most often found to have opposing effects in habenula and parafasciculus regions, as cocaine most often induced a suppression, and morphine induced excitation of single unit activity. Moreover, the cocaine antagonist desipramine, and the opiate antagonist naloxone, did not show interactive effects upon these agents. These results further underscored the conclusions that cocaine and morphine induce states of dependence that are distinct in both behavioral as well as neuronal characteristics.

268.13

COCAINE WITHDRAWAL IN RATS: INCREASE IN INTRACRANIAL SELF-STIMULATION THRESHOLDS AFTER CHRONIC COCAINE SELF-ADMINISTRATION. A. Markou, C.B. Hubner and G.F. Koob. Dept. of Psychology, Univ. of California, San Diego, CA 92093 and Scripps Clinic and Research Foundation, 10666 North Torrey Pines Road, BCR 1, La Jolla, CA 92037

Cocaine use frequently occurs in episodic, prolonged binges. Immediately following a period of cocaine use, the person suffers from severe depressive symptoms mixed with irritability and anxiety (post-cocaine "crash") which constitute cocaine withdrawal. The present study is an attempt to develop an animal model of post-cocaine depression or withdrawal.

Male Wistar rats were implanted with self-stimulating electrodes in the lateral hypothalamus and intravenous self-administration catheters in the jugular vein. At several time points after prolonged periods (6, 12, 24 and 48 hours) of cocaine self-administration, the animals' self-stimulating current thresholds are assessed. Current self-stimulation thresholds are assessed with a discrete trial procedure which is a modification of Kornetsky and Esposito's procedure (Federation Proceedings, 38, 2473-2476, 1979). It is presumed that self-stimulation thresholds are a measure of an animal's "hedonic-anhedonic" state.

Control animals that have never self-administered cocaine tend to have stable baseline self-stimulating thresholds over time. Preliminary data indicate that prolonged periods of cocaine self-administration lead to an elevation of self-stimulating thresholds above pre-drug baseline levels. Hence, termination of chronic cocaine self-administration may result in an anhedonic state.

268.14

LESIONS OF THE DORSOMEDIAL NUCLEUS OF THE THALAMUS PRODUCE DECREASES IN COCAINE SELF-ADMINISTRATION IN THE RAT. C.B. Hubner and G.F. Koob. Scripps Clinic and Research Foundation, La Jolla, CA. 92037.

Previous studies from our laboratory have demonstrated that 1) presynaptic dopamine terminals within the region of the nucleus accumbens (N.acc.), and 2) the ventral pallidum (V.Pall.), a major recipient of N.acc. efferent fibers, are critical in mediating cocaine's reinforcing effects. Efferent projections from the V.Pall. to the dorsomedial nucleus of the thalamus (DMT) have been described and the purpose of this study was to assess the importance of this second-order efferent projection from the N.acc. in maintaining cocaine self-administration.

Rats trained to self-administer 0.75 mg/kg/inj cocaine on an FR 5 schedule in 3 hour daily sessions received either bilateral injections of vehicle (n=8) or ibotenic acid (n=6) into the DMT. When tested 5 days post-lesion, subjects in the lesion group showed a significant decrease in cocaine self-administration when compared to vehicle control animals. In contrast, similar lesions (n=5) of the hippocampus (HPC) did not produce a significant effect.

These results demonstrate that V.Pall. efferent fibers to the DMT play an influential role in cocaine self-administration. Further, the HPC does not appear to be a substrate for psychomotor stimulant reinforcement.

24 HOUR EFFECTS FOR A SINGLE LOW DOSE OF BROMOCRIPTINE. I. Extein,* M.S. Gold, D.R. Sweeney. Fair Oaks Hospital, Summit, NJ 07901.

We have recently reported in a double-blind, random assignment, crossover study superiority for bromocriptine over DMI in the acute treatment of cocaine withdrawal. To further evaluate the efficacy of the dopaminergic agonist bromocriptine in cocaine abstinence, we studied within 72 hrs. of hospital admission 12 young adults (3 women, 9 men) with DSM-III-R cocaine dependence and clinically significant cocaine withdrawal symptoms. Patients gave written informed consent for oral administration of a single low-dose of bromocriptine (1.25 mgs) utilizing a single-blind design. Craving, mood, and energy were self-rated before and 1,3,5,8,12 and 24 hrs. after bromocriptine on 100 mm lines. From pre-treatment baseline ratings bromocriptine's anti-withdrawal effects were noted at 1 hour. Peak medication effects were demonstrated at 3-6 hours. Bromocriptine reduced mean craving 48% ($p<.05$ paired t-test), improved depressed mood 38% ($p<.10$). At 24 hrs. bromocriptine effect was marked and significant mean ($p<.05$) with craving remaining at 50% of baseline. The higher baseline symptomatology the greater the reduced craving ($p<.01$) and improved depressed mood and energy ($p<.05$). A single low-dose of bromocriptine has acute effects beginning one hour after administration, peaking at 3-6 hrs. but continuing for at least 24 hrs. This response suggests DA supersensitivity and supports the DA hypothesis for cocaine withdrawal symptoms.

268.16

AN OPEN TRIAL OF MAZINDOL TO TREAT COCAINE CRAVING IN A METHADONE MAINTENANCE CLINIC. F.H. Gawin*, T.R. Kosten*, , B. Schumann*, D. Wright*, P. Berger*. (SPON: L. Marks). Dept. of Psychiatry, Yale Univ., New Haven, CT 06519

Mazindol is a widely prescribed, well tolerated anorectic drug that shares several preclinical properties with cocaine. It is a potent dopamine uptake inhibitor, induces similar stereotopy and most notably is self-administered in a variety of species but has not been reported to be abused in man. Recently it was reported that there may be a receptor on the dopamine transporter mediating the self-administration of cocaine-like drugs. Because mazindol is thought to work preclinically through the same receptor as cocaine but clinically lacks abuse potential we decided to evaluate its effect on cocaine craving in an open pilot of 10 DSM-III cocaine addicts in our methadone maintenance program. Data will be presented on daily craving scales, biweekly urine toxicology, and weekly cocaine inventories. Our preliminary impressions are that mazindol is exceedingly well-tolerated with little abuse potential of its own. It appears to have some anti-craving efficacy. In those patients who have abused cocaine while on mazindol no adverse interaction was noted although mazindol did not antagonize cocaine euphoria.

268.17

TREATMENT OF ACUTE COCAINE TOXICITY. M.S. Gold, J.R.L. Ehrenkranz,* J.M. Jonas,* C.A. Dackis.* Fair Oaks Hospital, Summit, NJ 07901; Franklin Diagnostics, Inc., Morristown, NJ 07960.

Emergency room visits linked to cocaine have increased by 500% since 1982-1983 and a corresponding rise in fatal reactions to cocaine has occurred. We developed an animal model, using male beagles, to investigate the pathophysiology and therapy of acute cocaine toxicity. Twenty-eight animals received 1 mg/kg/min (-)-cocaine HCl (provided by the National Institute on Drug Abuse) in normal saline by intravenous infusion until a generalized motor seizure occurred while continuously electrocardiographically and neurologically-monitored for 15 minutes prior to, during and for 1 hour after each infusion. All 28 animals exhibited deranged temperature regulation, characterized by a progressive rise in core body temperature into the hyperpyrexic range occurring after cocaine infusion was discontinued and associated with peripheral vasoconstriction and absence of panting. We studied the effects of lowering core body temperature on cocaine toxicity by immersing the trunk and extremities of each animal in 12°C. water for 15 minutes following cocaine administration. Ventricular tachycardia, ventricular fibrillation, and death seen in controls was not seen in any of the immersed animals. Based upon this animal model we conclude that life-threatening cardiac effects and acute, fatal reactions to cocaine result from hyperpyrexia. Cocaine toxicity may be safely and effectively treated by physical cooling.

268.18

EFFECT OF COCAINE ON IN VITRO NORADRENERGIC- AND PHORBOL ESTER-STIMULATED HYPOTHALAMIC GnRH RELEASE. TS King, RS Schenken*, and MA Javors*. Depts of CSB, OB-GYN, and Psychiatry, Univ Texas Hlth Sci Ctr, San Antonio, TX 78284.

Although a common drug of abuse, cocaine's effects on hypothalamic neurotransmitter activities, GnRH secretion, and reproductive function have not yet been studied. The purpose of this study was to examine the effects of cocaine on in vitro noradrenergic- and phorbol ester-stimulated GnRH release in Sprague-Dawley rats. Bilaterally ovariectomized rats were injected subcutaneously daily for 2 weeks with saline vehicle or with 10 mg/kg cocaine. Each of 2 days prior to sacrificing the rats, each rat was "primed" by s.c. injection of 50 ug/kg estradiol. Hypothalamic tissue slices were prepared and placed in 0.1 ml microchambers and perfused with modified Krebs-Ringer buffer (pH 7.4) using a programmable perfusion system. Our results are as follows: (1) Ten min pulses of 10^{-7} M progesterone increased norepinephrine (NE) and serotonin (5HT), but not dopamine (DA), release in the control group. In the cocaine-treated animals, basal release of NE and 5HT was elevated over controls and pulsed progesterone caused increased NE, but not 5HT or DA, release compared to controls. (2) Ten min pulses of 100 nM NE increased GnRH release in control and cocaine-treated animals, but the response was less in the cocaine group. (3) A 10 min pulse of phorbol-12-myristate-13-acetate (PMA) induced dramatic increases in GnRH release in the control group, but had no effect in the cocaine-treated animals. These results suggest that cocaine may down-regulate pulsatile hypothalamic NE release and, thereby, pulsatile GnRH release. Additionally, cocaine inhibits GnRH released through a PMA-stimulated protein kinase C mechanism, possibly via cocaine's adverse effects on plasma membrane Na^+ transport. (Supported by NIH grant number HD-10102 [Neuroendocrine core]).

COCAINE INDUCED REDUCTIONS IN D1 RECEPTOR DENSITY AND BEHAVIOR DO NOT OCCUR IN THE PRESENSE OF MAGNESIUM. K.M. Kantak and M.J. Potegal. Dept. Psychol.,Boston Univ.,Boston, MA 02215 and Dept.Dev.Psychobiol., New York State Psychiat. Inst., New York, NY 10032.

Magnesium (Mg^{2+}) has behavioral actions similar to acute cocaine. One previous study showed the reversal of the disruptive effect of chronic cocaine on aggression following acute $MgCl_2$. This suggests an interaction between Mg^{2+} and cocaine at the dopamine receptor. Presently, aggression in mice was measured after 15 days of saline, cocaine, $MgCl_2$, or cocaine + $MgCl_2$. Parallel drugs treatments in rats were administered and D1 receptor density was determined autoradiographically in the substantia nigra (SN) and striatum (STR) using ^{3}H-SCH 23390 in 0.16 to 4.5 nM conc. Cocaine significantly reduced aggression to 53% of baseline. This disruption was not observed with Mg^{2+}. D1 receptor density in the SN and STR following cocaine showed a significant 10% mean reduction from control.Cocaine also induced a 14% reduction in individually determined K_d's in the STR. Such reductions were not found with Mg^{2+}. These data suggest that the disruption in behavior might be related to alterations in D1 receptors which are not present following Mg^{2+}.

DIFFERENT MECHANISMS UNDERLIE THE ACQUISITION AND EXPRESSION OF HEROIN-INDUCED PLACE PREFERENCE. M. LE MOAL, L. STINUS* and T.H. HAND. INSERM U.259 - Université de Bordeaux II, Rue Camille Saint-Saëns, 33077 Bordeaux Cedex, France.

Heroin is known to produce a preference for stimuli reliably paired with its administration or predictive of its onset of action. However, little is known about how this conditioned place preference (CPP) develops, and there has been no investigation of what underlies the post- conditioning expression of this CPP.

Using a novel 3-compartment place conditioning apparatus, we confirmed that heroin (50-1000 μg/kg) produces a strong and long-lasting (8 weeks) CPP. Pretreatment on all 6 days of conditioning with naloxone (50 μg/kg), clonidine (20 μg/kg) or pimozide (100 and 200 μg/kg) prevented the development of CPP induced by 250 μg/kg heroin. We then attempted to determine whether these same treatments could disrupt an already established CPP. Animals were subjected to the conditioning procedure with 250 μg/kg heroin, and were given naloxone (50 μg/kg and 1 mg/kg), clonidine (10-100 μg/kg) or pimozide (50-200 μg/kg) prior to the test session only. Only the highest doses of pimozide and clonidine disrupted the established CPP ; naloxone failed to do so, even at 1 mg/kg. Together, these results suggest that while opiate and catecholamine systems are involved in the acquisition of heroin CPP, the post-conditioning expression of CPP in drug-free animals is not opiate-mediated, only partially catecholamine-mediated, and attributable to largely unidentified mechanisms. These data do not support the position that the conditioned effects of opiates are related in the release of endogenous opioid compounds.

269.2

DOPAMINE AND PREPARATORY FEEDING BEHAVIOUR: EFFECTS OF METOCLOPRAMIDE AND THIORIDAZINE. J.R. Blackburn[1], A.G. Phillips[1], and H.C. Fibiger[2], Depts. of Psychology[1] and Neurological Sciences[2], University of British Columbia, Vancouver, BC, Canada, V6T 1Y7.

A conditional stimulus (CS+) that has been consistently presented prior to the delivery of meals will elicit conditioned preparatory responses from rats. In particular, rats will enter the niche where food is to be delivered. Previous experiments have determined that these responses are severely attenuated by the dopamine (DA) receptor antagonist pimozide. We now report the effects of two additional DA receptor blockers. Metoclopramide (MET) is a weak antipsychotic agent associated with extrapyramidal side effects (EPSEs). In contrast, thioridazine (THIO), an "atypical" neuroleptic, is a potent antipsychotic agent that does not produce EPSEs at clinically effective doses. MET decreased entries into the niche (≥5.0 mg/kg) and the total time spent in the niche (≥5.0 mg/kg) prior to food delivery. In contrast, once food was delivered the animals entered the niche and consumed the meal in a normal manner. In a separate study, food intake was decreased only by ≥7.5 mg/kg MET. Thus consummatory behaviour, unlike preparatory responses, was not disrupted by MET. THIO (10-30 mg/kg) produced a non-significant attenuation of preparatory responding. The more pronounced impact of MET may be related to its putative preferential affinity for nigrostriatal DA receptors.

269.3

CONDITIONED LOCOMOTION FOLLOWING MICRO-INJECTIONS OF AMPHETAMINE INTO THE NUCLEUS ACCUMBENS.
G.D. Carr & A.G. Phillips. Department of Psychology, University of British Columbia, Vancouver, B.C., Canada. V6T 1Y7

Increased locomotor activity is a prominent unconditional effect of systemic amphetamine injections. Repeated pairings of amphetamine with salient stimuli result in conditioned locomotion upon subsequent exposure to the stimuli alone. Since unconditional locomotion can be produced by micro-injecting the drug directly into the nucleus accumbens, the present study examined whether conditioned locomotion would also result from these injections.

Male hooded rats had either amphetamine (10 ug in 0.5 ul) or a saline vehicle injected into the nucleus accumbens and were then placed in an activity chamber. Relative to saline, the intra-accumbens amphetamine injections produced significantly greater locomotor activity over six pairing days. When the rats were subsequently placed into the chambers without prior microinjections, those that had previously received the amphetamine injections displayed significantly greater activity than did the saline-injected group. This demonstrates that stimuli that are paired with intra-accumbens amphetamine can elicit conditioned locomotion.

269.4

AMPHETAMINE INJECTED INTO THE MEDIAL PREFRONTAL CORTEX ATTENUATES THE LOCOMOTOR ACTIVATING EFFECTS OF AMPHETAMINE IN THE N. ACCUMBENS.
J.-P. Tassin*, P. Vezina, G. Blanc* and J. Glowinski* (SPON: T.M. Jay). Chaire de Neuropharmacologie, INSERM U. 114, Collège de France, 75231 Paris Cedex 05, France.

Support for an inhibitory role of frontal cortical dopamine on locomotor behavior has come from lesion studies showing that depletion of dopamine in this site correlates well with the appearance of hyperactivity (e.g., Tassin et al., Brain Res., 141:267, 1978). In the present study, the effect of amphetamine injection into the medial prefrontal cortex (PFC) on the hyperactivity produced by a similar injection into the n. accumbens (NAC) was assessed. Rats were implanted with chronic bilateral injection cannulae aimed at both the PFC and NAC and their locomotor activity measured on four separate occasions: after injections of amphetamine into the NAC (1.5 µg/0.5µl saline/side) and saline into the PFC, amphetamine into the PFC (2.5µg/0.5µl saline/side) and saline into the NAC, amphetamine into both sites and saline into both sites (control). Order of injection was counterbalanced across subjects. Amphetamine injected into the PFC alone had little or no effect while in the NAC alone it produced a mean 314% increase in locomotion compared to control injections. However, when amphetamine was injected into both sites, PFC amphetamine reduced the hyperactivity produced by NAC amphetamine alone injections by a mean 42.2%. Although an effect of PFC norepinephrine cannot yet be ruled out, these results, together with those of lesion studies, support the view that PFC dopamine plays an inhibitory role in locomotor behavior.

269.5

UNILATERAL 6-OHDA LESION OF THE NIGROSTRIATAL SYSTEM OF THE RAT: DIFFERENT FUNCTIONAL CONSEQUENCES FOLLOWING NEONATAL AND ADULT LESION.
N. Abrous*, M. Le Moal and J.P. Herman* (SPON: L. Tapia-Arancibia). INSERM U.259 - Université de Bordeaux II., 33077 Bordeaux, France.

The nigrostriatal dopaminergic pathway was destroyed by the stereotaxic injection of 6-OHDA into the lateral hypothalamus of neonatal (PD2; 8 µg; NL group) or adult (2x6 µg; AL group) male rats. Rotational behavior, postural assymetry, lateralization of arm choice in a Y-maze, sensory neglect and paw use in a food-reaching task were tested 3 months after the lesion.

Biochemical measurement made four months after the lesion indicated a 97 % drop of dopamine content in the ipsilateral striatum as compared to the contralateral control side, 94 %, 54 % and 80 % in the nucleus accumbens, medial frontal cortex and amygdaloid complex resp. These value were comparable to those measured following adult age lesion. NL rats presented a contralateral spontaneous rotation following mild stress, which was potentiated by haloperidol. Animals of both groups presented a ipsilateral rotation upon treatment with d-amphetamine (5 mg/kg) and a contralateral rotation following injection of apomorphine (0.1 mg/kg). However the latter was less pronounced in the NL group. Animals of the AL group displayed a marked contralateral deficit: lack of contralateral choice in the Y-maze, contralateral sensory deficit and inability to use contralateral paw to retrieve food from a distant tray. These deficits markedly attenuated (paw use, sensory neglect) or missing (Y-maze). These results suggest a functional replacement by some other neuronal system following the neonatal lesion of the dopaminergic neurons.

NUCLEUS ACCUMBENS CONTRIBUTES TO THE DIRECTION OF DOPAMINE-DEPENDENT CIRCLING.
L.M. Colle and R.A. Wise. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Quebec H3G 1M8.

Asymmetric activation of dopamine systems results in circling behavior. Direction and speed of circling are traditionally associated with caudate and nucleus accumbens (NAS) activation, respectively. Two experiments indicate a role for NAS in direction. First, animals with electrolytic lesions restricted to the NAS circled toward the lesion side when given d-amphetamine (d-A; 1.25 mg/kg i.p.) one day to 12 weeks post-lesion. The rate of circling ranged from 1 to 3 circles a minute in a 60 minute test. Second, NAS microinjections of d-A (2.5, 5.0, and 10.0 ug in 0.5 ul) caused circling away from the injection; l-amphetamine was ineffective. Ventral caudate injections caused behavioral activation but ipsilateral and contralateral circling were equally increased. Taken together these data suggest that asymmetric activation of the NAS is sufficient to induce a directional bias in animals, a role traditionally attributed to the caudate.

EFFECTS OF AMPHETAMINE AND APOMORPHINE BEFORE AND AFTER RECOVERY FROM BEHAVIORAL ASYMMETRIES INDUCED BY UNILATERAL VIBRISSAE REMOVAL
H.Milani*, H.Steiner*, R.K.W.Schwarting and J.P.Huston Inst. Physiological Psychology, Univ. Düsseldorf, D-4000 Düsseldorf, F.R.G.

Unilateral vibrissae removal (UVR) induces changes in the nigrostriatal projections, which are time-related to the recovery of asymmetries in spontaneous open-field behavior. Results of previous experiments suggest a close relationship between vibrissae function and dopaminergic systems in the basal ganglia. The present experiments were undertaken to analyze the influence of the dopaminergic agonists apomorphine (APO) and amphetamine (AMPH) on behavioral asymmetries after UVR.

Behavioral testing was performed either 4 hours after one UVR or after 9 days of daily UVR. Rats tested after 4 hours of UVR showed more peritaxis (facial scanning of the walls of the open-field) with the intact vibrissae side under APO and AMPH. Also, turning occurred towards the intact side under APO. After 9 days of UVR, however, the behavioral asymmetries were reversed as more peritaxis with the shaved side was observed under APO and AMPH.

These results are discussed in context of other results suggestive of an analogy between effects of unilateral 6-OHDA lesions and unilateral vibrissae removal.

A BEHAVIORAL INVESTIGATION OF GBR 12909: EFFECTS ON MOTOR ACTIVITY, FIXED INTERVAL RESPONDING, AND CONDITIONED REINFORCEMENT.
A.E. Kelley and C.G. Lang*, Dept. of Psychology, Harvard University, Cambridge, MA 02138

GBR 12909 (GBR) is a potent and selective dopamine uptake inhibitor. In the present studies, the behavioral effects of GBR were investigated in rats. We first studied the locomotor stimulating properties of GBR. GBR (1,10,20 mg/kg) elicited dose-dependent enhancement of motor activity, lasting approximately 4 hours. Chronic treatment with a high dose (20 mg) resulted in a long-lasting subsequent sensitization to subthreshold (1,3 mg/kg) doses of GBR. In a test of fixed-interval responding for food reinforcement GBR (1,10,20 mg/kg)produced a dose-depedent increase in lever-pressing and disrupted timing behavior. This effect was not clearly rate-dependent, although low rates were affected more than high rates. In a final experiment, hungry rats were conditioned to associate presentation of a food pellet with a compound stimulus (light and click). After 2 weeks of training, two levers were present in the box for the first time. Responding on one (CR lever) resulted in presentation of the compound stimulus, but no food. Responding on the other lever (NCR lever) produced no consequences. GBR (1, 10, 20 mg/kg) selectively and markedly enhanced responding on the CR lever. These experiments demonstrate that GBR is a potent psychostimulant drug. GBR may be a very useful compound for studying the behavioral effects of cocaine-like substances.

CHANGES IN AMPHETAMINE STIMULUS GENERALIZATION FUNCTIONS PRODUCED BY APOMORPHINE, HALOPERIDOL, COCAINE AND ELECTRICAL STIMULATION OF THE VTA. J.P. Druhan, H.C. Fibiger and A.G. Phillips. Dept. Psychol.; Div. Neurol. Sci., Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Rats were trained to discriminate 1.0 mg/kg amphetamine (ip) from saline, and then tested for generalization to a range of amphetamine doses (0.0, 0.25, 0.5 & 1.0 mg/kg) administered either alone, or in combination with apomorphine (0.05, 0.1, 0.15 and 0.2 mg/kg, sc), haloperidol (0.1 & 0.125 mg/kg, ip), cocaine (2.5 & 5.0 mg/kg, ip) or electrical stimulation (15 & 20 uA) of the ventral tegmental area (VTA). Low doses (0.05 & 0.1 mg/kg) of apomorphine attenuated the amphetamine cues resulting in rightward shifts in the generalization functions, whereas higher doses of apomorphine (0.15 & 0.2 mg/kg) substituted for the amphetamine cues. Haloperidol antagonized the amphetamine cues, thus shifting the generalization functions to the right. Finally, cocaine and VTA stimulation potentiated the amphetamine cues, causing the generalization functions to be shifted to the left. These shifts in the amphetamine generalization functions are consistent with the actions of the drugs and VTA stimulation on dopamine neurotransmission, therefore confirming a role for dopamine neurons in mediating the cue properties of amphetamine.

ENHANCEMENT OF DA ACTIVITY IN ACCUMBENS BUT NOT FRONTAL CORTEX FACILITATES SELF-STIMULATION IN MFB. M. E. Olds. Biol. Div., 216-76, Caltech, Pasadena, CA 91125.

The effects of selective enhancement of dopamine (DA) transmission in n. accumbens (ACC) or frontal cortex (FC) on self-stimulation (SS) of the medial forebrain bundle (MFB) and gross motor activity were investigated. Bilateral injections of 2.0 µl/side of a solution containing DA + pargyline + amphetamine into ACC of self-stimulators induced first a facilitation of responding lasting 90-120 min, then a depression lasting several hours, followed by transient facilitation/depression phases and a return to baseline rates. The same injections given to non-self-stimulators led to increases in lever-pressing which did not, however, meet SS requirements. Injections of amphetamine or in combination with pargyline in ACC induced similar effects but of smaller magnitude and duration. Injections of pargyline or DA, or their combination, in ACC were not effective in inducing a facilitation of SS or an increase in gross motor activity. Bilateral injections of DA + pargyline + amphetamine in FC of self-stimulators either had no effects or attenuated responding for the MFB reward. In non-self-stimulators, such injections reduced the already low response rate. These findings lend support to the notion that the DA projection to ACC, but not FC, has the capacity to regulate reinforcement produced by MFB stimulation.

BEHAVIORAL EFFECTS OF DOPAMINERGIC AGONISTS AND ANTAGONISTS IN THE PREFRONTAL CORTEX. G. E. Jaskiw, G. Christison*, W. J. Freed and D. R. Weinberger. Clinical Brain Disorders Branch, NIMH, Washington, D.C. 20032.

Though evidence for increased subcortical DA transmission following chronic dopaminergic (DA) denervation of medial prefrontal cortex (MPFC) has been presented (Pycock, CJ et al, Nature 286:74, 1980) the modulation of subcortical DA systems by cortical DA projections remains poorly understood. To elucidate this behaviorally, bilateral indwelling cannulae were implanted in the MPFC of male rats. Rotational bias (complete turns in one direction/total turns) was determined by administering d-amphetamine (1.5 mg/kg i.p.) (AMP) prior to one hour of rotometer testing. In different sessions over 21 days rats received 0.5µl injections of vehicle (VEH), sulpiride 10µg (SUL) or apomorphine 10µg (APO) into MPFC, following which either spontaneous or AMP accentuated rotational activity was used to reassess rotational bias. SUL and APO were administered unilaterally and accompanied by contralateral injection of VEH.

Rats who received SUL on the side opposite to their preferred side of rotation 10 min before AMP increased their rotational bias towards the injection side (non-preferred side), from .13 to .59 ($p < .004$). In contrast, following unilateral APO rats showed a greater spontaneous bias contralateral to the injection. Bilateral injections of VEH did not affect rotational bias. Though rotation is a complex phenomenon most studies suggest that DA activity in the striatum is a major determinant of rotational bias. Our findings confirm those of others (Morency, MA et al, J Neurosci 7:812, 1987) and suggest that under some conditions changes in DA activity within the striatum may parallel those within the MPFC.

269.13

EFFECTS OF COCAINE ON MULTIVARIATE MEASURES OF SPONTANEOUS LOCOMOTOR ACTIVITY IN MICE. D.M. Fritsch*, J.H. Porter and M.G. Hadfield. Depts. of Biology, Psychology, and Pathology, Virginia Commonwealth Univ., Richmond, VA 23284.

Adult, male mice were administered cocaine (0, 2.5, or 5.0 mg/kg, i.p.) for 7 consecutive days 15 min prior to a 10 min test session. Spontaneous motor activity was measured in a Digiscan Activity Monitor (Omnitech Electronics) that measured horizontal activity (number of horizontal beam interruptions), horizontal distance (cm), number of horizontal movements, stereotypy activity, number of stereotypies, revolutions, and vertical activity.

Analysis of the data revealed a significant dose-dependent increase in horizontal activity and horizontal distance travelled; however, there was no change in the number of horizontal movements (movement episodes separated by at least one sec). Cocaine also produced a significant dose-dependent increase in stereotypy activity, but the number of stereotypy episodes was not changed. The number of revolutions (clockwise and counter-clockwise combined) was significantly increased. There were no significant changes in vertical activity. Both horizontal activity and stereotypy activity increased over the 7 days of drug administration, but the other activity measures remained stable. These findings demonstrate the usefulness of automated systems for measuring motor activity.

269.14

AMPHETAMINE DISRUPTS PREPULSE INHIBITION OF ACOUSTIC STARTLE RESPONSE IN RATS: REVERSAL BY NUCLEUS ACCUMBENS DENERVATION. R.S. Mansbach (1) N.R. Swerdlow (1) M.A. Geyer (1), G.F. Koob (2) and L. Pulvirenti (2) (1) Dept. Psychiatry, UCSD Sch. of Med., San Diego, CA 92093; (2) Preclin. Neurosci., RISC, La Jolla, CA 92037.

The amplitude of the acoustic startle response [ASR] is depressed when the strong acoustic startle pulse is preceded by a weak acoustic prepulse. This "prepulse inhibition" [PPI] appears to be modulated in rats by brain dopamine [DA] activity, since DA agonists disrupt PPI, an effect reversed by DA antagonists. PPI is also disrupted in schizophrenic patients, where this loss may reflect endogenous DA overactivity. We examined the anatomical substrates of the DA modulation of PPI.

Rats (n=16) received infusion of either vehicle or 6-hydroxydopamine (6OHDA) bilaterally into the nucleus accumbens [NAC]. 1 wk later, animals were treated with either saline (SAL) or amphetamine [AMPH; 2.0 mg/kg sc free base] and ASR amplitude was measured during acoustic pulses (118 dB) alone, and during pulses preceeded 100 msec earlier by a weak (80 dB) prepulse. 1 wk later, the procedure was repeated, with treatments (SAL and AMPH) reversed within each animal. All animals were then sacrificed and analysis revealed 85% depletion of NAC DA in 6OHDA-infused rats.

AMPH injections significantly potentiated ASR amplitude in both vehicle- and 6OHDA-infused rats. AMPH injections resulted in a near-total disruption of PPI in vehicle-infused rats; this effect of AMPH was completely reversed in NAC 6OHDA-infused rats. These findings suggest a pharmacological dissociation of the effects of AMPH on ASR amplitude and PPI. These results are also consistent with our previous reports implicating NAC DA activity in the modulation of PPI, and support the notion that abnormalities of forebrain DA activity may underlie the loss of PPI in schizophrenic patients.

269.15

APOMORPHINE FACILITATES PENILE ERECTION IN RHESUS MONKEYS. S. M. Pomerantz. Dept. of Physiology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

Although much is known regarding the role of dopamine in regulating male sexual behavior of rodents, very little progress has been made in evaluating the potential influence of this neurotransmitter on male sexual behavior of primate species. Based on a number of studies indicating that dopamine agonists facilitate male sexual behavior of rodents, studies have been initiated to examine the effects of the mixed D1/D2 dopamine agonist, apomorphine (APO), on male sexual behavior of rhesus monkeys. Erectile potency and male sexual interest was assessed by observing the monkeys' achievement of penile erections and their performance of courtship behavior to an estrogen-treated female rhesus monkey that they could see, hear, and smell, but not physically contact. Using this paradigm, APO treatment (100 µg/kg, IM) resulted in a 25-fold increase in the frequency of full penile erections and a 5-fold increase in the frequency of incomplete penile erections, but did not alter the frequency that the glans penis was visible outside of the penile sheath. In contrast to its effect on penile erection, APO treatment did not facilitate the display of male courtship behaviors. Thus, the beneficial effects of APO on male sexual behavior of rhesus monkeys appear to be limited to the stimulation of penile erections. Furthermore, in the absence of a female, no such stimulatory effects of APO on penile erection were observed. These results indicate that psychosocial factors exert a regulatory influence over the effectiveness of APO in facilitating penile erection. Future studies will examine the effects of APO on rhesus male sexual behavior by evaluating the monkeys' behavior at other dosages of APO and in different tests of sexual behavior.

THE EFFECTS OF CENTRAL ADMINISTRATION OF THE DOPAMINE AGONIST APOMORPHINE ON GENITAL RESPONSES IN THE RAT. E.A. Pehek, J.T. Thompson* and E.M. Hull. Dept. of Psychology, SUNY at Buffalo, Amherst, NY 14260.

The aim of the present experiments was to investigate the roles of CNS DA receptors in the regulation of penile reflexes and seminal emission in the restrained, supine rat.

Injections of apomorphine (APO) into the medial preoptic area (MPOA) facilitated penile reflexes (both erections and penile flips) but did not affect seminal emission. Similar injections into the paraventricular nucleus facilitated seminal emission and erection but not flips. APO injections into the subarachnoid space of the lumbosacral cord inhibited penile reflexes ex copula, impaired copulatory performance, and decreased the number of intromissions preceding ejaculation.

These results suggest that the populations of CNS DA receptors regulating seminal emission and penile reflexes may have largely separate anatomical distributions. DA receptors in sites such as the MPOA and lumbosacral cord may integrate the reflexive and voluntary motor aspects of male sexual behavior.

269.17

HYPERSENSITIVITY OF THE 6-HYDROXYDOPAMINE TREATED HEMISPHERE TO AMPHETAMINE PERSISTS FOR ONE WEEK POSTOPERATIVE. R.J.Carey and M.R.Lynch, VA and SUNY Med.Ctrs, Syracuse, New York 13210

Amphetamine elicits contralateral rotation in unilateral 6-OHDA rats during the initial 24-36 hrs postoperative when dopamine levels in the striatum increase but ipsilateral rotation is assumed to occur thereafter when striatal dopamine levels decline. Recently, contralateral rotation was observed to occur at 5 days postoperative when striatal dopamine levels are substantially reduced. Presently, we found that vigorous contralateral rotation could be elicited up to 7 days postoperative and at dose levels (0.5 mg/kg) not usually found to elicit reliable rotation in rats with chronic lesions. On day 8 and thereafter, only ipsilateral rotation was observed. This drastic change suggests an important alteration in catecholamine function between days 7 and 8 postoperative. This observation of amphetamine-induced circling, away from the dopamine deficient hemisphere, raises basic questions regarding the validity of using the direction of amphetamine-induced rotation to determine functional hemispheric dominance.

269.18

DIAZEPAM DEACTIVATION OF HALOPERIDOL-INDUCED CATALEPSY IN THE RAT. Dennis P O'Brien, Sergio M Pellis, Vivien C Pellis, and Philip Teitelbaum. Dept. Veterinary Medicine, University of Missouri, Columbia, MO 65211 and Dept. Psychology, University of Florida, Gainesville, FL 32611.

Behavioral studies of GABAergic drugs in catalepsy supported the theory of an inhibitory feedback to A9 dopamine cells. These studies relied on measures of immobility and are inconsistent with physiologic and other behavioral studies. An analysis of the effects of diazepam on all the various manifestations of haloperidol-induced catalepsy was performed. Rats were injected with either 0.5 or 5.0 mg/kg haloperidol followed by 0(vehicle), 0.5, 1.0, or 5.0 mg/kg diazepam then tested 15-120 m later. At the threshold dose of haloperidol, diazepam enhanced measures of immobility (ipsilateral crossed legs, awkward posture, four cork and open field latency). However, measures of catalepsy involving active responses (clinging, grasping, bracing, righting, placing, vocalizations or cataleptic jumping) were never enhanced and in some cases diminished. At the higher dose of haloperidol, diazepam diminished these active responses. This data shows that diazepam deactivates the enhanced postural support characteristic of haloperidol-induced catalepsy. Thus the behavioral evidence does not support an enhancement of feedback inhibition of A9 cells by diazepam.

269.19

DIFFERENTIAL EFFECTS OF HALOPERIDOL AND CLOZAPINE ON AMPHETAMINE-INDUCED CHANGES IN BEHAVIOR AND NEOSTRIATAL SINGLE-UNIT ACTIVITY IN FREELY-MOVING RATS. J. L. Haracz, J. T. Tschanz,* M. T. Ciancone,* J. Greenberg,* and G. V. Rebec. Dept. of Psychology, Indiana Univ., Bloomington, IN 47405.

All clinically-effective neuroleptics reverse amphetamine (AMP)-induced behavioral effects, but little is known of the underlying neurophysiological mechanisms. These were studied in freely-moving rats subjected to simultaneous videotaping of behavior and recording of neostriatal single-unit activity. To date, 19 lateral neostriatal neurons exhibited baseline firing rates of 3.6±1.6 spikes/sec during quiet rest, 10 of which increased during motor activity, such as locomotion (n=7) or head movements (n=3). These and other cells frequently altered their activity in relation to the probing of specific body regions. D-AMP (1mg/kg) was administered 30 min before the injection of either haloperidol (HAL; 0.1-1.0mg/kg) or clozapine (CLZ; 5-10mg/kg). AMP-induced stereotyped behaviors often developed in correspondence with increases or decreases in neuronal activity. Motor-related cells showed AMP-induced excitations (>300% of baseline) significantly more frequently than non-motor cells ($p<0.05$). HAL generally inhibited behavior while suppressing the activity of all 10 cells tested, usually to a rate well below the pre-AMP baseline. Paradoxically, 3 cells were inhibited by both AMP and HAL. In contrast, CLZ induced both decreases and increases in activity. These findings differ from results obtained from the immobilized rat preparation, in which acutely administered neuroleptics either elevated or did not affect neostriatal neuronal activity (Skirboll & Bunney, Life Sci. 25:1419, 1979; Rebec et al., Neuropharm. 19:281, 1980; Hu & Wang, Soc. Neurosci. Ab. 12:1389, 1986). The differential effects of HAL and CLZ may reflect mechanisms underlying the differential propensity of these drugs to produce motor side effects. Supported by PHS Grant DA 02451.

HOMOLOGOUS DOWNREGULATION OF ANGIOTENSIN II RECEPTORS ON DIFFERENTIATED MURINE NEUROBLASTOMA N1E-115 CELLS. S.J. Fluharty* and L.P. Reagan*. (SPON: L. Amini-Sereshki) Dept. of Animal Biology and Institute of Neurological Sciences, Univ. of Pennsylvania, Phila. PA 19104.

Murine neuroblastoma N1E-115 cells possess angiotensin II (Ang II) receptors and their density increases during in vitro differentiation. We have used this cell line to examine homologous regulation of Ang II receptors. Incubation of these cells with Ang II produces a rapid (< 15 min) decrease in the density, but does not alter the affinity, of these receptors. This apparent down-regulation is dose related with an ED_{50} of 1 nM, and maximal decreases were observed with 100 nM Ang II (B_{max}: control = 343.3 ± 12.3; Ang II = 27.3 ± 2.8 fmols/mg prot). Receptor loss was unaffected by postincubations of membranes with GTP for 30-120 min at 37°C to insure ligand dissociation. This loss of receptors was reversible with partial recovery in 4-6 hr. Ang III also produced this downregulation but the high affinity antagonist, $Sarc^1$, Thr^8-Ang II was ineffective except at doses exceeding 100 nM. These results suggest that differentiated N1E-115 cells are an ideal cell line to examine factors regulating the expression of neuronal Ang II receptors. Supported by NS 23986 and the Univ. of PA Research Foundation.

270.2

IN VITRO DIFFERENTIATION SELECTIVELY ALTERS ANGIOTENSIN II AND VIP RECEPTOR-EFFECTOR INTERACTIONS IN N1E-115 CELLS. L.R. DePalo* and S.J. Fluharty*. Dept. of Animal Biol. and CVP Div., Univ. of PA., Phila. PA 19104. (SPON: J. Hendricks).

Murine neuroblastoma N1E-115 cells were induced to differentiate by low serum (0.5%) and 1.5% DMSO. In vitro differentiation maximally increased Ang II receptors at 72 hr (B_{max}: cont. = 13.4 ± 1.4; diff. = 310 ± 38 fmols/mg prot). This upregulation increased the sensitivity of Ang II-induced cGMP production 1000x, whereas Ang II inhibition of adenylate cyclase (AC) did not change. On the other hand, VIP receptors were unaltered during differentiation (B_{max}: cont. = 46.7 ± 3.8; diff. = 55.9 ± 7.3 fmols/mg prot). Further, VIP (1 uM) stimulated AC from basal values of 17.9 ± 1.2 to 79.3 ± 2.1 pmols/min/mg prot and this also was unaffected by differentiation (81.5 ± 3.4); although forskolin (100 uM) stimulation of AC was increased (cont. = 298 ± 32.3; diff. = 460 ± 22.5 pmols/min/mg prot). Therefore, differentiation of N1E-115 cells selectivity enhances receptor-effector interactions both by upregulating specific receptors, as well as altering their coupling to biochemical effectors. Supported by NS 23986 and Univ. of PA Research Foundation.

270.3

CHARACTERIZATION OF ANGIOTENSIN II BINDING SITES ON MURINE NEUROBLASTOMA N1E-115 CELLS. L.P. Reagan* and S.J. Fluharty*. (SPON: J.M. Sprague) Dept. of Animal Biology and Institute of Neurological Sciences, Univ. of Pennsylvania, Phila., PA 19104.

The murine neuroblastoma N1E-115 cell line contains binding sites for the angiotensin II (Ang II) receptor antagonist [^{125}I]-$Sarc^1$,Ile^8-Ang II (SARILE). Binding of [^{125}I]-SARILE to N1E-115 membranes was rapid, reversible and specific for Ang II related peptides. The rank order potency of [^{125}I]-SARILE binding was: $Sarc^1$-Ang II = $Sarc^1$, Ile^8-Ang II > Ang II > Ang III = $Sarc^1$,Thr^8-Ang II >> Ang I. Bradykinin or Substance P did not compete for [^{125}I]-SARILE labelled sites. Scatchard analysis of membranes prepared from confluent monolayers revealed a homogenous population of high affinity (K_D = 383 ± 60 pM) binding sites with a B_{max} of 25.4 ± 1.6 fmols/mg protein. Moreover, the density, but not the affinity, of the binding sites increased as the cells progressed from logarithmic to stationary growth in culture. Finally, agonist- but not antagonist-binding to N1E-115 cells was regulated by guanine nucleotides. Collectively, these results suggest that the murine neuroblastoma N1E-115 cell line may provide a useful model in which to investigate the signal transduction mechanisms utilized by neuronal Ang II receptors. Supported by NS 23986 and Univ. of Pennsylvania Research Foundation.

270.4

LOCALIZATION OF ANGIOTENSIN II RECEPTORS ALONG THE VISCERAL AFFERENT PROJECTION SYSTEM. R.R. Miselis, X. Bao, and S.J. Fluharty. Dept. of Animal Biology, Inst. Neurol. Sciences, Univ. of Penna, Phila, PA 19104.

Using in vitro quantitative autoradiographic procedures and [^{125}I]-(Sar^1, Ile^8)-angiotensin II (Sarile) as the ligand, angiotensin II (AngII) receptors were mapped in the normal rat brain. In preliminary studies using brain homogenates we determined that SARILE labels a homogenous population of high-affinity binding sites that are specific for Ang-II related peptides. Binding of ^{125}I-SARILE reached equillibrium in 2 hrs at 25°C and was stable for at least 2 additional hrs. Autoradiographic analysis revealed AngII receptors in the circumventricular organs and nucleus of the solitary tract (20 fm/mg protein) and high densities in the nucleus medianus, paraventricular nucleus and subthalamus area (6-20 fm/mg). In addition there were very significant levels of AngII receptors in the gustatory NTS (3-8 fm/mg) and the parabrachial complex. AngII receptors were also high in parts of the lateral parabrachial nucleus (10-20 fm/mg) and moderate in the medial components (3-8 fm/mg). Thus AngII receptors are located along the projection system of visceral afferents in the hindbrain and may be identified with functional systems mediating sodium and fluid homeostasis. Support: GM27739, NS23986, MacArthur Foundation, Univ. of PA Res. Fdn.

270.5

REGULATION OF BRAIN ANGIOTENSIN II AND ATRIAL NATRIURETIC PEPTIDE RECEPTORS IN SPONTANEOUSLY HYPERTENSIVE RATS AFTER TREATMENT WITH A CONVERTING ENZYME INHIBITOR. A.J. Nazarali*, J.S. Gutkind, F.M. Correa and J.M. Saavedra Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

We have investigated the effect of chronic administration (25mg/Kg p.o. for 14 days) of converting enzyme inhibitor enalapril on the binding density of angiotensin II (ANG II) and atrial natriuretic peptide (ANP) in selected brain nuclei of spontaneously hypertensive rats (SHR) and Wistar-Kyoto (WKY) rats employing receptor autoradiography. In specific brain areas, ANG II receptors were higher in the SHR than in WKY rats. Chronic treatment of the SHR selectively decreased brain ANG II receptors by almost 50% in only the subfornical organ. However no difference in ANG II receptor density was observed in the treated WKY. In many brain nuclei, significantly lower ANP receptors were found in the SHR compared to the WKY. Treatment resulted in a significant increase in ANP receptor density (almost 50%) in only the area postrema of treated SHR animals. Conversely treated WKY animals showed a 23-25% decrease in ANP receptors in both the subfornical organ and area postrema when compared to untreated WKY. These results indicate that in genetic hypertension, converting enzyme inhibitors may mediate part of their antihypertensive effects by regulating ANG II and ANP receptors in the circumventricular organs.

270.6

EXPRESSION OF ANGIOTENSIN II RECEPTORS IN *XENOPUS* OOCYTES FROM TRANSCRIPTS OF A cDNA CLONE. E. Butler* and F. Sutton* (SPON: B. Schrier). LDN/NICHD and LBG/NHLBI, NIH, Bethesda, MD 20892

Xenopus oocytes that have been injected with RNA transcripts of pMcAR-1, a mouse neuroblastoma-derived cDNA clone, become responsive to angiotensin II (AII). Responses are manifested as current fluxes that are elicited by perfusion of 10^{-7} M AII over voltage-clamped oocytes that have been injected with 1) mouse neuroblastoma NS20Y RNA, 2) SP6 transcripts of pMcAR-1, or 3) NS20Y RNA that has been purified by hybrid selection with filter-bound pMcAR-1. Uninjected or water-injected oocytes do not exhibit significant responses to AII under our conditions. Hence we consider it highly probable that pMcAR-1 encodes an angiotensin II receptor. More definitive assertions of the identity of pMcAR-1 may be possible when investigations with appropriate AII antagonists have been completed. RNA blot-hybridization analyses show that the major McAR-1 hybridizing species in NS20Y and mouse brain RNAs are ca. 4.7 Kb in length; however, less prevalent species of other sizes are detected also.

MODULATION OF OXYTOCIN BINDING BY ESTRADIOL AND PROGESTERONE. M. Schumacher*, H. Coirini* A.E. Johnson and B.S. McEwen. Lab.Neuroendocrinology, The Rockefeller University, New York, N.Y. 10021

One mechanism by which estradiol (E) and progesterone (P) may activate female reproductive behavior is to increase the sensitivity of the ventromedial nucleus of the hypothalamus (VMN) to excitatory neurotransmitters. Thus oxytocin (OT) facilitates lordosis behavior and E-treatment increases OT-binding in the VMN. By using quantitative autoradiography, we showed that 3H-OT binding is most efficiently increased by estrogen in the ventrolateral part of the VMN, Treatment of ovariectomized females with 10 ug of estradiol-benzoate (EB) for 2 days resulted in a twofold increase in OT-binding in this part of the VMN. A recent study suggests that OT-induced facilitation of lordosis behavior is P-dependent. Experiments are now in progress to determine the effect of P alone or in combination with EB on OT-binding in the VMN. We found that in addition to their genomic effects, E and P also exert direct effects on OT-binding in the uterus. These effects are dependent on the hormonal status of the animal. When added to the incubation medium, 10-7 M of E and P decrease OT-binding in the uterus of EB+P treated animals but increase OT binding in females treated with EB alone. We are now investigating if E and P also exert such effects in the brain.

NIH Grant NS 07080 (BMC), EMBO fellowship (MS).

OXYTOCIN RECEPTORS IN RAT BRAIN: CHARACTERIZATION WITH THE SELECTIVE ANTAGONIST ^{125}I-d(CH$_2$)$_5$Tyr(Me)^{2}Thr^{4}Tyr(NH$_2$)^{9}OVT (OTA). J. Elands*, C. Barberis* and E.R. de Kloet* (SPON: H. Rigter). Rudolf Magnus Institute for Pharmacology, University of Utrecht, The Netherlands.

Central nervous system receptors for oxytocin (OT) and vasopressin (AVP) have been shown with tritiated OT and AVP. Because of the restricted localization, the limited binding capacity and the cross-specificity (for AVP and OT) of these receptors it has been difficult to assess their characteristics with the tritiated ligands. Iodination of OT or AVP was accompanied by a dramatic loss of affinity for their respective receptors. OTA, the Tyr^9 substituted OT analogue, however exhibited an enhanced OT receptor affinity (Kd=0.038 nM) after iodination. While having a 300-500 fold lower affinity for V_2 and V_1 receptors it appeared to be one of the most selective OT receptor ligands. Autoradiography revealed a great number of rat brain regions containing specific OTA binding sites. Due to the high selectivity of OTA it can now be concluded that these binding sites represent OT receptors. Identification of OT receptors in the brain was confirmed with membrane receptor assays. A heterogeneity in affinity of AVP/OT analogues for OT receptors in the hypothalamic ventromedial nucleus and the ventral hippocampus was demonstrated. Heterogeneity and regional distribution of the OT receptors as well as the availability of highly selective OT receptor ligands have provided the criteria to specify the role of the peptide in centrally regulated functions.

EFFECTS OF SOMATOSTATIN-28 ON SUPRAOPTIC MAGNOCELLULAR NEURONS IN THE RAT. W.N. Raby, C.W. Bourque, R.A. Benoit and L.P. Renaud. McGill Univ. Centre for Research in Neuroscience, Montreal, Canada H3G 1A4.

Somatostatin-14 (SS-14) and somatostatin-28 (SS-28) are the two main bioactive forms of somatostatin within the rat hypothalamus. Fibers displaying SS-28-like immunoreactivity have recently been visualized in and around the supraoptic nucleus (Sawchenko et al., J. Chem. Neuroanat. 1988). During intracellular recordings in hypothalamic explants, certain supraoptic cells displayed a prolonged hyperpolarization within 0.5-2 minutes exposure to 0.1-10 µM SS-28. In 6/10 phasic neurons, a gradual reduction in burst length and intraburst firing frequency lead to a complete cessation of spontaneous activity. In 3/6 continuously firing cells on-going activity also stopped. Full recovery from hyperpolarization required 2-5 minutes. Similar results were obtained in TTX (0.5 µM)-containing media. Therefore, it appears that SS-28 depresses the excitability of rat supraoptic neurosecretory neurons. Supported by FCAR and MRC.

SOLUBILIZATION AND PARTIAL PURIFICATION OF BRAIN SOMATOSTATIN RECEPTORS. H-T. He* and T. Reisine, Dept. of Pharmacology, Univ. Pennsylvania Sch. Medicine, Phila. PA 19104

Somatostatin (SRIF) is a neurotransmitter in the central nervous system. Its physiological actions are mediated by cell surface receptors. In order to investigate the physical properties of brain SRIF receptors, we have attempted to purify the receptor. Photocrosslinking studies employing a SRIF analog, [125I] CGP 23996, the crosslinking agent HSAB and UV light suggest that the size of the brain SRIF receptor is 60 kilodaltons (kd). Treatment of brain membranes with detergents solubilized the [125I] CGP 23996 labelreceptors. The solubilized and membrane bound SRIF receptors have the same size. To attempt to purify the SRIF receptor, brain membranes solubilized with CHAPS were applied to a sepharose column coupled to Trp8-SRIF. Following extensive washing, two major protein components could be eluted from the affinity column by lowering the pH of the column buffer with sodium acetate. The size of the proteins eluted were 60 kd and 45 kd. Treatment of the solubilized brain proteins with Trp8-SRIF prior to their application to the affinity column specifically reduced the amount of these two proteins that subsequently bound to the column. The size of the 60 kd protein eluted from the Trp8-SRIF affinity column is similar to the size of the brain SRIF receptor covalently labeled with [125I] CGP 23996. Proteolysis of brain SRIF receptors yields a major protein component of 45 kd suggesting that the smaller protein eluted from the affinity column is a degradation product of the SRIF receptor. Presently, attempts are being made to sequence these putative SRIF receptors. Supported by NIH grants DK37404 and GM34781.

COVALENT LABELLING OF THE SOMATOSTATIN RECEPTOR FROM RAT ANTERIOR PITUITARY. J.F. Bruno* and M. Berelowitz, Div. of Endocrinology, SUNY Stony Brook, NY 11794.

Somatostatin (SRIF) inhibits pituitary growth hormone secretion by binding to a high affinity G protein-linked membrane receptor. In the present study, the molecular characteristics of this receptor were investigated by covalently cross-linking ^{125}I-Tyr^{11}-SRIF to its putative receptor in rat anterior pituitary membranes using four cross-linking agents: ANB-NOS, HSAB, SANPAH and DSS.

When membranes were crosslinked with ANB-NOS, a broad band was labeled with an apparent molecular weight(M_r) of 68,0000; however, with HSAB, the broad band was resolved into a doublet with M_r's of 66,000 and 69,000. SANPAH covalently labeled the M_r 69,000 protein and a minor species with a M_r of 45-47,000. Crosslinking with DSS labelled only the M_r 66,000 band. Labelling of both bands was specific since affinity labelling with each of the 4 agents was abolished when 1uM cyclic SRIF was included in the binding reaction. Increasing concentrations of unlabelled SRIF resulted in dose-dependent inhibition of specific membrane binding and of affinity labelling of both the 66,000 and 69,000 proteins. Competition curves constructed from binding and cross-linking studies were superimposable. Experiments are now in progress to determine the molecular basis for the difference in M_rs.

270.12

DEVELOPMENTAL PATTERN OF FUNCTIONAL RECEPTORS FOR SOMATOSTATIN (SRIF) IN NEURONAL AND GLIAL CELL CULTURE DERIVED FROM FOETAL MOUSE HYPOTHALAMUS. J. Epelbaum, R. Rasolonjanahary*, M. Fodor*, C. Kordon, C. Loudes*, A. Tixier-Vidal*, A. Faivre*. U. 159 INSERM et Groupe de Neuroendocrinol. Mol. et Cell., Paris, France.

Embryonic cells were cultured in a defined medium. In neurons, SRIF levels increased steadily up to 21 days while they were undetectable, at all times, in glial cells. At 13 days in culture, SRIF cells, visualized with an antibody raised against SRIF28(1-12), amounted to 3.6 % of total cell number. SRIF binding sites, assessed by 125I-TyrO-DTrp8-SRIF binding in saturation experiments, were four time more concentrated on neurons than on glia (606 vs 156 fmol/mg protein) ; both preparations displayed similar affinities (neurons : Kd = 2.2 nM ; glia : Kd = 2.3 nM). Using SMS 201 995 as competitor, two sites were detected on neurons (K1 = 5 pM and K2 = 4.5 nM) while only the lower affinity site was present in glia (K = 1.7 nM). SRIF inhibited basal and forskolin or VIP stimulated adenylate cyclase activity up to 52 % in neurons and 23 % in glia. 24 h pretreatment with pertussis toxin (100 ng/ml) blocked completely these effects of SRIF.

The results demonstrate that SRIF receptors develop on hypothalamic neurons and glia, being more concentrated on the former. As soon as 6 days in vitro receptors are functional since they are coupled with inhibition of adenylate cyclase activity.

270.13

SELECTIVE REDUCTIONS IN CEREBROCORTICAL SOMATOSTATIN RECEPTOR BINDING DENSITY IN ALZHEIMER'S DISEASE. D.L. Knight*, G. Bissette, C.D. Kilts, G.P. Reynolds*, C.B. Nemeroff (Spon: J. McCubbin). Depts. of Psychiat. & Pharmacol., Duke Univ. Med. Center, Durham, NC 27710.

High affinity somatostatin (SRIF) receptor binding sites were measured in post mortem human brain tissue using [^{125}I]-Tyr$_{11}$-SRIF. Although there have been consistent reports of reductions in the concentration of SRIF-like immunoreactivity in the cerebral cortex in Alzheimer's disease (AD), there is some controversy surrounding changes in the number (Bmax) of SRIF receptors. Beal et al. (Science 229: 289-291, 1985) demonstrated significant reductions in the Bmax of SRIF receptors in frontal pole (BA 10), frontal cortex (BA 9), premotor cortex (BA 6), middle temporal gyrus (BA 21) and the hippocampus in AD. Whitford et al. (Reg. Pept. 15: 198, 1986) reported an increase in SRIF receptors in hippocampal tissue in AD, and Crow et al. (Brit. J. Pharmacol. 84(suppl): 8P, 1985) reported no changes in SRIF receptor Bmax in the frontal or temporal cortices in AD.

The present study confirmed and extended the findings of Beal et al. There was a 40% reduction in the Bmax of SRIF receptors in the frontal pole (BA 10) and the temporal pole (BA 38). Small decreases in SRIF receptor number in the hippocampus and caudate did not attain statistical significance. No changes were found in the amygdala or hypothalamus.

DEGLYCOSYLATION OF RAT BRAIN AND PITUITARY CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS. D.E. Grigoriadis and E.B. De Souza. Neurosci. Branch, NIDA Addiction Research Center, P.O. Box 5180, Baltimore, MD 21224.

CRF receptors in brain and pituitary have been previously shown to migrate as two distinct bands of different molecular weights (MW) (brain, 58 kDa; pituitary, 75 kDa). Since both proteins exhibit similar pharmacological characteristics, we determined whether the difference in the MW was due to differential glycosylation of the proteins in the two tissues. Using the homobifunctional crosslinking reagent dissuccinimidyl suberate, covalently labeled CRF receptors from brain and pituitary were solubilized in 6 mM CHAPS, adsorbed onto columns of wheat germ agglutinin (WGA) and specifically eluted using N-acetyl glucosamine. This indicated that both labeled proteins were glycoproteins containing complex sugar moieties. In order to partially define the glycoprotein nature of the CRF receptors in both brain and pituitary, covalently labeled receptors were treated with the enzyme neuraminidase (1 U/ml) which specifically cleaves terminal sialic acid residues. In the frontal cortex, neuraminidase treatment caused an increase in the mobility of the labeled protein thus decreasing the apparent MW of the CRF receptor from 58 to 52 kDa. Similar decreases were observed in the anterior pituitary. In summary, although CRF receptors in brain and pituitary have different MW, both appear to be glycoproteins containing terminal sialic acid residues.

270.15

CHARACTERIZATION OF CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS IN THE INTERMEDIATE LOBE OF THE PITUITARY. E.B. De Souza and D.E. Grigoriadis. (SPON: N.S. Buckholtz) Neurosci. Branch, NIDA/Addiction Res. Ctr., Baltimore, MD 21224.

CRF is the major physiological regulator of proopiomelanocortin (POMC)-derived peptide secretion in the anterior pituitary. In addition, CRF has also been shown to regulate the synthesis and secretion of POMC-derived peptides in the intermediate lobe. Autoradiographic studies have identified specific binding sites for CRF in the intermediate lobe of pituitary, however, their characteristics remain undefined. The binding of ^{125}I-oCRF to intermediate lobe homogenates was guanine nucleotide-sensitive, saturable and of high affinity (K_D = 400-600 pM; B_{max} = 100-120 fmoles/mg protein). The pharmacological rank order of potencies for various analogs or fragments of CRF was characteristic of the well-established CRF receptor in the anterior pituitary. Affinity cross- linking studies revealed that the molecular weight of the CRF binding protein in the intermediate lobe was identical to that of the anterior lobe (74,800 Da). The autoradiographic localization of CRF receptors in rat, porcine and bovine pituitaries will also be presented. In summary, CRF receptors in the intermediate lobe appear to have virtually identical binding characteristics to those in the anterior lobe. These data further substantiate the physiological role of CRF in regulating intermediate lobe hormone secretion.

270.16

EFFECTS OF CHRONIC ANTIDEPRESSANT AND BENZODIAZEPINE TREATMENT ON CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS IN RAT BRAIN. D. Pearsall*, D.E. Grigoriadis and E.B. De Souza. Neuroscience Branch., NIDA Addiction Research Center., Baltimore, MD 21224.

Recent clinical data suggest that CRF may play a major role in several neuropsychiatric disorders including major depression and panic/anxiety disorders. CRF administration in rats has been reported to produce several behavioral changes characteristic of anxiogenic compounds. In addition behavioral and biochemical data suggest that CRF and benzodiazepines may interact in brain. The present study was designed to examine the effects of chronic treatment (s.c. administration 21 or 28 days) with antidepressants (imipramine or desipramine) or benzodiazepines (diazepam, alprazolam or adinazolam) on modulation of CRF receptors in discrete areas of rat brain and in anterior pituitary. As previously reported, we found that chronic antidepressant treatment down regulated 5HT$_2$ serotonin and beta adrenergic receptors in cerebral cortex. While there was a trend toward increased CRF binding in cerebral cortex, brain stem and striatum following antidepressant treatment, these changes were not statistically significant. In addition, no significant changes were seen in CRF binding in other brain regions including cerebellum, olfactory bulb, hypothalamus, hippocampus and in anterior pituitary. Following chronic benzodiazepine treatment, CRF receptors were not significantly altered in cerebral cortex, cerebellum or brain stem. These data demonstrating minimal effects of chronic antidepressant and benzodiazepine treatment on CRF receptors in discrete regions of rat brain suggest that alternate mechanisms may be involved in the actions of these drugs on CRF neurotransmission in brain.

270.17

CORTICOTROPIN-RELEASING FACTOR (CRF) STIMULATES ADENYLATE CYCLASE ACTIVITY IN MOUSE SPLENIC MACROPHAGES. Elizabeth L. Webster*, George Battaglia, and Errol B. De Souza (SPON: M.S. Kafka). Neuroscience Branch, Addiction Research Center, National Institute On Drug Abuse, Baltimore, MD 21224.

We have previously identified a high affinity, magnesium-dependent, and guanine nucleotide-sensitive binding site for CRF in mouse splenic macrophages comparable to the well-characterized CRF receptors in pituitary and brain. The regulation of ^{125}I-ovine CRF binding by divalent cations and guanine nucleotides indicates that splenic CRF receptors are coupled to a guanine nucleotide regulatory protein. In the present study, we examined adenylate cyclase activity in splenic homogenates in order to determine the transduction mechanism(s) through which CRF produces its effects in mouse spleen. CRF receptor-mediated stimulation of adenylate cyclase activity was dependent on time, and tissue protein concentration. Guanine nucleotide facilitation of basal and CRF-stimulated adenylate cyclase activity was dose-dependent and nucleotide specific. The pharmacological potencies of various CRF analogs and fragments in stimulating adenylate cyclase correlated with their relative affinities for CRF receptors in spleen, brain, and pituitary. These results suggest that at least some of the actions of CRF on immune function may be due to CRF receptor mediated stimulation of cAMP production in mouse splenic macrophages.

270.18

FUNCTIONAL ALTERATIONS IN LOCAL CEREBRAL GLUCOSE UTILIZATION FOLLOWING CENTRAL ADMINISTRATION OF CORTICOTROPIN-RELEASING FACTOR (CRF) IN RATS. J. Sharkey*, N. M. Appel and E. B. De Souza (SPON: P.A. Schueler). Neuroscience Branch, NIDA Addiction Research Center, Baltimore, MD 21224.

CRF is the primary physiological regulator of basal and stress-induced proopiomelanocortin-derived peptide secretion from the pituitary gland. In addition, recent data suggest that CRF may act as a neurotransmitter in brain to coordinate the endocrine, behavioral and autonomic responses to stress. In order to further elucidate the neuroanatomical substrates underlying the actions of CRF in brain, we have examined the effects of intracerebroventricular administration of CRF (5.25 nmol in 10 µl of saline) on function-related glucose utilization (GU) in 50 anatomically discrete regions of rat brain using the ^{14}C-2-deoxyglucose quantitative autoradiographic technique. CRF differentially affected GU in discrete regions of rat brain. Consonant with the hypophysiotropic role for CRF, pronounced increases in GU were seen in the median eminence and lateral nucleus of the hypothalamus. In contrast, reductions in GU were observed in cingulate cortex and nucleus accumbens, brain regions which have been implicated in mediating stress responses. Other stress-related brain areas that showed increased GU included the locus coeruleus and median raphe nucleus. Punctate increases in GU were noted in the cerebellar cortex and vermis substantiating the functional role of CRF in the cerebellum. Additional brain areas showing elevated GU in response to CRF included the fornix, red nucleus and ependymal lining of the ventricles. The changes in GU in response to CRF administration provide additional evidence for a neurotransmitter role for CRF in brain and further support the importance of this neuropeptide in coordinating responses to stress.

270.19

EFFECTS OF CHRONIC STRESS ON BRAIN AND PITUITARY CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS. G.J Kant, S.M. Anderson and E.B. De Souza. Dept of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307 and Laboratory of Neuroscience, Addiction Research Center, National Institute on Drug Abuse, Baltimore, MD 21224.

CRF is thought to be involved in the integration of neuroendocrine, autonomic and behavioral responses to stress. In the present study, CRF receptors were measured in membrane homogenates prepared from anterior pituitary, frontal cortex, motor cortex, somatosensory cortex, mesolimbic area, caudate, hypothalamus, midbrain and cerebellum of rats stressed for 3 or 14 days (around-the-clock intermittent footshock), which could be avoided or escaped on 90% of the trials presented).

Plasma corticosterone levels were significantly elevated in both the 3 day and 14 day stress groups as compared to controls. [^{125}I]oCRF binding was decreased in anterior pituitary and frontal cortex following 3 days of chronic stress. After 14 days of chronic stress, hypothalamic CRF binding was decreased as compared to control animals but no other differences were seen. We suggest that the decrease in CRF receptors in the anterior pituitary following 3 days of stress may be due to increased plasma corticosterone levels and/or increased CRF release. The down-regulation of frontal cortex and hypothalamic receptors is more likely to be primarily in response to sustained stress-induced CRF release at those sites.

270.20

ANTIBODIES TO A PEPTIDE COMPLEMENTARY TO EGG-LAYING HORMONE ARE SPECIFIC FOR A PROTEIN FROM THE OVOTESTIS. J.V.A. Choate, T.E. Kruger* and J.E. Blankenship. Marine Biomed. Inst., Univ. Tex. Med. Br., Galveston, TX 77550.

Egg laying in Aplysia californica has served as a model for studying the control of a behavior by a peptidergic neuroendocrine system. Several peptides, including egg-laying hormone (ELH) participate in the regulation of this behavior. ELH is thought to effect its targets by acting on a specific receptor. In an attempt to isolate and characterize the ELH receptor, we have generated antibodies by immunizing rabbits with a peptide encoded by the mRNA sequence complementary to the mRNA of residues 1-19 of ELH (see Proc. Natl. Acad. Sci. USA, 82:1372-1375, 1985). This complementary peptide antibody (anti-HLE) shows high specificity for HLE using an immunodot blot assay. The antibody was purified on a DEAE column, coupled to Reactagel 6X and used as an immunosorbant for Triton X-100-solubilized ovotestis tissue. Preliminary results suggest that this antibody specifically recognizes a high molecular weight, multisubunit ovotestis protein, as determined by polyacrylamide gel electrophoresis. The specificity of the antibody for this protein is supported by analysis of the column eluate by ELISA. Supported by NINCDS NS 23169(JEB), 07185(TEK), 11255, and NSF BBS8711368.

PEPTIDES: ANATOMICAL LOCALIZATION II

271.1

TRANSMITTER IMMUNOCYTOCHEMISTRY USING WHOLEMOUNTS OF THE DEVELOPING SPINAL CORD OF Xenopus. J.W. Gazzerro* and R.H. Nordlander (SPON: T. Whittingham). Dept. Oral Biol., Case Western Reserve Univ., Cleveland, OH 44106.

We examined the distribution of several neurotransmitters known to be present in sensory pathways of the spinal cord. Antibodies to substance P (SP) were applied to the dissected embryonic and larval CNS of Xenopus (stages 24-48). Antibodies to somatostatin (SS), vasoactive intestinal peptide (VIP) and calcitonin gene related peptide (CGRP) were applied to the CNS of mid-larval stages (47-48). Our eventual goal is to use these antibodies to examine the distribution and time of onset of immunoreactivity in order to follow the development of subsets of sensory neurons and their central processes.

Clear marking of some sensory and cranial nerve ganglion cells occurred with each of the four antibodies as did staining of fibers in the dorsolateral fiber tract occupied by ascending Rohon-Beard and sensory ganglion fibers. Only one antibody (CGRP) was restricted to this pathway in its CNS distribution. The rest marked many other longitudinal axons and showed stereotyped cellular distributions within the spinal cord and brain. Anti-SP stained axonal growth cones of a descending pathway that appeared early in development.

Supported by Short Term Training Grants NS-07118-10 and DE-07158-04 to JWG and NS-18773 to RHN.

271.2

NEURONAL LOCALIZATION OF CHOLECYSTOKININ mRNA IN RODENT BRAIN WITH IN SITU HYBRIDIZATION HISTOCHEMISTRY. S.M. Ingram*[1], R.G. Krause II*[2], F. Baldino, Jr.[3], L.C. Skeen*[1] and M.E. Lewis[3] (SPON: B. Wolfson[2]) [1]Dept. of Psychology and the Institute for Neuroscience, University of Delaware, Newark, DE. [2]Medical Products Dept., E.I. du Pont de Nemours & Co., Wilmington, DE., [3]Cephalon, Inc., West Chester, PA

The distribution of cholecystokinin (CCK) mRNA in the rat and mouse brain was determined using in situ hybridization histochemistry with a synthetic oligonucleotide probe 3' end labelled with [^{35}S]. Our results demonstrate a widespread distribution of CCK mRNA throughout the rodent brain. Individual cell bodies containing CCK mRNA were identified in the neocortex, claustrum, amygdala, the dentate gyrus and regions CA1-CA3 of the hippocampus, and several subnuclei of the thalamus and hypothalamus. Heaviest concentrations of CCK label were in the endopiriform/piriform cortex and the ventral tegmental area of the mesencephalon. These results expand the boundries of CCK maps previously made using immunocytochemistry and radioimmunoassay by demonstrating the existence of CCK-synthesizing cells in regions such as the tenia tecta and periaqueductal grey where the presence of CCK cell bodies was uncertain. The distribution of CCK mRNA is consistent with that of neuronal CCK-like immunoreactivity and is reflective of the diverse physiological actions of this peptide.

271.3

IN SITU HYBRIDIZATION HISTOCHEMISTRY USING ENZYME LABELED SYNTHETIC OLIGONUCLEOTIDE PROBES. R.G. Krause II*[1], F. Baldino, J.L. Ruth*[2] and L.G. Davis[1] [SPON: K. Wilcox]. [1]Medical Products Dept., E.I. Dupont de Nemours & Co.,Inc., Wilmington, DE 19898, and [2]Molecular Biosystems, Inc., 10030 Barnes Canyon Rd., San Diego, CA 92121.

Conventional in situ hybridization protocols use radiolabeled DNA and RNA probes to identify specific mRNAs within individual cells. This histochemical technique involves hybridizing fixed tissue sections with a radiolabeled probe whose sequence is complementary to the mRNA of interest. After washing, the sections are exposed to X-ray film to determine the effectiveness of the hybridization and to localize the identified mRNA on a regional scale. The sections are then dipped in photographic emulsion to ultimately obtain cellular resolution.

Synthetic oligonucleotide probes have proved very useful in these procedures. In order to improve cellular resolution, we have developed oligonucleotides coupled to an enzyme which replaces the radioisotope as the reporter system. The signal is obtained by providing the enzyme with an appropriate substrate. This allows the colorimetric visualization of the mRNA-related signal. We have successfully used alkaline phosphatase or horseradish peroxidase labeled probes to detect various endogenous mRNAs at the cellular level within twenty-four hours of hybridization rather than the extended autoradiographic exposure sometimes needed (e.g. tyrosine hydroxylase).

A number of advantages exist for these new probes which include the ability to identify mRNAs in a day versus the weeks or months of autoradiographic exposure needed for some mRNAs, an improved cellular resolution, and ease of use. Most importantly, the detection of multiple mRNA species in a single section using a combination of probes differentially labeled will more readily allow studies on co-localization and differential gene expression.

271.4

IMMUNOCYTOCHEMISTRY IN RAT FOREBRAIN USING A CRF ANTI-IDIOTYPIC ANTIBODY. D.T. Piekut and K.M. Knigge. Neuroendocrine Unit, Univ. of Rochester, Rochester, NY 14642.

A polyclonal anti-idiotypic antibody was generated by immunization of a rabbit with IgG of a primary (idiotype) CRF antiserum. In the present study, the anti-idiotypic antibody is used to demonstrate and localize immunoreactive images in rat forebrain. Immunocytochemistry was performed on vibratome-cut sections of fixed rat brain. CRF anti-idiotypic antisera revealed punctate granules, 1.2-1.6μm in diameter, associated with cell bodies and fibers or present in dense fields in which there are no visible perikarya or processes. These immunoreactive images are seen in several regions of rat forebrain including cerebral cortex, caudate-putamen, nucleus accumbens and olfactory areas. These areas possess abundant CRF-immunostained fibers and terminal fields. Under the present conditions of tissue fixation and immunocytochemical procedures, no immunoreactive images are associated with perikarya of CRF-immunoreactive neurons. Preliminary characterization of the anti-idiotypic antisera has been conducted. Pre-incubation or co-incubation of the antisera with rat neural membranes or synthetic CRF reduced or eliminated staining of the tissue sections in a dose-dependent manner. Immunostaining was eliminated when 0 3mg neural membrane protein was incubated with 1ml diluted antisera (1:1000); neural membranes were completely inactive after heat treatment. High concentrations of synthetic CRF were needed in competition studies to eliminate staining. The distribution of immunostained images visualized with the anti-idiotypic antibody and the concurrent distribution of receptors for CRF in brain as revealed by biochemical assay and morphologically by autoradiographic methods suggests that the anti-idiotypic antibody may recognize a receptor or receptor-associated structure for CRF in rat forebrain. Supported by NIH grants NS18626 and NS00869.

271.5

IMMUNOCYTOCHEMISTRY OF RAT BRAINSTEM AND WESTERN BLOT ANALYSIS USING A PUTATIVE CRF ANTI-IDIOTYPIC ANTISERUM. G. J. Michael, S. A. Joseph, and K. M. Knigge. Neuroendocrine Unit, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

A polyclonal antiserum generated against an ammonium sulfate precipitated IgG fraction of CRF antisera was used in immunochemical studies in the rat brainstem. This antiserum specifically recognizes an antigen on the plasma membrane as determined by the ability of rat neural membranes to eliminate staining following preabsorption. This preabsorption effect is eliminated by heat treatment. By western blot, a membrane protein of relative molecular weight 110-120,000 is recognized by the antiserum. Following preincubation of the antiserum with the 110-120 kD nitrocellulose-bound protein, a reduction in histologic labling is noted. These results suggest the protein labeled on western blots is antigenically related to a protein labeled in fixed brain sections. Immunocytochemistry reveals an extensive distribution of labeled neuronal perikarya and apparent dendritic processes in defined anatomic regions. A high density of labeling is found within the superior and inferior colliculi, periaqueductal grey, dorsal raphe nucleus, ventral tegmental area, interpeduncular nucleus, laterodorsal tegmentum, pedunculopontine tegmental nucleus, nucleus of the solitary tract and the nucleus of the spinal tract of the trigeminal nerve. A comparison between this staining pattern and reports of CRF receptor localization supports the hypothesis that neurons postsynaptic to CRF are labeled with our antibody.

271.6

OPIOMELANOCORTIN PROJECTIONS TO RAT BRAINSTEM NUCLEI. L.J. Sim and S.A.Joseph, Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642.

Physiological and pharmacological evidence indicates that the opioid peptides function in pain modulation at both spinal and supraspinal levels. In the brain, the periaqueductal gray (PAG) and nucleus raphe magnus (nRM) produce analgesia upon electrical stimulation or morphine microinjection. We have demonstrated that opiomelanocortin neurons in the arcuate nucleus project to nocioceptive brainstem nuclei (PAG and nRM) by using combined horseradish peroxidase-wheat germ agglutinin (HRP-WGA) retrograde transport and peptide immunocytochemistry (ICC). In order to identify the brainstem neurons that may interact with efferent projections from hypothalamic opiomelanocortin neurons, *Phaseolus vulgaris*-leucoagglutinin (PHA-L) was iontophoretically injected into discrete regions of the arcuate complex in the rat. Animals were sacrificed 5-10 days after injection and the PHA-L was visualized using routine immunocytochemistry. Terminals were observed in various forebrain and brainstem nuclei, including the PAG and raphe complex. Double ICC staining of PHA-L transport and peptide/neurotransmitter localization was then utilized to determine the neurochemical content of the terminal neuronal field. These studies further characterize arcuate opiomelanocortin participation in the descending pain pathway.

271.7

THE PARAVENTRICULAR NUCLEUS IN THE HUMAN BRAIN: IMMUNOCYTOCHEMICAL ORGANIZATION OF CRF, OXYTOCIN, AVP AND PUTATIVE VASOPRESSIN RECEPTORS. S.A. Joseph and W.H. Pilcher. Neuroendocrine Unit, Univ. of Rochester, Rochester, NY 14642

Antisera generated against corticotropin releasing factor (CRF), oxytocin (OXY), and arginine vasopressin (AVP) were used to immunocytochemically map the localization of neuronal elements containing these neuropeptides in the human paraventricular nucleus (PVN). The peptidergic pattern of organization was related to the magnocellular and parvocellular divisions of the PVN as determined by routine cresyl violet Nissl staining. Dual staining methods revealed that while colocalization exists among these neuropeptides no coexistence within perikarya could be demonstrated.

A polyclonal vasopressin anti-idiotype antibody was generated by immunization with an ammonium sulfate precipitated IgG fraction obtained from primary anti-vasopressin antiserum. Anti-idiotype antisera have been shown to recognize and interact with specific receptor proteins. Initial characterization of the AVP anti-idiotype antiserum showed that it specifically reacted (western blot) with the 62 and 55 kilodalton proteins of rat brain, which had been demonstrated to be associated with the AVP recognition site. In addition the antibody reacted with similar proteins in bovine posterior pituitary (Abood et al). In the human PVN, immunocytochemistry with the AVP anti-id revealed a distribution pattern similar to that seen with vasopressin antisera. Double stained (PAP/GAG) immmunocytochemical analysis using this anti-id antiserum plus antiserum generated against vasopressin revealed a coexistence of vasopressin and a putative vasopressin autoreceptor in vasopressinergic perikarya. Supported by grants NS #21323 and AHA #87 1011.

OXYTOCINERGIC SYSTEMS IN THE PREOPTIC AREA ARE SENSITIVE TO ESTROGEN, Caldwell, J.D., Brooks, P.J., Jirikowski, G.F. & Pedersen, C.A. Dept. of Psychiatry, Univ. of North Carolina, Chapel Hill, NC 27599

The effect of estrogen in sensitizing animals to the facilitative effects of oxytocin (OXT) on maternal and female sexual behaviors may be the result of its extensive influence on central OXT physiology. Implanting 10 mm silastic tubing filled with estradiol into ovariectomized (OVXed) females significantly ($p<.05$) increased immunoreactive levels of OXT in extracts from the preoptic area (blank implanted = 418 $\pm$ 90pg vs. estradiol = 798 $\pm$ 148pg; $t_{16}=2.19$). Estrogen implants of this size increased immunostain intensity of oxytocinergic cells in the dorsal preoptic lateral subcommissural nucleus (LSN), while 4 mm implants had no effect after 10 days. Analysis of immunostaining patterns 1 or 2 days after 20 µg estradiol benzoate (EB) injection found similar increased immunostain intensity in the LSN. Cells immunostained for OXT in the preoptic area also expressed OXT mRNA. An I^{125}-labelled 38-base oligodeoxyribonucleotide probe was hybridized to 30 µm thick sections for 16 hours at 37° C. Slides were washed to a final stringency of 0.1X SSC at 37° C, dried, dipped in emulsion and exposed for 36-60 hours. The number of hybridizing cells in the LSN, the periventricular nucleus and the lateral hypothalamus increased 1 and 2 days after an im injection of 20 µg EB versus oil in OVXed animals. Estrogen affects immunoreactive levels of OXT, oxytocinergic distribution and OXT-oligomer hybridization in the preoptic area.

LOCALIZATION OF CCK AND METHIONINE-ENKEPHALIN (m-ENK) IMMUNOREACTIVITY WITHIN CELL BODIES IN THE PREOPTIC AREA AND ANTERIOR HYPOTHALAMUS OF THE BRAZILIAN GRAY SHORT-TAILED OPOSSUM. C.A. Fox, D.E. Adam, G.E. Hoffman, R.E. Watson, Jr. and C.D.Jacobson. Dept. Veterinary Anatomy, Iowa State University, Ames, Iowa 50011; Dept. Physiology, University of Pittsburgh, Pittsburgh, PA. 15261; and Dept. Anatomy, University of Kentucky, Lexington, Ky. 40536.

Sex differences in the distribution of CCK and m-ENK have been observed in the rat. In this study, we have studied the anatomical localization of CCK and m-ENK immunoreactive cell bodies in the medial preoptic area (MPOA) and anterior hypothalamus (AH) of adult colchicine treated male and female Brazilian gray short-tailed opossums, (Monodelphis domestica) using the avidin-biotin, nickel enhanced immunocytochemical technique. CCK immunoreactive cell bodies are scattered along the third ventricle, and within the paraventricular (PVN) and suprachiamatic (SCN) nuclei. In addition, males have more CCK positive cell bodies than females rostral to and within the MPOA. Also there is a group of m-ENKergic cell bodies in the dorsal MPOA, PVN and SCN. These results indicate that the localization patterns of CCK and m-ENK like immunoreactivity are in part similar to those observed previously in the rat. In addition, to our knowledge, this is the first evidence of a sex difference within the brain of a marsupial and support the use of this animal in studies investigating sexual differentiation of the brain.

271.10

CCK AND SUBSTANCE P FIBER DENSITY WITHIN THE MEDIAL PREOPTIC NUCLEUS: SEX DIFFERENCES AND CASTRATION EFFECTS. C.W. Malsbury & D.M. Nance. Dept. Psychology and Div. of Basic Med. Sci., Memorial U. of Newfoundland, St. John's, NF, Canada, A1B 3X9, and Dept. Anatomy, Fac. Med., Dalhousie U., Halifax, Nova Scotia, Canada, B3H 4H7.

Computer-based video microscopy was used to measure optical density from alternate sections stained using rabbit antibodies to CCK-8 and substance P (SP) with the PAP technique. The average optical density within the medial preoptic nucleus was taken from representative sections (one for each peptide from each rat) located rostral to Gorski's sexually dimorphic nucleus. No rats were colchicine-treated, thus stained perikarya were not visible within the nucleus. Using 4 male-female pairs we found that both CCK and SP fiber staining was denser in males than in females, but this sex difference was significant only for CCK. The effects of castration were examined at 2, 4 and 8 wks post-surgery in three groups of males (N=4/group), either sham operated (SHAM), castrated (C), or castrated and given a 45 mm silastic capsule of testosterone at the time of surgery (C+T). At 8 wks CCK staining was significantly less in group C as compared to group SHAM (30% less) and group C+T (24% less). CCK staining was also less dense in the castrated groups than in the other groups at 2 and 4 wks, but these differences were not significant. SP fiber staining was reduced slightly by castration at 8 wks: C vs SHAM, 9% lower; C vs C+T, 14% lower. Testosterone capsules maintained the density of staining for both peptides at levels comparable to those in sham operated controls.

INNERVATION OF RAT HYPOTHALAMIC PARAVENTRICULAR (PVN) PRO TRH SYNTHESIZING NEURONS BY IMMUNOREACTIVE NEUROPEPTIDE Y. R.Toni*,I.M. Jackson,R.M.Lechan.Div. of Endo., New England Med Ctr.Boston,MA 02111 and R.I.Hosp.,Providence,R.I.02902.

To determine whether neuropeptide Y (NPY)-containing afferents to the PVN terminate on thyrotropin releasing hormone (TRH)synthesizing neurons, we performed double-immunolabeling studies at light and ultrastructural levels using antisera recognizing NPY and proTRH. SD rats were perfused through the aorta with 0.2% glutaraldehyde/4% paraformaldehyde for 20 min and the brains postfixed 2 hs at 4C. Some animals were studied after 3 weeks of hypothyroidism(0.02% methimazole) to increase perikaryal immunostaining of pro-TRH. Immunocytochemistry was performed on 40 um sections through the PVN by the ABC technique using antiserum to NPY (1:2000,provided by Dr.J.Polak) and the DAB chromogen was amplified by silver-gold intensification. In a sequential step, antiproTRH(#351 or #373,1:500) was incubated with the same tissue section and identified by the brown DAB chromogen.Sections were prepared for light microscopic evaluation or embedded in Epon resin for ultrastructural analysis.NPY-immunoreactive (IR) axons densely innervated the PVN and enveloped proTRH-IR neurons in all subdivisions of the PVN making both axo-somatic and axo-dendritic contacts. Synapses were also observed between NPY-IR axons and unlabeled neurons.These studies demonstrate that the NPY afferents to the PVN innervate proTRH synthesizing neurons and provide a morphologic basis to suggest NPY-mediated regulatory function over tuberoinfundibular TRH.PHS Fellowship 1F05TW03924

RADIOIMMUNOHISTOCHEMICAL LOCALIZATION OF ANGIOTENSIN II-LIKE IMMUNOREACTIVITY IN RAT BRAIN. D.P. Healy. Department of Pharmacology, Mount Sinai School of Medicine, New York, NY 10029.

Ang II-like immunoreactivity has been localized by immunohistochemistry to discrete populations of neurons throughout the brain. The immunoperoxidase and immunofluorescent staining procedures, however, are not quantitative, such that only qualitative assessments can be made on the levels of immunoreactivity in various brain regions under normal or altered physiological states. In this report semi-quantitative radioimmunohistochemistry has been utilized in order to measure relative levels of Ang II in whole brain sections. Slide-mounted sections of rat brain were incubated with rabbit antisera directed against Ang II followed by donkey anti-rabbit [125I]-Ig-Fab secondary antibody. The sections were exposed to autoradiographic film and grain densities converted to quantities of radioactivity bound per unit area by microdensitometry. The highest concentrations of Ang II were found within the median eminence and the central nucleus of the amygdala. High densities of Ang II were found within the bed nucleus stria terminalis, supraoptic nucleus, paraventricular nucleus, spinal trigeminal nucleus and nucleus of the solitary tract. These results suggest that radioimmunohistochemistry can be utilized to measure changes in brain Ang II content within discrete nuclear groups.

271.13

RENIN AND ANGIOTENSIN-RELATED CARBOXYPEPTIDASE (ARC) ACTIVITIES CO-LOCALIZED IN SYNAPTOSOMAL FRACTION FROM RAT BRAIN. R.S. Levy, D.G. Changaris* & N.W. Lesousky*. Depts. Biochemistry, Surgery, & Lab. Biol. Psychiatry, Univ. Louisville Sch. of Med., Louisville, Ky 40292.

Des-leu angiotensin I (AI-dl) is a biologically-active peptide with markedly greater activity within the brain as opposed to the vascular system. Sucrose gradient fractions of a crude synaptosomal preparation of whole rat brain showed the highest concentrations of both renin and ARC activities within a 1.4 M sucrose pellet. This consistent finding, despite many experimental manipulations, suggests that these enzymes may be localized to the same subcellular structure. Synaptosomes were isolated from whole rat brain according to the method of V. P. Whittaker et al. (Biochem. J., 90:293, 1964). The S_3 pellet was applied to a discontinuous (0.6, 0.8, 1.0, 1.2, 1.4 M) sucrose gradient. The layers and pellet were separated, frozen, sonicated, and assayed for renin and ARC activity. Each sample was incubated either with 0.3 mM tetradecapeptide or with angiotensin I, pH 5.5. The products were assayed by HPLC. The renin and ARC activities were concentrated 83- and 43-fold, respectively, within the 1.4 M lysed pellet (absolute values: 175 and 48 nmoles/mg/min, respectively). These data suggest that AI-dl can be generated from angiotensin I within neurons without the presence of converting enzyme activity.

271.14

A NEW GASTRIN 34(1-9)-LIKE PEPTIDE IN THE HYPOTHALAMO-HYPOPHYSIAL SYSTEM OF THE FROG. F. Vandesande and S. Marivoet* Laboratory for Neuroendocrinology, Zoological Institute, Naamsestraat 59, B-3000 Leuven, Belgium.

An immunocytochemical study using mice antisera specific for the NH2 terminal of h-gastrin 34(1-9) and an anti-CCK-8 (Vanderhaeghen), recognising the penta-gastrin terminal, was performed in the hypothalamo-hypophysial system (HHS) of the frog. With the anti-CCK, immunoreactive (ir) perikarya projecting to the external region of the median eminence (EME), were observed in the nucleus infundibularis ventralis. ir-fibres were absent in the posterior lobe (PL). A strong ir was present in the cells of the pars intermedia (PI) and in some unidentified cells of the pars distalis (PD). With our anti-gastrin antisera ir-perikarya were found in the nucleus preopticus (NPO). ir-fibres were present in the EME and a very strong ir-staining was observed in the PL and the PI-cells. Some unidentified cells in the PD were ir. As the ir-cells in the PI and the PD are recognised by the anti-CCK and our anti-gastrin 34(1-9) antisera, our results suggest that in the frog a gastrin 34 like peptide or two processed peptides related to gastrin 34 are present in the PI and the PD. The material in the NPO and the PL is only ir with anti-gastrin 34(1-9) and not with anti-CCK. Therefore we conclude that in the frog HHS an unknown peptide related to gastrin 34(1-9) is present.

SOMATOSTATIN AXONS DIRECTLY SYNAPSE ON GROWTH HORMONE RELEASING HORMONE SYNTHESIZING NEURONS IN THE HYPOTHALAMIC ARCUATE NUCLEUS OF THE RAT. Zs. Liposits*, I Merchenthalar*, B. Flerko* and W.K. Paull*. (SPON: J. Dexter). Depts. of Anatomy, Univ. Med. Sch. Pecs, Pecs, Hungary and Univ. of Missouri-Columbia, Columbia, MO, USA, 65212.

Physiological studies have suggested that hypophysiotropic somatostatin (SS) and GHRH systems are functionally interrelated (Lumpkin et. al., Science 211:1072, 1981: Wehrenberg et. al., Biochem. Biophys. Res. Comm. 109:562, 1982). This immunocytochemical (ICC) double labelling study (SS antiserum 669, gift from S. Reichlin; GHRH antiserum R567) demonstrated that within the arcuate n., fusiform and multipolar GRH-synthesizing neurons demonstrating indented nuclei and immunopositive rER and 80-100nm dia. neurosecretory granules received SS-IR positive afferent fibers on their dendrites and cell bodies. Ultrastructural ICC showed SS-IR axons frequently surrounded the GRH neurons and formed direct synapses. These data support the view that the central somatostatin system is directly interconnected with the hypothalamic GRH-IR system and has the capability of influencing the activity of GRH-IR cells. Supported by grants from the U.S. NIH (NS19266), NSF (INT8703030) and (INT8602688) and the Hungarian Academy of Sciences (OTKA 104).

271.16

ULTRASTRUCTURAL LOCALIZATION OF NEUROTENSIN IN THE VENTRAL TEGMENTAL AREA AND CENTRAL NUCLEUS OF THE AMYGDALA. *V. E. Bayer, V. M. Pickel, and A. C. Towle.* Dept. of Neurology, Divs. of Neurobiology and Molecular Cornell Univ. Med. Coll., New York, NY 10021.

We determined the ultrastructural localization of a rat polyclonal antiserum to neurotensin within the ventral tegmental area (VTA) and central nucleus of the amygdala (CNA) in the rat using the peroxidase-anti-peroxidase method. Immunoblot analysis showed that this antiserum recognizes neurotensin and known neurotensin-related peptides (LANT-6, neuromedin N, Gln-neurotensin, neurotensin 8-13). In the VTA, neurotensin-like immunoreactivity (NTLI) was detected almost exclusively in the dense-core vesicles (DCV's) occurring throughout the soma and processes of labeled neurons. In the CNA, different populations of neurons were characterized either by (1) NTLI localized primarily to the DCV's, or (2) NTLI present both in the DCV's and heterogeneously throughout the cytoplasm. Neurons with NTLI from these two regions also differed in relative density of somatic contacts (more in the CNA), and relative density of glial investments (greater in the VTA). Labeled terminals from both regions displayed a number of axo-axonic appositions. The differences between the NTLI neurons in these regions may reflect contrasting distributions of dopamine (or other neurotransmitters) in the perikarya and terminals of the VTA and CNA, respectively. (Supported by NIMH grants MH00078 and MH40342 to V.M.P.).

AUTORADIOGRAPHIC DISTRIBUTION OF SOMATOSTATIN RECEPTORS IN MOUSE BRAIN DURING NORMAL DEVELOPMENT AND AFTER THE NEONATAL LESION OF BASAL FOREBRAIN. G.Forloni, C.F. Höhmann and J.T. Coyle. Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD, 21205.

Somatostatin (SOM) appears early in CNS development, and several studies suggest that it plays a role in the early organization of the brain. We previously showed that the immunocytochemical distribution of SOM in the cortex during postnatal development could be modified by neonatal lesion of the cholinergic basal forebrain (nBM). In the present study, we extended our investigations to the SOM receptors by the analysis of the autoradiographic distribution of [^{125}I]SOM binding sites during normal development and after nBM lesion. BALB/c mice received unilateral electrolytic lesion to nBM within 24 hours of birth. Animals were killed postnatal days (PD) 1, 3, 7, 14, 21, 30. Brain coronal sections were incubated with 0.5-1 nM of [^{125}I] SOM; the non-specific binding was determined in the presence of 100 μM SOM or SOM analog SMS-201-995. At PD 1, there was a high density of SOM receptors in the hippocampus, pyriform cortex and layers 5 and 6 of cerebral cortex. At PD 7, the amygdala, habenula and cingulate cortex also showed high levels of [^{125}I] SOM binding. During development and in adulthood, the concentrations of SOM receptors in thalamus appeared low. At PD 7, a decrease of [^{125}I]SOM binding sites was evident in the frontal cortex ipsilateral to the nBM lesion. The present study demonstrates the early appearance of SOM receptors during postnatal development and support a functional relationship between cortical SOM and nBM cholinergic innervation.

HIPPOCAMPAL SOMATOSTATIN HYBRIDIZATION HISTOCHEMISTRY. **R.S. Greenwood, S King*, R. Meeker, and J.N. Hayward. Dept of Neurol. and Neurobiology Prg., UNC Sch. of Med., Chapel Hill, NC 27599**

In situ **hybridization histochemistry and immunocytochemistry detect mRNA and proteins coded by mRNA, respectively and may offer alternative ways of mapping peptides. To compare these techniques in an anatomically well-defined region of the brain, the distribution of preprosomatostatin (PPSRIF) mRNA in the septal hippocampus was compared to that of somatostatin-like (SRIF-L) immunoreactivity.**

Coronal sections of the septal hippocampus from adult Sprague Dawley rats were processed by *in situ* hybridization using a ^{125}I-labeled 30-mer oligonucleotide directed against the 3' coding region of PPSRIF mRNA. Grain counts from the resulting autoradiograms were made in each of the subdivisions of the hippocampus and over individual cells. Sections from some animals were also processed for combined *in situ* hybridization and immunocytochemistry for localization of PPSRIF and SRIF-L immunoreactivity in the same section. *In situ* hybridization of adjacent sections with a PPSRIF mRNA nonsense probe were used as controls. The distribution of PPSRIF mRNA in the septal hippocampus corresponded well with SRIF-L immunoreactivity. In sections undergoing combined *in situ* hybridization and immunocytochemistry cells labeled by the oligonucleotide probe had SRIF-L immunoreactivity.

We conclude that the distribution of PPSRIF mRNA in the septal hippocampus is the same as SRIF-L immunoreactivity. These results provide validation that *in situ* hybridization of PPSRIF may be an alternative means for localizing and perhaps quantifying SRIF-L neurons in the hippocampus.

DIFFERENTIAL REGULATION OF STRIATAL NEUROPEPTIDE Y AND SOMATOSTATIN CONTAINING NEURONS IN THE RAT. R.J. Boegman, Y. Smith, A. Parent, J-C. Martel, and R. Quirion. Departments of Pharmacology and Toxicology, Queen's University; Laboratoire de Neurobiologie, University Laval, Douglas Hospital Research Centre; and Department of Pharmacology, McGill University.

Neuropeptide Y (NPY) has been localized to a subpopulation of medium-sized aspiny interneurons in the striatum also containing somatostatin (SS) and NADPH-diaphorase activity. Previously, Kerkerian et al. (Neurosci. Lett. 66: 106, 1986) reported an increase in striatal NPY immunoreactive neurons following a unilateral 6-hydroxydopamine (6-OHDA) lesion of the nigra. Our study sought to establish whether following a unilateral 6-OHDA nigral lesion the striatal NPY and SS immunoreactivity increased in parallel. In addition, binding of NPY and SS to striatal tissue was evaluated. Rats showing a behavioural response to dextroamphetamine were used. Six weeks after the lesion, animals were perfused and serial sections stained for NPY or SS immunoreactivity. While striatal NPY staining increased by 35% ipsilateral to the lesion, SS immunoreactivity remained unaltered. In striatal tissue ipsilateral to the lesion, there was a 27% decrease in NPY binding and a 76% increase in SS binding. Our data indicate that striatal NPY immunoreactive neurons are under tonic dopaminergic control.

DISTRIBUTION OF SUBSTANCE P-CONTAINING FIBERS IN THE HUMAN PREFRONTAL CORTEX. K. Satoh, S. Iritani*, M. Fujii*, and S. Takahashi*. Dept. of Psychiatry, Shiga Univ. of Medical Sciences, Otsu 520-21, Japan.

As shown in previous neuroanatomical studies, the prefrontal cortex of mammalian brain possesses unique substance P (SP)-containing neuronal systems, and the existence of SP-containing fibers has been briefly reported in the human neocortex. In the present study, a detailed morphological description of SP-immunoreactive cell bodies and fibers in the human prefrontal cortex is given using normal post-mortem materials. The brains were sliced and fixed with Zamboni mixture immediately after being dissected out, and standard ABC-immunoperoxidase histochemistry was conducted using a monoclonal antibody against SP. Many SP-immunoreactive fibers were observed throughout the layers of prefrontal cortex. The laminar distribution of SP fibers was similar to those of the monkeys (Macaca fuscata), and fine immunoreactive puncta were seen throughout the superficial layers, I-III, particularly dense in the molecular layer.

271.21

CHEMOARCHITECTONIC PATTERNS OF PEPTIDES IN HUMAN BASAL FOREBRAIN: EVIDENCE FOR A SYSTEM COMPRISING THE BED NUCLEUS, SUBSTANTIA INNOMINATA, AND CENTRAL AMYGDALA. L.J. Martin*, V.E. Koliatsos, R.G. Struble, R.E. Powers*, and D.L. Price SPON: (M.V. Wagster). Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182

Chemoarchitecture peptidergic systems in the human basal forebrain were studied to investigate relationships between the bed nucleus of the stria terminalis (BST), the substantia innominata (SI), and the central amygdala (CEA). Acrolein-fixed autopsy material (postmortem delay 5-11 hours) from six controls (27-66 years of age) was processed immunocytochemically for the presence of leucine-enkephalin (LENK), somatostatin (SOM), and neurotensin (NT). In the BST and CEA proper, three similar types of coextensive immunoreactivities were shown: LENK-, SOM-, and NT-positive, medium-sized, ovoid, and pyriform somata bearing 2-4 primary dendrites; LENK- and SOM-positive woolly fibers; and LENK-, SOM-, and NT-positive puncta. In the SI, a dense plexus of LENK/SOM woolly fibers and LENK, SOM, and NT puncta extended from the ventral BST to dorsal CEA; peptide-positive perikarya with the same morphology as those in BST/CEA were rarely observed. These results indicate that human BST and CEA exhibit similar chemoarchitectonic features and are interconnected through SI and that this continuum may represent a reciprocal en passant system with punctate terminations on unidentified target neurons.

271.22

DETECTION OF VASOPRESSIN mRNA IN CELLS OF THE MEDIAL AMYGDALOID NUCLEUS BY IN SITU HYBRIDIZATION. J. H. Urban, M. A. Miller* and D. M. Dorsa. Depts. Pharmacol. and Med., Univ of WA and GRECC, VAMC, Seattle, WA 98108.

Vasopressin (VP)-immunoreactive cell groups have been reported in the amygdala. The purpose of this study was to verify the presence of VP synthesizing neurons in the medial amygdala using in situ hybridization histochemistry.

Brain sections (15um) from 3 adult male Wistar rats were hybridized using an oligonucleotide probe that is complementary to the glycopeptide portion of the mRNA encoding vasopressin. The sections were dipped in NTB$_2$ emulsion, exposed for 10 days and developed. Semiserial sections of the medial amygdala were analyzed under dark-field microscopy and cells were quantified using an automated grain counting system.

Cells expressing VP mRNA were localized in the medial amygdala from the anterodorsal through the posterodorsal aspect of the nucleus. Twelve to 32 cells were found per section with the heaviest density of cells occurring at 2.12 to 3.40mm caudal to bregma (Paxinos and Watson, 1986). Labeling intensity of cells averaged 53.1 ± 3.3 grains/cell and was relatively constant throughout the nucleus. This data demonstrates the presence of AVP synthesizing cells in the medial amygdaloid nucleus and provides a method for quantifying their activity.

DISSOCIATION OF 5-HT FROM THYROTROPIN RELEASING HORMONE (TRH) IN RAT FOREBRAIN REGIONS. A. Sattin, M.J. Kubek, W.C. Low, C.J. Staley*, and J.R. Simon. Depts. of Psychiatry, Anatomy and Physiology, VA Med. Center and Indiana U. School of Med., Indianapolis, IN 46223.

TRH is known to be co-localized with 5-HT in a portion of the raphé neurons that project to the spinal cord of rat. Co-localization was explored in forebrain by use of chemical lesioning with 5,7 dihydroxytryptamine (DHT) and by surgical lesioning of fiber tracts projecting to the hippocampus (HC). TRH was assayed by specific RIA and 5-HT and 5-HIAA by HPLC. Three weeks after 100 µg DHT (free base injected in 10 µl over 1 min) i.c.v. (desipramine 25 mg/kg i.p. at -45 min) 5-HT and 5-HIAA were depleted in anterior and pyriform cortex and dorsal and ventral HC, but TRH was unchanged in all regions. Results of surgical lesions of fimbria-fornix (FF) alone and FF plus dorsal or ventral perforant path (PP) revealed, after 3 weeks, a major 5-HT input via FF and a smaller one via PP (undetectable 5-HT and reductions in 5-HIAA). TRH was also significantly reduced. Previous immunohistochemistry has localized TRH to the intrinsic CA and granule cells of HC and to other forebrain neurons, but extrinsic TRH is also possible in HC. Since 5-HT axons terminate on CA cells, granule cells and other forebrain neurons these results suggest that 5-HT and TRH are not co-localized in the forebrain, but might, instead, interact indirectly in cell-cell regulation. Supported by VA, MDA and AG5575.

INSULIN-LIKE IMMUNOREACTIVITY IN HUMAN BRAIN. **C.A.Bennett-Clarke*, G.C.Budd*, B.Pansky* and M. Velasco (SPON: A.McGrady). Depts. Anatomy, Physiology & Pathology, Medical College of Ohio, Toledo, OH 43699.**

Several reports indicate that insulin and its receptors are present in the mammalian CNS. In this study, adult human brain was examined for insulin localization using routine immunocytochemical techniques. Frontal cortex and hypothalamus fixed in formalin were sectioned with a vibratome or a sliding microtome, pretreated in 3% H_2O_2, rinsed in PBS and stained immunocytochemically. We used a monoclonal antibody (purified ascites fluid) to human insulin (Biogenex Labs.). Sections were sequentially incubated in primary antiserum (1:100 - 1:500), biotinylated anti-mouse IgG (1:100),streptavidin /HRP (1:100) and DAB. Rat and human pancreas sections were used as positive controls. Negative controls included (1) absence of the primary antisera or (2) immunoabsorbed ascites fluid. In both areas positive staining was limited to neuronal perikarya in two patterns. The first was a diffuse brown cytoplasmic stain, while the second pattern appeared as a group of punctate granules within the cytoplasm or maybe on the cell surface. Within the cortex, immunoreactive cells were usually pyramidal. Hypothalamic insulin-IR neurons occurred mostly in the paraventricular and lateral regions.

LOCALIZATION OF SPINALLY PROJECTING M-ENK-LIKE IMMUNOREACTIVE LOCUS COERULEUS NEURONS IN THE CAT. V.K. Reddy*, S.J. Fung, H. Zhuo* AND C.D. Barnes, Dept. of VCAPP, Washington State University, Pullman, WA 99164

Studies in the past have revealed the presence of several peptidergic and cholinergic somata in relation to catecholaminergic cell bodies in the locus coeruleus (LC) complex of the cat. Most catecholaminergic cells are also said to contain enkephalin. The purpose of this study was to localize spinally projecting neurons containing either M-ENK-, SP-, TH- or ChAT-like immunoreactivity. In anesthetized cats, a 30% solution of HRP was injected either into cervical or lumbar enlargements followed by intraventricular injection of colchicine 48 hrs later. The animals were perfused after a 24 hr survival period and appropriate levels of the brainstem were sectioned (25 - 30 µm) on a freezing microtome. The sections were reacted for HRP using DAB following heavy metal intensification. The sections were then incubated in antisera raised to either M-ENK, SP, TH or ChAT and processed by peroxidase immunochemistry.

Spinally projecting M-ENK- and TH-like immunoreactive neurons were frequently evident in various nuclear groups of the LC complex. On the other hand none of the SP and ChAT positive neurons appeared to project to the spinal cord. Quantitative analyses are currently underway to ascertain the extent of the descending M-ENK- and TH-like immunoreactive neurons. (Supported by NIH grant NS24388).

Computer-aided mapping of specific neuronal populations in the human brain. Edward T. Koh*, Edward G. Stopa, Joan C. King, Wade T. Rogers, and James S. Schwaber. Dept. of Anesthesiology, UMass Medical Center, Worcester, MA 01605, Depts. of Neurosurgery, Pathology, and Anatomy & Cell Biology, Tufts Univ. Medical School, Boston, MA, and duPont Experimental Station, Wilmington, DE (SPON: A. Tischler)

It has recently become possible to stain human autopsy brain tissue with informative marker substances. Analyzing such tissue effectively has been very difficult using conventional manual charting methods because of scaling problems resulting from the sheer size of the brain. We have used a computer-aided microscopic mapping system to study the distributions of several peptide-containing neuronal populations in this tissue. To our knowledge, these are the first high-resolution panoramic maps of specific neuronal populations in the human brain.

Relatively large (2x2x1 cm) blocks encompassing the preoptic area, hypothalamus, and portions of the amygdala were sectioned and stained with antibodies to either mammalian LHRH, lamprey LHRH, neurotensin, or neuropeptide Y. With computer assistance, maps were generated which represent the positions of labeled cell bodies and axons, to a resolution approaching one micron in the X and Y dimensions. Computer-aided three-dimensional reconstructions help to clarify the organization of the projection systems. The use of IBM-compatible microcomputer-based systems to perform such mapping and reconstruction will be discussed.

SELECTIVE IRBP ACCUMULATION ON THE SURFACE OF CULTURED MOUSE PHOTORECEPTORS: EVIDENCE FOR THE EXISTENCE OF IRBP BINDING SITES? **L. Politi*, L. Lee*, B. Wiggert*, G. Chader* and R. Adler, (SPON: E. Adler-Graschinsky) Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD. and NEI, Bethesda, MD.**

The retinoid binding protein IRBP is synthesized by photoreceptor cells, and may function in vitamin A transport between them and the pigment epithelium. We are investigating mechanisms regulating IRBP synthesis, secretion and binding, using cultures of isolated mouse retinal neurons and photoreceptors in retinoid-free, chemically-defined medium. Western and slot blot analysis of the cultures demonstrated the presence of IRBP both in cell extracts and conditioned medium. IRBP immunoreactivity was exclusively associated with photoreceptors, and was not detectable in non-photoreceptor neurons. IRBP appeared to accumulate in photoreceptors in a developmentally regulated manner, both in detergent-permeated and in unpermeated cultures. In the latter, IRBP-like immunoreactivity was restricted to the surface of the photoreceptor inner segment. This surface labeling became undetectable within 6 hrs after switching the cultures to fresh, IRBP-free medium, suggesting a correlation between the presence of IRBP in the medium and its accumulation on the photoreceptor cell surface. Thus, our studies indicate that isolated mouse photoreceptors accumulate and secrete IRBP even when grown in the absence of retinoids, and suggest that they may also have cell surface binding sites for this molecule.

NICOTINIC ACETYLCHOLINE RECEPTORS AND CHOLINE ACETYLTRANSFERASE IN THE DEVELOPING CHICK RETINA. K.T. Keyser*, T.E. Hughes, P.J. Whiting*#, J.M. Lindstrom# and H.J. Karten, (SPON: N.Lugo-Garcia). Dept. of Neurosciences, UCSD, 92093 and Receptor Biology Laboratory#, Salk Institute for Biological Studies, La Jolla, CA 92138.

A population of amacrine cells in the vertebrate retina is thought to use acetylcholine as a neurotransmitter. Putative cholinergic neurons in the chick retina have been studied using antisera directed against choline acetyltransferase (ChAT). Similarly, putative *cholinoceptive* cells were recently identified with monoclonal antibodies directed against the nicotinic acetylcholine receptor (nAChR). We have used these markers in combination to visualize presumptive pre- and postsynaptic elements in the developing chick retina.

Embryonic day 6 (E6): In the central retina, near the vitreal surface, both ChAT-positive and nAChR immunoreactive cells were present. **E8:** Two rows of cells, separated by the nascent inner plexiform layer (IPL), exhibited ChAT immunoreactivity. nAChR positive somata were present in both rows interspersed among the ChAT positive cells. **E10:** ChAT immunoreactivity was visible in two laminae of the IPL adjacent to the rows of immunoreactive somata. Many of the nAChR-positive somata in the inner nuclear layer (INL) were tear-drop shaped and some gave rise to short processes. **E14:** A few large nAChR immunoreactive cells, possibly displaced ganglion cells, were visible in the INL. nAChR-positive processes were visible in two laminae of the IPL. **E18:** The distribution of both ChAT and nAChR-positive cells was comparable to that seen in the hatchling with immunoreactive cells present in both the INL and GCL and a bilaminar distribution of processes in the IPL. These results suggest that ChAT and nAChRs are present in discrete populations of cells in the embryonic eye from at least E6 onward. The populations are present well before the onset of synaptogenesis. Supported by EY06890 and NS24560 to H.J.K.

DEVELOPMENT OF THE INNER PLEXIFORM LAYER OF THE NORTH AMERICAN OPOSSUM. [1]T.M. Fischer,[2]M.A. Kirby, and [1]P.D. Wilson. [1]Dept. of Psych., Univ. of Cal. Riverside, Riverside CA 92521, [2]Depts. of Ped. and Anat., School of Med., Loma Linda Univ., Loma Linda, CA 92350.

We have examined synaptogenesis and formation of the IPL in opossum pups at light and electron microscopic levels.

The presumptive IPL is first apparent at postnatal day 12 (P12, gestation = 13 days) as a narrow zone separating the cytoblast layer from the developing ganglion cell layer. The width of the IPL remains relatively constant until P30, when it begins to exhibit rapid growth. At the EM level, opposing membrane densities lacking vesicles can be seen at P17. Contacts resembling conventional synapses can be detected at P26, near the time of peak axon counts in the developing optic nerve, and prior to the period of the highest rate of axon elimination. Contacts resembling bipolar cell ribbon synapses appear to be present at P51, 9 days prior to eye opening.

In general, the pattern of synaptogenesis observed in the opossum is similar to that seen in placental mammals, with a possible exception being the occurrence of conventional synapses prior to the period of peak axon elimination.

A GRADIENT OF CELL ADDITION TO THE OUTER NUCLEAR LAYER MAY INFLUENCE DIFFERENTIAL RETINAL EXPANSION. A.D. Springer, M. Berk*, J. Vogel*, and B. Wilson*. Dept. Of Anatomy, New York Medical College, Valhalla, NY 10595.

An intraocular injection of tritiated-thymidine labels cells born over a 1 week period. The number of labeled cells in the goldfish retinal ganglion cell (GCL) and outer nuclear (ONL) layers increases for 1 week post-injection. Excluding the germinal zone, about 20,000 cells are added across the entire GCL and 16,000 cells to the ONL over the 1 week period. By 16 weeks post-injection, only 400 labelled cells remain in the GCL, but 8,000 cells (presumably rods) remain in the ONL. Densitometric analysis of silver grains overlying cells in the GCL indicates that the disappearance of these cells is not related to multiple divisions diluting out the label. Instead, most of these cells may die within 2 weeks of being born. Reconstruction of the position of the labelled ONL cells indicates that there is a peripheral-central gradient of cell addition to the ONL. Excluding germinal zone cells, 43% of the cells added to the ONL are in the outer 8% of the retina. Comparable areas located more centrally contain a progressively smaller proportion of the new cells: 12% and 5%. The central 76% of the retina contains only 40% of the new ONL cells. More cells being added peripherally to the ONL may cause the periphery of the other retinal layers to expand more than their centers.

ANALYSIS OF THE OPTIC NERVE FIBER DIAMETER SPECTRUM IN THE WL-WABBLER-LETHAL MOUSE. E.W.CARROLL*, R.L.CURTIS, AND J.L.MELVIN* DEPT.BASIC SCI.MARQUETTE U. SCH. OF DENT. AND DEPTS. OF ANAT. & CELL BIOL., PHYSICAL MED. & REHAB., MED. COLL. OF WIS., MILWAUKEE, WI 53233.

The purpose of this investigation was to contrast optic nerve fiber diameter spectra in C57BL/6J wl-wabbler lethal mice (wl/wl) with controls (+/+). We have demonstrated that the pathology observed in wl/wl optic nerves fits the criteria of primary axonal (Wallerian) degeneration (Carroll & Curtis, Anat. Rec. 202:28A, 1982). The ALICE image processing system at the Argonne National Laboratory (Potts et. al., Invest. Ophthal., 11:980, 1972) provided total counts and cross sectional area of all myelinated optic nerve axons in 10 control and 7 wl/wl mice at 28 days post-partum.

No significant difference was found in either the total cross-sectional area of optic nerves in +/+ vs wl/wl ($0.05>p>0.025$) or in the total number of myelinated optic nerve fibers in +/+ ($\bar{X}$=37,357) vs wl/wl ($\bar{X}$=34,890) ($0.3>p>0.02$). Analysis of axonal diameter spectra indicates that while no significant differences exist for fibers less than 1μm in dia. (90% of total), wl/wl optic nerves exhibited fewer fibers greater than 1 μm in dia. ($p<0.01$ after Bon Feronni correction).

MOUSE RETINAL GANGLION CELL MORPHOLOGY. S.D.Schlussman*, S.C.Sharma and A.Bernstein*(SPON. S.Fraley). Depts. Anatomy and Ophthalmology, N.Y.M.C., Valhalla N.Y.10595 and Medical Genetics, Univ. of Toronto.

The intricate pattern of retinal neuronal connectivity is refined through a process of developmentally regulated cell death. Previous studies have demonstrated that this naturally occuring cell death can be reduced experimentally, indicating that this process is at least partially dependent on competition between ganglion cell (g.c.) axons for terminal sites. Analysis of g.c.morphology in these experimentally manipulated "crowded" retinae reveals a general reduction in soma size and dendritic field area. It has been suggested that the size of g.c. dendritic fields is influenced by interactions with nieghboring cells. Thus there appears to be both intra and extra retinal factors determining cell size and density.

Recently a transgenic microphthalmic mutant mouse has been described, and it may provide a useful model for analysis of g.c. and dendritic field size. In order to ascertain whether the transgenic mouse g.c.have reduced dendritic arborizations it was neccesary to first characterize the normal mouse g.c. morphology. Following HRP injection into the superior colliculus, retinal g.c. were analyzed based on soma size and dendritic morphology. This report details the characterization of the normal and transgenic mouse retina. Supported by NEI 01426

DENDRITIC GROWTH OF IMMATURE GANGLION CELLS FOLLOWING THE DEATH OF MATURE ONES IN THE GOLDFISH'S RETINA. P. F. Hitchcock, Department of Ophthalmology, The University of Michigan, Ann Arbor, MI 48105

The retina of the goldfish grows throughout its life, in part, by the continual addition of new neurons at the margin. New ganglion cells, on average, grow a minor proportion of their dendritic arbor toward central retina (Hitchcock and Easter, J. Neurosci., 6:1037, 1986). Hitchcock and Easter (op. cit.) proposed that this lack of dendritic growth into more central regions resulted from the dendrites of older ganglion cells excluding the dendrites of the younger ones.

I tested this proposal by killing existing ganglion cells with retrogradely transported propidium iodide, allowing the retina to continue growing up to 8 months, and observing the dendritic morphology of the cells located near the margin. The dendritic arbors were stained by filling them intracellularly with lucifer yellow.

Two results were found: 1) In the experimental retinae, those ganglion cells residing near the margin grew their dendrites preferentially toward central retina. 2) The branching pattern of these cells' dendrites was often abnormal. These results suggest that interactions among the growing dendrites of adjacent ganglion cells (see Wassle et al., Nature, 292:344, 1981) control both their orientation and branching pattern.

272.8

RETINAL GANGLION CELL (RGC) DEATH AFTER AXOTOMY IS INFLUENCED BY THE DISTANCE BETWEEN THE LESION AND THE NEURONAL SOMATA M.P. Villegas-Perez*, M. Vidal-Sanz*, G.M. Bray and A.J. Aguayo (SPON: S.A. Keirstead). Neurosciences Unit, The Montreal General Hospital and McGill University, Montréal, Québec, Canada, H3G 1A4.

Axotomy close to the perikaryon, which is a requisite for the regrowth of CNS axons into peripheral nerve grafts, also causes the death of large numbers of neurons (Villegas-Pérez et al., J.Neurosci. 8:265, 1988). To quantitate the effect of distance of axotomy from the cell body on neuronal survival, we retrogradely labelled RGCs with diI applied to the superior colliculus and dLGN of adult Sprague-Dawley rats, transected the optic nerve (ON) at four points along its course in different groups of animals, and determined the densities of surviving (diI labelled) RGCs in 12 standard areas of each retina.

In control retinas, the mean density of diI-labelled RGCs was 2288 +66; one month after ON transection, these values were 18% of controls for ON lesions 0.5 mm from the eye; 31% for 3 mm, 55% for 8 mm, and 71% for 10 mm. These results indicate that small changes in the location of ON lesions can lead to substantial differences in RGC survival. Variations in a source of trophic influences available in ON stumps of different lengths may be one of several possible explanations for the observed relationship between RGC survival and the distance of the axotomy from the cell body.

A SINGLE CELL ANALYSIS OF THE EARLY STEPS OF RETINAL GANGLION CELL DIFFERENTIATION IN *XENOPUS*: FROM SOMA TO AXON TIP.

Christine E. Holt. Dept. of Biology, B-022, UCSD, La Jolla, CA 92093.

Intracellular dye injections of Lucifer yellow (10%) were made into retinal ganglion cells (RGCs) of embryonic *Xenopus* retina in part to determine whether the growth cones of these cells make dye-coupling junctions with other cells along the primoridial optic pathway. Wholemount preparations were treated with α-LY Ab after injection, reacted for HRP with DAB and sectioned at 40 μm. No evidence of dye-passing contacts could be found at any stage of the pioneering growth cone's route suggesting that junctional mediated intercellular signalling does not play a major role in pathfinding.

Quantitative analysis of the dimensions and complexity of growth cones at different points in the pathway revealed that those at the optic nerve head (onh), where growth cones turn to leave the retinal surface, are significantly larger than elsewhere and possess more filopodia than growth cones in the rest of the ipsilateral stretch of the pathway (retinal surface, optic nerve, brain entry point). Growth cones in the contralateral stretch of the pathway (chiasm and optic tract) show a similar degree of complexity as those in the onh but are smaller.

To determine whether dendrite elaboration is coordinated with target arrival, dendrite genesis was examined in single RGCs whose axon tips were at varying positions along the pathway. 20% of RGCs whose axon tips were located within the retina have begun to elaborate dendrites. This figure increases linearly with respect to axon length such that ~90% possess dendrites by the time their growth cones reach the dorsal optic tract. This study also revealed the surprising finding that ~5% of RGCs send more than one axon into the optic pathway.

EM ANALYSIS OF SINGLE RETINAL GANGLION CELL TERMINALS IN DEVELOPING *RANA PIPIENS*

Lai-Hsing Yen*and M. Constantine-Paton. Dept. of Biology, Yale University, New Haven, CT 06511

Retinal ganglion cell (RGC) terminals in developing frog tecta are dynamic structures that continually make new synapses at distal sites and retract established branches in proximal parts of the arbor. We are asking whether these dynamic processes are reflected in either the morphology or distribution of synapses within single arbors.

Forty micron vibratome sections of aldehyde fixed tecta containing a few HRP filled RGC terminals are reacted with DAB, post-fixed with osmium ferricyanide, dehydrated and embedded in Spurr's medium. The entire morphology of well isolated individual terminals is reconstructed at the light microscope level. Semi-thick and intervening ultra-thin sections through these terminals are used to localize HRP labeled profiles at the EM level. Vesicle density, synaptic distribution, and organelles of these profiles are recorded.

We find that most labeled RGC synapses are made on small clear profiles, many of which in turn synapse onto other clear profiles. Less frequently, the clear profile post-synaptic to a RGC terminal receives an additional synapse from an unlabeled process. Post-synaptic profiles rarely contain glycogen but frequently show irregularly shaped vacuoles. The preceeding properties are common to proximal and distal regions of the terminals. The synaptic density does not vary greatly between these two regions. However, the density of synaptic vesicles is clearly higher in distal regions, suggesting that vesicle accumulation precedes morphologically discernable synapses. (Supported by NIH grant EY06039)

SYNAPTIC OVERLAP FOLLOWED BY SEGREGATION OF DIFFERENTIALLY LABELED OPTIC TERMINALS IN THE GOLDFISH OPTIC TECTUM.

R.L. Meyer & G.H. Kageyama. Dev Bio Center, UC Irvine, CA 92717.

When optic fibers from both eyes are made to grow simultaneously into one tectum in goldfish, regenerating fibers from the two eyes initially overlap, then segregate into discrete columns. In order to determine if the early overlapping fibers formed transient synapses we developed a method by which we could differentially label terminals from the two eyes so that they could be distinguished from each other at the E.M. level. The optic nerve of one eye was crushed and the fish returned to its tank for 2 days, then a tube filled with HRP was applied to the cut end of the left optic nerve and allowed to survive for another 2 days, during which time HRP was allowed to fill the optic axons of the opposite eye. In this way one set of optic terminals was labeled by electron dense degeneration while the other set was labeled with HRP. During the early phase of regeneration (1 mo post deflection + optic nerve crush) HRP labeled fibers were readily observed at the light microscope level. Axons from either eye formed a diffuse overlapping projection in anterior to middle and eventually posterior tectum. At the E.M. level the differentially labeled optic fibers are intermingled and form overlapping synapses. After column formation the optic terminals undergoing electron dense degeneration were clearly segregated from those labeled with HRP. This is a clear example of synaptic plasticity in adult CNS. Support:NIH NS-16319.

REGENERATING OPTIC AXONS FORM TRANSIENT TOPOGRAPHICALLY INAPPROPRIATE SYNAPSES IN GOLDFISH TECTUM:A WGA-HRP EM STUDY.

GH Kageyama, RL Meyer. Dev Bio Center, UC Irvine, CA 92717.

Crushed optic axons in the mature goldfish will gradually reinnervate the contralateral tectum and restore correct retinotopography. Regenerating axons often follow abnormal routes to reach their topographically correct position. Along the way, axons may branch and form early terminal-like arborizations. Since normal numbers of optic synapses are observed as early as 1 mo postcrush when optic axons are not yet refined, it is likely that many early synapses are both transient & topographically inappropriate. Small 2nl injections of WGA-HRP were made in ventronasal retina to label a corresponding set of axon terminals that normally terminate within a topographically discrete & predictable 200 um diam spot in the contralateral medial posterior tectum. These spots were revealed with a modified TMB method. At the EM level the TMB reaction product was readily identified almost exclusively in optic terminals located within the spots. Similar injections in ventronasal retinae of early 3 wk regenerates labeled only transient ectopic synapse-forming terminals in anterior tectum. Most of these early regenerating fibers were small & formed immature en passant type synapses. No label was found in the topographically appropriate (medioposterior) area of tectum. By 5wk postcrush, large tectal areas were labeled including both appropriate and inappropriate regions. After 2 mo, label was again confined to small spots. Support:NIH NS-16319.

272.13

THE EFFECTS OF GLUTAMATE RECEPTOR AGONISTS AND ANTAGONISTS ON THE EVOKED TECTAL POTENTIAL IN *RANA PIPIENS*.

E.A. Debski and M. Constantine-Paton. Dept. of Biology, Yale University, New Haven, CT 06511.

The NMDA receptor, a subclass of glutamate receptors, appears to play a role in the establishment of retinal-tectal topography in tadpoles (Cline et al., PNAS, 84: 4342, 1987). We have used our cannulated tadpole preparation (Debski et al., Neurosci. Abstr. 13: 1691, 1987) to examine the effects of NMDA and the antagonist APV on the tectal potential evoked by bipolar stimulation of the optic nerve. Unexpectedly, we found that post-synaptic activity is blocked reversibly by NMDA in a dose-dependent manner: perfusion of the preparation with 6 μM NMDA blocks approximately 50% of the post-synaptic response; perfusion with 12 μM NMDA, essentially all of the response. In contrast, APV at physiological doses (60μM) increases slightly the positive component of the post-synaptic response. This effect too is fully reversible and as with NMDA, the changes are stable and complete within 15 minutes of drug application.

We are currently investigating if NMDA decreases synaptic transmission by affecting directly retinal ganglion cell terminals and/or by increasing tectal inhibition. This work was supported by NIH grants EY05829 and EY06039.

272.14

NMDA RECEPTOR ANTAGONIST, APV, DISORGANIZES THE RETINOTECTAL MAP.

H.T. Cline & M. Constantine-Paton. Dept. Biology, Yale Univ. New Haven, CT 06511.

The NMDA receptor plays a role in eye-specific segregation of retinal ganglion cell (RGC) terminals in the optic tecta of three eyed tadpoles (Cline et al, 1987, PNAS 84: 4243). We have shown that chronic application of the NMDA receptor antagonist, aminophosphonovaleric acid (APV), to the optic tectum results in the desegregation of the RGC terminals without blocking pre- or post-synaptic activity and without altering arbor morphology as seen with TTX treatment.

We have mapped the retinotectal projection in APV-treated tadpoles by focally injecting HRP into the rostro-medial tectum to label the RGCs projecting to that tectal site. Care was taken to inject uniform amounts of HRP. HRP-labeled RGCs were located primarily in the ventral-temporal retina, but in APV-treated tadpoles, labeled RGCs were dispersed over a greater area of the retina than in staged control tadpoles. In addition, individual labeled RGCs were occasionally seen in the nasal retina. These data support the hypothesis that the NMDA receptor is involved in the activity-dependent fine-tuning of the retinotectal projection. This work is supported by NIH grants EY05818 and EY06039.

272.15

NMDA BLOCKERS PREVENT BOTH RETINOTOPIC SHARPENING AND LTP IN REGENERATING OPTIC PATHWAY OF GOLDFISH. J.T. SCHMIDT, Dept. Biol. Sci., SUNY Albany, NY 12222.

The regenerating retinotectal projection of goldfish has an increased capacity for LTP that may be related to the activity driven sharpening of the retinotopic map. In normals, field potentials elicited by optic nerve shock are very stable. In newly regenerated projections (20-40 days), responses are initially small (<1mv), but giving 20 stimuli at 0.1Hz results in a 100-200% increase in amplitude that is stable for hours. Topical application of NMDA blockers AP5 or AP7 at 25μM prevents potentiation without decrementing ongoing responses (AP6 does not). To test whether NMDA blockers also prevent retinotopic sharpening, I infused AP5 or AP7 into the ventricle for 2-3 weeks during regeneration using osmotic minipumps (3-4μl/day of 500μM soln; approx. 50X dil. in CSF). Electrophysiological mapping at 53-107 days postcrush showed that AP5 and AP7 (but not AP6) blocked the sharpening. At each tectal point, responsive areas in the visual field were enlarged to 28°(vs 10° normally). This was comparable to data from fish regenerating with activity blocked (TTX) or strobe synchronized and indicates uncorrected errors in targeting of regenerated arbors (Schmidt, Cell & Molec. Neurobiol. 5:65, 1985). In the current model, retinotopically appropriate synapses (and branches) are stabilized because the normally correlated firing of neighboring ganglion cells should result in the summation of postsynaptic responses and in effective activation of NMDA receptor channels triggering Ca^{++} entry.(NIH grant EY03736).

272.16

THE ROLE OF NMDA RECEPTORS IN THE DEVELOPMENT OF BINOCULAR MAPS IN XENOPUS TECTUM. W.S. Scherer* & S.B. Udin. Dept. of Physiol., SUNY, Buffalo, NY 14214.

The tectum of Xenopus frogs receives input from both eyes. The contralateral eye's projection reaches the tectum directly, via the optic nerve, and the ipsilateral eye's projection reaches the tectum indirectly, via the nucleus isthmi. The isthmotectal (IT) map shows great plasticity during development and it will reorganize in response to rotation of one eye.

The effects of chronic treatment with the agonist NMDA and antagonists APV and CPP on development of binocular tectal maps in Xenopus reared with 90° rotation of the left eye were examined electrophysiologically. Drugs were administered topically via slow release from Elvax polymers implanted below the tectal pia. Animals treated with NMDA exhibited congruent, rotated maps on the right tectum (5 out of 6). In 4 out of 4 APV-treated animals, the retinotectal map was rotated 90° as expected, but the isthmotectal map from the unrotated eye was unrotated; and thus the two maps were approximately 90° out of register. CPP-treated animals (5 out of 6) also had appropriately rotated contralateral maps but the IT map was incongruent and only the central 40% of the ipsilateral visual field was represented. These results indicate that NMDA receptors play a role in the topographic organization of binocular tectal maps. Supported by USPHS Grant EY-03470 to S.B.U.

272.17

MICROSTIMULATION IN THE AREA OF NUCLEUS ISTHMI ENHANCES TECTAL RESPONSES TO OPTIC TRACT STIMULATION IN GOLDFISH. W.M. King & J.T. Schmidt, Biol. Dept., SUNY Albany, NY 12222

Although the retinotectal transmitter is most likely an excitatory amino acid, a cholinergic modulation is likely since 1) nicotinic receptors are present on retinal terminals 2) cholinergic agents affect transmission and 3) ChAT pos. fibers are present in the same lamina of tectum and originate from both tectal pyriform neurons and the Nucleus Isthmi (NI) which is reciprocally connected with tectum. We have used an in vitro preparation of goldfish tectum and brainstem to test whether activity from NI may modulate retinotectal transmission. We used metal microelectrodes to stimulate in the area of NI and verified the sites histologically. Retinotectal field potentials were similar to those recorded in vivo and stable for hours. The short latency monosynaptic response was followed by a polysynaptic response about 15 msec later. Single shocks to the optic tract also evoked repetitive field potentials in NI, as observed by Vanegas et al. When optic tract stimulation was preceded by a shock to NI, the mono- and polysynaptic tectal responses were larger (about 15 and 50% respectively) and the latency of the polysynaptic response decreased. The effect was apparent at intervals of 10 to 100msec following NI stimulation and maximal when optic tract stimulation was submaximal. In summary, we have found that single shocks to the optic tract elicit repetitive field potentials in NI and that stimulation of NI area enhances subsequent tectal responses to optic tract stimulation. (NIH grant EY03736).

272.18

FIBRE ORDER IN THE RODENT'S OPTIC TRACT: DISTRIBUTION OF OPTIC AXONS, GENESIS OF RETINAL GANGLION CELLS, AND THE POSITION OF GROWTH CONES IN DEVELOPMENT **B.E. Reese* and R.J. Colello* (SPON: F.A.W. Wilson) University of Oxford, Dept of Human Anatomy, Oxford, U.K.**

The generative periods for neuronal sub-populations in the retinal ganglion cell layer were examined by combining tritiated thymidine autoradiography with horseradish peroxidase histochemistry, and were then compared with the relative distributions of their axons in the optic tract of adult rats. The distributions of axon-like and growth cone-like profiles in the developing optic tract was also examined during the neurogenetic period in embryonic rats and mice.

In adult rats, the largest optic axons are found deep in the tract, and their cells of origin (Type I) are generated early (E.14-16). The finer optic axons are found at all locations across the optic tract, and their parent cells (Types II/III) are generated simultaneous to and well after Type I cell genesis (E.14-20). Uncrossed optic axons are found relatively deep in the optic tract, but with very few positioned at the deep and superficial borders; genesis of their cells peaks relatively early (E.16), with few cells generated before (E.14) or after (E.18). During this neurogenetic period, the developing optic tract continues to accumulate axonal profiles, yet the profiles of presumed growth cones are found only along the tract's superficial (sub-pial) border. These results suggest that fibre position within the adult optic tract is an index of axonal arrival during development, and indirectly, a chronology of neurogenesis.

272.19

IS THERE SUBSTANTIAL TOPOGRAPHIC ORDER DURING DEVELOPMENT OF THE RAT RETINOCOLLICULAR PROJECTION? J.P.A. Yhip* and M.A. Kirby (SPON: S. Yellon). Depts. of Pediatrics and Anatomy, Sch. of Med., Loma Linda University, Loma Linda, CA 92350.

It is well demonstrated that during development retinal projections are both more extensive and numerous than at maturity. At present, however, little is known of the topographic order of these projections. To explore this, we have examined the distribution and density of labeled retinal ganglion cells following placement of discrete deposits of a tracer into the superior colliculus (SC) of neonatal and adult rats.

Small deposits of rhodamine filled latex microspheres (0.02-0.1 μl using glass pipettes, tip diameter 25-30 μm) were placed into the SC of pigmented rats ranging in age from the day of birth to adulthood (hypothermia or barbiturate induced anesthesia). Following a 36-48 hr survival period, the animals were deeply anesthetized with barbiturate and perfused through the heart with saline, followed by a 10% formal-saline solution. The location and density of labeled ganglion cells were plotted on drawings of retinal wholemounts.

In all ages examined where deposits were localized to the SC, an area of high density labeled ganglion cells was observed in a restricted portion of each retina. The area of labeled cells was always topographically appropriate in relation to the location and extent of the SC deposit. At all ages examined this pattern was most pronounced for deposits into the peripheral-caudal pole of the SC (which avoids the problem of fibers of passage). Also present in each retina were a small number of labeled ganglion cells that were widely dispersed and distant to the high density area and are presumed to represent topographic errors. These results suggest a high degree of topographic order is present during neonatal development of the rat retinotectal projection.

272.20

A RETROGRADE LABELLING STUDY OF THE UNCROSSED RETINOFUGAL PATHWAYS IN DEVELOPING NORMAL RATS AND RATS WITH UNILATERAL NEONATAL THALAMECTOMY OR EYE REMOVAL. S.O. Chan* and L.S. Jen. Department of Anatomy, The Chinese University of Hong Kong, Hong Kong.

The present study has compared the numbers of ipsilaterally projecting retinal ganglion cells(IPRGCs) observed in developing Sprague-Dawley albino rats and rats which received left thalamectomy(T) or monocular enucleation(E) at birth, with WGA-HRP introduced to their right thalami.

The results obtained from normal rats showed that the average total number of IPRGCs decreased from 3700 cells/retina on day 0(day of birth) to reach the adult level of 1200 cells/retina on postnatal day 5. The number of IPRGCs in T cases however increased to about 4500 cells/retina on postnatal day 1 before it decreased rapidly to achieve the adult figure of about 2400 cells/retina on postnatal day 5. Similar trend of changes in the total number was also observed in E cases, with the maximum reaching about 4000 cells/retina on day 1.

These results indicate not only that the elimination of IPRGCs in one eye during development can be prevented by a contralateral thalamic lesion or eye removal made at birth, but also suggest that there is misrouting or rerouting of optic axons at the optic chiasma following the lesion, which probably leads to retention of some of the IPRGCs which normally do not persist into adulthood.

273.1

ISOLATION AND CHARACTERIZATION OF HUMAN MUSCLE cDNA CLONES IMMUNOREACTIVE TOWARDS ANTIBODIES PRODUCED IN HUMAN MYASTHENIA GRAVIS. M. Mihovilovic*, A.E. Waters*, A.D. Roses. Duke Univer. Med. Ctr., Durham, NC., 27710.

In human myasthenia gravis (MG) circulating auto antibodies to several uncharacterized antigens are produced. We have found MG antibodies that bind to at least 5 (non-cholinergic) muscle proteins resolved by SDS electrophoresis and also to different muscle structures in muscle tissue sections.

We have used MG antibodies to screen an expression muscle cDNA library and isolated 4 immunoreactive cDNA clones.

Nucleotide sequence analysis (of about 300 base pairs) indicate that 3 of them (8/3, 9/3 and 7/9) carry identical cDNA sequences. The cDNAs have a length from 1.38 to 1.9 Kb. Northern blot analysis employing mRNA purified from different human tissues have shown that these cDNAs exclusively hybridize to mRNA species expressed in human muscle.

The fourth clone (7/3) carries a 1.8 Kb insert which hybridizes to at least 3 muscle mRNA species and to a unique mRNA species present in MG thymoma.

Studies are currently in progress to obtain the complete sequence of these clones and to characterize the fusion proteins that they encode. These cDNAs will be further used to study the relationship that exists between circulating antibody to non-cholinergic muscle antigens and disease expression of myasthenia gravis.

GENETIC LINKAGE STUDIES IN FAMILIAL AMYOTROPHIC LATERAL SCLEROSIS (ALS). D. A. Figlewicz*[1,2], G.R. Rouleau*[1], J.L. Haines*[1], R.H. Brown, Jr.*[1] and the Collaborative Familial A.L.S. Study Group. (SPON: J.A. Nathanson). [1] Neurology Service, Ma. General Hosp., Boston, MA 02114; [2]CNS Research, Cambridge, MA 02139.

The etiology of motorneuron death in ALS is unknown. In the 5-15% of cases which are familial, genetic analysis may lead to the identification of the defective gene(s) and provide insight into the molecular basis of the disorder. We are evaluating 36 multi-generational ALS families in which the inheritance pattern appears to be autosomal dominant. Blood specimens have been obtained and lymphoblastoid lines established for 160 family members including 24 individuals with ALS. Potential informativeness of families was evaluated using the LIPED program, varying parameters such as penetrance, polymorphism information content and map position. In these families, a random search of the entire genome is underway using standard genetic linkage techniques employing highly polymorphic DNA markers. Results of the genetic linkage search are analyzed by LIPED. Updated results will be presented.

MATHEMATICAL SIMULATION OF THE EFFECTS OF AXIAL DIFFUSION AND NON-ZERO-ORDER KINETICS ON OXYGEN DELIVERY IN PERIPHERAL NERVE. T. D. Lagerlund and P. A. Low. Department of Neurology, Mayo Clinic, Rochester, MN 55905 USA

We have extended our previous mathematical model of the oxygen supply of peripheral nerve tissue to include additional effects which make the model more realistic. Our simulation of the release, diffusion, and consumption of oxygen in the capillaries and surrounding tissue of peripheral nerve now includes axial diffusion in blood and in surrounding tissue in addition to bulk flow of blood and radial diffusion of oxygen out of the capillary. Also, our simulation assumes that the oxygen consumption of nerve tissue obeys Michaelis-Menten kinetics rather than zero-order kinetics as had been assumed in the Krogh model. With these assumptions, we could calculate via numerical solution of the relevant differential equations, the oxygen tension at all points in the capillary and surrounding tissue, as a function of distance from the center of the nearest capillary and distance along the capillary from the arterial to the venous end. Using average measured values for microcirculatory parameters in rat nerve, we calculated a distribution of oxygen tension values which agrees reasonably with experimentally measured distributions. The effects of axial diffusion and of Michaelis-Menten kinetics on the oxygen distributions were noticeable under normal conditions, but these effects were even more important in situations in which oxygen delivery was adversely affected.

MUSCULAR DYSTROPHY: ISOPROTERENOL-DEXAMETHASONE SYNERGISM IN CHICKENS. R.K. Entrikin, R.T. Abresch*, R.H. Lantz*, D.B. Larson*, and D.P. Bradford*. Dept. of Physical Medicine & Rehab., Univ. of California, Davis, CA 95616.

Earlier we showed that glucocorticoids (GLU) increase muscle function (ES, exhaustion score) in genetically dystrophic chicks. More recently, a GLU improved muscle strength in Duchenne dystrophy patients. Unfortunately, adverse effects (such as weight loss in chicks) were noted at effective doses. In this study we administered (i.p.) dexamethasone (DEX), a GLU, in combination with isoproterenol (ISO), which reduces body weight less than DEX at effective doses. DEX alone (0.1 mg/kg/day) and ISO alone (1.0 mg/kg/day) produced 22-day ESs (mean $\pm$ SEM) of 4.2 $\pm$ 1.3 (n = 23) and 1.8 $\pm$ 0.7 (n=24), respectively. (Mean ES for untreated normal chicks is about 20; for dystrophics only about 1.5.) In combination, the same doses of DEX and ISO increased the 22-day ES to 15.4 $\pm$ 2.5 (n = 11) and produced weight reduction similar to that with DEX alone. In brief, ISO potentiates the beneficial effects of GLUs, but does not ameliorate the adverse effects in avian dystrophy. (Supported by MDA and NIDRR Grant # H133B80016.)

ULTRASTRUCTURE OF SKELETAL MUSCLE IN MULTIPLE SCLEROSIS. A. Márquez*, C. García*, H.J. Finol and I. Mosquera*. Medicine and Sciences Faculties, Universidad Central de Venezuela. Apartado 50587, Sabana Grande, Caracas, Venezuela.

Although motor disturbances are common in multiple sclerosis and muscle atrophy may occasionally be present in this disease, its skeletal muscle pathology has not been studied. In this work we report the findings observed in a muscle biopsy made for diagnosis purposes in a multiple sclerosis patient, a 20 years old woman who presented blurred speech, ataxic gait, bilateral ptosis of eyelids, tongue fasciculations, increased deep tendon reflexes, and mental disorders. EMG study was no conclusive. Alterations found were: atrophy which varied from slight to severe, disorganized contractil and sarcotubular systems, bizarre mitochondria, presence of glycogenosomes some of them limited by mitochondrial membranes, muscle basement membrane thickened and reduplicated in some areas. Satellite cells were abundant and proliferative. Capillary alterations included thickening and reduplication of basement membrane and occlusion of lumen. Macrophages were present in the extracellular space and next to capillaries. Multiple sclerosis is not considered a muscle disease but the histopathological changes we observed can not be explained only in a neurological basis. Because of that, the presence of a primary miopathic component could be part of the etiopathogenesis in this entity.

EVIDENCE AGAINST FUNCTIONAL DENERVATION AT THE WOBBLER MUTANT MOUSE NEUROMUSCULAR JUNCTION J.H. LaVail, K.P. Irons* and D.C. Bowen* Dept. Anatomy and Neuroscience Program, U.C.S.F., San Francisco, CA 94143

Based on the extensive degeneration of motoneurons in the cervical spinal cord, the wobbler (*wr/wr*) mutant mouse has served as a model for human neurodegenerative diseases, such as Werdnig-Hoffman disease. In the course of the first ultrastructural investigation of neuromuscular junctions (nmj) in the lateral rectus muscles of *wr/wr*, we found the major distinguishing feature of the *wr/wr* muscle compared to control muscle was that the postjunctional folds of endplates were shallower and less numerous than those of age-matched controls (Soc. Neurosci. Abst. 1986, 262). To investigate the nmjs further we have now used a variety of techniques. Labeling of dissociated muscle fibers with ^{125}I-a-bungarotoxin showed that acetylcholine receptors (AChR) were clustered at the nmj, but there was a 1.4 to 1.9-fold increase in extrajunctional binding within 100 μm of the endplate; beyond 100 μm the level of binding was indistinguishable from that of control muscles. Indirect immunocytochemical studies using antibodies against AChR subunits (donated by Z. Hall and Y. Gu, UCSF) indicated the presence of mature subunits clustered at the nmjs. Although we have no quantitative estimates, our histochemical evidence indicates that acetylcholinesterase is present in the cleft of the *wr/wr* nmj. Since the nerve terminal shows no degenerative features, there is no increase in extrajunctional binding beyond 100 μm of the vicinity of the endplate, and the AChR are apparently composed of mature subunits, we conclude that the changes in the endplate membrane of the *wr/wr* lateral rectus muscle are not due to denervation. Furthermore, the maintenance of postjunctional folds and the insertion of mature AChR at the *wr/wr* nmj are apparently independent events. (Supported in part by N.I.H. NS 13533).

ALTERATION OF SODIUM CHANNEL INACTIVATION IN A RAT MODEL OF MYOTONIA PRODUCED BY REDUCING EXTRACELLUAR CHLORIDE. R.L. Ruff. Dept. of Neurology, Cleveland Veterans Administration Med. Ctr. and Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106

Several forms of myotonia in humans and animals including myotonia congenita, Becker's form of myotonia and myotonia in goats are associated with reduced muscle chloride conductance. Myotonia can be produced in vitro by reducing skeletal muscle membrane chloride conductance. The effects of reducing extracellular chloride concentration on sodium channel gating in rat extensor digitorum longus muscle was studied using the loose-patch voltage clamp. Cells were studied in solutions with 132.5 mM or 14 mM chloride concentration. Chloride was replaced by methylsulfate. In 14 mM chloride muscle cells were hyperexcitable with depolarizations of about 10 mV from the resting potential producing repetitive action potentials. Sodium channel fast inactivation was shifted by +15 mV and the rate of fast inactivation was slower in low chloride solutions. Slow inactivation appeared to be shifted by +18 mV, and the shift in slow inactivation increased the current available for depolarizations from the resting potential by 287% in 14 mM chloride. In contrast, the voltage dependence of sodium channel activation did not appear to be altered. The changes in sodium channel inactivation could contribute to the hyperexcitability seen in this model of myotonia. However, it is not clear if similar changes occur in any of the natural forms of myotonia.

A COMPARATIVE STUDY OF DISEASED HUMAN MUSCLE XENOGRAFTS IN ATHYMIC RATS AND MICE. A.K. Gulati*, M.H. Rivner* and T.R. Swift* (SPON: D.S. Feldman). Departments of Anatomy and Neurology, Medical College of Georgia, Augusta, GA 30912.

We studied the fate of skeletal muscle biopsied from patients with Duchenne muscular dystrophy, amyotrophic lateral sclerosis and polymyositis after transplantation into athymic (i.e. immunodeficient) rats and mice. In each recipient rodent, the extensor digitorum longus (EDL) muscle was removed. The biopsied human muscle was then placed in the site previously occupied by the EDL muscle and sutured in place under slight tension. Muscles were removed at one, 3, 6 and 10 months after transplantation for morphological analysis. In nude mice, the muscle transplants survived, underwent successful regeneration and innervation by host motor neurons. In contrast, muscles in nude rats after initial regeneration underwent regression and extensive replacement by connective tissue. It is concluded that human muscle xenografts do not survive in nude rats but do in nude mice. This difference in the acceptance of transplanted human muscle may be related to differences in the immunocompetency between the two species. Transplantation of human muscle into nude mice offers an in vivo model to study the etiology of various neuromuscular disorders.

CLINICAL AND ELECTROMYOGRAPHIC RESPONSES TO INDUCED PARALYSIS IN INHERITED CANINE PERIODIC PARALYSIS. G.A. Hegreberg, M. Paloheimo*, M. Moore*, S. Jenkins* and B. Rigor*. Washington State University, Pullman, WA 99164 and University of Louisville, Louisville, KY 40292.

An autosomal recessive disorder of dogs is accompanied by generalized muscular weakness and progressive muscle atrophy with extreme sensitivity to cold, exercise and excitement stress. The severe and intermittent muscle weakness associated with the canine condition has clinical similarities to the periodic paralyses of people, especially hypokalemic periodic paralysis. Clinical and electromyographic studies were performed to compare this canine condition to the human hypokalemic periodic paralysis. These studies included 1) induction of skeletal muscle paralysis, 2) measurement of evoked compound muscle action potentials (ECMAP) before and after induction of paralysis and 3) measurements of serum electrolytes levels before and after the induction of paralysis. Muscle paralysis was induced in three affected adult male dogs by the intravenous administration of glucose and insulin with subsequent metabolic alkalinization with sodium bicarbonate. The ECMAP's were measured from the interosseous muscles of the forelimb after stimulation of the ulnar nerve. Clinically, a profound generalized muscle paralysis was produced in the affected dogs after administration of gluocose, insulin, and sodium bicarbonate. The post-administration ECMAP's were depressed to 40-60% of baseline levels. Serum potassium and sodium levels were within normal range prior to the induction of paralysis. Potassium levels were decreased to 1.5-3.0 mmol/liter during the height of the paralysis. Respectively, sodium levels were elevated to 162-179 mmoles/liter. The clinical and electromyographic changes found in this canine disorder are similar to human hypokalemic periodic paralysis and this canine disease provides an animal model for further characterization of the pathophysiology of this disease. Supported in part by NIH RR00515, Washington State University, the University of Louisville, Datex, and Cadwell Laboratories.

A QUANTITATIVE ANIMAL MODEL FOR STUDYING THE EFFECTS OF SHORT TERM ELECTRICAL STIMULATION ON THE REHABILITATION OF DENERVATED MUSCLE PARALYSIS. W.Bedingham* and D.G.Ericson*. (SPON: J.Heltzel). 3M Biosciences Laboratory, St. Paul, MN 55144.

The clinical utility of electrotherapy in the treatment of flaccid muscle paralysis remains controversial. The present study was designed to quantify and evaluate the rehabilitative efficacy of electrical stimulation on the fundamental electrophysiology and pathology of denervated muscle in controlled animal studies (Chinchilla sp.). The animals were divided into 3 primary groups: (1) unilateral denervation of the tibialis anterior (TA) muscle, (2) bilateral denervation of the TA muscle, and (3) control - no denervation. Each primary group was subdivided into a stimulated or nonstimulated subset, and each subset was further subdivided according to the method of stimulation (intramuscular, epysmisal), duration of stimulation, and stimulus pattern. After the prescribed stimulation period, each TA muscle was examined by quantitative electrophysiological and histochemical techniques. The treatment methods were compared by nonparametric analysis between independent subgroups and within subgroups, using the test and contralateral TA muscle in each animal as a matched pair.

Denervation caused significant reduction in muscle tissue weight and fiber diameter, decreased tetanic tension and fatigue resistance, and prolonged single twitch contraction times. Depending on the treatment methodology used, it was shown that electrical stimulation could provide significant improvement in these deficits. Comparison between matched denervated TA pairs showed that 20 minutes of electrical stimulation per day provided significant increase in muscle weight, fiber diameter, and tetanic tension. Only a limited increase in benefit was observed in animals treated with longer daily stimulation times. When compared to matched normal TA muscles, however, the electrically stimulated denervated TA muscles remained significantly inferior in mechanical performance and morphology.

MYOBLAST INJECTION TREATMENT FOR MUSCLE WEAKNESS. P.K. Law, T.G. Goodwin*, H.J. Li* and M. Chen*. Depts. of Neurology and Physiology/Biophysics, University of Tennessee Memphis, Memphis, TN 38163

A treatment has been developed to prevent hindlimb and intercostal muscle weakness in murine dystrophy. Injection of histoincompatible normal myoblasts/fibroblasts (co-culture) into dystrophic muscles improved the structure and function of the muscles to almost normal. Immunosuppression of the C57BL/6J-$dy^{2J}dy^{2J}$ hosts was by way of daily subcutaneous injection of cyclosporin-A. Injected dystrophic muscles exhibited greater cross-sectional area, total fiber number, wet weight, and twitch and tetanus tensions six months postoperatively. Fiber typing was more defined and they contained more normal-appearing and less abnormal-appearing fibers than non-injected controls. Eleven out of nineteen mice that received myoblast injections on both sides showed such behavioral improvement that their locomotive patterns were indistinguishable from normal. Using dimeric isozymes as genotype markers for host and donor cells, the demonstration of parental and hybrid isozymes inside the injected muscles substantiated the survival and development of donor myoblasts into normal myofibers, and the fusion of normal myoblasts with dystrophic satellite cells to form genetically mosaic myofibers. Since the treatment design is based on muscle developmental processes universal to all mammals, it has potential for clinical application. (Supported by USPHS NS-20251 and NS-26185).

LAYER VII OF RODENT CEREBRAL CORTEX. G.S. Goodwin and R.L. Reep. Department of Neuroscience, J-244 JHMHC, University of Florida, Gainesville, FL 32610.

The cerebral isocortex is usually considered to be a six-layered structure. However anatomical findings suggest that a seventh layer be recognized in rodent isocortex. Injections of retrograde fluorescent tracers into medial agranular cortex produce labeled cells in somatic sensory and visual cortex. These occur as sheets or clusters in layers II/III, V and the deepest portion of the gray matter immediately adjacent to the underlying white matter. Injections in lateral agranular, somatic sensory, or visual cortex result in similar laminar labeling patterns in those isocortical regions containing labeled neurons. Adjacent stained sections reveal that the deep lying cells reside in a thin continuous layer closely adherent to the underlying white matter and separated from layer VI by a cell-sparse fiber plexus zone (which we have previously demonstrated to contain corticocortical axons). It is this deep cell layer to which we refer as layer VII. All isocortical regions of the rat brain exhibit a well defined layer VII with overlying cell sparse zone. Maximilian Rose identified layer VII in several other species of rodents as well.

Developmental studies (including our own) indicate that layers VII and I originate from an early primordial plexiform layer which is later split by the cortical plate that forms layers II-VI.

We suggest that layer VII be considered a distinct entity on cytoarchitectural, developmental and connectional grounds. It remains to be seen to what extent layer VII is definable in all rodents and among other mammalian orders.

RAT MEDIAL AGRANULAR CORTEX CONNECTIVITIES. Sherry L. Stuesse and Donald B. Newman, NEOUCOM, Rootstown, OH, 44272 and USUHS, Bethesda, MD 20814-4999.

Rat medial agranular cortex (AGm) may be homologous to monkey frontal eye fields (FEF). To test this hypothesis, AGm connections were determined by use of a Phaseolus lectin, WGA-HRP, or the Wiitanen/Fink-Heimer method. AGm projected to cortex: orbital, AGm, motor, anterior cingulate, retrosplenial, and perirhinal. AGm received input from dorsopeduncular cortex and contra AGm. Subcortical projections were similar to those of monkey FEF and targeted gaze control and visual orientation areas: rostral interstitial nucleus of the medial longitudinal fasciculus, paramedian pontine reticular formation (reticularis pontis oralis, caudalis and reticularis gigantocellularis), nuclei cuneiformis and subcuneiformis, subthalamicus, pretectalis, raphe centralis superioris, and superior colliculus. Reciprocal connections were made with the following thalamic nuclei: intralaminar, mediodorsal, ventrolateral, ventromedial, parafascicular, and posterior. AGm projected to caudate-putamen, basilar pontine gray, central gray, and zona incerta. AGm received input from raphe dorsalis and globus pallidus. Differences in connections between rostral and caudal injections were observed: caudal AGm projected more heavily to those regions implicated in eye movement control. These experiments confirm that AGm in rat contains the homologue of primate FEF. AGm may also be homologous to the primate supplementary motor area as evidenced by connections with globus pallidus, caudate-putamen, and motor cortex.

274.3

DISTRIBUTION, ONTOGENY AND CONNECTIONS OF CHOLECYSTOKININ (CCK) mRNA NEURONS IN THE RAT CORTEX. J-M. Burgunder*, W.S. Young III Lab of Cell Biology, Natl. Inst. Mental Health, Bld36, Rm 3A17, Bethesda, MD 20892.

CCK-immunoreactive neurons are located in all cortical layers. These neurons participate in local circuitry but a role in more distal innervation is debated. In the present study, CCK neurons were studied by *in situ* hybridization (using a synthetic, 48base oligonucleotide probe, labeled with [S35]dATP using terminal deoxynucleotidyl transferase) and fluorogold retrograde labeling. Different neuronal types containing CCK mRNA were present in all cortical layers: moderately labeled neurons were few in I, plentiful in II to superficial IV, and few in deeper IV and superficial V, whereas many, more heavily labeled neurons, were present in deep V and VI. In addition, some very heavily labeled neurons were found scattered in all layers.

In the developing cortex, CCK mRNA was seen for the first time in some cells of the primordial plexiform layer at E15, followed two days later by cells in the cortical plate. This pattern matured gradually, in parallel to the cortical morphogenesis, reaching adult-like patterns at the 20th postnatal day.

After several injections of the fluorescent dye fluorogold into cortical and subcortical target areas of the neocortex of adult rats, many cortical neurons with CCK mRNA were retrogradely labeled. These results indicate that cortical CCK neurons establish extensive associational (e.g. parieto-frontal), commissural (e.g. frontal) and corticofugal (e.g. corticostriatal) pathways.

274.4

CORTICOSPINAL (CS) NEURONS MAY SEND MULTIPLE AXONAL BRANCHES THROUGH THE PYRAMIDAL TRACT. D.L. O'Donoghue, M.T. Cox and D.R. Humphrey. Lab. of Neurophysiology, Emory Univ., Atlanta, GA 30322

The number of CS cells has been estimated after placements of Fast Blue (FB) in the mid-cervical spinal cord of adult rats (over 3 weeks of age; n=3). Dye placements were maximized by transecting the dorsal funiculus and placing gelfoam soaked in 5% FB within the transection. After a week survival, rats were sacrificed and the cerebral cortex was sectioned coronally at 50um. The numbers of FB labeled cells in 500um bins were counted and sections were sampled every 400um. Cell distributions were constructed and the number of FB labeled CS cells was estimated.

The estimated total number of CS cells was 28,293 (± S.E.6933) in one hemisphere. Even if this represents an underestimate, there are still far more axons in the rat CS tract: 80,000 cervical CS fibers (Leenan et al. '85, Brain Res. 359:65). Electron microscopic studies are underway to verify the number of fibers in the cervical CS tract. Because of the disparity between the number of labeled CS cells and the reported numbers of CS fibers, we suggest that many CS neurons have 2 or more axonal branches in the CS tract. (Supported by NIH Grant NS20146).

274.5

COLLATERAL PROJECTIONS OF SENSORY CORTICAL NEURONS IN HOODED RATS THAT PROJECT TO THE TECTUM AND THE PONS. L.E. Hallman, B.R. Schofield, and C.-S. Lin. Dept. Anatomy, Duke Univ. Med. Cntr., Durham, NC 27710.

We have used the retrograde transport of Fluoro-Gold and rhodamine-coated beads to determine the incidence of sensory cortical neurons which send axon collaterals to both the tectum and the pons. Recently, we have used this combination of dyes to show that in primary visual cortex over 60% of the neurons that project to the superior colliculus also project to the pons (Hallman et al., J. Comp. Neurol., in press).

We examined 442 cells from four cases. The data from auditory and extrastriate cortices were similar. Over 60% of the labeled layer V neurons had collaterals to both the tectum and the pons. Of the labeled corticotectal cells over 75% were double-labeled and of the labeled corticopontine cells over 74% were double-labeled. Similar precentages were found in somatosensory cortex, even though the pontine injection may have labeled corticospinal and corticobulbar, as well as corticopontine cells. Thus, corticotectal and corticopontine projections arise to a large degree from the same cells in each of these cortical areas. This property may be a general characteristic of all cortical areas.

274.6

INTERACTION OF SEROTONIN AND GABA IN CEREBRAL CORTEX AND HIPPOCAMPUS. I. Törk* and J.-P. Hornung. (SPON: C. Straznicky). School of Anatomy, University of New South Wales, Kensington, NSW 2033, Sydney, Australia and Institute of Anatomy, University of Lausanne, 1005 Lausanne, Switzerland.

The cerebral cortex is innervated by two distinct and morphologically different serotonergic subsystems (Kosofsky and Molliver, *Synapse* 1:153, 1987; Mulligan and Törk, *J. Comp. Neurol.* 270:86, 1988). One of the fiber systems is characterized by large axon terminals, and is in synaptic contact with the somata and dendrites of a subpopulation of non-pyramidal neurons in the neocortex and hippocampal formation. A significant percentage of cortical non-pyramidal neurons is GABAergic (Gabott and Somogyi, *Exp. Brain Res.* 61:323, 1986), and we have used double labelling immunohistochemical techniques to demonstrate the direct interaction between serotonergic axons and glutamic acid decarboxylase- (GAD), or GABA-immunoreactive neurons, in the cat. We have surveyed large populations of cortical GABAergic neurons in sections of the auditory, somatic sensory and prefrontal cortex in which we have also demonstrated serotonergic axons using a monoclonal antibody against serotonin. All layer I neocortical neurons densely innervated by serotonergic axons were also immunoreactive for GAD or GABA. The innervating axons made multiple synaptic contacts with their target cells and many single boutons exhibited multiple synaptic densities. However, many layer I GABAergic neurons did not receive serotonergic input. Densely innervated GABAergic neurons were less common in layers II and III and could not be observed in any of the deeper layers. Further evidence for interaction of serotonergic axons with GABAergic neurons was found in the dentate gyrus in which a distinct layer of serotonergic axons innervated the dendrites and somata of basket cells at the interface between granule and polymorph layers. These results strongly suggest that the brainstem reticular formation has direct access to some of the key neurons in cortical circuitry and could modulate cortical inhibition via the ascending serotonergic pathways.

INHIBITION SHAPES THE SIZE OF MOTOR CORTEX REPRESENTATIONS K.M. Jacobs and J.P. Donoghue Center for Neural Science, Brown University, Providence, RI 02912

Intracortical electrical stimulation mapping reveals a somatotopically organized representation in cerebral motor cortex (MI). We have shown that this representation reorganizes within hours of a peripheral nerve transection that disconnects one part of the representation from its target muscles. In the present experiments we examined the hypothesis that intracortical inhibitory circuitry blocks the expression of connections that can effectively alter the MI representation pattern.

The MI representation pattern was mapped using standard intracortical electrical stimulation techniques in 8 ketamine anesthetized rats. Vibrissa (Vib) and forelimb (FI) sites were localized by stimulating with pulse trains (60 μA) at 11-40 sites spaced 250-500 μm apart. The FI area was defined by recording the electromyogram (EMG) from the elbow flexor and wrist extensor muscles contralateral to the mapped cortex. After initial mapping the stimulating electrode was fixed at a single site 0.25 to 1.0 mm medial to the Vib-FI area border. At this site Vib movements were observed, but no FI EMG was elicited at 60 μA. Next, a glass micropipette (tip diameter 1-2 μm) containing 10 mM bicuculline methylbromide (BMB) was placed at a depth of 1.8 mm in the FI area, 1.0 to 2.0 mm lateral to the stimulating electrode. After 15-75 minutes of continuous BMB ejection (50-150 nA) FI EMG (as well as Vib movement) was elicited by stimulating at the Vib site; 30-290 minutes after stopping the ejection only Vib movements were evoked at this site. Similar iontophoretic ejections of either AChCl or Na glutamate were applied separately from the BMB at the FI site for up to 2 hours. Neither caused a shift in MI representation. In no case was a spread of distant representations into the stimulated region observed.

These experiments indicate that the strength of excitatory connections between somatic representations and thus, the amount of cortex involved in the control of individual muscle groups is regulated by intracortical inhibition. It is not yet clear whether bicuculline unmasks circuits that are already present or whether secondary time-dependent processes are involved. However, it appears that increasing intracortical excitation alone is not sufficient to produce map shifts. Finally, these results demonstrate that a cortical substrate exists for producing shifts in MI organization similar to those we have observed following peripheral nerve lesions.

REGIONAL DIFFERENCES IN DISTRIBUTION AND STAINING INTENSITY OF ASPARTATE-LIKE IMMUNOREACTIVITY IN RAT CEREBRAL CORTEX. C. Toomim, P. Petrusz* and J. Caffrey*. University of North Carolina, Chapel Hill, NC 27599 and Baylor College of Medicine, Houston, TX 77030.

Major divisions of the rat cerebral cortex were examined for differences of distribution and intensity of staining with an antiserum formed against aspartate-glutaraldehyde-hemocyanin (Hepler et al., J. Histochem. Cytochem., 36:13, 1988). Rats were anesthetized with chloral hydrate or pentobarbital and perfused with 1% paraformaldehyde (PF) followed by 4% PF-0.5% glutaraldehyde. Coronal vibratome and paraffin sections were incubated with anti-Asp and stained by standard immunoperoxidase methods. Staining was seen in perikarya and dendrites in all layers. Sections were analyzed visually and given intensity values from 0 (no stain) to 3 (dark specific stain). Staining patterns in various cortical areas include: Cingulate: gradual increase from light rostrally to dark caudally. Retrosplenial: dark throughout. Frontal: light at the medial border, moderate laterally. Parietal: light ventrolaterally, dark dorsomedially. Occipital: light medially and laterally, moderate to dark centrally. Temporal: light to moderate. Insular and perirhinal: light. Piriform and entorhinal: little or no stain. These results suggest that there are substantial differences in the distribution and intensity of Asp-like immunoreactivity between topographically and functionally distinct areas of the rat cerebral cortex.

274.9

ZINC-CONTAINING AXONAL TERMINALS IN RAT NEOCORTEX ARE PREDOMINANTLY CORTICAL IN ORIGIN. S. D. Hill and C. J. Frederickson, Lab. for Neurobiology, Univ. of Texas at Dallas, Richardson, TX 75080.

Laminae I-III and V of the neocortex are innervated by zinc-containing axonal systems, the boutons of which can be stained by zinc:TSQ fluorescence or neo-Timm's silver methods. These boutons have been shown to have Gray's Type I morphology (Perez-Clausell and Danscher, Brain Res., 1985, 335: 91-98), but the cells of origin have not been determined.

We have studied the zinc staining in the neocortex of the rat after either (a) surgical isolation of cortical "islands" or (b) destruction of local cortical neurons with ibotenic acid. The results indicate that the zinc-containing boutons are predominantly of intrinsic origin. Thus, in 2-4 mm diameter cortical islands (undercut through the white matter and surrounded by a circular knife cut from pia to white matter) the zinc staining in laminae I-III and V persisted with minor alterations throughout 7 day survival periods. In contrast, after focal destruction of cortical neurons by ibotenic acid (10 ug in 1 ul), zinc staining was completely abolished throughout most of the lesioned area. Efforts to identify specific cells of origin by retrograde transport of ZnSe from the boutons are in progress. Supported by MH 42798.

ANTIBODY TO A SOLUBLE PROTEIN PURIFIED FROM BRAIN SELECTIVELY LABELS LAYER V CORTICOFUGAL PROJECTION NEURONS IN RAT NEOCORTEX. B. B. Stanfield and D. M. Jacobowitz. Laboratory of Clinical Science, NIMH, Poolesville, MD 20837.

Protein 36 is a soluble protein isolated and purified from rat brain. In the rat neocortex, antibody to this protein labels the cell bodies and processes of pyramidal cells within layer V (Fukuda, T., and Jacobowitz, D.M., *Brain Res.*, 441:185-194, 1988). We have used the fluorescent retrograde tracer, Fast Blue (FB), in combination with FITC immunocytochemistry to determine the projection sites of the cortical neurons detected by this antibody. FB was injected (0.3-0.5 μL of 2% FB) into either the pyramidal decussation, the pyramidal tract in the pons, the inferior colliculus or the parietal cortex on one side. Six days later the rats were perfused, the brains sectioned and the sections processed for immunocytochemistry.

Following injections into the pyramidal decussation or into the pyramidal tract many of the FB labeled pyramidal tract neurons in the parietal cortex were also FITC labeled. Similarly, after inferior colliculus injections many FB labeled corticotectal neurons in the auditory cortex were FITC labeled. In these cases there were, in addition, many FITC labeled neurons which were not FB labeled, but in only a relatively small number of FB labeled neurons was FITC labeling not detected. In contrast, after injections into the contralateral cortex, FB labeled callosally projecting neurons in layer V were not FITC labeled. Thus, antibody to protein 36 may selectively detect within the neocortex a particular neuronal cell type, the corticofugal projection neurons of layer V.

QUANTITATIVE ANALYSIS OF CHOLINERGIC FIBERS IN THE RAT CEREBRAL CORTEX. H. Ojima*, T. Yamasaki*, H. Kojima*, and A. Akashi* (SPON: Y. Shinoda). Research Institute, Daiichi Seiyaku, Co., Ltd., Tokyo 134, JAPAN

No systematic investigation of the regional heterogeneity in the distribution pattern of cortical cholinergic fibers has yet been carried out. We determined their density over various regions in the rat cerebral cortex.

Cholinergic fibers were visualized using a monoclonal antibody to choline acetyltransferase. The number of positive fibers crossing the ruled lines of a counting grid in the microscope ocular was counted. Measurement was made at regular intervals from the pial surface of the sections passing through six anteroposterior levels.

In the frontal cortex, the density of positive fibers was constant throughout the layers. In the parietal, temporal, and occipital cortices, the density in the superficial and deep layers was 1.5 to 3 times higher than that in the middle layer. In the anterior cingulate cortex, the density in the middle layer was 1.5 times higher than that in the superficial and deep ones, but this difference became obscure at more posterior level. In the piriform cortex (PC), the middle density was 2.5 to 3 times higher than the superficial and deep one. The entorhinal cortex showed a laminar distribution pattern similar to that in the PC, but the middle density was only 1.5 times higher than the superficial and deep one. These results show the region-specific distribution pattern of cholinergic fibers.

TRANSNEURONAL RETROGRADE TRANSPORT OF TETANUS TOXIN C FRAGMENT TO MOTOR CORTEX FOLLOWING INJECTIONS IN RAT VIBRISSAL MUSCLES. E. McGuinness and J. Allman. Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

The C fragment of tetanus toxin (TTC) retains its parent molecule's capacity for retrograde transneuronal transport but lacks its toxicity. We injected TTC in the vibrissal muscles in rats and, following a 24 hour survival time, mapped the retrograde transport of TTC in the brain using immuno-peroxidase labeling of monoclonal antibody to TTC developed by Evinger and Erichsen (Brain Res. **380:** 383, 1986). Dense labeling was present in the lateral part of the facial nucleus ipsilateral to the injection site, which had previously been demonstrated with HRP to project directly to the vibrissal muscles (McGuinness, Neurosci. Abstr. **7:** 986, 1981). The most densely labeled neurons resulting from retrograde transneuronal transport were located throughout the reticular formation. There were clearly labeled cells bilaterally in the nucleus of the solitary tract and in some cases in the contralateral red nucleus. There also was consistent labeling of neurons in the deeper layers of the portion of the contralateral motor cortex corresponding to the vibrissal representation (Hall and Lindholm, Brain Res. **66:** 23, 1974). Since in rats, the motor cotex does not project directly to the facial nucleus, the TTC presumably passed through at least one intermediate neuron between the facial nucleus and the motor cortex. In the transneuronal retrogradely labeled neurons, the TTC-immuno-peroxidase reaction product was located in the cytoplasm of the cell body and proximal dendrites. Labeled dendrites could sometimes be traced for several hundred microns. The cell nucleus stood out as an unlabeled structure.

We thank Dr. Craig Evinger for providing the antibody to TTC. This research was supported by a Markey Foundation Grant in Developmental Biology (CIT).

MORPHOLOGICAL IDENTIFICATION OF DENDRITIC BUNDLES IN PRIMARY VISUAL AND MOTOR CORTEX OF GALAGO CRASSICAUDATUS, HEDGEHOD AND RAT. H.Ginzler and K.Fleischhauer*, Anatomical Institute, Univ. of Bonn, D 5300 Bonn and Neurological Hospital Köln-Merheim, D 5000 Köln 91, F.R.G.

Dendritic bundles formed by apical dendrites emerging from layer 5 large pyramidal cells were identified on Klüver stained 10µm paraffin sections in a prosimian primate, insectivor and rat.The apical dendrites of clustered neighbouring pyramidal cells converge and lay in close apposition and traverse the upper layers in form of tightly apposed bundles. In visual cortex these bundles reach the upper part of layer 2 without branching appearing as parallel vertical structures. In contrast dendritic bundles in motor cortex display extensiv and regular branching and form secondary bundles within layer 3 with apical dendrites from neighbouring primary bundles. These two bundling types with parallel unbranched bundles in primary visual cortex and regularly branched apical dendrites and secondary bundles in motor cortex are almost identical in all three examined species.

The functional significance of these different branching patterns may correlate with the difference in functional organization between visual and motor cortex: the branching pattern in motor cortex may allow integration over a larger area of cortex, whereas the close apposition of apical dendrites without branching may reflect the preoccupation of the visual system with high spatial resolution.

TRANSMITTERS UPTAKE, STORAGE, SECRETION AND METABOLISM II

ACUTE EFFECTS OF LITHIUM ON CATECHOLAMINES, SEROTONIN AND THEIR MAJOR METABOLITES IN DISCRETE BRAIN REGIONS. **T.A. Reader, E. Gottberg* and L. Grondin***. Département de physiologie, Université de Montréal, Montréal, Québec, H3C 3J7, Canada.

The acute effects of lithium on the central monoamine systems were investigated in the anterior cingulate (CIN), the primary visual (VIS) and the piriform-entorhinal (PiEn) cortices as well as in the hippocampus (HIP), the neostriatum (CPU; caudate-putamen) and the olfactory bulbs (OB). One hour after the administration of LiCl (2 and 10 mEq/kg; i.p.) the endogenous noradrenaline (NA) levels increased in the CIN and PiEn cortices, in the HIP and the CPU, while dopamine (DA) only increased in the CIN and PiEn regions. These changes in endogenous DA were accompanied by reductions in the metabolites DOPAC and HVA. The levels of HVA and DOPAC, but not 3-MT, were also found to be decreased in the CPU in spite of an unchanged DA content. The serotonin (5-HT) contents was increased in all regions, except in the OB, but with 5-HIAA levels which were either normal or decreased (CIN and VIS cortices). These results are compatible with a reduced turnover and/or with an inhibition of monoamineoxidase. Alternatively, the particular properties (synthesis regulation and release) of the terminal NA, DA and 5-HT fibers in the different regions could account for this differential action of lithium on steady state monoamine levels and turnover rates.

275.2

RELEASABLE PROTEINS FROM THE BASAL GANGLIA OF THE RAT. A.M. Sierra-Honigmann,*B.Antón,*P.Leff†, M.Sordo,*N.Jiménez,*J.Calderón* and A. Bayón. Inst. Invest.Biomédicas,UNAM,04510 México,D.F.; Dept.Biol.Celular,CINVESTAV,IPN; and Inst. Mexicano Psiquiatría, S.S. México D.F.

The release of unidentified protein material during perfusion of the rat striatum has been documented (Bayón, et al.in:"In vivo Perfusion and Release of Neuroactive Substances", Acad. Press, 1985). The release of this material is stimulated by tissue depolarization and is, in part, calcium-dependent suggesting that it could be stored in and secreted from synaptic vesicles. Preliminary analysis show that this releasable protein material is very heterogeneous and the individual components are collected in too small amounts to facilitate traditional purification strategies. In a first approach we immunized mice with the soluble contents of enriched preparations of striatal synaptic vesicles -and more recently with material obtained from perfusates. We have produced monoclonal antibodies; several of these antibodies recognize components present both in synaptic vesicles and perfusates from rat striatum and are used to identify the releasable proteins.

275.3

ALTERATION OF THE STRIATAL DOPAMINERGIC TRANSPORT SYSTEM BY ASCORBIC ACID. E.A. Debler, A. Hashim*, A. Lajtha, and H. Sershen*. Center for Neurochemistry, N.S. Kline Inst. Ward's Island, NY, NY 10035.

Previously we demonstrated that 0.1 mM ascorbic acid (AA) reduced the uptake of 1-methyl-4-phenylpyridine (MPP^+) into striatal synaptosomes in a noncompetitive fashion, but did not alter the transport of dopamine (DA), a phenomenon unique to AA and not due to lipid peroxidation (J. Neurosci. Res. 17:298, 1987; Soc. Neurosci. Abstr. 13:1110, 1987). With the thought that this effect of AA may be related to its oxidative capacity, the effects of succinate and NADPH on DA and MPP^+ uptake were studied. Both compounds were ineffective (IC_{50} > 10 mM) in inhibiting either DA or MPP^+ transport. In an effort to localize the site of AA action, we evaluted its effects on the binding of mazindol to the DA transporter. AA increased the K_d (3.5-fold) of binding of [^{3}H]mazindol to the dopamine transporter, but reduced the K_i (a factor of 4 or more) of MPP^+ in inhibiting [^{3}H]mazindol binding. The effect of AA in increasing MPP^+ affinity to the DA transporter is in discord with the AA-induced inhibition of MPP^+ transport, and demonstrates that AA affects components in the transport system other than the recognition site for DA uptake blockers. Thus, AA-induced inhibition of MPP^+ transport continues to appear unique and probably relates to an action of AA on events occurring after the binding of MPP^+ to the carrier. (Support: The Council for Tobacco Res.-USA).

VERY FAST PHOSPHORYLATION AND DEPHOSPHORYLATION OF SEVERAL Mr < 20000 PROTEINS FROM PLASMA MEMBRANE FROM BOVINE CHROMAFFIN CELLS. W.De Potter*, J.Cosaert* and J.De Block*. (SPON: A. Dahlström).Dept. of Med., Lab. of Neuropharmacology, University of Antwerp(UIA) Antwerpen, B2610 Belguim.

Chromaffin cells secrete catecholamines by exocytosis. Phosphorylation, triggered by an increase in free Ca^{2+}-concentration has been postulated to play a role in this process.(Trifaro et al., J. Mol. Pharmacol., 7:52, 1971) We therefore studied phosphorylation and dephosphorylation of chromaffin cell plasma membrane proteins.

Plasma membranes were prepared according to Zinder et al.,(Zinder et al.,Cell Tiss. Res., 188:153, 1978).They were incubated with (γ32P)ATP for 15", 1' and 2' at 0°C, 22°C and 17°C as well as in varying incubation media.Proteins were separated by SDS polyacrylamide gelelectrophoresis and phosphorylated proteins were detected by autoradiography.Several proteins (Mr < 20000) were labeled within 15", even at 0°C.The proteins were labeled intensively and the bands disappeared upon further incubation at 37°C (within 2').Incubation with EDTA instead of EGTA at lower free Ca^{2+}-concentration showed only minor labeling.A partial characterization of these proteins revealed that none of these fast phosphorylated proteins are identical with myosin light chain.

These data suggest the presence in the chromaffin cell membrane of a Mg^{2+}-dependent protein kinase as well as a divalent cation dependent protein phosphatase.

ENDOGENOUS ADENOSINE REGULATES NEURONAL EXCITABILITY IN LOW CALCIUM MEDIUM. J.C. Fowler. Life Sciences Division, Los Alamos National Lab., Los Alamos, NM 87545.

Levels of neuromodulators, in contrast to those of classically defined neurotransmitters, need not be regulated by calcium dependent synaptic release mechanisms. It is not clear whether basal and/or evoked levels of the putative neuromodulator adenosine are necessarily dependent on the presence of calcium and functional synapses. In the hippocampal slice superfused with medium containing sufficient calcium to support synaptic transmission, adenosine is present in adequate concentration to exert a tonic inhibitory influence on neuronal excitability. The adenosine antagonist theophylline and adenosine deaminase, an enzyme that converts adenosine to the inactive inosine, increase the amplitude of the extracellularly recorded synaptic response in the brain slice presumably by reducing the tonic inhibitory influence of endogenously released adenosine (Dunwiddie and Hoffer, Br. J. Pharmac. 69:59,1980). Experiments were designed to determine if endogenous adenosine could be demonstrated in the hippocampal slice superfused in a modified low Ca^{++}(.2 mM), high Mg^{++} (4 mM) medium that blocks synaptic transmission. Standard extracellular stimulating and recording techniques were used.

At a flow rate of 2 ml/min, stimulation of the alvear fibers elicited an extracellularly recorded antidromic population spike in CA1 pyramidal neurons which was usually followed by 2-4 afterpotentials. Reductions in flow rate were associated with a marked depression of the afterpotentials with little change in the initial antidromic population spike. The depression of the afterpotential at the lower flow rates was largely reversed by theophylline (100 µM) and by adenosine deaminase (10 µg/ml). The selective depression of the afterpotential was mimicked by the application of the adenosine reuptake blocker, dipyridamole (100 µM) and this depression was reversed with theophylline. These results suggest that lowered flow rates favor accumulation of endogenous adenosine. Since synaptic transmission was blocked, it is concluded that sufficient endogenous adenosine exists in the absence of synaptic function to alter neuronal excitability.

BIOSYNTHESIS AND RELEASE OF N-ACETYLASPARTYL-GLUTAMATE FROM AMPHIBIAN RETINAL NEURONS. L.C. Williamson and J.H. Neale. Dept. of Biology Georgetown University, Washington, D.C. 20057.

N-Acetylaspartylglutamate (NAAG) is a nervous system specific dipeptide which we have localized in the visual system neurons in several species. In a previous study, we identified NAAG-IR within vesicles in synaptic endings of amacrine and bipolar neurons in the inner plexiform layer of the amphibian retina as well as in ribbon synapses of photoreceptor cells.

In the present study, we have examined the biosynthesis and release of NAAG from these retinal neurons. Grass frogs were injected intraocularly with ^{3}H-glutamate. Retinas were removed and incubated in a series of physiological buffers with varying amounts of calcium and potassium. The radiolabeled molecules released by these retinas under control and depolarized conditions were purified by cation exchange chromatography followed by anion exchange HPLC. ^{3}H-NAAG was found to be released by the retinal cells upon depolarization with elevated potassium and this release process required extracellular calcium. These results support the hypothesis that the neuropeptide, NAAG, functions in synaptic communication.

LONG-TERM INHIBITION OF THE DOPAMINE UPTAKE COMPLEX BY METAPHIT. I. Zimányi*, A.E. Jacobson*†, K.C. Rice†, A. Lajtha, and M.E.A. Reith (SPON: I. Wajda). Center for Neurochemistry, N.S. Kline Institute for Psychiatric Research, Ward's Island New York, NY 10035, †NIH, NIDDKD, Bethesda, MD 20892

Metaphit (MET) an isothiocyanate derivative of PCP was shown to acylate PCP receptors and irreversibly inhibit the binding of labeled ligands to the dopamine uptake complex. The present study examines the effect of MET on [^{3}H]mazindol binding in mouse striatum in vitro and ex vivo. MET inhibited the [^{3}H]mazindol binding with an IC_{50} of 6.4 uM. The effect of 10 uM MET was still present after removal of MET by washing and centrifugation. A 15-min exposure to 10 uM MET was sufficient to inactivate all susceptible sites. The long-term nature of the effect of MET is suggested by the findings that at least in 3 hr MET did not dissociate significantly from its binding site. In equilibrium and dissociation experiments 10 uM MET significantly decreased the B_{max}, whereas the K_d and the dissociation rate constant remained essentially unchanged. The presence of cocaine protected the mazindol binding site from the action of MET. The potency of MET was greater under slightly alkaline conditions consonant with reaction between isothiocyanate and amino or sulfhydryl groups. In ex vivo experiments 5 hr after i.c.v. administration of MET, no changes were observed in the mazindol binding. MET irreversibly inhibits the the mazindol site in vitro by chemical modification. CHARACTERISATION OF A PROTON-ATPASE ACTIVITY IN RAT BRAIN SYNAPTIC VESICLES:ENERGETIC COUPLING WITH L-GLUTAMATE TRANSPORT. T. S. Sihra and S. Cidon (SPON: J. K. T. Wang). Lab. of Molec. and Cell. Neurosci., The Rockefeller University, New York, NY 10021-6399.

The ATP-dependent proton-pumping and L-glutamate transport activity of a highly purified rat brain synaptic vesicle preparation was characterised. Proton uptake was sensitive to low concentrations of NEM (IC_{50}=10uM) and NBD-Cl (IC_{50}=30nM). However, neither vanadate nor azide had any effect on the proton-pumping. Subcellular fractions obtained during the purification of synaptic vesicles were immunoassayed for their cross-reactivity with antibodies raised against the 115kDa, 72kDa and 39kDa subunits of the purified chromaffin granule proton-ATPase. Cross-reactivity increased in fractions progressively enriched in synaptic vesicles. These data suggest that the synaptic vesicle proton-ATPase belongs to the vacuolar class of ATPases rather than either the E_1/E_2 or F_1/F_0 groups. Acidification of the synaptic vesicle interior was enhanced in the presence of either permeant anions or valinomycin; conditions expected to cause the dissipation of an inside-positive membrane potential. In the absence of a pH-gradient, synaptic vesicles are therefore seen to maintain a trans-membrane potential. Importantly, this potential is seen to provide the energetic coupling of the ATP-dependent transport of L-glutamate into synaptic vesicles since uptake was greatly enhanced in the presence of impermeant anions but compromised with valinomycin. In conclusion, the results presented show the proton-ATPase found in synaptic vesicles is a vacuolar-type of ATPase. This proton-ATPase energises the ATP-dependent uptake of L-glutamate largely by virtue of the membrane potential component of the proton electrochemical gradient generated, in the absence of a significant pH-gradient.

MULTIPLE ADENOSINE TRANSPORT SYSTEMS IN RAT AND GUINEA PIG SYNAPTOSOMES. W. J. Baldy* and R. P. Shank. Dept. of Biological Research, Janssen Research Foundation, Spring House, PA 19477-0776.

We have used initial uptake conditions to study adenosine transport by synaptosomes (P_2 fraction depleted of mitochondria) from discrete regions of the rat and guinea pig brain. Based on transport kinetics and pharmacological criteria our data indicate the existence of 3 to 5 systems. In the rat two pharmacologically distinct [nitrobenzylthioinosine (NBI) sensitive and insensitive] systems exist which have apparent K_m values between 1 and 10 µM, and a third system has an apparent K_m of ∿0.4 µM. A low-affinity system with a K_m >100 µM probably exists but can not be characterized with our experimental conditions because the rate of uptake becomes non-linear within 30 s when adenosine is 100 µM or greater. Our kinetics data suggest the existence of a site with an affinity constant of ∿1 nM, which may represent binding to a receptor, rather than uptake by a carrier. Adenosine monophosphate (AMP) selectively inhibits two systems, the NBI sensitive one and the one with the K_m of ∿0.4 µM. A major difference between rat and guinea pig is that the NBI sensitive system is much more prevalent in the latter. In both rat and guinea pig, the NBI sensitive system is less prevalent in cerebellum than in cerebral cortex and diencephalon plus mesencephalon.

STIMULATION OF NOREPINEPHRINE UPTAKE BY ATPγS IN PC12 CELLS. J.E. Chaffee, Y.H. Ehrlich, and E.D. Hendley. Depts. of Physiology & Biophysics, Psychiatry, and Biochemistry, Univ. of Vermont, Burlington, VT 05405.

The potential modulation of norepinephrine (NE) uptake by extracellular ATP and divalent cations was examined in PC12 cells. An analog of ATP, ATPγS, was chosen for these studies since ATPγS can be utilized by protein kinases and the resulting thiophosphate bonds are resistant to phosphatase activity. Previous work in our laboratory has shown that both ATP and ATPγS (0.1 µM) can stimulate NE uptake. In this study, cells were incubated for 5 min at 37°C, in a Krebs-Ringer buffer conatining 1.87 mM Ca^{2+} and no added Mg^{2+}, with and without 1 µM ATPγS. The cells were then washed and NE uptake assayed 30 min later. ATPγS produced a persistent stimulation of uptake and this effect was dependent on the presence of Ca^{2+} in the pretreatment medium. Preincubation with ATP produced no increase in uptake, suggesting that there was an inactivation by dephosphorylation. Pretreatment with ATPγS and an excess of ATP resulted in the inhibition of the ATPγS-induced stimulation. The ATPγS pretreatment protocol was used to examine kinetic changes and the results showed an increase in the Vmax, with no change in the apparent Km for NE. Experiments are currently in progress to determine if inhibitors of NE uptake such as antidepressants, α-blockers, or alkylating agents, can also inhibit extracellular protein phosphorylation in PC12 cells. (Supported by NSF: R11-860679 and USAFOSR: 88-004).

HIGH AFFINITY GLUTAMINE UPTAKE IN RAT BRAIN PLASMA MEMBRANE VESICLES. R.J. Roon*, S.A. Shofner* and J.F. Koerner. Department of Biochemistry and Neuroscience Graduate Program, University of Minnesota, Minneapolis, MN 55455

Plasma membrane vesicles prepared from rat brain contain a saturable, high affinity uptake system for L-glutamine which exhibits the following characteristics: 1) The rate of L-glutamine uptake is linear up to 200 μg/ml of membrane protein. 2) The uptake rate is optimal in the range of pH 7.0 - 8.0. 3) The system exhibits a K_m for L-glutamine of ~1.7 μM and a V_{max} of ~50 pmol/min·mg protein. 4) Uptake of ^{3}H-L-glutamine is significantly reduced by lowering the assay temperature to 4^{0}C and is essentially abolished by the addition of excess unlabeled L-glutamine. 5) The system is not highly dependent upon the addition of monovalent or divalent cations. 6) Inhibitor studies reveal that the amino acid amides exhibit the highest affinity for the system and that there is a high specificity for the L-isomers. 7) Under our standard assay conditions L-glutamine uptake is significantly higher than L-glutamate uptake. Furthermore L-glutamate uptake gives a different inhibition profile than L-glutamine uptake. 8) Although no exogenous energy sources are required L-glutamine uptake activity is somewhat sensitive to cyanide and 2,4-dinitrophenol. (Supported by NIH NS 17944.)

RELEASE OF CATECHOLAMINES, [MET]ENKEPHALIN, AND NEUROPEPTIDE Y FROM EX SITU PERFUSED ADRENALS DURING HYPOGLYCEMIA. M. K. Dousa*, S. L. Chritton*, D. L. Lucas*, D. R. Roddy*, T. L. Yaksh*, and G. M. Tyce (SPON: C. L. Kornblith). Depts. of Physiology and Neurosurgery, Mayo Clinic, Rochester, MN 55905.

Hypoglycemia is a strong stimulus for adrenomedullary secretion. The present study is focused on nonneurogenic component of adrenal release of free catecholamines (CAs), [Met]enkephalin-like immunoreactive material([Met]enk), and neuropeptide Y-like immunoreactive material (NPY) under normoglycemic and hypoglycemic (20 mg % and 50 mg % glucose) conditions using ex situ isolated perfused dog adrenals. In perfusate samples taken before, during, and after 2-min stimulation with 3x10^{-5}M carbamylcholine (carbachol), norepinephrine (NE), epinephrine (E), and dopamine (DA) were determined by HPLC with electrochemical detection, and [Met]enk and NPY, by specific radioimmunoassays. Perfusion with 50 mg % glucose in the medium did not significantly change adrenomedullary secretion. At 20 mg % glucose levels, the basal effluxes of NE and DA were significantly increased, that of NPY was decreased, and no efflux changes were noted for E and [Met]enk. Evoked releases of CAs, [Met]enk, and NPY at both hypoglycemic levels were comparable to the releases in controls. These results indicate that adrenomedullary basal efflux is affected by severe hypoglycemia, whereas, carbachol-evoked secretion remains remarkably stable.

275.13

SIDEDNESS, CHEMICAL AND KINETIC PROPERTIES OF THE VESAMICOL (AH5183) RECEPTOR OF CHOLINERGIC SYNAPTIC VESICLES. W.D. Kornreich* and S.M. Parsons (SPON: K. Noremberg). Dept. of Chemistry and the Neurosciences Research Program, IES, University of California, Santa Barbara, CA 93106.

Binding of [^{3}H]vesamicol ((-)-trans-2-(4-phenylpiperidino)cyclohexanol) to its receptor in Torpedo synaptic vesicles is inhibited by the protein modification reagents 4-chloromercuriphenylsulfonate and N,N'-dicyclohexylcarbodiimide and by protease treatment of cholate solubilized receptor. Binding depends on deprotonation of a group of pK_a 6.26 ± 0.03 in the receptor. A membrane-impermeant vesamicol analogue was found to be an effective inhibitor of acetylcholine active transport with an IC_{50} value of 51 ± 8 x 10^{-9} M. Vesamicol bound the receptor with a rate constant of 1.74 ± 0.06 x 10^5 M^{-1} sec^{-1}, and unlabeled vesamicol displaced bound [^{3}H]vesamicol at 0.29 ± 0.01 min^{-1}. The dissociation process under some conditions exhibited fast and slow phases. The vesamicol receptor is a stable kinetically heterogenous protein facing the cytoplasmic compartment. It probably contains a binding site carboxylate in a hydrophobic environment and a cytoplasmically oriented sulfhydryl group.

275.14

CHOLINERGIC SYNAPTIC VESICLE HETEROGENEITY: EVIDENCE FOR REGULATION OF ACETYLCHOLINE TRANSPORT. L.M. Gracz*, W. Wang*, and S.M. Parsons (SPON: S.K. Fisher). Dept. of Chemistry and the Neurosciences Research Program, IES, University of California, Santa Barbara, CA 93106.

Classical, fully loaded VP_1 and recycling VP_2 synaptic vesicles from the electric organ of Torpedo californica were separated in an isosmotic sucrose density gradient.

The properties of the vesamicol receptor and acetylcholine (ACh) active transport system in the two vesicle types were studied. Based on a vesicle concentration standardization obtained with the SV2 antigen, characteristic of secretory granules, a typical preparation of VP_1 and VP_2 vesicles contained 237±15 and 102±3 pmol vesamicol receptor/mg of vesicle protein, respectively. The Hill coefficients, α_H, and the equilibrium dissociation constants, K, for vesamicol binding to VP_1 and VP_2 vesicles were essentially the same with α_H = 2.0 and K = 19 nM. The positive Hill coefficient suggests that the vesamicol receptor exists as a homotropic oligomeric complex. Furthermore, VP_2 vesicles transported ACh 2- to 3-fold more actively than VP_1 vesicles. The results demonstrate that VP_1 and VP_2 synaptic vesicles exhibit functional differences in the vesamicol receptor -ACh transport system, presumably as a result of regulatory phenomena. Structural differences between the two vesicle populations are currently being studied.

275.15

AN ACETYLCHOLINE BINDING SITE COPURIFIES WITH THE VESAMICOL (AH5183) RECEPTOR FROM CHOLINERGIC SYNAPTIC VESICLES. Ben A. Bahr and Stanley M. Parsons. Dept. of Chemistry and the Neuroscience Research Program (IES), University of California, Santa Barbara, California 93106.

Uptake and storage of acetylcholine (ACh) by purified Torpedo VP_1 synaptic vesicles (SV) is blocked by the potent drug l-trans-2-(4-phenylpiperidino)cyclohexanol (vesamicol, formerly AH5183). A saturable receptor is present on SVs that binds 300-400 pmoles of [^{3}H]vesamicol/mg SV protein. This receptor (VM-R) is present at 6-8 binding sites/SV and can be solubilized in cholic acid. Exogenous ACh has no effect on [^{3}H]vesamicol binding to intact vesicles but inhibits the binding to hyposmotically-shocked (lysed-SV) or solubilized (sol-SV) vesicles with an IC_{50} of 2 to 40mM, depending on the SV preparation. Increasing [^{3}H]vesamicol concentrations cause decreasing ACh effects, suggesting ACh uses a noncompetitive mechanism.

The VM-R was purified using a succession of chromatographic steps - hydroxylapatite, agarose-wheat germ lectin, DEAE ion-exchange, and size exclusion. The result was a 40-fold increase in binding specific activity and a final yield of 14%. The apparent particle M_r of the native detergent-solubilized VM-R was 230kDa, consisting of 107 and 96kDa subunits. After purification, ACh inhibited the binding activity of the VM-R with an IC_{50} of 37 ± 9mM. Therefore, an allosteric ACh binding site is present on the VM-R.

275.16

STIMULATION OF RIBOSOMAL S6 PROTEIN KINASE ACTIVITY IN PC12 PHEOCHROMOCYTOMA CELLS. A.L. Cahill and R.L. Perlman. Depts. of Peds. and Pharmacol. and Physiol. Sci. and Kennedy Mental Retard. Res. Cent., University of Chicago, Chicago, IL 60637.

Nerve growth factor (NGF), bradykinin (BK), high K^+ and phorbol dibutyrate (PDBu) increase the phosphorylation of a common tryptic peptide in tyrosine hydroxylase in PC12 cells. Because NGF, BK and high K^+ stimulate tyrosine hydroxylase phosphorylation in cells that have been depleted of protein kinase C, these agonists all appear to activate a novel protein kinase in the cells. In this study we have investigated whether this novel kinase might actually be a ribosomal S6 protein kinase. S6 kinase activity was assayed in the 100,000 x g supernatant of PC12 cells, using γ^{32}P-ATP and 40S ribosomes from rat liver as substrates. ^{32}P-labeled S6 was isolated by SDS-PAGE and ^{32}P incorporation was quantitated by Cerenkov counting. Treatment of PC12 cells with NGF, BK or high K^+ increased the activity of the S6 protein kinase. This S6 kinase in PC12 cells appears to be similar or identical to the NGF-activated protein kinase N described in PC12 cells (Rowland et al., J. Biol. Chem. 262, 7504-7513, 1987) and to the growth factor-activated S6 kinase that has been described in other cell types. This kinase may mediate the effects of NGF, BK and high K^+ on tyrosine hydroxylase phosphorylation. (Supported by NIH grants HD04583 and HL29025).

ADENOSINE UPTAKE AND METABOLISM IN MOUSE ASTROCYTES AND NEURONS IN PRIMARY CULTURES. Henry Matz and Leif Hertz, Dept. of Pharmacology, Univ. of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0, Canada (SPON: R.W. Ledeen).

We have previously reported (Trans. Am. Soc. Neurochem. 19, 90, 1987) pronounced differences in adenosine metabolism between cerebral cortical astrocytes (mainly phosphorylation) and cerebral cortical neurons (mainly deamination). In both cell types the content of adenosine itself remains remarkably low, i.e., not significantly different from the adenosine concentration in the medium (10 µM). However, in the presence of the deaminase inhibitor, deoxycoformycin, it increases 15-25-fold. The very low adenosine content under control conditions might suggest that the uptake mechanism for adenosine consists of facilitated diffusion followed by a very rapid metabolism, maintaining a low adenosine concentration. In order to test this hypothesis total uptake of radioactivity from [^{14}C]adenosine in the cells (i.e., adenosine plus all retained metabolites), was measured both under control conditions and in the presence of 10 µM deoxycoformycin. No effect was observed in astrocytes, which could be explained by the relatively low deamination rate under control conditions. However, even in neurons, where deamination is the major metabolic pathway, the total uptake was unaffected by the inhibitor. In both astrocytes and neurons large amounts of labelled inosine were formed in the medium already after "zero time" incubation. This was inhibited by deoxycoformycin.

EVIDENCE FOR A SYNAPTOSOMAL CYTOSOLIC FACTOR MODULATING VESICULAR GLUTAMATE UPTAKE. A.T. Lobur*, P.E. Kish* and T. Ueda (SPON: R. Richardson) Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Evidence accumulated over the past 26 years has led to the wide acceptance of glutamate as a major excitatory neurotransmitter in the mammalian brain. We have previously demonstrated that L-glutamate is taken up into isolated synaptic vesicles in an ATP-dependent manner. We now report that a nerve terminal cytosolic factor inhibits the ATP-dependent vesicular uptake of glutamate in a dose dependent manner. This factor appears to be a protein with a molecular weight greater than 100,000 as estimated by size exclusion chromatography, and is precipitated by ammonium sulfate (40% saturation). The inhibitory factor is inactivated by heating at 100°C. Proteolytic digestion of the ammonium sulfate fraction by trypsin and chymotrypsin did not reduce, but increased slightly the inhibition of glutamate uptake. The digest retained inhibitory activity after heating, suggesting that the proteolytic digestion may generate active fragments. The inhibition of ATP-dependent vesicular glutamate uptake is not species specific, as the factor obtained from both rat and bovine brains produced an equal degree of inhibition of glutamate uptake into vesicles from both species. The mechanism of action is not presently known. These observations suggest that vesicular uptake of glutamate may be regulated by endogenous factors *in vivo*. (Supported by NSF Grant BNS 8509679.)

A KINETIC APPROACH TOWARDS UNDERSTANDING THE LONG DURATION OF ACTION OF RESERPINE **J.D. Deupree, Department of Pharmacology, University of Nebraska Medical Center, Omaha NE 68105**

Classically the duration of action of reserpine has been known to exceed its biological half life. Reserpine acts by competitively inhibiting catecholamine transport into chromaffin granules by binding to the catecholamine transporter with an apparent Kd of 3 nM. An estimate of the rates of association (k_1) and dissociation (k_2) was obtained by analysis of specific ^{3}H-reserpine (0.4 to 3.6 nM) binding with time. The data indicated steady state binding conditions are reached in 20 min with a k_1 of 0.12 $nM^{-1}min^{-1}$ and a $t_{1/2}$ for dissociation of 9 min. However direct analysis of the rate of dissociation following the addition of 1 µM reserpine or 1 mM norepinephrine indicated that over 80% of the ^{3}H-reserpine remained bound for over 8 hours. Reserpine does not appear to be covalently bound. It is probably not being transported into the inside of the granule since reserpine is not released if the granules are made permeable with saponin. I propose that the transporter starts to transport reserpine to the inside of the granule. However, the fatty acid portion of the membrane has a high attraction for reserpine preventing both complete transport and dissociation and rendering the transporter inaccessible to catecholamines. **(Supported by NIH grant #NS 15187)**

CARBACHOL-INDUCED COSECRETION OF IMMUNOREACTIVE ATRIAL NATRIURETIC PEPTIDES WITH CATECHOLAMINES FROM CULTURED BOVINE ADRENAL MEDULLARY CELLS. M. Okazaki*[1], N. Yanagihara and F. Izumi. Dept. of Pharmacol. and [1]2nd Dept. of Int. Med. Univ. of Occupational and Environmental Health, Sch. of Med. Kitakyushu 807, Japan.

The distribution and secretion of atrial natriuretic peptides (ANPs) were investigated in bovine adrenal medulla. (1)Stimulation of nicotinic but not muscarinic acetylcholine receptor caused the secretion of α-human ANP-like immunoreactivity (α-hANP-LI) and catecholamines corresponding to the ratio of catecholamine/α-hANP-LI in cultured bovine adrenal medullary cells. (2)Secretion of α-hANP-LI by carbachol was dependent on extracellular Ca^{2+}. (3)Chromaffin granules isolated from bovine adrenal medulla contained large amounts of ANP and catecholamines with the same ratio as in cultured cells. (4)Separation on reverse phase HPLC showed two components of adrenal ANP, α-ANP and γ-ANP. These results indicate that ANPs are stored as α and γ forms in chromaffin granules, and cosecreted with catecholamines in a Ca^{2+}-dependent manner by stimulation of nicotinic acetylcholine receptor.

275.21

SODIUM / PROTON EXCHANGE SYSTEM IN CULTURED BOVINE ADRENAL MEDULLARY CELLS. N. Yanagihara, K. Yokota*, H. Kobayashi*, A. Wada* and F. Izumi. Depts. of Pharmacology and Ophthalmology, Univ. of Occupational & Environmental Health, School of Medicine, Kitakyushu 807, Fukuoka, Japan.

When cultured adrenal medullary cells were incubated in Na^+-free sucrose medium, the intracellular pH was shifted down from 7.14 to 6.56. Readdition of Na^+ to the cells caused a rapid increase in intracellular pH to 7.30. Associated with the increase in intracellular pH, $^{22}Na^+$ uptake by the cells was observed. Both the increases in intracellular pH and $^{22}Na^+$ uptake were inhibited by amiloride, an inhibitor of Na^+/H^+ exchange, in a similar concentration-dependent manner. The increase in intracellular pH by addition of Na^+ was partially inhibited by quinidine, other inhibitor of Na^+/H^+ exchange, but not by 4-acetamido-4'-isothiocyanatostilbene-2,2'-disulfonic acid, an anion exchange (Cl^-/HCO_3^-) inhibitor. Li^+ could substitute for Na^+ in this system.

These results suggest the existence of amiloride-sensitive Na^+/H^+ exchange system in cultured bovine adrenal medullary cells which may be involved in the regulation of intracellular pH.

276.1

NERVE GROWTH FACTOR (NGF) STIMULATES THE RELEASE OF ARACHIDONIC ACID (AA) FROM PC12 CELLS. D.W. Fink, Jr.,* M.L. Contreras and G. Guroff. Section on Growth Factors, National Institute of Child Health and Human Development, NIH, Bethesda, MD 20892.

Increased hydrolysis of phosphatidyl inositol (PI) is rapidly observed following treatment of PC12 cells with NGF, resulting in the formation of inositol triphosphate (IP_3) and diacylglycerol (DAG) (Contreras and Guroff, J. Neurochem. 48:1466, 1987). Involvement of IP_3 in calcium mobilization and second messenger signalling is well established, whereas DAG function remains to be clarified; it may provide a mechanism for coupling NGF-stimulated PI hydrolysis with arachidonic acid (AA) metabolism through DAG lipase-mediated formation of arachidonic acid. A second messenger role for arachidonic acid and its metabolites has been proposed. The effect of NGF on AA metabolism has been examined in PC12 cells. Addition of NGF (100 ng/ml) to PC12 cultures labelled with (^{3}H)-AA caused a 53.9 ± 6.4% increase in the release of labelled AA during a 30 minute incubation at 37°C. Both epidermal growth factor (50 ng/ml) and bradykinin (1 μM) enhanced AA release to a similar extent. NGF-stimulated AA release was associated with a 113.1 ± 7.6% increase in inositol monophosphate formation suggesting interaction between PI-hydrolytic and AA-metabolic pathways. Studies are being conducted to characterize the calcium requirement of NGF-stimulated AA release, and to determine whether antagonists of AA metabolic pathways will modulate the PC12 response to NGF.

276.2

REGULATION OF NERVE GROWTH FACTOR SYNTHESIS IN VARIOUS GLIAL CELL TYPES. J.P.Schwartz and K. Mishler*. CNB, NINCDS, NIH, Bethesda,MD 20892

Although many cell types synthesize nerve growth factor(NGF), glial cells appear to be a primary source at certain periods during development and regeneration in the PNS. We have asked two questions: 1) do CNS glial cells also synthesize NGF, thereby functioning as a source of the NGF found in the brain?; 2) what agents can regulate NGF synthesis in different glial cell types? Primary cultures of CNS astrocytes prepared from newborn rat cortex synthesize and secrete NGF, with an NGF mRNA content 7-8 fold higher than in the rat C6 glioma cell line. In both cell types, forskolin (which elevates cyclic AMP) stimulates synthesis of NGF mRNA, with a maximal increase by 2-3 hr. The β-adrenergic agonist isoproterenol(IP) can also increase NGF mRNA content in both astrocytes and C6 cells, with a time course comparable to that seen for forskolin. Since IP is known to stimulate adenylate cyclase(AC) in C6 cells, these results suggest that astrocytes contain a β-adrenergic receptor which activates AC. VIP increases the NGF mRNA content of astrocytes: whether this increase occurs as a result of increased cAMP is under investigation. No comparable effect is seen in C6 cells, suggesting the lack of a VIP receptor. These results demonstrate that the NGF gene can be regulated through a cAMP promoter element, which may provide a mechanism by which to turn on NGF synthesis in specific tissues or brain regions.

276.3

IN SITU HYBRIDIZATION OF NGF mRNA IN ADULT RAT BRAIN. R. C. Hayes, M.B. Rosenberg, G. A. Higgins, K. S. Chen, F. H. Gage, and D. M. Armstrong. Dept. of Neurosciences, University of California, San Diego, CA 92093.

Several lines of recent evidence would indicate that basal forebrain cholinergic neurons are dependent on Nerve Growth Factor (NGF) for their daily maintenance and survival. Moreover, NGF deficiencies are hypothesized to account for the dysfunctioning of cholinergic neurons in Alzheimer's disease and normal aging.

In the present study we employed in situ hybridization using ^{35}S-labeled riboprobes to localize NGF mRNA in the forebrain of Sprague-Dawley and Fischer 344 rats. In all animals the message was localized in the granule cell layer of the dentate gyrus, the pyramidal cell layer of the hippocampus, and layer II of the entorhinal cortex. Quantitation of differences in NGF and mRNA levels between behaviorally characterized young (8 months) and aged (91-24 months) animals is presently being determined.

Supported by NIH grant AG05344.

276.4

DEVELOPMENTAL REGULATION OF NGF RECEPTOR EXPRESSION IN FIBROBLASTS. S.L. Patterson*, S.J. Thompson*, G.C. Schatteman*, R Underwood*, M. Bothwell, K.A. Holbrook*, and A. Gown* (SPON: J.B. Simpson). Depts. of Physiology and Biophysics, and Biological Structure, Medicine (Dermatology), Univ. of Washington, Seattle, WA 98195.

Using immunocytochemical methods, we have investigated the role of NGF receptor in normal embryonic development, and during remodeling and repair in more mature tissues. NGF receptors were localized in human, monkey and rat tissues using monoclonal antibodies directed against human NGF receptor (Marano et al., J. Neurochem. 48: 225-232 1987) and against rat NGF receptor (Chandler et al, J. Biol. Chem. 259: 6882-6889 1984).

In addition to expected sites of expression in the nervous system, extensive immunoreactivity was detected on fibroblasts adjacent to developing epithelium, bone, muscle and vasculature. Immunoreactivity appeared to peak during periods of morphogenesis; it decreased in maturing tissues, and in normal adults, was restricted to some perineurial and perivascular cells.

Preliminary results suggest that the NGF receptor may be reexpressed in adult fibroblasts under some conditions. Immunoreactivity has been detected in stromal tissues associated with certain types of neoplasms.

It appears that fibroblastic NGF receptor expression is regulated throughout life, and that under some circumstances, adult mesenchyme may, to some extent, recapitulate developmental patterns of receptor expression.

276.5

DEDUCED AMINO ACID SEQUENCE OF THE CHICKEN NGF RECEPTOR cDNA

M. Bothwell, J. G. Heuer*, and S. Fatemi-Nainie* . Dept. of Physiology & Biophysics, University of Washington, Seattle, WA 98195.

A cDNA library representing mRNA of E10 chick head was screened using a fragment of a human NGF receptor cDNA as a probe. Two hybridizing clones were obtained containing inserts of approximately 4 kb. These were subcloned into M13mp18 for sequence analysis by the dideoxy chain termination method. Extensive sequence identity between these clones and human and rat NGF receptor indicates that these clones represent the chicken NGF receptor. Comparison of the deduced amino acid sequences of chicken with human and rat reveals that some regions are relatively poorly conserved, while others are more strongly conserved. Like human and rat NGF receptors, the extracellular domain of the chicken NGF recepor contains a 4-fold repeat of a cysteine-rich sequence motif. One highly conserved region falls within this cysteine-rich segment. We postulate that this conserved region comprises the NGF binding site. A second highly conserved region includes the membrane-spanning segment and residues at the extracellular and intracellular borders of the membrane spanning segment. We postulate that this region may be involved in lateral association in the plasma membrane with a second uncharacterized intrinsic membrane protein involved in NGF receptor signal transduction.

276.6

THE ESTABLISHMENT AND USE OF STABLE CELL LINES THAT OVEREXPRESS A TRANSFECTED β–NERVE GROWTH FACTOR (NGF) GENE: STUDIES IN VITRO, IN OCULO, AND INTRACRANIALLY. L. Olson, P. Ernfors*, T. Ebendal*, P. Mouton, I. Strömberg, H. Persson†. Dept. of Histology & Neurobiology, Karolinska Institute, S-104 01 Stockholm; *Dept. of Developmental Biology, Uppsala Univ., S-751 22 Uppsala; Dept. of Molecular Neurobiology, Karolinska Institute, S-104 01 Stockholm, Sweden.

The rat NGF gene was cloned in a mammalian expression vector under the control of the rabbit β-globin promoter containing a four tandem repeat of an 18-bp sequence which confers an inducibility to heavy metals. This contruct was cotransfected into Balb/c 3T3 cells with a plasmid containing a neomycin gene and G418-resistant cells were isolated. Conditioned medium from G418-resistant cells was then assayed for the presence of NGF in a bioassay using chick sympathetic ganglia and using ELISA for NGF. Genomic digests followed by Southern blotting of the cells producing the highest levels of NGF (3T3/3E) showed the presence of several hundred copies of the rat NGF gene per cell. RNA-blot analysis showed rat NGF hybridizing mRNA of the predicted size at levels approximately 50 times higher than the level of endogenous NGF mRNA in 3T3 cells. Medium in which 3T3-3E cells had grown contained 5- to 10-fold elevated amounts of NGF. When 3T3-3E cells were injected into the anterior chamber of the eye of mice or immunocompromized rats, the cells expressed NGF immunoreativity and caused adrenergic hyperinnervation of the host irides as compared to control eyes given similar amounts of the parent 3T3 cells. Grafting studies now in progress will further evaluate the usefulness of these cells as a source of NGF that may stimulate injured or intact NGF neurons in the host brain and peripheral nervous system, and that may support cografted NGF-dependent neurons or chromaffin cells.

High Level Expression of Recombinant Mouse β-Nerve Growth Factor (NGF) in *E. coli* with a Gene Fusion Vector.
Y. Luo* and K. E. Neet. Department of Biochemistry, Case Western Reserve University, Cleveland, Ohio 44106.

Nerve Growth Factor is an important neurotrophic factor required for the development and maintenance of neurons in the sympathetic, sensory, and central nervous systems. We previously reported that biologically active, recombinant NGF has been produced in *E. coli* (G.-L. Hu and K. E. Neet Gene (1988) in press), albeit in small quantity. We now report the high level expression of recombinant NGF in *E. coli* using a gene fusion vector. The 373 base pair cDNA fragment (HaeII to Pst I) encoding mature mouse β-NGF was fused to the truncated protein A gene under the control of the thermoinducible lambda P_R promoter in the vector pRIT2T , using a synthetic oligonucleotide linker. The resulting plasmid, pRIT2NGF, was selected and confirmed by restriction mapping. The protein A-NGF fusion protein was highly expressed by temperature induction in *E. coli* (strain N4830-1) containing the plasmid pRIT2NGF . Purification of this protein over an IgG affinity column yielded about 4 mg/liter of nearly homogeneous fusion protein. The recombinant NGF was cleaved from the fusion protein by CNBr treatment and purified by cation exchange chromatography. The characterization of this recombinant NGF is in progress. (Supported by an NIH grant, NS24380)

Synthesis of chimeric mouse nerve growth factor precursor and human β-nerve growth factor in Escherichia Coli : Immunological properties.

E. Dicou and B. von Wilcken-Bergmann (spon. P. Brachet) INSERM U 298, CHR, 49033 Angers, France (E.D.); Institut für Genetik der Universität zu Köln, Weyertal 121, 5000 Köln 41, F.R.G.

The complete mouse prepro-nerve growth factor (NGF) cDNA was fusioned to the carboxyl terminus of the β-galactosidase (lacz) gene of E.Coli in a plasmid vector that contains a transcription stop signal at the end of the lacz gene. Similarly, a genomic fragment encoding the human βNGF comprising codons 11 to 106 (from a total of 118) was fusioned to the amino terminus of β-galactosidase. Both bacterial vectors produce high amounts of the chimeric proteins.Purification of the fusion proteins from the soluble fraction was achieved by affinity chromatography. Their antigenic similarity to the preproNGF and mouse β NGF was examined by their interaction to sera raised against synthetic peptides which reproduce sequences of the precursor protein and to sera directed against native and denatured mouse NGF using ELISA techniques. The results provide direct evidence that antisera to mouse β NGF can crossreact with the human β NGF molecule.

276.9

INTRACELLULAR APPLICATION OF GTP INCREASES THE BINDING OF ^{125}I-NERVE GROWTH FACTOR TO PC12 CELLS.
T. Koike and S. Tanaka*, Department of Natural Science, Saga Medical School, Nabeshima, Saga 840-01, Japan.

We have previously shown that the binding of ^{125}I-NGF to PC12 cells is enhanced upon membrane depolarization, suggesting the dynamic nature of NGF receptors under physiological conditions (J. Neurochem. 49: 1784-1789, 1987). Here we show that the binding is also enhanced by pulse-mediated application of GTP into cytoplasm. ^{35}S-GTPγS, a non-hydrolyzable analogue of GTP, was maximally incorporated into the cells suspended in PBS, pH 7.2 without any significant decrease in cell viability when appropriate electrical pulses (15 times at 2000 V/cm) were delivered. We found that introduction of GTPγS (30 μM) into cytoplasm caused an increase (142± 12% of control) in ^{125}I-NGF binding (100 pM at 30C for 1h). This enhancement occurred in a dose-dependent manner. GTPγS was the most potent, and less effective compounds were GTP, Gp(NH)pp and GMP. However, other nucleotides such as GDP and ATP were ineffective. Thus, the enhancement observed in this assay system suggests a possible involvement of G-protein or other GTP-binding proteins such as microtubules.

276.10

ANTIBODIES DIRECTED AGAINST NGF RECEPTOR.
D.D. Eveleth* and R.A. Bradshaw. Dept. of Biological Chemistry, University of California, Irvine, Ca. 92717

We have generated antisera targeted to the Nerve Growth Factor (NGF) receptor by immunizing rabbits with synthetic peptides. These peptides were chosen from the sequence of the cloned rat NGF receptor and represent fragments of the extracellular (NGF-binding) domain. Some of these antisera are capable of inhibiting NGF-induced neurite outgrowth from rat PC12 pheochromocytoma cells. Some antisera are also capable of inhibiting the binding of NGF to PC12 cells. Inhibiting antisera identify multiple species on immunoblots, including species corresponding in size to the NGF receptors observed in crosslinking experiments. We believe these antisera bind NGF receptors and interfere with the association of the receptor and NGF. These antisera should prove to be useful probes for molecular studies of the NGF receptor.

276.11

NGF RECEPTOR INCREASE IN THE OLFACTORY BULB AFTER EARLY ODOR DEPRIVATION IN RATS.
F. Gómez-Pinilla, K. Guthrie, M. Leon and M. Nieto-Sampedro. Dept. of Psychobiology, University of California, Irvine, CA 92717.

Sensory experience affects development of neuronal types in the CNS and selective competition for neurotrophic factors may regulate the survival of neurons under specific environmental pressure. NGF and its receptor (NGFR) are present in the brain and appear to play a major role in the development and maintenance of normal connectivity of cholinergic neurons. The olfactory system of the rat is an interesting model to study the neurotrophic role of the NGF/NGFR system because turnover of olfactory receptors continues throughout life, and the amount of NGF detected in the olfactory bulb is the third most abundant in the brain. Here we describe the response of NGFR in the bulb after olfactory deprivation. Experimental rats received unilateral sealing of the nostril at postnatal day 1, and NGFR density was measured in the olfactory bulb 20 or 60 days later. We used an affinity purified monoclonal antibody (IgG 192 kindly provided by Dr. E. Johnson,Jr.) which was visualized by ABC immunohistochemistry or iodine-125 autoradiography (autoradiograms were quantified by computer image analysis). In normal rats NGFR immunoreactivity was located mainly in the glomerular layer along the rostrocaudal extent of the bulb. In the odor deprived rats there was an increase of NGFR density in the OB ipsilateral to the nasal occlusion. The increase of NGFR density was most dramatic in the rostral one third of the bulb, especially in the 60 days post-lesion rats. These findings suggest that NGF plays a role in the development or survival of neuronal elements in the bulb after loss of sensory input. (Supported by Grant AG 00538-09A from the NIA).

276.12

β-NGF ENDOPEPTIDASE IS A MOUSE SUBMAXILLARY KALLIKREIN (MGK 22).
J.E. Woo,* M. Fahnestock, J. Snow,* D. Walz,* and W.C. Mobley (SPON: I. Diamond). Dept. of Neurology, University of California, San Francisco, CA 94143, and SRI International, Menlo Park, CA, 94542.

β-NGF Endopeptidase (β-EP) is a serine protease which cleaves the β-subunit of NGF at the his^8- met^9 bond to release an NH_2-terminal octapeptide. The finding that this peptide has biological activity prompted further characterization of β-EP.

β-EP was purified by the method of Wilson and Shooter (J. Biol. Chem. 254:6002, 1979). In agreement with earlier studies, we found that β-EP was a single chain molecule (Mr~25 kDa) with pI = 5.6. The sequence of the NH_2-terminus was determined thru thirty amino acids . The sequence was identical to that given for EGF binding protein type A, as reported by Anundi et al (Eur. J. Biochem. 129:365, 1982); the protein is encoded by a gene designated mGK-22 (Evans et al. J. Biol. Chem. 262:8027, 1987). Contrary to its prior designation as an EGF binding protein, we found no evidence for interaction of β-EP with EGF by either kinetic or chromatographic analyses. Interestingly, the NGF octapeptide behaved as a competitive inhibitor of the enzyme; greater than 90% inhibition of β-EP activity on an artificial substrate was produced by preincubating β-EP with the octapeptide. β-EP appears to be quite specific in its interaction with growth-related factors and may have a physiological role in releasing a biologically active fragment from NGF.

276.13

HYPERALGESIC PROPERTIES OF NGF-OCTAPEPTIDE IN THE HAIRY SKIN OF THE RAT. J.D. Levine*, Y.O. Taiwo*, J.E. Woo* & W.C. Mobley. (SPON: K. Thind) Division of Neurobiology, Univ. of Calif. SF, CA 94143.

Although no biological function of the octapeptide cleaved from the NH_2-terminal end of NGF (NGF-OP) has been described, it was of interest to study its effects on peripheral nociceptive mechanisms because it has sequence homology with bradykinin (BK), NGF has recently been implicated in inflammatory mechanisms and NGF-OP may be cleaved from NGF in inflammatory lesions.

Experiments were performed in 300 g male rats in which a local irritation was induced by cutaneous application of chloroform. Hyperalgesia (HA) was quantified using the Randall-Selitto test. Drugs were injected intradermally in a volume of 2.5 ul. NGF-OP induced a potent, dose-dependent, hyperalgesia at a dose range 1/1000th that of norepinephrine (NE). This effect of NGF-OP resembles the recently described hyperalgesic effects of NE (Nature323:158, 1986) in that it is also prevented by prior sympathectomy or treatment with non-steroidal antiinflammatory analgesics. It differs, however, from the HA induced by BK in that it fails to produce hyperalgesia in normal skin. These data point to a function for a peptide found in mature NGF chains.

276.14

NGF ENHANCES THE OUTGROWTH OF NEURITES FROM AXOTOMIZED SEPTAL-BASAL FOREBRAIN NEURONS IN VITRO. M. Schinstine & C.J. Cornbrooks. Dept. of Anat. & Neurobiol., Univ. of Vermont, Burlington, VT 05405.

An in vitro model of regeneration was developed to test the ability of NGF to facilitate the outgrowth of neurites from septal-basal forebrain (SBF) neurons. Primary SBF explant cultures, prepared from fetal (E15) rats, were maintained on a collagen substrate for 5 days in either a NGF-supplemented (+NGF) or control (-NGF) media. The rate of neurite outgrowth in these cultures was not effected by NGF. Axotomized SBF neurons, prepared by severing the neuritic fields of primary SBF explants, were maintained on a collagen substrate for an additional 5 days in either the same medium used in the primary cultures or the opposite test medium. Most geurites from axotomized SBF neurons demonstrated similar growth rates (~37% slower than the rate in primary cultures). In contrast, axotomized SBF neurons exposed to NGF both before and after axotomy demonstrated an ~40% increase in neurite outgrowth as compared to control cultures. These results demonstrate that NGF can enhance the outgrowth of neurites from axotomized SBF neurons, but only if the neurons have been exposed to NGF prior to and after axotomy. Supported by NS 21811.

276.15

PROTEASE NEXIN I IS A SUBSTRATE FOR β-NERVE GROWTH FACTOR ENDOPEPTIDASE. DE Rosenblatt[1], JE Woo*[2], WC Mobley[2]. 1. Div. on Aging. Harvard Med. Sch., Boston, MA 02115. 2. Dept. Neurol., U. of C., S.F., CA 94143.

Proteolytic activity is required for processing biologically active polypeptides. β-nerve growth factor endopeptidase (β-EP) is a mouse submaxillary gland kallikrein which cleaves β-NGF releasing a biologically active N-terminal octapeptide. β-EP has little protease activity but is active on mouse plasma kininogen,its only other known substrate. We report here that protease Nexin I, a serine protease inhibitor recently shown to be identical to Glial Derived Neurite Promoting Factor is also a substrate for β-EP.

Purified β-EP and PN I formed a complex of MW 66KD that was stable on reduced SDS-PAGE. Western blot analysis with anti-PNI antibody and autoradiography for ^{125}I β-EP proved that the complex contained both PN I and β-EP. Complex formation mediated the cellular binding of β-EP to glial cells. The binding was time and temperature dependent and inhibited by heparin.

The activity of β-EP against PN I is remarkable in view of its marked substrate specificity: the data reemphasizes the potential significance of nexin's complexation of growth factor related enzymes. Biological activity may reflect enzyme inhibition or bioactive peptide formation from nexin.

276.16

IDENTIFICATION OF b-FGF AS A CHOLINERGIC NEUROTROPHIC FACTOR IN EXTRACTS OF SKELETAL MUSCLE. J. L. McManaman,* F. G. Crawford,* J. O. Richker* and R. C. Clark* (SPON: L. J. Haverkamp). Wagner ALS Research Laboratory, Dept. of Neurology and Prog. in Neurosciences, Baylor College of Med., Houston, TX 77030

Extracts of skeletal muscle contain chromatographically distinct molecules which enhance the cholinergic development of cultured embryonic rat spinal cord neurons. We have recently purified a 20-22 kDa cationic polypeptide (CDF) from rat skeletal muscle extracts which stimulates the development of CAT activity in rat spinal cord cultures (McManaman et al, J. Biol. Chem., in press). We now show that muscle extract also contains basic Fibroblast Growth Factor (bFGF) and that bFGF also stimulates CAT development in rat spinal cord cultures. Basic FGF differs from CDF in its physicochemical, chromatographic and immunological properties and by its mitogenic action on non-neuronal cells. In addition, the effects of bFGF and CDF on CAT development are additive, suggesting that their actions are mediated by different cellular mechanisms. Our findings identify two distinct polypeptides with trophic factor activities in extracts of rat skeletal muscle. These findings support the hypothesis that the embryonic development of cholinergic neurons is influenced by multiple target-derived neurotrophic factors.

CULTURED VASCULAR SMOOTH MUSCLE CELLS PROVIDE NGF-DEPENDENT NEURONAL SURVIVAL. D. J. Creedon and J. B. Tuttle, Physiology and Neuroscience, Univ. of VA Sch. of Medicine, Charlottesvl., VA 22908.

Knowledge of the regulation of NGF synthesis by the synaptic partners of NGF-dependent neurons has been elusive. The present work addresses this issue using cultures of vascular smooth muscle cells (VSM), a normal target cell of sympathetic neurons.

Primary rat aortic VSM cells were passaged as they approached confluency and plated into 24-well microplates at 10^3-10^4/cm^2. Neurons dissociated from superior cervical ganglia (SCG) of neonatal rats were plated onto the VSM. After 48 to 72 hrs, the cultures were immunohistochemically labeled with a neuron-specific cytoskeletal marker and the remaining neurons counted. Survival on VSM was always substantial compared to a general failure to survive on a collagen or laminin substrate. NGF (100ng/ml) fostered survival equivalent to the VSM. Added to VSM co-cultures the NGF enhanced neuronal survival to a variable extent, suggesting that trophic production is regulated by the VSM. Survival in all conditions could be effectively blocked by the addition of an anti-NGF monoclonal antibody (1ug/ml). These results demonstrate production and export of probable authentic NGF by normal target cells of sympathetic neurons in cell culture and suggest NGF supply by the target is under cellular control. Supported by Am. Heart Assoc (Va Affiliate) and NIH 5 T32 HL07284.

UP-REGULATION OF NERVE GROWTH FACTOR MESSENGER RNA SYNTHESIS IN ASTROCYTES. P.J. Isackson*, R. Bridges, E. Frohman, S.L. Wagner*, E.G. Jones and D.L. Benson. (SPON: H. Schwark) Dept. of Anatomy and Neurobiology, Dept. of Neurology, Dept. of Microbiology and Molecular Genetics, University of California, Irvine, CA 92717.

Nerve growth factor (NGF) mRNA levels were quantitated in several types of cultured cells by Northern blot analysis. Human neuroblastoma and glioblastoma cell lines and primary cultures of human foreskin fibroblasts produce levels of NGF mRNA comparable to total adult mouse brain. NGF mRNA of glioblastoma cells appeared to be distinctively smaller than NGF transcripts from all other sources examined when probed with either RNA or single-stranded DNA probes. Primary cultures of astrocytes prepared from frontal cortex of neonatal rat brains and a fetal human brain produced greater than 10-fold higher levels of NGF mRNA than normal brain. This is consistent with high levels of NGF protein reported to be present in the media of cultured rat astrocytes (Furukawa et al.,BBRC,136:57,1986). The level of NGF mRNA synthesis was found to be related with the extent of confluency of the astrocytes. These results suggest that glial cells may produce NGF in the brain normally and are capable of producing higher levels in certain trauma or disease states. INTRASPINAL SYNAPTOGENESIS OF PRIMARY AFFERENT FIBERS INVOLVES NGF. C.E. Hulsebosch and S.M. Carlton. Dept. of Anat. and Neurosci. and Marine Biomed. Inst., Univ. Tex. Med. Br., Galveston, TX 77550.

We previously reported an increase in the number of unmyelinated sensory fibers in the dorsal root and Lissauer's tract in adult rats after daily treatment with rabbit antibodies for β-Nerve Growth Factor (Anti-NGF, 3 µl/gm body weight undiluted sera) from birth for 1 month. We interpret this increase to be sprouting of the unmyelinated population in response to NGF deprivation. To test for synaptogenesis, we immunostained for calcitonin gene-related peptide (CGRP), a marker for unmyelinated and small myelinated primary afferent terminals in laminae I and II. We report a 103% increase in CGRP immunoreactivity as determined by computer assisted image analysis, in the Anti-NGF treated rats compared to controls. The increased immunoreactivity diminishes after a unilateral dorsal rhizotomy of 12 segments. This supports the hypothesis of synaptogenesis of CGRP afferent terminals after Anti-NGF treatment. (Supported by Spinal Cord Research Foundation, NIH grants NS11255 and NS25450, Marie Hall Foundation and Bristol-Meyers.)

NEURAL PLASTICITY IN ADULT ANIMALS: NEUROMUSCULAR AND AUTONOMIC

LONG-TERM UNCOUPLING OF MUSCLE AND MOTONEURON: EFFECTS ON IA SYNAPTIC FUNCTION. S. Vanden-Noven and M. J. Pinter. Dept. Anatomy, Medical College of PA at EPPI, Philadelphia, PA 19129.

In deeply anesthetized cats, we studied heteronymous Ia synaptic function in axotomized medial gastrocnemius (MG) motoneurons that were denied the possibility to reinnervate muscle. The severed MG nerve was sutured onto the lateral gastrocnemius (LG) muscle and the MG muscle excised. At various days post-operative (DPO, up to 150), we recorded composite Ia EPSPs evoked by electrical stimulation of the undamaged LG-soleus nerve. At 44 DPO, significant changes were found in average EPSP amplitude (decrease) and time-to-peak (increase). Between 60, 90 and 120 DPO, however, there was a clear trend for the values of these parameters to return to control levels. Detailed analysis, however, indicates that this does not represent a restoration of normal synaptic function. For example, at several DPOs, post-tetanic depression of Ia EPSPs was observed. Moreover, the apparent recovery of EPSP amplitude was not evident at 150 DPO.

Supported by NIH grants NS24000 and NS24707.

277.2

LONG-TERM UNCOUPLING OF MUSCLE AND MOTONEURON: EFFECTS ON MOTONEURON ELECTRICAL PROPERTIES. M.J. Pinter and S. Vanden-Noven (SPON:F. Haun). Dept. Anatomy, Medical College of PA at EPPI, Philadelphia, PA 19129.

We studied the extent to which changes in motoneuron (MN) electrical properties provoked by axotomy persist when reinnervation of muscle is prevented. In deeply anesthetized cats, axotomized medial gastrocnemius (MG) MNs were studied by intracellular recording at various days post-operative (DPO). Reinnervation by MG MNs was prevented by suturing the severed MG nerve onto the normally-innervated lateral gastrocnemius (LG) muscle and excising the MG muscle. For DPOs up to 150, we found no trends for recovery of control values among the variety of MN electrical properties studied. Significant correlations observed among control values of certain parameters could be found at all post-operative intervals, but the occurrence of significant correlations decreased over time. Although disruption of connections between muscle and MNs markedly affects MN electrical properties, these connections are not required for the expression of correlations among motoneuron properties.

Supported by NIH grants NS24000 and NS24707.

277.3

ATROPHY OF THORACIC MUSCLES FOLLOWS HINDLIMB AUTOTOMY IN GRASSHOPPERS. EA Arbas ARL Div. of Neurobiol. Univ. of Ariz., Tucson AZ 85721.

We have reported earlier (Weidner & Arbas, 1985 Soc. Neurosci. Abstr. 11, 959.) that undamaged, fully innervated muscles intrinsic to the thorax of grasshoppers Barytettix psolus atrophy to <15% of their normal mass after hindlimb autotomy. Experimental cutting of nerves and muscle loading/unloading indicated that it is the severing of the leg nerve (N5) during autotomy that induces muscle atrophy. We have now also studied the grasshoppers (Schistocerca americana) and (Melanoplus differentialis), and find significant differences among these taxa. Grasshoppers were made to autotomize a leg in the first days of adult life and certain of their thoracic muscles were individually weighed 35-70 days later. All 6 muscles studied in Barytettix atrophied significantly, to 3-16% of control (n=10 insects). In Schistocerca (n=15) only two muscles atrophied significantly to 70-80% of control. In Melanoplus (n=10) 5 muscles atrophied to 58-90% of control. For example, the mass of muscle #133 was reduced as follows by 35-70 days after autotomy: In Barytettix to 3 +/- 0.6% of control; Melanoplus, 58 +/- 3%; Schistocerca, 72 +/- 5%. Thus, hoppers of these taxa show different sensitivities to autotomy-induced nerve damage as adults. If Schistocerca (n=10) were made to autotomize a leg earlier in development (2nd instar), muscle atrophy increased significantly. Weighed individually on the 1st day of adulthood (26 days post-autotomy), 5 muscles showed significant atrophy, weighing 39-93 % of control. In this group, muscle #133 weighed 39 +/- 4% of control, representing significantly greater atrophy than in the adult-treated group above. It appears that Schistocerca is quite sensitive to nerve damage early in its development, and loses this sensitivity as an adult. In Barytettix, sensitivity to nerve damage persists throughout the entire life cycle. [Supp. by the Univ. of Ariz. Foundation]

277.4

STRUCTURE OF MOTORNEURONS TO MUSCLES THAT ATROPHY FOLLOWING HINDLIMB AUTOTOMY IN GRASSHOPPERS. AR Villalobos*, EA Arbas (SPON: T Kingan), Dept Physiol & ARL Div of Neurobiol, Univ of Ariz, Tucson AZ 85721

Grasshoppers often autotomize a hindleg to escape predators or to shed it when damaged. This severs the leg nerve (N5) and causes undamaged, separately innervated thoracic muscles to atrophy (e.g. Weidner & Arbas, 1985 Soc. Neurosci. Abstr. 11; 959). Atrophy could be initiated if damage to axons in N5 caused regression of motorneurons (MNs) innervating these muscles. MNs might degenerate or withdraw their axons from target muscles or atrophy in the CNS. We have tested for this by cobalt backfilling MNs of tergo- trochanteral muscle (M #133 b,c), which atrophies to <5% of normal mass after hindlimb autotomy in grasshoppers Barytettix psolus. MNs were stained 4-6 weeks post-autotomy, or in controls of the same age. Different fills in controls revealed up to 3 ventral neurons that could always be identified as either a large (ca. 47-61 um diam.) anterior soma; or one of pair of smaller (ca.32-50 um diam.) neurons. All 3 MNs could be identified in backfills of atrophied M #133 in treated insects. Clearly, muscle atrophy is not due to degeneration of the MNs. Dendrites of MNs in both groups showed variability but no differences indicating atrophy in treated insects were apparent. Somata were traced on a digitizing tablet and profile areas calculated. Comparison of 5 larger anterior somata from normals with 10 from the treated group showed no significant differences. Comparison of 9 smaller somata from normals with 16 from the treated group showed the latter to be ca. 46% smaller (t-test $P<0.001$). Thus, soma shrinkage in the smaller pair accompanies muscle atrophy. Shrinkage of somata may indicate reduced biosynthetic activity. The relationship of this change to muscle atrophy is a subject for future research. [Supp. by Univ. of Ariz. Foundation].

THE RELATIONSHIP BETWEEN MOTORNEURON CELL SIZE & THE SIZE OF THE PERIPHERAL FIELD. H.Tissenbaum*& D.J. Parry* (SPON: J.Thakar), Dept. Physiol., Univ. Ottawa, Ottawa, ON K1H 8M5.

To elucidate the relationship between motorneuron soma size and the size of the peripheral field we examined changes in the motorneuron soma size using horseradish peroxidase (HRP) retrograde labelling in both control (C57BL) and dystrophic (dy2j/dy2j) mice. After partial denervation of the anterior tibialis (TA) muscle, mean soma size of the surviving motorneurons was significantly increased when compared to the unoperated side. In 12 C57 mice, mean soma area was 245.1±18.5μm^2 on the control side and 298.5±15.9μm^2 on the partially denervated side. In 12 dy2j mice, mean soma area on the control side was 235.4±17.6μm^2 and 291.8±17.6μm^2 on the operated side. It is possible that the increased motorneuron size may be associated with the increased motor unit size known to occur with partial denervation. To prevent this increase, experiments were performed involving partial denervation accompanied by partial extirpation of TA. Following recovery, in 12 C57 mice, cell soma size was 250.7±14.5μm^2 on the control side and 255.7±19.1μm^2 on the operated side. In 12 dy2j mice, mean area on the control side was 257.3±16.3μm^2 and 247.3±10.5μm^2 on the operated side. We conclude the size of the motorneuron in the spinal cord is related to the total number of muscle fibers innervated (ie. motor unit size). Supported by Medical Research Council of Canada.

CENTRAL AND PERIPHERAL NEURONAL ALTERATIONS IN EXPERIMENTAL DIABETES. A.M.Di Giulio, B. Tenconi*, R. La Croix*, M.P. Abbracchio*, F. Cattabeni, and A.Gorio. Inst. Med. Pharmacol., Faculty of Med., Via Vanvitelli 32, and Inst. Pharmacol. Sci., Via Balzaretti 9, Milano, Italy

It is known that diabetes is correlated with sensory and motor peripheral degenerative atrophy. We now report that alterations are present also in CNS and in neurons innervation the gut. The caudate is hyperinnervated by met-enkephalinergic axons with a correlated decrease in the efficiency of the inhibitory transduction signal of the dopaminergic receptor, clearly suggesting an alteration of the Gi protein system. 5-HT containing neurons display a proximal-distal atrophy, as suggested by the significant 5-HT decrease in the pons-medulla oblongata and by lack of changes distally. The gut shows a typical hyperinnervation by the NA system in the duodenum, while the ileum shows a degeneration of the enteric substance P system.

DIMINISHED SPINAL CORD CONDUCTION VELOCITY IN DIABETIC RATS. L.R. Whalen*, R.E. Carsten*, and D.N. Ishii (SPON: N. Chaudhari) Dept. Anatomy and Neurobiology, and Dept. Physiology, Colorado State Univ., Ft. Collins, CO 80523.

Insulin can support the survival of sensory and sympathetic neurons and enhance neurite formation at physiological concentrations (reviewed in Ishii and Mill, Curr. Topics Membranes Transport 31: 31, 1987). Because similar effects are observed in cultured spinal cord neurons (see Glazner and Ishii, this meeting), we predicted that a decrease in insulin activity may cause functional disturbances in the cord. A novel procedure to measure evoked spinal cord potentials was devised. The sciatic nerve was stimulated, recording electrodes were placed at interarcuate levels C2-3 and T8-9, and the distance between the recording electrodes measured. The difference in latency of the compound action potentials recorded at the two sites permitted calculation of the conduction velocity. This is the first demonstration that conduction velocity is decreased in the spinal cord of diabetic rats ($P < 0.05$). A common mechanism is suggested because the kinetics and magnitude of the decreases were similar in the spinal cord, common peroneal nerve, and saphenous nerve following the induction of diabetes with streptozotocin. The results suggest that insulin may help maintain conduction velocity through direct effects on central and peripheral neurons. (Supported by NIH grant R01 NS24327).

PROLONGED AXONAL SURVIVAL FOLLOWING AXOTOMY. E.R.Lunn*, V.H.Perry*, M.C.Brown, H.Rosen*, S.Gordon*. University Laboratory of Physiology, Dept. of Experimental Psychology and Sir William Dunn School of Pathology, Oxford University, Oxford, England

Myelomonocytic cells are recruited into the distal half of sectioned mammalian peripheral nerves. The following experiments suggest that they do not simply phagocytose debris but actively bring about axonal destruction and stimulate Schwann cell mitosis. i) In one strain of C57BL mouse, sciatic nerve section is not followed by the usual rapid loss of form and function in the distal half: nearly all axons appear normal 7 days after axotomy at both light and EM levels and most conduct action potentials. In this strain myelomonocytic cell recruitment and Schwann cell mitosis are absent at 7 days. ii) In all other strains of mice examined the ability to conduct action potentials is lost by day 2 after axotomy and all axons have disintegrated by 3 days. When cell recruitment is prevented in these strains by intravenous injection of a monoclonal antibody that hinders leucocyte migration across the blood vessel wall (Rosen,H. & Gordon,S., J.Exp.Med., 166:1685, 1987) axonal integrity was preserved for up to 5 days in 14 out of 22 treated mice.

277.9

A QUANTITATIVE STUDY OF NEURONAL DEGENERATION INDUCED BY RICINUS TOXIN IN THE CILIARY GANGLION OF QUAIL. §P. Paggi, ◊A. Ciofi Luzzatto*, #M.E. De Stefano*, #D. Guidolin*, ◊G. Mangano* and ◊G. Toschi*. §Università de L'Aquila, ◊Università "La Sapienza" Roma, #Fidia Laboratories, Abano Terme. Italy.

One useful approach to the study of synaptic contacts formation and maintenance consists of target cells removal. The experimental model chosen for this purpose was the quail ciliary ganglion, where we can compare two independent cell populations, showing different types of preganglionic terminals. Ricinus toxin was applied to crushed postganglionic nerves and after a 3 to 40 day period the ganglia were examined by light microscopy, for changes in neuron number, volume and morphology. Normal and crush-treated controls were also analyzed. At day 40 a 40 to 50% loss of both the ciliary and choroid cells was observed in the toxin-treated ganglia. However, the two cell populations showed different degeneration patterns: in fact, at day 3 the degenerating ciliary neurons showed a massive nuclear pycnosis and nucleolar fragmentation, a phenomenon never observed at any stages in the choroid cells. Moreover, the surviving ciliary cells, unlike the choroid cells, revealed an increased cellular volume.

These observed behavioral differences between the two cell populations may affect the survival of their respective preganglionic terminals differently, and/or may be attributed to the diversity between the two types of terminals themselves.

277.10

DISUSE AND FUNCTIONAL OVERLOAD INDUCED BY TOOTH EXTRACTION ALTERS NMJ MORPHOLOGY IN C57BL/6J MICE. M.K. El Kerdany, M.H. Andonian, and M.A. Fahim, USC Andrus Gerontology Center, Los Angeles, CA 90089-0191.

The effects of functional disuse and overload on the morphology of neuromuscular junctions (NMJ) in masseter muscles of 12 month old C57BL/6J mice were studied. In order to simulate disuse associated with tooth loss, teeth were extracted from one upper quadrant of 10 mice. The side where teeth were removed was functionally disused (D), since no occlusion could be achieved. Similarly, the intact contralateral (CL) side experienced overload. Morphological measurements were taken from zinc iodide osmium (ZIO) stained NMJs from control animals, and treated animals at 7 days (7D) and 4 months (4M) post extraction. Data was analyzed with repeated measures multivariate analysis of covariance (MANCOVA).

Test animals did not loose weight, indicating sufficient food was consumed after tooth extraction. Fiber diameters from the 7D group were smaller than the controls, while those from the 4M animals were larger. In both the 7D and 4M animals, the CL fibers were larger than the D fibers. There was a trend toward larger NMJs in the 4M animals when compared with control animals of the same age. NMJs from the CL side of the 4M animals had 14% larger nerve terminal areas ($P < .01$), while the 4M D side was 6% larger ($P < .10$). NMJs from the 4M D group had 5% longer nerve terminals ($P < .07$); while the 4M CL NMJs were 6% longer ($P < .05$). NMJs from the D side of the 7D animals were 5% smaller areas while the CL side were 11% smaller ($P < .01$). Nerve terminals from 7D disused were 6% longer ($P < .05$) than controls.

Changes in NMJ morphology following tooth extraction were probably due to differences in degeneration - regeneration of nerve terminals. Acute disuse and overload probably produced greater nerve terminal retraction, whereas chronic changes consisted of a recovery characterized by NMJ elaboration similar to that observed in exercise, disuse and aging studies. 277.11

EFFECTS OF SPINAL CORD TRANSECTION ON SYNAPTOLOGY OF PREGANGLIONIC NEURONS IN THE SACRAL PARASYMPATHETIC NUCLEUS OF CATS. M.G. Leedy, M.S. Beattie, and J.C. Bresnahan. Depts. of Anatomy and Neurosurgery, Ohio State University, Columbus, OH 43210.

The preganglionic neurons (PGNs) of the sacral parasympathetic nucleus (SPN) were labeled by placing HRP onto the pelvic nerve in cats which received: 1) no spinal cord transection (Normal), 2) transection four days prior to sacrifice (Acute TX) or 3) transection 10 weeks prior to sacrifice (Chronic TX). Ultrastructural analysis indicated that removal of the supraspinal inputs, while not affecting the number of terminals per 100 um of membrane perimeter, significantly decreased the terminal coverage of the labeled somata and proximal dendrites in the Chronic TX animals. Changes in terminal types were also seen, with the Normal group exhibiting a greater proportion of terminals containing dense cored vesicles than did the transection groups. In addition, terminal size was significantly reduced in the Chronic but not the Acute TX animals. These results provide evidence of alterations in synaptic inputs to the preganglionic neurons of the SPN in response to spinal cord transection.

277.12

CHANGES IN IN VITRO MOUSE SPINAL CORD FOLLOWING NERVE CRUSH AND HIND LIMB UNLOADING.
C.J. Somps and M.W. Luttges. Aerospace Engineering Sciences, University of Colorado, Boulder, Colorado 80309.

Rapid (days) changes in electrophysiological indices of spinal cord function have been observed following peripheral nerve injury. These changes include time dependent depressions/elevations in primary afferent depolarizations and interneuron responses, as well as injury dependent somatotopic reorganizations of afferent specificity. Recent histological and in vitro biochemical studies have revealed post-injury changes in neuronal peptide concentrations and synaptic uptake of neurotransmitter. These chemical changes occur in the same general time-frame, and commonly in the same direction, as electrophysiological changes. In order to best correlate post-trauma chemical and electrical changes, present tests were done on an in vitro, hemisected, adult mouse spinal cord preparation. Alterations in afferent input were induced, in vivo, by crushing the sciatic nerve 3,6,9, & 12 days prior to testing, or by unloading the animal's hind legs for 30-40 days prior to testing. Stable (>8 hrs), multi-component, electrophysiological responses (latencies of 1-10 msec) were obtained from dorsal horn laminae using both dorsal root and dorsal tract stimulations. These responses showed clear sensitivities to temperature, ion concentrations, and drug concentrations, as well as experimental manipulations of afferent inputs. Mechanisms underlying these sensitivities are postulated.

NORMAL SUCCINATE DEHYDROGENASE ACTIVITY IN MOTONEURONS SIX MONTHS AFTER SPINAL ISOLATION
G. R. Chalmers, R. R. Roy, and V. R. Edgerton. Kinesiology Department and Brain Research Institute. UCLA, Los Angeles, CA 90024.

Five female adult cats underwent surgical spinal isolation (SI), i.e., complete spinal cord transection at T12-T13 and at L7-S1 with all dorsal roots between transection sites severed, to eliminate electrical activity in the motoneurons of the lumbar spinal cord. The cats were maintained in excellent health for 6 months. The right leg muscles received cyclic passive stretching for 30 min/day, 5 days/week. An almost total lack of neuromuscular activity was verified by EMG recordings. Succinate dehydrogenase activity (SDH), an aerobic marker enzyme, of a population of motoneurons in the lumbosacral enlargement was determined using the technique described by Chalmers and Edgerton (Soc. Neurosci. Abstr., 13:1416, 1987). Six normal cats served as controls (C). In the SI cats, 289 and 319 cells were sampled in the left and right ventral horns respectively. There was no significant difference in mean SDH between the two sides, thus the data were pooled for subsequent analyses. There was no significant difference between the SI and C animals in motoneuron mean SDH ±SD (SI=0.0155 ±0.048 OD/min, n=608; C=0.0164 ±0.0047 OD/min, n=720). The soma cross-sectional area was determined for cells in which there was a visible nucleus. There was no significant difference in mean soma area ±SD between the two groups (SI=3754 ±1295 um^2, n=214; C=3850 ±1192 um^2, n=289). A plot of SDH activity vs. soma size (for cells with nuclei) showed that small cells had a wide range of SDH activities (i.e., low to high) while larger cells had only low SDH activities. These data indicate that soma size and SDH activity of lumbar motoneurons are not affected by a large reduction in number of action potentials. *Supported by NIH Grant NS16333*

LONG-TERM ADAPTATION OF CRAYFISH EXTENSOR MOTONEURONS. A.J. Mercier and H.L. Atwood, Dept. of Physiol., Univ. of Toronto, Toronto, Ont. M5S 1A8

Previous studies with the crayfish claw (eg. Lnenicka et al, J. Neurosci. 6:2252, 1986) have shown that conditioning the phasic closer excitor motoneuron in situ for 3 or more days (at 5 Hz for 2 hrs/day) changes its synaptic properties to more closely resemble those of more active, tonic neurons. This "long-term adaptation" involves a reduction in EPSP size and a decrease in the rate of fatigue of EPSP's. The present study shows that similar conditioning (2.5 Hz, 4 hrs/day for 3 days) applied in situ to phasic abdominal extensor motoneurons causes a marked reduction in EPSP size, apparent 1 day after cessation of conditioning. Mean quantal content, determined using a focal extracellular electrode to record excitatory synaptic currents, was found to decrease in response to conditioning. Calculated values for binomial parameters n and p also decreased, suggesting a reduction in the number of active release sites and in release probability. The results show that long-term adaptation occurs in several crustacean phasic neurons and provide direct evidence that the reduction in EPSP size involves presynaptic mechanisms.

MULTI-UNIT ANALYSIS OF A NEURAL ENSEMBLE CONTROLLING DIRECTED MOVEMENT. J.P. Dowd[1*], S.R. Smith[2*], C.M. Comer[1] and B.C. Wheeler[2]. [1]Dept. Biological Sciences & Committee on Neuroscience, Univ. of Illinois-Chicago. [2]Dept. Electrical and Computer Engineering & Bioengineering Program, Univ. of Illinois-Urbana.

Intracellular recordings from the giant interneurons (GIs) of the cockroach (P. americana) have shown that these cells respond selectively to winds from certain directions. Evidence suggests that GI information orients the animal's escape turning response to wind. We sought to understand group properties of the GIs, and their ensemble coding, using multi-unit recording techniques.

Simultaneous intracellular and extracellular recordings from the cockroach nerve cord showed that single units could reliably be separated from multi-unit records using computerized signal analysis. Identification of these separated cells was accomplished through template matching with our intracellularly-derived GI receptive fields. This approach has discerned the relative timing of neural activity of cells within one connective and between cells on the two sides of the nerve cord. It also enabled analysis of the covariance between specific units in their responses to winds. We are currently using this method of signal analysis to determine the ensemble coding of GIs recorded from chronically implanted electrodes in an intact animal.

278.2

COMPARISON OF WIND-ELICITED EVASIVE BEHAVIOR MEDIATED BY GIANT INTERNEURON (GI) AND NON-GI PATHWAYS IN THE COCKROACH, Periplaneta americana.
I.E. Stierle*, M.E. Getman* and C.M. Comer (SPON: E. Polley). Dept. Biol. Sciences, Univ. of Illinois, Chicago, IL 60680

Giant interneurons (GIs) in the nerve cord of the cockroach receive cercal sensory input and play a role in triggering the animal's wind-elicited escape response; a turn away from the wind and then a run. However, we recently found that when GI input to thoracic ganglia was blocked by section of the abdominal portion of the cord, evasive responses to wind persisted. Animals with this lesion responded at a low rate (30%) to a standard wind stimulus, and their responses were about 3 times longer in latency than normal. This behavior was supported by non-GI pathways which apparently receive input from head sensory structures, such as the antennae (Brain Res. 445:370-375, 1988).

We have now characterized non-GI mediated responses to wind in animals with the cerci removed or with all the GIs ablated from the cord by electrocautery. Tested under free-ranging conditions, these animals responded to wind on 50-75% of all trials, and the average latency of responses was approximately doubled. The directionality of these responses was roughly normal: they were oriented away from the wind source, but with a poorer correlation between turn angle and wind stimulus angle than is normally seen.

In animals with either of these lesions, subsequent removal of the antennae significantly reduced responsiveness to wind and further elevated latency. Antennal removal alone does not affect response rate or latency.

RESPONSE INCONSTANCY IN THE FLASH COMMUNICATION SYSTEM OF FEMALE PHOTURIS VERSICOLOR FIREFLIES. Jonathan Copeland, Kathleen King*, and Albert D. Carlson. Dept. of Biol., Swarthmore Coll., Swarthmore, PA 19081 and Dept. Neurobiol. and Beh., SUNY Stony Brook, Stony Brook, NY 11794.

Prior to mating, a female Photuris versicolor firefly readily responds to the triple pulse flashes of its conspecific male. After mating, a female versicolor undergoes a behavioral shift, becoming predatory. A mated female responds to a wide range of different flash patterns. This mating-induced behavioral switch appears to involve the modulation of neural circuits in the firefly's brain.

Is this behavioral switch permanent or does female versicolor response behavior change as the animal ages? Comparisons between predatory females captured early in the summer and those captured 4 weeks later reveal that older versicolor females become less discriminating in their flash responses. Whereas younger versicolor females respond mostly to double flashes, older ones respond equally well to single, double, and triple flashes.

Anatomical examination of older field-captured versicolor females reveals that they possess significantly fewer motile sperm than those captured earlier in the summer. Although the nutritional state of these fireflies could not be determined, our earlier experiments indicate that fed versicolor females live longer than unfed controls. They also mature and lay more eggs than unfed controls.

Multiple internal and external factors may shape this firefly's flash communication system.

BEHAVIORAL CHOICE IN THE LEECH; CHARACTERIZATION OF THE SHORTENING MOTOR PATTERN. G. Wittenberg and W.B. Kristan, Jr. Dept. of Biology, University of California at San Diego, La Jolla, CA 92093-0322.

The leech, *Hirudo medicinalis*, may react variably to repetitions of a constant stereotyped mechanical stimulus, producing at least two different behaviors: swimming, an undulatory movement, or shortening, a withdrawal involving several segments near the stimulated site. We addressed the issue of whether this choice is a choice between sets of motor neurons (MNs), that is, whether the two behaviors use the same set of MNs or use two different sets.

Because shortening and swimming both use longitudinal muscles, we studied the responses of the motor neurons innervating them. These muscles are innervated by a set of 16 pairs of MNs in each segmental ganglion. Of these MNs, the L-cell pair excites the entire cylinder of longitudinal muscle in its segment, while the others excite or inhibit more restricted bands. Although L cells have the appropriate motor output to produce shortening and receive excitatory input directly from mechanosensory neurons within their own ganglion, most of them are hyperpolarized in segments that are producing the shortening motor pattern. The exception is in the stimulated segment and the adjacent ones, in which the direct excitation from mechanosensory cells predominates.

By contrast, the responses of the other longitudinal excitatory MNs (eg. cell 3) during shortening are pure depolarizations, are larger, and have a segmental extent that correlates well with the extent of the shortening behavior. Thus, the shortening behavior uses the same set of MNs as does swimming. The difference between the two behaviors is in the pattern of MN activity producing them. These data imply that some of the interneurons mediating the shortening response make interganglionic excitatory connections onto this set of longitudinal MNs. We will search for these interneurons and determine whether they also inhibit both the swimming behavior and the L-cells.

HINDSIGHT AND RAPID ESCAPE IN AN AQUATIC OLIGOCHAETE. C.D. Drewes* and C.R. Fourtner. Zool. Dept. Iowa State Univ., Ames, IA 50011 and Bio. Sci. SUNY Buffalo, NY 14260.

Mechanosensory stimuli applied to posterior segments are effective in evoking lateral giant nerve fiber (LGF) spikes and rapid posterior shortening in a wide variety of aquatic and terrestrial oligochaete worms (*Can. J. Zool.* 1983, 6:2688-2694; *J. Com. Physiol.* 1987, 161:729-738). We report the first instance of an oligochaete (Lumbriculus variegatus) in which LGF spikes and posterior shortening are elicited by decreased light intensity or moving shadows. Experiments from freely behaving intact worms showed that abrupt cessation of background illumination triggered multiple LGF spiking (latency, 321 ms ± 41 SD; n=11) and rapid shortening (latency, 389 ms ± 64 SD; n=16). Nearly identical responses to cessation of light were observed in amputated tail-piece preparations (latency to LGF spiking = 365 ms ± 87 SD; n=13). Since responses to light cessation and moving shadows never occurred in amputated pieces from mid-body or anterior regions, we conclude that LGF photosensitivity is resident in posterior segments. Electron microscopic observations of tail segments suggest that the photoreceptor candidates are isolated epidermal cells invaginated distally to form a cavity (phaosome) filled with microvilli. These cells closely resemble the known photoreceptors of anterior segments in earthworms and leeches. We suggest that the adaptive significance of this LGF-mediated escape response to shadow is related to the worm's habitat and lifestyle, which involve living in shallow margins of ponds and conspicuously positioning tail segments at air-water interface.

ORGANIZATION OF EGG LAYING BEHAVIORS IN THE POND SNAIL, *LYMNAEA STAGNALIS*. G.P. Ferguson, A.W. Pieneman* and A. Ter Maat. Department of Biology, Free University, Postbus 7161, 1007 MC Amsterdam, The Netherlands.

The egg laying behavior of *Lymnaea* is induced by the electrical discharge of the neuroendocrine Caudo Dorsal Cells (CDCs) and then continues until the eggs are deposited on the substrate. Animals show three distinct phases of egg laying behavior; Resting, Turning and Oviposition. These phases are characterized by specific postures and by the temporal patterns of locomotion and rasping movements of the buccal mass.

Immediately after the CDC discharge the animal enters the Resting phase, and locomotory and rasping activity decrease. The reduction in rasping still occurs when animals are exposed to a chemical stimulus (high sucrose in the water) that would normally stimulate rasping behavior. This suggests that the peptides released by the CDCs have an inhibitory effect on the buccal system of *Lymnaea*.

During the subsequent phases of egg laying (Turning and Oviposition) rasping increases in frequency and animals show slow locomotion around the area of the tank where the eggs will be deposited. Lesions disrupting specific neuronal pathways between the reproductive tract and the ganglia of the CNS that control locomotory and buccal activity abolish these behaviors, demonstrating that sensory input from the reproductive tract is essential for coordinated egg laying behaviors.

Chronic recordings from the muscles of the buccal mass showed that the rasps made during egg laying were characterized by a different pattern and duration of activity to those made during feeding. This suggests that in addition to the inhibitory effects that the CDC peptides have on the buccal system in the Resting phase, they also have a modulatory effect on buccal activity during the later phases of egg laying.

THE NEUROETHOLOGY OF THE EYE-BAR RESPONSE: THE MOTOR CONTROL. M.M. Hagedorn and R.D. Fernald. Institute for Neuroscience, University of Oregon, Eugene, OR 97403.

We are investigating the eye-bar response in the African cichlid, *Haplochromis burtoni*, as a neuroethological model for visual processing. The eye-bar response is a visually mediated chromatic color change in the melanocytes below the eye, displayed between territorial males.

Attached to the modified scale of the eye-bar are two fine nerves which branch from the facial nerve, and appear to be under sympathetic control (Muske and Fernald, 1986). Methylene blue dissections of these nerves show that they follow the mandibular branch of the facial nerve into the trigeminal ganglion complex. In our current investigation, we have focused upon the anatomy and physiology of the peripheral nerves, henceforth called the eye-bar nerves.

Stimulation of the eye-bar nerves with hook-electrodes causes an immediate contraction of the melanocytes in the eye-bar region, as previously reported. These nerves were severed and injected with horseradish peroxidase. Filled ganglion cells were found in the trigeminal ganglion complex with some fibers projecting into the brain. These direct projections suggest that the two nerves are not both of sympathetic origin, perhaps, with only one directly controlling the melanocytes. Tyrosine hydroxylase immunocytochemistry is currently being used to resolve this issue. During immobilization with curare, the animal maintains its eye-bar in a pale state, severing the eye-bar nerves at this time causes an immediate darkening of this region. This suggests that there is some spontaneuos activity in these nerves. When the eye-bar is dark, however, recordings from these nerves shows no spontaneous activity.

OPERCULAR DILATOR MUSCLE INNERVATION IN AN "AGGRESSIVE" AND A "NON-AGGRESSIVE" FISH. Dennis L. Gorlick, Department of Biological Sciences, Columbia University, New York, N.Y. 10027.

Respiratory movements of the operculum are produced by the adductor operculi and dilator operculi muscles. In the Siamese fighting fish, *Betta splendens*, the dilator operculi is also the effector muscle for aggressive gill-cover erection behavior. In carp (*Cyprinus carpio*), which do not perform the gill-cover erection display, the dilator operculi is exclusively a respiratory muscle whose motor neurons are located in cranial nerve motor nucleus V (trigeminal) (Luiten, J. Comp. Neurol. 1976). To see whether differences in the function of this muscle were reflected in the organization of the CNS, I used retrograde transport with HRP to identify motor neurons that innervate the dilator operculi in *Betta*.

Although neurons that innervate the dilator operculi are located in cranial nerve motor nucleus V in both carp and *Betta*, the topographical organization of the nucleus and the distribution of motor neurons within the nucleus differ in the two species. While the rostral nucleus of n.V (Vr) has distinct medial and lateral subnuclei in carp, it consists of only a medial part in *Betta*; the caudal nucleus of n.V (Vc) consists only of a medial part in carp, but has a medial subnucleus with large cells and a lateral subnucleus with smaller cells in *Betta*. Dilator operculi motor neurons in *Betta* are located in both the lateral and medial subnuclei of Vc. The medial subnucleus of Vc does not exist in carp, and all dilator operculi motor neurons are found in the lateral subnucleus of Vc in this species.

The presence of a separate Vc subnucleus in *Betta*, but not in carp, may be related to the use of the dilator operculi muscle for aggressive display behavior in *Betta*. (Supported by BNS-84-11437).

AUTORADIOGRAPHIC LOCALIZATION OF ESTROGEN-CONCENTRATING CELLS IN THE BRAIN AND PITUITARY OF THE OYSTER TOADFISH. M.L. Fine, H. Russel-Mergenthal* and D.A. Keefer*. Depts. of Biology, Virginia Commonwealth University, Richmond, VA 23284 and Loyola College, Baltimore, MD 21210.

We examined the distribution of ^{3}H estradiol concentrating neurons in gonadectomized male and female oyster toadfish (Opsanus tau) by thaw-mount autoradiography. Compared to other teleosts studied in this fashion, the toadfish is of interest because of its reliance on male sound production in courtship. Labelled cells were found in periventricular midline regions of the forebrain. These included the ventral telencephalon pars ventralis, thalamus, nucleus preopticus parvocellularis and magnocellularis, ventral hypothalamus (equivalent to the nucleus lateralis tuberis), and dorsal hypothalamus, including portions lining the lateral recess of the third ventricle in the inferior lobes. Labelled cells were also present in large areas of the pars distalis of the pituitary. In contrast to a previous study with testosterone, the brainstem and rostral spinal cord were negative for labelled cells. The distribution of estrogen-concentrating neurons conformed to the general pattern seen in other teleost fishes.

Supported by NIH MH38921 and NSF PCM8309144.

278.10

5HT DISTRIBUTION IN APTERONOTUS LEPTORHYNCHUS BRAIN AND RELATION TO MALE SOCIAL BEHAVIOR. S. Johnston, L. Maler and B. Tinner*. Dept. of Anat, U. of Ottawa, Canada K1H 8M5

We investigated the effect of 5HT agonist DMT 2mg/kg and antagonists methysergide 1.7mg/kg, citalopram and fluoxetine 0.1-5mg/kg (all IM) on the social responses of male fish under rest conditions (spontaneous chirps(sc)) and during simulated social encounters with a conspecific (evoked chirps (ec) and jamming avoidance response (JAR)). Immunohistochemical brain mapping of 5HT was undertaken with attention to the electro-sensory-motor pathway. DMT which inhibits the firing of dorsal raphe neurons increased sc and ec for 35 min. Methysergide, a 5HT receptor antagonist and fluoxetine and citalopram 5HT uptake inhibitors (0.5mg/kg and higher) significantly increased sc and ec for 2 hr. No consistent effects on JAR were evident. 5HT was located in cell bodies at the preoptic area, posterior periventricular nucleus, hypothalamus and raphe nuclei. Terminations were evident in ventral telencephalon, hypothalamus and electroreceptive areas. Specifically, there were dense terminations at the lateral inferior olive (IOl), and medium terminations at the prepacemaker nucleus. The terminations indicated a role for 5HT of modulation of the electro-sensory-motor pathway. Notable questions are: **1.** the possible electroceptive role of 5HT in reference to the dense terminations at the IOl and **2.** the neuroendocrine role of dense cells, fibers and terminations at the nucleus tuberis lateralis in relation to these social behaviors.

INTRASEXUAL DIMORPHISM IN A SOUND PRODUCING FISH: ALTERNATIVE REPRODUCTIVE MORPHS ? R. K. Brantley and A. H. Bass. Sect. Neurobiology and Behavior, Cornell University, Ithaca, NY, 14853.

Two classes of sexually mature males are found in the sound-producing ("sonic") teleost fish, the plainfin midshipman (*Porichthys notatus*). They are distinguishable by a number of traits including: (1) body length, (2) body coloration, (3) relative gonad size, (4) sonic muscle size, (5) vocalization behavior, and (6) nest occupancy during the breeding season. Nesting *Porichthys* larger than 11 cm standard length (SL) were designated "Type I" males, while those smaller than 11 cm were designated "Type II" males. Type I males have a dark, gray-olive ventral coloration, while Type II males have a female-like yellow coloration ventrally. Type II males have an average gonad to body weight ratio of 8.3% (N=21) , which is several fold larger than that of Type I males (N=23, 1.2%). There are also significant differences between the two male morphs in the size of the sound-generating "drum" muscles which are attached to the swimbladder walls. Muscles of the Type I males (N=19) are on average 62% of total bladder weight. By contrast, muscles of the Type II males (N=10) and females (N=8) average only 11% and 7.5% of total bladder weight, respectively.

Type I males produce several types of "vocalizations", unlike Type II males and females which have not been found to vocalize. Additionally, Type II males were *never* found to nest independently; instead they were *always* found in the nests of Type I males, frequently coincident with spawning females.

We suggest the smaller size class, Type II males, possessing female-like coloration and sonic muscles, but with greatly enlarged testes, pursues an alternative reproductive tactic of cuckoldry of the larger size class of mate-calling, nest and egg guarding, Type I males. Supported by NIH, NSF and Hatch Grants and a Rosenblatt Fellowship.

SEXUAL POLYMORPHISMS IN CENTRAL AND PERIPHERAL ELEMENTS OF A SONIC MOTOR SYSTEM IN A TELEOST FISH (*PORICTHYS NOTATUS*). M. Marchaterre, A.H. Bass and J. Olvarchuk*. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

In the sound-producing teleost fish, *Porichthys notatus*, there are two classes of sexually mature males: "Type I" and "Type II". Type II males resemble females in a number of morphological and behavioral traits. This sexual polymorphism extends to the level of peripheral sonic muscle fibers and central motoneurons that underlie the production of sounds. The sonic muscle fibers of Type I males differ significantly from those of Type II males and females (which resemble each other) in several ways: 1) They are 3-5 times larger and have a characteristically large volume of sarcoplasm that is densely filled with mitochondria. 2) The average Z-line length (1.2 um) of their myofibrils is 20 times greater. 3) The sarcoplasmic reticulum which lies between adjacent myofibrils is more highly branched. The mean diameter of sonic motoneurons is also significantly greater in Type I males (45um) compared to Type II males (27um) and females (30 um) which are significantly different from each other.

The peripheral and central elements of juvenile males and females are monomorphic and resemble those of adult females. Preliminary data indicate that gonadal steroid hormones (testosterone) can induce Z-line expansion in juvenile males and females and adult females; their effects on other traits of peripheral and central elements are being studied.

The distinct features of the sonic motor system in Type I males are considered adaptations related to their known role in sound production and the unique long duration "hums" generated during the breeding season. The similarity in the sonic motor system between females and Type II males, which are not known to "vocalize", are considered adaptations related to alternative reproductive tactics adopted by Type II males. Supported by NSF, NIH and Hatch Grants.

SPATIAL AND TEMPORAL INTEGRATION OF TASTE AND TACTILE INFORMATION IN THE RETICULAR FORMATION OF A TELEOST. J. S. Kanwal & T. E. Finger. Dept. of Cell. & Struct. Biology, Univ. of Colorado Sch. Med., Denver, CO 80262.

Ictalurid catfish possess an elaborate and highly sensitive extraoral taste system, innervated by the facial nerve, which enables them to search for and acquire food in the aquatic environment. Neuroanatomical and electrophysiological results obtained previously suggested the involvement of the reticular formation (RF) during the target-tracking (homing) phase of food search.

The gross organization of reticular neurons was examined by injecting horseradish peroxidase in the spinal cord. This labelled clusters of medium (20 um) and large (30 um) sized reticulospinal neurons arranged in a rostrocaudal segmental fashion. The location of a subset of these neurons coincided with the previously specified anteroposterior level of projections from the facial lobe to the RF. The existence of a facio-reticulo-spinal pathway was confirmed by electrophysiological experiments where a reticular neuron sensitive to tactile stimulation of the extraoral surface also responded to electrical stimulation of the spinal cord. Electrophysiological recordings also indicated that reticular neurons had either small (restricted to the snout region) or large bilateral receptive fields. The large receptive field units exhibited different response characteristics (inhibition versus excitation) to gustatory stimulation of the ipsi- and contralateral flank regions, respectively. In contrast to the response of the facial nerve, the activity of reticular neurons was adaptive to continuous tactile stimulation of the receptive field. Thus, reticulospinal neurons within the medullary region integrate spatial as well as temporal aspects of taste and tactile information and may accordingly modulate locomotion via spinal motoneurons.

2-DEOXYGLUCOSE ACCUMULATION FOLLOWING OPTOKINETIC STIMULATION IN THE RED-SIDED GARTER SNAKE (THAMNOPHIS SIRTALIS PARIETALIS). E.E. Allen and D. Crews, Zoology Dept., Univ. Texas, Austin, TX 78712.

In addition to using chemical cues in foraging and sexual behaviors, the Canadian red-sided garter snake (Thamnophis sirtalis parietalis) uses visual cues such as motion for orientation to relevant stimuli. As a preliminary stage in examining the functional neurology of sexual behaviors in this species, unilateral visual stimulation was combined with injection of ^{14}C-2-deoxyglucose (2DG) in order to establish the suitability of this method for delineating the extent of CNS activity. Subjects with unilateral visual blockade were injected with 2DG (0.2 uCi/g body weight) and restrained in the center of a drum patterned with alternating vertical black and white stripes (1.3 cm width). This drum was rotated about the subject for 45 - 85 minutes such that the stripe pattern moved at 7.5 cps. Drum rotation for 5 minutes was alternated with 1 minute periods during which it was stationary in order to reduce the probability of visual system habituation. Immediately after the period of stimulation the brain was removed, frozen in liquid freon-12 (-20°C), and sectioned at 20 u in a cryostat. Sections were mounted on cover slips, quickly dried, and exposed with X-ray film (Kodak SB-5) for one week. Examination of the autoradiograms revealed differential accumulation of 2DG ipsilateral to the stimulated (uncovered) eye distal to the optic chiasm in optic nerve. Proximal to the chiasm, accumulation was predominantly contralateral to visual stimulation and was greatest in optic tracts, thalamus, and superficial tectum.

Supported by NIH T32-HDO7264 and NICHD 16687.

278.15

NEURAL MECHANISMS OF SHORT-TERM MEMORY IN FROGS. D. Ingle and K. vS. Hoff*. Marine Science Center, Northeastern University, Nahant, MA 01908.

Earlier studies in our lab showed that integrity of the uncrossed tectomedullary projections is essential to the frog's ability to turn away from approaching visual threat. This generalization is complicated by a recent finding that unilateral lesions within the ventromedial tegmentum (which do not interrupt tectal efferent fibers) cause frogs to turn toward threat approaching within the opposite visual field. The lesion also causes frogs escaping from pinching the dorsum to turn toward and collide with striped barriers placed within the hemifield opposite the lesion. However, a second lesion in ventromedial tegmentum of the opposite side will immediately "cure" wrong-way turns produced initially by unilateral lesions. We hypothesize that the tegmentum plays a role in establishing "preparatory response sets" for escape routes in the frog's natural environment, but is not necessary for fleeing from an immediate threat.

In an attempt to test this idea, we devised a task in which frogs maintain (for at least 10s) a tendency to avoid an area where a barrier has recently been seen while escaping from a looming disk. Frogs with tegmental lesions are deficient in maintaining this response set, as are frogs with ablations of the striatum, although neither lesion reduces efficiency of avoiding seen barriers (see abstract by Hoff and Ingle). We propose that a system involving the frog's striatal-tegmental projections mediates this kind of memory.

278.16

FROGS HAVE SHORT-TERM MEMORY OF OBSTACLES. K. vS. Hoff* and D. J. Ingle. (SPON: J.N. Evanoff) Marine Science Center, Northeastern University, Nahant, MA 01908.

We have previously proposed that the biasing effects of tegmentum on the frog's escape routes from threat reflects a mechanism for "preparatory response set" - a kind of short-term memory (see Ingle and Hoff abstract). Here we have demonstrated the operation of such response sets using the following procedure: (1) a striped barrier is positioned near the frog, (2) the barrier is removed after 10s, and (3) after a further 10s delay in an empty arena a black disk is loomed at the frog from a constant retinotopic direction. The difference between the distributions of jump directions elicited by threat with previously seen barriers and without previously seen barriers shows that normal frogs avoid only those areas where obstacles were recently seen.

In a second test, each animal was rotated on a turntable by 45^{o} clockwise or counterclockwise after the barrier was removed. The direction of avoidance jumps elicited by the subsequent visual threat showed that frogs remembered the real-world barrier location rather than the retinotopic location of the barrier. This kind of memory is, therefore, not analagous to an eidedic image with retinotopic coordinates.

In a third experiment, a dark obstacle was set 90^{o} from the frog's midline and the threat approached from the front. In this case as well, frogs did not jump directly toward the remembered position of the object. Rather, they preferentially jumped into the rear quadrant behind the obstacle's former location, as if hiding from the threat. We propose that this robust kind of memory for obstacles and for hiding places would be useful during foraging when a frog is focussed on potential prey, but must retain some representation of the environment in order to guide rapid escape from suddenly appearing threat.

278.17

A MULTIVARIATE ANALYSIS OF PUTATIVE MEASURES OF EMOTIONALITY IN THE RAT. S.E.Maier, D.P.Crowne*& K.A.Dawson. Dept. of Psychology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

In the study of cortical specialization and its lateralization in non-human species,many different measures of emotionality have been used,often interchangeably.In a study examining the various dimensions of rodent emotionality,71 rats were given a battery of tests including exploration,timidity,fear-induced defecation, passive avoidance and reactivity to handling.The tests yielded 217 separate measures that were systematically reduced by aggregation and factor analysis within each test situation to a final set of 14.A factor analysis of these final 14 variables resulted in 4 well defined orthogonal factors identified as elimination,exploration, cautiousness and reactivity to handling. Behaviours such as defecation and exploration seem to be generalizable to different test situations,while behaviours such as cautiousness and reactivity to handling are situation specific.The emergence of 4 independent dimensions of rodent emotionality stresses the need for researchers to represent them in studies of the underlying brain substrate of emotional behaviour.

278.18

NEURAL SUBSTRATE FOR VOCALIZATION AS DETERMINED BY STIMULATION OF PAG CALL SITES WITH 2DG AND HRP METHODS. F. F. Lang* and N. C. de Lanerolle. Section of Neurosurgery, Yale University School of Medicine, New Haven, CT 06510.

In order to define the neural substrate of vocalization, electrical brain stimulation of the periaqueductal grey (PAG) for the evocation of vocalizations in the domestic cat was combined with the 2-deoxyglucose (2DG) method and horseradish peroxidase (HRP) tract tracing method.

Stimulation of the PAG yielded pure vocalizations which included growls, hisses, and long and short meows. Quantitative analysis of 2DG data showed: 1) increased metabolic activity in the PAG both around and beyond the electrode tip, 2) increased activity in the lateral and ventrolateral tegmentum extending from the PAG and continuing caudally just beyond the inferior colliculus, 3) an altered pattern of activity in the deep layer of the superior colliculus, 4) bilateral reduced activity in the facial nucleus, vestibular/cochlear nucleus, and superior olive, 5) bilateral decreased activity in the caudate, and bilateral increased activity in the visual cortex (area 17) and in a well demarcated band in cortical area 7. HRP studies with injections into ventrolateral pontine call sites demonstrated that the number of retrogradely labelled cells was highest in the PAG.

From these studies it can be concluded that a descending pathway from the PAG into the ventrolateral tegmentum may represent a common pathway of vocalization and that such a pathway may be used in human speech and emotional utterances. Further, attention mechanisms may be critical for vocalization since all of the rostral brain areas, namely the superior colliculus, caudate, visual cortex and cortical area 7, have been demonstrated to play an important role in the generation of orienting movements associated with attentional mechanisms.

278.19

ACOUSTIC DIFFERENCES IN SEPARATION CALLS OF RHESUS MONKEYS FOLLOWING NEONATAL ABLATION OF TEMPORAL LOBE LIMBIC AREAS. J.D. Newman and J. Bachevalier. Lab. of Comparative Ethology, NICHD and Lab. of Neuropsychology, NIMH, Bethesda, MD 20892.

Eight rhesus macaques receiving bilateral ablations to the amygdala or hippocampal formation in the first week of life were briefly separated from familiar conspecifics at 1 year of age in order to assess the acoustic characteristics of the species-typical isolation call ("coo"). Sound spectrograms were subjected to quantitative analysis and compared with isolation calls from 5 normal controls. Significant differences from the control group were found in the acoustic structure of the calls from animals with amygdalar ablations. The clearest difference was in the reduction of the peak frequency of the calls. Animals with hippocampal lesions exhibited less clear and more variable differences in their isolation calls. These findings support the view that the amygdala plays an important role in the development of normal affective vocal responses, and suggest for the first time that the hippocampal gyrus may be involved in the development of this aspect of nonhuman primate behavior, as well.

278.20

CYTOCHEMICAL TRACING OF CEREBRAL CONNECTIONS OF MIDLINE FRONTAL CORTEX IN SAIMIRI MONKEYS. P.D. MacLean. SCSBB/Lab. Clin. Sci., NIMH, Poolesville, MD 20837.

The separation cry ranks as a basic mammalian vocalization. Ablation of midline frontolimbic cortex entailing areas 24, 25, and 12 eliminates the spontaneous cry in squirrel monkeys (MacLean and Newman, Brain Res., in press). With focus on area 25, the present study provides a comparison of the cerebral connections of this infragenual area with those of other midline areas. Site injections of 0.2 µl of 4% WGA-HRP are made in Saimiri monkeys (survival time 72 h; TMB as chromogen).

WGA-HRP applied to area 25 results in retrograde thalamic labeling of cells in certain parts of N. ventralis anterior et lateralis; N. anterior ventralis et medialis; N. centralis medialis; N. paraventricularis; N. parataenialis; N. centralis superior lateralis; dorsal and caudal N. medialis dorsalis; N. pulvinar medialis; N. limitans; and N. parafascicularis. Elsewhere, cellular labeling appears in posterior cingulate and retrosplenial cortex; posterior parahippocampal gyrus; claustrum; and in anterior and basal nuclei of amygdala.

Together with clinical data, the thalamic findings on area 25 and neighboring midline frontal areas suggest a linkup of frontal lobe and striopallidonigral mechanisms implicated in both the affect and expression of crying and laughter. Cerebellar mechanisms are also implicated.

279.1

SOMATOTOPIC ORGANIZATION OF HINDLIMB MUSCLE AFFERENT PROJECTIONS TO THE COLUMN OF CLARKE OF THE RAT STUDIED WITH CHOLERAGENOID HORSERADISH PEROXIDASE CONJUGATE

C. Rivero-Melian and G. Grant (SPON: F, Valverde), Karolinska Institutet, Dept. of Anatomy, Stockholm, Sweden

The aim of this study has been to investigate hindlimb muscle afferent projections to the column of Clarke (CC) in the rat. The binding subunit of cholera toxin conjugated to horseradish peroxidase (B-HRP) was used for the labeling of primary afferent fibers. Injections of B-HRP were made into either the tibial, peroneal, femoral, obturator, superior gluteal nerves or into the dorsal ramus at the L1 and L2 levels. Following 2 days survival the animals were perfused with an aldehyde mixture. Frozen 60µm thick sections were cut from the upper thoracic to the lower sacral spinal cord. The sections were processed using TMB as the chromogen. In the CC, the main subject of this study, the projections from the injected nerves were somatotopically organized, even though an overlap between different nerves was found to exist. The tibial nerve projected to the medial part of the CC and the projections from the other nerves, in the order given above, were shifted toward successively more lateral parts. Furthermore, for each nerve, a lateral to medial shift in the rostral direction was seen. This study indicates that the projections from distal hindlimb muscle afferent fibers are located medial to those from proximal hindlimb muscle afferent fibers in the CC in the rat.

279.2

SOMATOTOPY OF CUTANEOUS AXONS IN CAT DORSAL HORN LAMINAE III - IV: QUALITATIVE.

P. Brown, R. Sonty*, R. Millecchia, W. Gladfelter, and J. Culberson. Anatomy and Physiology Depts., WV Univ. Med. Ctr., Morgantown, WV 26506.

Injection of HRP into identified hindlimb cutaneous axons on both sides of the spinal cord was used to analyze somatotopy of projections to laminae III and IV. Terminal fields of axons injected in the same animal always had relative positions in laminae III-IV in accord with the somatotopy of dorsal horn cells and projections of dorsal roots and cutaneous nerves, described in previous studies: The mediolateral III-IV axis mapped a distoproximal trajectory on the leg, and the rostrocaudal axis mapped a preaxial-postaxial trajectory. Axon projections were subsets of their parent cutaneous nerve projections, with shapes in the horizontal plane which varied in accord with somatotopy similar to shape variations of cutaneous nerves and dorsal roots: lateral projections from hip were long and thin, and medial projections from toes were short and fat, as expected from the shapes of the map representations. Curvatures of projections could also be accounted for by somatotopy.

Supported by NIH grants NS12061 and NS25238.

279.3

SOMATOTOPY OF CUTANEOUS AXONS IN CAT DORSAL HORN LAMINAE III - IV: QUANTITATIVE.

R. Sonty*, P. Brown, R. Millecchia, W. Gladfelter, and J. Culberson. Anatomy and Physiology Depts., WV Univ. Med. Ctr., Morgantown, WV 26506.

Terminal fields of HRP-filled hindlimb cutaneous axons in laminae III and IV were analyzed to determine precision of somatotopy. Approximately 20 receptive fields could be lined up along the length of the leg, but only 5 - 6 terminal fields could be lined up across III-IV. Similar smearing occurred in the projections of toes and glabrous pads to III-IV, and for rostrocaudal distributions of axon terminals. Good correspondence existed between the average map locations of receptive field centers for primary afferents and dorsal horn cells, and for the widths and lengths of primary afferent projections and the distributions of responding dorsal horn cells. These calculations were from averages across animals; agreement may not be as good within individual animals. Given widths and lengths of dorsal horn cell dendrites, passive sampling of the presynaptic terminals by dendrites would produce larger cell receptive fields; either more peripheral connections to dorsal horn cells are inactive or axodendritic contacts are selective.

Supported by NIH grants NS12061 and NS25238.

279.4

CUTANEOUS AFFERENT FIBER PROJECTIONS TO DEEP DORSAL HORN LAMINAE (V - VI).

J. Culberson, R. Sonty*, R. Millecchia, W. Gladfelter, and P. Brown, Anatomy and Physiology Depts., WV Univ. Med. Ctr., Morgantown, WV 26506.

Low threshold mechanoreceptor axons send collaterals to terminate, usually with well-defined spatial resolution, in laminae III-IV of the dorsal horn. Some collaterals reach deeper laminae; this study examines these with respect to afferent fiber types of origin and relationship to dorsal projections of the same axon. Deep collaterals are always a minor part of an axon's projection field. In our sample, hair afferents have occasional small inputs to lamina V, typically in mediolateral register with the dorsal projection field. Pacinian corpuscles have numerous deep endings; they are located in medial V-VI, not aligned with the dorsal field. Slowly adapting fibers generate wider deep fields, again not in exact register with dorsal projections. These data suggest that all collaterals of these mechanoreceptive afferents are not necessarily aligned in the dorsoventral axis; precision of alignment appears to vary with afferent fiber type.

Supported by NIH grants NS12061 and NS25238.

279.5

ORIGIN OF S-7B8 IMMUNOREACTIVITY IN THE SPINAL CORD.

S.S.Kanekar, T.C.Ritchie and J.D.Coulter, Neuroscience Program and Department of Anatomy, The University of Iowa, Iowa City, Iowa 52242.

The S-7B8 monoclonal antibody binds to an integral membrane protein in selected nerve terminals in the CNS. In the spinal cord, S-7B8 immunoreactivity is concentrated in laminae I and IIi of the dorsal horn. Less dense staining extends into lamina V and sparse staining is present in the ventral horn. Most of the S-7B8 immunoreactivity in the dorsal horn arises from primary afferent nerve terminals. However, descending projections also give rise to S-7B8 immuno-staining in the spinal cord. Double-labelling studies employing retrograde tracers indicate that neurons of origin of the corticospinal, rubrospinal, vestibulospinal and reticulospinal tracts contain the S-7B8 antigen. Also, thoracic spinal transections result in accumulation of the S-7B8 antigen in axons rostral to lesions, in the corticospinal tract and in the lateral and ventral spinal funiculi, indicating that axonal transport of the S-7B8 antigen occurs in spinal descending systems. Studies are in progress to identify the neurotransmitter content of the neurons of origin of spinal cord S-7B8 immunoreactivity. Supported by NIH grant NS23783.

279.6

A MONOCLONAL ANTIBODY THAT IDENTIFIES LARGE DIAMETER PRIMARY AFFERENTS IN THE SPINAL CORD.

K. A. Martin and S. Hockfield. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

One aim of our laboratory has been to generate reagents that identify specific neurons and pathways. We have generated a monoclonal antibody (Rat-102) which identifies large diameter primary afferents. Rat-102 identifies a cytoplasmic protein of 200 kd in apparent molecular weight. Rat-102 -labeled axons include the Ia and Ib primary afferents which are seen to ramify extensively and distribute terminals in laminae VII through IX, including a dense arborization in Clarke's column. Antibody staining completely excludes the substantia gelatinosa. Rat-102 identifies primary afferent axons throughout both their central and peripheral processes. In normal rats the antibody does not label cell bodies in the dorsal root ganglia (DRG). However, blocking transport of the antigen recognized by Rat-102 by siatic nerve ligation has allowed us to visualize DRG cell bodies labeled with the antibody. To determine the contribution of primary afferents to labeling in the spinal cord, we have performed chronic dorsal rhizotomies. The reduction of Rat-102 in target regions of lesioned dorsal root axons suggests that the majority, if not all, the Rat-102 staining derives from primary afferents.

We have also studied Rat-102 staining during development in the rat. Rat-102 identifies primary afferents very early in development. Antibody positive axons can be seen in the dorsal root by embryonic day 12. Examination of rat DRG neurons in culture has confirmed that the DRG is a source of the early detected Rat-102 antigen.

CHANGES IN SPINAL CORD PEPTIDERGIC NEURONAL NUMBERS FOLLOWING PERIPHERAL NERVE LESIONS

J.D. Leah*, T. Herdegen* & M. Zimmermann
II Physiol. Inst., U. Heidelberg, Germany.

To determine whether there are changes in peptidergic neurones in the spinal cord following peripheral nerve damage the sciatic nerve was ligated and cut distally in 6 anaesthetised rats. After three weeks colchicine was administered to the lumbar cord. After 48 hr the animals were perfused, 50 µmsections of L4-L5 cord immunocytochemically processed and examined for the numbers of DYN, ENK, SOM, NPY, NT, VIP and GAL neurones. There was an increase in the numbers of all types of peptidergic neurones except NPY on the side of the spinal cord with the sciatic nerve lesioned. Different peptidergic neurones showed differing increases, which depended on the neurones location. The most marked (50-120%) were for DYN, ENK, NT and VIP. SS and GAL showed smaller (~20%) increases. Sciatic nerve section thus produces alterations in the numbers of several types of spinal peptidergic neurones. It may be part of a generalized one where the numbers of most peptidergic neurones are altered following perturbations to sensory nerves, mediating the long-term changes in spinal physiology seen following peripheral trauma.

GLUTAMATE DEHYDROGENASE IMMUNOREACTIVITY IN THE RAT SPINAL CORD AND DORSAL ROOT GANGLIA.

K.E. Miller, J.A. Bigness, J.E. Madl, and A.A. Larson. Dept. Neurol. Surgery, Univ. Miami, Miami, FL 33136 and Dept. Vet. Biol., Univ. Minn., St. Paul, MN 55108.

Glutamate dehydrogenase (GDH) is an enzyme involved in glutamate metabolism. Because of the role glutamate plays in spinal synaptic mechanisms, the distribution of glutamate dehydrogenase was examined with immunohistochemistry in the rat spinal cord and dorsal root ganglion (DRG). Male rats were anesthetized and perfused transcardially with a 2% glutaraldehyde, 0.2% picric acid solution. Spinal cords and DRG's were removed, frozen or vibratome sectioned and processed for GDH-immunoreactivity (IR) by the avidin-biotin peroxidase procedure. With light microscopy, no GDH-IR was observed in the DRG's. In the spinal cord, small immunoreactive puncta were observed throughout the white and gray matter. The heaviest GDH-IR occurred in laminae I-II of the dorsal horn. With electron microscopy in dorsal horn, GDH-IR was located within mitochondria. Most immunoreactive mitochondria were located in astrocytes that contacted terminals containig large dense core vesicles and/or small clear vesicles. Many terminals were glomerular in morphology, indicative of primary afferent terminations. Occasionally, glomerular terminals contained GDH-immunoreactive mitochondria. These results support the hypothesis that glutamate dehydrogenase may play a role in the metabolism of neurotransmitter glutamate.

SEROTONIN FIBERS APPOSE ENKEPHALIN- and NEUROTENSIN-IMMUNOREACTIVE NEURONS IN THE RAT SPINAL CORD.

A.T. SALVATIERRA and K.E. MILLER. Dept. Neurological Surgery, University of Miami, Miami, FL 33136.

Recent studies have shown immunohistochemical localization of enkephalin (ENK) and neurotensin (NRT) immunoreactive (IR) cell bodies in the sixth lumbar (L6) and first sacral (S1) spinal cord segments in the rat. Other studies have shown brainstem nuclei giving rise to descending serotonergic (5HT) projections to the spinal cord. The extent and density of 5HT innervation is prominent in areas overlapping the locations of ENK and NRT neurons, namely marginal zone, substantia gelatinosa, nucleus proprius, and dorsal gray commissure. The present study examines the close apposition of 5HT fibers with ENK- and NRT-IR cells in the lumbosacral region of the rat spinal cord.

Male Sprague-Dawley rats, weighing 250-300 g, were anesthetized and intrathecal cannulae were introduced to the level of L5-L6. Colchicine (2.5 mg/ml, 10 ul volume) was administered through the cannulae at 0 and 24 hours after cannulation. After 48 hours animals were perfused with buffered paraformaldehyde and the segments of the spinal cord that corresponded with the cannulae tip were dissected. Cryostat sections were cut at 10 um and processed for simultaneous double immunofluorescence. Examination of lumbosacral segments indicated 5HT-IR fibers in close apposition to ENK and NRT immunofluorescent cells. Many of these cells were found in the substantia gelatinosa layer of the dorsal horn and in the dorsal gray commissure. A few cells were also found in the marginal zone and intermediate gray. These results further implicate serotonin as a modulator of nociceptive sensory input via interaction with enkephalin and neurotensin neurons in the spinal cord.

IMMUNOHISTOCHEMICAL DEMONSTRATION OF CALCITONIN GENE-RELATED PEPTIDE AXONS CONTACTING DYNORPHIN A 1-8 DORSAL HORN NEURONS IN A RAT MODEL OF PERIPHERAL INFLAMMATION AND HYPERALGESIA.

O. Takahashi, R.J. Traub and M.A. Ruda. NAB, NIDR, NIH, Bethesda, MD 20892.

Spinal cord dynorphin peptide (DYN) and preprodynorphin m-RNA have been shown to increase following unilateral experimental acute inflammation. Calcitonin gene-related peptide (CGRP) in the spinal dorsal horn likely originates exclusively from small diameter primary afferents and may play a role in the processing of nociceptive information. This study examines potential interactions between DYN-like immunoreactive (DYN-LI) neurons which demonstrate an upregulation in response to acute inflammation and hyperalgesia, and small diameter CGRP-like immunoreactive (CGRP-LI) primary afferent axons.

Inflammation of one hindpaw in 11 male rats was induced by injection of 150 µl complete Freund's adjuvant/saline (1:1; s.c.). Three or four days later, the animals received an intrathecal injection of colchicine and 24 hours later were perfused with 4% paraformaldehyde. The lumbar spinal cord was cut into 24 µm transverse or parasaggital cryostat sections and processed for two-color PAP immunocytochemistry using first an antiserum to human CGRP (black chromogen) and second, an antiserum to DYN A 1-8 (brown chromogen).

CGRP-LI labeled varicosities were observed contacting approximately half of the DYN neurons in laminae I, II and V of the dorsal horn. The contacts were located on both the cell soma and proximal dendrites and typically numbered greater than 25 per cell. DYN-LI neurons in other laminae rarely received CGRP-LI contacts.

These observation suggest that there are direct contacts between presumptive nociceptive small diameter primary afferents and opioid neurons which exhibit an upregulation of DYN as a result of peripheral inflammation and hyperalgesia.

279.11

THE PROJECTION OF SMALL DIAMETER PRIMARY AFFERENTS CONTAINING CALCITONIN GENE-RELATED PEPTIDE-LIKE IMMUNOREACTIVITY IN THE CAT LUMBOSACRAL SPINAL CORD: A LIGHT AND ELECTRON MICROSCOPIC ANALYSIS.

R.J. Traub, A. Solodkin* and M.A. Ruda. NAB, NIDR, NIH, Bethesda, MD 20892.

Previous studies have shown that some small diameter primary afferents project the length of the lumbosacral enlargement in Lissauer's tract (LT). Additionally, it has been reported that a subpopulation of small diameter primary afferents contain calcitonin gene-related peptide-like immunoreactivity (CGRP-LI). We examined the projection of CGRP-like immunoreactive (CGRP-IR) axons in the lumbosacral spinal cord following dorsal rhizotomies.

Unilateral dorsal rhizotomies were performed on 5 consecutive dorsal roots (L4-S1 or L5-S2) under sterile surgical conditions in 5 cats. In order to eliminate caudal projections, an ipsilateral hemisection was made in the most rostral rhizotomized segment in 2 cats. Two weeks later the animals were sacrificed and sections from segments L2-S3 were treated immunocytochemically for CGRP-LI using standard PAP methodology.

CGRP-LI was greatly reduced in all rhizotomized segments compared to the intact contralateral side. The hemisections did not appreciably alter the location or density of the CGRP-LI in the ipsilateral segments. Most of the remaining CGRP-LI was observed in LT, the dorsal surface of the dorsal columns, and the lateral part of laminae I, IIo, and V. A few CGRP-IR axons were also observed in medial laminae I, IIo, and the central canal region. At the electron microscopic level, unmyelinated CGRP-IR axons were observed in LT throughout the length of the rhizotomized region. In laminae I and V, CGRP-IR varicosities containing oval agranular vesicles and a few dense core vesicles were observed to form asymmetrical synaptic contacts on unlabeled dendrites.

These results demonstrate CGRP-IR axons and synaptic terminals 4-5 segments rostral to the closest ipsilateral intact dorsal root. Ascending branches of small diameter primary afferents originating in these distal intact dorsal roots are the most likely source of the CGRP-LI.

279.12

EFFECTS OF CAPSAICIN ON SPINAL CORD AXONS THAT COLOCALIZE SUBSTANCE P AND CALCITONIN GENE-RELATED PEPTIDE.

Solodkin, A.* & M.A. Ruda. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Previous studies have shown a time-dependent return of thermal sensitivity and partial recovery of spinal calcitonin gene-related peptide (CGRP) after neonatal capsaicin (CAP) treatment. Recovery of primary afferent substance P (SP) could not be determined since spinal SP originates from several sources. However, CGRP in the dorsal horn likely originates exclusively from small diameter primary afferent axons and can be utilized to mark them. This study used the colocalization of immunoreactive SP and CGRP (SP-IR/CGRP-IR) to examine the effect of neonatal CAP on SP primary afferent axons.

Two day old rats were treated with CAP (50 mg/kg; sc) or vehicle. At 10 days and 3, 4, 6, 8, 12 & 16 weeks, animals were perfused with 4% paraformaldehyde. Transverse and sagittal 18 µm cryostat sections of spinal cord were processed for species-specific double immunofluorescence staining using rat monoclonal antiserum to SP and rabbit polyclonal antiserum to CGRP.

At 10 days, few SP-IR/CGRP-IR axons remained in Lissauer's tract (LT), and laminae I, II and V compared to controls. No SP-IR/CGRP-IR axons were visible in the lamina X ependymal bundle. At 6-8 weeks, the density of SP-IR/CGRP-IR axons was similar to that at 10 days. However, traversing laminae III and IV, there was a reappearance of some CGRP-IR axons which did not colocalize SP-IR. Most of these were of the non-varicose type. At 12-16 weeks, more SP-IR/CGRP-IR axons in LT and laminae I and II were apparent in CAP animals than were observed at earlier time points, although laminae V and X were still depleted.

These data suggest that neonatal CAP treatment significantly depletes primary afferent SP but does not destroy all SP primary afferent axons in either the superficial or deep dorsal horn laminae. Also, there appears to be a partial return of SP primary afferents more than two months after CAP treatment.

279.13

SPONTANEOUS ACTIVITY OF CAT DORSAL ROOT GANGLION NEURONS. M.J. Hoffert, G.W. Lu, and V.Miletic. Spalding Hospital, Denver, CO 80218, and University of Wisconsin, Madison, WI 53706.

The intraganglionic portion of dorsal root ganglion (DRG) cells is not silent under pathologic conditions. This study investigated the characteristics of the spontaneous discharges of DRG neurons under both normal and abnormal situations.

Spontaneous discharges were recorded from 50 of 130 sampled neurons in the L5-S1 ganglia of anesthetized cats. The spontaneous activity occurred in animals in which: (1) the preparation was left intact, (2) both dorsal and ventral roots were cut, and (3) ventral roots were cut and dorsal roots were locally anesthetized. Of the spontaneously active units, 40 discharged without intentional stimulation of their peripheral or central branches, or their receptive field. In the remaining 10 neurons spontaneous discharges were stimulus-related. In 1/5 of the spontaneously active neurons no collision of orthodromic and antidromic activity could be attained, although such collision was easily achieved in the remaining 4/5.

These results indicate that DRG neurons possess the ability to spontaneously discharge under both normal and abnormal conditions. It is possible that at least some of this activity is due to the presence of active synaptic and/or other types of junctional linkages within the DRG.

279.14

EPSP-LIKE ACTIVITY RECORDED FROM CAT DORSAL ROOT GANGLION NEURONS. V. Miletic and G.W. Lu. Depts. of Comp. Biosci. and Neurology, Univ. of Wisconsin, Madison, WI 53706.

The frequency dependence of dorsal root ganglion (DRG) neurons suggests the presence of synaptic and/or other types of junctional contacts in the DRG. This study investigated the existence of potentials that might be generated from the activation of these postulated contacts.

Intracellular recordings were made from 70 neurons in the L5-S1 spinal ganglia of anesthetized cats. The ganglia had their dorsal and ventral roots sectioned. Two types of action potentials were observed. In 56 of the sampled neurons, action potentials exhibited sharp rise-times and the absence of detectable prepotentials. In 14 neurons, however, individual spikes showed distinct EPSP-like components, variable latencies, inflections on their rising and/or falling phase, and a poor ability to follow electrical stimulation even at frequencies of 1-2Hz. These two very different spikes were recorded even in cases in which a single neuron was activated from both the dorsal root and the sciatic nerve.

These results demonstrate the occurrence of EPSP-like activity in DRG neurons, and imply the presence of synaptic and/or other types of junctional contacts in the DRG.

279.15

FREQUENCY DEPENDENCE OF EVOKED ACTIVITY IN CAT DORSAL ROOT GANGLION NEURONS. G.W. Lu and V. Miletic. Depts. of Neurology and Comp. Biosci., Univ. of Wisconsin, Madison, WI 53706.

The intraganglionic portion of dorsal root ganglion (DRG) neurons might play an important role in primary afferent impulse propagation. This study systematically investigated the responses of DRG neurons to repetitive electrical stimulation of their central and peripheral processes.

Extra- and intracellular recordings were made from 50 neurons in L5-S1 ganglia of anesthetized cats while the sciatic nerve and relevant dorsal root were stimulated at different frequencies. Twenty of the sampled neurons were able to follow stimulus frequencies of 100-300Hz, and an identical number could follow frequencies of 5-25Hz. The remaining 10 DRG units exhibited jitter in their response latency and an inability to follow even very low (1-2Hz) frequencies. As frequency of stimulation would increase, the shape and size of the action potential of these units would degrade into its IS and/or M components. The ability to follow high frequency stimulation decreased in the order of M > IS > S.

These results indicate that somata of DRG neurons are highly susceptible to high frequency volleys, and imply the possible involvement of synaptic and/or other types of junctional contacts in the DRG.

279.16

RAT DORSAL ROOT GANGLION (DRG) CELLS DIFFER ACCORDING TO THEIR PERIPHERAL RECEPTOR. A.M. Ritter* and L.M. Mendell Dept. Neurobiol. and Beh., SUNY, Stony Brook, NY, 11794

To establish the generality of previous findings in cat that DRG somal spikes[1] and functional central projections[2] differ according to peripheral receptor type, intracellular recordings were made in DRG cells of anesthetized female Sprague Dawley rats aged 5-8 weeks. An inverse correlation was noted between baseline AP duration and peripheral fiber conduction velocity (PFCV). However, within each PFCV group, high threshold mechanoreceptors (HTMRs) had broader spikes than low threshold mechanoreceptors (LTMRs) due to an inflection on the falling phase of their AP, observed in no LTMR. AP amplitude was larger in HTMR somata than in LTMRs, independent of PFCV. Afterhyperpolarization (AHP) of HTMRs tended to be of long duration, but a few LTMRs also had long AHPs. The second of 2 cord dorsum potentials (CDP) evoked by paired stimulation (50 ms ISI) of single HTMRs was facilitated; LTMR CDPs facilitated to a small extent or depressed. The CDP evoked by the second of 2 shocks to rapidly-adapting units depressed more than the response to paired stimulation of slowly-adapting units. These results, similar to those reported in the cat[1,2], suggest that the rat, which offers technical advantages for pharmacological studies, can be used to extend results obtained in the cat.

EFFECT OF ERGOTAMINE ON SPINAL CORD PROCESSING OF SENSORY INFORMATION FROM THE CRANIAL VASCULATURE. G.A.Lambert*, A.S.Zagami* and J.W.Lance* (SPON: B.Walmsley) Dept. of Medicine, University of New South Wales, NSW, 2031. Australia

Electrical stimulation of cranial blood vessels activates neurons in the trigeminal nucleus and upper spinal cord, an effect which can be blocked by peripheral administration of the antimigraine drugs ergotamine and DHE. In these experiments we have examined whether the site of action is at the spinal or, (as suggested by Saito et al; Neurosci. Abstr. 13,1669) in the periphery. Cats anesthetised with chloralose/urethane were used. A length of the dura and falx containing the sagittal sinus (SS) was isolated, placed on platinum hook electrodes and stimulated with supra-maximal shocks (40-120V, 250 usec, 1 per 5 sec). Multi-barrelled glass/tungsten electrodes were used to record single unit activity and to apply drugs. Electrical or chemical (bradykinin) stimulation of the SS evoked field potentials and activation of single neural elements in the C2 spinal cord. These responses were blocked by application of xylocaine to the sinus, demonstrating that they arose from direct stimulation of SS. Responsive units were accelerated by the iontophoretic application of homocysteic acid, and were therefore probably cell bodies, rather than fibers. IV injection of ergotamine and DHE (4 and 40 ug/kg) reduced or abolished the responses to electrical stimulation. Iontophoretic application of DHE (10 to 30 nA) to responsive units reversibly blocked the responses, but local application of DHE or ergotamine solutions (1 mg/ml) to SS did not. We conclude that the effects of ergotamine and DHE are primarily at the central and not the peripheral ends of the trigeminal nerve.

279.18

STIMULATION OF THE SUPERIOR SAGITTAL SINUS INCREASES LOCAL GLUCOSE UTILIZATION IN THE DORSOLATERAL AREA OF THE CERVICAL SPINAL CORD OF THE CAT *P.J. Goadsby, A.S. Zagami* and G.A. Lambert** Department of Neurology, The Prince Henry Hospital, and School of Medicine, University of New South Wales, Sydney, Australia.

The pain of migraine and other vascular headache involves regions innervated by the trigeminal and cervical sensory systems and is usually accompanied by changes in cerebral blood flow (Lance, J.W. et al., *Headache*, 23:258,1983). In this series of experiments a pain sensitive intracranial vascular structure was stimulated electrically and local glucose utilization (lCGU) measured in the cervical cord.

Cats were anesthetised with α-chloralose (60mgkg^{-1}) and prepared for monitoring. The animals were paralysed and ventilated with continuous observation of blood pressure, core temperature, FI_{O2}% and end-expiratory CO_2. The superior sagittal sinus (SSS) was stimulated with platinum hook electrodes that delivered stimulus-isolated single shocks (40-120 V ≡ 500 μA - 1.5 mA, 250 μsec duration) and lCGU was determined using [^{14}C]-2-deoxy-D-glucose, tissue autoradiography and computerised densitometry.

Metabolic activity (lCGU) in the dorsolateral (DLA) cervical cord at the C_1 level was 8.5 μmol/100g/min in control and 8.0 μmol/100g/min in stimulated animals. It was, however, significantly increased to 108 μmol/100g/min in the DLA of the C_2 level of the cord in stimulated but unchanged in the corresponding area in unstimulated animals (11 μmol/100g/min). The activation of a discrete area of the DLA of the C_2 cervical cord corresponds with single cell activity that is linked to SSS activation that we have previously reported (Lambert et al., *Soc. Neurosci. Abstr.* 13:115,1987). These results suggest that there may be a region in the upper cervical cord of the cat more caudal than that of the classical spinal trigeminal nucleus that mediates head pain in conditions such as migraine and cluster headache.

CAPSAICIN RELEASES PURINES FROM PRIMARY AFFERENT NERVE TERMINALS IN THE SPINAL CORD. J. Sawynok, T.D. White and M.I.Sweeney. Dept. of Pharmacology, Dalhousie Univ., Halifax, Nova Scotia, Canada. B3H 4H7.

Morphine and K^+ release adenosine, while serotonin releases a nucleotide, from capsaicin-sensitive primary afferent terminals in the spinal cord. Capsaicin depolarizes specific primary afferent neurons and releases peptides such as substance P. The purpose of the present study was to determine whether capsaicin releases purines from primary afferent nerve terminals in the spinal cord. Release of adenosine and ATP by capsaicin from rat spinal cord synaptosomes was determined by HPLC of etheno-adenosine (JPET 243:657, 1987) or by the firefly luciferin-luciferase assay (J.Neurochem.30:329, 1978), respectively. In some cases, rats were pretreated with capsaicin either as neonates or adults and used in release studies 17-20 weeks or 1 week later, respectively. Capsaicin (1-100 μM) produced a dose- and Ca^{2+}-dependent increase in the release of endogenous adenosine from dorsal, but not ventral, spinal cord synaptosomes which was reduced by both methods of capsaicin pretreatment and inhibition of ecto-5'-nucleotidase. Release of endogenous ATP from dorsal spinal cord synaptosomes was observed with the highest concentrations of capsaicin. These results indicate that purines in primary afferent nerve terminals in the spinal cord are released by depolarization with capsaicin. (Supported by MRC of Canada)

USE OF A RAT SPINAL CORD SLICE-DORSAL ROOT GANGLION IN VITRO PREPARATION TO STUDY SYNAPTIC TRANSMISSION. S. Jeftinija. Dept. Vet. Anatomy, Iowa State University, Ames, IA 50011.

To study the transfer of information from the sensory neuron to the dorsal horn (DH) neuron, a horizontal spinal cord slice (400-500um thick) and the functionally connected dorsal root with the dorsal root ganglion (DRG) were prepared from 18-28 day old rats. Conventional intracellular recording from DH and DRG neurons using 3M K-acetate-filled electrodes was employed. Dorsal roots were electrically isolated from the spinal cord and stimulated with pulses of different intensity and duration to evoke afferent volleys monitored intracellularly from DRG neurons. Results are based on the recordings from 55 DH neurons located in the three most superficial laminae of the spinal DH. Low intensity stimulation of the DR elicited excitatory post-synaptic potentials (e.p.s.p.) in all of the DH neurons tested. In 24% of the neurons this initial e.p.s.p. was followed by a hyperpolarizing potential. High intensity stimulation of the DR sufficient to activate small DRG neurons resulted in a large and more complex e.p.s.p. Thus, the initial burst of action potentials was followed by a prolonged depolarization with (27% of neurons) or without (49% of neurons) subsequent firing of action potentials. Neurons that were hyperpolarized in response to the low intensity stimulus maintained the same response to the high intensity stimulus, but with increase in the amplitude and duration. Supported by DHHS/NIH and USDA.

EFFECTS OF KYNURENIC ACID ON ACTIVATION OF DORSAL HORN NEURONS BY NATURAL STIMULI *IN VITRO*. S.P. Schneider and E.R. Perl. Department of Physiology, Univ. of N. Carolina, Chapel Hill, NC 27514

An *in vitro* preparation of mammalian spinal cord and a patch of skin with intact intervening innervation has been used to study synaptic transmission between identified primary afferent units and the spinal neurons upon which they synapse.

Neurons were synaptically excited by electrical volleys in a cutaneous nerve and by a variety of mechanical stimuli applied to the skin surface.

Kynurenic acid (KYN; 1 mM) reversibly blocked the synaptic activation and responses to cutaneous stimuli for 6 of 8 of the neurons excited selectively by Aδ fibers from high threshold mechanoreceptors (nociceptors) and for 7 of 9 of the neurons excited by field-type afferents. KYN was much less effective in antagonizing the responses to skin manipulation and nerve volleys of neurons excited by tactile Type II (0/3) and hair afferent sense organs (1/3).

These results suggest that at least two functional classes of myelinated, cutaneous afferent fibers, high threshold mechanoreceptors and field receptors, utilize a glutamate-like amino acid to excite second order cells and that Type II and hair receptors appear to use an excitatory transmitter that is not blocked by KYN.

SUBLIMINAL FRINGES AND THE PLASTICITY OF DORSAL HORN NEURONS' RECEPTIVE FIELD PROPERTIES. C.J. Woolf* and A.E. King* (SPON:ENA) Dept. of Anatomy, University College London, London WC1E 6BT, UK.

Because of their large polysynaptic input, the size of the cutaneous receptive fields of dorsal horn neurones is not related in a direct way to their dendritic spread (Woolf, C.J. & King, A.E. J. Neurophysiol., 58: 105, 1987). Brief C-afferent fibre conditioning stimuli can in fact produce increases both in the size and in the responsiveness of these neurons' receptive fields (Cook, A.J., Woolf, C.J., Wall, P.D. & McMahon, S.B., Nature 325: 151, 1987). We have now investigated the contribution of subliminal zones in determining the capacity of dorsal horn neurons to dynamically alter their response properties.

Intracellular recordings have been made from deep dorsal horn neurons with cutaneous mechanoreceptive fields in decerebrate-spinal rats. Mechanical stimulation of the centre of the receptive field generated both supra and subthreshold excitatory responses. As stimuli are applied more peripherally the subthreshold responses predominate. Application of the chemical irritant mustard oil to the skin results in the firing zone of the receptive field expanding to incorporate and often extend beyond the preconditioning subliminal zone. The subliminal fringe of dorsal horn neurons enables small changes in synaptic efficacy or excitability to generate a considerable plasticity of receptive field properties.

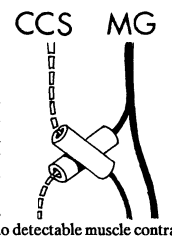
279.23

COMPARISON OF SPINAL CORD POTENTIALS ELICITED BY CUTANEOUS VERSUS MIXED NERVE STIMULATION IN HUMANS. A. Beric, J. Halter. Division of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, TX 77030.

We have been interested in the characteristics of spinal cord evoked potentials elicited by different types of peripheral input, in particular the differences between cutaneous and mixed nerve. Similar to animal studies, two major post-synaptic events can be recorded. In humans the generators of the initial negative potential followed by lower amplitude longer duration positivity have yet to be confirmed. We recorded spinal cord potentials from percutaneously introduced 4-contact epidural electrodes placed over the conus medullaris region after stimulation of the tibial or sural nerve at the ankle. These electrodes were being used for the evaluation of the effectiveness of spinal cord stimulation on pain and spasticity in two incomplete cervical spinal cord injury patients. The positive potential was of very low amplitude or absent during stimulation of the sural (cutaneous) nerve compared to the tibial (mixed) nerve resulting in a higher value of the negative versus positive potential ratio (N/P). These observations suggest differences in the generators of these spinal cord potentials.

279.24

PROPERTIES OF NEURONS CROSS-INNERVATED IN SENSORY AND MOTOR NERVES. H. Nishimura*, D. Mosier, G. Sypert and J. Munson. Univ of FL Coll of Med, Gainesville FL 32610.



We are interested in the ability of foreign targets to sustain or alter the properties of peripheral neurons. In cats, the caudal cutaneous sural (CCS: commonly "sural") and half of the MG muscle nerve were cut. The proximal portion of cut MG was cross-connected (x-conn) with the distal portion of CCS. Proximal CCS was x-conn with the distal portion of cut MG. Properties of cross-innervated (x-inn) sensory and motor neurons were tested 1 year later. MG motoneurons (Mns) x-inn into the CCS nerve had electrical properties (I_{rh}, CV, R_N) intermediate between those of normal and those of axotomized MG Mns (Foehring et al. JNp 55), but their stimulation produced no detectable muscle contraction. Stimulation of MG muscle afferents, x-inn into CCS nerve, gave EPSPs of normal configuration in uncrossed MG Mns, as did uncrossed MG afferents in crossed MG Mns. Stimulation of CCS afferents, x-inn into the distal MG nerve, gave PSP complexes with normal EPSP/IPSP configuration (Burke et al. JNp 39), but of reduced amplitude (mV ms), in both crossed and uncrossed MG Mns, as did stimulation of the presumably unaltered lateral cutaneous sural nerve.

This suggests: 1) intra-spinal connections of sensory nerves were not respecified following cross-innervation in peripheral nerves; 2) normal motor and sensory nerve functions were at least partly sustained following such cross-innervation.

CENTER-PERIPHERY RELATIONSHIPS OF SINGLE FIBERS AFTER REGENERATION OF TRANSECTED PERIPHERAL NERVES. H.R. Koerber, A.W. Seymour* and L.M. Mendell. Dept. of Neurobiology & Behavior, SUNY, Stony Brook, NY, 11794.

Individual neurons projecting through regenerated tibial nerves were impaled in the dorsal columns (HRP (15%) filled electrodes) or the L7 DRG (3M KCl) in chloralose anesthetized cats. After establishing its receptive field (RF) the single afferent was stimulated while simultaneously recording the cord dorsum potentials (CDPs) at 4 locations. HRP was then injected into selected fibers. Afferents were studied at various intervals after transection (3, 8-14 months). Unlike fibers in intact nerves, many fibers conducting centrally with cutaneous RFs produced no CDP whereas others with muscle RFs did. This, combined with the finding that many such afferents evoked CDPs in spinal cord regions out of register with their RF location, suggests that afferents failed to reinnervate the correct target. CDPs whose properties and distributions were consistent with the peripheral target (location & modality) were largest. Otherwise CDPs from the regenerated fibers were smaller than those from intact ones. Fibers with no RF could evoke CDPs but the number of such fibers as well as this ability decreased with time. Anatomical results confirmed that some fibers had reinnervated the wrong peripheral receptors, e.g., a) a group Ia fiber (C.V. = 88 m/s; boutons in laminae VI, VII & IX) innervating a slowly adapting cutaneous receptor; b) a nociceptive afferent (boutons in laminae II & V) innervating a rapidly adapting, low threshold cutaneous receptor. SIGNIFICANT TONIC SEROTONERGIC INHIBITION OF SOME SPINAL DORSAL HORN NEURONS EXISTS IN INTACT, AWAKE, DRUG-FREE CATS. Y. Saito,* J.G. Collins, H. Iwasaki.* Dept. of Anesthesiology, Yale Univ. School of Medicine, New Haven, CT 06510

The presence of descending modulation of spinal dorsal horn neuronal activity has been well established in many acute preparations. Information about the influence and pharmacology of tonic systems in intact preparations has been lacking. The systemic administration of methysergide to intact, awake, drug-free cats while recording from single spinal dorsal horn neurons has provided evidence of significant tonic serotonergic modulation of stimulus response functions of some neurons. Methysergide (0.05-2.0 mg/kg) may produce a dose dependent increase in the area of the receptive field activated by non-noxious stimuli, an enhanced response to noxious pinch and heat, and an increased correspondence between stimulus intensity and neuronal firing frequency. These data demonstrate that some spinal dorsal horn neurons have their stimulus response functions significantly modulated by serotonergic systems. This modulation may provide a mechanism to open additional channels of spinal sensory transmission.

IN VIVO INTRACELLULAR INVESTIGATION OF THE VIBRATON-INDUCED DEPRESSION OF NOCICEPTIVE DORSAL HORN NEURONES IN THE CAT SPINAL CORD. Y. De Koninck and J.L. Henry. Depts. Physiol. and Anæsthesia Res., McGill Univ., Montréal, Qué. Canada, H3G 1Y6.

In a previous extracellular study, we described an adenosine mediated vibration-induced depression of nociceptive dorsal horn neurones (Salter & Henry, *Neurosci.*, 22:631,1987). To further investigate the mechanism of this depression, we undertook intracellular recording from dorsal horn neurones. Cats were anæsthetised with α-chloralose, paralysed and artificially ventilated. Glass microelectrodes were prepared from single capillary tubes (filled with K-acetate; resistances of 20-50 MΩ in saline) and, in some cases, combined with an extracellular iontophoretic electrode. A feed back controlled mechanical stimulator was used to apply a vibration to the glabrous skin of the receptive field. Vibration induced a reversible hyperpolarization of the membrane potential (10mV; slowly decaying over 2-3s) associated with a decrease in membrane resistance. It was also possible to abolish this IPSP by hyperpolarizing the membrane potential. Thus, the results implicate a direct postsynaptic component in the vibration-induced depression of dorsal horn neurones in the cat spinal cord. DYNAMICS OF, AND INFLUENCE OF WHOLE BODY SINUSOIDAL TILT ON, NECK MUSCLE SPINDLE ACTIVITY IN THE DECEREBRATE, UNPARALYZED CAT. J. Kasper, B.J. Yates and V.J. Wilson. The Rockefeller University, N.Y., NY 10021.

We recorded the activity of presumed neck muscle spindle afferents from the C2 ganglion of decerebrate, unparalyzed cats. In contrast to findings in paralyzed preparations (Chan et al., J. Neurophysiol. 57: 1716, 1987), few afferents show high gain, non-linear responses to muscle stretch during neck rotation (body rotation on a fixed head): 2/16 vs. 24/51. This may be because of static fusimotor tone. In view of previous suggestions that the vestibular system acts on neck spindles via fusimotor neurons (Ezure et al., J. Neurophysiol. 41: 459, 1978) we tested the effect of sinusoidal whole body tilt in vertical planes on spindle activity. Wobble stimuli at 0.05 and 0.5 Hz, with amplitudes of 5 and 10 deg., were typically used. Firing of only a few afferents was weakly modulated by these stimuli, and similar modulation could be observed in labyrinthectomized animals. These results suggest that during moderate amplitude, passive, vertical head movements, the vestibular system exerts little or no effect on neck spindle activity. EFFERENT PROJECTIONS TO RAT SPINAL CORD FROM TRIGEMINAL NUCLEUS ORALIS UTILIZING THE METHOD OF PHA-L. L. A. Smith*, W. M. Falls and J. I. McMillan*, Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

Rat trigeminal nucleus oralis (Vo) contains ventrolateral (VL), dorsomedial (DM), and border zone (BZ) subdivisions. Utilizing retrograde and anterograde techniques efferent projections from all three subdivisions terminate in cranial nerve nuclei. In addition, projections from VL terminate in the medullary dorsal horn while DM and BZ innervate the cerebellum. In this study the anterograde transport of Phaseolus vulgaris leucoagglutinin lectin (PHA-L) was used to determine the overall pattern and organization of efferent projections from each Vo subdivision to the spinal cord (SC). Injection sites were localized within the boundaries of each Vo subdivision. Neurons in DM and VL innervate cervical, thoracic and lumbosacral levels of SC bilaterally. Cells in BZ project only as far as upper cervical segments bilaterally. Axons from neurons in each subdivision arborize in dorsal, ventral and intermediate horns. Based on these findings an extensive Vo-SC projection may contribute to the modulation of sensory projection neurons in the dorsal horn; influence the output of motor neurons involved in withdrawal reflexes (e.g., trigemino-neck reflex); or contribute to the expression of other reflexes involving the integration of trigeminal and spinal somatic and autonomic systems. COMPARISON OF SPINAL RESPONSES FOLLOWING CORTICAL STIMULATION TO CORTICAL RESPONSES FOLLOWING SPINAL STIMULATION. JB Myklebust, JF Cusick, DJ Maiman. Zablocki VA Medical Center and Medical College of Wisconsin, Milwaukee, WI 53295

With spinal cord stimulation, a short latency spike is recorded anterior to the central sulcus of the cerebral cortex. The latency of this potential is consistent with a conduction velocity of approximately 50-60 m/s and is similar to that of the corresponding efferent response (recorded from the spinal cord secondary to cortical stimulation). In global ischemia, it is obliterated at approximately the same time (2-3 minutes) as are the post synaptic responses recorded from the dorsal root entry zone of the spinal cord, from the thalamus, and the cortex-to-cord potential. Both the short latency cord-to-cortex and the cortex-to-cord potentials areunaffected by increases in stimulus frequency up to 300 to 400 Hz. They follow at reduced amplitude up to 700-900 Hz. The latency, waveform, and frequency response imply that the short latency response is monosynaptic. The behavior in ischemia suggests that it is dependent upon the integrity of a cell body. Although the spinal stimulation is applied over the dorsal columns, the pyramidal tract is in the dorsal half of the cord and has relatively large poopulation of large, low-threshold fibers. It is reasonable to hypothesize that spinal stimulation would activate the pyramidal tract. While direct spino-cortical afferent connections have been reported, this response is probably due to antidromic conduction in the pyramidal tract.

MEASUREMENT OF MONOAMINES AND METABOLITES IN DORSAL HORN WITH MULTIPLE DIALYSIS FIBERS IN URETHANE-ANESTHETIZED RATS. JL Steinman, DB Masters & BR Komisaruk. Rutgers Univ, Inst. Animal Behav. Newark NJ 07102.

We have shown previously that vaginal stimulation (VS) evokes increases in NE & 5HT measured in spinal superfusates and that VS-induced analgesia is blocked by monoamine (MA) receptor antagonists. Using dialysis of extracellular fluid within unilateral dorsal horn, the present study analyzed the VS- or KCl-induced efflux of MA and metabolites. Two dialysis tubes (DF: 168 u dia, Cuprophan), coated with epoxy except for a 0.5 mm segment, were inserted transversely across the cord at S1 after laminectomy. DF(A) was placed 1 mm caudal to DF(B). Sample periods were 30 min. After a 2 hr baseline period, VS (400 g, every 30 sec) was administered; KCl was infused more than 90 min later. At the end of each experiment, each DF was infused with fast green dye and the spinal cord prepared for histological verification. NE levels during VS were four-tenfold greater than those in the pre-VS interval; NE levels also were elevated by KCl. In a preliminary study, KCl was infused first through DF(A): NE levels measured from this DF rose from 2.7 to 4.7 pg/ul whereas the NE levels measured in DF(B) were unaffected by the KCl infusion 1 mm away (2.7 & 2.5 pg/ul). When KCl was added to DF(B), the NE level rose to 4.5 pg/ul. Similar findings were observed for 5HIAA levels measured in the same samples.

Nd:YAG LASER EFFECTS ON NERVOUS TISSUE IN THE RAT. U. Wesselmann, S.-F. Lin* and W. Z. Rymer, Dept. of Physiology and Biomedical Engineering, Northwestern University Medical School, Chicago, IL 60611.

This study was designed to evaluate the effects of Q-switched Nd:YAG laser light (1064 nm) on spinal cord dorsal column white matter in rats (n=14). Nd:YAG laser light penetrates biological tissue for several millimeters because of weak absorption by water and high scattering. To evoke a synchronous sensory input the sciatic nerve was stimulated electrically at supramaximal intensities. The resulting spinal cord potential was recorded from the dorsal columns of the ipsilateral side and consisted of three components: An early positive peak (P1), representing the responses of the most rapidly conducting fibers, followed by two negative waves (N1, N2), which are mainly due to synaptic effects of small afferent fibers on dorsal horn cells. Laser pulses at 50 mJ/pulse and above caused a severe reduction in the amplitudes of N1 and N2. In contrast, the amplitude of P1 was not significantly altered.

The observed selective loss of the synaptic field in the spinal cord might be due to preferential impairment of high threshold fiber input to dorsal horn neurones by laser irradiation, since studies on compound action potentials of dorsal roots (n=7) and the sciatic nerve (n=13) showed that irradiation with Q-switched Nd:YAG laser light caused a progressive reduction of the late component of the electrically evoked compound action potential, implying a differential effect on slow versus fast conducting fibers. Alternatively, the selective impairment of the synaptic field in the spinal cord could be due to differential effects of laser irradiation on synaptic transmission. In either event it is likely that the mechanism of the observed effects of laser irradiation on electrically evoked potentials in the spinal cord is at least in part photothermally mediated, since intracord temperatures during laser application were above 60° C (denaturation point).

MEMORY SUBSTRATES IN PRIMATE SPINAL CORD PRODUCED BY OPERANT CONDITIONING OF H-REFLEX: ANATOMIC METHODS DEVELOPMENT. C.L. Lee, J.S. Carp, and J.R. Wolpaw. Wadsworth Labs, NYS Dpt Hlth, Albany, NY 12201.

Monkeys can increase or decrease the largely monosynaptic triceps surae (TS) H-reflex in one leg when reward depends on reflex amplitude (J. Neurophysiol. 57:443-458, 1987). Conditioned reflex asymmetries persist after the animal is anesthetized and thoracic cord transection isolates the lumbosacral cord (Wolpaw & Lee, this vol.). A probable site of plasticity is the Ia afferent synapse on the alpha motoneuron.

To define this cord plasticity, conditioned animals are anesthetized, transected, studied physiologically for 2-3 days under deep anesthesia, and then sacrificed by overdose and perfused. The anatomic goal is to identify and compare TS motoneurons and their Ia synapses on conditioned and control sides of cord.

We have labeled TS motoneurons with horseradish peroxidase (HRP) by muscular injection, peripheral nerve crush, and intracellular injection. Muscle or nerve application 2-7 days before perfusion does not give sufficiently consistent or complete labeling, possibly due to the 2-3 days of anesthesia and the chronic TS nerve cuffs. Intracellular injection provides much more complete and reliable labeling of soma and dendrites. Primary afferent fibers are labeled by crushing HRP onto L6-S1 dorsal roots 15-24 hr prior to perfusion. Labeling of afferents in ventral horn begins within 5 hr, and synapses on TS motoneurons may be counted and measured.

Intracellular TS motoneuron labeling combined with primary afferent labeling by dorsal root crush is allowing identification and assessment of Ia synapses and TS motoneurons. The crucial control is furnished by the unconditioned side of the spinal cord.

MORPHINE WITHDRAWAL FOLLOWING INTRACEREBROVENTRICULAR ADMINISTRATION: FUNCTIONAL ANATOMY AND BEHAVIOR. R.E. Adams and G.F. Wooten. Dept. of Neurology, Univ. of Virginia, Charlottesville, Va 22908.

Regional cerebral glucose utilization (RCGU) has been studied using [^{14}C]-2-deoxyglucose (^{14}C-2-DG) autoradiography during morphine (MS) withdrawal in rats following chronic systemic administration of MS (Brain Res. 332: 69-78, 1985). In the current study, rats were made dependent on MS administered by intracerebroventricular (ICV) infusion to determine whether any of the behaviors or RCGU changes in withdrawal result from peripheral rather than central MS effects. MS was administered into the right lateral ventricle (75µg/µL/hr) for 5 days using an Alzet osmotic minipump. Two hrs after the MS infusion, naloxone (5mg/kg) and ^{14}C-2-DG (10µCi/100g) were administered intravenously. Morphine withdrawal syndrome (MWS) behaviors were recorded for the next 50 min, the animals then killed,and brains prepared for autoradiography. RCGU increased by 27% in the lateral hypothalamus, 58% in the central nucleus of the amygdala, and 29% in the lateral habenular nucleus, changes similar to those previously described for the MWS. Behavioral signs of the MWS (jumps, wet dog shakes, weight loss and autonomic signs, including diarrhea) were present in all rats and indistinguishable from rats treated with systemic MS. Our results suggest that the behavioral characteristics of, and RCGU changes during, the MWS are similar whether dependence is produced by systemic or ICV MS administration.

MU OPIOID RECEPTORS IN THE DORSAL RAPHE ARE AN IMPORTANT SITE OF ACTION FOR SYSTEMICALLY ADMINISTERED OPIOIDS. J.K. Belknap, S.E. Laursen* and K.E. Sampson*, Dept. of Pharmacology, School of Med., Univ. No. Dakota, Grand Forks, ND 58202.

One line (strain) of mouse has been selectively bred in our laboratory for 15 generations to exhibit a very high sensitivity to levorphanol-induced analgesia on the hot plate assay (HAR or high antinociceptive response line). Concurrently, a second line (LAR or low antinociceptive response line) has been bred in the opposite direction, i.e., to exhibit a very low sensitivity to i.p. levorphanol, a morphine-like opioid, under the same conditions. A 7-fold difference in sensitivity between HAR and LAR mice has been bred into these animals through changes in gene frequency. Receptor autoradiographic studies were carried out using ^{3}H-DAGO to find receptor populations differing greatly in density between HAR and LAR mice to parallel their in vivo sensitivity differences: such receptors would then be implicated in mediating in vivo analgesia. The caudal portions of the dorsal raphe showed about two-fold differences in density of mu sites, while the periaqueductal gray showed no significant difference, suggesting that the latter is not involved at the mu receptor level.

280.3

EFFECTS OF OPIOID PEPTIDES ON THE EXCITABILITY OF CA3 HIPPOCAMPAL PYRAMIDAL CELLS IN VIVO AND IN VITRO. W. Liu*, M. Washburn* and H.C. Moises (SPON.: S. R. Barry). Dept. of Physiology, Univ. of Michigan, Ann Arbor, MI 48109

Opiates and various opioid peptides have been shown to increase the excitability of hippocampal pyramidal cells (HPCs) in CA1. These actions have been attributed to a disinhibitory mechanism mediated via the activation of mu (u) and delta (∂) opiate receptors. The issue examined here was whether dynorphin, an endogenous opioid localized in the mossy fiber (MF) projection from dentate granule cells, exerts similar electrophysiological actions on HPCs in CA3 and if such actions involve the activation of kappa (K) rather than u- or ∂-receptors.

In acute experiments *in vivo*, 5-barrel micropipettes were used to record extracellularly from single CA3 HPCs in halothane-anesthetized rats and to apply peptides by iontophoresis or pressure ejection. Dynorphin A_{1-8}, Dynorphin A_{1-17} and Leu-enkephalin had consistent, naloxone(NX)-reversible excitatory effects on spontaneous activity. The u-receptor agonists morphine and morphiceptin had similar but less robust facilitating effects on HPC firing. In contrast, the K agonist U50488H consistently produced NX-insensitive inhibitions of HPC discharge. Inhibitory responses to DYN A_{1-17} were observed in a small percentage of HPCs and these effects were also insensitive to NX blockade.

Superfusion of peptides in the hippocampal slice revealed a similar pharmacological profile of peptidergic effects on CA3 population spike responses evoked by MF stimulation. Dynorphin A_{1-8} and a stabilized analogue of DYN A_{1-13},DAFPHEDYN, generally increased the amplitude of the population spike and NX typically blocked this effect. However, U50488H routinely attenuated population spike amplitude both in the absence and presence of the antagonist (1-10 uM).

These results clearly distinguish the electrophysiological actions of dynorphin in CA3 from that of a prototypical K-receptor agonist. This raises the possibility that endogenous dynorphins might influence HPC excitability in this region of hippocampus via interaction at u and/or ∂ receptors, as occurs in CA1. USE OF BIOTINYLATED β-h-ENDORPHIN IN PURIFICATION OF SOLUBILIZED CALF BRAIN OPIATE RECEPTORS. D. Helmeste. Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Canada M5T 1R8.

The high affinity between avidin and biotin (K_d=10^{-15} M) makes possible the isolation of numerous biological materials via derivatization with either biotin or avidin and subsequent affinity chromatography. This method has been applied to the isolation of the opiate receptor, by derivatizing βh-endorphin (β-EP), a potent opiate peptide, which maintains high affinity for the opiate receptor throughout the solubilization procedure. β-EP was derivatized with sulfosuccinimidyl 2-(biotinamido) ethyl-1,3'-dithiopropionate (NHS-SS-Biotin) using 2 to 1 molar ratio of biotin to peptide. With 0.05 M potassium phosphate (pH 7) as the incubation buffer, 90% of the peptide precipitated during the 4 h, 22°C incubation. HPLC analysis revealed that this precipitate represented biotinylated β-EP (BBE) only. Underivatized (free) β-EP (<10% of total peptide) remained in the supernatant. The precipitated BBE was then redissolved in dimethyl sulfoxide and characterized in terms of: (1) radioligand binding to calf brain membrane opiate receptors; (2) binding to solubilized calf brain opiate receptors; (3) HPLC analysis of tryptic digests and native peptide. Affinity of BBE for opiate receptors is only slightly reduced compared to β-EP alone. Use of BBE for affinity purification (avidin-sepharose) of solubilized opiate receptor appears to be useful as an initial step in purification of the opiate receptor.

Supported by the Medical Research Council of Canada (MA-10179).

280.5

SOLUBILIZATION OF AN OPIATE RECEPTOR COMPLEX FROM CALF BRAIN. L.R. Murthy*, M.A. Gistrak*, M. Price*, and G.W. Pasternak (Spon: W.R. Shapiro). The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Cornell U. Medical College, New York, NY 10021.

^{3}H-NalBzoH, the benzoylhydrazido derivative of naloxone, is a unique opiate ligand. In binding studies it labels mu receptors and a non-mu, non-delta site which may represent a novel kappa receptor subtype. Binding to mu receptors is unique in that the half-life of dissociation at 25°C is approximately 24 hours. Despite this slow rate of dissociation, binding is not covalent and can be reversed readily by lowering the pH of the buffer or adding GTP or stable GTP analogs. In view of the stability of binding, we attempted to solubilize receptors prebound with ^{3}H-NalBzoH. CHAPS (10 mM) solubilzed approximately 20-35% of specific ^{3}H-NalBzoH binding. The solubilized binding remained sensitive to both lowered pH and GTP analogs, implying that the solubilized binding was not covalent. Attempts to identify residual binding in the membrane pellet have been unsuccessful, but we cannot be certain whether all sites have been solubilized. Preliminary exclusion chromatography suggests a molecular weight of greater then 200 kdaltons, which probably reflects a complex of the receptor and other associated proteins.

280.6

SOLUBILIZATION AND CHARACTERIZATION OF SIGMA RECEPTOR FROM GUINEA PIG BRAIN MEMBRANES. M. P. Kavanaugh*§, J. Parker*§, D. H. Bobker*§, J. F. W. Keana*¶, and E. Weber§. § Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201 and ¶Department of Chemistry, University of Oregon, Eugene, OR 97403

The sigma receptor, a distinct binding site in brain tissue which may mediate some of the psychotomimetic properties of benzomorphan opiates and phencyclidine, has been solubilized using the ionic detergent sodium cholate. The solubilized receptor has been biochemically and pharmacologically characterized using gel permeation chromatography, isoelectric focusing, and binding studies with tritiated sigma-selective ligands. Brain membrane suspensions were treated with 20 mM cholate followed by ultracentifugation at 105,000 x g and filtration through a 0.45u filter. Binding assays were performed with the solubilized receptor using vacuum filtration over polyethyleneimine-treated glass fiber filters. The pharmacological specificity of the solubilized binding site for sigma receptor ligands is very similar to the membrane-bound form of the receptor, with the order of potencies for displacement of the selective sigma ligand [^{3}H]-di-o-tolylguanidine ([^{3}H]DTG) well correlated (r=.88). The stereoselectivity for (+) benzomorphan opiate enantiomers was retained by the solubilized receptor. The soluble receptor retained high affinity for binding of [^{3}H]DTG (Kd = 31 ± 4 nM) and [^{3}H] (+)-3-(3-hydroxyphenyl)- N-(1-propyl) piperidine ([^{3}H](+)-3-PPP) (Kd = 33 ± 7 nM). Estimation of the Stokes radius of the [^{3}H]DTG binding site was obtained by Sepharose Cl-6B chromatography in the presence of 20 mM cholate and calculated to be 8.7Å. This value was identical to the molecular size of the binding sites of the sigma-selective ligands [^{3}H](+)-3-PPP and [^{3}H](+)-SKF-10,047. These results demonstrate that the sigma receptor is a membrane-bound complex which can be solubilized in a form that retains the pharmacological characteristics of the native form, providing a basis for further biochemical characterization and purification of the receptor.

280.7

PURIFICATION AND PHARMACOLOGICAL CHARACTERIZATION OF THE SIGMA RECEPTOR FROM RAT AND BOVINE CEREBELLUM. F.J Arnold, D.I. Schuster and R.B. Murphy. Dept. of Chemistry and Center for Neural Science, New York University, New York, N.Y. 10003

We have purified to apparent homogeniety and pharmacologically characterized the sigma receptor from both rat and bovine cerebellum. Tissue was solubilized with the detergent CHAPS and recirculated through an affinity column derivatized with a 3-PPP analog previously prepared in our laboratories. The column was eluted with 20 uM haloperidol. Purified material was desalted, subjected to SDS-PAGE, and pharmacologically characterized. The material was purified ~6,000 fold based upon biological activity. It consisted of two major bands on SDS-PAGE of M_r 63 and 65 KD. In order to examine the pharmacology of the purified receptor it was necessary to reconstitute into bimolecular lipid vesicles. Reconstituted material possessed appropriate pharmacology of the sigma receptor; enantiospecificity with both (±) SKF 10,047 and (±) butaclamol, high affinity toward haloperidol, and the newly described sigma ligand 1,3-di-o-tolyl-guanidine. Spiperone, ketanserin, prazosin, phencyclidine, and etorphine possessed little or no activity. Current studies are directed toward the molecular sequencing and structural determination of the isolated proteins.

280.8

PHOTOAFFINITY LABELING OF AFFINITY PURIFIED RAT AND BOVINE CERRBELLAR SIGMA RECEPTOR WITH [^{3}H]-AZIDO-1,3-DI-O-TOLYL-GUANIDINE (DTG). D.I. Schuster, F.J. Arnold, and R.B. Murphy. Dept. of Chemistry and Center for Neural Science, New York University, New York, N.Y. 10003

We have recently purified to apparent homogeniety the sigma receptor from rat and bovine cerebellum (Arnold et al Soc. Neurosci. Abstr., this meeting). The receptor consists of two bands on SDS-PAGE of M_r 63 and 65 KD. Recent studies of the sigma receptor in guinea pig brain homogenates using the highly selective photoaffinity label [^{3}H]-Azido-DTG indicate that a single component on SDS-PAGE of 29 KD is covalently labeled (Kavanaugh et al PNAS in press). In order to elucidate the relationship between these observations we photolysed [^{3}H]-Azido-DTG with the affinity-purified sigma receptor. Under non-denaturing conditions, a high molecular mass complex (300-400 KD) was covalently labeled. Incorporated activity was displaced in the presence of the selective sigma ligand haloperidol. A similar fraction was labeled in crude tissue homogenates. These results suggest that the 29 KD photoaffinity labeled protein is a component of the affinity purified sigma receptor. We extend our sincere thanks to M.P. Kavanaugh and E. Weber for their gift of [^{3}H]-Azido-DTG.

280.9

CHARACTERIZATION OF LOW AFFINITY DELTA OPIOID RECEPTORS COUPLED TO ADENYLATE CYCLASE IN RAT BRAIN MEMBRANES. S. R. Childers, J. Harris and J. King, Dept. of Pharmacology, Univ. Florida Coll. Med., Gainesville, FL 32610.

Since receptor-mediated inhibition of adenylate cyclase (AC) requires NaCl and GTP, μM concentrations of opioid agonists are required to inhibit AC in brain membranes. Our previous studies showed that blockade of high affinity (nM) opiate receptors with alkylating agents or phospholipase A (100 ng/ml) had no effect on opioid inhibition of AC. To determine whether AC is coupled to low affinity receptor sites, we performed binding studies in brain membranes with [3H]naloxone in buffer containing both NaCl and GTP. The affinity of naloxone in blocking opiate-inhibited AC is 30-50 nM, so we used 50 nM [3H]naloxone to label low affinity binding sites, and displaced naloxone binding with various unlabeled agonists. Under these conditions, IC_{50} values of both mu and delta agonists were μM, with the most potent being mu agonists. However, the delta agonists DPDPE and DSTLE exhibited a biphasic displacement of [3H]naloxone binding, with a distinct plateau at 1 μM agonist concentration. This plateau was approx. 25% of total [3H]naloxone binding, and was defined as low affinity delta sites. These sites had an identical distribution to opiate-inhibited AC in rat brain, with highest levels in striatum and frontal cortex. Like opiate-inhibited AC, the low affinity delta sites were not sensitive to naloxonazine or ß-FNA, but were blocked by ß-CNA. Compared to high affinity delta sites ([3H]DPDPE binding without NaCl/GTP), the low affinity delta sites were significantly less sensitive to phospholipase A and ß-CNA. Protection experiments, in which the effects of ß-CNA were blocked by pre-incubation with specific ligands, revealed clear differences between high and low affinity delta sites, since high affinity delta sites were protected by 200 nM DPDPE but not 200 nM naloxone, while low affinity delta sites, and opiate-inhibited AC, were protected by equal concentrations of both naloxone and DPDPE. These studies show that properties of opiate-inhibited AC correlate with those of low affinity delta receptors, and suggest that these two states of delta sites have different binding properties.

OPIATE REGULATION OF ADENYLATE CYCLASE IN C-6 GLIOMA CELLS AND NEONATAL RAT PRIMARY NEURONAL CULTURES. D.R. Marckel and S.R. Childers. Dept. of Pharmacology, Univ. of Florida Coll. Med., Gainesville, FL 32610.

Opiates regulate adenylate cyclase activity in various cell lines (i.e. NG108-15) and mammalian brain. C-6 glioma cells express opiate receptors when treated with desmethylimipramine, but supposedly lack opiate receptors when left untreated. We now report that opiates have both inhibitory and stimulatory actions on adenylate cyclase in untreated C-6 cells, and we confirm some of these actions in primary neuronal cell cultures from neonatal rat brain.

Suspensions of C-6 glioma cells in EGTA buffer were incubated with theophylline and various agents for 10 min at 37°. cAMP levels were assayed by the protein binding method. D-ala-met-enkephalinamide (D-ala enk) produced a biphasic response with inhibition predominant at low (nM) concentrations and stimulation at higher (μM) concentrations. The inhibitory component was best observed in the presence of 0.1-1.0 μM forskolin, where D-ala enk inhibited 20-30% of forskolin stimulated cAMP levels. Preincubation with phorbol 12-myristate 13-acetate (PMA) eliminated the inhibition and shifted the stimulation to slightly lower concentrations. In PMA-treated cells, basal cAMP levels were decreased, while the % stimulation of cAMP by isoproterenol was increased. Similarly, stimulation by D-ala enk was increased to 2-3 fold. To confirm that these effects of opiates were mediated through adenylate cyclase, identical experiments were conducted with C-6 cells permeabilized with saponin, with adenylate cyclase assayed in the presence of [3H]ATP, GTP, and opiate agonists. Results were identical to those seen in intact cells.

Primary neuronal cultures were made from 1 day old rats in which the whole brain was removed, cleaned of pia, triturated, treated with trypsin and DNAse I, and plated. Cultures were treated with cytosine arabinoside for 3 days to decrease the glial population and obtain cultures of 80-85% neurons. After 10 days of culture, cAMP levels were determined in cells incubated for 5 min at 37° with isobutylmethylxanthine (IBMX) and various agents. D-Ala enk produced a marked stimulation (≈5 fold) of cyclic AMP levels, whereas isoproterenol was able to stimulate cyclic AMP levels 10-20 fold. These results suggest that in C-6 glioma cells, as well as primary neuronal cultures, opiate receptors have dual effects on adenylate cyclase activity.

INHIBITION OF MEMBRANE PROTEIN PHOSPHORYLATION BY OPIATE-INHIBITED ADENYLATE CYCLASE IN RAT BRAIN MEMBRANES. L. M. Fleming, G. Ponjee and S. R. Childers, Dept. of Pharmacology, Univ. Florida Coll. Med., Gainesville, FL 32610.

Opiate-inhibited adenylate cyclase (AC) results in decreased protein phosphorylation by cAMP-dependent protein kinase. Pretreatment of rat brain membranes at pH 4.5 maximizes opiate-inhibited AC. In order to discern which proteins are ultimately affected by this opiate inhibition, rat striatal membranes were pretreated at pH 4.5 and resuspended in a Mg++/Tris buffer containing IBMX, GTP, NaCl, and EGTA. Membranes were preincubated with 0.5 mM App(NH)p for 5 min at 30°C before addition of 10 μCi (0.1 μM) of γ-[32P]ATP for 20 sec. The reaction was terminated with SDS sample buffer, and protein samples were subjected to gradient SDS-PAGE and autoradiography. Incubation with EGTA blocked calcium and calmodulin-dependent kinases and provided for maximum effects of cAMP-dependent phosphorylation. App(NH)p is a substrate for AC, but is not a good substrate for most ATP-kinases and therefore did not block phosphorylation of most proteins.

In the presence of App(NH)p, proteins stimulated directly by cAMP were also stimulated by forskolin. Forskolin had no effect on protein phosphorylation in the absence of App(NH)p. Since forskolin stimulates AC, it should also increase the signal for opiate inhibition and aid in identifying opioid-inhibited phosphoproteins. Addition of D-ala-met-enkephalinamide (D-ala-enk) decreased phosphorylation of two protein bands of MW 63 kDa and 85 kDa. Both bands were stimulated by forskolin. D-Ala enk-inhibited phosphorylation was observed in both basal as well as forskolin-stimulated conditions, as long as forskolin concentration was <1 μM. Consistent with the idea that D-Ala enk-inhibited phosphorylation was mediated by opiate-inhibited AC, μM concentrations of agonist were required for inhibition, and inhibition was more pronounced in low pH pretreated membranes than in untreated membranes. The inhibition of phosphorylation by D-ala enk was blocked by naloxone. Inhibition by D-Ala enk was maximal in striatum, while inhibition of the same protein bands by the mu agonist DAGO was observed in membranes from thalamus. These results suggest that two principal targets of opiate-inhibited AC in brain membranes are cyclic AMP-dependent membrane phosphoproteins of 63 kDa and 85 kDa.

RAT BRAIN MICROSOMES CONTAIN G-PROTEIN UNCOUPLED OPIOID RECEPTORS. M. Sztics* and C.J. Coscia, Dept. of Biochemistry, St. Louis Univ. Sch. Med., St. Louis MO 63104.

Using subcellular fractionation techniques developed in our laboratory we have separated two discrete populations of opioid receptors from rat brain. One is associated with a synaptic plasma membrane (SPM) enriched fraction, and the other with smooth microsomes. The relative distribution of high affinity agonist μ, δ and κ receptor binding and its modulation by guanyl nucleotides, Na+ and divalent cations were examined using highly selective radioligands. Mn++ (0.2-50 mM) elicited a concentration-dependent inhibition of μ and κ binding, but increased δ binding in both fractions. Microsomal sites were more sensitive to divalent cations and the inhibitory effect of Na+ than SPMs, and they also lacked the sensitivity to the dose-dependent guanyl nucleotide inhibition displayed by SPMs and crude membrane fractions. To determine whether GTP-binding (G) proteins were present in microsomes, they were treated with [32P]NAD in the presence of pertussis toxin. A doublet with molecular weights of 39 and 41 kDa was labeled in both microsomes and SPMs. Thus, microsomes also possess the α-subunit of pertussis toxin-sensitive G protein. Combined with independent binding kinetics data, these results suggest that opioid receptors in rat brain microsomes are not coupled to G-protein. Supported by NSF grant BNS 85-08933.

PRENATAL OPIOID RECEPTOR BINDING IN RAT BRAIN: [125I]BETA-ENDORPHIN AUTORADIOGRAPHY . H.I. Kornblum, S.E. Loughlin and F.M. Leslie. , U.C. Irvine, Irvine,CA 92717.

Previous studies have demonstrated the presence of opioid receptors in the developing rat brain. These studies have shown that the different receptor subtypes change in both distribution and density during development. However, the majority of these studies have been performed using postnatal rats. In the present study we have used [125I]Beta-endorphin (BE) to localize opioid receptors in the embryonic and postnatal rat brain. The development of these receptors is correlated with the ontogeny of opioid peptides in selected brain areas. Rat brains from embryonic day 13 (E13) to adulthood were frozen and prepared for in vitro autoradiography using 50 pM [125I]BE in the presence or absence of a variety of unlabelled competing ligands. In the adult, binding was to mu and delta receptors, with the mu receptor component being completely inhibited by 300 nM DAGO. All binding was inhibited by 1 uM levallorphan. In the embryonic rat, binding was present by E16. Binding was present almost entirely within the developing neostriatum and was completely inhibited by DAGO. By E19 binding sites were more extensively distributed. Binding within the neostriatum was homogeneous. Binding was also present within the brainstem, the epithalamus, and the olfactory bulb, as well as within the germinal zone bordering the lateral ventricles. By P0, binding was present in many more brain regions, taking on a distribution more similar to the adult. Within the neostriatum the ontogeny of opioid receptors correlates with that of enkephalin-immunoreactive striato-pallidal fibers which are present by E17. The presence of binding sites within the germinal zone suggests that opioid receptors are present on dividing or migrating cells, and is consistent with previous observations of Beta-endorphin immunoreactive cells within that region. The present data and previous studies demonstrate the presence of opioid peptides and receptors early during brain development, indicating that endogenous opioid systems are functional in the developing brain.

NEONATAL RAT BRAIN δ OPIOID RECEPTORS. C.J. Coscia and M. Szücs*, (SPON. S. McLean) E.A. Doisy Dept. of Biochemistry St. Louis Univ. Sch. Med., St. Louis MO 63104.

Rat brain contains at least three classes of opioid receptors, μ, δ, and κ, which undergo differential postnatal development. While both μ and κ opioid receptor binding are detectable in brain of new-born rats, high affinity δ binding is absent. During the first two weeks after birth δ receptor binding rapidly emerges. By analyses of homologous displacement curves with the LIGAND computer program, we have compared the binding parameters, Kd and Bmax, of the δ selective enkephalin analog, ^{3}H(D-Pen^2,D-Pen^5) enkephalin (^{3}H-DPDPE) for opioid binding sites in 5-day-old neonates and adult rats. Although binding affinity did not change appreciably, >5-fold increases in Bmax were observed. Heterologous displacement of ^{3}H-DPDPE with μ and δ selective ligands gave the same rank order of potency in neonates and adults. Pertussis toxin-mediated ADP ribosylation experiments revealed the presence of the α subunit of guanine nucleotide binding proteins, Go and Gi, in brain as early as 0.5 h after birth. Inhibition of ^{3}H-DPDPE binding by Gpp(NH)p did not change significantly between day 5 and adulthood. The authentic δ character of the sites recognized by ^{3}H-DPDPE in the neonate was further evidenced by divalent cation stimulation of its binding. Supported by NIH grant DA05412.

CYCLIC [D-PEN^2,D-PEN^5]ENKEPHALIN (DPDPE) ANALOGUES WITH INCREASED AFFINITY AND SELECTIVITY FOR DELTA OPIOID RECEPTORS. G.K. Lui*, G. Toth*,R.J. Knapp*, V.J. Hruby*, and H.I. Yamamura.(SPON: P. Deshmukh).Departments of Pharmacology and Chemistry, University of Arizona, Tucson, Arizona 85724.

[D-Pen^2,D-Pen^5]enkephalin (DPDPE) is a cyclic, conformationally constrained enkephalin analogue with high delta opioid receptor selectivity. DPDPE was modified by halogenation of the phenylalanine residue . A series of modified DPDPE analogues were evaluated by radioligand binding studies using rat brain (minus cerebellum) membranes in Tris-buffer (50mM). Incubation was for 2 hr at 25C. The binding affinity and selectivity of four DPDPE analogues were the following:

	[^{3}H]DPDPE	[^{3}H]CTOP	RATIO
Analogue	IC_{50}(nM)		μ/δ
DPDPE	5.25	609	116
pF-Phe^4-DPDPE	2.50	623	249
pCl-Phe^4-DPDPE	1.57	901	574
pI-Phe^4-DPDPE	4.74	964	203
pBr-Phe^4-DPDPE	1.73	418	242

Halogenation in the para position of the DPDPE phenylalanine residue increased both its affinity and selectivity for the delta opioid receptor.

COMPARATIVE SATURATION STUDIES ON TWO NON-SELECTIVE OPIOID LIGANDS IN GUINEA-PIG BRAIN. J. Magnan and M. Tiberi. Dép. de pharmacologie, Univ. de Montréal, Montréal H3C 3J7 Canada

In order to ascertain whether [^{3}H]-bremazocine and [^{3}H]-ethylketazocine are interchangeable universal opioid ligands, we have used these and selective μ-, δ- and κ-opioid ligands and measured their relative equilibrium dissociation constant (K_D) and respective maximum binding capacity. Results show that μ-, δ- and κ-selective ligands respectively label 7.22 $\pm$ 0.66, 3.33 $\pm$ 0.10 and 4.47 $\pm$ 0.20 pmoles/g tissue for a total opioid binding capacity of 15.0 pmoles/g tissue. The saturation curve for [^{3}H]-ethylketazocine is best-fitted to a two-sites model with a high-affinity K_D of 0.19 $\pm$ 0.02 nM and a capacity of 5.32 $\pm$ 1.11 pmoles/g tissue and a low-affinity component with a K_D of 2.38 $\pm$ 0.83 nM for a capacity of 9.34 $\pm$ 0.72 pmoles/g tissue. Total binding capacity for [^{3}H]-ethylketazocine is 14.7 $\pm$ 1.11 pmoles/g tissue which corresponds with the total (μ + δ + κ) opioid capacity. [^{3}H]-bremazocine binding can also be resolved into high and low affinity components of respective K_D 0.09 $\pm$ 0.01 nM and 0.90 $\pm$ 0.14 nM and capacities of 11.0 $\pm$ 1.34 and 16.2 $\pm$ 1.69 pmoles/g tissue. Thus its total binding capacity is 27.2 $\pm$ 0.86 pmoles/g tissue, a value significantly higher than that of [^{3}H]-ethylketazocine. It seems that these two cannot be used indiscriminately as non-selective opioids.

EVIDENCE FOR KAPPA OPIOID RECEPTOR HETEROGENEITY, D.E. Hurlbut, R.S. Broide* and F.M. Leslie, University of California, Irvine, Ca. 92717, U.S.A.

Using membrane binding techniques, we have compared the binding properties of [^{3}H]ethylketocyclazocine (EKC) and [^{3}H]diprenorphine (DIP) binding in guinea pig and rat brain. In all experiments, selective blockers were included within the assay buffer to preclude ligand binding to mu and delta receptor types. Specific binding was defined as the difference in radioactivity in the absence and presence of levallorphan (1uM). In guinea pig brain, saturation curves for both radioligands best fit a one-site model. However, there were significantly fewer [^{3}H]EKC than [^{3}H]DIP binding sites. Dose-response curves for inhibition of [^{3}H]DIP binding by several competing ligands were biphasic, and could be best fit to a two-site model; Dynorphin A and U50,488H exhibited over 1000-fold differences in affinity at these two sites. In contrast, dose-response curves for inhibition of [^{3}H]EKC binding were monophasic and best fit a single site model. K_i values for inhibition of [^{3}H]EKC binding were highly correlated with K_i values for inhibition of the U50488H-sensitive [^{3}H]DIP binding site. These data are consistent with the hypothesis that [^{3}H]DIP labels two sites with equal affinity in guinea pig brain, one of which is selectively labeled by [^{3}H]EKC. Preliminary membrane binding and autoradiography data have indicated a differential regional distribution of U50-sensitive and -insensitive sites throughout guinea pig brain. In rat brain, dose-response curves for inhibition of [^{3}H]DIP binding were consistently monophasic. There was a high correlation between K_i values for inhibition of [^{3}H]DIP binding in rat brain and K_i values for inhibition of the U50488H-insensitive [^{3}H]DIP binding site in guinea pig brain. These data suggest that guinea-pig brain contains two kappa-like [^{3}H]DIP binding sites while rat brain contains only one.

NEUROANATOMICAL DISTRIBUTION OF RAT AND GUINEA PIG BRAIN KAPPA OPIOID RECEPTORS: EVIDENCE FOR MULTIPLE KAPPA RECEPTOR SUBTYPES. E.M. Unterwald and R.S. Zukin. Dept. Neuroscience, Albert Einstein Col. of Med., Bronx, NY 10461.

Recent data from our laboratory have suggested the presence of two populations of κ opioid receptors in brain. The κ_1 site predominates in guinea pig, is of high affinity and U-69,593-sensitive, and the κ_2 site predominates in rat brain, is of lower affinity and U-69,593-insensitive. This study investigates the neuroanatomical distribution of κ receptor subtypes in rat and guinea pig brain using quantitative *in vitro* autoradiography. Total κ receptors were labelled with [^{3}H](-)bremazocine or [^{3}H](-)ethylketocyclazocine (EKC) in the presence of an excess of DAGO and DADLE, κ_1 receptors with [^{3}H]U-69,593 and κ_2 sites with [^{3}H](-)bremazocine or [^{3}H]EKC in the presence of DAGO, DADLE and U-69,593. Guinea pig κ_1 sites were most dense in layers I and V-VI of the neocortex, striatum, endopiriform nucleus, cerebellum and primary olfactory cortex. κ_2 sites were found in guinea pig striatum, nucleus accumbens, hippocampus, thalamus, and inferior colliculus. Distribution of κ_1 sites in rat brain was similar to that of guinea pig in the striatum, nucleus accumbens and endopiriform nucleus but differed in the neocortex, cerebellum and hippocampus and overall, were of much lower density in rat brain. κ_2 receptors in rat brain were of higher density and more widely distributed than in guinea pig brain. Results from this study provide evidence for heterogenous neuroanatomical distributions of κ_1 and κ_2 opioid receptors.

UNEXPECTED BINDING PROFILE OF [^{3}H]-BREMAZOCINE IN GUINEA-PIG BRAIN. M. Tiberi and J. Magnan, Dép. de pharmacol., Univ. de Montréal, Montréal H3C 3J7 Canada

We have previously demonstrated that the non-selective ligand [^{3}H]-bremazocine labels more than μ-, δ- and κ-opioid binding sites in guinea-pig brain. The pharmacological characterisation of this additional opioids site was studied using a series of opioid compounds known to be μ-, δ- and κ-selective and also non-selective opioid ligands. Competition assays were performed with [^{3}H]-bremazocine in the presence of unlabelled μ-, δ- and κ-selective opioids to suppress its binding at those sites. The relative equilibrium dissociation constants (K_d) were calculated from the displacement curve using a computerized curve fitting program. The results show that μ- and δ-selective compounds have a very low affinity (K_d > 5 μM) for this binding site. Opioids such as diprenorphine, cyclazocine, ethylketazocine, levallorphan, U-50,488H and nalorphine have higher affinity with K_D values varying between 5 and 125 nM. Furthermore, (-) SKF 10,047 and (+) SKF 10,047 have respective K_d values of 45 nM and 7227 nM demonstrating the stereoselectivity of this non-conventional opioid site. We have established a correlation between the affinities of the various opioids at this binding site and their effects in different bioassays. The results suggest that this unexpected opioid site labelled with [^{3}H]-bremazocine might be a κ-related site.

280.21

COMPARATIVE DISTRIBUTION OF OPIOID RECEPTOR SUB-TYPES IN HUMAN STRIATAL TISSUES. C. Pilapil, J. Magnan and R. Quirion. Douglas Hosp. Res. Centre and Dept. of Pharmacology, Univ. of Montreal, Quebec, Canada H4H 1R3.

In the rat striatum, mu opioid receptors are concentrated in "patches" or "striosomes" associated to acetylcholinesterase-poor areas. We report here on the comparative localization of mu, delta and kappa opioid binding sites in human striatal tissues. Post-mortem human brain brains were processed as recently described (Quirion et al, Synapse 1, 448-454, 1987). Brain sections were then incubated under appropriate conditions (Pilapil et al, Brain Res. Bull. 19, 611-615, 1987) in presence of [^{3}H]DAGO, [^{3}H]DTLET and [^{3}H]bremazocine (with mu and delta blockers) or [^{3}H]U-69,593 to label mu, delta and kappa sites, respectively. Our results clearly demonstrate the differential distribution of mu, delta and kappa sites in human striatal tissues. In contrast to rat brain, mu sites are densely but diffusely distributed in rat striatum. Interestingly, kappa binding sites are heterogeneously distributed in the human striatum. This is especially evident in the caudate nucleus where kappa binding sites are clearly associated to acetylcholinesterase-poor striosomes. Thus, important species differences exist in regard to the association between striosomes and opioid receptor sub-types in striatal tissues.

280.22

OPIATE RECEPTORS IN THE SUBSTANTIA NIGRA EXIST PRIMARILY ON STRIATO-NIGRAL AFFERENTS. N.L. Ostrowski and A. Pert. LCM and BPB, NIMH, Bethesda, MD 20892.

Autoradiographic studies were conducted to examine opiate receptor binding relative to dopamine neurons. Afferent and efferent connections to the substantia nigra were eliminated in male rats with 6-hydroxydopamine lesions of the medial forebrain bundle or electrolytic lesions of the internal capsule. Internal capsule lesions produced significant decreases in the dorsal (pars compacta) and ventral (pars reticulata) substantia nigra, the ventral tegmental area and the medial terminal nucleus of the accessory optic tract. In contrast, elimination of the dopamine cells produced minimal change in [^{3}H]naloxone binding in the same regions. These data suggest that the primary site of opiate receptor binding is on nigral afferents, and not on dopamine neurons.

280.23

MEDIOBASAL AND PREOPTIC AREA OPIOID BINDING SITES ARE DECREASED FOLLOWING TRANSECTION OF THE ASCENDING NORADRENERGIC PATHWAY. M.G. Dube*, A. Sahu*, S.P. Kalra, and W. Jacobson* (SPON: M.W. HEFT). Department of Obstetrics and Gynecology, University of Florida, Gainesville, FL 32610

LH secretion can be influenced both by endogenous opioid peptidergic (EOP) as well as adrenergic systems. However, uncertainty persists as to the nature of the anatomical relationship between the two. Using intact brain slices (Life Sciences 39: 2037, 1986), we have investigated the effect of interrupting the ascending noradrenergic fibre pathway (ANP) on [^{3}H]-Naloxone (NAL) binding sites in the mediobasal hypothalamus (MBH) and the preoptic area (POA). Two weeks following transection of the ANP in intact male rats, MBH levels of norepinephrine were decreased by 54.4%, and epinephrine levels were undetectable. Neither dopamine nor serotonin systems were affected by the transection. Similar changes were noted in the POA. Saturation binding curve analysis indicated that this loss of catecholamines was accompanied by a parallel loss in the number of NAL binding sites in slices of MBH (B_{max}: sham=45.9±2.5; cut=27.1±9.5 fm/mg tissue) and of POA (B_{max}: sham=58.7±3.6; cut=36.6±2.3 fm/mg tissue). The affinity of the receptor for the ligand was unaffected by the transection (MBH: K_D: sham=3.8±0.4 nM; cut=3.0±1.9 nM; POA: K_D: sham=3.0±0.3 nM; cut=2.2±0.3 nM). Cortical NAL binding sites were unaffected by ANP transection. The receptor population was further investigated in the MBH at 5 and 8 weeks following ANP transection. The amount of NAL bound remained depressed in the transected group and did not recover with time (7.0 nM NAL; 2 wk: sham= 28.7±1.7, cut= 22.2±1.5; 5 wk sham= 24.7±2.0, cut= 19.6±1.3; 8 wk sham= 25.8±1.7, cut= 20.1±0.9 fm/mg). These data indicate the presence of opioid binding sites presynaptically on noradrenergic nerve fibers innervating the preoptic area and the mediobasal hypothalamus. Supported by NIH HD11362.

DISTRIBUTION OF SPECIFIC OPIOID RECEPTOR SUBTYPES AND THEIR CORRELATION WITH ENKEPHALIN IMMUNOREACTIVITY IN THE DORSOLATERAL PONS. Robert M. Bowker and Roger P. Dilts, Dept. of VCAPP, Washington State Univ., Pullman, WA. 99164

The nuclei of the dorsolateral pons--the medial and lateral parabrachial nuclei and the locus coeruleus--are known to have wide spread connectivities. In the present study the localization of the specific opioid receptor subtypes were ascertained using in vitro autoradiography and were correlated with the enkephalin immunoreactivity.

In vitro receptor autoradiographic studies were performed with the selective ligands DAGO and DPEN 2,5-enkephalin. After incubations these two receptor subtypes were evident in the dorsolateral pons. Differential distributions of the receptors were seen within a subregion of these nuclei. Immunocytochemistry was performed using the peroxidase reaction which revealed dense patterns in both the lateral and medial parabrachial nuclei, as well as the locus coeruleus nucleus. Differential distributions of the immunoreactive fibers and neurons were also evident. The opioid receptor subtypes and the enkephalin immunoreactivity are being correlated. These findings suggest that these nuclei probably have sub regions mediating different functions and support the notion that opioid neurotransmission is quite complex and entails many subtleties necessary to carry out their actions. Supported by NIH grants NS22321 and NS24388.

CHRONIC ADMINISTRATION OF MORPHINE AND NALTREXONE UP-REGULATE MU OPIOID BINDING SITES LABELED BY ^{3}H-DAGO: FURTHER EVIDENCE FOR TWO MU BINDING SITES. R.B. Rothman[1], V. Bykov[1], J.B. Long[2], L.S. Brady[3], M. Little[3], M. Herkenham[3], A.E. Jacobson[4], K.C. Rice[4] and J.W. Holaday[2]. [1]LCS and [3]Unit on Functional Neuroanatomy, NIMH, and [4]Section on Drug Design and Synthesis, NIDDK, Bethesda, MD, 20892. [2]Neuropharmacology Branch, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

In this study we examined the hypothesis of two mu binding sites (mu_{CX} and mu_{nCX}) by studying the effect of chronic administration of morphine and naltrexone to rats (via subcutaneous pellet implantation) on mu binding sites labeled by ^{3}H-DAGO. We additionally measured kappa binding sites labeled by ^{3}H-bremazocine, and conducted receptor autoradiography studies at the level of the thalamus to localize which brain areas were up-regulated by chronic morphine.. Mu opioid binding sites were labeled with ^{3}H-DAGO, using membranes preincubated in the absence (CNT-P2) or presence of 1 uM beta-funaltrexamine (FNA-P2). Kappa binding sites were labeled using membranes pretreated with the site-directed acylating agents BIT (mu-selective) and FIT (delta-selective). ^{3}H-DAGO results:

	CNT-P2		FNA-P2	
	Bmax	Kd	Bmax	Kd
PLACB.	74±2.5	2.9±0.04	69.7±4.3	7.5±0.1
MORPH.	150±5.0*	6.1±0.12*	75±6.0	8.0±0.20
NALTRX	130±2.2*	2.7±0.05	94±3.7*	5.8±0.12*

These data indicate that up-regulated mu binding sites are completely (chronic morphine) or partially (chronic naltrexone) sensitive to FNA. Chronic naltrexone, but not chronic morphine, increased the Bmax of kappa binding sites by 26%. Receptor autoradiography of mu binding sites at the level of the thalamus localized the areas of greatest increase to the hypothalamus, amygdala and striatum. The major finding of this study is that chronic morphine selectively up-regulates the mu_{CX} (FNA-sensitive) binding site, while chronic naltrexone up-regulates both the mu_{CX} and the the mu_{nCX} (FNA-insensitive) mu binding site.

280.26

OPIOID RECEPTOR UPREGULATION IN SPECIFIC BRAIN REGIONS SHOWS CONCOMITANT CHANGES IN BRAIN FUNCTIONAL ACTIVITY. A. Tempel[1] and L. Brown[2]. Dept. Neuroscience[1] and Neurology[2], Albert Einstein College of Medicine, Bronx, NY 10461.

The phenomenon of naltrexone-induced upregulation of brain opioid receptors is well documented (Tempel et al., 1984; 1985). However, the functional neuroanatomical changes associated with this phenomenon remain unclear. In order to identify brain regions with changes in functional neuronal activity following opioid receptor blockade, 2-deoxy-D-[^{14}C]glucose (2DG) autoradiography was carried out on brain tissue from chronic naltrexone treated and control rats (Sokoloff 1977). Analysis of selected brain regions revealed significant increases in glucose utilization in several thalamic nuclei (including the lateral geniculate, lateral ventroposterior, ventrolateral and rhomboid nuclei) basolateral nucleus of the amygdala and the molecular layer of the hippocampus. Decreases in glucose utilization were seen in the anterior ventral thalamic nucleus. Each of these regions also showed upregulation of opioid receptors in our previous study (Tempel et al., 1984). At least two of the thalamic areas are involved in somatosensory processing, but it is clear that multiple systems are affected. These results suggest that naltrexone-induced upregulation of opioid receptors in a specific brain region can have an impact on functional neural activity in that region, in a quiet, awake animal.

280.27

[^{125}I]β-ENDORPHIN BINDING TO δ AND μ OPIOID RECEPTORS IN NG108-15 AND SK-N-SH CELL MEMBRANES: REGULATION BY GUANINE NUCEOTIDES AND CATIONS D.E. Selley and J.M. Bidlack. Department of Pharmacology, University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642.

The binding of opioid agonists to μ and δ opioid receptors is inhibited by μM concentrations of GTP. However, we have previously shown that the binding of the opioid agonist, [^{125}I]β$_h$-endorphin ([^{125}I]β$_h$-EP), to rat brain membranes is not inhibited by GTP unless monovalent cations are present. In the present study, regulation of [^{125}I]β$_h$-EP binding by guanine nucleotides was examined in membrane preparations of two opioid receptor-containing cell lines, NG108-15 cells, which contain only δ opioid receptors, and SK-N-SH cells, which contain predominantly μ receptors. In the absence of cations, the binding of [^{125}I]β$_h$-EP to NG108-15 cell membranes was not altered by GTP or Gpp(NH)p. However, a significant, concentration-dependent inhibition of [^{125}I]β$_h$-EP binding by GTP was observed in the presence of NaCl, but not LiCl, KCl, $MgCl_2$, $CaCl_2$, or $MnCl_2$. This inhibitory effect was shared by GDP, but not GMP or any of the non-guanine nucleotides tested. [^{125}I]β$_h$-EP binding to SK-N-SH cell membranes was also not altered by GTP in the absence of cations. As with the NG108-15 cells, GTP did inhibit [^{125}I]β$_h$-EP binding to SK-N-SH cell membranes in the presence of NaCl. Experiments are underway to further characterize guanine nucleotide regulation of [^{125}I]β$_h$-EP binding to SK-N-SH cell membranes. [USPHS grants DA05319 and DA03742.]

14 β-BROMOACETAMIDOMORPHINE SPECIFICALLY LABELS MU OPIOID RECEPTORS IN RAT BRAIN. D.K. Frey[1], J.M. Bidlack[1], A. Seyed-Mozaffari[2] and S. Archer[2]. [1]Dept. of Pharmacology, University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642 and [2]Dept. of Chemistry, Rensselaer Polytechnic Institute, Troy, NY 12181.

In the absence of a disulfide reducing agent, 14β-bromoacetamidomorphine (BAM) bound only reversibly to opioid binding sites in rat brain membranes and exhibited binding characteristics similar to those of morphine. However, when membranes were incubated with dithiothreitol (DTT), followed by the addition of BAM, and then extensive washing, BAM bound irreversibly to μ opioid binding sites. The binding of 0.25 nM [^{3}H][D-Ala^2,MePhe^4,Gly-ol^5] enkephalin (DAGO) and 0.8 nM [^{3}H]naloxone was inhibited to a maximum of 90% and 80%, respectively. BAM alkylation of membranes had no effect on the binding of δ and κ opioid ligands. The irreversible inhibition of μ opioid binding was dependent on the concentrations of DTT and BAM. With 20 mM DTT present, an IC_{50} value of 400 nM BAM was obtained for the irreversible inhibition of 0.25 nM [^{3}H]DAGO. The alkylation of the μ opioid binding site with BAM resulted in an apparent decrease in the number of binding sites without a change in affinity of the sites. These studies demonstrate that upon reduction of a specific disulfide bond in the vicinity of the μ binding site, BAM will alkylate this site, resulting in the specific affinity labeling of μ opioid receptors.

PHOTOAFFINITY LABELING OF OPIOID RECEPTORS: REDUCTION OF NON-SPECIFIC BACKGROUND. J.C. SCHAEFFER, E.T. CONSORTI* AND T.M. SCHWAB*. Department of Chemistry, California State University, Northridge, CA 91330.

To investigate the molecular structure of opioid receptors, a potential photoaffinity label, 7α-[N-3-(4-azido-2-nitroanilino)propionyl]aminomethyl-6,14-endo-ethenotetrahydrooripavine, was prepared. Using a ^{3}H-naloxone/rat brain membrane binding assay, this compound exhibited an I_{50} of 0.47nM and totally inhibited specific ^{3}H-naloxone binding at 10nM. A tritiated analog of this label was synthesized and found to associate with rat brain membranes mainly in a non-specific manner; at 10nM only 10% of the total binding could be displaced by a 100-fold excess of unlabeled levallorphan. Octanol/buffer and membrane/buffer partition coefficients of 49 and 58, respectively, suggest that the label partitions into the hydrophobic core of the membranes. In order to decrease non-specific background before photolysis, a variety of mild extraction procedures were studied. Of these, gentle washing with 0.1% Triton X-100 of membranes after equilibration with label was the most effective. This method increased specific binding to 33% of total and increased specific binding/mg membrane protein by 8-fold. Also, several more polar candidate photoaffinity labels were synthesized and found to be potent inhibitors of ^{3}H-naloxone binding. Thus, a combination of Triton X-100 washing and a more polar label may offer the best solution to this problem. Supported by California State University Foundation, Northridge.

CHARACTERIZATION OF SIGMA RECEPTORS ON PC-12 CELLS: PHARMACOLOGICAL DIFFERENCES FROM RAT AND GUINEA PIG BRAIN INDICATE SIGMA RECEPTOR HETEROGENEITY. W.D. Bowen and S.B. Hellewell*. (SPON: R. Church) Div. of Biology and Medicine, Brown University, Providence RI 02912.

Sigma receptors have been shown to be present on the NCB-20 hybrid neurotumor cell line (Largent et al. Eur. J. Pharmacol., 124:183, 1986). We investigated the rat pheochromocytoma (PC-12) cell line for the presence of sigma receptors and compared the receptor characteristics to those of rat and guinea-pig brain. [^{3}H](+)-3-PPP bound to PC-12 cell membranes with K_d= 86 nM and B_{max}= 1539 fmol/mg protein. The corresponding values in rat brain membranes were 90 nM and 563 fmol/mg protein, while those of guinea pig brain membranes were 40 nM and 389 fmol/mg protein. [^{3}H]DTG bound to PC-12 membranes with K_d= 24 nM and B_{max}= 2024 fmol/mg protein. The corresponding values in rat brain were 30 nM and 651 fmol/mg protein. Thus, PC-12 cells contain high affinity binding sites for [^{3}H](+)-3-PPP and [^{3}H]DTG which exhibit parameters similar to those of rat and guinea pig brain. In competition binding studies using 3 nM [^{3}H](+)-3-PPP, unlabelled DTG exhibited nearly equal IC_{50} values in the three tissues (15-20 nM). However, the ability of (+)-benzomorphans to displace [^{3}H](+)-3-PPP differed markedly across tissues. (+)-Pentazocine exhibited IC_{50} values of 1.3, 37, and 1030 nM in guinea pig, rat, and PC-12 tissues, respectively. (+)-SKF 10,047 exhibited values of 70, 529, and >7,000 nM in guinea pig, rat, and PC-12 tissues, respectively. This is in contrast to the NCB-20 cell line where binding affinity of (+)-benzomorphans at sigma receptors was similar to guinea pig brain. These data suggest the existence of sigma receptor subtypes which bind (+)-3-PPP and DTG with similar affinity, but which differ in their affinities for (+)-benzomorphans. These subtypes may exist in varying ratios in different species. The PC-12 cell line possesses a novel sigma receptor with low affinity for (+)-benzomorphans. This cell line may prove useful in further investigations of the role of putative sigma receptor subtypes. (Supported by NIDA Grant #DA03776 and the Dystonia Medical Research Foundation.)

PHOTOLABELLING OF SIGMA RECEPTORS IN GUINEA PIG BRAIN, RAT BRAIN, AND PC-12 CELLS USING [^{3}H]AZIDO-DI-TOLYLGUANIDINE: EVIDENCE FOR RECEPTOR HETEROGENEITY. S.B. Hellewell* and W.D. Bowen. (SPON: R. Patrick) Div. of Biology and Medicine, Brown University, Providence RI 02912.

We have shown that [^{3}H](+)-3-PPP binding sites in guinea-pig brain, rat brain, and PC-12 cells have nearly equal affinity for DTG but differ markedly in affinity for the (+)-benzomorphans, (+)-pentazocine and (+)-SKF 10,047 (see abstract, this meeting). This suggests either species differences in sigma receptors or the existence of multiple sigma receptor types. Kavanaugh et al. (Proc. Natl. Acad. Sci. USA 85:2844, 1988) have demonstrated specific labelling of a 29 kDa sigma receptor polypeptide in guinea pig brain membranes using the photoaffinity probe [^{3}H]azido-di-tolylguanidine ([^{3}H]Az-DTG). Possible molecular heterogeneity in sigma receptors from these three sources was investigated using this probe.

Membranes from guinea pig brain, rat brain, and PC-12 cells were incubated with 10 nM [^{3}H]Az-DTG. After rapid centrifugal washing and resuspension in fresh buffer, the membranes were irradiated for 5 min with ultraviolet light of 254 nm. Membranes were then solubilized and subjected to SDS polyacrylamide gel electrophoresis. Radiolabelled proteins were visualized by fluorography. Labelling in presence of 1 μM haloperidol was used to determine specifically labelled bands. In guinea pig brain, a band of 28 kDa was strongly labelled, with a more weakly labelled band at 54 kDa. In rat brain, a band of 32 kDa was strongly labelled, with weakly labelled bands at 15 and 54 kDa. In PC-12 cell membranes, bands of 15 and 32 kDa were strongly labelled, with a more weakly labelled band at 58 kDa. These results indicate that sigma receptors occur in different molecular forms in different species and cell types and further supports the existence of multiple sigma receptor types. We wish to acknowledge Dr. Eckard Weber of Oregon Health Sciences Univ. for supplying [^{3}H]Az-DTG. (Supported by NIDA Grant #DA03776 and the Dystonia Medical Research Foundation.)

280.32

EVIDENCE FOR TWO POPULATIONS OF HALOPERIDOL-SENSITIVE SIGMA BINDING SITES IN GUINEA PIG BRAIN. A. A. REID, R. B. ROTHMAN, C. H. KIM*, A. E. JACOBSON* and K. C. RICE Lab of Clin Sci, NIMH and Section on Drug Design and Syn, Lab of Neurosci, NIDDK, Bethesda, MD 20892.

Benzomorphan opiates produce psychotomimetic effects in man. Binding sites thought to mediate these effects include the phencyclidine (PCP) receptor and the halperidol-sensitive sigma receptor. Ligand binding and autoradiographic studies support the hypothesis that sigma and PCP binding sites are distinct entities.

In order to further characterize the sigma receptor system in guinea pig brain, two sets of binding surfaces were generated, which involved displacement of ^{3}H-1,3,-di(2-tolyl)guanidine (^{3}H-DTG) by DTG, (+)-cyclazocine and (+)-pentazocine. The data from these experiments (134 data points) were pooled and fit to a one site binding model. The sum of squares (SS) was 0.98. When fit to a two site model, the SS decreased to 0.12, which was highly significant ($p<0.001$). The best fit parameter estimates (± SE) indicated the presence of two binding sites for ^{3}H-DTG, with Bmax values of 6780 ± 313 and 4500 ± 212 fmol/mg protein. The Kd's of DTG for the two sites were 191 ± 1.4 and 349 ± 4.8 nM, respectively; the Kd's for (+)-pentazocine were 20 ± 0.2 and 3462 ± 61 nM and for (+)-cyclazocine were 62 ± 0.4 and 6073 ± 92.5 nM, respectively. Pre-incubation of the membranes with di-o-tolyl-guanidine-isothiocyanate (DIGIT), a DTG site directed alkylating agent which does not bind to PCP sites, produced a 61 ± 5 percent decrease in ^{3}H-DTG binding (5 nM). Other studies indicated that drugs that bind to PCP receptors with high affinity such as PCP and TCP did not inhibit ^{3}H-DTG binding at concentrations of 1 uM. Taken collectively, these data demonstrate that ^{3}H-DTG labels two binding sites in a preparation of guinea pig membranes, which are distinguished by the benzomorphan opiates (+)-cyclazocine and (+)-pentazocine, and which are unrelated to the PCP receptor.

280.33

RECEPTOR BINDING PROPERTIES OF THREE WIDELY USED CLINICAL ANALGESICS (*d*-PROPOXYPHENE, MEPERIDINE AND *l*-METHADONE) IN THE GUINEA-PIG BRAIN. K.-Z. Wu* and T.-P. Su (SPON: D. Jasinski). Neuropharmacology Laboratory, NIDA, Addiction Res. Ctr., Baltimore, MD 21224.

d-Propoxyphene (PR; Darvon®), meperidine (MP; Demerol®) and *l*-methadone (MT; Dolophine®) are widely prescribed analgesics in most parts of the world. Nonetheless, a systematic examination of the interactions of these drugs with related receptors has been lacking although fragmented data may be obtained from the literature. This study examined the interactions of PR, MP and MT with *mu*, *delta*, and *kappa* opioid receptors and with *sigma* and phencyclidine (PCP) receptors in guinea-pig brain homogenates. All three drugs appeared to be most potent at *mu* receptors. Ki's for PR, MP and MT at the *mu* receptor were 82, 234 and 5 nM, respectively. The same orders of relative potencies were observed at both *delta* and *kappa* receptors. Ki's of PR at *delta*, *kappa*, *sigma* and PCP receptors were 4x, 17x, 524x and 150x higher, respectively, than its Ki at the *mu* receptor. The respective Ki's were 23x, 19x, 14x and 518x higher than the Ki at the *mu* receptor for MP and 24x, 174x, 328x and 276x higher for MT. Therefore, the analgesic effects of PR may derive from interactions at both *mu* and *delta* receptors and those of MP and MT from interactions mainly at *mu* receptors. MP may have psychotomimetic propensity, as its Ki at the *sigma* receptor is only 14 times its Ki at the *mu* receptor.

CORTICOTROPIN-RELEASING FACTOR (CRF) IS ALTERED IN BRAINS OF RATS EXHIBITING HIGH PREFERENCE FOR ETHANOL. C.A. Naranjo, S.R. George, T. Fan* and L. Roldan*. Departments of Medicine and Pharmacology, University of Toronto, Toronto, ONT M5S 1A8 Canada.

Adult male rats were offered tap water and ethanol solution in a 2 bottle free choice paradigm. Ethanol concentrations during the preference acquisition period were increased sequentially to 6% at 4 day intervals. Rats were classified as having low preference if alcohol consumption was < 35% of fluid intake, moderate preference if consumption was between 35-50% and high preference if > 50%. A control group of animals were maintained on water alone. Animals were singly housed in an environmental room with a 12 hr light-dark cycle, were handled daily and had the position of the 2 drinking tubes reversed daily to prevent position bias. Rats were sacrificed by decapitation and brain regions assayed for CRF immunoreactivity with a RIA specific for rat CRF. Rats with high preference for ethanol had significantly lower CRF concentrations in medulla-pons compared to controls ($p=0.035$), and higher levels of CRF in hypothalamus outside of median eminence ($p=0.018$), whereas levels in median eminence did not differ. CRF concentrations in the neurointermediate pituitary of all rats given ethanol were higher than in controls ($p=0.035$) regardless of preference. No changes of CRF content were evident in frontal cortex, hippocampus, midbrain or cerebellum. These results suggest significant interactions of certain brain CRF systems in promoting ethanol consumption or mediating its consequences.

281.2

ETHANOL EFFECTS ON NMDA MODULATED PHOSPHOINOSITIDE HYDROLYSIS IN RAT CORTEX. R.A. Gonzales and L.D. Minor. Dept. of Pharmacology, LSU Med. Ctr., New Orleans, LA 70112.

The interaction of NMDA type glutamate receptors with muscarinic and α_1-adrenergic receptor mediated phosphoinositide (PI) hydrolysis was investigated. Rat cortical slices were labelled with [^{3}H]inositol, and the accumulation of [^{3}H]inositol phosphates in the presence of 8 mM LiCl was determined. Glutamate (GLUT) (1-10 mM) stimulated PI hydrolysis in a concentration-dependent manner, but did not alter the responses to 1 mM carbachol (CARB) or 10 µM norepinephrine (NE). NMDA inhibited the CARB-stimulated PI response with an IC50 of 10 µM and maximal (70%) inhibition at 100 µM. The inhibitory effect of 100 µM NMDA on CARB-stimulated PI hydrolysis was blocked by 1 mM 2-amino-5-phosphonovalerate (AP5). NMDA (0.3-3 mM) potentiated the NE-stimulated response in a concentration related manner, and this effect was not blocked by 1 mM AP5. Ethanol in vitro (100-500 mM) did not alter the PI response to CARB alone or NMDA + CARB. However, in vitro addition of ethanol (100-500 mM) inhibited PI hydrolysis stimulated by 10 µM NE alone or NE+NMDA (1 mM). The results suggest that NMDA type GLUT receptors can modulate receptor coupled PI hydrolysis positively or negatively depending on the receptor which is coupled. Ethanol's actions on NMDA modulated PI hydrolysis are also dependent on the type of receptor which mediates the PI response. (Supported by NIAAA grant 07297 and the ABMRF.)

281.3

EFFECT OF ETHANOL ON PHOSPHORYLATION OF SYNAPTOSOMAL (Na+K)-ATPase. PM Wixom and AY Sun (SPON: V St. Omer). Sinclair Comp. Med. Res. Farm and Biochem. Dept., Univ. of MO, Columbia, MO 65203

Ethanol is known to inhibit neural membrane-bound (Na+K)-ATPase, due to the hydrophobic interaction of alcohol with membrane components. When synaptic plasma membranes (SPM) were incubated with [^{32}P]-ATP, a 96 kDa protein was phosphorylated as revealed by SDS-gel electrophoresis and autoradiography. The phosphorylated protein was dephosphorylated upon the addition of 20 mM KCl and was sensitive to ouabain. In the absence of K^+, the phosphorylation of the 96 kDa protein was enhanced by ethanol, possibly by the exposure of additional active sites on the (Na+K)ATPase. Also, the dephosphorylation step upon the addition of K^+ was blocked by ethanol in a concentration-dependent manner. The transmembrane conformational changes accompanying dephosphorylation may be sensitive to the alteration of the microenvironment by ethanol. Thus, ethanol exhibits a biphasic mode of action upon the intermediate steps of synaptosomal (Na+K)-ATPase, exposing more active sites and simultaneously blocking the transmembrane process, resulting in activity changes as demonstrated earlier in our laboratory. (Supported in part by NIH grant AA02054.)

281.4

REGULATION OF NEURONAL GENE EXPRESSION BY ETHANOL. M. F. Miles. Dept. of Neurology and the Ernest Gallo Research Center, U.C.S.F., San Francisco, CA 94110.

The acute/chronic effects of ethanol on neuronal gene expression were investigated using the NG108-15 neuroblastoma-glioma hybrid cell line. In vitro translation coupled with 2-D gel electrophoresis identified prominent increases and decreases in the amount of specific mRNAs with ethanol treatment. Several mRNA species appeared only in the ethanol treated cells.

Northern blot analysis with certain marker genes showed that lactate dehydrogenase (LDH) M-type mRNA decreased in reponse to chronic ethanol while the heat shock cognate gene, Hsc-70 was a member of the induced class of ethanol responsive genes (ERGs). These changes were more prominent with isomolar amounts of increasing chain length aliphatic alcohols. This suggests that the membrane "destabilizing" effects of ethanol are causal in these alterations of gene expression.

These results indicate that ethanol produces prominent and complex alterations in neuronal gene expression that may play a role in the development of the tolerant/dependent phenotype. Further characterization of ERGs and mechanistic studies will be presented.

281.5

INCREASE IN NUMBER AND K_d OF MUSCARINIC CHOLINERGIC RECEPTORS IN HIPPOCAMPUS OF ADULT RATS EXPOSED TO ALCOHOL DURING THE BRAIN GROWTH SPURT. S.J. Kelly, A.C. Black, Jr., and J.R. West. Dept. of Anatomy, University of Iowa, Iowa City, IA 52242 and Dept. of Basic Sciences, Mercer University School of Medicine, Macon, GA 31207.

Since rats exposed to cyclic blood alcohol concentrations (BACs) with high peaks but not rats exposed to stable, moderate BACs during the brain growth spurt have been shown to be impaired on tasks that involve the septohippocampal cholinergic system, we examined the muscarinic cholinergic receptors in the hippocampus of these animals. An artificial rearing procedure was used to expose rats to the different patterns of BACs from postnatal day 4 to 10. Two control groups consisted of rats reared artificially but without alcohol and rats reared normally by dams. In adulthood, the rats were exposed to ether and decapitated. The hippocampi were assayed for muscarinic cholinergic receptors using QNB as the binding ligand. The dissociation constant and number of muscarinic cholinergic receptors in the hippocampus were increased by exposure to cyclic BACs with high peaks but not by exposure to stable, moderate BACs. Thus, changes in the septohippocampal system may underlie some behavioral changes seen in rats exposed to cyclic BACs with high peaks during the brain growth spurt. (Supported by NIAAA Grants AA05523 to J.R.W.and AA07000 to A.C.B.)

281.6

PATERNAL AND MATERNAL ALCOHOL CONSUMPTION INCREASE SUSCEPTIBILITY OF OFFSPRING TO INFECTION. E. Abel, L. Hazlett and R. Berk. Fetal Alcohol Ctr. and Depts. Anat. and Immunol., Wayne State U., Detroit, MI 48201.

Prenatal alcohol exposure is associated with a range of adverse effects ranging from spontaneous abortion and fetal alcohol syndrome at one extreme to subtle functional deficits in the absence of physical effects at the other. Nearly all studies of prenatal alcohol exposure have focussed on maternally-mediated effects. Recently, we have also found paternally-mediated effects and we report one such effect here.

Long-Evans male rats were fed liquid alcohol diets containing 35%, 17.5% or 0% ethanol derived calories (EDC) for a minimum of three weeks. Animals receiving the 17.5% and 0% EDC diets were pairfed to those given the 35% diet. These males were bred to females who were fed these same diets beginning on gestation day 8. The same pairfeeding procedure was used for females. At approximately 50 days of age, offspring were anesthetized with ether and a bacterial cell suspension containing a concentration of $1x10^8$ CFU of Pseudomonas aeruginosa was topically delivered to the surface of the incised corneas. The occular response to infection was macroscopically evaluated "blindly" at 18-24 hours after challenge, and then at every other day through the first week of infection.

After one week, almost all animals exhibited corneal perforation. There was a significant dose-related effect of both maternal ($p< .05$) and paternal ($p< .05$) alcohol exposure such that the higher the alcohol consumption, the earlier the time to perforation. There was no effect of sex of offspring or interaction between maternal and paternal factors (see Table 1).

Table 1

	Fathers			Mothers		
	35%	17.5%	0%	35%	17.5%	0%
Days	5.26	5.41	6.16	5.09	5.41	6.07

These results show that both maternal and paternal alcohol consumption increase susceptibility to infection in offspring. The fact that paternal alcohol consumption increases this risk is surprising and has not been previously reported. However, it supports other findings from our laboratory that such exposure can affect offspring, e.g., decreased locomoter activity.

Supported in part by grant NIAAA P50AA07606, EY02986, EY01935 and Core Vision Grant P30EY04068.

REGIONAL ANALYSIS OF BRAIN CHOLINERGIC ENZYME ACTIVITY IMMEDIATELY FOLLOWING POSTNATAL ALCOHOL TREATMENT OF RAT PUPS. K.E. Light and D.C. Serbus, Center for Addiction Studies, College of Pharmacy, University of Arkansas for Medical Sciences, 4301 West Markham, Little Rock, AR 72205

Male and female rat pups were treated with ethanol (3g/kg/dose) twice daily by intragastric intubation from postnatal day (PN) 1 to 20. Control pups were treated identically by intubation of an equal volume of an isocaloric vehicle solution. On PN21 the rats were sacrificed and their brains were removed, dissected on ice, and frozen for subsequent regional analysis. The four regions involved in this study included: cortex (CX), striatum (ST), hippocampus (HP), and cerebellum (CB). Acetylcholinesterase (AChE) and choline acetyltransferase (CAT) activities were analyzed in aliquots of the S_1-supernatant using spectrophotometric and radioisotopic assays, respectively. AChE activity (micromoles hydrolyzed/ mg protein/hour) and CAT activity (nanomoles formed/mg protein/hour) showed regional differences in control animals with ST showing the greatest activity of both enzymes and CB the least. Pooled across gender, CAT activity was decreased within the CB by ethanol. Although no gender differences were noted between control pups for any of the endpoints measured, females had less AChE activity in the CB following ethanol exposure, when compared to males. Supported by AA06483.

PRENATAL ETHANOL EXPOSURE DELAYS ASTROCYTE DEVELOPMENT: A POSSIBLE MECHANISM FOR FETAL ALCOHOL SYNDROME S.F. Hoff and E. Anton*, Dept. Pharmacology, The Chicago Medical School, North Chicago, IL 60064.

Glial cells play a crucial role in CNS development by promoting neuronal migration, directional growth and survival. However, their contribution to the onset of Fetal Alcohol Syndrome has not been adequately studied. Pregnant Sprague-Dawley rats were fed an ethanol liquid diet throughout gestation. A control group was pairfed the liquid diet without ethanol and a third group was given free access to rat chow and water. At 30 and 60 days postnatal, sagittal sections from the brains of male offspring were stained for astrocytes by the Cajal's gold sublimate method. Astrocytes were counted in the hippocampal CA1 stratum radiatum, the dorsal and ventral dentate molecular layer, and the outer molecular layer of the cerebellar simple and paramedian lobules. The ethanol exposed group demonstrated a significant 17% reduction in the numbers of astrocytes in the hippocampal CA1 region at 30 days postnatal. All groups were at equivalent numbers at 60 days postnatal. Barnes and Walker (Dev. Br. Res. 1:333, 1981) previously reported a permanent loss of CA1 pyramidal neurons after prenatal ethanol exposure. Ethanol-induced deficits in astrocyte development and function may be responsible for the neuronal loss in the hippocampus and perhaps in other areas of the CNS. (Supported by NIAAA grant AA06156 to SFH)

281.9

HIGH AFFINITY [^{3}H]-OUABAIN BINDING SITES IN VARIOUS REGIONS OF RAT BRAIN AFTER ACUTE AND CHRONIC ETHANOL ADMINISTRATION. E. Voisin-Lestringant*, J. Karanian*, B. Giblin*, C. Gleiter*, M. Linnoila and S. Paul* SPON: P. Hanson. Clinical Neuroscience Branch, National Institute of Mental Health, Laboratory of Clinical Studies, National Institute of Alcohol Abuse and Alcoholism, Bethesda, MD 20892.

Recent evidence suggests that ethanol administration may affect Na^+ K^+ ATPase in rat brain, however the nature of this effect remains controversial. High affinity [^{3}H]-ouabain binding specifically labels the neuronal form of Na^+ K^+ ATPase. We examined the effects of acute and chronic ethanol administration on [^{3}H]-ouabain binding sites in membranes prepared from various brain regions of the rat. Acute ethanol administration (2g/kg i.p.) resulted in a significant increase in [^{3}H]-ouabain binding in brain stem (+56%) and hypothalamus (+45%) ($p<0.01$) but not in the cerebral cortex or cerebellum. Following chronic ethanol administration (rats were exposed to ethanol for 7 days in an inhalation chamber resulting in blood ethanol levels of 194±48 mg%), [^{3}H]-ouabain binding was significantly increased in cerebral cortex (44%), hippocampus (39%), hypothalamus (34%), cerebellum (33%) and brain stem (30%) ($p <0.01$). These data suggest that ethanol administration induces alterations in [^{3}H] ouabain binding to neuronal Na^+ K^+ ATPase which is apparent in some, but not all brain regions.

281.10

EXAMINATION OF HIPPOCAMPAL AREA CA3 IN LONG-SLEEP AND SHORT-SLEEP MICE FOLLOWING 3 MONTHS OF ETHANOL EXPOSURE Jeffrey A. Markham and Eva Fifková, University of Colorado, Boulder, CO 80309-0345.

The ultrastructural morphology of the connection between mossy fibers and dendritic spines in the CA3 region of the hippocampus was examined in long-sleep (LS) and short-sleep (SS) lines of mice following 3 months exposure to an ethanol-containing liquid diet (Bioserv). Ethanol-treated mice consumed an average of 24 gm ethanol/kg body weight/day with no line differences noted. Control mice received an isocaloric liquid diet. Morphological analysis revealed a slightly greater spine area and perimeter in both LS and SS ethanol-treated mice (NS). In addition, the length of synaptic appositions was found to be increased (+10%) in ethanol-treated LS mice compared to controls (NS). SS groups did not differ in this measure. In order to gain insight into the effects of ethanol on individual dendritic spines, we also calculated the percentage of spine membrane occupied by the synaptic density for each spine. Measurements were averaged for each mouse and group. Ethanol was found to have no effect on this measurement. However, the LS mice (both ethanol and control) were found to have a significantly greater percentage of spine membrane occupied by the postsynaptic density ($p<.01$) when compared to SS mice. The overall results show that in contrast to longer exposure times (e.g. Paula-Barbosa et al., *Soc Neurosci Abstr*, 13:75, 1987), 3 months of ethanol-exposure is insufficient to induce changes in the parameters measured in either the ethanol-insensitive SS or ethanol-sensitive LS lines of mice. However, differences in morphology between LS and SS mice may be involved in the differential physiological response of these mice to acute ethanol and other CNS depressants. *Supported by AA06196-04.*

PORTOCAVAL ANASTOMOSIS IN THE RAT: EFFECTS ON CEREBRAL AMMONIA METABOLISM: J.F.Giguère, G. Girard*, R.F. Butterworth. Lab. of Neurochem., André-Viallet Clin. Res. Ctr., Hôpital St-Luc, Montreal, Qué., Canada H3X 3J4.

Construction of a portocaval anastomosis (PCA) in both man and in experimental animals produces sustained hyperammonemia and associated neurological disturbances. In patients, an acute ammonia challenge resulting from gastrointestinal bleeding or protein ingestion results in neurological deterioration leading to coma. Four weeks after PCA, rats exhibit liver atrophy and region-selective increases of brain glutamine and ammonia (320% cerebral cortex, 200% brainstem). Following administration of a coma-inducing dose of ammonium acetate (5.2 mmol/kg i.p.) rats with PCA show a dramatic increase in brain ammonia (4.5 mM cerebral cortex, 3.4 mM brainstem) but further increases of glutamine are restricted to brainstem. The inability of cerebral cortex to remove blood-borne ammonia following PCA undoubtedly accounts for the disproportionately high concentrations of ammonia in this structure. These results suggest that the capacity for brain to remove ammonia is limited following PCA. Such a mechanism may play an important role in the pathogenesis of hepatic encephalopathy associated with portal-systemic shunting. [Supported by MRC (Canada)].

281.12

SELECTIVE CHANGES OF NEUROTRANSMITTER-PRECURSOR AMINO ACIDS IN AUTOPSIED BRAIN TISSUE FROM CIRRHOTIC PATIENTS WITH HEPATIC ENCEPHALOPATHY. J. Lavoie, M. Bergeron*, J.-F. Giguère, G. Pomier Layrargues* and R.F. Butterworth, Lab. of Neurochem., André-Viallet Clin. Res. Ctr., Hôpital St-Luc, Montreal, Que., Canada H2X 3J4.

A substantial body of evidence suggests that alterations of cerebral amino acids play an important role in the pathogenesis of hepatic encephalopathy (HE) associated with chronic liver disease. In order to evaluate this hypothesis, brain tissue was obtained at autopsy from 9 cirrhotic patients dying in hepatic coma and an equal number of age-matched controls. Amino acids were measured as their o-phthalaldehyde derivatives by HPLC with fluorescence detection. The following results were obtained: (i) A 3-fold increase of brain glutamine throughout brain; (ii) Glutamate decreased by 20-30% in cerebral cortex and caudate nuclei; (iii) No change of GABA content; (iv) 2-3 fold increases of phenylalanine and tyrosine in cerebral cortex and caudate nucleus.

Selective changes of neurotransmitter-precursor amino acids (glutamine, phenylalanine, tyrosine) may play an important role in the pathophysiology of HE associated with chronic liver disease. [Supported by MRC (Canada)]

281.13

EFFECT OF ACUTE ETHANOL ADMINISTRATION ON THE BRAIN AND PITUITARY B-ENDORPHIN SYSTEM IN MICE WITH VARIABLE SENSITIVITY TO ETHANOL. J.P. De Waele and C. Gianoulakis. Douglas Hospital Research Center, McGill University, Verdun, Quebec, Canada.

The objective of the present studies was to examine wether acute ethanol treatment has a differential effect on the pituitary and brain B-endorphin systems of three inbred strains of mice. These strains are selectively bred for their high (C57BL/6) or low (DBA/2) ethanol consumption. The content of immunoreactive B-endorphin (irB-EP) in the serum, anterior and neurointermediate lobes of the pituitary gland and 10 distinct regions of the brain as arcuate nucleus, nucleus accumbens, septum etc. was estimated at the resting state as well as 15 minutes after i.p. injection of either ethanol , 3.5g per Kg B.Wt., or saline. Results indicated that ethanol increased the release of B-endorphin from the pituitary gland. Ethanol treatment decreased the content of irB-EP in a number of brain areas as the nucleus accumbens and septum or had no effect as in the preoptic hypothalamic area. In addition, it was noticed that following acute ethanol treatment the content of irB-EP was decreased in the arcuate nucleus of the C57BL/6 mice but not of the DBA/2 or BALB/c mice. Thus the results indicate that there are strain specific differences in the response of the brain B-endorphin system to acute ethanol exposure in vivo.

ETHANOL-INDUCED HYDROLYSIS OF SIALOCONJUGATES IN BRAIN SLICES. J. Mathew* and W. R. Klemm (SPON: B. H. Rohde). Dept. Vet. Anat., Texas A&M U., College Sta., TX 77843

Acute ethanol reportedly decreases total sialic acid (SA) in brain. Here, we evaluated ethanol's effect on hydrolysis of brain and liver sialoconjugates. Mouse tissue slices were pulse labeled with ^{3}H-N-acetyl-D-mannosamine, the precursor of SA. Incorporation was linear for up to 4hr of incubation. When labelled slices were incubated with ethanol, liver SA was significantly affected only at 1M ethanol, while brain SA decreased in a concentration-dependent way. Sialidase activity decreased steadily with increasing concentrations of ethanol, indicating that the elevated hydrolysis was not attributable to enhanced sialidase activity. n-Propanol and t-butanol had the same degradative effect as ethanol; and 3mM pyrazole, an inhibitor of alcohol dehydrogenase (ADH), had no effect on ethanol-induced degradation of labeled SA. The data thus confirm the in vivo reports of ethanol-induced cleavage of SA and suggest that intoxication may be related to brain sialoconjugate hydrolysis as the cause.

ENDOCRINE CONTROL AND DEVELOPMENT III

ANDROGENS REGULATE DENDRITIC GROWTH AND RETRACTION DURING THE DEVELOPMENT OF A SEXUALLY DIMORPHIC RAT SPINAL MOTOR NUCLEUS. L.A. Goldstein, E.M. Kurz, and D.R. Sengelaub. Program in Neural Science, Department of Psychology, Indiana University, Bloomington, IN 47405.

Motoneuron number and size in the sexually dimorphic spinal nucleus of the bulbocavernosus (SNB) of rats are sensitive to androgens which determine their masculine pattern of development. This study demonstrates that SNB dendritic growth during postnatal development is also androgen dependent.

Male rats were castrated at postnatal day (P) 7 or P28 and treated with testosterone [either daily injections of .1mg testosterone propionate (TP) in oil or 45 mm silastic implants of testosterone] or an equal volume (.05ml) of vehicle alone or blank implants. An additional set of males was left intact and untreated. Motoneuron morphology was visualized with unilateral injections of cholera-toxin HRP (.3-.5 µl, .2%) into the bulbocavernosus, an SNB target muscle, at P7, P28, or P49 (n= 3-4 per group). After processing with TMB, dendritic length of all HRP-labeled SNB motoneurons was measured.

At P7, SNB dendritic length in normal males averaged 1463.2 µm per motoneuron. Dendritic length increased five-fold after P7 to an average of 7394.7 µm at P28, and this exuberant growth was then reduced by almost half to adult levels by P49 ($\bar{x}$=3868.6 µm). At P28, TP-treated castrates had a dendritic length similar to that of normal males ($\bar{x}$=7360.9 µm). Oil-treated castrates at P28 had a significantly shorter dendritic length ($\bar{x}$= 1449.2 µm) than that of normal males. At P49, dendritic length in oil-treated males ($\bar{x}$=2278.5 µm) continued to be significantly below that of normal males ($\bar{x}$=3868.6 µm); the early exuberant dendritic length was retained in androgen treated males ($\bar{x}$=6781.1 µm). These results suggest that in addition to regulating motoneuron number and size, androgens also regulate the dendritic growth and retraction of SNB motoneurons during development. Supported by NIH grant NS24877.

ANDROGEN TREATMENT DOES NOT PREVENT THE DEATH OF SEXUALLY DIMORPHIC RAT SPINAL MOTONEURONS FOLLOWING EARLY TARGET REMOVAL. A.R. Cover* and D.R. Sengelaub. Program in Neural Science, Department of Psychology, Indiana University, Bloomington, IN 47405.

In rats, the sexually dimorphic spinal nucleus of the bulbocavernosus (SNB) contains many more motoneurons in adult males than in females. Androgens produce this sex difference by regulating normally occurring motoneuron death during development, and this death is reduced to masculine levels in females treated with testosterone perinatally. Androgens may masculinize the SNB system by acting on the motoneurons or their target musculature, which are also dimorphic and androgen sensitive. We tested if androgens can act at sites other than the musculature by attempting to prevent or delay the death of SNB motoneurons with androgens consequent to muscle removal.

Female pups were masculinized with prenatal injections of testosterone proprionate (TP, 2 mg) from embryonic days (E)16-22. SNB target muscles (the bulbocavernosus and levator ani) were removed surgically on the day of birth [E23=postnatal (P) day 1], pups were cross-fostered, and either continued to receive TP (1 mg) on P1, 3, and 5 or were not treated further. Counts of SNB motoneurons were made prior to surgery at E22 and at P2, 4, and 10 (n=3-7 per group per day) and corrected for split nucleoli. At E22, TP-treated females had a fully masculine number of SNB motoneurons (282). Following muscle removal, SNB motoneuron number declined sharply, and postnatal androgen treatment produced no differences in the magnitude or timing of this loss. By P10, SNB motoneuron number in either group was not different from that of normal females (80-88). Thus, just as the lack of androgens results in muscle degeneration in normal females and a feminine SNB motoneuron death, muscle removal also produces a feminine SNB death. These results suggest that androgens act at, or in concert with, the perineal muscles to masculinize SNB. Supported by NIH grant NS24877.

EVIDENCE OF ANDROGEN RECEPTORS IN NEONATAL MALE PERINEAL MUSCLE. R. Fishman, L. Chism, & S.M. Breedlove, Dept. Psych., U. of Calif., Berkeley, CA 94720

The sexually dimorphic spinal nucleus of the bulbocavernosus (SNB) innervates the perineal muscles bulbocavernosus (BC) and levator ani (LA) in adult male rats. Neonatal females possess both SNB motoneurons and BC/LA muscles at birth, but in the absence of androgen, these structures degenerate. Previous studies indicate that androgen directly interacts with the BC/LA to spare them, and thereby indirectly preserves SNB cells. To further examine the site of androgen action in masculinizing the SNB system, we assayed for the presence of androgen receptors in both the BC/LA and spinal cord of neonatal male rats.

BC/LA muscles and spinal cords of neonatal castrates were removed, separately incubated with tritiated methyltrienolone (+/- 100-fold cold ligand) for two hours, and assayed for the presence of androgen receptors using a glass fiber filter method. This procedure exploits the tendency of receptors to adhere to glass without compromising steroid binding.

Preliminary results suggest that specific binding occurs at both sites, but binding is approximately 5-fold greater per mg tissue in the muscles than in the spinal cord. It is not yet clear whether spinal levels of receptor binding are physiologically significant and therefore, comparison with Tfm spinal tissue is planned. These results demonstrate that receptors are present in newborn male BC/LA, confirming that androgen may act directly on these muscles to spare them. NIH# NS19790 & Muscular Dystrophy

2-D GEL ANALYSIS OF PROTEINS FROM BULBOCAVERNOSUS MUSCLE OF NEWBORN RATS. Nancy G Forger, G L Firestone, S M Breedlove, Depts. Psychology & Physiology, U. C. Berkeley, CA 94720.

The bulbocavernosus (BC) muscle is present in rats of both sexes at birth, but normally involutes in females during the first week of life. Exposure of females to androgen early in development permanently rescues BC muscles and their innervating motoneurons. We have utilized 2-dimensional gel electrophoresis to characterize and compare the proteins synthesized in the perinatal BC of males and females. BC muscles from 1-2 day old rats were incubated at 37 C_5 for 18-20h in serum-free medium containing 150 uCi ^{35}S-methionine. Equally radioactive aliquots of labeled proteins were separated using isoelectric focusing in the first dimension and SDS polyacrylamide gel electrophoresis in the second.

Autoradiography of the gels revealed that although the BC of newborn females has already undergone substantial involution, protein synthesis is essentially indistinguishable between the sexes. There were no consistent differences in the number or relative abundance of the > 200 proteins resolved. Despite gross morphological sex differences in the BC at birth, the fibers present in the female appear metabolically active and relatively normal. Since the female BC will completely degenerate unless rescued by androgen, it seems inescapable that androgen alters muscle gene expression, either directly or indirectly. We are currently testing whether BC proteins may be transiently induced or repressed by androgen.

282.5

MOTONEURONAL SEXUAL DIMORPHISM IN THE ABSENCE OF SEXUAL FUNCTION. Marianne Leslie, N.G. Forger, S.M. Breedlove, Psychology Dept, U.C. Berkeley, Berkeley CA 94720

The retrodorsolateral nucleus (RDLN) of the lumbo-sacral spinal cord innervates the intrinsic musculature of the foot. Motoneuron number in the RDLN is not sexually dimorphic (Jordan et al, '82), but our pilot study revealed a subtle sex difference in RDLN cell size. We now examine the relationship between RDLN neuron size and the mass of one of its target muscles, the flexor digitorum brevis (FDB). Tissues from gonadectomized (GdX) male, intact male and intact female Sprague-Dawley rats were compared. GdXs were performed at 90 days of age and all animals were sacrificed at 120 days. Spinal cords were frozen-sectioned at 50μ and thionin stained. Mean nuclear and soma areas were determined from camera lucida drawings of 20 RDLN cells from each animal. FDB muscles were removed and weighed.

There was a striking sex difference in FDB mass and RDLN soma and nuclear areas. RDLN size in GdX males was intermediate, while FDB mass was unaffected by castration:

		RDLN		FDB
	N	Soma(μ^2)	Nucleus(μ^2)	Mass(mg)
Intact males	12	1216 ± 31	340 ± 10	62 ± 3
GdX males	9	1140 ± 39	308 ± 10*	65 ± 3
Intact females	11	1083 ± 13**	302 ± 08*	43 ± 2**

(significantly different from intact males, *p<.05, **p<.001)

Such sexual dimorphisms may thus be widespread in rats and not limited to systems involved in sexual behavior.

DENERVATION ELIMINATES TESTOSTERONE'S ANABOLIC EFFECT ON BULBOCAVERNOSUS. M.N. Rand and S.M. Breedlove, Psych. Dept., U.C. Berkeley, Berkeley, CA 94720.

We previously showed that the anabolic effect of androgen on adult male bulbocavernosus and levator ani (BC/LA) muscles occurs at or near the muscle. The present study tested the idea that this effect may be due to direct action of androgen on BC/LA exclusive of motoneuronal innervation.

Adult male rats 60-120 days of age were castrated and implanted with two capsules, one containing testosterone (Sigma) and the other anti-androgen (SCH16423, Schering Corp.). These capsules had a single small diffusible Silastic surface and were sutured on each side of the BC so that the diffusible surface faced the muscle. The branch of the pudendal nerve innervating each BC/LA half was cut. After 30 days the animals were sacrificed and the BC/LA muscles dissected out. The muscles were trimmed, cut in half medially and then weighed without knowledge of their steroid treatment. Muscle half weights were compared using a repeated measures T-test.

There was no uniform effect of steroid treatment on muscle half weights. This is consistent with previous findings of no effect of systemic testosterone treatment on denervated LA -muscle weight in adult male rats (Buresova et al., J. Endocrinol. 54:3, 1972). The dystrophic effect of denervation may preclude testosterone's anabolic effect at or near the BC/LA muscle.

METABOLISM AND NUCLEAR UPTAKE OF [^{3}H]TESTOSTERONE IN THE BRAIN OF THE FETAL MACAQUE. R.W. Bonsall*, H.D. Rees and R.P. Michael. Dept. Psychiatry, Emory Univ. School of Medicine, Georgia Mental Health Inst., 1256 Briarcliff Road NE, Atlanta, GA 30306.

Testosterone is secreted by the fetal testis during gestation and is thought to have organizational effects on the brain. To study the way in which testosterone acts on brain cell nuclei, 3 female and 2 male fetuses (day 122-124 of gestation) were injected with 250 uCi [^{3}H]testosterone via the umbilical vein. After 60 min, a blood sample was taken from the heart, and brain and peripheral tissues were removed and homogenized in ice-cold buffer. Cell nuclei were purified by centrifugation through 2M sucrose and extracted with ether. Extracts were fractionated by reverse phase HPLC and radioctivity was identified by its coelution with internal standard steroids. Concentrations of radioactivity (dpm/mg DNA) were significantly higher (P<0.05) in hypothalamus than in seven other brain regions studied (amygdala, hippocampus, midbrain, cerebellar cortex and 3 samples of cerebral cortex), and a major proportion of this radioactivity (40% in males, 72% in females) coeluted with estradiol. Radioactivity in the form of estradiol was also detected in cell nuclei from the amygdala where it accounted for 33% of the radioactivity extracted. In contrast, radioactivity extracted from cell nuclei from the pituitary gland was largely (64%) in the form of testosterone and that from the male genital tract was largely (84%) in the form of dihydrotestosterone. Results demonstrated that aromatization of testosterone occurs in vivo in the hypothalamus and amygdala at this stage of gestation and indicate that the metabolite binds to receptors in cell nuclei. ANDROGEN REGULATES GAP JUNCTIONS BETWEEN MOTONEURONS IN THE RAT SPINAL CORD. A. Matsumoto, A.P. Arnold, G.A. Zampighi*, and P.E. Micevych. Depts. Anat. and Psychol., Brain Res. Inst., UCLA Los Angeles, CA 90024.

Gap junctions are considered to play an important role in metabolic and electrical coupling between cells. We studied androgenic influence on the occurrence of gap junctions between androgen-sensitive motoneurons in the spinal nucleus of the bulbocavernosus (SNB). Adult male rat (Sprague-Dawley) were castrated and implanted with silastic tubes containing testosterone or nothing under Nembutal anesthesia. Four weeks later, animals were sacrificed and the somata and proximal dendrites of SNB motoneurons were examined by thin section and freeze fracture techniques. Of the gap junctions observed, 45% were somatodendritic, 35% were dendrodendritic, and 20% were somatosomatic. Castration decreased the number and length of gap junctions by 29% and 39% respectively. These values in castrates given testosterone were not significantly different from those in sham castrates. The evidence that the removal of testosterone by castration reduced the number and length of gap junctions, and that these changes were prevented by testosterone treatment suggests that androgen regulates the degree of coupling between SNB motoneurons which may allow for the synchronization of metabolic or electrical activity in the SNB. (supported by NIH grants NS23468 and HD15021).

THYROXINE STIMULATES NEURAL DEVELOPMENT OF THE PERIPHERAL OLFACTORY SYSTEM IN THE CLAWED FROG, XENOPUS LAEVIS. G.D. Burd. Depts. of Anatomy and Molecular & Cellular Biology, University of Arizona, Tucson AZ.

The olfactory nerve in tadpoles at stages 48-50 contains 10,000-15,000 axons, but it has 88,000-130,000 axons at stage 57. I hypothesized that thyroxine might be an important factor controlling the increase in the number of olfactory axons observed after the thyroxine surge at stage 54. To test this hypothesis, I blocked thyroxine synthesis with 1% propylthiouricil (PTU) in one group of tadpoles (stage 48) and implanted small pellets of thyroxine (10% in cholesterol) adjacent to the olfactory nerve in another group (stage 48). PTU-treated tadpoles, sacrificed when their age-matched controls reached stage 57, had 51% fewer olfactory axons than control tadpoles. Thyroxine-treated tadpoles had 10% more axons on the side of the implant. Other tadpoles with thyroxine implants for 7 days received a single I.P. injection of ^{3}H-thymidine (1 μCi) and were processed for autoradiography 3 days later. The olfactory epithelium of the hormone-treated animals contained 9 times more heavily labelled cells and several fold more lightly labelled cells than control tadpoles. These data suggest that thyroxine may increase the number of olfactory receptor cells, and thus axons, by stimulating neurogenesis. Supported by PHS NS25596, the Whitehall Fndn., and NIH-BRSG.

SPECIFIC ^{3}H-VINYLIDENE KAINIC ACID BINDING IS DECREASED IN HIPPOCAMPAL FORMATION OF 31-DAY-OLD HYPOTHYROID RAT. D.D. Savage, C.Y. Montano, S.Razani-Boroujerdi, M.A. Carrasco and L.L. Paxton. Dept. Pharmacol., Univ. New Mexico School of Medicine, Albuquerque, N.M., 87131.

Neonatal hypothyroidism (NH) has a profound effect on the development of the CNS. In rat, the hippocampal formation (HPF) is particularly sensitive to NH. We have previously observed a striking reduction in histochemically detectable HPF mossy fiber zinc, in both dorsal and ventral HPF, after perinatal treatment with propylthiouracil (PTU). ^{3}H-Vinylidene kainic acid (VKA) binds to the kainate-sensitive subtype of glutamate receptor binding site. In the HPF CA_3 region, VKA binding has a similar pattern of distribution as HPF mossy fiber zinc. Given this similarity and the effect of NH on HPF mossy fiber zinc, we examined ^{3}H-VKA binding sites in 31-day-old NH rats.

Timed pregnant Sprague-Dawley rat dams were given water containing either 0.02% PTU or untreated water from Day 18 of gestation until their litters were weaned at 31 days of age. Offspring were then sacrificed and their brains frozen. Serum thyroxine, triiodothyronine, total body weight and brain weight all indicated that the PTU-treated rats were severely hypothyroid. Eight μm sections of dorsal and ventral HPF were collected and processed for *in vitro* ^{3}H-VKA autoradiography.

Compared to the untreated controls, specific ^{3}H-VKA binding was reduced by 43% in the stratum lucidum of ventral HPF of 31-day-old PTU-treated rats. Specific ^{3}H-VKA binding was unchanged in the dorsal HPF. Experiments are in progress to determine whether the decrease in ^{3}H-VKA binding in the ventral HPF of PTU-treated rats is due to a change in the affinity or number of ^{3}H-VKA binding sites. The results indicate that NH affects ventral but not dorsal HPF ^{3}H-VKA binding, a pattern dissimilar to the effects of NH on HPF mossy fiber zinc.

THYROID HORMONES AND GROWTH PLASTICITY OF THE RAT OLFACTORY MUCOSA. M. A. Paternostro* and E. Meisami. Dept. of Physiol., Univ. Illinois, Urbana, IL 61801.

The rat's olfactory mucosa (OM) grows markedly postnatally: between birth to day 25 (weaning) thickness increases by 40% and surface area (SA) by 8x, resulting in about 10x increase in the number of olfactory neurons (ON); another 2x increase in SA of OM occurs between day 25 to 50 and a 1.5x between 50 to 90 days. Thyroid deficiency (HT) retards brain development but its effects on olfactory system is poorly known, although HT patients are hyposmic. The reversible goitrogen propylthiouracil (PTU) was added to the litter's drinking water to inhibit thyroid secretion. Quantitative analysis of OM in HT rats at day 25 (weaning) revealed 40% reduction in SA and 30% in ON number. Basal and supporting cell nos. were proportionally reduced too. OM thickness was however unchanged. OM growth at later ages slowed down markedly in HT rats with no growth in the third month. When HT rats are allowed to recover by receiving PTU-free water, OM growth resumes remarkably so that by day 90, SA deficiency is fully compensated but OM is thinner and neuron number, while markedly increased, is not fully recovered. It is proposed that thyroid hormonal effects on OM growth may in part be mediated via submucosal connective tissue.

SEXUAL DIFFERENTIATION OF LARYNGEAL MUSCLE FIBER TYPE AND TENSION CHARACTERISTICS IN *XENOPUS LAEVIS*. Martha Tobias, Melanie Marin, and Darcy Kelley, Department of Biological Sciences, Columbia University, New York, N.Y. 10027

Male specific vocal behavior of *Xenopus laevis* frogs requires masculinization of the effector organ, the larynx. When the laryngeal nerve is stimulated at male mate call rates, male laryngeal muscle produces rapid tension transients in response to each stimulus pulse. Female laryngeal muscle produces a maintained tension at these rates (Tobias & Kelley, *J. Neurosci.* 1987). Sex differences in tension (transient vs. maintained) reflect the presence of exclusively fast twitch muscle fibers in males and predominantly slow twitch muscle fibers in females (Sassoon et al., *J. Neurosci.* 1987). At metamorphosis the fiber composition of laryngeal muscle is monomorphic and female-like.

In this study we determine when, during postmetamorphic development, fiber type and tension become masculine. The ability of male laryngeal muscle to produce tension transients is highly correlated (r=.87) with larynx weight. At metamorphosis the larynx weighs 0.008 gms; adult male larynx weighs 0.49 gms. Tension produced by male larynges weighing less than 0.05 gms is female-like, while tension produced by male larynges weighing more than 0.18 gms is male-like. Larynges weighing between 0.05 and 0.18 are partially masculinized and highly variable. These data are in good agreement with the fiber composition of laryngeal muscle at these stages. Laryngeal muscle composition is female-like (i.e. primarily slow twitch) at 0.06 gms larynx weight. Above 0.12 gms, laryngeal muscle composition is male-like (i.e. exclusively fast twitch). At larynx weights between 0.06 and 0.12 gms, fiber composition is transitional; there is a gradual decrease in the number of slow twitch fibers. These data suggest that tension characteristics, which are essential for sound production, are controlled by fiber type.

PAIN MODULATION: STRESS AND SENSORY STIMULATION

283.1

DISSOCIATION OF OPIOID AND NONOPIOID FORMS OF ANALGESIA BY ADULT MONOSODIUM GLUTAMATE TREATMENT IN RATS. N.S. Sathaye and R.J. Bodnar. Dept. of Psychol. and Neuropsychol. Doctoral sub-Program, Queens College, CUNY, Flushing, NY 11367.

Neonatal, but not adult administration of monosodium glutamate (MSG) selectively destroys circumventricular organs, especially the medial-basal hypothalamus (MBH). Neonatal MSG attenuates both nonopioid (continuous cold-water swim, CCWS, 2°C, 3.5 min) and morphine (5 mg/kg, SC) analgesia in adult rats. Since adult administration of MSG produces effects opposite to neonatal MSG for ingestive responses, the present study evaluated the effects of adult MSG administration (1-6 g/kg, SC) upon basal nociception on the tail-flick and jump tests as well as CCWS and morphine analgesia. While adult treatment with MSG failed to affect basal nociception, the 6 g/kg dose significantly potentiated CCWS analgesia and significantly decreased morphine analgesia. An osmolarity control (NaCl, 2.37 M) failed to exert effects. MSG (1 g/kg) generally failed to affect either form of analgesia. These data indicate a clear dissociation in opioid and nonopioid forms of analgesia by adult MSG, possibly through excitation of MBH neurons by MSG.

283.2

PRESENTATION OF A CAT PRODUCES INCREASED TAIL FLICK THRESHOLDS IN RATS. A. H. Lichtman and M. S. Fanselow*. Dept. of Psychology, Dartmouth College, Hanover, NH 03755.

Using the formalin test, Lester and Fanselow (Behav. Neurosci.,99:756, 1985) have demonstrated that exposure to a cat produces a naltrexone reversible hypoalgesia in rats. Because much evidence indicates that different neural mechanisms underlie different types of pain, we examined whether exposure to cat would also produce analgesia in the tail flick test.

In Experiment 1, half of the rats were exposed to a cat and the other half of the subjects served as controls. Approximately 2 minutes after presentation of the cat or an equivalent period of time in control animals, 3 consecutive ascending series of tail shock were given until a tail flick was detected. Exposure to a cat significantly elevated the intensity of shock required to elicit a tail flick.

In Experiment 2, subjects were administered either naltrexone (7 mg/kg, ip) or saline and 15 minutes later half of the subject in each group were exposed to a cat, while the other half served as controls. As in Experiment 1, exposure to a cat increased tail flick thresholds, however, naltrexone failed to attenuate this decrease in pain sensitivity. These results suggest that opioid involvement in antinociception produced by the presence of a cat depends on the type of pain test used.

283.3

THE IMPACT OF CHOLINERGIC DRUGS ON MILD SHOCK-INDUCED ANALGESIA PARALLELS THEIR IMPACT ON MEMORY. J. W. Grau and M. W. Meagher. Dept. of Psychology, Texas A & M University, College Station, TX 77843.

We have previously shown that mild shock (3, 0.75 sec, 1.0 mA) elicits a strong analgesia in rats on the tail-flick test. We have suggested that the memory of the aversive event mediates the activation of the analgesic systems in this situation (Grau, J. W., Beh. Neurosci., 101: 272, 1987). If this is true, then cholinergic drugs which influence memory should have a parallel impact on the analgesia observed after mild shock.

To test this, we first assessed the impact of the cholinergic antagonist scopolamine (0, 0.1, 1.0, 10 mg/kg), a drug which others have shown can disrupt memory. We found that scopolamine also disrupts mild shock-induced analgesia. We then tested the impact of the anticholinesterase, physostigmine, a drug which others have reported can enhance memory. We found that a low dose of this drug (0.1 mg/kg) also enhances mild shock-induced analgesia.

Others have suggested that these analgesic effects can only be observed if subjects receive baseline testing prior to the administration of shock (Gower, A.J., & Tricklebank, M.D., Neuropharm., 25: 1161, 1986). We tested this hypothesis and found that mild shock induced a strong analgesia, and a low dose of physostigmine (0.1 mg/kg) potentiated this analgesia, irrespective of whether or not the subjects received baseline testing.

283.4

INTENSE, BUT NOT WEAK, SHOCKS INDUCE A TRANSIENT NONOPIOID, AND A LONG-LASTING OPIOID, ANALGESIA IN SPINAL RATS. M. W. Meagher and J. W. Grau. Dept. of Psychology, Texas A & M University, College Station, TX, 77843.

Elsewhere we have shown that 3 brief (0.75 sec) or 3 long (25 sec) tail-shocks (1 mA) elicit analgesia on the tail-flick test. Here we examined whether these shock schedules directly activate intraspinal analgesic systems by examining the impact of T2 cord transection. We found that spinal transection entirely eliminated both examples of analgesia, which suggests that these analgesias are mediated by supraspinal systems. Since others (Watkins et al., Brain Res., 245: 97, 1982) have suggested that more severe shock schedules elicit a spinally mediated non-opioid analgesia, we then examined whether increasing shock intensity or duration would induce analgesia in spinal rats. We found that increasing the intensity of the three 25 sec shocks from 1 mA to 3 mA induced a strong analgesia, but that increasing the duration of the three 1 mA shocks from 25 sec to 75 sec did not. Since both of these manipulations yielded the same coulometric product, this result suggests that the coulometric hypothesis cannot be used to predict the conditions under which intraspinal analgesic systems are directly activated. Finally, we tested whether the analgesia induced by the three 25 sec 3 mA shocks was opioid mediated. We found that naltrexone (14 mg/kg) had no impact on the analgesia observed 2 and 4 min after shock, but that it totally blocked the analgesia observed at 6, 8 and 10 min post-shock.

283.5

VAGINOCERVICAL STIMULATION SUPPRESSES NOXIOUS SENSORY INPUT AT THE SPINAL CORD; 2-DG AUTORADIOGRAPHIC EVIDENCE. Byron M. Johnson*, Claudia Pott, Allan Siegel, Norman T. Adler, and Barry R. Komisaruk. Inst. Animal Behavior, Rutgers Univ. and Dept. Neurosci., Univ. Med. Dent. N.J., Newark, N.J. 07102, and Dept. Psych., Univ. Penn., Phila. 19104.

Based on 2-DG autoradiography and computerized densitometry, we present evidence that a significant component of vaginocervical stimulation (VS)-produced analgesia occurs at spinal cord level L5 in rats. Four groups were used (n=4/gp): unilateral foot pinch (FP), VS, FP+VS, no stimulation. FP activated ipsilateral laminae 1-2 significantly more (16.7%) than did FP+VS (Mann-Whitney U-test, $p<0.03$, 2-tailed). FP activated ipsilateral laminae 1-2 significantly more than the contralateral laminae 1-2 ($p<0.03$, Wilcoxon test, 1-tailed). The difference between right and left laminae 1-2 in the FP group was significantly greater than either the right-left difference in the control group ($p<0.03$) or in the FP+VS group ($p<0.03$; Mann-Whitney U-tests, 2-tailed). These findings support our hypothesis that VS suppresses responses to noxious stimulation at the spinal afferent level. Support: NIH:1RO1NS22948-02 and GRS5- S06RR08223-04; Rutgers Univ. POST-SURGERY ELECTROCORTICOGRAM (ECoG) ZERO-CROSSING INDEX INCREASE REVEALED FOLLOWING NALOXONE IN THE RAT. Vahn A. Lewis, Univ. of Texas, Dental Branch, Houston, Tx. 77459

Wall (1) has proposed that an behavioral arousal follows injury. The ECoG Zero Crossing Index (ZI) is increased during arousal(2). In another study a trend toward an increased Z index was observed following a surgical procedure(SP). In this study, the effect of a SP on the ZI was assessed in the presence of 10 mg/kg naloxone (NX). 13 Sprague Dawley rats were used. Bipolar ECoG, neck muscle EMG electrodes and intrajugular catheter were implanted. This SP was the experimental treatment. Four hours following surgery the rats were administered NX and 30 minutes of ECoG activity was recorded. Control data was recorded one week following surgery when the rats were administered surgical anesthetics followed 4 hours later by NX. ZI was measured by computer. The surgical rat's ZI was 28% greater than that for control $P=<0.05$. The current report would support the hypothesis that a NX reversible inhibitory factor is present 4 hours post surgery and can act to mask Wall's post injury arousal.

ROLE OF SUBSTANCE P (SP) METABOLISM IN SP-INDUCED DESENSITIZATION IN MICE. O.J. Igwe*, X. Sun* and A.A. Larson. Dept of Veterinary Biology, University of Minnesota, St. Paul, Minnesota 55108.

Intrathecal (i.t.) injection of SP in mice results in a behavioral syndrome characterized by caudally-directed biting and scratching (CBS). This behavior has been postulated to reflect nociception and is produced by injections of as small as 7.5 pmol of SP. Repeated injection of SP at 90 sec intervals has been shown to result in desensitization to the SP-induced CBS (Larson, Pain 33: 367, 1988). Both the SP-P (NK-I) receptor subtype and activation of the endogenous opioid system have been implicated in the induction of SP desensitization. The effects of various peptidase inhibitors [phosphoramidon, SQ20881 and bacitracin] on SP-mediated CBS in mice were examined in order to assess the roles of "enkephalinase", angiotensin converting enzyme and "bacitracin sensitive enzymes" in the behavioral syndrome. The protease inhibitors themselves did not induce CBS at the doses used but significantly increased both the magnitude and the duration of the SP response when coadministered i.t. Protease inhibitors also prevented the development of SP-induced desensitization over the same dosage interval. Coadministration of N-terminal fragments of SP (SP_{1-4}, SP_{1-7} and SP_{1-9}) at doses that did not elicit the CBS response when administered alone, decreased the magnitude of SP-induced CBS. The inhibition was dose-related for SP_{1-7}. Administration of the C-terminal fragment SP_{3-11}, which elicits CBS, did not result in desensitization to CBS after multiple i.t. injections at 1 min intervals. The present results strongly suggest that N-terminal metabolic fragments of SP are involved in the modulation of SP-induced desensitization at the spinal cord level. MODULATION OF SPINAL NOCICEPTIVE TRANSMISSION BY VAGAL AFFERENT STIMULATION (VAS) IN THE RAT. K. Ren, A. Randich and G.F. Gebhart. Departments of Pharmacology and Psychology, University of Iowa, Iowa City, IA 52242.

VAS has been shown to modulate nociceptive behavior. To distinguish between modulation of the sensory event from the motor response to the noxious stimulus, the effect of VAS on responses of dorsal horn neurons to noxious heating of the skin was studied. Unit activity was recorded extracellularly in anesthetized, paralyzed rats. VAS was delivered to the central end of the cut cervical vagus nerve. All units responded to mechanical stimuli and 50°C heating of the skin. Responses of 55% of neurons to noxious heating were facilitated, followed by inhibition, as intensities of VAS increased; 34% of the units were only inhibited and 9% only facilitated. VAS decreased the slope of the stimulus response function (SRF) at intensities inhibiting unit responses to noxious heat, but had no effect on the slope of the SRF at lower, facilitatory intensities of VAS. The apparent latencies for VAS effects were 91 ± 11ms for inhibition and 278 ± 59ms for facilitation. The effects of VAS on spinal unit activity was dissociable from hemodynamic changes produced by VAS. The results establish that vagal input to the CNS has modulatory effects on spinal nociceptive transmission. Differences between VAS-produced facilitatory and inhibitory effects suggest a selective and complex influence of vagal input on central processing of somatosensory information.

COUNTERIRRITATION: INHIBITION OF VISCERAL AND CUTANEOUS NOCICEPTION. T.J.Ness and G.F.Gebhart. Dept. Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

Counterirritation is the phenomenon whereby one noxious stimulus reduces the sensation of pain arising from another noxious stimulus. The present study examined the interactions between visceral and cutaneous nociceptive mechanisms in the rat using colorectal distension (DIST, 40-100 mmHg, 10-40 s), heat (50-60°C) and pinch as noxious stimuli. Pseudaffective reflexes and spinal dorsal horn neuronal responses were evoked by these stimuli. The magnitude of these reflex and neuronal responses was decreased in an intensity-dependent fashion by conditioning noxious stimuli presented elsewhere in the body. Specifically, the following was observed:

(1) Dorsal horn neurons excited by radiant heating of the hindpaw were inhibited by conditioning noxious DIST.

(2) Dorsal horn neurons excited by noxious DIST were inhibited by conditioning noxious heat and pinch.

(3) The tail flick reflex evoked by heating of the tail was inhibited by conditioning noxious DIST.

(4) The visceromotor reflex (contraction of abdominal muscles) evoked by DIST was inhibited by conditioning noxious heat and pinch.

CONVENTIONAL AND ACUPUNCTURE-LIKE TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS) EXCITES SIMILAR TYPES OF PERIPHERAL AFFERENT FIBERS. M.F.Levin and C.W.Y.Chan. School of Physical and Occupational Therapy, McGill University, Montreal, Canada H3G 1Y5.

Two types of TENS, commonly used clinically for pain relief, are: 1) Conventional (conv-) TENS, applied at low intensity and high frequency; and 2) Acupuncture-like (acu-) TENS, applied at high intensity and low frequency. They are alternately reported to excite only large diameter, or large and small diameter, afferent fibers. The purpose of our study was to resolve this controversy by determining which peripheral afferent fiber(s) is(are) activated by the two types of therapeutic TENS.

Seventeen healthy volunteers, aged 19 to 30 years, participated in the study. Two main types of TENS-like stimulation were delivered to the median nerve at the wrist: 1) conv-TENS: single pulses at an intensity of 3 x T = sensory threshold; and 2) two kinds of acu-TENS: single pulses at 0.1 Hz, and trains of 100 Hz pulses at 4 Hz, both delivered at an intensity greater than 3 x T. For averaging purposes, 30 compound action potentials per type of stimulation were recorded with surface electrodes placed over the median nerve in the cubital fossa. Nerve conduction velocities were computed as the distance divided by the time to the peaks of the negative and of the positive waves of the compound action potentials.

Our results showed that the mean conduction velocities of the afferent fibers excited by conv-TENS, single pulse and short train acu-TENS ranged from: 65.4±SD 9.5 to 50.3±5.0, 61.4±5.5 to 46.4±7.4, and 54.8±6.2 to 41.3±5.4 m/sec respectively. In man, large diameter afferent fibers conduct between 80 and 55 m/sec. Thus, conv- and acu-TENS activated similar fiber types, predominantly in the A-beta range. This finding suggested that the pain-relieving effects of these two types of TENS may be mediated by the activation of similar peripheral afferent fibers.

VASOPRESSIN-INDUCED SCRATCHING AND ANTINOCICEPTION. C.L. Thurston, J.G. Campbell*, E. Carstens, and L.R. Watkins. Animal Physiol., U.C. Davis, Davis, CA 95616

Lumbosacral intrathecal (IT) injection of vasopressin (VP) produces antinociception and scratching bouts. These experiments characterize the antinociception and scratching with respect to receptor specificity, interactions with opiates, and possible relationships to convulsant activity. IT injection of a V1-specific VP antagonist (dEt2AVP, 50 ng, gift from Dr. M. Manning) blocked IT VP-induced antinociception and scratching. The opiate antagonists naloxone (1 mg/Kg IP) and naltrexone (10 mg/Kg IP) both attenuated the antinociceptive effects of VP. Naltrexone, but not naloxone, potentiated the scratching bouts. IT injection of morphine (20 ug) tended to potentiate the VP-induced scratching, but the effect was not significant. IT injection of the anticonvulsant valproic acid (5 and 7.5 ul) had no effect on either IT VP-induced antinociception or scratching. To further clarify possible convulsant activity, some rats were injected IT at the high thoracic level with either VP (25 ng), morphine (200 ug), or substance P (40 ug). Convulsant activity induced by these substances would be indicated by motor activity initiated at the dermatome level of drug injection, whereas a sensory effect of the drug would be indicated by scratching directed at the dermatome level of drug injection. Thoracic injection of all 3 drugs induced hindlimb scratching directed more rostrally (face, neck, shoulders, forelimbs, sternum and upper ribs) than lumbosacral injection (flanks and abdomen). These data suggest that IT VP-induced scratching involves activation of V1-like VP receptors, interaction with opiate systems, and probably activation of sensory fibers as opposed to motor convulsions. These data also show that IT VP-induced antinociception is mediated by V1-like VP receptors, at least partially opioid in nature, and does not appear to result from convulsant activity.

BASES OF PHENYLEPHRINE (PHE) ANALGESIA. LR Watkins & CL Thurston. Dept. Animal Physiol., Univ. CA at Davis, Davis, CA 95616.

Acute hypertensive states can produce analgesia, via unknown mechanisms. The purpose of the present study was to define neural & potential hormonal bases of analgesia induced by i.v. infusion of the hypertensive agent PHE. Since PHE can (1) excite baroreceptor afferents to the n. tractus solitarius (NTS), (2) release pituitary ACTH & B-endorphin, & (3) mimic the action of stress-induced (nor)epinephrine release, neural & hormonal pathways are both possible. All rats were implanted with right jugular & left carotid cannulae for PHE infusion & blood pressure/heart rate monitoring, respectively, & were tested ≥ 1 day later in the unanesthetized state using tail flick (TF) as the measure of pain responsivity. TF latencies were recorded prior to PHE, each 5 min of the 26 min PHE infusion & through 50 min post-PHE. Pretreatment with dexamethasone (DEX, 3 mg/kg 16 hr pre-PHE) abolished PHE-analgesia. This DEX dose blocks PHE-induced ACTH (but not B-endorphin) release, suggesting involvement of the pituitary-adrenal axis. However, acute block of all adrenal hormones (via closure at time of testing of pre-implanted adrenal ligatures) did not alter baseline TF latencies & did not block PHE analgesia. Thus PHE analgesia is not due to adrenal hormones. Since PHE induced copious urination only in DEX rats, this suggests that PHE normally releases vasopressin (VP) from the paraventricular hypothalamus (PVH), possibly via the known NTS-PVH link. Since (1) pilot studies suggest that spinal cord dorsolateral funiculus (DLF) lesions block PHE analgesia, (2) PVH sends VP projections to the spinal cord via the DLF, & (3) intrathecal (IT) VP produces analgesia via V1-like VP receptors & partly via opiate receptors, the effects of IT V1 antagonist & naloxone were tested. The V1 VP antagonist, but not naloxone, blocked PHE analgesia. To date, then, these studies suggest that PHE analgesia may be mediated by a baroreceptor-NTS-PVH-DLF pathway leading to VP release at spinal levels. NIH NS20037; V1 antagonist a gift from Dr. M. Manning.

SPATIAL SUMMATION IN HUMAN PAIN PERCEPTION. D.K. Douglass*, E. Carstens and L.R. Watkins (SPON: P.A. Pappone) Dept. Animal Physiology, University of California, Davis, CA 95616.

While spatial summation has been shown electrophysiologically to occur in reflexes involving unmyelinated "pain" fibers, previous psychophysical research has suggested that there is no spatial summation in human pain perception. However, the majority of these psychophysical studies have looked only at pain threshold, or at a single stimulus intensity. The intent of this study is to explore summation over a range of suprathreshold thermal stimuli. Visual analog scales (VAS) were used to rate the sensory and affective components of pain elicited by 45-51°C contact heat applied to the volar forearm with Peltier thermodes (area=0.42cm^2 each). To compare possible summation effects within and between dermatomes, two separate dermatomes were used, one innervated primarily by the musculocutaneous nerve (D1) and one by the medial cutaneous nerve (D2). These nerves enter the spinal column at the sixth cervical and first thoracic vertebral level, respectively. Five trained subjects attended two sessions each. In session 1, one thermode was placed an equal number of times in D1 and D2. In session 2, two thermodes were placed, 5 cm apart, an equal number of times on the same dermatome (D1+D1 or D2+D2) and across dermatomes (D1+D2). Comparisons were made between VAS ratings of pain produced by one vs. two thermodes. Both sensory and affective responses were significantly greater with two thermodes than with one (ANOVA, $p<.005$), with this effect being greater at the higher temperatures. We interpret this as spatial summation of pain, and preliminary data suggest that this summation is greater across dermatomes than within one dermatome. Supported by NIH Grant NS20037 (NINCDS) and UCD Grant D-1554.

EFFECTS OF INTRATHECAL ADENOSINE RECEPTOR AGONISTS ON NOCICEPTIVE, MOTOR AND BLADDER FUNCTION IN THE RAT. M. Sosnowski*, C.W. Stevens and T.L. Yaksh (SPON: P.R. Wilson). Mayo Clinic, Rochester, MN 55905.

We analyzed the effects of intrathecal (IT) adenosine analogues given through chronically implanted IT catheters and antagonists on nociceptive (tail flick: TF; hot plate: HP), motor dysfunction (MD) and bladder function in awake rats. Following IT administration A_1 (CHA and L-PIA) and A_2 (NECA) agonists resulted in dose-dependent increases in HP and TF response latencies, significant MD and blockade of the volume evoked micturition response.

	IT ED_{50} Values (nmol)			
	HP[1]	TF[1]	MD[2]	Bladder Block[2]
NECA	1.0	0.5	5.0	1.5
L-PIA	0.3	0.2	3.0	-
CHA	0.5	1.3	5.0	1.5

[1]mean, n=9-16; [2]lowest dose at which 50% or more of animals affected.

The BP and HR were continuously monitored during injection of 1.5 NM of NECA and 3 nmol of L-PIA. In spite of significant hindlimb paralysis, no significant changes were recorded. Pretreatment with IT caffeine (2 µmol) antagonized the antinociceptive and the motor dysfunction produced by L-PIA (1 nmol and 3 nmol). These data support a possible role of spinal A_1 and A_2 receptors in modulation of thermal nociceptive processing and bladder function, as well as motor outflow. (Supported by grant DA-02110.)

PHARMACOLOGY OF INTRATHECAL STRYCHNINE EVOKED ALLODYNIA: A PROBABLE ROLE OF EXCITATORY AMINO ACIDS IN A MODEL OF CENTRALLY MEDIATED HYPERESTHESIA. T.L. Yaksh and G.J. Harty*. Mayo Clinic, Rochester, MN 55905.

The intrathecal (IT) administration of strychnine (STRY; doses <30 µg/3 µl) results in minimal behavioral changes in the unanesthetized rat. Tactile stimuli applied in the dermatome acted upon by the IT STRY, however, results in prominent vocalization and aggressive behavior (touch evoked agitation; TEA). In the anesthetized rat following IT STRY such tactile stimulation yields marked (>50 mm Hg) increases in MABP. IT administration of doses of µ (morphine; 45 µg) δ (DADL; 30 µg) or α_2 (ST-91; 45 µg) which readily block the nocisponsive behavior evoked by a variety of somatic or visceral stimuli, produced only a mild (<25-35%) reduction in the TEA score evoked by IT STRY. In contrast, agents known to act as excitatory amino acid antagonists resulted in a clear dose dependent reduction in TEA at doses which did not produce significant motor dysfunction. The ordering of activity was: MK-801 > AP5 > kynurenic acid > SKF10047 > ketamine. The hypertensive effects of IT STRY were similarly diminished by IT MK-801. These data suggest that 1) light tactile stimuli can evoke pain-like behavior in the presence of subconvulsive doses of IT STRY; 2) that these effects are refractory to opioid and adrenergic modulatory effects; and 3) that the tactile evoked spinally mediated dysesthesia is mediated by an NMDA class of glutamate receptors. (Supported by grant DA-02110 (TLY).)

EVIDENCE FOR THE INVOLVEMENT OF BOTH THE MU AND DELTA OPIOID RECEPTOR SUBTYPES IN THE ANTINOCICEPTIVE EFFECTS OF OPIATES IN THE VENTROMEDIAL MEDULLA (VMM). N.R.F. Al-Rodhan and T.L. Yaksh. Dept. of Neurologic Surgery, Mayo Clinic, Rochester, MN 55905.

We have examined the effects of several selective opioid ligands following their administration (0.5 µl), through chronically implanted guides placed stereotaxically into the VMM. Antinociception was measured using 1) the hot plate (HP; 52.5°C; baseline latency = 9.7 ± 2.9 sec; 60 sec cutoff) and the thermally evoked tail flick test (TF; baseline latency = 2.8 ± 0.4 sec; 6 sec cutoff). The ordering of agonist potency on the HP and TF was: sufentanil > β-endorphin > PL017 = DPDPE = DSTLE >> meptazinol = U50488H ≈ 0. The antinociceptive effects of all agonists were naloxone-reversible. The irreversible mu-selective non-competitive antagonist β-funaltrexamine (β-FNA; 5 nmol) given at the site 24 hrs in advance produced a significant antagonism of SUF, β-End, PL017, DSTLE but not DPDPE (the most selective delta agonist). These results suggest that in the VMM, both the mu and delta receptors are involved in the antinociceptive effects of opioids to thermal noxious stimuli as measured by the HP and TF tests. These results are in contrast to our previous observations in the PAG where similar experiments suggested the sole involvement of the mu receptor (Al-Rodhan and Yaksh, Soc. Neurosci. Abst. 13:638, 1987). (Supported by the Mayo Fdn.; the King Faisal Specialist Hosp., Saudi Arabia (NRFA); NIH grant NS-16541 (TLY).)

CHOLINERGIC INHIBITION OF A SPINAL NOCICEPTIVE REFLEX IN THE RAT: COMPARISON OF SENSORY AND MOTOR EFFECTS. A.M. Lohof, M.M. Morgan, B. Beilin*, and J.C. Liebeskind. Department of Psychology, UCLA, Los Angeles, CA 90024-1563.

Intrathecally-administered cholinomimetic drugs can produce antinociception. Cholinergic binding sites exist in both the dorsal and ventral horns of the spinal cord, suggesting roles in both sensory and motor functions. Prior studies have not addressed in detail the possible contribution of a motor deficit in the production of nociceptive reflex inhibition. Three experiments were designed to quantify motor function as well as nociceptive reflex inhibition after intrathecal administration of a cholinergic agonist. Rats were anesthetized with pentobarbital and implanted with an intrathecal catheter terminating at the level of the lumbar enlargement. Pain sensitivity was assessed with the tail-flick test. 1) Anesthetized animals received carbachol HCl (5 µg) or artificial CSF in a volume of 10 µl followed by a 5 µl flush; treatment with carbachol produced a pronounced increase in tail-flick latency. This effect was eliminated in animals pretreated with scopolamine (0.5 mg/kg). 2) A group of unanesthetized animals receiving intrathecal carbachol or CSF one day after catheter implantation also showed inhibition of the tail-flick with no apparent motor deficit produced by carbachol. 3) To quantify motor function, a third group was observed in an open field after intrathecal administration of carbachol or CSF. A small decrease in spontaneous motor activity was evident after carbachol treatment. These results indicate that stimulation of spinal cholinergic receptors may alter function in both the dorsal and ventral horns, but it seems unlikely that the inhibition of nociceptive responses is entirely attributable to a motor deficit. (NIH grant NS07628)

283.18

THE TAIL-FLICK REFLEX: INTERACTIONS BETWEEN TESTING SITE, PENTOBARBITAL ANESTHESIA, TRIAL, AND INTER-FLICK-INTERVAL. J.T. Cannon, E.W. Walsh*, D.B. Roat* and R.J. Liskowicz*. Dept. of Psychology, University of Scranton, Scranton, PA 18510-2192.

The tail-flick response to heating is one of the most widely used indices of nociception in rodents. Ness, Jones and Gebhart (Brain Research, 426:169-172, 1987) recently reported that the site of heating caused systematic changes in flick latencies in either pentobarbital anesthetized or spinalized rats.

Here we examined interactions between tail-flick latencies and a number of variables, including site of testing. Forty male, albino rats (350-450g) were studied during the dark phase of a 12-12 hr light-dark cycle. Animals were divided into 4 groups of 10 that received 30 tail-flick trials at 1 or 2 min intervals while awake or anesthetized (pentobarbital, 55 mg/kg, IP, 40-70 min prior to testing). Five tail spots, separated by 2 cm beginning 2 cm from the tail tip, were tested in a random fashion by blocks of 5 with no spot being retested in sequence. The .05 level of significance was used throughout.

A 2 (interval) x 2 (anesthesia) x 5 (testing site) x 6 (trial blocks) ANOVA revealed significant main effects for trial blocks and testing site. There were no significant 2-way interactions. The only significant 3-way interaction was between flick intervals, anesthesia and trial blocks.

Overall, tail-flick latencies decreased across the first 3 trial blocks. The decrease in latencies across trials was greatest in anesthetized animals tested at 2 min intervals. Unexpectedly, our longest flick latencies were obtained at both the most proximal and the most distal tail sites. In contrast, Ness et al. (1987) found that latencies increased across testing sites from distal to proximal.

We agree with the main conclusions of Ness et al.; controls should be incorporated in tail-flick research to eliminate the possibility of confounds due to latency differences that are testing site-dependent and, when possible, testing site should be included as a variable in statistical analyses of tail-flick data.

283.19

THE EFFECT OF PENTOBARBITAL ON GABAERGIC MODULATION OF NOCICEPTIVE THRESHOLD. Edward J. Drower and Donna L. Hammond. CNS Diseases Research, G.D. Searle & Co., Skokie, Illinois 60077

Microinjection of GABA receptor agonists and antagonists in the n. raphe magnus (NRM) and n. reticularis gigantocellularis parsα (NGCpα) produces hyperalgesia and hypoalgesia, respectively, suggesting that these neurons are subject to GABAergic regulation. This study examined the potency of pentobarbital (P) pretreatment on the potency of GABA receptor agonists or antagonists microinjected in the NRM/NGCpα. Rats were injected with P prior to microinjection of either a $GABA_A$ receptor antagonist (bicuculline; BIC, 40 ng) or agonist (THIP; 300 ng) in the NRM/NGCpα. Alterations in nociceptive threshold were determined using the tail flick test. In rats pretreated with 7.5 mg/kg s.c. P, the effects of THIP or BIC on nociceptive threshold were comparable to their effects in untreated rats. Following administration of 50 mg/kg s.c. P, the hypoalgesia produced by microinjection of BIC was augmented as compared to its effect in the unanesthetized rat. This observation is consistent with previous biochemical studies indicating that barbiturates modulate the GABA receptor. It additionally suggests that the tonic inhibition of NRM/NGCpα neurons is enhanced in anesthetized rats.

284.1

INTRATHECAL MORPHINE CAUSES NALOXONE-REVESIBLE SUPPRESSION OF REFLEX RESPONSES TO NOXIOUS AND INNOCUOUS STIMULI IN PATIENTS WITH CHRONIC SPINAL CORD LESIONS. M.C. Wainberg*, R.M. Herman. (SPONS: M.J. Perlow) Catholic Med. Ctr., Manchester, NH 03102; Good Sam. Med. Ctr., Phoenix, AZ 85006.

In normal animal and man, intraspinal morphine (MOR) inhibits reflex motor responses to noxious cutaneous stimulation, but not to innocuous stimulation. Such specificity of action was examined in 8 patients with "spasticity" secondary to complete (3) and incomplete (5) suprasacral spinal cord lesions, each exposed to one or more injections of intrathecal (i.t.) MOR (50-400 μg). Reflex EMG discharges from bilateral proximal and distal lower limb, and striated ano-urethral muscles were elicited by noxious (electrical) and innocuous (brush) cutaneous stimulation of the foot and penis (or clitoris). All stimuli induced widespread discharges in the sphincter, and proximal and distal lower limb muscles, often producing flexor, "mass", motor contractions. At all doses, i.t. MOR suppressed nociceptive and non-nociceptive reflexes; in patients with sensory discrimination of pain and touch, i.t. MOR reduced pain perception while tactile perception was unaltered. Naloxone, i.v. (≥10 μg/kg), readily reversed the actions of i.t. MOR. These results suggest that i.t. MOR acts on opiate receptor sites located in the dorsal horn (sensory: nociceptive reflexes), and in the ventral horn (motor: non-nociceptive reflexes); apparently, the ventral site is released from suprasacral inhibition by spinalization. (Partial Support: Cath. Med. Ctr., Spinal Cord Soc.).

284.2

ROLE OF ADENYLATE CYCLASE IN SPINAL ANTINOCICEPTION PRODUCED BY MORPHINE, NORADRENALINE AND BACLOFEN. D. Nicholson* and J. Sawynok. Dept. Pharmacology, Dalhousie Univ., Halifax, Canada.

Pertussis toxin and agents which increase cyclic AMP levels inhibit opioid effects in cultured spinal cord ganglion explants (Brain Res. 370, 1986, 61; 400, 1987, 185). In vivo pretreatment with pertussis toxin inhibits spinal antinociception by morphine, noradrenaline and baclofen (Eur. J. Pharmacol. 146, 1988, 65). In this study, we examined the effects of forskolin (adenylate cyclase activator) and Ro 201724 (phosphodiesterase inhibitor) on antinociception (tail flick and hot plate tests) in rats implanted with chronic indwelling intrathecal cannulas. Pretreatment with forskolin (10 μg) did not affect or slightly reduced antinociception produced by morphine (5-10 μg), inhibited noradrenaline (5-15 μg) and increased the effect of baclofen (0.8 μg). Pretreatment with Ro 201724 (30 μg) inhibited the action of morphine but did not affect noradrenaline or baclofen. These results provide some in vivo support for inhibition of adenylate cyclase in spinal antinociception produced by morphine and noradrenaline (although their actions do not appear identical) but not by baclofen. (Supported by MRC Canada)

SUFENTANIL, K-AGONIST U-50,488H, AND D-ala[2]-met[5]-ENKEPHALINAMIDE (DAME) INHIBIT SUBSTANCE P RELEASE FROM PRIMARY SENSORY NEURONS. **H. M. Chang,*[1] R.M. Kream,*[2] and G.G. Holz[2]. Dept. Anesthesia, Harvard Medical School, Children's Hospital, Boston, MA[1] and Dept. Anesthesia Research, Tufts University-New England Medical Center, Boston, MA[2].**

Presynaptic inhibition of transmission in nociceptive sensory pathways may result from activation of opioid receptors located on spinal terminations of primary sensory neurons. Specifically, opioids may act to suppress excitation-secretion coupling in sensory nerve terminals, thereby blocking transmitter release at first order synapses in the spinal dorsal horn. The mechanism underlying this phenomenon may be studied *in vitro* using primary cultures of embyonic dorsal root ganglion neurons. In this model system, effects of opioid receptor-specific ligands may be assessed by measuring their affect on the electrically-evoked release of substance P (Holz et al., *J.Neurosci.* 8(2): 463-471). Here, we report that opioid agonists with preferential affinity for μ (sufentanil), κ (U-50,488H), and δ (DAME) receptors inhibit the release of substance P in a high affinity, dose-dependent manner, exhibiting saturability, stereoselectivity, and blockade by specific opioid receptor antagonists.

EFFECTS OF μ OPIOID AND EXCITATORY AMINO ACID (EAA) AGONISTS ON PROJECTION NEURONS IN RAT SPINAL CORD. S. Lei and G. L. Wilcox, Department of Pharmacology, University of Minnesota, Minneapolis, MN 55455.

Electrophysiological studies of EAAs in the spinal cord have suggested their involvement in spinal synaptic excitation. Previous studies in this laboratory have shown that hyperalgesia, biting and scratching induced by intrathecal (i.t.) NMDA was inhibited by extremely low doses of the highly selective μ opioid agonist, DAMGO, and that this action was naloxone-reversible. By contrast, the selective δ opioid agonist DPDPE had no effect. DAMGO, at much higher doses near the toxic threshold, had little effect on Quisqualate (Quis) or Kainate action. Electrophysiological studies in this laboratory have shown selective excitation of nociceptive neurons by NMDA and Quis or the more selective agonist, AMPA. To examine the generality of the DAMGO-NMDA interaction, we tested DAMGO for inhibition of NMDA- and AMPA-induced excitation in further electrophysiological studies.

Extracellular recordings were conducted in rat spinal cord. Rats were anaesthetized with urethane (1.2g/kg, i.p.), paralyzed with gallamine (27mg/kg, i.v.) and artificially ventilated. Laminectomies were performed to expose both the lumbar and cervical enlargements of the spinal cord. The cervical laminectomy allowed antidromic activation of axons ascending in the lateral funiculi of the spinal cord. Eight barreled compound microelectrodes were used to apply drugs iontophoretically and to record from single spinal neurons.

Of a small initial sample, one third of AMPA-excited cells and one third of NMDA-excited cells were inhibited by DAMGO. In one cell, EAA-induced excitation was enhanced by morphine, and this enhancement was not blocked by i.v. injection of naloxone (0.3mg). Preliminary results agree with behavioral studies showing DAMGO to be more selectively inhibitory than morphine. However, they do not support a one-to-one association between NMDA excitation and DAMGO inhibition.

MULTIPLICATIVE INTERACTION BETWEN INTRATHECALLY APPLIED OPIOIDS AND COCAINE INVOLVES δ RECEPTORS. S. C. Roerig*, K. F. Kitto*, S. Lei, and G. L. Wilcox, Department of Pharmacology, University of Minnesota, Minneapolis, MN 55455

Previous studies have suggested that cocaine (i.t.) potentiates spinal morphine antinociception possibly through α_2-adrenergic receptors (Lei and Wilcox, Neurosci Abst. 1987). The present studies were designed to evaluate which opioid receptor types were involved since morphine interacts with both μ and δ receptors. Caudally directed biting and scratching behavior elicited during the first min after i.t. injection of substance P (SP) (10ng) was counted in male mice (ICR, 17-23 g). When co-injected with SP, morphine sulfate (MS), cocaine HCl (Co), the μ agonist DAMGO (Tyr-D-Ala-Gly-NMe-Phe-Gly(ol)) and the δ agonist DPDPE (D-Pen2-D-Pen5-enkephalin) inhibited the response. Opioids were then co-administered with Co in constant dose ratios and interactions were evaluated by isobolographic analysis. ED50 (95% CI) values were:

Drug Alone	Drug Combination
Co-10 (7.9-12) nmol	
MS-5.5 (4,7-6.6) nmol	Co-1.0 (0.9-1.2)nmol+MS-0.9 (0.8-1.1) nmol
DAMGO-0.17 (0.12-0.24) pmol	Co-6.7(6.0-7.6)nmol+DAMGO-0.08(0.07-0.10)pmol
DPDPE-0.62 (0.47-0.85) nmol	Co-0.8(0.6-0.9)nmol+DPDPE-0.04(0.03-0.05)nmol

Interactions between Co and MS and between Co and DPDPE were multiplicative, while the interaction between Co and DAMGO was additive. Thus, it appeared that opioids interact at spinal δ receptors to produce a multiplicative interaction with cocaine (i.t.). These results agree with those previously found for the same opioids co-administered with clonidine (i.t., α_2-adrenergic agonist) using the tail flick antinociceptive test (Roerig and Fujimoto, Fed. Proc. 1988), further supporting the role of spinal δ receptors in the opioid-adrenergic multiplicative interaction.

MORPHINE SUPPRESSES NOXIOUS STIMULATION-EVOKED EXPRESSION OF THE *C-FOS* ONCOGENE IN SPINAL CORD NEURONS. R.W. Presley*, D. Menétrey*, J.D. Levine, and A.I. Basbaum (SPON: H.L. Fields). Depts. of Anesthesia, Anatomy, and Internal Medicine, UCSF, CA 94143.

The *c-fos* oncogene encodes a nuclear protein (Fos) that is associated with the regulation of differentiation in a variety of cell types. In spinal cord neurons, *c-fos* expression is evoked by peripheral noxious stimulation (Hunt et al, *Nature* 328:1987). Here we report on the effect of subcutaneous morphine on *c-fos* expression evoked in a tonic pain model, formalin injection into the hindpaw of rats.

After perfusion with 4% paraformaldehyde, 50 μm frozen sections of lumbar spinal cord were cut and immunostained with a rabbit antiserum directed against the *c-fos* protein. There were no *c-fos*-immunoreactive neurons in the spinal cords of unstimulated rats, either with or without morphine pretreatment. Formalin injection produced maximal *c-fos* activity at the L4-5 levels, and was confined to the side of the cord ipsilateral to the stimulus. After one hour, there was dense labelling of *c-fos* positive neurons in laminae I and II; many fewer cells were found in laminae III, IV, and V. Peak expression of *c-fos* occurred at two hours post-injection with similar dense labelling in Laminae I and II, but also with many cells labelled in laminae V and VII, and some in laminae III, IV, VIII, and X. After subcutaneous morphine (1.0 mg/kg) 30 minutes prior to formalin injection, *c-fos* expression was not significantly different from control. At a dose of 2.5 mg/kg, suppression was only noted in laminae V, VII, VIII, and X; however, morphine (5 or 10 mg/kg) profoundly reduced *c-fos* activity in all laminae. This was most apparent in the deeper laminae, V, VII, VIII, and X, but there was also a substantial reduction in *c-fos* expression in laminae I and II. This effect was naloxone reversible.

These data indicate that, in addition to the expected contribution of superficial dorsal horn neurons, there is a delayed activation and greater morphine susceptibility of deeper dorsal horn and more ventral neurons, which may be important features of "tonic" pain states.

OPIOID RECEPTOR SUBTYPES MEDIATING ANTINOCICEPTION IN THE FORMALIN AND TAIL-IMMERSION TESTS. L.Chen*, F.V.Abbott, Depts of Psychiatry and Pharmacology, McGill Univ. Montreal, PQ, Canada H3A 1A1

The receptor interactions underlying antinociceptive effects of morphine are complex and vary with to the nociceptive test and during the time course due to the presence of an active metabolite (Abbott et al 1986; Abbott & Palmour in press). The present studies used - funaltrexmine (FNA) and naloxonazine (NXINE) to explore antinociceptive mechanisms in the formalin (FN) and tail-immersion (TI) tests. FNA (4 g icv 4h before) blocked morphine in both tests indicating kappa receptor involvement is unlikely. NXINE (1 g icv 4h before) split the morphine time-effect curve into 2 components in the TI test: the late but not the early effects were attenuated. Sufentanyl, like the early component, was unaltered. Morphine-6-glucuronide (M6G) effects were attenuated by NXINE in the TI test. In the FN test NXINE had little effect on either the early or late components of morphine. The data imply 2 distinct mechanisms in the TI test. In the FN test morphine effects are mediated by receptors sensitive to FNA and insensitive to NXINE.

EFFECTS OF THE CHOLECYSTOKININ (CCK) ANTAGONIST, LORGLUMIDE (LGM) ON SPINAL MORPHINE-INDUCED ANTINOCICEPTION AND TOLERANCE. D.E. Kellstein and D.J. Mayer, Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298.

Previous studies in this laboratory demonstrated that acute intrathecal (IT) injection of proglumide, a CCK antagonist, enhanced IT morphine analgesia whereas chronic (22 day) treatment attenuated opioid antinociception (S.N. Abs. 1987, 13, 1592). The present study investigated the effects of IT LGM (Rotta Research Lab.), a more potent analog of proglumide, on IT morphine analgesia and tolerance. Rats were implanted with lumbar IT catheters and allowed one week to recover. Morphine (1 µg, IT) analgesia was assessed weekly with a tail-flick assay during and after 22 days of LGM (7 ng, IT) treatment. On day one, LGM pretreatment reliably ($P<0.01$) enhanced morphine antinociception, but this enhancement was absent on days 8 and 15 and replaced by inhibition ($P<0.05$) of morphine on day 22. After daily LGM injections were terminated, opioid analgesia was unaltered by LGM pretreatment on days 29 and 36. Weekly co-administration of LGM with morphine had similar effects except that attenuation of morphine was not observed. In a separate study, daily IT co-injection of morphine (1 µg) with LGM (70 ng; does not alter morphine acutely) for 6 days prevented induction of opioid tolerance; i.e., analgesia was equivalent to that in non-tolerant rats and reliably ($P<0.01$) greater than in tolerant animals. These results suggest a complex interaction between spinal CCK and opioid systems, since 1) chronic IT injection of LGM (or proglumide), at a dose which enhances IT morphine acutely, inhibits analgesia, whereas 2) IT co-administration of morphine with a dose of LGM which has no acute effect upon morphine analgesia prevents development of tolerance. A ROLE FOR HISTAMINE H_2-RECEPTORS IN MORPHINE ANTINOCICEPTION. K.R. Gogas[1], L.B. Hough[1], M.B. Eberle*[1], R.A. Lyon[1], S.D. Glick[1], S.J. Ward*[2], R.C.Young*[3] and M.E. Parsons*[3]. [1]Dept. of Pharmacology and Toxicology, Albany Medical College, Albany, NY 12208; [2]Dept. of Pharmacology, Sterling Winthrop Research Institute, Rensselaer, NY 12144; [3]Smith, Kline and French Res. Ltd., The Frythe, Welwyn, Hertfordshire, England AL6 9AR.

To test the hypothesis that brain H_2-receptors are involved in the mediation of opiate antinociception, the effect of the first brain-penetrating H_2-antagonist, zolantidine, was determined on several opiate actions in male Sprague-Dawley rats. Zolantidine (s.c.) caused a dose-related inhibition of morphine antinociception in both the tail-flick (ID50=.135 umol/kg, Emax = 87%) and hot plate tests, with no effect on baseline responding. Morphine-induced increases in locomotor activity were also reduced by zolantidine, but no effect was seen on morphine-induced hyperthermia, catalepsy or lethality. Zolantidine (10^{-5}M) did not antagonize mu, delta or kappa agonists in vitro and showed at least 35-fold higher affinity at the H_2-receptor than at serotonergic, adrenergic or dopaminergic binding sites in brain. Furthermore, zolantidine had no effect on morphine brain levels measured by GC-MS methods, indicating the absence of a drug-drug interaction. To further clarify the role of H_2-receptors in zolantidine's anti-opiate activity in vivo, the potencies of 7 structural congeners of zolantidine on the H_2-receptor and on morphine antinociception were determined. Over 3 orders of magnitude, the rank order of potency of the compounds for inhibiting morphine antinociception was highly correlated ($p < .05$) with their potency as H_2-antagonists, suggesting an H_2-receptor involvement in opiate antinociception. DOPAMINERGIC MEDIATION OF D-AMPHETAMINE- AND MORPHINE-INDUCED ANALGESIA IN THE FORMALIN TEST. M.J. MORGAN and K.J.B. FRANKLIN, Dept. of Psychology, McGill University, P.Q., Canada, H3A 1B1.

D-amphetamine induced dose-dependent analgesia in the formalin test. Furthermore, sub-effective doses synergised with sub-effective doses of morphine to produce strong analgesia. Selective depletion of striatal dopamine by intra-VTA administration of 6-OHDA abolished analgesia produced by D-amphetamine or morphine. D-amphetamine analgesia was dose-dependently attenuated by the selective D1 and D2 antagonists SCH 23390 and pimozide, and was eliminated by the mixed antagonist alpha-flupentixol (0.5 mg/kg). Flupentixol also blocked morphine analgesia. Pimozide (0.5 mg/kg) and the high dose of SCH 23390 (0.1 mg/kg) increased the analgesia produced by low doses of morphine (0.75 to 3 mg/kg) and antagonized the effect of higher morphine doses. A low dose of SCH 23390 (0.01 mg/kg) was found to increase the analgesic activity of morphine and morphine-amphetamine mixtures. These data suggest that dopamine, acting at both D1 and D2 receptors, is involved in D-amphetamine- and morphine-induced analgesia in the formalin test.

284.11

DIFFERENTIAL EFFECTS OF POST-NATAL MORPHINE TREATMENT UPON OPIATE, OPIOID-MEDIATED AND NON-OPIOID-MEDIATED ANALGESIA IN ADULT RATS. D. Arjune and R.J. Bodnar. Dept. of Psychol. and Neuropsych. Doctoral Sub-Program , Queens College , CUNY , Flushing , NY 11367.

Post-natal exposure to opiates decreases hot-plate and tail-flick latencies and produces short-term reductions in opiate receptor number. The present study evaluated the effects of post-natal morphine (0 , 1 and 20 ug , SC , Days 1-7) upon subsequent analgesia induced by either morphine (2.5 and 5 mg/kg , SC) or continuous or intermittent cold-water swims (CCWS , ICWS , 2°C , 3.5 min) in adult rats. As established previously , male rats displayed significantly greater analgesic responses than female rats. Post-natal morphine significantly potentiated morphine analgesia in adult females , but slightly decreased these responses in adult male rats. In contrast , post-natal morphine failed to affect CCWS or ICWS analgesia in either gender. These data indicate an important interaction between gonadal steroids and post-natal exposure to opiates in the mediation of opiate , but presumably not non-opioid analgesic responses.

DIFFERENTIAL DEVELOPMENT OF THE ANALGESIC EFFECTS OF FOCAL MORPHINE AND GLUTAMATE ADMINISTRATION TO THE PERIAQUEDUCTAL GREY AREA OF THE RAT. L. A. Tive* and G. A. Barr. Biopsychology Dept., Hunter College of the City University of New York, New York, N.Y., 10021 and Dept. of Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y.

The periaqueductal grey area (PAG) of the midbrain supports both opiate induced analgesia (OA) and stimulation produced analgesia (SPA) in many species including man. The ventral aspect of the PAG mediates SPA and OA that show cross-tolerance to each other and to systemic morphine and are naloxone reversible. The dorsal region of the PAG supports SPA that is neither cross-tolerant with morphine nor naloxone reversible. In this study, SPA and OA supported by the dorsal and ventral PAG were compared in developing rats. Ten day old pups were implanted with cannula aimed at either the dorsal or ventral PAG area. Injections of glutamate were administered to either the dorsal or ventral region in doses of 0, 60, or 180 mM/0.2 µl and subjects were tested for analgesia against noxious thermal and mechanical stimuli applied to the forepaw, hindpaw and tail. Morphine was administered to the ventral PAG in doses of 0, 2, or 6 µg/0.2 µl and analgesia was measured in the same manner. Glutamate injections to the dorsal PAG produced dose dependent analgesia against mechanical but not thermal stimuli. Glutamate administration to the ventral PAG did not produce analgesia against either stimulus type. Morphine administration to the ventral PAG induced robust, dose dependent analgesia against the thermal, but not the mechanical stimulus, that was stronger in the forepaw and hindpaw than in the tail. These results indicate that the SPA and OA supported by the ventral PAG area can be distingushed developmentally despite their pharmacological similarities in the adult. These two types of analgesia may be mediated by concurrent, rather than identical, spinopetal neuronal systems. The SPA supported by the dorsal and ventral aspects of the PAG can also be distinguished by their ontogeny indicating that they may be subserved by distinct neuroanatomical substrates.

TEMPORAL CHARACTERISTICS OF EXPLORATORY FINGER MOVEMENTS AND ACTIVATION OF MECHANORECEPTORS. E.Kunesch*, F.Binkofski*, H.-J.Freund. Dept. of Neurology, University of Düsseldorf, FRG

Little is known about the discharge patterns of skin mechanoreceptors (MRs) during exploratory finger movements. We recorded from single afferent nerve fibers innervating low threshold MRs of the finger pads during natural exploratory finger movements which were consistently performed at frequencies between 0.5–2 Hz. The velocity profiles of these movements along one single scan path were bell-shaped. When the object passed the receptive field of a slow (SA I, SA II) or fast (FA I, FA II) adapting unit, a discharge burst was elicited. Discharge rate within the burst increased with movement velocity.

Passive touch experiments in monkeys have shown that the spatial characteristics of grated surfaces are encoded in the population response rather than in the firing characteristics of single MRs (Darian-Smith I. et al., J.Physiol. 309:117,1980). We calculated the sequential activation of FA I MRs on the basis of their density distribution and movement velocity during natural exploratory movements. The maximal number of sequential receptor hits approximated 700/s. The limitation of exploratory finger movements during active touch to serial scan frequencies below 2 Hz may indicate that the central demodulator neurones cannot resolve higher sequential sampling rates.

SLOWLY ADAPTING TYPE I MECHANORECEPTOR DISCHARGE AS A FUNCTION OF DYNAMIC FORCE VERSUS DYNAMIC DISPLACEMENT STIMULATION OF GLABROUS SKIN OF RACCOON AND SQUIRREL MONKEY HAND. Benjamin H. Pubols Jr. The Robert S. Dow Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209.

The discharge rate of slowly adapting Type I (SAI) mechanoreceptive afferent fibers has been shown to be adequately described as a power function of displacement velocity (dynamic displacement) over a wide range of values (Pubols and Pubols, 1983). Apparently, the effect of rate of change in force (dynamic force) on dynamic discharge of glabrous skin mechanoreceptors has not been investigated in any mammalian species.

In 10 raccoon SAI units and 8 squirrel monkey SAI units, the effects of dynamic force and dynamic displacement on discharge rate during ramp stimulation were compared. In all 18 cases, power function exponents, b, were higher for the effect of displacement ramp velocity (range = .39-.70) than for the effect of dynamic force (range = .09-.59) on ramp discharge frequency. Thus, these SAI mechanoreceptors are more sensitive to variations in displacement velocity than to variations in dynamic force.

A possible explanation lies in the fact that the relationship between dynamic force and dynamic displacement is, itself, nonlinear, dynamic displacement being a power function of dynamic force, with values of $b < 1.0$. (Support: NS-19487, USPHS.)

STIMULUS INTEGRATION IN CUTANEOUS RECEPTIVE FIELDS. E.P. Gardner and C.I. Palmer. Dept. of Physiology, NYU Sch. Med., NY, NY 10016.

RA afferents innervate clusters of Meissner's corpuscles, showing 12-17 points of high sensitivity within their receptive fields (RFs). Pacinian corpuscles (PCs) also integrate information from a wide skin area. In order to determine whether RAs and PCs summate inputs from multiple sites within their RFs, we used the OPTACON (144 miniature probes arranged in a 6 column x 24 row matrix) to vary the density of tactile stimuli to the glabrous skin of the macaque monkey's hand. A four ms pulse was applied simultaneously to the central four columns of single rows, or to groups of 2-5 rows spanning 4.4 mm on the skin. Active rows were shifted in 1.1 mm steps across the OPTACON at 10, 20 or 40 ms interpulse intervals.

75% of RAs fired one spike/pulse to single rows, yielding uniform sensitivity in the RF, while PC responses peak at the center. Neither RAs nor PCs summate inputs from multiple stimulation sites. Simultaneous activation of 2-5 rows evokes the same or fewer spikes per pulse than the most effective individual row tested alone. Primate RAs and PCs thus follow activity in the dominant branch or terminus, suppressing additional inputs. Moving patterns evoke responses as long as at least one row stimulates the RF; broader patterns evoke longer spike trains. Suppression of activity was observed only at 100 Hz pulse rates using broad bars. Simultaneous activation of 5 adjacent rows at 100 Hz suppressed responses to the last 1 or 2 rows in 8 of 16 RAs, and 10 of 13 PCs. All RAs and 11 of 13 PCs responded to the entire set of 5 rows at 50 Hz, corresponding to a lateral speed of 55 mm/s. Recovery from stimulation of adjacent receptors is rapid, and nearly complete at intervals as short as 10 ms, allowing RAs and PCs to encode stimulus width by their duration of firing.

Multiple spike responses showed similar recovery cycles. Eight of 24 RAs responded with two spikes to OPTACON pulses to the RF center when tested with widely spaced single row patterns, or the leading edge of a multiple row array. Double spikes were reduced to one when 5 active rows in the RF were spaced 1 mm apart, at all Hz, suggesting that skin mechanics rather than receptor adaptation attenuate activity. Uniform sensitivity, short recovery cycles, and selection of a dominant branch, allow RAs to transmit information concerning maximum rate of curvature change from a wide skin area. As a stimulus shifts across the RF, this most salient stimulus feature is transmitted repetitively by each RA at the expense of fine grain localization. *(Supported by USPHS Research Grant NS11862.)*

TEMPORAL SUMMATION IN VIBROTACTION IS NOT PERIPHERALLY MEDIATED. C.M. Checkosky* and S.J. Bolanowski, Jr. (SPON: R Verrillo). Dept. Physiol., Univ. Rochester Med. School, Rochester, N.Y. 14642.

Temporal summation refers to the psychophysical phenomenon in which increases in stimulus duration produce decreases in the stimulus amplitude required for threshold detection. For bursts of sinusoidal stimuli having durations from 10–300 msec, the effect in both audition and vibrotaction produces a 5.3-fold increase in sensitivity, requiring a -3dB change in sensitivity per doubling of duration. For audition, the effect is centrally located, as shown for binaural-stimulus conditions, but no experiments have assessed the locus of the effect for vibrotaction. Vibrotactile thresholds mediated by the Pacinian-corpuscle (PC) fiber population in skin exhibit temporal summation. If the phenomenon is peripherally located, then activity recorded from individual PCs should show the -3dB/doubling effect. PCs isolated from cat mesentery were stimulated with sinusoidal displacement bursts of different durations and the intensity of the stimulus adjusted for a fixed criterion response of 1 impulse/burst. The average decrease for increases in stimulus duration was only -1dB/doubling of duration. The result indicates that temporal summation is not a property of PC fibers but that, as for audition, the process probably occurs centrally. The slight effect that did occur may be statistical in nature, in that longer durations may provide for greater probability that an impulse will occur. Support by NS23933

EFFECTS OF STATIC INDENTATION ON THE PACINIAN-CORPUSCLE RECEPTOR POTENTIAL. S.J.Bolanowski, Jr. and C.M.Checkosky* Dept. Physiol., Univ. Rochester Med. Sch., Roch., NY 14642

The receptor-potential (RP) of cat Pacinian corpuscles (PC) in response to sinusoidal displacements exhibit asymmetric, full-wave rectification. Furthermore, there are apparently two populations of PC types, one more sensitive to stimulus compression, the other to stimulus withdrawal. Based on these findings, we have proposed the presence of two groups of neural elements within each PC, the neural elements producing half-wave rectification with the two groups in polarity opposition. The RP is thus dependent upon the relative contribution to it from the two groups. If true, then changes in the RP should occur with selective deactivation of one group of elements. We have assessed this by varying the static indentation of the vibrating probe, noting that small static indentations should permit only the most sensitive group of elements to be excited, revealing a half-wave rectified RP. Increasing indentations should then produce concomitant changes in the RP shape as the other group becomes more active, eventually resulting in a full-wave rectified RP. The experiments show that changes in static indentation do indeed produce changes in the RP shape. The effect, however, is not half-wave to full-wave, but considerably more complicated. The results indicate that while the two-group hypothesis may still be correct, the transductive mechanism in each element does not half-wave rectify but more likely produces some degree of full-wave rectification. Supported by NS 23933.

CENTRAL PROJECTIONS OF DEEP AND SUPERFICIAL VIBRISSAL NERVES IN RAT MYSTACIAL PAD. E.L.Rice, J.Arvidsson, K. Johansson*, and H.Aldskogius. (SPON: R. Oesterreich) Anatomy Dept., Albany Medical College, Albany, NY 12208; Anatomy Dept., Karolinska Institute, Stockholm, Sweden

Each vibrissal follicle-sinus complex (F-SC) in the rat mystacial pad is innervated by a single, large deep vibrissal nerve (DVN) and several, small superficial vibrissal nerves (SVN's). DVN's and SVN's supply a similar variety of sensory endings, but differ in their distribution within each F-SC (Rice et al., JCN 252:154: 1986). Thus, DVN's and SVN's may have different functions and central projections. In 52 adult rats, HRP was applied to various combinations of isolated, transected DVN's (Arvidsson, JCN 211:84, 1982) or SVN's, or WGA-HRP was selectively applied to intact sites of SVN innervation. The distribution of TMB-revealed label differed in all the trigeminal nuclei, especially in the laminated portion of nucleus caudalis (L-NC). Label from a DVN formed a continuous column that angles from deep lamina III in rostral L-NC to lamina V in caudal L-NC. The somatotopic organization of the DVN's is in the transverse plane. Label of SVN's from each F-SC formed discreet loci in lamina I and in deep lamina II and superficial lamina III at a mid-level in L-NC. SVN somatotopic organization is in a longitudinal plane with only the dorso-ventral axis in register with the DVN organization. (Support: Swedish Medical Research Council)

TRIGEMINAL AFFERENT PROJECTIONS IN A DIVER, THE MUSKRAT

S. DeLisa Jarrell* and S.O.E. Ebbesson (SPON: D. Feist) Insts. Arctic Biol. and Mar. Sci., Univ. Alaska Fairbanks, Fairbanks, AK 99775

The diving response (DR) comprises reflex apnea, bradycardia and peripheral and visceral vasoconstriction, conserving oxygen for the brain and heart while maintaining central blood pressure. It is exhibited by aquatic representatives of all the vertebrate classes, and appears related to protective responses elicited under a variety of other conditions. It has been described as an "external narial reflex" in muskrats, triggered by wetting the nares and blocked by coating them with vaseline. Similar but less intense responses can be elicited in anesthetized muskrats by stimulation of the soft palate (SP) or anterior larynx (AL). In a preliminary search for connections that may be involved in mediating the DR, we have traced neural projections from the nares, SP and AL in muskrats. This report concerns projections to the sensory trigeminal complex.

Muskrats (*Ondatra zibethicus*) were injected with horseradish peroxidase (HRP) or wheatgerm agglutinin-HRP under halothane anesthesia, and transcardially perfused with fixative 24-48 h later under deep pentobarbital sodium anesthesia. Serial sections of frozen brains were thawed onto slides, and sets at intervals of 100 µm were reacted for HRP using tetramethylbenzidine; adjacent sets were Nissl stained. Projections from the nares included: dense, extensive terminals in marginal and gelatinous layers and sparse terminals in magnocellular layer of caudal spinal trigeminal subnucleus (Sp5C); paratrigeminal nucleus (Pa5); interpolar (Sp5I) and oral (Sp5O) subnuclei (with processes of labeled facial nerve cells extending into Sp5O); and principal trigeminal nucleus (Pr5). Projections from SP to Sp5C were sparse and restricted to the dorsal margin at lower levels; Sp5I, Sp5O and Pr5 received moderate, diffuse projections, whereas Pa5 was heavily labeled. AL injections produced labeling of Pa5, Sp5I, Sp5O and Pr5. In addition, projections from the nares were traced in feral Norway rats with results similar to those for muskrats except that Pa5 was not labeled.

NON-INVASIVE APPROACH TO 3 - DIMENSIONAL MAPPING OF THE HUMAN SOMATOSENSORY CORTEX. L. Narici°, L. Modena°*, V. Pizzella*, G.L. Romani&, P.M. Rossini#*, G. Torrioli*, Istituto di Elettronica dello Stato Solido, CNR Roma, Italy.

We show the results of a series of totally non-invasive neuromagnetic measurements on healthy human subjects aimed at resolving different cortical sensory areas activated by somatosensory stimulations of different body parts (wrist, elbow, ankle, etc.). The localizations of these areas agree well with the known somatosensory homunculus, which has been mapped in the past by a series of very invasive measurements. A few neuromagnetic localizations of sensory areas activated by periferal nerve stimulations have been reported previously, here we show that the entire homunculus can be reconstruct via non-invasive measurements.

Whenever the measured field presents a dipolar structure, the same technique permits to follow, non invasively, in three dimensions, the successive activation of different cortical areas following the presentation of the sensory stimulation. The time resolution is limited by the acquisition bandwith, and in the cases presented here, is of the order of 1 ms. The spatial resolution, limited by the external noise, is about 5 mm. The fitting routine gives the position, direction and strength of the equivalent dipole generating the measured field.

The presented results enphasize the usefulness of the neuromagnetic technique as a powerful tool aimed at studying non-invasively, the brain functional behaviour.

DIFFERENT CONTRIBUTION OF SI AND SII CORTICES TO SCALP-RECORDED SEPs IN MAN. H.Hämäläinen, J.Kekoni*, K.Reinikainen*, R.Näätänen*, M.Sams*, and M.Hämäläinen*. Dept. Psychol., Univ. Helsinki, and Low Temp. Lab., Helsinki Univ. Technol., Finland.

Somatosensory evoked potentials were measured to tactile pulses and vibration applied to the fingertip in order to determine the scalp topography of different SEP components.

The first distinct contralateral response was an anteriorly negative and posteriorly positive peak at about 50-ms latency. On the ipsilateral side, no polarity reversal was seen. The isopotential field analysis revealed that at this latency a clearly dipolar electrical field pattern was located on the contralateral hemisphere. Similar pattern could be produced by fitting a dipole at the contralateral SI somatosensory area. Therefore this early response is probably generated by activation of the contralateral SI cortex, and the responses seen ipsilaterally are due to volume conduction.

The early response was followed by a negative (N70) deflection and by a bilateral positive (P100) peak. The isopotential field analysis revealed that N70 cannot be explained by a single contralateral generator, but rather by several which might be bilateral. Furthermore, the isopotential field pattern at the latency of P100 was best accounted for by generators placed bilaterally at the approximated sites of SII cortices.

MANY-NEURON RECORDINGS DEFINE SYNCHRONOUS ACTIVITY AND BEHAVIORAL GATING IN THALAMIC AND CORTICAL NETWORKS. J.K. Chapin, H.-C. Shin, and I.M. Patel, Dept. Physiology, Hahnemann U., Philadelphia, PA 19102

As part of an effort to define neural circuit bases for higher order somatic sensory processing we have developed a technique for simultaneous recording and discrimination of up to 12 single neurons in awake, behaving rats. For this, arrays of 25µ microwires were chronically implanted in the forepaw subregions of the somatosensory (SI) cortex and/or VPL thalamus. Sensory responses of these neurons could be tested by stimulating through electrodes chronically implanted in the forepaw. Previously we had shown that sensory transmission to SI and VPL neurons is gated according to phase of the forelimb step cycle. Here we found that several different temporal patterns of gating exist among the simultaneously recorded neurons, demonstrating that sensory inputs are dynamically routed along different paths through thalamic and cortical networks according to the phase of limb movement. Another use of this technique was to construct spike-triggered histograms to cross-correlate the activity of pairs of neurons. Most often these histograms exhibited relatively broad peaks around the trigger point, indicating that the two neurons were driven by some sort of common input. When these were observed during sensory stimulation it was possible to measure precise response latency relationships between the two neurons. Such histograms were also used to define phase relationships between neurons during episodes of synchronous firing, which often occurred during resting behavior. Finally, some spike-triggered histograms exhibited discrete short latency post-spike responses, indicating functional connections between the neurons. Thalmocortical functional projections were observed, which were phasically suppressed during limb movements, as would be predicted from the earlier gating studies. Cortico-thalamic functional connections were also observed, indicating a cortical inhibitory effect on thalamic neurons. Finally,cortico-cortical functional connections were observed, whose strength varied according to the phase of limb movement. These studies thus provided evidence at the synaptic level that information transmission within thalamocortical networks is dynamically modulated during behavior.

VIBROTACTILE INTENSITY DIFFERENCE THRESHOLDS MEASURED BY TWO METHODS. G.A.Gescheider, S.J.Bolanowski, Jr. and R.T. Verrillo. Dept. Psychol., Hamilton College, Clinton, NY 13323 and Institute for Sensory Research, Syracuse Univ., Syracuse, NY 13244.

The difference thresholds for the detection of changes in vibration amplitude was measured as a function of the intensity and frequency of stimuli delivered through a 2.9 cm^2 contactor to the thenar eminence. Stimuli were either 25- or 250- Hz sinusoids or narrow-band noise centered at 250 Hz. Thresholds were measured by two-interval, forced-choice tracking under two methods of stimulus presentation. In the two-burst method, subjects had to judge which of two 700-ms bursts of vibration separated by 1000 ms was more intense. In the increment-detection method with continuous pedestal, subjects had to detect an increment in the amplitude of vibration. In the increment-detection method with 1500 ms pedestal bursts, the subject had to detect which of two successively presented pedestals contained an amplitude increment. Thresholds were consistently lower for detecting increments in the amplitude of continuous vibration than for detecting amplitude differences between successive bursts or amplitude increments in successive bursts. A "near miss" to Weber's Law was found for both sinusoidal and noise stimuli under both methods of stimulus presentation. The difference threshold was not affected by stimulus frequency. Supported by NS 24255 and NS 09940.

VIBRISSAL TACTILE DISCRIMINATION IN THE RAT. G.E. Carvell* and D.J. Simons (SPON: T.-K. Hung), Depts. of Physical Therapy and Physiology, Univ. of Pittsburgh, Pittsburgh, PA 15261.

A testing procedure was developed to investigate discriminative tactile behavior in the rodent whisker system. Blindfolded adult rats were trained to jump to one of two platforms for a food reward. The edge of each platform had a rough or smooth surface. The distance between the start platform and the discrimination platforms was adjusted so that rats could contact the discriminanda with their whiskers by stretching across the gap. Discriminanda consisted of metal surfaces that were periodically cleaned to eliminate possible odor cues. Most animals learned to correctly discriminate between a smooth and a rough surface in 10-14 days. Frame-by-frame video analyses confirmed that the rats used only their whiskers to contact the discriminanda. The search phase was characterized by large head and whisker movements. Upon contact, the head remained relatively stationary and whisking amplitude was markedly reduced. Rats maintained whisker contact for many 10's of msecs during which time the hairs were continually bent. Thus whiskers do not engage objects as independent, rigid levers. Results demonstrate that rats can use their vibrissae to obtain detailed tactile information from the environment. Supported by NIH NS 23047.

RESPONSES TO TENDON VIBRATION IN MONKEY SOMATOSENSORY CORTEX. N. Bite* and W.A. MacKay. Dept. of Physiology, Univ. of Toronto, Toronto, Ont. M5S 1A8

Muscle tendon vibration has been shown to distort position sense. For example, vibration of the biceps muscle of humans produces the illusion of extension about the elbow joint. A possible explanation for this illusion is that the activation of muscle receptors in the biceps informs the cortex that the muscle has been stretched.

The purpose of the present study was to determine whether cells in the somatosensory cortex which are sensitive to joint position, could also be activated by tendon vibration.

Single unit chronic recording was performed in an awake, unanesthetized cynomolgous monkey. All of the somatosensory areas from 3a to 5 were examined. Once a sensitive cell was found, vibration was applied to the appropriate tendon at ~80 Hz, using a small solenoid driven by a function generator.

Cells which fired tonically for joint positioning gave a sustained response when vibration was applied, while phasic cells produced only an initial burst of spikes. The proportion of tonic cells responsive to vibration varied as follows: Area 3a, 12/18; Area 1, 5/22; Area 2 and 5, 15/40. The results suggest that the most likely locus for the kinesthetic illusion produced by tendon vibration is Area 3a. Supported by MRC Canada.

SI CORTICAL NEURONS PARTICIPATE IN THE ENCODING PROCESS BY WHICH MONKEYS PERCEIVE THE INTENSITY OF NOXIOUS THERMAL STIMULATION D.R. Kenshalo, Jr., E.H. Chudler, F. Anton* and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892

In the present series of studies, we have obtained additional evidence that the activity of SI cortical nociceptive neurons correlates with the monkey's ability to detect small increases in noxious temperatures. Monkeys initiated a trial by pressing an illuminated button. A contact thermode, positioned on the upper lip, subsequently increased in temperature from 38° to 46°C (T1). After a random foreperiod of 4 to 10 sec, the thermode increased in temperature an additional 0.2° to 0.8°C (T2). The monkey received a fruit juice reward for releasing the button within 2 sec of the onset of T2. The activity of 18 wide-dynamic-range neurons was recorded while the animal performed the thermal detection task. In addition, mean detection speed (MDS) to the onset of T2 was determined.

The monkeys' ability to detect near threshold T2 (0.2°C at 46°C) temperature increases was correlated with the discharge of SI neurons. A correct detection of T2 by the monkey resulted in a statistically significant increase ($p<.01$) in discharge frequency of SI neurons as compared to occasions when the monkey did not detect T2. In addition, increases in the foreperiod resulted in an increase in both the MDS and peak neuronal discharge.

These data support the hypothesis that SI cortical nociceptive neurons are involved in the encoding process by which monkeys perceive the intensity of noxious thermal stimulation.

QUANTITATIVE DIFFERENCES IN PREMOVEMENT ACTIVITY OF PRIMARY SOMATOSENSORY CORTICAL NEURONS DURING VISUAL VERSUS VIBRATORY CUED HAND MOVEMENTS. R.J. Nelson and V.D. Douglas*. Department of Anatomy & Neurobiology, College of Medicine, University of Tennessee, Memphis, Memphis, TN 38163.

We measured the timing and magnitude of premovement activity changes of SI neurons associated with movements made after vibratory and visual go-cues. Rhesus monkeys were rewarded for making reaction time flexion (against a 0.07 Nm load) or extension (with load) wrist movements in response to palmar vibration of 27, 57 or 127 Hz, or to a visual cue. Cues remained on until the animal had moved. Single SI neuronal activity and wrist position were digitized by conventional means. This study met NIH animal utilization guidelines. Non-stimulus related premovement activity changes for vibratory and visually triggered movements were compared for each neuron. Changes deviating from the mean background by ≥ 50% for 30 consecutive msec were deemed significant, and determined the response onset. Response magnitudes were calculated as the absolute value of the mean response activity minus the mean background activity.

The responses of 72 neurons have been analyzed. Fifteen showed no significant premovement responses. Of the remaining 57, 43 and 47 had earlier premovement activity for at least one vibratory frequency or no premovement response during visually-cued trials during flexion and extension movements, respectively. Activity changes occurred earlier (mean= 22.4msec, prob<.001) and response magnitudes were less (mean=-4.3 spikes per sec, prob<.03; paired t-test), for extension movements during vibratory as compared to paired visually-cued trials. Means for flexion trials were not significantly different (prob>.05). Linear regressions were fit to the magnitude data using the formula *vib-response= constant+ Coeff * visual-response*. This resulted in these relationships:

Variable	Value	S.E	T	P 2 tail	Variable	Value	S.E.	T	P 2 tail
Flex const	12.45	5.25	2.38	0.02	Flex Coeff	0.69	0.09	7.72	0.00
Ext const	5.18	3.51	1.46	0.15	Ext Coeff	0.81	0.06	13.33	0.00

These results suggest that premovement activity onset times and magnitudes differ quantitatively, depending upon the type of stimulus used to elicit movement and may suggest that different mechanisms are at work during the premovement interval under the two stimulus conditions. SI CELL ACTIVITY DURING MOVEMENT: CYTOARCHITECTONIC CORRELATES. Michel Prud'homme, Dan A.D. Cohen and John F. Kalaska, Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, H3C 3J7.

We studied SI cutaneous cells in a two-dimensional reaching task requiring movements of the arm in 8 directions away from a central starting position. We demonstrated previously that the probability and strength of movement-induced activity correlated with certain receptive field properties (D.A.D. Cohen et al. (1986), Neurosci.Abstr. 12:1430). Many of these penetrations have been reconstructed. Slowly-adapting cells are more common in area 3b than area 1 and are concentrated in intermediate layers. Rapidly-adapting cells are found in all laminae. Cutaneous cell activity during arm movement is more intense in area 3b than area 1. Movement-induced activity is weakest in lamina 2 and strongest in deep laminae, especially lamina 5. Cells with certain distinct patterns of movement-related activity are selectively located in certain laminae. For instance, cells which are excited in all 8 movement directions are found in lamina 4, and cells which are inhibited in all directions are concentrated in deep laminae. Proprioceptive cells are concentrated in areas 3a and 2. These areas are much more active overall during movement than are areas 3b and 1. Supported by MRC Group Grant in neurological sciences.

MODIFICATION OF SOMATOSENSORY CORTICAL (SI) RESPONSE PROPERTIES BY GABA SYSTEMS. T. Kaneko, T.P. Hicks and C.A. Stark. Dept Med Physiol, Fac Med, Univ Calgary, Calg, Alta, Canada.

From somatosensory experiments comparing effects of GABA with baclofen (B) it seems that not only bicuculline (BMI)-sensitive processes but also those activated by B are involved in controlling response properties of SI neurones (Kaneko & Hicks, Brain Res 443: 360-366, 1988). To help understand the roles of diverse types of SI inhibition, we tested compounds related to different classes of GABA receptor on SI receptive field (RF) properties. B-induced suppressions of excitations were reversable & stereospecific, the (+)isomer being inactive. Sometimes B increased airpuffer responses on certain RF subregions while suppressing others, an effect not mimicked by M. Glutamate-induced and VPL-evoked firing was differentially sensitive to suppression by B and M (M>B & B>M, resp.) THIP acted similarly to GABA & M but with reduced potency. THIP-induced suppressions of puffer firing, but not those by B, were blocked by BMI. Phaclofen (<200 nA) invariably failed to affect B's actions yet occassionally reduced puffer or glutamate excitations. δ-amino-n-valerate did not block effects of B even while showing potent effects of it's own. The spectra of suppressant effects produced by GABA, M & THIP suggest that actions observed by ejected GABA are due almost solely to $GABA_A$ processes, those mediated by $GABA_B$ being masked. Diffusional constraints & uptake processes also intervene here. $GABA_B$ processes are extant and are likely to be active presynaptically on distal sites from the somata and additionally may be involved in presynaptic inhibitory events

QUANTITATIVE MEASUREMENTS OF RECEPTIVE FIELD EXPANSION BY BICUCULLINE ON CAT SI NEURONS. K. Alloway, P. Rosenthal*, and H. Burton. Department of Anatomy and Neurobiology, Washington University School of Medicine, St Louis, MO 63110

We recorded responses of 50 SI neurons to punctate stimuli before and during iontophoresis of bicuculline methiodide (BMI) in barbiturate anesthetized cats. Constant amplitude indentations were applied to depilatated skin along linear proximal-distal and radial-ulnar axes that intersected the most sensitive site in the receptive field (RF). Responses were largest at the center of the RF and gradually decreased at more distant points. During BMI, responses increased at all sites previously tested, including sites outside the original RF. The extent of a cell's RF was measured from the center to the boundary along four directions. RFs were usually oblong, having a mean radius of 4.0 mm in the ulnar or radial direction and 8.6 mm in the proximal or distal direction. BMI increased the length of these dimensions by an average of 132% and 160% in the ulnar/radial and proximal/distal directions. RFs located on the distal paw tended to expand more proportionally than RFs found on the wrist or arm. This suggests that GABAergic inhibition might be more important for limiting RF size in distal areas that contribute more towards making a tactile discrimination.

The spatial distribution of inhibition was determined by subtracting the mean normalized responses during control conditions from the corresponding responses during BMI and plotting the difference along the axes of the RF. This created a symmetrical, tent-like curve with a dip located at the center of the RF. These results suggest that inhibitory processes have a center-surround organization that serves to restrict the effect of excitatory inputs. NIH NS22012

VASOACTIVE INTESTINAL POLYPEPTIDE-IMMUNOREACTIVE (VIP-IR) NEURONS IN THE RAT SOMATOSENSORY CORTEX. E. Muly, S.M. Lu, and C.-S. Lin. Dept. Neurobiology, Duke University Medical Center, Durham NC 27710.

The laminar distribution of VIP-IR neurons in the granular and dysgranular regions and posteromedial barrel subfield (PMBSF) of SI and in SII were examined and compared. Further, the relation of VIP-IR neurons to the barrels of the PMBSF was studied.

Pigmented rats were perfused with PLP fixative. VIP immunocytochemistry was done on coronal and flattened tangential sections of cortex by the PAP method.

Cells, fibers and terminals in the somatosensory cortex were well stained and most neurons were of the bipolar class. The laminar distribution of VIP-IR neurons was determined in coronal sections. Labeled neurons were present in every layer, with the highest density in layer II/III. Labeled neurons appeared to be more prevalant at the borders between laminae. No significant difference was found between the laminar distribution in the granular and dysgranular regions and the PMBSF of SI and in SII. The relationship between VIP-IR neurons in layer IV and the barrels of the PMBSF was studied in tangential sections. Labeled neurons sometimes appeared to be preferentially located in the barrel walls or septa. Serial sections are being examined to assess this possibility.

SOME PYRAMIDAL NEURONS IN THE SOMATIC SENSORY CORTEX OF CATS CONTAIN TACHYKININ IMMUNOREACTIVITY. F. Conti, M. Fabri, L. Abdullah*, T. Manzoni. Inst. of Physiol., Univ. of Ancona, Ancona, (Italy) and *Dept. of Anatomy, Univ. North Carolina, Chapel Hill (Usa).

Neuropeptides have never been convincingly demonstrated in pyramidal neurons. We have reinvestigated the issue of peptide-containing pyramidal neurons by using policlonal antisera raised in rabbits against substance P (SP) or substance K (SK) conjugated to keyhole limpet hemocyanin with glutaraldehyde. Adult cats were perfused with paraformaldehyde and 25μm vibratome sections were incubated with anti SP (1:1.250) or anti SK (1:500) sera. Neuronal cell body visualization required colchicine pre-treatment. In this case, SP- and SK- positive neurons were present in SI and SII. The majority of these neurons were non-pyramidal but a fraction (about 10%) of tachykinin-containing cells was composed of clear pyramidal neurons, with triangular perikarya, basal dendrites, axons emerging from the base and, most importantly, a long vertical apical dendrite. Experiments are currently in progress to ascertain whether SP and SK immunoreactivities co-exist in the same neurons and whether they are co-localized with glutamate.

NEURONS IN THE SOMATOSENSORY CORTEX OF THE AWAKE RESTRAINED RAT: SINGLE UNIT RECORDINGS AND MICROIONTOPHORESIS. M.H. Bassant*, J.M. Baleyte* and Y. Lamour, INSERM, U 161, 75014 PARIS, FRANCE.

Experiments were performed on unanaesthetized rats using a chronic restraint system. The animal's head was held in a stereotaxic apparatus by means of two metallic tubes fixed on the skull with dental cement. After a period of habituation, the rat tolerated easily this painless holding system for several hours. Electrode consisted of a recording micropipette (filled with 1M NaCl and 2% pontamine blue) attached to a multibarreled micropipette for iontophoresis. At the end of each track, pontamine blue was ejected. Electrodes penetrations were reconstructed on camera lucida drawings of frontal brain sections. The mean spontaneous activity of the cortical somatosensory neurons was 6.8 ± 8 impulses per second (n = 111, with 68% of spontaneously active cells), compared to about 2 impulses per second under urethane anesthesia. Virtually all cells were activated by glutamate and inhibited by GABA. 64% of the neurons were excited by acetylcholine and 53% by carbachol. The effects of cholinergic agonists-observed for the first time in awake rats - are significantly different from those previously obtained under urethane anaesthesia (respectively 32 and 34.5% of neurons excited). Most of the cholinoceptive neurons were located in infragranular layers.

LAMINAR DISTRIBUTION OF GLUTAMATE DECARBOXYLASE IMMUNOREACTIVITY IN THE RAT SmI BARREL CORTEX. N. D. Akhtar and P. W. Land. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

Immunocytochemical methods were used to examine the distribution of glutamate decarboxylase (GAD) in the vibrissa region of the rat somatic sensory (SmI) barrel cortex. GAD positive cell bodies are present in all cortical laminae and in the white matter beneath SmI. GAD stained neurons are nearly uniformly distributed among the cortical laminae with slightly higher densities occurring within laminae II and VI. In lamina IV immunoreactive cells are clustered in the sides of the smaller, anterior barrels, but in general the distribution of stained cells bears little relationship to the location of the barrel centers.

GAD positive puncta appear on the surface of stained and unstained cell bodies as well as in the neuropil. Puncta are largest and most darkly stained in lower lamina III and lamina IV where they are organized into patches, each of which is centered upon a cortical barrel. The intervening septal regions are much less GAD immunoreactive. Lamina Vb is densely stained, laminae II/III, Vc and VI have moderate levels of GAD staining and laminae I and Va are least reactive.

The morphological details of GAD positive neurons are enhanced in sections from rats receiving intraventricular colchicine injections. Here it is seen that the stained cells are non-pyramidal in shape. Interestingly, colchicine pretreatment reveals a sublaminar organization of GAD stained puncta in SmI. While puncta staining is markedly attenuated throughout cortical laminae in treated animals, two prominent bands persist: one in lower lamina IV and one in lamina Vb. A similar pattern of puncta staining is present in untreated animals that have been deprived of vibrissa input for prolonged periods of time. GAD containing neurons in SmI thus are a heterogeneous population of cells that exhibit laminar and perhaps sublaminar differences in their functional characteristics. (Supported by NIH grant NS 23047)

DEMONSTRATION OF REGIONALLY SPECIFIC N-ACETYL-ASPARTYLGLUTAMATE IMMUNOREACTIVITY IN THE CORPUS STRIATUM OF THE RAT. Moffett, J.R. Cassidy, M. Neale, J.H. and Namboodiri, M.A.A. Biology Dept. Georgetown University, Washington, DC 20057.

The acetylated dipeptide, N-acetylaspartylglutamate (NAAG) was found by immunohistochemistry to be selectively localized in the ventral striatum of the rat. Exhaustive carbodiimide coupling prior to aldehyde post-fixation greatly enhanced NAAG-like immunoreactivity (NAAG-IR) as compared with mixed carbodiimide/formaldehyde fixations. The cellular NAAG-IR in the corpus striatum was almost exclusively localized in the pallidum, confluent ventrally with heavily labeled neurons of the hypothalamus. Multipolar neurons surrounding fascicles of the internal capsule were labeled throughout the globus pallidus. The neuropil between pallidal neurons exhibited punctate NAAG-IR associated with neuronal processes, presumably representing NAAG containing synaptic terminals. In contrast, the caudate and putamen were almost devoid of NAAG positive neurons. These results suggest that NAAG may be functionally involved in the extrapyamidal motor system, in the striatal output projections from the pallidum to the thalamus or midbrain. (Supported by Grant DK 37021)

287.2

ANISOMYCIN CAUSES EXACERBATION OF THE IMINODIPROPIONITRILE (IDPN)-INDUCED DYSKINETIC SYNDROME IN RATS. J.L. Cadet, R. Stennet† M. Katz† V. Jackson-Lewis and S. Fahn. Columbia University, Department of Neurology, New York, NY 10032

Chronic administration of IDPN causes a complex motor syndrome consisting of lateral and vertical neck movements, circling, and hyperactivity. The syndrome develops after 7 daily injections of the drug. The syndrome is accompanied by increases in serotonin levels in the caudate and nucleus accumbens of rats (Cadet, J.L. et al. Brain Res. (in press)). The present study evaluates the role of protein synthesis in the development of these abnormalities.

Rats were treated with IDPN alone, anisomycin alone, the combination of IDPN and anisomycin, or saline. Administration of IDPN alone causes the persistent abnormalities as expected. Anisomycin alone caused no behavioral changes. The combination of the two drugs caused significant exacerbations of all aspects of the syndrome.

The present data and previous ones on striatal protein phosphorylation in similarly treated animals (Cadet, J.L. et al. Soc. Neurosci. Abst 13:462, 1987) raise the possibilitiy that both translational and post-translational processes might be involved in the development of the IDPN-induced persistent spasmodic dyskinetic syndrome. Biochemical data on the serotonin system will be presented.

BEHAVIORAL EFFECTS OF MUSCIMOL-INDUCED PREVENTION OF TRANSSYNAPTIC DEGENERATION FOLLOWING UNILATERAL IBOTENIC ACID LESIONS OF THE CAUDATE NUCLEUS M.D. Lindner, T. Schallert. Dept. of Psychology and Institute for Neurological Sciences University of Texas, Austin, Texas 78712

Saji and Reis (Science,235:66-69,1987) recently developed a procedure to prevent the transsynaptic degeneration of cells in the ipsilateral substantia nigra following unilateral ibotenic acid infusions into the caudate nucleus. They demonstrated that GABA-ergic cells in the caudate were destroyed by the neurotoxin and that chronic intraventricular infusions of muscimol prevented the subsequent degeneration of target cells in the substantia nigra. With more cells surviving, the assumption has been that treatment with a GABA-agonist facilitates restoration of function following the loss of GABA-ergic projections.

However, no behavioral observations were obtained. Thus, it remained possible that muscimol might facilitate, disrupt, or have no effect on functional outcome after striatal lesions. GABA agonists have been found to retard recovery of function following cortical lesions (Schallert et al., 1986; Brailowsky et al., 1986; Hernandez et al., 1988), but the neurochemical circuitry was very different.

Saji & Reis's procedure was replicated and the results of a battery of behavioral tasks which are sensitive to the effects of this lesion, including motor, postural, and somatosensory tasks, will be reported. Supported by NS-23964.

287.4

THE FUNCTION OF DOPAMINE IN THE STRIATUM: A SHARPENER OF SENSORY INFORMATION? L.L.Brown, Albert Einstein College of Medicine, Bronx, NY 10461.

14C Deoxyglucose autoradiographic mapping studies were carried out in awake, restrained rats receiving a tactile stimulus, and either with or without a unilateral 6-OHDA lesion of the substantia nigra. The tactile stimulus was a stroke of a nylon bristle (0.5 g or 2.5 g pressure) across 1 cm of the forelimb above the wrist at the rate of 3-4/sec. EMG was recorded. Lesion effectiveness for significant dopamine depletion of striatum was verified with an apomorphine rotation trial and by tyrosine hydroxylase staining of histological sections. Glucose utilization (GU) was estimated using the technique of Sokoloff et al. (1977). In the cortex of non-lesion animals, the tactile stimulus caused focal increases in GU in SI, and in the striatum a region of no difference from the other side or an increase (-2 ± 2 to $+7\pm2$ %) surrounded by a significant decrease (-8 ± 1 to -13 ± 2 % for the two pressure groups). Thus there was a "spared" or increased focal area in dorsolateral striatum with a decreased surround. In the lesion rats, the focal area was larger, showed a higher GU rate than non-lesion rats, and there was no significant decreased surround region. The results suggest that the striatum plays a role in the localization of tactile stimuli, and that dopamine plays a role in increasing the signal-to-noise ratio for this information by decreasing surrounding activity.

ETHANOL ALTERS LOCOMOTOR AND TONE EVOKED UNIT ACTIVITY IN NEOSTRIATUM OF RAT. R.-S. Lee, N. Shimizu*, and D.J. Woodward. *Dept. of Cell Biol. & Anat., The Univ. of Tx. Southwestern Med. Ctr. at Dallas, TX 75235.*

The objective of the present study was to determine whether ethanol modulates (1) the increases in neostriatal neuronal activity during treadmill (TM) locomotion; and (2) the neostriatal response to a tone stimulus used as a cue to the onset of each TM on/off cycle. Adult Long-Evans hooded rats were used for chronic recording of single neostriatal neurons. Animals were trained to walk on a treadmill (30 sec on/30 sec off) and a tone (800 Hz, 0.2 sec, 60 dB) served as a cue (0.5 sec before TM-onset) for the onset of TM locomotion. Ethanol (0.6-1.2 g/kg, i.p.) suppressed the TM-induced increased firing by a maximum of 35% (no change in TM response in 3 of 15). This effect was observed within 10 min and peaked at 10 to 30 min. The spontaneous firing rate during resting state remained unchanged in 8 of 15 neurons or decreased by 40% in 4 of 15 cases. The effect of ethanol on neostriatal unit activity lasted for 0.7-1.5 hours, well beyond the acute effect of ethanol on observable locomotor behavior (such as ataxia). Ethanol also suppressed the learned tone response, which recovered earlier than TM response. At a dose of 1.2 g/kg ethanol there was a decreased resting firing rate and an increased delay (1-1.5 sec) for the peaks (in 2 of 4 cases) in unit responses which correlated with the first steps during each cycle of TM exercise. These observations suggest that ethanol at moderate doses exerts a substantial effect on neural processing in neostriatum which may degrade the linkage between sensory and motor units. *(Supported by AA-3901, DA-02338 and the Biological Humanics Foundation.)*

287.6

SOMATOMOTOR ACTIVITY OF GLOBUS PALLIDUS UNITS C.Manetto*and T.I. Lidsky. CUNY Med.Sch., N.Y., N.Y. 10031

Units were recorded in the globus pallidus (GP) of awake cats. Animals were painlessly restrained during recording sessions in a device that permitted a variety of activities including buccolingual movements. Buccolingual movements were displayed by the cats spontaneously and also were elicited by delivering a small volume of milk.

A majority (75%) of the sampled cells changed firing rate during buccolingual movements. For 57% of the responsive cells, activity changes were related to the sensory concomitants of ingestion rather than the movements per se. For example, the majority had perioral somatosensory receptive fields that were stimulated by the delivery of milk. It should be noted that, in this respect, the activity of GP cells was quite similar to that of striatal neurons described in earlier work by this laboratory.

The remaining responsive neurons (43%) became active in relation to movement. Typically, such cells fired during all buccolingual movements regardless of the initiating conditions. However, a subgroup (27%) responded only during movements that were triggered by milk delivery. Although movement related responses similar to those seen in the GP have also been observed in the striatum, there were two noteworthy differences. 1) A higher proportion of GP cells showed movement related activity. 2) The responses of GP cells were time-locked to individual phasic contractions of jaw muscles. Similar specificity was never observed in striatal neurons. (NINCDS:NS 21418)

THE HUMAN SUBCOMMISSURAL BASAL FOREBRAIN. N. Sakamoto*, J. Pearson and B. Reisberg. New York University Medical Center, New York, NY 10016

The human subcommissural pallidum (often called the ventral pallidum) extends ventrally in finger-like processes interdigitating with "pseudostriatal" cell groups structurally and chemically similar to the nucleus accumbens. Islands of Calleja and small islands of putaminal gray matter are scattered in the "pallido-pseudostriatal interdigitation complex" (PPSIC). Large neurons of the nucleus basalis interpolate with the lateral side of the PPSIC. The PPSIC abuts onto the olfactory bulb and nucleus of the diagonal band. Enkephalin-immunoreactive (EIR) woolly fibers are densely packed in the external and subcommissural components of the pallidum but are scarce in the interdigitating process which have a dense population of SPIR woolly fibers. Thus the subcommissural pallidum is chemo-architectonically "duplex", consisting of a enkephalinergic dorsal component resembling the external segment of the globus pallidus and a substance Pergic ventral component resembling the internal segment. The duplex structure is seen in monkey subcommissural pallidum but ventral interdigitations are not present.

287.8

LESIONS OF THE PRIMATE SUBTHALAMIC NUCLEUS (STN) REDUCE TONIC AND PHASIC NEURAL ACTIVITY IN GLOBUS PALLIDUS.

I. Hamada* and M.R. DeLong (SPON: R.T. Richardson). Depts. of Neurology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205

In the primate, lesions of the STN result in severe dyskinesias of the contralateral limbs. These have previously been postulated to result from removal of inhibitory STN input to the internal segment of globus pallidus (GPi), which gives rise to the major output from the basal ganglia. Recent evidence, however, suggests that STN input to GPi is excitatory (Kita, H. and Kitai, S.T. J. Comp. Neurol. 260:435-452, 1987). To examine these issues, we recorded neural activity in both GPi and GPe (external segment of pallidum) of a rhesus monkey before and after lesions of the STN. The monkey held a manipulandum in a small zone and received torque perturbations of the elbow. After collecting control data, small amounts of ibotenic acid or kainic acid were injected into several STN locations, producing acute (5-10 minutes latency) contralateral dyskinesias of the arm and leg. Recordings were begun after recovery from acute dyskinesia (5 days). Tonic discharge rates were significantly lower than control and phasic responses to torque perturbation, particularly increases in discharge, were significantly reduced in number both in GPi and GPe. These findings provide support for the view that the STN provides a major excitatory input to both GPe and GPi and suggests that decreased GPi output may play a role in the pathogenesis of dyskinesias.

287.9

SINGLE UNIT ACTIVITY OF PRIMATE CAUDATE NUCLEUS IN A PRECUE TASK. D. Jaeger, S. Gilman and J.W. Aldridge. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48104

We have examined caudate nucleus unit activity responses to the presentation of visual stimuli that precue the target position of learned reaching movements. The behavioral task used requires a monkey to touch one of a set of 8 target knobs that have stimulus lights mounted on them. A subset of these lights was flashed for 2 s before a go-cue triggered the reaching movement. The locations of these lights precued partial to complete information about the required target position of the following movement. For example, partial information could indicate movement direction or movement distance. One to 4 single units were recorded simultaneously with a multiwire electrode from caudate nucleus during task execution. Of 72 recorded caudate units, 68 (94%) had responses to the task. Responses related to precue presentation were found in 43 units (60%). Precue responses were excitatory and lasted 200 to 800 ms. These responses could occur during precue presentation or following precue offset, lasting through the hold phase that preceded the go-cue. Each unit with a precue dependent response was activated only for a subset of all precue types presented. Some responses during the reaching movement occurred only when a certain precue preceded the movement. Units located within 1 mm from each other often showed similar response types during task execution. A cross-correlation analysis showed that there was no close coupling in the activity of such units. Units with precue specific responses often showed additional responses during other phases of the task. Precue responses were not predictive of such other response types. This independence of responses in different task phases suggests that units are dynamically associated with different neural assemblies. The functional properties of unit responses in caudate nucleus indicate involvement of this structure in the recognition of task requirements and preparation for further task execution. A COMPARISON OF AUDITORY AND VISUAL GO-CUES ON SINGLE UNIT ACTIVITY IN THALAMUS R.N.S. Sachdev *, C. Hekmatpanah *, D. Jaeger, S. Gilman, and J.W. Aldridge. Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104

The aim of this investigation is to compare the properties of single units that respond during a movement in cat thalamus. Unit responses associated with movements initiated by visual and / or auditory go-cues were compared to determine whether responses depend on stimulus type. Unrestrained cats were trained to make discrete paw movements with the right limb. The task began after an initial hold period in the rest position. Following this hold period a go-cue - flashing light, sound, or both - was presented to trigger the movement. The randomly presented go cues remained on throughout the movement, and were turned off 250-500 ms after the movement was completed. Thalamic unit activity was assessed by constructing peri-event time histograms and cumulative sum diagrams for each discriminated unit collected during the task. Sixty-two units from the thalamus were analyzed. Sixty-one percent of the units had responses starting 80-550 ms before the movement. These responses typically lasted for the duration of the movement. Eight percent of the units altered their discharge only during the movement and 31% had no response. The responses of 55% of the movement related units did not depend on the type of cue. The remaining 45% exhibited responses dependent on the cue. The cue-dependent responses were distinguished on the basis of excitation, inhibition and latency. For example, 12% of the movement related units had a shorter latency with the sound cue than with the visual cue. Also, other units were excited during movements with one cue and inhibited with the other cue. These results suggest that the sensory features of a stimulus may have a role in determining the movement-related response characteristics of the thalamic neurons. NIH grants N519613, NS07222 and Hereditary Disease Foundation.

ORGANIZATION OF EFFERENT CONNECTIONS OF THE TWO PALLIDAL SEGMENTS IN PRIMATE AS REVEALED BY PHA-L ANTEROGRADE TRACING METHOD. Y. Smith, A. Parent and J. Dumas*. Lab. of Neurobiology, Fac. of Med., Laval Univ., Québec, Canada.

The lectin Phaseolus vulgaris-leucoagglutinin (PHA-L) was used as an anterograde tracer to study the pattern of termination of pallidofugal fibers arising from the external (GPe) and the internal (GPi) pallidal segments in squirrel monkey (*Saimiri sciureus*). Small iontophoretic PHA-L injection in the dorsal half of GPe led to profuse anterograde labeling in the central core of the subthalamic nucleus. In addition a small to moderate number of fibers detached from the pallidosubthalamic axons to descend toward the substantia nigra (SN) where they formed small, diffuse plexuses in the lateral two-thirds of the pars reticulata (SNr). Other anterogradely-labeled fibers were visualized in smaller number in the dorsal part of the GPi, the putamen (PUT) and the caudate nucleus. At thalamic level, a very small number of fibers were seen in caudal intralaminar nuclei. Finally, at brainstem level few labeled fibers were scattered in the mesencephalic reticular formation (MRF) and periaqueductal gray (PAG). Following PHA-L injection in the dorsal two-thirds of GPi, a rich contingent of anterogradely-labeled fibers traversed the internal capsule and coursed through the lenticular fasciculus to invade massively the ventral anterior/ventral lateral (VA/VL) thalamic nuclei where they formed several small plexuses that were mainly confined to the VA and the oral part of VL. In addition a significant number of fibers extended more caudally to arborize profusely in the centre médian (CM) and centromedial (CeM) intralaminar nuclei, the dorsal part of zona incerta and the ventral two-thirds of the lateral habenular nucleus. It is worth noting that numerous pallidofugal fibers crossed the midline at the CeM level. At striatal level a small number of labeled fibers oriented dorsoventrally occurred in the dorsomedial part of PUT. Other fibers arising from the injection site invaded the dorsomedial third of GPe where they arborized in all directions. Finally, few labeled fibers were scattered in the SNr, MRF and the area of the pedunculopontine nucleus. (Supported by MRC, FRSQ and FCAR).

DISTRIBUTION OF SEROTONIN IMMUNOREACTIVITY IN PRIMATE BASAL GANGLIA. B. Lavoie*, Y. Smith and A. Parent (SPON: M. Filion). Lab. of Neurobiology, Fac. of Med., Laval Univ., Québec, Canada.

A 5-hydroxytryptamine (5-HT) antibody was used to study the serotoninergic innervation of the basal ganglia in the squirrel monkey (*Saimiri sciureus*). At midbrain level, numerous 5-HT-immunoreactive axons of the dorsal raphe neurons coursed laterally and rostrally toward the substantia nigra (SN) where they arborized into a multitude of heterogeneously distributed 5-HT terminals. The latter were particularly abundant in the pars reticulata and pars lateralis, but much less so in the pars compacta of SN. Other 5-HT fibers arched dorsally and reached the subthalamic nucleus where they formed a dense network of varicosed fibers. Numerous fibers also traversed the internal capsule and arborized profusely in the globus pallidus (GP). The external pallidum was much less densely innervated than the internal pallidum which contained numerous 5-HT varicosed fibers and terminals arranged in a typical band-like pattern. At striatal levels, the 5-HT terminals were particularly abundant in the ventral striatum comprising nucleus accumbens, in the ventrolateral region of the putamen (PU) and the ventromedial aspect of the caudate nucleus (CD). In both CD and PU the number of 5-HT terminals decreased progressively along the rostrocaudal axis and several large and elongated zones rather devoid of 5-HT immunoreactivity were visualized, particularly in CD and dorsal PU. These zones of poor 5-HT immunoreactivity were in register with similar areas devoid of tyrosine hydroxylase immunoreactivity, but the correspondence with other neurochemical markers remains to be established. (Supported by MRC, FRSQ and FCAR).

THE EXACT DISTRIBUTION OF STRIATALLY-PROJECTING THALAMIC NEURONS IN THE MONKEY. C.A. Hunt and E.G. Jones, Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Wheatgerm agglutinin-horseradish peroxidase (WGA-HRP, Sigma, 2%) was injected into the caudate nucleus and putamen of adult monkeys, using approaches that avoided contamination of the cerebral cortex. After large injections, retrogradely labeled cells were present throughout the intralaminar complex: Large numbers in the rhomboid, dorsal central lateral, centre médian, and parafascicular nuclei, with fewer in the central medial and paracentral nuclei and in the remainder of the central lateral nucleus. Small injections into the putamen resulted in a small number of labeled neurons in the centre médian nucleus. Labeling of cells in other nuclei could usually be attributed to HRP spread to non-striatal structures. However, a consistent finding was the labeling of a few neurons in the ventral anterior nucleus (VA), including its magnocellular part, even when spread of HRP to the cortex was minimal. The intralaminar nuclei are thus the major sources of the thalamostriate projection in the monkey, with a likely contribution from VA.

CHANGES IN PUTAMEN ACTIVITY IN BEHAVING PARKINSONIAN MONKEYS. E.B. Montgomery, Jr. and S.R. Buchholz*. Dept. of Neurology, Washington Univ. Sch. of Med., St. Louis, MO 63110

At the last meeting we reported single unit recordings in the putamen of a normal monkey trained to perform wrist extension and flexion movements. The major finding was the high incidence of neurons (6 of 14 related to the tasks) best related to and active in advance of the achievement of final target. In the same monkey made parkinsonian by intravenous injection of 1.2 mg/kg of MPTP, only 1 out of 8 units in the putamen showed this pattern. These neurons may represent the major output function of the putamen since they were active before reaching final target and were lost following MPTP induced disruption of putamenal physiology.

Following MPTP most putamenal neurons were related to and active after the "go" signal or at or after movement onset. These patterns, also seen in normal monkeys, may represent input responses from areas not affected by MPTP.

CHOLECYSTOKININ BINDING IN MACAQUE NEOSTRIATUM. M.F. Kritzer, R.B. Innis, and P.S. Goldman-Rakic, Yale Univ. Sch. Med., New Haven, CT. 06510.

Cholecystokinin (CCK) binding sites were labeled with [3H]- and [125I]-CCK-8 in macaque neostriatum by in vitro receptor autoradiography. Non-specific binding was assessed using 1 uM CCK-8; analysis included comparison of Nissl and AChE stained sections with autoradiograms.

CCK binding in macaque striatum was highly selective. Patches of reduced binding were evident in much of the striatum; comparison of binding and AChE staining showed poor correlation with striosomal organization. A striking feature of binding, however, was the sharp demarcation of heavily labeled areas located ventromedially throughout the striatum and weakly labeled areas located dorsolaterally. Thus, heavy label in the ventromedial striatum contrasted with sparse label in the dorsolateral one-third of the body of the caudate and nearly all of the putamen lateral to the pallidum. The dense binding in the ventromedial striatum overlies regions innervated by association cortex (Selemon & Goldman-Rakic, J. Neurosci. 5: 1985) whereas dorso- lateral regions of light binding appear to correspond to areas innervated mainly by motor cortex (Kunzle, Brain Res. 88: 1975). The present results have a parallel in our previous finding that CCK binding in macaque cortex is dense in association regions of cortex and diminished in motor and premotor regions (Kritzer et al., J. Comp. Neurol. 263: 1987). Supported by MH38546, NS22807.

DOPAMINERGIC, SEROTONERGIC, CHOLINERGIC AND B-ADRENERGIC SYSTEMS IN NORMAL AND SCHIZOPHRENIC STRIATUM WITH REFERENCE TO STRIOSOME/MATRIX COMPARTMENTS J.N. Joyce, N. Lexow*, B. Neal and A. Winokur, Departments of Psychiatry and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA

Quantitative autoradiography was used to examine the pre- and postsynaptic elements of several transmitter systems in the striatum of post-mortem brains derived from non-disease controls and of long-term hospitalized schizophrenics. As previously described, the matrix could be visualized with AChE histochemistry, [^{3}H]hemicholinium-3 labeling of choline uptake sites on cholinergic terminals or [^{3}H]mazindol labeling of DA uptake sites on DA terminals. In all cases the matrix was enriched as compared to less dense labeling of the striosomes. Serotonin uptake sites labeled with [^{3}H]CNMI were densest in the ventral striatum and tended to be enriched in the striosomes. DA D2 receptors were denser in the matrix, whereas D1 receptor patches could be seen to be congruent with or avoid the D2-rich zones. The density of M1 receptors was greater dorsally in the striatum, with distinct patches of higher density apparent in all regions of striatum. M2 receptors were more homogeneously distributed and less numerous. None of the serotonin receptors examined (5-HT$_{1a}$, 5-HT$_{1c}$, 5-HT$_2$) bore any apparent relationsip to the patterning of serotonin terminals, as visualized with [^{3}H]CNMI. In contrast, B$_1$ (but not B$_2$ receptors) receptors were densest where serotonin terminal labeling was highest. In the striatum of the schizophrenic cases, D2 receptor density was increased 1.8-fold without any change in D1 receptor density or DA terminal labeling. **Funded by NIH NS19597 to AW and a grant from the Scottish Rite Foundation to JNJ**

ORGANIZATION OF PRIMATE BASAL GANGLIA "MOTOR CIRCUIT": 1. MOTOR CORTEX (MC) AND SUPPLEMENTARY MOTOR AREA (SMA) PROJECT TO COMPLEMENTARY REGIONS WITHIN MATRIX COMPARTMENT OF PUTAMEN G.E. Alexander, V.E. Koliatsos, L.J. Martin*, J. Hedreen, J. Hamada* and M.R. DeLong, Depts. of Neurology, Pathology and Neuroscience, The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

We have proposed recently that in primates there are several parallel circuits that link distinct, structurally and functionally segregated, portions of cortex, basal ganglia and thalamus (Alexander, et al., Ann. Rev. Neurosci. 9:357-381, 1986). To investigate the organization of the basal ganglia-thalamocortical "motor circuit", we have carried out a series of combined anatomical and physiological studies, the results of which are outlined in the present series of abstracts. In this first study, the organization of cortical inputs to the electrophysiologically-defined arm area of the putamen was examined in the rhesus monkey. Tritiated aminoacids and WGA-HRP were injected into the respective arm areas of MC and SMA, both of which were identified by microstimulation. SMA terminals were distributed over a large part of the putamen arm area. MC terminals were distributed ventrolateral to the SMA terminal field. Both sets of terminals were confined to the matrix zone, as defined by AChE histochemistry. The densely labeled central portions of the two terminal fields were clearly separated, whereas the peripheral zones of sparse labeling showed some overlap. These results suggest that within the putamen arm area segregation of inputs from anatomically distinct precentral motor fields is largely maintained.

287.18

ORGANIZATION OF PRIMATE BASAL GANGLIA "MOTOR CIRCUIT": 2. PUTAMINAL PROJECTIONS TO INTERNAL (GPi) AND EXTERNAL (GPe) GLOBUS PALLIDUS ORIGINATE IN DISTINCT NEURONAL POPULATIONS WITHIN THE MATRIX COMPARTMENT. V.E. Koliatsos, L.J. J. Martin*, J. Hedreen, G.E. Alexander, J. Hamada*, D.L. Price, and M.R. DeLong, Depts. of Neurology, Pathology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Double retrograde tracing utilizing the fluorescent dyes Fast Blue (FB) and Diamidino Yellow (DY) was employed to show the anatomical relations of striatal neuronal populations projecting to GPi and GPe in the rhesus monkey. GPi and GPe were mapped electrophysiologically and their arm areas identified; each pallidal segment was injected using a compound recording-injecting system. AChE histochemistry was used to visualize patch-matrix striatal compartments. Retrogradely labeled populations of putamen neurons were confined primarily to the matrix zone. Retrogradely labeled neurons were clustered in groups, which were comprised almost exclusively of neurons projecting to either GPi or GPe. Target-specific groups were peripherally intermixed and a few double-labeled neurons (not exceeding 10% of the total of overlapping cells) were noted in the areas of intermixing. These results further support the concept of segregation of striatal efferent systems. We are currently analyzing the precise relations between GPe- and GPi-projecting neurons and cortical afferents to the putamen.

287.19

ORGANIZATION OF PRIMATE BASAL GANGLIA "MOTOR CIRCUIT": 3. RELATIONS OF STRIATAL MICROEXCITABLE ZONES TO AFFERENT AND EFFERENT PROJECTIONS. M.R. DeLong, I. Hamada*, G.E. Alexander, V. Koliatsos, L.J. Martin*, and J. Hedreen. Depts. of Neurology, Pathology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

In previous electrophysiological studies we have shown that the primate putamen is functionally heterogeneous (Alexander & DeLong, J. Neurophysiol. 53:1401-1416, 1417-1429, 1985, Crutcher & DeLong, Exp. Br. Res. 53:244-258, 1984). Microstimulation along individual electrode tracks through the putamen has revealed discrete regions from which uniform motor responses are evoked. These regions have been termed striatal microexcitable zones (SMZ). In order to characterize the 3-dimensional structure of SMZs and their relations to the anatomical organization of the striatum, the microexcitable putamen was stimulated at 100 um intervals with closely spaced (1mm) microelectrode penetrations. We found that SMZs are irregularly shaped 3-dimensional structures whose maximal dimensions may reach several mm along the rostro-caudal axis. When these findings were examined in relation to the results of anatomical studies carried out in the same animals (see preceding abstracts), we found that: 1) SMZs were located in the central portion of the putamen, which appeared to consist only of matrix, as defined by acetylcholinesterase staining, 2) arm SMZs appeared to overlap with regions receiving dense inputs from the arm area of the motor cortex but not from the supplementary motor area, and 3) SMZs overlapped with clusters of neurons projecting to GPe and GPi.

287.20

ORGANIZATION OF PRIMATE BASAL GANGLIA "MOTOR CIRCUIT": 4. VENTROLATERAL THALAMUS LINKS INTERNAL PALLIDUM (GPi) AND SUPPLEMENTARY MOTOR AREA (SMA). J.C. Hedreen, L.J. Martin*, V.E. Koliatsos, I. Hamada*, G.E. Alexander and M.R. DeLong. Depts. of Neurology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The concept of a closed basal ganglia-thalamocortical "motor circuit" linking motor areas of cortex, basal ganglia and thalamus has been proposed on the basis of diverse physiological and anatomical studies in different animals (see Alexander, et al., Ann. Rev. Neurosci. 9:357-381, 1986). In order to demonstrate the continuity of this circuit in individual animals, injections of two different anterograde/retrograde tracers were made into two non-contiguous stations of this circuit. Wheat germ agglutinin-horseradish peroxidase (WGA-HRP) was injected into the arm region of the SMA and Fast Blue (FB) into the GPi. Retrograde and anterograde transport of WGA-HRP to thalamus from SMA was largely confined to pars oralis of the ventrolateral thalamic nucleus (VLo). FB-labeled terminals from GPi were scattered within VLo, and often overlapped the distribution of VLo cells projecting to SMA. As described in companion abstracts (Alexander, et al. and Koliatsos, et al.), the arm area of putamen was anterogradely labeled from SMA, and these labeled terminals overlapped with cells projecting to GPi. These studies provide further evidence for the maintenance of structural and functional segregation between the "motor" and other basal ganglia-thalamocortical circuits.

287.21

ORGANIZATION OF PRIMATE BASAL GANGLIA "MOTOR CIRCUIT": 5. CORTICAL AND PALLIDAL CONNECTIONS ARE SEGREGATED WITHIN THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS (PPN). F.H. Baker, L.J. Martin*, V.E. Koliatsos, J. Hedreen, D.L. Price, I. Hamada*, G.E. Alexander, and M.R. DeLong. Depts. of Neurology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Despite reports that the PPN projects to globus pallidus (GP) and receives input from internal GP (GPi) and the supplementary motor area (SMA) in primates, it is not known whether GP and cortical circuitries converge or remain segregated within PPN. It is also not known whether PPN projections to GP arise from cholinergic or non-cholinergic subpopulations of PPN neurons. We, therefore, injected the retrograde marker Fast Blue (FB) into GPi and the anterograde tracer wheat germ agglutinin-horseradish peroxidase (WGA-HRP) into SMA. Retrogradely labeled FB neurons were found throughout PPN (pars compacta and dissipata), with a predominant dorsomedial distribution. Combined retrograde tracing and ChAT immunofluorescence revealed that <2% of these neurons were cholinergic and that pallidopetal neurons were only minimally admixed with cholinergic PPN neurons. Pallidal neurons were predominately found dorsal and ventral to cholinergic neurons. GPi terminals were distributed medially in the same general area as GPi-projecting neurons. SMA terminals were primarily distributed in lateral PPN and showed minimal overlap with GPi-projecting neurons and GPi terminals. The results indicate that cortical and pallidal circuitries in PPN are largely segregated, with a lateral-medial topography, and that pallidopetal PPN neurons are noncholinergic.

LEARNING AND MEMORY: PHARMACOLOGY III

288.1

DIRECT COMPARISON OF THA AND 3,4 DAP, METHANESULFONYL FLUORIDE, PHYSOSTIGMINE AND CLONIDINE: DIFFERENTIAL EFFECTS ON IMPROVING MEMORY IN AGED MONEYS. Bartus, R.T. and Dean, R.L. Lederle Laboratories, Pearl River, NY 10965

The effects of several different drugs recently suggested to have therapeutic value for treating the cognitive symptoms of aging and Alzheimer's were evaluated for their ability to reduce memory impairments in aged, test-sophisticated Cebus monkeys (20 to 30 years old). Included were tetrahydroaminoacridine (THA), 3,4 diamino pyridine, methanesulfonyl fluoride, physostigmine and clonidine. Several doses of each drug were tested (P.O.) in each of ten different monkeys, allowing for direct and extensive comparison of each drug's efficacy in this model.

The results of this comparative test revealed several potentially interesting findings: (1) all drugs, except clonidine, produced improvement in a portion of the monkeys tested; (2) as in many past tests with aged monkeys and humans, wide variations in most effective dose, per subject, were observed; (3) different monkeys responded more effectively to one drug than another; and (4) under these tightly controlled conditions, physostigmine and methanesulfonyl fluoride produced the most reliable and robust effects ($p<.005$), in more monkeys, than did either THA ($p<.05$) or 3,4 DAP ($p<.10$). In contrast, neither acute, nor subchronic doses of clonidine improved performance of any monkey, while some exhibited clear impairments at higher doses.

288.2

DIFFERENTIAL EFFECTS OF CHOLINERGIC, DOPAMINERGIC, ADRENERGIC AND HISTAMINERGIC ANTAGONISTS INJECTED INTO THE HIPPOCAMPUS ON THE PERFORMANCE OF A T-MAZE WORKING-MEMORY TASK IN THE RAT. G.N.O.Brito, L.S.O.Brito, S.P.Silva and F.A.R.Prado. Lab.Neuropsicol.Exp., Setor de Neurociencias, Univ.Fed.Fluminense, Niteroi, RJ 24210, Brasil.

Previous research in our laboratory demonstrated that injections of scopolamine (a muscarinic antagonist) into the dorsal hippocampus impaired the performance of a working-memory task (discrete alternation), but did not alter the performance of a reference-memory task (visual discrimination) in a T-maze (Brito, G. et al., Psychopharm., 81: 315, 1983). In the present study, three groups of rats were tested on discrete alternation after bilateral intrahippocampal injections (1.0 ul), repectively, of scopolamine (39 mM) and sulpiride (19 mM, D2 blocker); propranolol (34 mM, beta blocker), prazosin (34 mM, alpha 1 antagonist) and yohimbine (34 mM, alpha 2 blocker); and antazoline (3 mM, histamine H1 antagonist), cimetidine (6 mM, H2 blocker) and betahistine (1 mM, H3 antagonist). The results demonstrated that only the injections of scopolamine disrupted the performance of the discrete alternation task. We conclude that the effects of intrahippocampal injections of scopolamine on working memory in rats is related to the specific blockade of cholinergic mechanisms, and not to the induction of imbalance among different neurotransmitter systems in the hippocampus.

PHARMACOLOGICAL DISSOCIATION OF THE HEART RATE AND SOMATOMOTOR COMPONENTS OF THE ORIENTING RESPONSE IN PREWEANLING RATS. Jane A. Saiers*, Rick Richardson* and Byron A. Campbell. Dept. Psychology, Princeton Univ., Princeton, NJ 08544

In response to a discreet auditory stimulus, rats exhibit a quick, lateral head jerk and a 40-50 bpm deceleration in heart rate. Both the head jerk and bradycardia are components of the orienting response (OR), which is presumed to reflect stimulus-directed attention. This research examined the effects of cholinergic and dopaminergic blockade on the OR to an 80 dB tone. In Experiment 1, scopolamine hydrobromide was found to inhibit the heart rate OR in a dose-dependent manner ranging from little effect at .125 mg/kg to complete inhibition of the cardiac OR at .5 mg/kg. No attenuation of the heart rate OR was observed in the saline control animals. The head jerk response, unlike the cardiac response, was undiminished by scopolamine. In the second experiment, haloperidol, administered at dosages ranging from 0 to 10 mg/kg attenuated the behavioral response (head jerk) in a dose dependent fashion but had no effect on the cardiac component of the OR. These results demonstrate that the autonomic and behavioral components of the orienting response are independent representations of a common central process. These results specifically contradict the view that the heart rate OR is simply a matter of cardiac-somatic coupling, in which cardiac deceleration is attributed to a change in somatic activity.

MEMORY FACILITATION PRODUCED BY DOPAMINERGIC AND CHOLINERGIC AGENTS: EFFECTS ON WIN-SHIFT AND WIN-STAY RADIAL MAZE TASKS. M.G. Packard, W. Regenold, R. Quirion, N.M. White. Department of Psychology and Douglas Hospital Research Centre, McGill University, Montreal, Quebec, Canada.

The role of DA and ACh receptor subtypes in the acquisition of two memory tasks was examined. The receptors were manipulated with S.C. injections of an ACh agonist (M2 receptor antagonist) AFDX-116 (1mg/kg), d-amphetamine (2mg/kg), a DA-D1 receptor agonist SKF38393 (2mg/kg), a DA-D2 receptor agonist LY171555 (2mg/kg), or vehicle controls. On a win-stay task (sensitive to caudate lesions) a light cue signalled the location of food in 4 randomly selected arms on each trial. Rats were given one trial per day and injected following trial 5. D-amphetamine, AFDX-116 and LY171555 (but not SKF38393) significantly improved performance compared to controls. On the win-shift task (sensitive to hippocampus/fornix lesions) food was available in all arms. Rats were trained to perform accurately with a 15 min delay between choices 4 and 5. They were then injected after choice 4 and tested 18 hours later. LY171555, but not AFDX-116 improved performance on this task. This is one of only a few reported cases of a direct behavioral effect of "pure" D2 receptor activation. These results suggest that post-training D2 receptor activation may influence both win-stay and win-shift memory. In contrast, post-training cholinergic activation influenced only win-stay memory; although a cholinergic substrate may be involved in win-shift memory it was not affected by immediate post-training activation.

288.5

EFFECTS OF NORADRENERGIC DEPLETION AND CHOLINERGIC ANTAGONISM ON COMPLEX MAZE PERFORMANCE IN YOUNG F-344 RATS. M. Chachich, E. Spangler*, K. Smith*, G. Wenk*, and D. Ingram*. Gerontology Research Ctr, Baltimore, MD 21224 and Dept. Psychology, Johns Hopkins U., Baltimore, MD 21218.

The muscarinic cholinergic (ACh) antagonist, scopolamine hydrochloride (SC), and the central norepinephrine (NE) neurotoxin, N-(2-chloroethyl)-N-ethyl-2-bromo benzylamine hydrochloride (DSP4), were given in combination to evaluate their effects on performance in a complex 14-unit T-maze. Male F-344 rats 3-mo old were given i.p. injections of either 0.9% saline (SAL) or DSP4 50 mg/kg bodyweight 2 wk prior to maze training. Rats were pretrained to criterion in 1-way active avoidance (0.8 mA) in a straight runway for 3 days with 10 trials/ day. On day 4 rats received 15 trials in a 14-unit T-maze. The rat had 10-sec to locomote past each of 5 gates to avoid shock (0.8 mA) enroute to the goal box. Each rat received either SAL or SC 0.25 mg/kg or 0.5 mg/kg (i.p.) 30-min prior to maze training. Drug groups were: SAL/DSP4, SAL/SC=0.25, SAL/SC=0.50, DSP4/SAL, DSP4/SC=0.25, DSP4/SC=0.50. Following maze training all rats were decapitated and the post-decapitation reflex (PDR) latency (sec), a behavioral assay for NE depletion, was measured. Dependent measures of maze performance included errors, alternation errors, runtime, shock frequency and duration. Analysis of variance was conducted for each dependent measure of maze performance. While a significant main effect of SC was observed on all measures of maze performance (p's<0.05) except shock duration, no main effect of DSP4 was observed in any of these measures (p's > 0.05). No interaction of SC and DSP4 was observed except in the alternation error measure where the DSP/SAL group exhibited superior performance during initial trials. PDR latencies for the DSP4-treated rats were significantly higher than for the SAL rats, $t(59)=8.61, p<0.01$, indicating that NE levels were depleted in DSP4-treated rats. These results further implicate ACh systems in learning this task and in age-related impairments previously observed, but suggest that central NE systems may not be critically involved.

STRIA TERMINALIS LESIONS ATTENUATE THE EFFECTS OF POSTTRAINING OXOTREMORINE AND ATROPINE ON MEMORY. I.B. Introini-Collison, Y. Arai*, and J.L. McGaugh (SPON: Gary D. Novack). Center for the Neurobiology of Learning and Memory and Department of Psychobiology. University of California, Irvine. CA 92717.

Previous evidence indicates that stria terminalis lesions prevent the memory-modulating effects of posttraining amygdala stimulation, as well as the facilitatory effects of epinephrine or naloxone and the impairing effects of beta-endorphin. The present experiments examined the effects of ST lesions on retention in rats given the muscarinic agonist oxotremorine (50 ug/kg; ip) or the muscarinic antagonist atropine (3.0 mg/kg; ip) immediately posttraining. Sprague Dawley rats (250-300 g) were submitted to sham operation or to bilateral lesions of the stria terminalis. One week later, they were trained in an inhibitory avoidance task and immediately after training they received saline, oxotremorine or atropine. Two weeks later they were trained on a Y-maze discrimination response and received saline or oxotremorine immediately postraining. Retention of each task was tested one week after training. Stria terminalis lesions did not affect retention of either response, but significantly attenuated both the enhancing effects of oxotremorine and the impairing action of atropine on memory. These findings support the view that the amygdala is involved in the memory-modulating effects of the cholinergic system.

EFFECTS OF CONCURRENT MANIPULATIONS OF CHOLINERGIC AND NORADRENERGIC FUNCTION ON INHIBITORY (PASSIVE) AVOIDANCE AND PLACE LEARNING. M.W. Decker and J.L. McGaugh. Dept. of Psychobiol. and Ctr. for Neurobiol. of Learn. and Mem., U. C., Irvine, CA 92717.

Cholinergic/noradrenergic interactions in learning and memory and in developmental plasticity have been identified, but whether such interactions generally characterize neural plasticity is not yet clear. To test the generality of this phenomenon, we evaluated the memory-impairing effects of scopolamine, a muscarinic antagonist, in normal and NE-depleted mice.

Administration of scopolamine i.p. 20 min before training impaired 24 h retention of inhibitory avoidance training (at doses of 0.1, 0.3 and 1.0 mg/kg) and the acquisition of place-training in a water maze (at a dose of 1.0 mg/kg). NE-depletion (to about 44% of control levels in hippocampus), which was produced by 50mg/kg DSP-4 i.p., did not affect performance on either task and did not alter the effects of scopolamine. NE-depletion did, however, impair the retention of place-learning when mice were retested on this task 16 d after initial learning. Since NE-depletion did not affect acquisition, this retention deficit is likely due to more rapid forgetting by NE-depleted mice. Interestingly, normal acquisition but rapid forgetting has also been observed in aged rodents displaying deterioration of the noradrenergic system. Thus, our results support the notion that noradrenergic dysfunction plays a role in age-related memory decline. Our failure to observe an enhancement of the disruptive effects of scopolamine by NE-depletion similar to that previously reported with rats in the radial arm maze, is likely due to species and task differences. Further, our NE-depletions were less extensive than in the previous report. Still, our findings suggest that cholinergic/noradrenergic interactions in learning and memory may be limited to certain forms of memory.

EFFECTS OF NORADRENERGIC DEPLETION ON NALOXONE-INDUCED MEMORY FACILITATION. A.H. Nagahara*, I.B. Introini-Collison, K.C. Liang, M. Kim* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology. University of California, Irvine, CA 92717.

Recent findings have indicated that beta-noradrenergic mechanisms in the amygdala participate in naloxone-induced memory facilitation. To further analyze this possibility Sprague Dawley rats (250-300 g) were bilaterally implanted with amygdala cannulae. One week later they were injected in the amygdala with water or the noradrenergic neurotoxin DSP 4 (30 ug/2.5 ul). They were then trained on an inhibitory avoidance task (IAT) and two weeks later on a Y-maze discrimination response (YMD). Immediately following training they were given intra-amygdala injections of buffer or naloxone (0.1 - 10.0 ug/1.0 ul). Pretreatment with DSP 4 significantly attenuated naloxone-induced memory facilitation (IAT: 0.1 ug; YMD: 0.3 ug). Further, in those rats pretreated with DSP 4, naloxone only facilitated retention when injected at the highest dose (IA: 10 ug). The blocking effects of DSP 4 on naloxone-induced memory facilitation appear to be related to the depletion of NE, since such a blockade was prevented by pretreatment with desipramine (DMI)(25 mg/kg; 4 and 1 hr before DSP 4). As expected, DSP 4 depleted NE in the amygdala (-24 %), and this depletion was prevented by DMI. The levels of NE in the amygdala correlated with the performance of the rats during the retention test. Unexpectedly, DSP 4 also decreased 5-HT levels in the amygdala (-27 %). No other changes in amine levels were found in any of the structures studied (amygdala, hypothalamus, hippocampus or striatum). We interpret these findings as providing further support for the view that naloxone-induced memory facilitation depends on the levels of NE in the amygdala.

LESIONS OF THE STRIA TERMINALIS ATTENUATE THE EFFECTS OF INTRA-AMYGDALA INJECTIONS OF NOREPINEPHRINE ON MEMORY. K.C. Liang & H.-C. Yao*. Dept. of Psychology, Natl' Taiwan Univ., Taipei, TAIWAN 10764, R.O.C.

Previous evidence indicates that post-trial injections of norepinephrine (NE) into the amygdala (Amyg.) affect retention of learned responses. The present study was designed to examine whether the memory modulatory effect of intra-Amyg. NE injections is attenuated by transecting a major Amyg. connection pathway--the stria terminalis (ST).

Male Sprague-Dawley rats received bilateral implantation of cannulae into the center of the Amyg.. Half of the rats also received radio frequency lesions (2.5 mA/30 sec) of the ST (ST-), while the rest received sham ST operations (ST+). Two weeks after surgery, all rats were trained on a one-trial step-through inhibitory avoidance task (1 mA/1 sec footshock). Immediately after training, rats received intra-Amyg. injections of vehicle or 0.2, 1.0 or 5.0 ug of NE (1 ul/Amyg.). Retention performance tested 24 hrs later indicated that in the ST+ rats, post-trial intra-Amyg. injections of 0.2 ug NE enhanced retention ($U=17$, $p<0.05$), while post-trial intra-Amyg. injections of 5.0 ug NE tended to impair retention ($U=26.5$, $0.05< p <0.10$). In contrast, various doses of NE injected into the Amyg. after training failed to affect retention in the ST- rats. These findings suggest that the integrity of the ST is critical for the memory modulatory effects of NE injected into the Amyg. Supported by a grant NSC 76-0301-H002-02 from NSC of R.O.C.

EFFECTS OF SCOPOLAMINE WITH DSP4 OR PCPA, ON WORKING AND REFERENCE MEMORY OF RATS. P. Prior and R.E. Hinson. Dept. of Psychology, Univ. of Western Ontario, London, Ont., N6A 5C2

This study investigated the effects of depletion of norepinephrine (NE) or serotonin (5HT) on scopolamine-induced deficits in 16-arm radial maze performance. After training, animals were placed into 4 groups, to receive different treatments prior to 2 maze tests, 3 days apart. One group received an i.p. injection of 400 mg/kg PCPA (5HT synthesis inhibitor) on each of the 3 days before the first maze test. A second had one i.p. injection of 50 mg/kg DSP4 (NE neurotoxin) 10 days before the first test day. Two other groups received saline in the pre-test period. The PCPA, DSP4 and one of the saline groups received 1.0 mg/kg scopolamine hydrobromide i.p. 30 min before one maze test, and 1.0 mg/kg scopolamine methylbromide before the other. The fourth group received only saline before tests. Assay after the second test showed 5HT depletion to 11% of control in the PCPA group, and to 60% of control in the DSP4 group. Working (re-entries into already visited baited arms) and reference (entries into the 8 never-baited arms) memory errors were elevated in the scopolamine and scopolamine+DSP4 compared to the analogous methylscopolamine conditions. Interestingly, working errors were not increased with PCPA+scopolamine; in fact they were decreased compared to all conditions including control. Serotonin synthesis blockade by PCPA may ameliorate some memory deficits produced by scopolamine in this task.

NORADRENALINE DEPLETION BY DSP4, LIKE CLONIDINE, IMPROVES SPATIAL LEARNING IN FORNIX SECTIONED RATS. S.J. Sara, C. Dyon-Laurent and C. Maho, Lab. of Psychophysiology, CNRS, LPN2, 91198 Gif/Yvette, France. (SPON: R.B. Messing)

The adrenergic alpha-2 receptor agonist, clonidine, which inhibits release of noradrenaline (NE) by its action on inhibitory autoreceptor, reversed the deficit in acquisition of a spatial working memory task in rats with fornix lesions (Sara, Amassari and Maho, 1987, Neurosci. Abstr.). To assess to what extent this facilitation was due to clonidine's inhibition of NE release, we lesioned the fornix and then injected the specific NE neurotoxin DSP4. Rats with fornix lesion alone were impaired, while those with both NE depletion and fornix lesion performed as well as controls. Neurochemical analysis of the hippocampus of these rats showed a unilateral decrease of 50% in choline acetyl transferase activity, along with 50% decrease in NE content and a slight increase in the NE metabolite MHPG, indicating a hyperactivity of NE in fornix lesioned rats. DSP4-treated rats showed low levels of both NE and MHPG. This hyperactivity of the NE system after fornix section, appears to exacerbate the behavioral deficits due to cholinergic deficits.

The interaction between NE and Ach requires an appropriate balance between the two for adequate cognitive function.

288.12

ENHANCED BEHAVIOURAL CONDITIONING TO CONTEXT BUT UNCHANGED CORTICOSTERONE RESPONSE IN NORADRENALINE DEPLETED RATS. N.R.W. Selden*, T.W. Robbins, and B.J. Everitt[1]. Departments of Experimental Psychology and [1]Anatomy, University of Cambridge, Cambridge, U.K. CB2 3EB

This study tested the hypothesis that cortical noradrenaline (NA) depletion induced by 6-hydroxydopamine widens attentional span, impairing the acquisition of conditioning to a punctate stimulus (CS), while enhancing conditioning to contextual surroundings. A conditioned suppression paradigm was used involving baseline lever pressing for food reward, in an operant chamber, and the conditioning of a clicker stimulus predicting shock, in a separate place-preference apparatus (PPA). After conditioning, NA depleted animals showed a longer latency to enter the shock side and greater preference for the safe side of the PPA, indicating greater contextual conditioning, as predicted by attentional theory. However, NA depleted rats also suppressed operant responding more than controls during CS presentation. Plasma corticosterone was increased after exposure to the PPA and to the CS, but was unaffected by NA depletion. Lesioned animals may have shown increased suppression to the nominal CS because of a deficit in temporal processing, causing them to treat the shock as temporally unrelated to CS onset. In this case, the CS would constitute another element of the context, and enhanced conditioning would further support an attentional interpretation.

288.13

EFFECTS OF VAGOTOMY ON THE FACILITATION OF LEARNING AND MEMORY PRODUCED BY 4-OH AMPHETAMINE. C.L. Williams* and R.A. Jensen. Department of Psychology, Southern Illinois University, Carbondale, IL 62901.

Previous studies have demonstrated that peripherally administered catecholamines (CA), or agents affecting CA release such as amphetamine or 4-OH amphetamine, modulate brain processes involved in memory storage (Martinez et al., Br. Res., 182:509, 1980). These agents may act indirectly to modulate memory since some (e.g. 4-OH amphetamine) do not easily cross the blood-brain barrier.

To determine the route by which these substances exert their effects, rats received either subdiaphragmatic vagotomies, sham surgeries, or no surgery. After recovery from surgery, all animals were trained in an inhibitory avoidance task with a 0.92 mA, 0.5 sec footshock. Immediately after training 2.0 or 4.0 mg/kg 4-OH amphetamine or saline was injected i.p. Retention was tested 24 hours later. Preliminary results indicate that the retention of vagotomized rats receiving either dose of amphetamine did not differ significantly from saline-injected controls. Injection of 2.0 mg/kg 4-OH amphetamine to sham operated animals enhanced retention performance compared to the vagotomized rats. At this dose, sham-operated animals did not differ from control rats. These findings suggest that vagotomy may attenuate the effects of peripherally acting agents that modulate memory and that vagal afferents may carry information about peripheral events that modulate memory storage processes.

288.14

ENHANCEMENT OF MEMORY FOR AN APPETITIVE LEARNING TASK BY GLUCOSE IN MICE. C. Messier and C. Destrade, Lab. Psychophysiologie, UA CNRS 339, Univ. Bordeaux I, 33405 TALENCE FRANCE.

Experiments have shown that a post-training glucose injection can retroactively and non-contingently improve the retention of a previously learned association (Messier and White, Physiol. Behav., 32, 195-203, 1984; Behav. Neural Biol., 48, 104-127, 1987). However this memory-improving action of glucose has only been shown in rats and for aversively motivated tasks. The present experiments sought to generalize these previous findings by demonstrating the memory improving action of glucose in an other species (BALB/c mouse) and for an appetitively motivated task (an operant bar pressing response to obtain a food reinforcer). The results show that a post-training 3 g/kg or 4 g/kg glucose injection could retroactively and non-contingently improve the retention of this task 24 h later while 2 or 5 g/kg glucose injections were ineffective. Post-training glucose did not produce any effect on the retention of yoked animals for which food reinforcement was not contingent on bar pressing, but were otherwise exposed to all the stimuli of the training situation. The lack of effect of glucose in the yoked animals suggests that the effect of glucose in the trained animals was dependent on the existence of an association between the act of bar pressing and the availability and consumption of the reinforcer and that glucose improved the memory for this association.

288.15

MEMORY FACILITATION BY GLUCOSE IN AGED HUMANS. C.A. MANNING, C.L. JONES, J.L. HALL and P.E. GOLD. Dept. Psychology, University of Virginia, Charlottesville, VA 22903 (SPON: J. HAHN).

Recent evidence suggests that the effects of epinephrine on memory in rodents may be mediated, in part, by the hormone's hyperglycemic actions. Consistent with these findings, glucose also enhances performance on some memory tests in elderly people. In addition, poor glucose regulation was related to poor memory performance in individual subjects. This study investigated the role of glucose on additional memory tests as well as on other measures of cognitive and motor functioning.

Subjects, aged 62-84 (n=17), were tested on two consecutive mornings. Subjects took a series of tests assessing memory, IQ, attention, and motor function after ingesting either 50 g of glucose or 32 mg of saccharin. Plasma glucose was measured at several times during testing. On Day 2, subjects received alternate treatments and test forms.

Glucose, but not saccharin, increased circulating glucose levels significantly. Performance on memory tasks, but no other tasks, was enhanced by glucose. Thus, the glucose effects appear to be selective to memory. As seen before, glucose control was related to memory in individual subjects. Thus, these findings provide additional evidence that glucose enhances memory, and that poor glucose regulation is related to poor memory, in elderly humans. REGIONAL BRAIN [^{3}H]2-DEOXYGLUCOSE UPTAKE IN MICE: EFFECTS OF AMNESTIC AND MEMORY-ENHANCING DRUGS. W.S. STONE and P.E. GOLD. Dept. Psychology, University of Virginia, Charlottesville, VA 22903.

Scopolamine (SCOP)-induced amnesia in mice can be attenuated with several non-cholinergic treatments, including epinephrine and glucose (GLU). On the basis of growing evidence that GLU regulates memory storage, we examined the effects of an amnestic dose of SCOP on regional brain [^{3}H]2-deoxyglucose (2DG) uptake, alone and in combination with drugs that attenuate SCOP-induced memory deficits.

Mice received combined injections (IP) of SCOP (3 mg/kg) and saline, or SCOP and GLU (100 mg/kg). Ten min later, animals received 2DG (10uCi/animal, SC) and were sacrificed 40 min after the 2DG injections. Eight brain regions were then dissected, solubilized, and assessed for specific activity.

SCOP reduced 2DG uptake in several areas, with maximal decreases (21-50%) seen in hypothalamus, hippocampus, septum and striatum. Preliminary data also suggest that peripheral GLU injections may attenuate SCOP-induced reductions in 2DG uptake in these areas, consistent with the view that GLU may enhance CNS GLU utilization and perhaps cholinergic function. (Supported by MH 31141, ONR N00014-85-K0472, the American Diabetes Association, and NIA Postdoctoral Fellowship AG 05408).

288.17

MEDIATION OF ADRENALECTOMY MEMORY EFFECTS BY CIRCULATING GLUCOSE. J.L. Hall & P.E. Gold. Dept. Psychology, University of Virginia, Charlottesville, VA 22903.

Epinephrine released from the adrenal medulla, modulates memory storage. Recent evidence suggests that these hormonal effects are mediated, in part, by increases in blood glucose (BG) levels. This study examined the possible contribution of BG to memory changes seen in rats after adrenalectomy (ADX).

Rats exhibited a transient impairment in retention of an inhibitory (passive) avoidance task after ADX. The deficit was most pronounced 48 hr after surgery; retention 8 days after surgery was comparable to that of controls. Baseline BG was decreased 1 and 2 days after ADX but had recovered after 8 days. Compared to the training-related increase in BG levels seen in sham-operated rats, ADX rats had a delayed BG increase after 1 Day, a BG decrease at 2 Days, and no change 8 days after surgery.

Preliminary studies indicate that BG increases after glucose injection are attenuated 2 days after ADX. By using a dose which produces a BG response comparable to that accompanying glucose memory enhancement in intact animals, posttraining glucose attenuated the ADX-induced memory deficit.

These findings suggest that altered BG baseline levels and responses to training may contribute to memory impairments and recovery after ADX. Additionally, the results further implicate blood glucose in the regulation of CNS information processing systems. (Supported by MH 31141, ONR N00014-85-K0472, and the American Diabetes Association).

COCAINE ENHANCES RETENTION OF AN ACTIVE AVOIDANCE TASK IN RATS. P.H. Janak and J.L. Martinez Jr. Dept. of Psychology, University of California, Berkeley, CA 94720.

Earlier work showed that posttraining intraperitoneal administration of d-amphetamine enhanced retention of a one-way active avoidance task in rats, and that these effects depend upon peripheral catecholamine stores (Martinez et al, Brain Res., 182:157-166, 1980). The current experiments show that posttraining administration of cocaine, which shares many pharmacological actions with amphetamine, also enhances retention of an active avoidance task in rats.

Male Sprague-Dawley rats were given cocaine HCl or saline i.p. immediately following 2 training trials in a one-way active avoidance task. The animals were given 10 s to avoid delivery of a 600 uA shock by crossing to a safe chamber. Rats were tested 24 h later; the number of avoidances made in 8 trials was used to measure retention. A posttraining 5.0 mg/kg cocaine dose enhanced retention of the avoidance task 24 h after training ($t=3.07$, $p<.01$); both a lower dose (2.5 mg/kg) and a higher dose (7.5 mg/kg) were without effect. Lidocaine was without effect indicating that local anesthesia does not account for cocaine enhancement of active avoidance performance. Cocaine's effect was time dependent such that it was only effective when administered immediately after the training trials.

Supported by PHS grant DA #04195.

288.19

THE EFFECTS OF THE ALPHA-2 AGONIST CLONIDINE ON DELAYED NONMATCH-TO-SAMPLE PERFORMANCE IN AGED RHESUS MONKEYS A.F.T. Arnsten and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale Medical School, 333 Cedar St., New Haven, CT 06510

The alpha-2 adrenergic agonist clonidine significantly improves the spatial working memory abilities of aged monkeys performing the delayed response task (Science 230:1273-1276, 1985). This type of memory is subserved by the principal sulcal prefrontal cortex (PS-PFC) and pharmacological data from 6-OHDA-lesioned monkeys suggest that clonidine's beneficial actions may occur at least partially in this brain region (ibid). The present study examined whether clonidine might improve another type of memory that is not dependent on the PS-PFC, visual object recognition memory, as tested by the delayed nonmatch-to-sample task (DNMS). Aged monkeys were trained on DNMS according to the methods of Presty et al. (Neurobiol. Aging 8: 435-440, 1987), and a wide range of clonidine doses was explored (0.00001-0.1 mg/kg). As with the delayed response task, clonidine improved performance on DNMS. However, the effective dose range was more limited, and the improvement less robust than with delayed response. These data suggest that clonidine's effects on cortical function are not limited to the PS-PFC, and that the beneficial effects of alpha-2 agonists on cognitive function are not restricted to spatial working memory.

288.20

SPATIAL WORKING MEMORY ON THE PLATFORM MAZE IS NOT IMPAIRED BY A NORADRENERGIC ANTAGONIST INJECTED INTO THE HIPPOCAMPAL DENTATE GYRUS. S. Benloucif, A. Packer*, E.L. Bennett and M.R. Rosenzweig. Dept. of Psychology, University of California, Berkeley, CA 94720.

Long-term potentiation in the dentate gyrus of the hippocampus is enhanced by application of norepinephrine (NE) and blocked by either NE depletion or beta-receptor antagonists. The integrity of hippocampal functioning is necessary for learning and performance of spatial working memory. We examined whether beta-receptor antagonism in the dentate gyrus would impair retention of a spatial working memory problem. Rats were trained on a working memory version of the Barnes' platform maze which required the animals to return to an escape hole they had found two hours earlier. The rats received two training trials followed by a 2 hr delay and a single test trial. Rats had to choose from among 12 goal locations spaced evenly around the outer edge of a 4 ft diameter circular platform. The goal location changed each day. After 20 days of training subjects were implanted with indwelling injection cannulas. Following recovery the rats were trained for an additional 8 days, then received pre- or post-training injections of one of 3 doses of propranolol or vehicle every third day for 24 days. At the conclusion of the experiment rats were divided into dentate gyrus (DG, N=7) or non-dentate (N=4) groups based on cannula placement. Propranolol did not impair retention in comparison with non-drug days. However, both cannula placement and injections increased errors and variability on non-drug days in the DG group that may have masked a more subtle impairment of performance with beta receptor blockade. Additional work with other amnestic agents (anisomycin, lanthanum chloride, glutamate) also indicates that retention of this task may not be susceptible to drugs injected into the dentate.

SUPPRESSION OF DRINKING IN RATS BY AMPHETAMINE-CONDITIONED STIMULI. P.M. Duncan . Psychology Dep't, Old Dominion Univ., Norfolk, VA 23508.

Pavlovian conditioning of d-amphetamine sulfate (DA) effects on suppression of water-drinking was investigated in two experiments. Rats (24-hrs water-deprived) were adapted to drinking from a touch-sensitive spout in the test-box over a 3-4 day period. A conditioning day followed, on which experimental groups were injected IP with DA 15-min prior to 20 presentations of a 10-sec, 5-hz, 75-db clicking stimulus (CS) which initially inhibited drinking. Habituation was indicated by less suppression (by nondrugged control rats:ND) to subsequent CS presentations both during this session, and 72-hours later during a test session. No-stimulus controls (NSC) had no CS exposure until the test day, and delayed-drug controls (DD) were not DA-injected until two hrs post "conditioning" in the home cage. DA produced dose-related drinking-impairment and greater suppression during the conditioning session. Suppression ratios (SR: 100=no drinking during CS, 0=no change in lick-rate) recorded on the test day (all groups non-drugged, and 24-hrs water-dep) indicated dose-related suppression in DA-groups, compared to ND and DD controls. Median CS presentations to SR<20, DA dose (mg/kg) and n() for each group: Exp#1; ND(11)=3, DA6(10)=12*, DA2(10)=12*, NSC(7)=12*. Exp#2; ND(10)=1, DD(7)=1.5, DA2(8)=18*, DA.6(8)=2, NSC(7)=5* (*=different ($p<.05$) from ND). Similar differences were indicated by ANOVA of SR-values. These results show that the adipsic effects of DA can be conditioned to environmental stimuli during one drug treatment at a dose of 2, but not .6 mg/kg. Suppression of drinking may have been elicited by overall test-situation cues as well as by the auditory stimulus.

ALPHA-2 ADRENOCEPTOR ANTAGONISTS DECREASE SCOPOLAMINE-INDUCED SWIMMING ACTIVITY WITHOUT ALTERING ACTIVITY PATTERNS. W. Lipinski*, M. Smith* and R.E. Davis (SPON: J.G. Marriott). Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105.

In previous work we have shown that the anticholinergic scopolamine alters two components of swimming activity eliciting excessive and stereotyped patterns of activity. Cholinesterase inhibitors and direct muscarinic agonists reverse both the total amount and stereotyped patterns of activity elicited by scopolamine. However, these two components of scopolamine-induced swimming activity may be independent and dissociable processes. In an attempt to demonstrate pharmacological dissociation of these two process, we examined the ability of a series of alpha-2 antagonists, compounds which are known to decrease locomotor activity, to differentially alter the total amount and stereotyped pattern of activity elicited by scopolamine.

To accomplish this, scopolamine (0.32 mg/kg, IP) was administered in combination with subcutaneous injections of vehicle (0.9% saline) or one of the following alpha-2 antagonists: yohimbine (Sigma), idazoxan (Reckitt and Coleman), WY 26902 (Wyeth, UK), or L-654,284 (Merck Sharp and Dohme) to male Long-Evans rats. Thirty minutes later these animals were placed in a white plastic enclosure filled to a depth of 33 cm with water (22° C) made opaque by the addition of powdered milk. Swimming activity was monitored continuously for the next 5 mins using a computerized system. Total distance traveled and several metrics for quantifying swimming activity patterns served as the dependent measures.

All alpha-2 antagonists tested decreased total distance traveled by scopolamine-pretreated rats at doses that did not decrease spontaneous swimming activity. In contrast, these alpha-2 antagonists did not alter the stereotyped patterns of activity induced by scopolamine. This suggests that these two components of scopolamine-induced swimming activity are pharmacologically dissociable and may be independent processes.

THE C57BL/10j MOUSE AS A MODEL OF IMPAIRED COGNITION: COMPARISON OF THE EFFECTS OF REFERENCE AGENTS ON WATER-MAZE PERFORMANCE. C. Bay-Gemmill*, M. Smith*, J. Kinsora*, M. Dickerson*, W. Lipinski* and R.E. Davis. Parke-Davis Pharmaceutical Research Div., Warner-Lambert Co., Ann Arbor, MI 48105.

Previous work has shown that mice with a small hippocampus (C57BL/10j, B10) have greater difficulty acquiring a spatial water maze task than mice with a large hippocampus, (NZBXNZW F1 strains). The performance deficits of B10 mice can be ameliorated by admininistration of some cholinomimetics suggesting that there may be a cholinergic deficiency contributing to the poor performance of B10 mice in the water maze. However, this does not exclude the possibility that pharmacological manipulation of other neurotransmitter systems might also improve the water-maze performance of B10 mice. Because of this, selected agonist and antagonists from several classes of drugs were studied for their ability to improve the water-maze performance of B10 mice.

To accomplish this B10 mice were tested in a square water maze with a small moveable platform hidden below the surface of opaqued water (21-23°C) and located in the center of one of four quadrants of the pool. Four trials were conducted each day over two consecutive days. Latency to find the hidden platform served as the dependent measure. Drugs were administered on both test days 30 minutes prior to testing.

Of the classes of agents tested most impaired or failed to improve the performance of B10 mice in this test. These included agonists and antagonists interacting with dopaminergic, alpha-1 adrenergic, serotonergic systems and monoamine uptake inhibitors. The exceptions were ±3-PPP, a dopamine autoreceptor agonist, and yohimbine, an alpha-2 adrenergic antagonist, both of which improved the water-maze performance of B10 mice. These findings suggest that most agents which alter classical neurotransmitter function do not improve the water-maze performance of B10 mice. However, agents representative of 3 classes of drugs appear to improve the performance of B10 mice in the water-maze, alpha-2 antagonists, dopamine autoreceptor agonists and cholinomimetics.

288.24

EFFECTS OF CHRONIC SEROTONIN RECEPTOR ANTAGONIST ADMINISTRATION ON ACQUISITION OF A COMPLEX SPATIAL DISCRIMINATION TASK IN YOUNG AND OLD RATS. H.J. Normile, M.P. Galloway and H.J. Altman, Department of Psychiatry, Wayne State University, Detroit, MI 48207

Previously research from this laboratory has shown that p-chloroamphetamine-induced chronic reductions in brain serotonin (5-HT) facilitated the performance of young and old rats in a complex spatial discrimination task (Stone 14-unit T-maze). The present experiment examined the effects of chronic 5-HT receptor antagonist administration on acquisition of the same task in both young and old rats. The rats (male Sprague-Dawley) were trained one trial per day for a total of 25 days. Ketanserin (1.0, 10.0 mg/kg) and mianserin (0.1, 1.0 mg/kg) were administered (ip) using a variety of treatment schedules, including a 14 day pretreatment period and daily injections commencing with the first maze trial. Analysis of the data (errors over days, days to criterion) suggests that the drugs interfered with the ability of the animals to acquire the task. Therefore, in contrast to the facilitative effects observed following cytotoxic destruction of 5-HT neurons, chronic blockade of post-synaptic 5-HT receptors appears to impair acquisition in the 14-unit T-maze.

Supported, in part, by ADRDA grant 87-087 to HJN.

288.25

FACILITATION OF COMPLEX MAZE LEARNING IN RATS FOLLOWING SELECTIVE 5-HT DEAFFERINATION OF THE DORSAL HIPPOCAMPUS. H.J. Altman[1], H.J. Normile[1], M.P. Galloway[1], T. Ramirez[2] and E.C. Azmitia[2]. [1]Dept. Psychiatry, Wayne State University School of Medicine, Detroit, MI, [2]Dept. Biology, New York Univivesity, New York, N.Y.

Recent evidence from this laboratory indicates that PCA-induced 5-HT depletion of the brain significantly enhances the performance of rats trained in the Stone 14-Unit T-maze. Although PCA depletes brain 5-HT indiscriminantly, the most profound reductions are observed in the hippocampus (HIPP) - an area repeatedly shown to play an important role in learning and memory. To determine a more specific locus of 5-HT action, the performance of rats trained in the Stone maze was determined following injection of the selective serotonergic cytotoxin 5,7-DHT into the fimbria-fornix which results in selective destruction of HIPP 5-HT terminals. The behavioral results indicated that the performance of the 5,7-DHT-lesioned rats was significantly better than that of both sham-operated and vehicle-injected controls (both in terms of mean number of errors and trials to criterion). The performance of the sham-operated and vehicle-injected controls did not differ. Neurochemical determinations revealed that HIPP, but not striatal, 5-HT was profoundly decreased following 5,7-DHT administration. The results of the present experiment are important because they extend our understanding of the role 5-HT plays in the processes underlying learning and memory.

PARTICIPATION OF THE RAT'S PELVIC, PUDENDAL AND GENITOFEMORAL NERVES IN SOME PERINEAL MUSCULAR REFLEXES. M. Martínez-Gómez, J. Manzo-Denes*, C. Beyer*, B.R. Komisaruk and P. Pacheco. Univ. Aut. de Tlaxcala, Méx.; Univ. Veracruzana, Xalapa, Ver., Méx.; CINVESTAV-Tlax., Méx.; Rutgers Univ., Newark, NJ, USA; and IIB-UNAM, Méx., D.F..

The iliococcygeus (icm) and pubococcygeus (pcm) muscles can be reflexively contracted by contralateral tail displacement, and by perineum, clitoral sheath and distal vagina stimulation. This reflexive contraction was abolished by gentle cervical stimulation while the psoas muscle (psm) was reflexively activated by the same stimulation. The icm and pcm contraction had a duration related to the origin of stimulation. Perineal skin stimulation is more effective than clitoral and both of them more than vaginal. When clitoris was held, the pudendal nerve's (PuN) clitoral receptors and the genitofemoral nerve's (GfN) groin skin receptors also initiated icm and pcm reflex contraction. Both cervical inhibitory action upon icm-pcm contraction and psm activation effect were partially abolished during the ipsilateral transection of the pelvic nerve's (PeN) viscero-cutaneous branch, and completely abolished after bilateral transection. In male rats PuN was activated by scrotal skin and thigh inner surface stimulation; PeN by perianal skin; and GfN by groin skin. When electrical stimulation was applied, PuN provoked contraction of the coccygeus muscle, external anal sphincter and the cremaster area closer to the epididymis' tail; PeN evoked icm and pcm contraction; and GfN contracted the cremaster that covers the testis. CONCLUSIONS: In male rats both PuN and GfN innervate the cremaster, PuN the scrotal skin, and PeN the perianal skin. In female rats cervical stimulation provides facilitatory and inhibitory reflex mechanisms involved in reproductive activities.

OLFACTORY AND VISCERAL PROJECTIONS TO THE NUCLEUS OF THE SOLITARY TRACT. R. Guevara-Aguilar, D.E. García-Díaz, L.L. Jiménez-Montúfar* and M.J. Wayner. Depto. de Fisiología, Facultad de Medicina, U.N.A.M., Apdo. Postal 70-250, 04510 México, D.F., and Division of Life Sciences, University of Texas at San Antonio, Texas 78285, U.S.A.

Electrophysiological studies were performed to determine if neurons of nucleus of the solitary tract (NTS) which receive inputs from the stomach via vagal afferents also respond to olfactory bulb (OB) stimulation. Experiments were conducted on twenty Wistar rats weighing between 230-280 g. The frequency of neuronal activity of the rostral ventral portion of the NTS was increased by gastric distension (GD). The evoked potentials in the same site due to vagal stimulation displayed short latencies; whereas, the evoked potentials in the dorsomedial part of the NTS due to vagal stimulation had considerably longer latencies. Gastric distension decreased neuronal activity in the dorsomedial NTS. Evoked potentials and increases in neuronal activity were also observed in the dorsomedial NTS due to electrical stimulation. In the dorsomedial NTS, OB stimulation enhanced the decrease in neuronal activity due to GD. Olfactory and visceral functions apparently interact in the NTS in modulating taste mechanisms involved in food selection and ingestion.

RESPONSES OF SPINE-ASSOCIATED PENILE MECHANORECEPTORS TO TANGENTIAL MECHANICAL STIMULATION. R.D. Johnson and V.P. Dugan*, Dept. of Physiological Sciences, University of Florida, College of Veterinary Medicine, Gainesville, FL 32610.

Single unit activity from penile mechanoreceptors were recorded from a teased fiber preparation of the dorsal nerve of the penis in barbiturate anesthetized male Wistar rats. By utilizing a modified Chubbuck mechanostimulator which provided "swept" tangential stimulation of the spiny penile surface, mechanoreceptors preferentially responding to these stimuli were studied. These receptors, classified as 'spiny RA units', were characterized by (1) 2 to 4 discrete receptive fields; each under a single proximally directed spine or spine cluster and separated by insensitive spines and interspinous skin (up to 4.5 mm spacing), (2) myelinated branching to each RF from a single myelinated parent axon as confirmed by collision techniques, (3) an exquisite vibratory sensitivity up to 1200 Hz as determined with 10 cycle entrainment, (4) a relative insensitivity to punctate vertical skin movement, and (5) greater responses to distal movements (as in copulatory withdrawal motion) than to proximal movements. Computer analysis of discharge patterns revealed coding of displacement and velocity components of stimuli swept over the receptive area.

The direction sensitivity and spatial coding ability of these mechanoreceptors even when only the spines were deflected suggests a sensory role for the penile spines of the rat in copulatory behavior.

AN INTRACRANIAL, PEPTIDERGIC, SENSORY MICROGANGLION IS ASSOCIATED WITH CRANIAL NERVE XI IN THE RAT C. J. Wetmore and R. P. Elde Dept. of Cell Biol. and Neuroanatomy and Graduate Program in Neuroscience, University of Minnesota, Minneapolis, MN 55455.

Cranial nerve XI (CnXI) is considered to be a purely motor nerve. However, a small ganglion (250-260 µm) associated with the arachnoid near the vertebral artery and the spinal trunk of CnXI on the ventrolateral aspect of the rat brainstem was noted in over 30 Sprague-Dawley rats. The ganglion was found to have 3-5 processes extending into the arachnoid, one of which joins the spinal trunk of CnXI. Exposure of the proximal stump of the severed peripheral CnXI to Fluoro-Gold (FG) resulted in fluorescent staining of all neurons within the ganglion, as well as several bipolar, intrafascicular neurons within CnXI.

Immunohistochemical studies were conducted on whole mounts of this ganglion with antisera to calcitonin gene related peptide (CGRP) and substance P (SP). Virtually all neurons were intesely immunoreactive for CGRP and many indicated some degree of SP immunoreactivity. Not suprisingly, two-color immunoflourescence analysis demonstrated doubly labeled neurons, indicating coexistence of SP and CGRP in over half of the cells. The morphology of these neurons resembled the small- and medium-diameter pseudounipolar primary afferent neurons in dorsal root ganglia. Support for the sensory, rather than sympathetic character of this ganglion was found in that neonatal capsaicin treatment significantly diminished the intensity of SP and CGRP immunoreactivity whereas, neonatal guanethidine treatment failed to alter the staining or morphology of the cells. Thus, this microganglion appears to have morphological and neurochemical properties similar to primary afferent, nociceptive neurons and may have intracranial as well as extracranial targets of innervation. MORPHOLOGICAL DIFFERENCES BETWEEN FINE NERVE FIBERS IN THE KNEE JOINT. R.F. Schmidt, B. Heppelmann*, K. Meßlinger*, and W.F. Neiss*. Inst. of Physiology and Inst. of Anatomy, Univ. of Würzburg, D-8700 Würzburg, Fed.Rep.Germany

In electrophysiological studies fine afferent joint units (group III and IV) revealed marked differences in their threshold and response patterns to passive movements: some units responded forcefully to movements in the normal working range of the joint, others only to noxious stimuli, still others to no stimuli at all (H.-G. Schaible and R.F. Schmidt, J. Neurophysiol., 49: 1118, 1983). To answer the question, whether there exist any structural correlates to the various functional types, we started a morphological examination of fine afferent nerve fibers in the cat's knee joint at the light and electron microscope level.

Here we report on the examination of fine nerve fibers in joint tissue of sympathectomized cats. The fibers were reconstructed and analyzed in serial sections over a distance of up to 100 µm using an electron microscope (Zeiss EM 902).

In their terminal parts (length up to several 100 µm) the fibers split up into several branches. Preterminal bulges in the whole terminal parts and true endings of the fibers show axonal membrane not covered by Schwann cell and accumulations of mitochondria, glycogen particles and vesicles. The number of these organelles, however, greatly varies between different fibers. This may reflect differences in the metabolic activity. On the assumption that the metabolic activity is correlated with the nerve fiber activity, it may be speculated that units which are activated by normal joint movements contain a high amount of mitochondria and glycogen particles. Fibers with a low content of organelles may be considered as nociceptive units only activated under extreme conditions.

DIFFERENTIAL DISTRIBUTION OF PEPTIDERGIC VISCERAL AFFERENT PROJECTIONS FROM THE NODOSE GANGLION TO THE LARYNX AND STOMACH. K.M. Hill* and C.J. Helke. (SPON: E. Frey) Uniformed Services Univ. of Health Sci., Bethesda, MD.

Several neuropeptides were localized in cells in the inferior vagal (nodose) afferent ganglion of the rat (Helke and Hill, Neurosci. in press). Substance P(SP), calcitonin gene related peptide (CGRP), and cholecystokinin (CCK)-ir cells were more numerous in the rostral compared to the caudal nodose ganglion. To determine if this chemotopic organization reflected a somatotopic organization, we studied peptide-ir in organ specific projections to a caudal (stomach) vs a rostral (larynx) vagal target. Fluoro-Gold (FG) was applied to the cut end of the anterior gastric vagus nerve (AGN) and the superior laryngeal nerve (SLN), respectively. FG application to the AGN labeled numerous cells in the caudal (main) nodose ganglion whereas FG transported by the SLN labeled more rostral and fewer caudal nodose neurons. Transection of the nerve just rostral to the FG application in control experiments eliminated ganglionic labeling. Peptide-ir of FG-labeled cells was detected with immunofluorescence. SP, CGRP, and CCK-ir nodose ganglion neurons projecting to the AGN were extremely rare. SP- and CGRP-ir (but not CCK-ir) neurons projecting to the larynx were found in the rostral and to a lesser extent caudal nodose ganglion. These studies demonstrate SP and CGRP vagal afferent projections in the SLN, and suggest a loose intraganglionic organization of projection and transmitter specific neurons. (NIH NS20991).

BRAINSTEM ACTIVITY EVOKED BY ABDOMINAL VAGAL STIMULATION IN FERRET. G.E. Lucier, K.A. Sharkey*, R. Egizii* and J.S. Davison*. Dept. of Physiology, University of Calgary, Calgary, Alta., T2N 4N1 Canada.

Electrical stimulation of the vagal communicating branch (VCB) elicits vomiting in anaesthetized ferrets. Neurophysiological mapping of the projection sites of the VCB in the region of the nTS is an essential preliminary to analysis of the central mechanisms involved in emesis. Adult male ferrets were anaesthetized with halothane. A cuff electrode was placed on the VCB and tested by inducing a single emetic episode, after which the animal was paralyzed. Hypertonic saline was infused into the stomach as an alternative stimulus for inducing emesis. Brainstem evoked activity was recorded using stereotaxically placed tungsten microelectrodes. Responses to either stimuli were obtained in units that were either previously silent or exhibiting low frequency discharge. Latencies to electrical stimulation were usually around 200 msec (range 75 - 300 msec). These units were found to lie in nTS, 2.0 mm rostral and 2.5 mm caudal to obex and from midline to 1.0 mm lateral at the level of obex. In the rostral nTS, they were found to be primarily ventral and medial to respiratory and cardiovascular units. In the caudal nTS, only evoked responses were found, indicating some degree of viscerotopic organization. (Supported by MRC Canada)

VISCERO-SOMATIC CONVERGENCE AT TWO LEVELS OF THE RAT SPINAL CORD. E.W. Akeyson* and L.P. Schramm (SPON: R. Taylor), Depts. of Neuroscience and Biomedical Engineering, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

We are studying viscero-somatic convergence at two spinal cord levels in chloralose-anesthetized rats. Splanchnic responsive (SPL) neurons at T_8-T_{11} and C_2-C_5 were tested with greater splanchnic (GSN) and ilio-hypogastric nerve (IHN) stimulation and mechanical stimulation of the skin. Thoracic SPL neurons responded to GSN stimulation with one or two excitatory bursts. IHN evoked responses were as long as GSN evoked responses, but much earlier in onset. Most neurons had cutaneous receptive fields (RF) located on the ipsilateral lower chest and upper flank regions. Two-thirds of the neurons were excited by light touch and intense, noxious stimulation (WDR type). The remaining neurons responded only to high intensity, noxious stimuli (HT type). Half of cervical SPL neurons are inhibited by GSN stimulation. Cervical SPL neurons displayed RF's on the ipsilateral shoulder and forepaw, which often extended to the contralateral side. Two-thirds of cervical neurons responded only to high intensity stimulation of the skin (HT type), but a few responded only to light touch of the skin (LT type). One-third of cervical neurons also responded to high intensity stimulation of the RF's of thoracic neurons. This data may suggest specificity of abdominal visceral and somatic inputs to cervical neurons. Supported by NIH grants HL16315 and 5-T32-GM07309-12.

SPINAL CORD DISTRIBUTION OF VISCERAL SENSORY AXONS FROM THE BLADDER AND LOWER COLON OF THE CAT. C. W. Morgan, W. C. deGroat, and I. Nadelhaft, Department of Anatomy and Cell Biology, Eastern Virginia Medical School, Norfolk, VA 23501; Department of Pharmacology, University of Pittsburgh Medical School and VA Medical Center, Pittsburgh, PA 15261.

Visceral sensory axons in the cat pelvic nerve play a major role in the micturition and defecation reflexes. Understanding their spinal distribution, established a number of years ago, has contributed to our continuing analysis of the mechanisms underlying these reflexes, partly by identifying areas of the spinal cord where interneurons may be found. Using the transganglionic HRP method, the present study has continued this analysis by comparing spinal distributions of branches of the pelvic nerve supplying the bladder with those branches to the lower colon. The bladder n. experiments were similar in pattern to earlier pelvic n. experiments, labelling Lissauer's tract, the lateral collateral pathway and the dorsal commissure region of sacral segments 1,2 and 3. Notably missing in the colon nerve experiments was the dorsal commissure terminal field while significant label appeared in Lissauer's tract and the lateral collateral pathway. These data suggest an organization of afferents corresponding to the different reflexes of these organs.

NEUROPEPTIDES IN DORSAL ROOT GANGLION CELLS INNERVATING THE COLON AND UROGENITAL ORGANS IN THE RAT AND CAT. J.R. Keast, A.W. Yau* and W.C. de Groat. (SPON: B. Dixit) Depts. Pharmacology and Behav. Neurosci., Univ. Pittsburgh, Pittsburgh, PA 15261.

Afferent neurons (AN) which supply three pelvic organs of the male rat and the colon of the cat were identified by injecting retrogradely-transported dyes into the colon, bladder or penis; 3 days to 6 weeks later dorsal root ganglia (L5-S2) were removed, incubated overnight in culture medium containing colchicine, fixed and processed for immunohistochemical localization of substance P (SP), calcitonin gene-related peptide (CGRP), leu-enkephalin (LENK), vasoactive intestinal peptide (VIP) or somatostatin (SS). SP and CGRP were present in many AN supplying these organs and were often colocalized. In rats there were fewer SP AN supplying the penis (15-20%) than the colon or bladder (25-50%). The proportion of VIP AN supplying different organs also varied. In cats, 20-30% of colonic AN contained VIP, whereas in rats $\leq$5% of these AN contained VIP. In rats there were slightly more VIP bladder AN (5-20%) but no VIP penile AN. Many VIP neurons contained SP. Dye-labelled neurons rarely contained LENK and none contained SS. These studies indicate that there are many similarities, but also some differences, in the populations of peptide-containing neurons supplying pelvic viscera. (J.K. is supported by an NH&MRC C.J. Martin Fellowship.)

SENSORY INPUT FROM CONTRACTIONS OF THE UTERUS IN THE RAT. K.J. Berkley, A. Robbins* and Y. Sato*. Dept. of Psychol., Florida St. Univ., Tallahassee, FL 32306; Dept. of Physiol., Tokyo Metropol. Inst. of Gerontology, Tokyo 173, Japan.

Although both the hypogastric and pelvic nerves contain afferent fibers innervating female reproductive organs, it is unknown how (or whether) information about uterine contractions is conveyed to the CNS. To address this question, the relationship between uterine contractions and activity of afferent fibers in the two nerves was studied in adult virgin anesthetized rats. Although fibers in both nerves readily responded to mechanical stimulation of reproductive organs, activity in the pelvic nerve was never associated with uterine contractions. Such a relationship was observed in about 50% of the cases for hypogastric nerve fibers, but only near the end of the experiment (after the uterus had been subjected to considerable mechanical stimulation). These results suggest that information about uterine contraction is conveyed to the CNS by fibers in the hypogastric, but not the pelvic nerve only under certain unknown conditions of uterine "sensitization."

DEVELOPMENT OF METHYLMERCURY-INDUCED MOVEMENT AND POSTURAL DISORDERS IN NEONATAL RATS IS CORRELATED WITH ABNORMAL ACTIVITY OF MESENCEPHALIC NEURONS DEMONSTRATED BY CYTOCHROME OXIDASE HISTOCHEMISTRY. R. H. Dyck and J. R. O'Kusky. Dept. of Pathology, Division of Medical Microbiology, and the Kinsmen Laboratory of Neurological Research, University of British Columbia, Vancouver, B.C., Canada.

The neurotoxicity of methylmercuric chloride (MeHg, 5 mg/kg/day), administered to neonatal rats beginning on postnatal day (PND) 5, produces movement and postural disorders which appear during the fourth postnatal week. In MeHg-treated animals at the onset of neurological impairment, an increase in the activity of an anomolous population of small neurons within the magnocellular red nucleus and interrubral mesencephalon was demonstrated using cytochrome oxidase histochemistry. Intensely stained neurons were observed beginning PND 17, 4-9 days before onset of the motor impairment. Hemi- or complete decortication on PND 3 or following five days of MeHg administration (PND 10) had no effect on the appearance of this anomolous population, while hemicerebellectomy on PND 10 resulted in fewer neurons within the contralateral rubral area. An increase in the number of intensely stained neurons was observed following thoracic spinal cord transection. The results indicate that the histochemical detection of abnormal neuronal activity precedes the onset of neurological impairment. Furthermore, the movement and postural disorders appear to be mediated via cerebellar but not neocortical afferents to the red nucleus.

290.2

REGIONAL EFFECTS OF DSP-4 TREATMENT ON NOREPINEPHRINE (NE) IN THE NEONATAL RAT. C.J. Gibson and C.C.G. Naus. Depts of Pathology and Anatomy, The University of Western Ontario, London, Ont. N6A 5C1.

The selective noradrenergic neurotoxin, DSP-4, was given to Sprague-Dawley rat pups 12 to 24 hr after birth (50 mg/kg, s.c.). Brain regions were examined neurochemically (for NE) and immunohistochemically (using antiserum to dopamine-β-hydroxylase (DBH)) at varying intervals postnatally. Two weeks after DSP-4 treatment cortical NE level was severely reduced (-94%); hypothalamic NE was unchanged (-9%); and pons-medulla (+40%) and cerebellar NE (+80%) were significantly increased compared to controls. Immunostaining of cortex and cerebellum indicated an initial reduction of DBH positive fibres 1 day after DSP-4 injection which persisted in cortex through postnatal day 15. In cerebellum, DBH staining and NE levels gradually increased to exceed control values from day 9 onward. Thus, the increase of cerebellar NE is due to an increased number of NE terminal fibres (the "pruning effect"; Jonsson, G., Hallman, H. and Sundstrom, E., Neurosci. 7:2895,1982). The effect of NE depletion on the development of intrinsic cortical neurons (e.g. somatostatin) is being investigated.

6-HYDROXYDOPAMINE LESIONS AND ROTATIONAL BEHAVIOR IN LONG-TAILED MACAQUES Richard H. Schmidt, Mark Dubach, Douglas M. Bowden. Neurological Surgery, Psychiatry and Behavioral Sciences, and Regional Primate Research Center, University of Washington, Seattle WA 98195.

We have devised a protocol of unilateral intranigral 6-OHDA injections in long-tailed macaques, producing degeneration of SN-derived striatal terminals and, consequently, asymmetric behavior measurable by automated rotometer (J Neurosci Meth, in press).

Lesions produced marked (70-85%) chronic rotational behavior, as well as contralateral akinesia and tremor. Contralateral turning that did occur may have been due in part to receptor supersensitivity, surviving innervation, or accumulation of small increments due to postural adjustments. In addition, however, contrary to expectations, the favored direction for two well-lesioned animals was actually toward the contralateral side, keeping the intact (ipsilateral) side near the wall. Similar paradoxical turning has been observed in rodents in related models, under conditions designed to emphasize wall-oriented behavior (Wise and Holmes, Brain Res Bull 16:267; Steiner et al., Exp Neurol 99:556).

Treatments in all monkeys caused massive depletion of ipsilateral striatal tyrosine hydroxylase-like immunoreactive terminals, and correspondingly diminished intensity measured densitometrically. Catecholamine cells in the striatum, on the other hand, had a more extensively ramified neuritic field on the lesioned side, suggesting the occurrence of sprouting (Dubach et al., current volume). (USPHS grants NS25724 and RR00166).

ASTROCYTE LESIONS IN RAT NEOSTRIATUM. X. Ou*, M.N. Gordon and D.G. Morgan, Dept. of Biological Sciences and Andrus Gerontology Center, Univ. of Southern California, Los Angeles, CA 90089-0191.

We have attempted astrocyte (AC) specific lesions in rat brain by coinjecting 2 toxins which are selective for ACs; alpha-aminoadipic acid (alpha-AAA) which is gliotoxic in culture (Huck et al, Neurosci 12:783-791, 1984), and fluorocitrate (FC) which selectively impairs AC energy metabolism (Paulsen et al, J Neurochem 48:1377-1385, 1987).

Male F344 rats were anesthetized with pentobarbital and injected directly into the neostriatum using a 30 gauge needle at 0.2 ul/min. For all injections the FC concentration was 0.8 ug/ul. L-alpha-AAA was varied from 0.048 to 2.4 ug/ul. The contralateral neostriatum was injected with the PBS vehicle to control for nonspecific damage.

All 1 ul injections failed to produce significant AC damage, except immediately around the injection site. A moderate to strong reactive astrocytosis occurred on both sides of the brain, which was slightly stronger on the toxin-injected side 2-7d post-injection. However, 2 ul injections of the highest concentration of L-alpha-AAA produced a complete loss of ACs (assessed by GFAP immunoreactivity) in most of the neostriatum, and the ventrolateral quadrant of the cortex 4 days later. Only a thin strip of ACs were apparent in lamina I of cortex, and these appeared to radiate their processes in toward the astrocyte lesion, instead of towards the glia limitans. Nissl-stains of the AC-free zone revealed some degenerating neurons, many healthy neurons, and a unique arrangement of neuronal profiles around what appeared to be blood vessels. Studies of the time course of this response are in progress. Supported by the John Douglass French Foundation for Alzheimer's Disease, and the Anna Greenwall Award from the AFAR (to DGM).

290.5

INTERACTION OF CADMIUM AND LEAD: EFFECTS ON SCHEDULE-CONTROLLED RESPONDING; DOPAMINERGIC AND SEROTONERGIC NEUROTRANSMISSION. G.D. Frye, J. Nation*, J. Von Stultz*, J. & G. Bratton*. Texas A&M Univ., Depts. of Med. Pharmacol., Psychol. & Vet. Anat., College Station, TX 77843

Operant responding of adult Sprague-Dawley rats was examined after being fed for 60 days either standard rat chow or chow containing lead (Pb, 500 ppm) and/or cadmium (Cd, 100ppm) on a fixed interval 1 min schedule for food. Both metals alone increased total lever presses without changing distribution, however, combined Cd and Pb did not change response rates. After 21 operant test sessions frontal cortex, n. accumbens, striatum, olf. tubercle and brain stem contents of dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), serotonin (5-HT) and 5-hydroxyindole acetic acid (5-HIAA) were measured. Both metals changed amines, metabolites and/or metab./amine ratios in all areas with most prominent effects after lead alone. However, there was a striking non-additive blunting of lead effects on DA and 5-HT metabolism when Cd was co-administered with Pb. These results suggest that behavioral and biochemical effects of Pb and Cd, when combined, are not simply additive but may be antagonistic. (Supported in part by PHS AA06322, AA00101 & TEES 90470)

290.6

NEUROTOXIC EFFECTS OF ALUMINUM: AN ELECTROPHYSIOLOGICAL STUDY. H. Meiri, M. Roll* and E. Banin*. Deptartment of Physiology, Hebrew University - Hadassah Medical School, Jerusalem, ISRAEL.

While the possible role of aluminum in various dementive disorders is still highly controversial, it's neuropathological influence is well established in experimental animals. In this work the influence of aluminum on neuronal function was examined using electrophysiological techniques and neuroblastoma clone cells, which offer a convenient model of prolifferating, differentiating and fully excitable cells. Two specific questions were addressed: (1) Can differentiated active cells maintain their normal excitable function when exposed to aluminum? (2) Can proper development of excitable properties be achieved in its presence?

We report that aluminum caused premature onset of deterioration in differentiated cells. Within 4 - 6 days they depolarized from the mean value of -29.3 ± 0.9 mV, to levels lower than -15 mV; compound polyphasic action potentials which could be evoked in 53% of control cells were gradually replaced by slow monophasic spikes that preceded the final loss of excitable properties and the onset of morphological deformations. A similar sequence of changes also characterized deteriorating control cultures but at a later time; the average lifespan of control cultures was 20.5 ± 1.4 days as compared to 15.7 ± 1.9 days in cultures exposed to aluminum on day 10. Developing cells followed the normal pattern of differentiation in the presence of aluminum: within 7 days they exteded neurites, hyperpolarized and 40% of the examined cells exhibited polyphasic spikes. However, this highly developed state could not be maintained for long and deterioration soon became the dominant process limiting the lifespan of these cultures to 10.7 ± 2.1 days. Developing cells did however survive more days of aluminum exposure than similarly treated "mature" - differentiated cultures.

These results show that neuroblastoma cells are apparently less susceptible to aluminum's toxicity during the process of development than after differentiation.

GROWTH OF EMBRIONC DOPAMINERGIC NEURON GRAFTS IN MICE AFTER SEVERE DOPAMINERGIC DAMAGE BY ACETALDEHYDE AND MPTP

A. Zuddas, G.U. Corsini*, I.J. Kopin, J.L. Barker^ and U. di Porzio^. Clinical Neuroscience Branch and ^Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20892.

Ethanol and acetaldehyde (ACE) potentiate MPTP toxicity in mice; striatal dopamine (DA) is depleted and loss of dopaminergic neurons in the substantia nigra is extensive (Life Scie. 40:827, 1987; Soc. Neurosci. Abst. 13:71,1987). Here we show that after treatment with MPTP and ACE, but not MPTP and ethanol, striatal MPP^+ levels remain elevated for at least four hours, whereas MPP^+ accumulated in the striatum after treatment with MPTP alone rapidly decreases. No significant differences in MPP^+ content in the whole brain are detectable between the ACE-MPTP and the MPTP treated mice. These data suggest that the potenciating effect of ACE on MPTP is, at least in part, related to the clearance of MPP^+ from the striatum. *In vitro*, neither ethanol nor ACE alter MPP^+ toxicity on DA neurons in mesencephalic primary cell cultures from mouse embryos. Striatal DA content remained at about 7% of controls for several months after this combined treatment. Five weeks after treatment, apomorphine (0.25mg/Kg) induced a marked increase of motor activity in the lesioned animals but not in control animals. Apomorphine-responsive mice and normal controls were injected with $3x10^6$ cells from E13 ventral mesencephalon in the right striatum. Forty days after the implant, amphetamine (2mg/Kg) induced a marked turning, contralateral to the side of the graft. Two months after the implant, immunohistochemical studies showed the presence of clusters of tyrosine hydroxylase positive cells in the right striatum. These data indicate that the combined ACE and MPTP treatment offers a useful animal model to study new therapeutic approaches to parkinsonism.

BEHAVIORAL DEFICITS IN RATS WITH MINIMAL CORTICAL HYPOPLASIA INDUCED BY METHYLAZOXYMETHANOL (MAM) ACETATE

M. Mercugliano*, S.L. Hyman*, M.L.Batshaw. Dept Pediatr & Kennedy Inst, Johns Hopkins Med Inst, Balto MD 21205

MAM, a short-acting antimitotic agent, produces cortical hypoplasia (45-67%) in fetuses. Offspring also have increased cortical concentrations of biogenic amines, hyperactivity and learning deficits. We studied rats with a lesser degree of MAM-induced cortical hypoplasia to see if these abnormalities persisted. Sprague Dawley pregnant rats were injected i.p. on d.15 gestation with either 25 mg/kg MAM acetate or saline. Total brain weight was reduced by 12% (1.35±.06 vs 1.54±.08, p<.001) and cortical slab weight by 28% (.127±.015 vs .177±.022, p<.001). Experimental animals were more active than controls on total distance (p<.05), average speed (p<.05), average distance (p<.005), and vertical activity (p<.05). There was a trend towards slower learning on a swim maze (p=.05). Experimental animals had increased cortical concentrations of norepinephrine (pmol/mg tissue) (3.95±.56 vs 3.35± .19, p=.01), 5-HIAA (4.68±.60 vs 3.45±.45, p<.001), and glycine (nmol/mg tissue) (1.19±.18 vs 1.04±.04, p<.001). There was no significant difference in serotonin, GABA, aspartic acid, glutamic acid and glutamine. MAM-lesioned animals with mild cortical hypoplasia and elevated norepinephrine remain measurably hyperactive. Further study of subtle lesions may clarify the neurochemical basis of the behavioral deficit.

290.9

THE ULTRASTRUCTURAL LOCALIZATION OF MAOB-ENZYME ACTIVITY ALONG THE NIGROSTRIATAL SYSTEM IN PRIMATE.

K.Nakai,Y.Naka*, M.Nakai*,T.Itakura*,M.Ueno*,T.Okuno*,N.Komai*. Dept.of Neurol. Surg.,Wakayama Med.Col., Wakayama 640 Japan

As an extension of the previous study (Nakai et al.Soc.Neurosci.Abst.13:787,1987) which demonstrated a strong monoamine oxidase B (MAOB) activity in the substantia nigra pars reticulata(SNr) and the white matter area dorsal to the substantia nigra(SN),an ultrastructural distribution of MAOB activity was investigated under the electron microscope for further clarification of the neurotoxicity of MPTP. Macaca fascicularis(5-10kg) were transcardially perfused with aldehyde mixture under deep anesthesia with Nembuthal. 50-micron-thick Vibratome sections of the brains including nigrostriatal system were processed for the enzyme histochemistry for MAOB, followed by the osmication for electron microscopy.

Most of the MAOB activities in the white matter dorsal to SN and in the striatum were found only in cell somatas of astroglia. We found two kinds of MAOB activity in SNr. One of them belonged to neuronal structures probably originated from hypothalamic neurons, the other appeared to be within thin structures surrounding the dendritic processes and corresponded to the diffuse staining in SNr under the light microscope. In conclusion, the MAOB activity either in the astroglial processes or in the extracellular space in SNr may be the most important MAOB activity in the pathogenesis of MPTP-induced parkinsonism.

LOCUS COERULEUS DEVELOPMENT IN RATS FOLLOWING PRENATAL EXPOSURE TO MORPHINE OR CLONIDINE.

B. Culver, A. Vaishnav* and I. Robberson*. Sch. of Pharm, Neurosci. Prog., Univ. Wyoming, Laramie, WY 82071

Several lines of evidence provide support for the concept of interactions between endogenous opioid systems and noradrenergic (NE) neuronal systems during growth and maturation of the nervous system. In the present study, drug delivery devices containing morphine sulfate (MS) or the α-2-adrenergic agonist, clonidine (CL), were implanted s.c. in rats on gd 14 to provide continuous delivery of drugs during pregnancy. Observations of litters revealed prenatal MS and CL both produced increased neonatal mortality, neonatal abstinence, transient growth retardation, and decreased nociception in rats up to 4 mo. old. As a first approach in the search for the substrate of these functional alterations, we assessed serial histological sections of the nucleus locus coeruleus (LC) from rats at different stages of postnatal development (5-,10-, or 30-days of age). A glyoxylic acid histofluorescent method was used to assess NA neurons. A marked reduction of histofluorescence in LC neurons and processes was shown for both MS & CL groups during early development. Diminished histofluorescence, albeit slight, was seen in LC, particularly the dorsal portion, of 30 day-old animals. However, the most impressive difference between both MS and CL rats and controls at 30 days was an increase in histofluorescent fibers projecting from the LC, particu-larly the ventral-posterior portion. These projections may represent a reinnervation response following drug-induced inhibition or degeneration which actually progresses to a state of hyperinnervation. Since descending NA axons of supraspinal origin have been suggested to inhibit nociception at the spinal level, hyperinnervation from the response seen in MS and CL animals may be involved in the enduring decreased nociception exhibited by these animals.

DEVELOPMENTAL NEUROTOXICITY OF ORAL ALUMINUM IN MICE.

M.S. Golub, J.M. Donald*, C.L. Keen*, M.E. Gershwin*. Depts. Internal Medicine and Nutrition, Univ. California, Davis, CA 95616.

Swiss-Webster mice were fed semipurified diets with 25, 500 or 1000 ppm Al as aluminum lactate from conception through weaning (21 days postnatal). Male and female pups were tested for neurobehavioral development [Wahlsten index (Wahlsten, D, Brain Res 72:251,1974), days 8-18, 2 pups/litter] and neurotoxicity [foot splay and NIEHS test battery (Pryor, GT et al, Neurobehav Toxicol Teratol 10:31,1982.), 21-25 days, 4 pups/litter]. Mortality and weight gain of dams and pups were not affected by Al (10 litters /group). Neurobehavioral maturation was unaffected but performance in the screen climb task was impaired in 1000 ppm pups. In weanlings, average foot splay distance was greater in both 1000 (N=28) and 500 (N=22) ppm groups than in 25 ppm controls (N=32) (28.5±0.7, 27.2±0.7, 25.2±0.6 mm respectively, mean±SE). Hind limb grip strength was greater in the 1000 ppm group than in controls (48.5±2.2 vs 37.6±3.1 g) and heat sensitivity was less (tail withdrawal latency 3.9±0.3 vs 3.0±0.2 sec). Negative geotaxis was slower in the 500 ppm group (9.4±1.2 vs 13.7±1.7 sec). Startle responses were unaffected in both treated groups. Thus dietary Al exposure can affect certain neurotoxicity indices during development. Supported by ES04190.

ETHYLENE OXIDE RETAINED IN HEMODIALYSIS MEMBRANES IS NEUROTOXIC IN VITRO

A. J. Windebank and M. D. Blexrud* Mayo Clinic, Department of Neurology, Rochester, MN 55905

Ethylene oxide (EO) gas is used to sterilize plastic medical equipment including capillary flow dialysis membranes. In order to test whether EO retained in the dialysers might be neurotoxic, tissue culture medium (Eagles Minimal Essential Medium supplemented with 15% calf serum, L-glutamine and 7S NGF) was incubated in the blood compartment of dialysers for periods of 1-12 hours. E15 rat dorsal root ganglion neurons (DRG) were then incubated in this medium for up to five days. During the first 24 hours, neurite outgrowth occurred at a normal rate. During the next 24 hour period, varicosities appeared on distal neurites followed by degeneration of neurites and finally, after four days by death of neuron cell bodies. The pattern of degeneration was identical to that observed when cultures were exposed to an atmosphere containing 1 p.p.m. EO gas. The degeneration produced by incubation in the dialysers was still present after routine prerinsing of the dialysers. The toxic effect was partially abolished by prerinsing with 5 liters of normal saline but was still not completely abolished by a 10 liters rinse. The toxic effect was not seen when identical dialysers sterilized by -irradiation were used.

Since EO is toxic to the human peripheral nervous system, it is proposed that retained EO in dialysers may contribute to the progressive neuropathy observed in patients on long term hemodialysis.

290.13

BEHAVIORAL CHANGES IN OFFSPRING OF RATS EXPOSED TO METHYL MERCURY DURING PREGNANCY. R. Cagiano, M. Colonna, M.A. De Salvia, E. Tortella, Z. Annau* & V. Cuomo (SPON: A. Hyndman). Inst. Pharmacology, Univ. of Bari, 70124 BARI, Italy and *Dept. of Environ. Health Sci., The John Hopkins University, Baltimore, MD 21205, U.S.A.

On day 15 of gestation, pregnant Sprague-Dawley rats were intubated with 8 mg/kg of methyl mercury (MMC) or vehicle. This dose produces no effect on neonatal birthweight or weight gain. Prenatal exposure to MMC did not significantly affect ultrasonic vocalization in rat pups removed from their nest, but open field-hyperactivity elicited by amphetamine (1 mg/kg i.p.) was significantly increased in 14 day old MMC-treated rats. Subjects were also given a passive avoidance task at 60 days. Approach latencies in the first and second trials were not influenced by MMC exposure; however, the avoidance latency of the MMC- pretreated group was significantly shorter than in controls. A comparison of these results with our previous findings (Cuomo et al., 1984; Cagiano et al., 1988) shows that the behavioral effects of a single prenatal dose of MMC depends upon the day of exposure. While the neuronal bases for these differences remain to be determined, our results confirm that prenatal exposure to MMC produces short- and long-term behavioral alterations in the absence of overt signs of neurotoxicity.

290.14

POTENTIAL NEUROTOXICITY OF TRYPTOPHAN: STRIATAL QUINOLINIC ACID MONITORED BY MICRODIALYSIS. M.J. During, A. Freese, M.P. Heyes*, K.J. Swartz, S.P. Markey, J.B. Martin, R.H. Roth. Dept. Pharm., Yale Univ. Sch. Med., New Haven, CT; Lab. Clin. Sci., NIMH, Bethesda, MD; Dept. Neurol., Mass. Gen. Hosp., Boston, MA.

The relationship of the precursor amino acid L-tryptophan to serotonin (5-HT), is well established. Much less is known about an alternative tryptophan metabolic route in brain - the kynurenine pathway. Several intermediates in this pathway are neuroactive, but perhaps of greatest importance is quinolinic acid (QUIN). This dicarboxylic acid is an endogenous ligand of the NMDA receptor, and acts as a potent excitotoxin. The compartment of most relevance to QUIN's neurotoxicity is the brain extracellular fluid (ECF). In rats, intrastriatal microdialysis was used to monitor ECF tryptophan, QUIN, 5-HT, and its major metabolite 5-HIAA, following an acute tryptophan load. At i.p. tryptophan doses ranging from 50 to 250 mg/kg, tryptophan levels in striatal dialysates increased by 4-17 fold; 5-HT by 50-90%; and 5-HIAA by 35-60%. QUIN levels were markedly elevated from 60 nM to 2-14 uM, corresponding to increases ranging between 40 and 230 fold. These results suggest that: (1) The kynurenine pathway in brain appears to be markedly precursor responsive; (2) ECF QUIN reaches potentially neurotoxic levels following a systemic tryptophan load. (3) Pharmacological effects of tryptophan may in part be mediated through intermediates of kynurenine and in particular QUIN.

FUNCTIONAL EFFECTS OF COCAINE GIVEN DURING CRITICAL PERIODS OF DEVELOPMENT L.A Freed *, T.H Milhorat and D.L. Dow-Edwards (spon. E.Elowitz); Laboratory of Cerebral Metabolism,, State Univeristy of New York, 450 Clarkson Ave, Brooklyn , N.Y 11203

At least one baby each day is born to a cocaine abusing woman in a single large N.Y metropolitan hospital. The affected children show neurobehavioral abnormalities. Direct effects of cocaine on brain development are suggested by recent animal studies. We have found that there are lasting changes in glucose metabolic activity in several brain regions following exposure to cocaine during the first 10 postnatal days in the rat (Dow-Edwards, et al. Dev. Brain Res., in press). We have now identified glucose metabolic changes in brain following late postnatal (days 11-20) exposure to cocaine. These changes are correlated with patterns of dopamine ligand binding in the same animals.

Sprague-Dawley rats were mated in our animal facility and housed under standard laboratory conditions until day of parturition. Litters were culled to 8 and pups assigned to receive cocaine or vehicle injections. The treated groups received 50 mg/kg cocaine sc each day between days 11- 20 and the controls received an equivalent volume of vehicle.

When the animals were 60-65 days of age, local rates of glucose utilization were determined using the deoxyglucose method of Sokoloff et al. (J. Neurochem. 28:897, 1977). Selective tritiated D1 and D2 ligands were used to quantify dopamine receptor concentrations autoradiographically in regions showing altered glucose metabolic activity.

HOMOPHILIC BINDING PROPERTIES OF THE NEURAL CELL ADHESION MOLECULE. A.K. Hall and U. Rutishauser* (SPON:R.J. Lasek). Neuroscience Center, Dept. Dev. Genetics & Anatomy, Case Western Reserve Univ. Sch. Med., Cleveland, OH 44106.

The neural cell adhesion molecule (NCAM) is a cell surface glycoprotein that mediates adhesion between cells. Previous studies have shown that purified NCAM can bind to itself in solution as well as when inserted in lipid membranes (Rutishauser et al., 1982. P.N.A.S. 79:685). The question remained as to whether NCAM is also the primary receptor for itself among the full complement of cell surface proteins.

An assay has been developed which allowed the identification of such components in a detergent extract of brain plasma membranes. This assay takes advantage of species-specific anti-NCAM reagents in combination with radio-iodination, such that after chicken and iodinated frog membranes were allowed to coaggregate, and the membranes solubilized, the chicken NCAM could be specifically immuno-precipitated. The iodinated frog proteins which were co-precipitated with chicken NCAM were subjected to one- and two-dimensional electrophoretic analysis in combination with Western immunoblots. Using these procedures, the radiolabelled frog proteins isolated by this assay were identified as NCAM polypeptidesm suggesting that the major cell surface receptor for NCAM is NCAM itself.

291.2

IDENTIFICATION OF AN mRNA ENCODING A SECRETED N-CAM ISOFORM. F.S. Walsh, H.J. Gower*, C.H. Barton*, V.L. Elsom*, J. Thompson*, S.E. Moore* and G. Dickson* Institute of Neurology, Queen Square, London WC1N 3BG, England.

A number of different membrane associated isoforms of the neural cell adhesion molecule (N-CAM) have previously been identified and have been found to be generated by specific alternative splicing pathways. We have identified a novel secreted isoform of N-CAM by analysis of a cDNA corresponding to an N-CAM mRNA from human skeletal muscle. The mRNA incorporates a novel sequence block into the extracellular domain, which introduces an in-frame stop codon and thus prematurely terminates the coding sequence. The polypeptide encoded by this RNA represents a truncated N-CAM form lacking a hydrophobic domain and is incapable of insertion into the plasma membrane. Analysis of genomic clones indicates that the inserted sequence is present as a discrete exon within the human N-CAM gene, and Northern analysis shows it to be associated specifically with a 5.2Kb mRNA species from skeletal muscle and brain. In addition, muscle cells were found to exhibit release of a 115Kd N-CAM isoform into culture media. These data suggest that in addition to mediating cell-cell adhesive events N-CAM may function as a recognition molecule in interactions between the cell and the extracellular matrix.

EXPRESSION OF MYELIN ASSOCIATED GLYCOPROTEIN (MAG) IN HUMAN NEUROBLASTOMA. J.D. CHAPMAN* AND R.C. McGARRY, Dept. of Paediatrics; University of Calgary, Calgary, Alberta, Canada

While MAG is defined histochemically as being myelin associated, we present evidence here that suggests it is expressed in human neuroblastoma (NB). FACS analysis shows that the monoclonal antibodies Gen S3 and B11F7 recognize the NB cell line SMS-KAN. Both of these antibodies recognize epitopes on the peptide backbone of MAG. As well, HNK-1 and F7F7 which recognize carbohydrate moieties of MAG react with SMS-KAN. Retinoic acid (RA) induced differentiation resulted in decreases in reactivity with GenS3, in contrast to an increased reactivity with HNK-1. These changes correlated with morphological differentiation to a neuron-like phenotype. To correlate peptide expression with mRNA levels we probed SMS-KAN RNA with a cDNA for MAG (clone 6.1, Arquint et al, PNAS, 84:600, 1987). Preliminary results from slot-blots indicate a titratable decrease in cDNA hybridization to RNA isolated from RA treated cells. Thus, we suggest that the MAG peptide is expressed in human NB in vitro and differentiation induction results in a decrease in MAG expression in this cell line. (Supported by the NCI of Canada).

THE APPEARANCE OF THY-1 IN THE RETINOTECTAL SYSTEM OF THE CHICK. A.M Sheppard*, M. Konopka* and P.L. Jeffrey. Children's Medical Research Foundation, Camperdown, Australia, 2050.

Thy-1 is expressed exclusively by the ganglion cell population of the avian retina. Work from this laboratory has shown that Thy-1 appearance during the latter phases of chick retinal development correlates with the formation of the inner plexiform layer (Sinclair, C.M., Greig, D.I. and Jeffrey, P.L., Dev. Brain Res. 35:43-53, 1987). In the present study we have employed a more sensitive immunohistochemical procedure to investigate the expression of Thy-1 during early retinal development. As this includes the time at which ganglion cell axons grow out to form the retinotectal projections (Rager, G.H., Development of the retinotectal projection in chicken, Springer-Verlag, Berlin, 1980), we also investigated the appearance of Thy-1 in the tectum. Our study demonstrates that Thy-1 is being made by the ganglion cells at or shortly after they cease dividing and begin to differentiate. It is first detected in the optic fibre layer at E6. The expansion of this layer that occurs as more and more axons grow out is reflected by an increase in immunoreactivity to Thy-1. By the time the majority of fibres have left the eye and are projecting to the tectum (about E9) high levels of Thy-1 are observed at the optic disk. As the layer of retinal axons on the tectal surface expands a corresponding increase in immunoreactivity occurs. At E12 three further tectal layers independently express Thy-1. Subsequently, from E14 Thy-1 expression extends across the entire tectum. From our data we speculate that Thy-1 may contribute to the formation of the highly ordered system of retinotectal projections.

EXPRESSION OF AN OX-2 HOMOLOGUE, GP39, IN AVIAN NERVOUS SYSTEM. A.M. Cunningham* and P.L. Jeffrey (SPON: J.A.P. Rostas). Children's Medical Research Foundation, Camperdown, Australia 2050.

A group of related molecules including Thy-1, OX-2 and N-CAM, have been found to possess some sequence homology, are members of the immunoglobulin gene superfamily, and are postulated to function in cell recognition or binding interactions. The OX-2 surface antigen was initially identified in rodents and the human gene for the molecule has been characterised.

A panel of monoclonal antibodies against chick neuronal membrane components was produced by immunisation of mice with a glycoprotein enriched fraction from chick brain. A Mab recognising an antigen with an apparent mwt of 39kDa was identified. This glycoprotein, GP39, is abundently distributed throughout the CNS. Developmentally, it is apparent from embryonic day 9 (ED9) in forebrain, cerebellum and tectum, and from ED10 in retina with levels rising to a maximum post-hatch. Immunohistochemical localisation studies from early embryogenesis to maturity reveal a distinctive pattern of distribution on certain neuronal populations and concentration in synaptic rich areas. In addition to surface localisation, some cell types eg Purkinje cells and retinal photoreceptors, show intracytoplasmic accumulation of antigen, presumably at the site of biosynthesis. GP39 is not unique to CNS, being also found at the myoneural junction in skeletal muscle and in adrenal medulla.

The antigen has been purified by monoclonal antibody affinity chromatography and further characterised. Avian GP39 and Thy-1 studied together may provide a means of further defining the role of cell surface interactions in neuronal development.

291.6

CLONING AND EXPRESSION OF A SOLUBLE 14 kDa ß-GALACTOSIDE BINDING LECTIN IN RAT NERVOUS SYSTEM. M.A. Hynes[1,2], L.B. Buck*[2], F.I. Casano*[2], K.K. Huang*[2], S.H. Barondes[3] and T.M. Jessell[1,2]. Center for Neurobiology[1] and Howard Hughes Medical Institute[2], Columbia University, New York, NY 10032, and Dept. of Psychiatry[3], UCSF, San Francisco, CA 94123.

Protein-glycoconjugate interactions have been suggested to play a role in neural cell recognition. Subsets of dorsal root ganglion (DRG) neurons express lactoseries oligosaccharides on their cell surface. These neurons also express two ß-galactoside binding lectins RL 14.5 and RL 29. To investigate further the role of lectins in neural development we have isolated a cDNA from rat nervous tissue that encodes RL 14.5. Sequence analysis reveals that RL 14.5 shows high homology to 14 kDa ß-galactoside binding lectins isolated from other vertebrate species.

Using RL 14.5 cDNA as a probe in Northern blot analyses, an mRNA of estimated size 0.75 kb was detected at high levels in poly A+ RNA isolated from dorsal root ganglion, lung, and heart in embryonic, postnatal and adult animals. Lower levels of this mRNA were found in spinal cord and brain and this mRNA was barely detectable in liver. By in situ hydridization, in adult animals RL 14.5 mRNA was localized to DRG neurons, and to spinal and brain stem motor neurons. RL 14.5 mRNA was detected in DRG neurons from embryonic day 13 and was expressed in a large proportion of DRG cells in embryonic, newborn and adult animals. These results are consistent with the distribution of RL 14.5 detected previously by immunochemistry. No hybridization to RL 14.5 mRNA was detected in neurons in the dorsal spinal cord or in forebrain structures. Expression of this lectin therefore appears to be highly restricted in the nervous system, and confined to neurons with peripheral projections. Antisera to synthetic peptides corresponding to different regions of the protein predicted by the RL 14.5 cDNA recognize the native lectin and may be useful in blocking carbohydrate binding function.

291.7

A GROWTH ASSOCIATED ANTIGEN IN THE ADULT REGENERATING NERVOUS SYSTEM OF THE COCKROACH. J.L. Denburg. Biology Dept., University of Iowa, Iowa City, IA 52242

Hybridoma techniques have been used to obtain a library of monoclonal antibodies (MAb) that bind to the cockroach embryonic nervous system and not to that of the adult. These MAbs were screened for binding to adult neurons undergoing axonal regeneration as a step towards identifying the role these antigens play in the development of the nervous system. One of the MAbs binds to all embryonic neurons and is absent from all but a small subset of adult neurons. After crushing the nerve containing the axons of motor neurons innervating leg muscles and of sensory neurons in the leg, this antigen reappears in these neurons. The time course of the appearance and disappearance of the antigen during axonal regeneration was determined and indicates a correlation between the presence of the antigen and the occurrence of axon growth. In this respect the antigen is similar to the growth associated proteins detected in vertebrate neurons undergoing axonal regeneration. However, unlike these proteins this antigen is a cell surface glycoprotein. These results support the view that axonal regeneration in adult insects is a good model for events occurring during embryonic development and indicates that studies in the adult nervous system will lead to an understanding of the mechanisms regulating the expression of developmentally important genes.

291.8

LOCALIZATION OF THE S-7B8 ANTIGEN DURING SYNAPTOGENESIS. L.M. Cabalka, T.C. Ritchie, and J.D. Coulter. Dept. of Anatomy, University of Iowa, Iowa City, IA 52242.

The S-7B8 antibody binds to a membrane protein in select nerve terminals of the adult rat CNS. The S-7B8 antigen co-localizes extensively, but not exclusively, with nerve terminals thought to use excitatory amino acid transmitters. Previous studies in developing rat spinal cord have shown the S-7B8 antigen to be present in elongating nerve fibers, becoming localized to nerve terminals during synaptogenesis. Present studies demonstrate the distribution of the S-7B8 antigen in several developing pathways in the rat brain. S-7B8 staining in developing fiber tracts and nuclei of the auditory and olfactory systems was found to correlate with their individual timecourse of synaptic development, ie, the S-7B8 antigen becomes localized to the nerve terminals during synaptogenesis. In the dentate gyrus, it has been previously demonstrated that the S-7B8-positive nerve terminals in the outer two thirds of the molecular layer arise exclusively from the superficial layers of the entorhinal cortex. In development, the perforant path fibers grow into the molecular layer during the first postnatal week, while synaptogensis is delayed by 2 to 3 days after arrival of the fibers. By P10, S-7B8 immunoreactivity is localized to nerve terminals in the molecular layer of the dentate gyrus. Studies of these developing systems indicate the S-7B8 antigen is developmentally regulated. Its localization in nerve terminals during development encourages further investigation into the possibility that the antigen may be involved in synaptogenesis. Supported by NIH grant NS23783.

DIFFERENCES IN MAb 1 A-6 REACTIVITY IN OLFACTORY EPITHELIUM OF NORMAL AND BULBECTOMIZED RATS. V.McM.Carr and A.I. Farbman. Dept. Neurobiol. and Physiol., Northwestern Univ., Evanston, IL 60208.

MAb 1 A-6 has been shown to react with olfactory receptor cell(ORC) surfaces and cilia and supporting cell(SC) surfaces and microvilli in olfactory epithelium(OE) of rat embryos (Neurosci.Abs.13:1410,1987). This reactivity disappears from ORC surfaces but remains on SCs into adulthood. Olfactory nerve(ON) bundles also stain more intensely in E14-E18 embryos than in older animals. To see if re-expression of 1 A-6 reactivity on ORCs is induced by olfactory bulbectomy(OB-X), which causes ORC degeneration and regeneration, adult rats were unilaterally OB-Xed. No re-expression of 1 A-6 reactivity occurred on ORCs 9-17 days after OB-X. However, increased ON staining, as at E14-E18, was seen. Western blots show that 1 A-6 reacts with material having Mr's of 77 and 52kD and 85 and 50kD in OE membranes and cytosol fractions, respectively. Con A is reactive with the 77kD component of the membrane fraction.

These findings suggest differences in glycoprotein expression may occur between initial OE development and the large-scale turnover after OB-X. Such results are especially interesting in light of observations by Brockes et al. (e.g.,TINS 10:364,1987) of differences in antigenic expression in preinnervated or aneurogenic regenerating limbs versus normal regenerating limbs in urodeles.

A DEVELOPMENTAL ANTIGEN IN EXTERNAL GRANULAR LAYER OF POSTNATAL MOUSE CEREBELLUM

L.B. Pickford,* D.N. Mayer,* L.M. Bolin & R.V. Rouse* (SPON: M. Smith) Dept. of Pathology L235, Stanford University School of Medicine, Stanford, California, CA 94025

We have described a rat monoclonal antibody OZ42 that defines a differentially expressed antigen in sections of early postnatal mouse cerebellum. Staining was observed from postnatal day 3 (P3) to P15 associated with post-mitotic, premigratory granule cells (GC) in the deep external granular layer (EGL), adjacent to the developing molecular layer (ML). There was no staining in the external proliferative zone, ML or internal granular layer. Weaver mutant mice, which have a defect in migration of GC showed differences in expression of the OZ42 antigen consistent with their abnormal morphology.

The OZ42 antigen appears to be specific to developing neural tissue. It was found in neonates (P0-P3) in the GC region of the hippocampus dentate gyrus. The anterior commissure and regions of corpus callosum were stained with a punctate pattern from P0 to P5. Mouse embryo staining was restricted to the nervous system including the CNS especially at the external margins of cellular areas, spinal cord, dorsal root ganglia, cranial nerve bundles and motor and sensory roots adjacent to the developing spinal cord and vertebrae. There was a gradual decrease in intensity of staining of these neural tissues with E10 > E13 > E17.

Preliminary western blot analysis of the antigen has shown that OZ42 specifically recognizes a protein of molecular weight of 120-140kD in P10 cerebellum while a second band of 60-70kD was also found under reducing and non-reducing conditions in P10 cerebellum and cerebrum. The restriction of the antigen to the described regions suggests an association with early axonal elongation. Further biochemical and localization studies are in progress.

GLYCOPROTEIN BIOSYNTHESIS BY CULTURED GRANULE CELLS
S.M. Nicholson* and J.W. Gurd, University of Toronto, Scarborough Campus, West Hill, Ont. M1C 1A4

The effect of development on the oligosaccharide composition of glycoproteins (gp) synthesized by rat cerebellar granule cells in primary tissue culture was investigated. Cultures were incubated with [^{3}H]mannose for 48 hours and oligosaccharides associated with cellular and secreted gp analyzed by con A-affinity and anion-exchange chromatography. The incorporation of [^{3}H]mannose into gp increased 3 to 4-fold between 4 and 10 days in vitro (DIV). Of the total [^{3}H]mannose associated with the oligosaccharides of cellular gp, 36 to 41% bound to Con A at all ages tested between 4 and 14 DIV. In the case of secreted gp con A$^+$ oligosaccharides accounted for 10.3 +/- 0.9% (n=16) of the radiolabel between 4 and 9 DIV, increased to 20.4 +/- 2.1% (n=10) at 10 DIV and then decreased to < 10% by 14 DIV. QAE ion exchange chromatography resolved con A$^-$ oligosaccharides into neutral and negatively charged species containing one, two, three or more sialic acid residues. The relative proportion of the more negatively charged species decreased with increasing time in vitro. These findings indicate that the differentiation of granule cells in vitro is accompanied by changes in the composition of cellular and secreted gp and that a transient increase in the secretion of gp containing con A$^+$ oligosaccharides occurs between 9 and 14 DIV.

A 2-DIMENSIONAL GEL ANALYSIS OF PROTEINS WHICH ARE REGULATED DURING RAT CORTICOGENESIS. D. Geschwind & S. Hockfield, Sect. Neuroanatomy, Yale Med. Sch., New Haven Ct. 06510

At E14 the developing rat cerebral cortex contains predominantly pre-mitotic precursor cells. At E17 and E22, the developing cortex contains large populations of post-mitotic migratory and post-migratory neurons, respectively. By comparing proteins expressed in E14 rat cortical bulbs to those expressed at E17 and E22, we hope to begin to understand some of the molecular events correlated with early cortical developement. To this end, we have run 2D-gels of crude membrane preparations from presumptive E14, E17, and E22 rat cortex labeled *in-vitro* with S^{35} methionine and cysteine. Fluorographs of these gels were then analyzed using a computerized gel scanner.

Gels resolving proteins with molecular weights between 20-240kD and isoelectric points between pH 4 and pH 7, and exposed for approximately 4 x 10^6 cpm x days yielded between 300 to 400 spots corresponding to individual proteins. Most of these proteins showed no significant changes between E14 and E22. We have indentified 15 proteins whose rate of synthesis changes more than three fold from E14 to E22. These can be divided into three major groups: 1.Those that increase between E14 and E22 (n=6). 2.Those that decrease between E14 and E22(n=6). 3.Those that appear *de-novo* between E14 and E22(n=3). The most striking of these age-related changes are three spots which are not present at E14 and appear at E17, growing even more abundant by E22 (MW 29-30kD, pI 5.1-4.6). Judging by the time course of their appearance, they are most probably neural, rather than glial in origin. Also intriguing are 6 proteins that are down-regulated from 3 to 17 fold from E14 to E22. The molecular weight and pI of these molecules suggest that they are previously uncharacterized developmentally regulated neuronal molecules.

291.13

REGULATION OF TISSUE PLASMINOGEN ACTIVATOR IN RAT SYMPATHETIC AND SENSORY NEURONS. A. Repka*, Z. Gajary* (SPON: E. Geller), and R. N. Pittman, Dept. of Pharmacology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104.

Cultured rat sympathetic and sensory neurons contain tissue plasminogen activator (t-PA) and have a high affinity, high capacity binding site for t-PA on their surface. t-PA has been shown to be an early differentiation marker for the neuronal phenotype in P19S1801A1 embryonic carcinoma cells (Whitford and Levine, Soc. Neurosci. Abstr., 13(pt. 2):892, 1987. In order to investigate the role of tPA in the differentiation of sympathetic and sensory neurons, we have generated monoclonal antibodies (mAbs) and a candidate cDNA for rat t-PA. The cDNA was isolated from a rat heart lambda gt 11 library and has a restriction map similar to that of human t-PA. Characterization of this cDNA is currently underway. Initial studies with mAbs indicate that t-PA immunoreactivity is regulated by tissue culture conditions and length of time in culture. These observations suggest that neuronal t-PA may be under dynamic control by local environmental factors.

SUBCELLULAR LOCALIZATION OF mRNAs IN DROSOPHILA RETINA REVEALED BY LIGHT AND ELECTRON MICROSCOPIC IN SITU HYBRIDIZATION J.A. Pollock, S. Benzer, T. Deerinck*, M.H. Ellisman. Div. Biol. 156-29, Cal.Inst.of Technol.; Dept. Neurosci., Lab. Neurocytol., UCSD.

The subcellular distribution of the mRNAs may be a mechanism for developmental control. We have studied the distribution of the mRNA transcripts for the Drosophila visual system genes, sevenless, chaoptic and ninaE (opsin Rh1) utilizing light microscopic (LM) autoradiographic in situ hybridization for the localization of endogenous mRNAs. Information obtained with LM indicating a differential distribution of mRNAs in both developing and mature photoreceptors stimulated us to develop a new, higher resolution procedure for in situ hybridization. This technique involves mild aldehyde fixation of dissected tissue, sucrose cryo-protection, and cryo-sectioning on an ultramicrotome. Probe DNA labeled by nick-translation with biotinylated-nucleotides is size-selected for optimal probe length. Hybridization and detection is performed on the sectioned tissue. The tissue is then post-treated for EM visualization in a manner similar to immuno-labeling. High voltage electron microscopy (1MeV) enables the use of thicker sections, 0.5-1.0 μm, which provide for greater stability through the subsequent steps of immunodetection and colloidal gold labeling. Using this technique we have obtained evidence that supports the LM observation of a non-uniform distribution of sevenless mRNA in the developing eye imaginal discs, and of the chaoptic mRNA in normal and mutant adult compound eyes. The abundant opsin transcript was also studied as a control in compound eye photoreceptor cells. This technique should aid further investigations into the mechanisms for control of cell polarity that may involve non-uniform distributions of mRNAs.

DEVELOPMENT OF A PERIPHERAL NERVE DURING METAMORPHOSIS IN DROSOPHILA: PHYLOGENETIC PARALLELS AMONG DIPTERA-MECOPTERA SPECIES. W.J. Costello, Dept. Zool., and Biomed. Sci./College of Osteopathic Med., Ohio University, Athens, Ohio 45701.

The nervous system of a holometabolous insect must undergo profound changes during transition from larva to adult. For a flying insect, these changes encompass modification to motor systems during metamorphosis to convert from the larval crawling form to the adult flying form.

I have conducted a scanning electron microscope study of the pupal nervous system of Drosophila melanogaster as it changes to the adult form. In the larva and prepupa, there is a major peripheral nerve exiting each side of the pre-, meso-, and metathoracic segments. These nerves are, respectively, T1, T2, and T3. T2 is modified during the mid-pupal stage to become two major adult nerves, ADMN and PDMN, providing innervation to the indirect flight muscles (DVM & DLM).

This singular modification of T2 during development has intriguing phylogenetic parallels among dipteran-mecopteran species. A survey of peripheral nerve innervation to the indirect flight muscles shows there are three major variants: 1) one nerve exits theganglion to bifurcate peripherally, providing innervation to DVM and DLM [mecoptera, Calliphoridae], 2) two major nerves, distinctly separate, exit the ganglion, one nerve innervating DVM, the other DLM [Drosophilidae, Muscidae,Sarcophagidae], 3) two nerves exit the ganglion closely together, almost joined [Syrphidae, Tephritidae]. All these variants, though distinct for the species, apparently represent developmental variants which can occur with T2 during metamorphosis. Such developmental changes provide possible restraints on evolutionary changes responding to selection pressures. (Supported by funds from OU-COM and an MBL Fellowship).

AUTONOMOUS DEFECTS AND FLIGHT MUSCLE CELL LINEAGE IN HEAT PULSED DROSOPHILA MOSAICS WITH TS-SHIBIRE TISSUE. M.R. Hummon and W.J. Costello, Dept. Zool. and Biomed. Sci./ College Osteopathic Med., Ohio Univ., Athens, OH 45701.

Drosophila adults with the ts mutation shibire (shi) exhibit a variety of predictable anomalies following pupal heat pulse (HP: 6h at 30C). The shi defect, revealed at 30C, involves membrane recycling and apparently includes blockage of endocytosis. Adults after HP< 20h pupal development at 25C lack all head and thoracic chaetae, have fused and/or deleted flight muscles (DLM; DVM), and an abnormal thoracic neural structure (neuroma). Using w^{ts} ring-X females and marked shi males ($y\ w\ sn^3$ shi), we are generating shi mosaic pupae and exposing them to HP< 20h. About 4% of F_1 are bilateral thoracic mosaics (30% of all gynanders). After HP, shi cuticle of head and thorax lacks all chaetae; chaetae in w^{ts} tissue are wild-type (WT). Phenotype of the thoracic ganglion matches the ventral cuticle and leg phenotype (behavioral test at 30C, leg paralysis indicating shi). However, phenotype of the dorsal thoracic cuticle (chaetae vs. bare) does not match the phenotype of flight muscles. In WT, non-HP shi, or w^{ts} flies, DLM has 6 fibers, while DVM has 7 fibers arranged in 3 sets; in shi after HP< 20h, DLM has 0-3 fibers and DVM has 0-5 fibers. Of 11 HP flies with bilateral mosaic dorsal thorax, 3 had a completely WT ganglion and flight muscles. Of 8 flies with bilateral ganglion: all muscles were WT (n=1), all muscles were shi (n=2), or both muscle phenotypes occurred, matching the cuticle in 4 of 5 flies. On the same side, DLM fibers were always of the same phenotype (n=16), whereas DVM I could differ from DVM II and III phenotype (n=3). Phenotypes of DLM and of DVM could differ as well (n=4). Thus shi anomalies induced by pupal HP are autonomously expressed in shi tissue, and have no effect on neighboring WT tissues. The patterns of flight muscle phenotype indicate that cell lineages for DLM and DVM are separate in normal development as revealed here by the rela tively late exposure of the shi defect and phenotype with pupal HP. Interestingly, lineage between DVM I and DVM II-III could also be developmentally separate. Supported by NIH-NRSA (MRH) and research funds of OU-COM (WJC).

EXPRESSION OF A STEROID HORMONE-REGULATED GENE IN THE CNS OF DROSOPHILA MELANOGASTER. L. L. Restifo and K. White*, Department of Biology, Brandeis University, Waltham, MA 02254.

In the nervous systems of both vertebrates and invertebrates, steroid hormones mediate neurogenesis, cell death, and changes in neuronal structure. We are currently investigating steroid hormone-regulated gene expression in the Drosophila CNS during metamorphosis. Others have shown that the steroid molting hormone, ecdysterone, regulates transcription of the X-linked complex genetic locus, the Broad-Complex (BR-C). Genetic evidence indicates that this locus is essential for metamorphosis, both for destruction of larval tissues and for differentiation of the adult epidermis. Furthermore, the BR-C is known to modulate the activity of a number of other ecdysterone-regulated genes at the onset of metamorphosis.

A cDNA clone (provided by G. Guild, U. of Pa.), representing portions of several variably spliced, hormone-inducible transcripts from the BR-C, was used to probe tissue sections of late third instar larvae. Following in situ hybridization, autoradiography reveals transcripts in cells of the larval brain and ventral ganglion. Transcripts are detected in neuronal precursors (neuroblasts) and in the large cells at the cortical-neuropil junction believed to be glia, as well as in mature neurons. In situ hybridization to adult heads indicates that transcription from the BR-C also occurs throughout the mature CNS.

We have begun a neuroanatomical analysis of BR-C mutants to identify aspects of CNS development which are influenced by this locus. In mutants lacking BR-C function entirely, axon bundles of the embryonic CNS appear normal by immunostaining using anti-horseradish peroxidase antibodies. In histologic sections, the larval CNS appears normal at the end of the third instar. However, some mutants possessing partial BR-C function die during metamorphosis and exhibit abnormalies in CNS morphology. In particular, the separation between the subesophageal ganglion and thoracic ganglion occurs only partially, if at all. On the basis of these data, we postulate that BR-C function is not essential for morphogenesis of the embryonic and larval CNS, but is required for proper CNS reorganization during metamorphosis. THYROXINE-INDUCED DEVELOPMENT OF THE OPTIC TECTUM IN LARVAL BULLFROG TADPOLES. N.J. Uray. Dept. of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501

As part of a larger study which explores the effect of thyroxine on brain development during early stages of differentiation and development, the optic tectum of the larval tadpole was examined using routine light microscopic methods. Bullfrog (Rana catesbeiana) tadpoles were raised from eggs and their ages were recorded using the time they swam free of their jelly-coat as a reference point. At various time periods ranging from 1 week to 1 year of age during which time the tadpoles are within the premetamorphic stage, groups of tadpoles were treated with thyroxine (Sigma, L-thyroxine sodium pentahydrate) by immersion for 2-4 weeks at the concentration of 1:100 M. After treatment the tadpoles were anesthetized, fixed and their brains were dissected out. Slides prepared in the three standard planes were stained with H and E and were examined.

Our findings emphasize development during the first half year period, during which time the optic tectum is capable of only partial development following thyroxine treatment. In general, 3 or 4 week treatment results in greater degrees of differentiation than 2 week treatment, and the antero-lateral half of the tectum is better formed than the postero-medial half. The fibrous layers of the tectum are consistently lagging behind the generation of the cellular layers, especially in the posteromedial part of the tectum. Supported by KCOM Warner Fund.

DEVELOPMENT OF NUCLEUS ISTHMI IN LARVAL STAGES OF BULLFROG TADPOLES. L.C. Towns and N.J. Uray. Dept. of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501

The development of Rana catesbeiana is extremely slow, usually lasting 2-3 years. This study examines the early, partial development of nucleus isthmi in this species.

Rana catesbeiana tadpoles were identified by age in weeks after emerging from eggshells (W) and by the stages of Shumway (S) or Taylor and Kollros (T-K). Ten groups of 20 tadpoles were used; each animal was given three intraperitoneal injections of [3H]-thymidine (10μCi/g per injection) on alternate days. Thus, the injections provided for 6 days of [3H]-thymidine availability. Each group of tadpoles was labeled at developmental periods of either W2+3(S25), W6,W8, W10(T-K I), W12(T-K II), W18, W20, W22(T-K IV) or W26(T-K V). All tadpoles were harvested at age W27(T-K V), and the brains were processed by routine autoradiographic methods. Sections were exposed at 4° C for 6 weeks, developed and lightly stained with H and E.

The autoradiographic data indicate there is some labeling during the entire six-month period. However, the rate of cell division does not appear to be uniform; there are some periods when many cells are labeled while only a few cells are labeled at other times. A spatial pattern of labeling at various ages is also seen.

292.1

AMPHETAMINE SENSITIZATION OF TRANSPLANTED DOPAMINE NEURONS ENHANCES STRESS RESPONSE.
A.M. Snyder-Keller and R.D. Lund. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Three-day old rat pups were given bilateral, intraventricular injections of 6-HDA to destroy dopaminergic nigrostriatal afferents and three days later received a unilateral intrastriatal injection of a cell suspension derived from embryonic ventral mesencephalon (E14). When tested repeatedly during development with both amphetamine (AMPH) and stress, these animals turned in response to AMPH by 15 days post-transplantation and turned to stress at 25 days (Carder, et al., 1987). Here we examined the influence of prior exposure, at 5-day intervals, to AMPH and/or stress on the emergence of stress-induced turning. Animals with prior exposure to AMPH (2 mg/kg, i.p.) and tail pinch, or AMPH alone, developed turning in response to tail pinch by 25 days post-transplantation. None of the animals exposed to tail pinch alone during development turned to stress by this time; however, these same rats did turn to stress after exposure to AMPH. Similarly, animals receiving no stimuli until 30 days post-transplantation rarely turned to stress on the first trial, but did so 5 days after being exposed to AMPH. Thus AMPH appears to have a sensitizing influence on transplanted dopamine neurons: early exposure to AMPH somehow primes the system so that turning to stress can develop by day 25 and later exposure subsequently enhances stress-induced turning. (Supported by USPHS grant NS19608.)

292.2

STRESS-INDUCED RELEASE OF DOPAMINE FROM MESENCEPHALIC TRANSPLANTS IN STRIATUM MONITORED BY MICRODIALYSIS.
R.W. Keller, Jr., A.M. Snyder-Keller, R.D. Lund, and M.J. Zigmond. Dept. of Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA

Neonatal rats given extensive, bilateral striatal dopamine (DA) depletions and unilateral mesencephalic transplants subsequently turn contralaterally in response to stress and amphetamine (Carder, et al. 1987). We sought to determine whether stress-induced turning was linked to release of dopamine from the transplant. Two months after transplantation, rats were implanted with a chronic loop-style dialysis probe and perfused at 1 ul/min with artificial CSF. Superfusate was collected in 15 min fractions and analyzed by HPLC. Subsequently, the proximity of the probe to the transplant was determined histochemically. Tail pinch (3 sec every 5 min for 30 min) produced contralateral rotation (3-5 turns/min). When probes were positioned adjacent to a transplant, extracellular DA levels rose 15-30 min after the onset of stimulation, peaked within the first post-stimulation fraction, and returned to baseline by 1 hr post stimulation. Delayed increases in DOPAC and HVA also occurred. Elevated levels of DA and its metabolites were observed after administration of amphetamine (2 mg/kg) and during the subsequent period of rotation. Neither neurochemical nor behavioral responses were observed in the absence of transplanted DA neurons. These results suggest that transplants can be influenced by the host tissue environment. (Supported in part by USPHS grant NS19608.)

292.3

STRIATAL ACTIVITY OF ADULT RATS RECEIVING DA DEPLETING LESIONS AND MESENCEPHALIC TRANSLANTS AS NEONATES.
JP Sidney, A Snyder-Keller & TW Berger, Dept. Behavioral Neuroscience, Univ. Pittsburgh, Pgh., PA 15260.

When DA-depleting brain lesions are given to neonatal rats, the spontaneous activity of adult striatal neurons is increased above control levels (Onn et al., Soc. Neurosci. Abstr., 1987). Here we investigated the possibility that transplants of mesencephalic neurons could restore striatal firing rates to control levels. Intraventricular injections of 6-hydroxydopamine (6-HDA) were given at day 3, and at day 6 rat fetal mesencephalic tissue was injected unilaterally into striatum. Animals exhibited tail pinch and amphetamine-induced contralateral turning. At 4 mo, extracellular single unit activity was recorded throughout the transplanted region of the striatum. Striatal cells were identified by spike waveform and orthodromic response to electrical stimulation of cortical afferents. Striatal cells recorded from animals with transplants exhibited lower spontaneous firing rates than animals only injected with 6-HDA on day 3. In addition, neurons often were encountered that did not respond to cortical stimulation and that exhibited spike waveforms and very high spontaneous firing rates atypical of animals not receiving transplants. Some of these putative transplant neurons displayed characteristics similar to those described for DA-containing pars compacta neurons. TH immunocytochemistry revealed transplanted DA cells and substantial innervation of the striatum. (Supported by NS19608 and MH00343).

FEEDBACK REGULATION OF DOPAMINE METABOLISM IN FETAL SUBSTANTIA NIGRA TRANSPLANTS.
R. Meloni* & K. Gale (SPON: J.A. McConnell). Dept. of Pharmacology, Georgetown Univ. Medical Center, Washington, D.C. 20007.

We previously reported that transplants of fetal substantia nigra respond to blockade of dopamine (DA) receptors with haloperidol (HAL), by increasing DA metabolism within the transplant itself as well as in its terminals in the adjacent regions of the adult host striatum. The present study examined the response of the transplants to the DA receptor agonist apomorphine (APO).

Solid transplants of fetal ventral mesencephalon were placed in cortical cavities overlying the 6-hydroxydopamine denervated (less than 1% DA remaining) striatum. Only those rats in which the transplant resulted in at least 50% reduction in amphetamine-induced rotational behavior, were used for the studies of DA metabolism; this consisted of over 75% of the rats with transplants. At least 3 months after transplantation, rats were given APO (1 mg/kg sc) and sacrificed at 40 min for measurement of DA and its metabolites (DOPAC and HVA). APO treatment induced a significant decrease in the ratio of DOPAC/DA (60% decrease) and HVA/DA (75% decrease) in the transplant terminals in the host striatum; only a small decrease occurred in the transplant itself. This was in contrast to the action of HAL, which caused a somewhat greater change in the transplant itself, as compared with its terminals. These results indicate that feedback mechanisms regulating DA utilization within the graft may be differentiated from those regulating DA utilization in the graft terminals innervating the host striatum.

292.5

APPARENT SUPERSENSITIVITY TO AMPHETAMINE OF GRAFTED FOETAL NIGRAL NEURONS IN THE RAT.
L. Rioux, P.J. Bédard, L. Grégoire,* T. Di Paolo, M. Daigle* and C. Rouillard. Lab. Neurobiol., Hôp. Enfant-Jésus and Dép. d'endocrinol. mol., Centre Hosp. de l'Univ. Laval, Québec, Canada.

20 female rats (250 g) were lesioned with 6-OHDA 12 µg in the left substantia nigra. At least one month later they were tested with amphetamine 5 mg/kg s.c. and apomorphine 0.25 mg/kg s.c. A suspension containing approximately 1.5×10^6 cells from the ventral mesencephalon of rat embryos was distributed in three sites in a triangular fashion in the center of the denervated striatum. The amphetamine test was then repeated every month for 6 months. The pattern of circling to amphetamine before the graft was strictly ipsiversive in all animals. From the first month we observed a progressive change and three patterns of evolution could be observed. In eight animals, the total number of ipsiversive turns in 90 minutes actually increased but during the first twenty minutes the animals turned contralaterally to the lesion (and the graft). In seven rats, the total number of turns switched from ipsiversive to contraversive with the animals turning initially towards the intact side and during the second half of the test towards the lesion. Finally four rats progressively switched to turning only towards the intact side. In all cases, maximal contraversive turning occurred during the initial twenty minutes and indeed in the first five minutes. Thus it would appear that especially during the first minutes after amphetamine, the dopaminergic stimulation on the lesioned side is stronger and occurs more rapidly than on the intact side. This could be explained by faster and greater release of dopamine by the grafted neurons, by supersensitivity of the dopaminergic receptors or by the position of the graft in a strategic area for contraversive circling. Apomorphine, 0.25 mg/kg given during the late (4-6 months) period still elicited contraversive circling but the number of turns was reduced. In one grafted rat, microdialysis was performed bilaterally in the striatum. Dopamine was detected before amphetamine only on the intact side. After amphetamine 30 pg/40 µl were detected on the grafted side and this represented one tenth of the level on the intact side. The response to amphetamine appeared on both intact and grafted sides in the first twenty minutes of perfusion. In this rat, tyrosine hydroxylase-positive cells were detected mainly in the dorsal striatum with a few in the central portion. (Supported by MRC of Canada.

GRAFTING OF GENETICALLY ENGINEERED FIBROBLASTS WHICH PRODUCE L-DOPA IN A RAT MODEL OF PARKINSON'S.
J.A. Wolff, L. Xu, T. Friedmann, M.B. Rosenberg, M.P. Iuvone[3], K. O'Mallery, L. J. Fisher, S. Shimohama[2], and F.H. Gage.[2] (SPON: P.M. Salvaterra). Dept. of Pediatrics (M-009), [2]Dept. of Neurosciences (M-024), UCSD, La Jolla, CA 92093, and [3]Dept. of Pharmacology, Emory University, Atlanta, GA 30322.

Previous studies have shown that rat fibroblasts can be genetically modified in vitro to express an exogenous reporter gene when implanted into the parenchyma of a rat brain. This study was undertaken to determine if this new mode of gene transfer can significantly ameliorate the signs of disease in an animal model of a brain disorder. Rats unilaterally damaged in the substantia nigra serve as an animal model of Parkinson's disease. Fibroblasts genetically engineered to produce L-DOPA should improve the signs of disease in these rats. 208F rat fibroblasts were infected with a retroviral vector carrying the rat gene for tyrosine hydroxylase (TH), which converts tyrosine into L-DOPA. Cell extracts of 208F cells infected with the TH vector had significant levels of TH activity (10.8 pmoles DOPA/min/mg protein) and L-DOPA (1.3 ng/mg protein). These 208F cells expressing the TH gene in vitro were implanted into the caudate of animals with unilateral 6-OHDA injections in the nigrostriatal bundle. In vivo TH expression in these cells transplanted into the caudate was found by immunocytochemical techniques. Studies are in progress to determine whether these cells can reverse the rotational asymmetry induced by unilateral dopamine depletion.

292.7

EXTRACELLULAR CHARACTERIZATION OF HRP-LABELED NEURONS IN DOPAMINE-RICH SUSPENSION GRAFTS TO THE RAT NEOSTRIATUM. L.J. Fisher, S.J. Young*, P.M. Groves, and F.H. Gage. Depts. of Psychiatry and Neuroscience, U.C.S.D., La Jolla, 92093.

We employed extracellular stimulation and recording techniques to characterize physiological properties of neurons in suspension grafts to the striatum. HRP intracellular labelling was combined with tyrosine hydoxylase (TH) immunocytochemistry to identify the location of these cells in relation to catecholamine containing neurons.

Adult rats with a unilateral lesion of the nigrostriatal dopamine pathway were injected with a suspension of fetal mesencephalon into the denervated striatum. Electrophysiological testing was performed after rats no longer displayed amphetamine induced rotational behavior. Recordings were obtained from urethane anesthetized rats using HRP filled microelectrodes. Bipolar stimulating electrodes, placed in striatum surrounding the grafts and in cortical white matter, were used to evoke activity from grafted cells.

Spontaneously active HRP labeled neurons with wide triphasic waveforms and slow regular firing rates, characteristic of pars compacta dopamine neurons, were localized in the grafts. Orthodromic responses were elicited with cortical stimulation in all of these neurons; in one case an antidromic response to striatal stimulation was observed. These cells were found within TH positive neuron clusters with some indication of TH and HRP double labeling. Both regular and deactivating burst firing patterns were observed in unlabeled neurons with characteristic dopamine waveforms. Other labeled neurons, characterized by faster firing rates, were found outside TH positive clusters but within the graft. Grafted neurons were readily distinquished on the basis of waveform and firing pattern from typical striatal neurons labeled outside the graft.

ADRENAL MEDULLARY AUTOGRAFTS IN NONHUMAN PRIMATES: FINE STRUCTURE OF THE IMPLANT SITE. J.T. Hansen, J.H. Kordower, M.S. Fiandaca, S. Okawara, S.S. Jiao*, and D.M. Gash. Dept. of Neurobiology and Anatomy, and Division of Neurosurgery, Univ. of Rochester Medical Center, Rochester, New York 14642, and *Capital Institute of Medicine, Beijing, China.

In light of the recent use of adrenal medullary autografts for the treatment of human parkinsonism, we have examined the fate of autografted chromaffin cells placed in the caudate nucleus of Cebus monkeys (*Cebus apella*).

Thirty days post-transplantation, the implant site exhibited massive liquefactive degeneration and macrophage infiltration. Fine structure analysis confirmed the presence of extensive macrophage invasion, cellular phagocytosis, and hematogenous cell infiltration. Surviving chromaffin cells, displaying their characteristic cytoplasmic vesicles and a distinct basal lamina, were observed in only two of seven implanted monkeys. In all cases, the chromaffin cells showed overt signs of autolysis and were in close proximity to macrophages. Profiles of portions of degenerating chromaffin cells were seen undergoing phagocytosis, and the interstitium was replete with collagen and cellular debris. Capillaries exhibited a non-fenestrated endothelium and plasma cells commonly were observed throughout the implant site. Overall, the implant site resembled a focal CNS injury with all of the characteristic signs of inflamation and cellular phagocytosis. Chromaffin cell survival was minimal, despite the transplantation of over 200,000 cells into each recipient.

Supported by USPHS Grant NS 25778.

292.9

ADRENAL MEDULLARY AUTOGRAFTS IN NONHUMAN PRIMATES: REGENERATION AND SPROUTING OF HOST DOPAMINERGIC SYSTEMS. D.M. Gash, J.H. Kordower, M.S. Fiandaca, S.H. Okawara, S.S. Jiao*, M.F.D. Notter, and J.T. Hansen. Dept. of Neurobiology and Anatomy, and Division of Neurosurgery, Univ. of Rochester Medical Center, Rochester, New York 14642, and *Capital Institute of Medicine, Beijing, China.

Twelve Cebus monkeys (*Cebus apella*) have received unilateral intrastriatal adrenal medullary autografts using an open microsurgical approach (n=3), a stereotactic injection technique (n=3), and a stereotactic implantation using a silver tissue carrier (n=6). Upon sacrifice, one month following transplantation, the animals' brains were evaluated via tyrosine hydroxylase immunocytochemistry, electron microscopy, and routine histochemical methods. In both MPTP-treated and normal monkeys, minimal viable adrenal medullary tissue was found in the graft sites one month following the transplant procedure. Macrophages were the primary cells seen in the region of the graft. Despite minimal survival of adrenal medullary cells, we have found dramatic increases in the number of tyrosine hydroxylase immunoreactive fibers in the median forebrain bundle, the nigrostriatal pathway, and the striatum on the grafted side.

There are two major hypotheses for explaining why adrenal medullary grafts may promote functional recovery in human parkinsonism: 1) replacement of lost striatal neurotransmitter (dopamine) by the grafted tissue, or 2) induction of recovery, by the graft, of remaining host catecholaminergic systems. Our data supports the latter theory.

Supported by USPHS Grant NS 25778 and the PEW Foundation.

292.10

ADRENAL MEDULLARY AND PERIPHERAL NERVE GRAFTS AND COGRAFTS IN THE RHESUS HEMIPARKINSONIAN MODEL: ANATOMICAL AND BEHAVIORAL RESULTS. M.S. Fiandaca, J.H. Kordower, J.T. Hansen, M.F.D. Notter, M.D. Kaniucki, J. Snyder, and D.M. Gash. Department of Neurobiology and Anatomy,University of Rochester Medical Center, Rochester, New York, 14642.

The mechanism(s) behind the amelioration of experimental parkinsonism via striatal grafts in primates and humans remains elusive. There is clear evidence, however, that adrenal chromaffin grafts survived poorly and local release of dopamine by implanted chromaffin cells is probably not mediating behavioral improvement. In an effort to delineate the anatomical and behavioral consequences of adrenal medullary and peripheral nerve grafts and cografts, we investigated their effects in the rhesus MPTP hemiparkinsonian model.

Eleven aged rhesus monkeys (Macaca mulatta) were evaluated regarding an upper extremity fine-motor task and rotation in response to intramuscular apomorphine (0.15 mg/kg) before and after unilateral intracarotid MPTP (0.4 mg/kg). One month later, the animals in the experimental groups received stereotaxic striatal grafts ipsilateral to the MPTP infusion. The grafts consisted of either pieces adrenal medulla, pieces of sural nerve, or cografts of both tissues. Control animals received a stereotaxic injection of vehicle only, following adrenalectomy and sural nerve resection. Results will be discussed regarding the behavioral findings (fine-motor task and apomorphine-induced rotation) during the three months following transplantation as well as the anatomical evaluations of the graft sites and surrounding brain regions at the light and electron microscopic levels.

292.11

ADRENAL MEDULLARY AUTOGRAFTS IN NON-HUMAN PRIMATES: EFFECT OF COCULTURE OF CHROMAFFIN CELLS WITH SURAL NERVE EXPLANTS IN VITRO. M.F.D. Notter, M.S. Fiandaca, J.H. Kordower, and D.M. Gash. Dept. of Neurobiology and Anatomy, Univ. of Rochester, Rochester, New York 14642.

In the present study, the importance of non-neural cells obtained from peripheral nerves as a source of trophic factors for medullary cells was investigated. Adult monkey sural nerve obtained from biopsy was placed in explant culture on collagen-coated coverslips. Suspensions of chromaffin cells obtained from the same monkey and enriched by an 18 hour differential plating were seeded onto coverslips with or without explants. Successful explants exhibted outgrowth of fibroblasts and Schwann cells determined by fibronectin or S100 protein staining, respectively. After one week of coculture, chromaffin cells showed tyrosine hydroxylase positive, catecholamine histofluorescent neuritic extensions growing over the surface of the explanted monolayer. Neuritic processes were similar to those induced by treatment of chromaffin cell cultures with NGF (100 ng/ml) alone for the same length of time. Moreover, the presence of chromaffin cells themselves or the conditioned medium from their culture stimulated outgrowth from sural nerve explants reliably and at a faster rate than that seen with cultures of sural nerve alone. These data indicate that factors released from non-neuronal peripheral nerve cultures induce and maintain the neuronal phenotype of chromaffin cells in vitro while, in turn, factors released from chromaffin cells stimulate the growth of these non-neuronal peripheral cells. Furthermore, these data suggest that adrenal medullary cell survival could be improved in neural transplants by cografting with peripheral nerve.

Supported by USPHS NS 25778.

COGRAFTS OF ADRENAL MEDULLA WITH PERIPHERAL NERVE IN THE DOPAMINE-DENERVATED RAT STRIATUM. G. Bing, S. Jiao*, M.F.D. Notter, J.T. Hansen and D.M. Gash. Dept. of Neurobiology and Anatomy, University of Rochester, School of Medicine, Rochester, New York 14642, and *Capital Institute of Medicine, Beijing, China.

Adrenal chromaffin tissue from young, 100-125 g, rats was transplanted into the striatum of adult (200-225 g) rat recipients whose substantia nigra were pre-lesioned on the grafted side with 6-OHDA. Functional effects of cografts of adrenal chromaffin cells with sciatic nerve, adrenal chromaffin tissue alone, sciatic nerve alone, optic nerve and culture medium were studied using rotational behavior induced by amphetamine. Immunohistochemistry using antibodies against tyrosine hydroxylase (TH), nerve growth factor receptor (NGFR), glial fibrillary acidic protein (GFAP) and S 100 protein was used to identify and characterize the grafted tissues. A few adrenal medullary cells survived in the group receiving just adrenal chromaffin tissue. However, the number of surviving chromaffin cells was significantly increased by cografting with sciatic nerve. Cografting with sciatic nerve also induced transformation of adrenal chromaffin cells towards a more neuronal phenotype and greatly enhanced nerve fiber outgrowth from the chromaffin cells. Grafts of adrenal medullary tissue had a moderate effect on the rotational behavior, but cografts with sciatic nerve were more effective in decreasing rotational behavior induced by amphetamine. NGFR immunoreactivity was much higher in the striatum of hosts that received grafts of sciatic nerve and cografted recipients. NGFR positive fibers were found both in the grafts and in the host brain adjacent to the grafts. GFAP immunoreactivity was heavier in the transplantation site. S 100 protein positive cells and fibers were found in both cografts and adrenal medulla grafts. The present study demonstrates that cografts of adrenal medullary tissue with peripheral nerve can significantly ameliorate the motor deficit symptoms of experimentally induced unilateral parkinsonism in the rats. AN EVALUATION OF THE POSSIBLE PROTECTIVE EFFECTS OF NEONATAL STRIATAL TRANSPLANTS ON KAINIC ACID INDUCED LESIONS. D.R. Nash, S.M. Kaplan,* A.B. Norman and P.R. Sanberg. Lab. of Behav. Neurosci., Depts. of Psychiat., Psychol., Neurosurg. and Physiol., Univ. of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

It was recently demonstrated that injection of neonatal striatal grafts into kainic acid (KA) lesioned striatum protected the contralateral striatum from KA lesions (Tullipan et al., Brain Res. 377, 1986, 163-167). In that study, animals with bilateral KA lesions had a 3% survival rate while those receiving transplants had an 85% survival rate. It was postulated that there was a neurohumoral influence provided by the graft in conjunction with the lesioned striatum acting to protect the contralateral striatum from the toxic effects of KA.

Our study examined whether the transplant acting alone may provide protection to the contralateral striatum from KA lesions. Ten male rats received a $1mm^3$ injection of day 3-4 neonatal striatal tissue into one striatum and a 10nMol KA lesion in the contralateral striatum. The control group (n=9) received a sham transplant consisting of 2ul lactated Ringer's solution into one striatum and a 10nMol KA lesion in the other striatum. The transplant did not appear to provide protection from the toxic effects of KA lesions of the striatum. Four of the 10 transplanted animals survived longer than 5 days while 6 of 9 control animals survived longer than 5 days. These results suggest that the transplant (acting without the possible benefit of trophic factors from a lesion) failed to provide protection from KA lesions.

FETAL STRIATAL TISSUE TRANSPLANTS INTO NORMAL STRIATUM: VOLUME EFFECTS ON BEHAVIOR. S.Y. Lu, M. Giordano, M. Ragozino,* A.B. Norman and P.R. Sanberg. Lab. of Behav. Neurosci., Depts. of Physiol., Psychiat., Psychol. and Neurosurg., Univ. of Cincinnati Coll. of Med., Cincinnati, Ohio 45267.

Fetal striatal transplants into normal striatum produced a decrease in locomotor behavior at three weeks post transplantation followed by a time dependent increase in locomotor activity (1,2). The present study examined the effects of different volumes of transplanted tissue to determine whether the behavioral deficits are volume related.

Male Sprague-Dawley rats (n=26) received three different volumes (1.5 ul, 3 ul and 6 ul) of fetal striatal tissue (E15-17) into both striata. A sham control group received 6 ul of Lactated Ringer's solution. A normal control group consisted of unoperated rats. Nocturnal locomotion was recorded in Digiscan Monitors one week before, and one and three weeks after surgery. Body weight was measured daily.

A volume related weight loss 1-3 days after surgery was found in all transplant groups. The 6, 3 and 1.5 ul groups lost 7%, 3.5% and 1.2% of initial weight respectively. Interestingly, the 6 ul sham group lost 6.3% of the initial weight. The rate of recovery from initial weight loss was similar among groups.

At three weeks post-transplant the experimental and sham transplant groups demonstrated hypoactivity compared to normal controls. Therefore, the initial weight loss and hypoactivity observed following surgery cannot be ascribed to the transplanted tissue. Whether the long-term hyperactivity is dependent on the volume of the transplant remains to be elucidated.

NIGRA GRAFTS IN NEONATAL BRAIN PROTECT FROM ADULT 6-OHDA LESIONS, BUT NEONATAL 6-OHDA LESIONS DO NOT. D.C. Rogers* and S.B. Dunnett. Dept. of Exptl. Psychology, Univ. of Cambridge, Cambridge CB2 3EB, U.K.

DA-rich grafts in the neonatal brain will protect from the severe ingestive deficits induced by bilateral 6-OHDA lesions in adulthood (Schwarz & Freed, Exp. Brain Res. 65, 1987), whereas similar grafts implanted in mature rats will not. Neonatal 6-OHDA lesions do not induce the severe ingestive deficits that follow comparable adult lesions (Smith et al, J. Pharmacol. Exp. Ther. 185, 1973). Do the grafts therefore disrupt normal dopaminergic development?

Two groups of rats received either i.c.v. saline or 6-OHDA lesions at postnatal day 1 (P1). Half of each group received bilateral embryonic day 15 nigra cell suspension grafts into the neostriatum at P7. At 3-4 months of age all rats received bilateral 6-OHDA lesions of the nigrostriatal bundle. No control rats with adult lesions could spontaneously eat and drink to maintain stable body weight within 12 days. By contrast, 36% of rats with neonatal grafts were able to maintain themselves. 20% of rats with neonatal lesions and 38% with both grafts and lesions could also maintain themselves.

The enhanced survival of the graft group replicates Schwarz & Freed. Although all rats with neonatal lesions were totally unresponsive to haloperidol in either activity or eating tests (indicating that these functions were independent of dopamine receptor activation), surprisingly, 80% of the animals nevertheless showed the full syndrome of ingestive deficits in response to adult lesions.

NORENEPHRINE DEPLETION IN THE LOCUS COERULEUS FOLLOWING BILATERAL TRANSECTION OF THE VENTRAL NORADRENERGIC BUNDLE. M.A. Cierpial*, L.E. Heyneman* & J.M. Weiss (SPON: G. Marsh). Department of Psychiatry, Duke University Medical Center, Durham, NC 27710.

It is well documented that there are adrenergic receptors on the dendrites and/or cell bodies of locus coeruleus (LC) neurons which respond to both epinephrine (EPI) and norepinephrine (NE), and that these receptors play an important role in the regulation of LC firing. A major EPI input to the LC has been identified arising from cells of the C_1 and/or C_2 groups. At present, the exact source of NE innervation to the LC is unknown; however, several studies have shown large depletions of NE in the LC following uncontrollable stress, indicative of a rapid release of this transmitter from nerve terminals. A possible candidate for NE input to the LC is the ascending ventral noradrenergic bundle (VNAB) which originates in brainstem nuclei caudal to the LC and terminates primarily in the hypothalamus. In this experiment, bilateral knife cuts were made through the VNAB caudal to the LC, and NE levels were measured 12-14 days following transection. Bilateral VNAB transections resulted in a 35% decrease in NE content of the LC compared to unoperated and sham operated controls. Hypothalamic NE was decreased by 61% and cortical NE was decreased by 32%, as has been reported with VNAB transection rostral to the LC. Examination of 50 um nissl stained sections revealed no apparent neuropathy in the LC of VNAB lesioned animals. These results suggest that the LC receives an afferent projection from the VNAB in that transections of the bundle caudal to the LC results in NE depletion in this nucleus.

293.2

NEUROPEPTIDE-Y LEVELS IN THE LOCUS COERULEUS AFTER UNCONTROLLABLE SHOCK. T.M. Brown*, M.A. Cierpial*, P.E. Simson, P.D. Butler & J.M. Weiss (Spon: L. Demski). Dept. Psychiatry, Duke Univ. Medical Center, Durham, NC 27710.

Neuropeptide-Y (NPY) is a 36-amino-acid peptide co-localized with noradrenaline in noradrenergic cells of the locus coeruleus (LC). It is known that the LC is highly activated by stress. To investigate the effect of stress on NPY in the LC, male Sprague-Dawley rats were exposed to stressful conditions. In the first experiment, one group received randomly-spaced, uncontrollable electric shocks for 19 hours while a control group consisted of unstressed animals removed directly from their home-cage. The shock condition significantly elevated NPY in the LC (107.4 $\pm$ 8.6 ng/mg tissue) relative to the control animals (39.2 $\pm$ 8.6 ng/mg tissue). In a second experiment, effects of a briefer shock exposure were tested. One group received randomly-spaced, uncontrollable electric shocks for 3 hrs; a second group was placed in the shock apparatuses for 3 hrs but received no shocks; and a third control group consisted of unstressed animals removed directly from their home-cage. Exposure to the shock apparatus for 3 hrs significantly elevated NPY in the LC (78.0 $\pm$ 10.2 ng/mg tissue) relative to the controls (39.0 $\pm$ 12.2 ng/mg tissue). In animals exposed to 3 hrs of shock, however, the NPY concentration was not elevated in the LC (39.6 $\pm$ 9.2 ng/mg tissue). These results suggest that mild acute stress (i.e., 3 hrs of confinement in the shock apparatus) elevates the NPY concentration in the LC whereas more severe acute stress (3 hrs of shock) causes sufficiently high release of the peptide that an elevation is not seen. However, if the severe stress is long-lasting (i.e., 19 hrs), then mechanisms increasing the availability of the peptide compensate for the increased release and an elevation in NPY is again seen.

293.3

QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF α1- AND β-ADRENERGIC RECEPTORS AND ELECTROPHYSIOLOGICAL ANALYSIS OF CONNECTIVITY IN INTRAOCULAR RAT LOCUS COERULEUS-HIPPOCAMPUS CO-GRAFTS. M. Mynlieff, P. Curella*, N.R. Zahniser, and T.V. Dunwiddie. Univ. Colo. Hlth. Sci. Ctr. and VAMC, Denver, CO.

Previous studies have shown the feasibility of "building" an isolated circuit between the locus coeruleus (LC) and hippocampus in oculo. The present study investigated the role of noradrenergic innervation in regulating α1- and β-adrenergic receptor development in the hippocampal portion of LC/hippocampus co-grafts and relate this to the development of functional connections between the co-grafts. LC from embryonic Sprague-Dawley rats was transplanted to the anterior eye chamber of sympathetically denervated 6-8 week old rats, followed 4 weeks later by co-transplantation of fetal hippocampal tissue. Two month and 6 month old co-grafts, single hippocampal grafts grown in normal hosts, and single hippocampal grafts grown in sympathetically denervated hosts were analyzed.

Quantitative autoradiographic analysis of saturation curves showed no significant difference in receptor numbers for either the α1-receptor (31-65 fmol/mg protein) or the β-receptor (14-19 fmol/mg) in the single grafts, 2 month co-grafts, or 6 month co-grafts. HPLC analysis in these grafts also showed approximately equal amounts of norepinephrine (NE) in all three types. The hippocampal grafts grown in the absence of NE input from the iris or LC exhibited higher numbers of α1-(109 fmol/mg) and β-receptors (41 fmol/mg). Intracellular electrophysiological studies showed that stimulation of the LC portion of 2 month old co-grafts almost always resulted in a β-adrenergic response in the hippocampus while in 6 month old co-grafts 1/3 showed α-adrenergic responses, 1/3 showed β-adrenergic responses, and the remainder showed a combination of α and β responses. Electrophysiological studies have shown that the denervated grafts are not more sensitive to NE. Immunohistochemical analysis of co-grafts showed that at 6 months the NE fibers have grown farther into the hippocampus and are denser than at 2 months. These results suggest that the number of adrenergic receptors in the hippocampus are regulated by NE content but the physiological response to NE is not necessarily predicted by the receptor number. REGULATION OF BRAIN Na,K-ATPase BY INTRAVENTRICULAR NORADRENERGIC RECEPTOR LIGANDS. Alan C. Swann and Jeffrey D. Steketee. Department of Psychiatry, University of Texas Medical School, Houston, Texas 77225.

Previous results have suggested that indirect noradrenergic stimulation increased brain Na,K-ATPase. We investigated the role of specific noradrenergic receptors using intraventricular infusions of receptor ligands and measuring ouabain binding in cerebral cortex and hippocampus. In the initial experiments, norepinephrine (NE; 1, 2, and 5 μg/h), phenylephrine (PH; 1, 2.5, 5, and 7.5), isoproterenol (ISP; 2.5, 5, 7.5, and 10), clonidine (CL; 1 and 5) were infused into the lateral cerebral ventricles with osmotic minipumps for one week. In addition, forskolin (FSK; 3, 6, and 12) was infused in order to examine the effect of direct stimulation of adenylate cyclase. Then, the optimal dose was infused into rats with 6-hydroxydopamine lesions of the dorsal noradrenergic bundle (>90% NE depletion). NE, ISP and FSK increased ouabain binding, PH had a biphasic effect with maximal stimulation at 2.5 μg/h, while CL reduced ouabain binding. All ligands except CL increased binding in DB lesioned rats. These results show that NE receptor stimulation, partially through cyclic AMP, increases ouabain binding in vivo.

NORADRENERGIC STIMULATION OF CYCLIC AMP SECRETION BY RAT EMBRYONIC CEREBRAL CORTEX IN DISSOCIATED CELL CULTURE. P. A. Rosenberg and M. A. Dichter. Depts. of Neurology, Children's Hospital and Harvard Medical School, Boston, MA 02115; Graduate Hospital and University of Pennsylvania, Philadelphia, PA 19146.

Beta adrenergic receptors have been demonstrated in cortical astrocytes but not neurons in primary culture. Secretion of cyclic AMP in response to beta adrenergic stimulation has been described in many cells of vertebrate origin. Cyclic AMP secreted by astrocytes stimulated by NE or other agents might affect the function of nearby neurons either directly or by way of metabolites.

Isoproterenol (ISO) at 10 uM stimulated intracellular cyclic AMP ($cAMP_{in}$) accumulation in mature (4-6 weeks in vitro) mixed neuron and glial cultures, with a peak occurring at approximately 10 minutes. ISO also stimulated extracellular cyclic AMP ($cAMP_{ex}$)accumulation, with a peak occurring at 40-60 minutes. The quantity of $cAMP_{ex}$ assayed in the medium at peak was comparable to $cAMP_{in}$ at peak (180 nmol cAMP/mg protein). We have also been able to demonstrate extracellular phosphodiesterase as well as nucleotidase activity in these cultures resulting in the degradation of $cAMP_{ex}$ to AMP and adenosine. Whether cAMP secretion affects neurons and if so by what mechanism remains to be determined. EXPRESSION OF TYROSINE HYDROXYLASE mRNA AND MORPHOMETRIC CHARACTERISTICS OF DOPAMINERGIC NEURONS IN TISSUE CULTURE. DK Sundberg*, BA Bennett, P Skrincosky*, F Baldino Jr, and M Morris*, Dept. of Physiol. and Pharmacol., Bowman Gray School of Medicine, Wake Forest University, Winston Salem, N.C. 27103 and Cephalon Corp, West Chester, PA.

Studies in our laboratory have focused on the use of primary cultures of specific brain regions. Results show that hypothalamic arcuate cultures develop dendritic processes, stain immunocytochemically for tyrosine hydroxylase (TH) and synthesize dopamine. The objective of these studies was to characterize the cultures using morphometric analysis and to determine whether the TH positive cultures express mRNA for this enzyme.

Hypothalami from 3-5 day old rats were dissociated enzymatically. The cultured cells were fixed and stained for TH or neuron specific enolase after 3,6 or 9 days of culture. Morphometric indices included cell size, density and length of processes. TH-positive neurons represent 6-8% of the total number of surviving neurons. They are somewhat smaller than the mean neuronal population and send out significantly longer projections ($p<.05$) than the mean population. TH mRNA was measured by dot blot in 6 day cultures. In addition to staining for TH, extracted mRNA hybridized to a 30 mer DNA probe complimentary to TH mRNA. (Supported by NIH grants NS 24723 and NS 22492).

SUCCESSFUL CRYOPRESERVATION OF DOPAMINE PRODUCING HUMAN SUBSTANTIA NIGRA CELLS. R. J. Robbins, I. Torres-Aleman*, C. Leranth, C. Bradberry, A. Deutch, D. E. Redmond, Jr., R. Roth, and F. Naftolin*. Sections of Neuroendocrinology and Neuropharmacology, Dept. of Medicine, OB/GYN, and Pharmacology, Yale Medical School, New Haven, CT 06510

Recent advances in transplantation biology have made possible the concept of implanting human dopamine producing cells into the brains of patients with Parkinson's Disease (PD). Survival of fetal substantia nigra (SN) cells in the striatum of adult rats and adult monkeys has been reported. In order to allow time to screen potential donor cells for a variety of characteristics including infectious agents, and to allow careful neurosurgical preparation of the recipients we have attempted cryopreservation of freshly isolated human dopamine cells. Cells from 9 to 12 week old human fetal cadavers were collected within one hour of death, transferred to cryoprotective solutions (DMSO or propanediol) and frozen according to several gradual freezing paradigms. Cells were stored at -196C. Viability of thawed cells was above 95% when thawed within two weeks of freezing but only 65% when thawed after three months. Monolayer cultures of these cells had tyrosine hydroxylase (+) neurons with long processes and HPLC analysis revealed authentic dopamine in the cells and medium. We conclude that human SN cells can survive short term cryopreservation and express specific adult dopaminergic characteristics.

MESOLIMBIC DOPAMINE AUTORECEPTORS CONTROLLING TYROSINE HYDROXYLASE ACTIVITY : EVIDENCE FOR THE INVOLVEMENT OF CYCLIC AMP AS A SECOND MESSENGER. P. Onali and M.C. Olianas. Dept. Neurosciences, University of Cagliari, Italy.

The cyclic AMP-dependent stimulation of synaptosomal tyrosine hydroxylase (TH) by forskolin (FSK),an activator of adenylate cyclase,has been used as a model to test whether dopamine (DA) autoreceptors of nucleus accumbens inhibit TH activity by a mechanism involving cyclic AMP. Homogenate of rat nucleus accumbens was preincubated with the test agents and the enzyme activity was assayed in extracts prepared by centrifugation and sonication of the tissue. FSK maximally stimulated TH by 2.5-3 fold with an EC50 of~1 μM. Quinpirole,a selective D2 DA agonist,inhibited basal TH activity by 25-30% and reduced the stimulation of the enzyme elicited by FSK (0.5-10 μM) by 35-50%. The IC 50 value of quinpirole was~ 25 nM. The quinpirole inhibition was antagonized by the selective D2 DA blocker l-sulpiride (2 μM). On the other hand,quinpirole failed to inhibit the stimulation of TH elicited by dibutyryl cyclic AMP (2 mM), which acts independently of adenylate cyclase. These results suggest that mesolimbic DA autoreceptors can regulate the cyclic AMP-induced activation of TH presumably by exerting an inhibitory input on a presynaptic adenylate cyclase system.

293.9

CENTRAL REGULATION OF ADRENAL TYROSINE HYDROXYLASE; INTERACTION BETWEEN DOPAMINE AND GABA SYSTEMS. S. Regunathan*, R. Gabor* and T.L. Sourkes. Douglas Hosp. Res. Cent. & Dept. of Psychiatry, McGill University, Montreal H3A 1A1.

The nigrostriatal dopamine (DA) system participates in the regulation of adrenal tyrosine hydroxylase activity (ATHA). To determine whether activation or inhibition of this system is responsible for the induction of adrenal TH, the role of presynaptic DA receptors was investigated. Apomorphine (0.2 mg/kg), (+)3PPP (10 mg/kg) and BHT920 (up to 3 mg/kg) caused significant increases of ATHA. These drugs bind to presynaptic DA receptors and thereby inhibit the release of DA. As a central GABA system is believed to exert inhibition over DA release, GABA agonists were tested for their effects on ATHA. Muscimol (3 mg/kg), GOBA (0.5 mg/kg) and HA966 (150 mg/kg) produced significant induction of adrenal TH which was not blocked by DA postsynaptic receptor antagonists such as sulpiride or SCH 23390. It is concluded that the inhibition of the nigrostriatal DA system is responsible for the induction of adrenal TH. This is achieved by activation of the striatonigral GABAergic feedback system or by presynaptic regulation of DA release through autoreceptors in the striatum. PROTEIN KINASE C PHOSPHORYLATES THREE PUTATIVE SITES ON TYROSINE HYDROXYLASE IN INTACT BOVINE ADRENAL CHROMAFFIN CELLS. J.P. Johnston, K. Hummer-Lickteig and J.C. Waymire. Dept. Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, TX 77225.

Tyrosine hydroxylase (TH) is phosphorylated *in vitro* by several protein kinases. Alberts *et al.* (PNAS 81:7731, 1984) have reported that purified TH is phosphorylated by PK-C on a site that is identical to that phosphorylated by PK-A. However, Tachikawa *et al.* (J Neurochem 48:1366, 1987) have reported that TH is phosphorylated *in situ* in PC-12 cells on distinct sites by forskolin and phorbol 12-myristate-13-acetate. We have investigated the role of PK-C phosphorylation of TH in bovine adrenal chromaffin cells where it appears there are seven putative phosphorylation sites (Waymire *et al.*, Neurosci Abstr 13, 1987). RP-HPLC analysis of TH tryptic peptides revealed that stimulation of intact chromaffin cells with 1 μM phorbol 12,13-dibutyrate produced an increased incorporation of ^{32}P into 3 of the 7 peptides. This response was dependent on both concentration and time (EC_{50} = 316 nM, $t_{\frac{1}{2}}$ = 4 min). One of the peptides (peptide 6) is also a substrate for protein kinase A both *in vitro* and *in situ*. Two other peptides (peptides 4 and 7) have not been shown to be substrates for any protein kinase *in vitro*, and correspond to those peptides which are phosphorylated with a slow time course in response to ACh stimulation of intact chromaffin cells. Supported by USPH NS 11061.

293.11

MAPPING THE ALTERATION OF THE COFACTOR DOMAIN OF TYROSINE HYDROXYLASE DUE TO cAMP DEPENDENT PHOSPHORYLATION. S.W. Bailey*, S.B. Dillard* and J.E. Ayling. (SPON: R.B. Moore). Dept. Pharmacology, Univ. South Alabama, Mobile, AL 36688.

The dihydroxypropyl side chain of R-tetrahydrobiopterin (R-BH_4) is not essential for catalytic activity of tyrosine hydroxylase (TH), the first committed step in catecholamine biosynthesis. That it enables several important regulatory properties is well established. Despite major changes in the kinetics of TH with assay pH, no study on the role of cofactor structure on specificity and function under physiological conditions has yet been reported. More than a dozen 6-mono- and 6,6-disubstituted tetrahydropterins have been synthesized and kinetics with bovine TH with respect to cofactor and tyrosine determined. The decrease in K_m for cofactor upon cAMP dependent phosphorylation that has been previously found with R-BH_4 and 6-methyl-tetrahydropterin is seen with all the analogs, but ranges from 40 to 2000 fold. With both forms of TH side chain hydrophobicity plays an important but limited role in binding in a manner similar to other carbohydrate-protein interactions. Phosphorylation induces a major rearrangement of cofactor specificity. For example, K_m for R-BH_4 shifts from a lowest to a moderate ranking. Several analogs possess significantly higher affinity for either form. This along with the unusual kinetics of the disubstituted analogs, and molecular mechanical calculations, suggest a model for the effects of phosphorylation different from those previously proposed. (Supported by GM-30368.)

293.12

INDUCTION OF TYROSINE HYDROXYLASE BY NICOTINIC AGONISTS IN BOVINE ADRENAL CHROMAFFIN CELLS IS ACCOMPANIED BY A MARKED, DISPROPORTIONATE INCREASE IN CATECHOLAMINE BIOSYNTHESIS CAPACITY. J.C. Waymire and G.L. Craviso. Dept. Neurobiol. & Anat., Univ. Tex. Med. Sch., Houston TX 77225.

Long-term treatment of chromaffin cells with the nicotinic agonist dimethylphenylpiperazinium (DMPP), increases the synthesis of tyrosine hydroxylase (TH). This study examined whether catecholamine (CA) synthesis rates in DMPP-induced cells are affected by the increase in TH levels. When chromaffin cells were treated with 1 μM DMPP for 3 days, TH activity, measured *in vitro*, increased 1.5- to 2-fold over that of untreated cells, whereas CA synthesis rates, measured *in situ*, increased in excess of 3.5-fold. The more pronounced stimulation of synthesis relative to the amount of increased TH was not due to TH activation or enhanced dopa decarboxylase activity. Elevated CA synthesis, unlike TH induction, was not completely blocked by protein synthesis inhibitors. Incubation of DMPP-induced cells with 100 μM acetylcholine for 10 min further increased CA synthesis (2- to 3-fold), indicating that the cells retained their ability to respond to subsequent short-term stimulation. Our results demonstrate that prolonged nicotinic receptor stimulation greatly augments CA synthesis capacity (at least 6-fold over control cells), and that induction of TH alone does not appear to account for the magnitude of the changes in synthesis rate. Supported by USPH NS11061.

293.13

INDUCTION OF TYROSINE HYDROXYLASE BY NICOTINIC AGONISTS IN BOVINE ADRENAL CHROMAFFIN CELLS IS CA^{2+}-DEPENDENT. G.L. Craviso and J.C. Waymire. Dept. Neurobiology and Anatomy, Univ. Texas Medical School, Houston, TX 77225.

Acute regulation of adrenal chromaffin cell tyrosine hydroxylase (TH) by acetylcholine is dependent upon extracellular Ca^{2+}. The present study examined whether Ca^{2+} also plays a role in the cholinergic-receptor mediated induction of TH. A 3-day exposure of chromaffin cells to varying concentrations of carbachol or dimethylphenylpiperazinium (DMPP) increased TH activity in a dose dependent manner (EC_{50} carbachol = 20 μM; EC_{50} DMPP = 0.25 μM) to a maximum of 158 ± 10%, and 146 ± 10% of control, respectively; muscarine had no significant effect at any concentration tested. Induction of TH by 56 mM K^+ (255 ± 6%) was similar in many respects to that produced by prolonged nicotinic receptor stimulation; induction was maximal at 3 days, blocked by protein synthesis inhibitors, and the increases in TH activity corresponded to the increases observed for TH immunoreactive protein. Increased TH synthesis also required Ca^{2+}. Induction of TH by DMPP increased with increasing extracellular Ca^{2+} up to 2.5 mM (121 ± 6% at 50 μM Ca^{2+}; 148 ± 4% at 0.5 mM Ca^{2+}; 184 ± 2% at 2.5 mM Ca^{2+}), and induction by K^+ was maximal at 0.5 mM Ca^{2+}; TH levels in non-induced cells were not affected by Ca^{2+}. These data strongly suggest that a Ca^{2+}-dependent mechanism is important in the long term regulation of TH. Supported by USPH NS 11061.

293.14

TYROSINE HYDROXYLATION IN INTACT CHROMAFFIN CELLS IN RESPONSE TO TETRAHYDROBIOPTERIN AND ANALOGS. J.E. Ayling and J.C. Waymire. Dept. Pharmacology, Univ. South Alabama, Mobile, AL 36688 and Dept. Neurobiology and Anatomy, Univ. Texas Med. Sch., Houston, TX 77225.

The activity of tyrosine hydroxylase (TH) is dependent on several factors, among which are its state of phosphorylation and the availability of its cofactor, tetrahydrobiopterin (BH_4). The current studies were undertaken to ascertain whether kinetic parameters for BH_4 and BH_4 analogs determined for TH in vitro (see abstract S.W. Bailey, S.B. Dillard and J.E. Ayling) parallel those in the intact cell. If so, these compounds may be useful probes of the state of phosphorylation in vivo.

Primary suspension cultures of bovine chromaffin cells were assayed for tyrosine hydroxylation in the absence or presence of varying concentrations of an added cofactor. Activity was determined by measuring $^{14}CO_2$ released from ^{14}C-1-tyrosine. HPLC analysis of dopa accumulated in the presence of a dopa decarboxylase inhibitor, m-hydroxybenzylhydrazine, gave similar results. All reactions were in pH 7.15 buffer and at 37°C, as with the isolated enzyme, and rates were linear for at least 18 minutes. Apparent Michaelis constants and maximum velocities for BH_4 and a series of BH_4 analogs with resting intact cells correlate with those determined with the isolated non-phosphorylated enzyme in vitro. This is consistent with findings that TH in these cells in the resting state is minimally phosphorylated. (Supported by NIH GM-30368 and NS-11061).

293.15

STIMULATION OF TYROSINE HYDROXYLASE (TH) ACTIVITY BY AN ANTISERUM AGAINST A PEPTIDE CORRESPONDING TO A SEGMENT OF TH. K.Y Lee[1*], J.Y. Lew[1], D. Tang[1*], D. H. Schlesinger[2*], A.Y. Deutch[3] and M. Goldstein[1] (SPON: R. Margolis). N.Y. Univ. Med. Ctr., New York, NY 10016, Dept. of Psychiatry[1], Dept. of Cell Biol. and Med.[2] and Yale Univ., Dept. Psychiatry, New Haven, CT 06510[3]

We have synthesized a peptide corresponding to position 34-47 in TH (TH-16) which is a substrate for phosphorylation by protein Kinase A, protein Kinase C and Ca^{+2}/calmodulin protein Kinase II (M. Goldstein et al., to be published). Antibodies to TH-16 were raised (anti-TH-16) and their effects on TH activity were compared with those raised against rat TH (anti-TH). The addition of anti-TH inhibits, while the addition of anti-TH-16 stimulates striatal TH activity. The stimulation elicited by anti-TH-16 is dose-dependent and the maximal stimulation was approx. 80%. To determine whether stimulation of TH activity by anti-TH-16 mimics the stimulation elicited by phosphorylation of TH we have determined the pH dependency and the effect on K_M for the cofactor $DMPH_4$. The stimulation is not pH dependent and the K_M for $DMPH_4$ was not significantly changed. Thus the enzyme stimulated by anti-TH-16 does not have the same kinetic properties as the phosphorylated TH. Immunohistochemical studies show that anti-TH-16 recognizes catecholaminergic neurons in the rat brain, and some immunoreactive sites are similar to those identified with anti-TH. Supported by grants from NIMH (MH 02717-30) and the Leon Lowenstein Foundation.

293.16

EFFECT OF TETRAHYDROBIOPTERIN (BH_4) ON RAT CIRCLING BEHAVIOR. W.E. Stroo* and J.E. Ayling. (SPON: P.R. Dyken). Dept. Pharmacology, Univ. South Alabama, Mobile, AL 36688.

BH_4, the natural cofactor for the aromatic amino acid hydroxylases, is clinically useful in treating the neurological symptoms of BH_4 deficiency and may have application in other neurological disorders associated with decreased levels of biogenic amines. However, the study of BH_4 and synthetic analogs (see abstract J.E. Ayling et al.) has been limited by the availability of an animal model to evaluate the CNS effectiveness of these compounds. Circling behavior of unilaterally lesioned rats (8 µg 6-OH-dopamine into substantia nigra) was monitored as an indirect index of dopamine (DA) release. BH_4 alone had no effect on circling behavior. However, BH_4 (0.1 mmole/Kg IP) after 0.5 mg/Kg amphetamine IP increased the 360° turns/2 hours from 173 ± 57 to 353 ± 70 (n=8). BH_4 was effective even when given up to 2 hours prior to amphetamine. Centrally effective inhibitors of DA synthesis (α-methyl tyrosine; m-hydroxybenzylhydrazine) at doses which did not significantly affect amphetamine induced behavior, blocked the effect of BH_4. A peripheral inhibitor (carbidopa) did not alter the response to BH_4. These data demonstrate that peripheral administration of BH_4 has behavioral effects consistent with enhanced synthesis of DA in the CNS. The unilaterally lesioned rat may be a useful animal model to evaluate synthetic analogs of BH_4. (Supported by GM-30368.)

THE EFFECTS OF PHYSIOLOGICAL STRESSORS ON TYROSINE HYDROXYLASE ACTIVITY IN CENTRAL AND PERIPHERAL CATECHOLAMINERGIC SYSTEMS. L.K. Nisenbaum, E.M. Stricker, and M.J. Zigmond. Dept. of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260

Norepinephrine turnover is elevated in the central and peripheral nervous systems during physiological stress. Changes in tyrosine hydroxylase (TH) activity have been implicated in this response. We have examined the effects of stress on TH activity in locus coeruleus (LC) of rat. TH activity in LC was increased by 26% when shaved rats were exposed to chronic cold (5°C) for 3 days and by 38% after 7 days. In cerebellum, TH was unchanged after 3 days of cold stress, but increased by 34% after 7 days, and remained elevated for at least 21 days. Comparable changes in TH activity were obtained with chronic insulin-induced hypoglycemia (PZI, 4-8 U/day). These responses to the two stressors are considerably lower than those we observe in the adrenal gland (e.g. +95% after 5 days of exposure to cold). This difference does not reflect a lower capacity for TH induction in brain, because reserpine (5 mg/kg) increased TH activity by 151% in LC, an amount comparable to the change in adrenal. Instead, the difference may reflect different demands placed on LC and adrenal during exposure to these stressors, different turnover rates of catecholamines in the two structures, and/or the requirement of LC to transport TH from the cell body to diffuse terminal projections. (Supported by USPHS Grants MH29670 and NS19608.)

EFFECTS OF REPEATED COCAINE OR AMPHETAMINE ON DOPAMINE SYNTHESIS MODULATING AUTORECEPTORS (ARs). M.J. Keegan*, J.B. Stahl*, and M.P. Galloway. (SPON: F.J. White) Wayne State Univ. Sch. Med.& Lafayette Clinic, Detroit, MI 48207

Although the ability of cocaine (COC) or amphetamine (AMPH) to increase synaptic levels of dopamine (DA) probably contributes to their acute psychoactive properties, less is known concerning their effects on nerve terminal ARs after repeated exposure. We have previously shown that COC, but not procaine, decreases both DA synthesis in vivo and K+-stimulated synthesis in vitro in a sulpiride sensitive fashion. To determine DA-AR responsivity after repeated COC or AMPH, we have measured DOPA synthesis both in vivo and in vitro after DA agonist challenge. In striatal slices obtained from rats treated with COC (20 mg/kg, bid, x16d), the dose response to 7-OH-DPAT was shifted to the right. However, this apparent decrease in AR responsivity was not accompanied by substantial alterations in regional levels of parent monoamines or metabolites, measured either 24 hrs or 5 wks after cessation of treatment (as above, x7d). After AMPH pretreatment in vivo, AMPH induced DA release in vitro was enhanced, however there was little change in the ability of quinpirole (QUIN) to inhibit synthesis in striatal slices. This dissociation between the effect of QUIN on DA synthesis (AR sensitivity) and AMPH induced release is consistent with the observation that QUIN (10uM) did not attenuate AMPH (3uM) induced release. THE CATECHOLAMINE TRANSPORTER IN CHROMAFFIN VESICLES IS INHIBITED BY 5-METHOXYTRYPTAMINE BUT NOT BY MELATONIN, A NON-PROTONATABLE ANALOGUE. Patrick M. Kelley, David A. Turner*, and David Nius*. Department of Biological Sciences, Wayne State University, Detroit, MI 48202.

The catecholamine transporter of adrenal medullary chromaffin vesicles concentrates biogenic amines some 3-4 orders of magnitude above the cytosolic concentration. Transport occurs via an exchange of catecholamines for protons but the mechanism for this exchange is controversial. Much of the controversy centers around which form of the amine (protonated or unprotonated) binds to and is transported by the transporter. We have used two derivatives of 5-hydroxytryptamine (5-HT), 5-methoxytryptamine and melatonin, to help elucidate the transport mechanism. 5-Methoxytryptamine, which is protonatable, is a good competitive inhibitor of 5-HT uptake (K_i about 5µM). By contrast, melatonin, which is N-acetylated and has an unprotonatable nitrogen, is a relatively poor inhibitor. Melatonin does inhibit catecholamine transport at very high concentrations (above 500µM) but the mechanism does not seem to involve inhibition of the transporter. Instead, melatonin abolishes the ATP-dependent membrane potential which drives amine transport. This indicates that melatonin interacts with the transporter very poorly if at all. Steric considerations are not likely to account for the poor binding of melatonin, since N-ethyl 5-methoxytryptamine is a good competitive inhibitor and isoproterenol is a good transportable substrate. This argues against the neutral, unprotonated form of the amine being the substrate for the transporter. This work was supported by NIH grant GM33849.

DOPAMINERGIC MESOCORTICAL-MESOLIMBIC INTERACTIONS MEASURED BY IN VIVO INTRACEREBRAL DIALYSIS. C.A.Leslie[1] and J.P.Bennett[2]. Departments of Behavioral Medicine and Psychiatry, [1,2] Neurology,[2] and Pharmacology,[2] University of Virginia School of Medicine, Charlottesville, VA 22908.

The "positive" symptoms of schizophrenia such as hallucinations, delusions and thought disorder may reflect "hyperactive" dopamine (DA) neurotransmission in subcortical mesolimbic sites. There are as well, "negative" symptoms in schizophrenia; flat affect, social withdrawal and avolition, and cognitive "deficit" symptoms which are more referable to higher cortical functions subserved by terminal fields of the mesocortical DA pathways. Many recent studies using a variety of techniques point to anatomical and functional abnormalities in the mesocortical DA system in schizophrenia. Biochemical and behavioral experiments suggest that mesocortical DA activity exerts modulatory influence over mesolimbic DA activity. A more thorough understanding of the neurochemistry of these feedback pathways, including the functional roles of D1 and D2 receptor subtypes, may enable a better understanding of the pathophysiology of schizophrenia and lead to more effective neuropharmacological interventions.

We are examining in the rat the effects of acute microinjection of selective D1 and D2 DA receptor agonists and antagonists into the medial frontal cortex (MFC) on DA synaptic transmission in the nucleus accumbens as measured by in vivo intracerebral dialysis. Preliminary studies have shown a rapid rise in DOPAC and HVA in the nucleus accumbens when the specific D1 agonist SK&F 38393 (500 pmol) is microinjected into the MFC. Biochemical studies suggest that this is mediated by augmentation of DA release in the nucleus accumbens. There is no change in mesolimbic DA synthesis estimated by acute DOPA decarboxylase inhibition.

294.2

DIALYSIS MEASUREMENTS OF DOPAMINE IN NUCLEUS ACCUMBENS AND VENTRAL TEGMENTAL AREA: EFFECT OF COCAINE.
C.W. Bradberry and R.H. Roth. Depts. of Pharmacology and Psychiatry, Yale Univ., School of Medicine, New Haven, CT.

Cocaine has previously been reported to increase dopamine (DA) levels in dialysis perfusates in striatum and nucleus accumbens, consistent with its ability to block DA reuptake. Cocaine has also been shown to inhibit the firing rate of meso-accumbens (m.-a.) DA neurons. One postulated mechanism by which cocaine might inhibit the firing rate of m.-a. DA neurons is by increasing the availability of DA to inhibitory dendritic autoreceptors. We report here that cocaine (1 mg/kg i.v.) increases extracellular DA levels in the ventral tegmental area as well as the nucleus accumbens in the chloral hydrate anesthetized rat. In the first twenty minute collection following cocaine administration, DA increases to 275%, and 175% of basal levels in nucleus accumbens and ventral tegmental area respectively. These data are consistent with a cocaine-induced enhancement of DA availability for somatodendritic regulation of DA neurons, thus providing a mechanism whereby cocaine may exert an inhibitory influence on m.-a. DA neuronal firing rate.

Supported in part by NIH Grant DA05119.

294.3

MICRODIALYSIS AND TISSUE LEVEL STUDIES OF PRESYNAPTIC DOPAMINE FUNCTION IN CHRONICALLY COCAINE-TREATED RATS.
P. Glue*, A. Mele*, C.C. Chiueh, D.J. Nutt*, and A. Pert. (SPON: L. Erinoff). NIAAA and NIMH, Bethesda, MD 20892.

Repeated administration of the psychostimulants cocaine (coc) and d-amphetamine (d-amp) cause behavioural sensitisation in rats, seen as increasing degrees of locomotor behaviour and stereotypy. Because these drugs act by increasing release and blocking reuptake of dopamine (DA), these may be the neurochemical mechanisms underlying this phenomenon. Although d-amp pretreatment causes increased d-amp-induced DA release, the effects of coc pretreatment on aspects of presynaptic DA function are unclear.

We investigated this by giving rats i.p. coc 30 mg/kg or saline daily for 1 week. Two indices of presynaptic function were studied; DA and metabolite levels in the striatum, and DA and metabolite responses to 1 mM coc infused via the microdialysis probe in the striatum and n.accumbens.

Striatal tissue levels of DA and metabolites were identical in the two groups, and ratios of metabolites to DA were also similar. In the microdialysis study, DA and metabolite baselines and responses were again identical in both groups. This suggests that, in contrast to d-amp, coc pretreatment does not alter presynaptic DA function. In addition, it would appear that in behavioural sensitisation, coc-induced changes in DA function are likely to be postsynaptic.

294.4

HIPPOCAMPAL NE AND DOPAC RELEASE FOLLOWING DAMAGE TO THE DORSAL BUNDLE: DIALYSIS STUDIES.
E.D. Abercrombie and M.J. Zigmond. Dept. of Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Microdialysis was used to examine the capacity for transmitter release of NE neurons spared after partial lesion of dorsal bundle (DB) afferents to the hippocampus. Hippocampal NE content was reduced by 30% to >90% by administration of 6-HDA (4 - 10 ug in 2 ul) into the DB. Two weeks later, extracellular levels of hippocampal NE and DOPAC were determined under basal conditions and in response to tail shock and elevated K^+ (60mM) in the perfusate.

% DEPLETION	pg NE/25 ul	pg DOPAC/25 ul	n
Sham	16 ± 3	26 ± 6	3
≤50%	18 ± 2	13 ± 3	3
70%	9 ± 3	4 ± 1	3
80%	5 ± 1	9 ± 3	3
>90%	2 ± 1	3 ± 1	5

Basal NE level did not decline significantly unless NE depletion exceeded 50%; however, basal DOPAC level declined linearly with lesion size. Stress and elevated [K^+] increased NE level in sham animals by 65% and 179%, respectively, and by 61% and 166%, respectively, in lesion animals with ≤50% NE remaining. DOPAC level was increased only modestly by these stimuli in sham animals but was increased dramatically in lesioned animals with ≤50% NE. Thus, compensatory processes exist by which a system of neurons can function normally despite the loss of up to half the population.

COMPARATIVE EFFECTS OF D-AMPHETAMINE AND COCAINE ON DOPAMINE RELEASE IN STRIATUM AND MEDIAL PREFRONTAL CORTEX: BILATERAL *IN VIVO* MICRODIALYSIS IN NORMAL RATS.
J.L. Baird*, J.N. Carlson and S.D. Glick. Department of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y. 12208.

Using the technique of *in vivo* brain microdialysis, we have monitored the bilateral release of dopamine and its metabolites (DOPAC and HVA) in the striatum and medial prefrontal cortex (PFC) of both anesthetized and awake female Long-Evans rats. Both d-amphetamine sulfafte (1.25 mg/kg, i.p.) and cocaine hydrochloride (20 mg/kg, i.p.) increased dopamine and decreased DOPAC and HVA in striatum; these changes were usually greater in one side of the brain than in the other and were more pronounced after d-amphetamine than after cocaine. In some rats we utilized an automated system for recording rotation (circling) concomitantly with collection of dialysis samples. For both d-amphetamine and cocaine, there appeared to be within-animal correlations between behavioral (i.e., rotation) and neurochemical (i.e., striatal dopamine) asymmetries during the time-course of drug effects. Preliminary data indicate that both drugs also increase dopamine in PFC but that, in contrast to striatum, the effect of cocaine is greater than that of d-amphetamine. Further studies are in progress to characterize dose-response relationships of these effects (Supported by NIDA grant DA03817 to S.D.G.).

294.6

EFFECT OF COCAINE AND AMPHETAMINE ON EXTRACELLULAR DOPAMINE LEVELS IN THE RAT PREFRONTAL CORTEX: A COMPARISON TO THEIR EFFECT IN THE NUCLEUS ACCUMBENS.
B. Moghaddam and B.S. Bunney, (Spons: R.N. Adams), Depts. Pharmacol. & Psychiat., Yale Univ. Sch. Med., New Haven, CT.

Several lines of evidence suggest that cocaine and amphetamine may elicit their psychotropic actions primarily by altering dopamine (DA) levels in the synapse. Of the major anatomical projections of the DA neurons, the nucleus accumbens (NAc) and prefrontal cortex (PFC) have been implicated most in reinforcing properties of cocaine and amphetamine. To test the involvement of NAc and PFC DA in cocaine and amphetamine reward, we have investigated the effect of systemic administration of these drugs on the extracellular levels of DA in the PFC and NAc using in vivo perfusion dialysis. These experiments were performed in chloral hydrate anesthetized rats and extracellular levels of DA were monitored simultaneously in PFC and NAc. Amphetamine (1 mg/kg i.v.) increased the extracellular DA levels in the NAc by 200-300% and in the PFC by 100-200%. Cocaine (1 mg/kg i.v.) increased DA levels in the NAc by 200-300% whereas very small or no effects were observed in the PFC (0-10%). Higher doses of cocaine (3-4 mg/kg i.v.) were fatal and lower doses (0.5 mg/kg i.v.) had no effect on the levels of DA in the PFC. These results indicate that systemic administration of cocaine has a more profound effect on the extracellular levels of DA in the NAc than in the PFC.

294.7

RELEASE OF DOPAMINE FROM STRIATUM OF FREELY MOVING RATS AFTER SINGLE AND REPEATED HALOPERIDOL. H. Tilson, M. K. Stachowiak, W. Zhang*, and J. S. Hong (SPON: R. King). Lab. Molec. Integ. Neurosci., NIEHS, Research Triangle Park, NC 27709.

The effects of acute or repeated administration of haloperidol on release of dopamine (DA) was studied in rats using a microdialysis procedure. 24 hrs after unilateral striatal implantation, rats were perfused with artificial CSF for 4 hrs; haloperidol (1 mg/kg, i.p.) was given and perfusate collected for 4 more hrs. Haloperidol produced a time-dependent increase in DA, peaking 1 hr after dosing, while HVA levels were still elevated 4 hrs later. Increase in DA but not HVA release was blocked by chloral hydrate anesthesia (300 mg/kg, i.p.). In another experiment, rats received 21 daily injections of haloperidol (1 mg/kg, i.p.) and were perfused 24 hrs after last injection. Repeated injections elevated basal DA release but not HVA. Acute administration of haloperidol to rats repeatedly treated with this drug failed to increase DA release, while HVA release increased. These observations suggest that repeated exposure to haloperidol causes a compensatory increase in extracellular DA release. The association of the inability of haloperidol to acutely increase DA release in those animals with the development of behavioral tolerance warrants further study.

REGIONAL DIFFERENCES IN THE EFFECT OF TYPICAL AND ATYPICAL NEUROLEPTICS ON TERMINAL RELEASE OF DOPAMINE: IN VIVO MICRODIALYSIS STUDIES. B.S. Bunney and B. Moghaddam. Depts. of Pharmacol. & Psychiat., Yale Univ. Sch. Med., New Haven, CT.

In vivo microdialysis has been used to study the acute effect of antipsychotic drugs on the release of dopamine (DA) from the nucleus accumbens (NAc), striatum, and prefrontal cortex (PFC). As previously shown by other investigators, we found that low doses of l-sulpiride (10-20 mg/kg i.v.) and haloperidol (0.05-0.1 mg/kg i.v.) cause a marked increase in striatal DA extracellular levels. However, we found that these low doses did not effect the release of DA from NAc and PFC. Higher doses of sulpiride (150-200 mg/kg i.v.) were required to effectively increase the extracellular levels of DAin the PFC. The effect of various doses of haloperidol on the release of DA from PFC and NAc is currently under investigation. The atypical neuroleptic clozapine, at low doses (5-10 mg/kg i.v.), had a larger effect on the release of DA from NAc than striatum. Our preliminary results indicate that clozapine (10 mg/kg) also increases the extracellular DA levels in the PFC. These data suggest that atypical neuroleptics are more effective than typical neuroleptics in inducing release of DA from the terminals of A10 dopaminergic neurons.

294.9

ENHANCEMENT OF IN VIVO DOPAMINE RELEASE FROM THE RAT STRIATUM BY 6R-L-ERYTHRO-TETRAHYDROBIOPTERIN AS STUDIED BY BRAIN DIALYSIS. K.Koshimura*, S.Miwa*, K.Lee*, M.Fujiwara* and Y.Watanabe*,¶ (SPON:K.Imamura). Dept. of Pharmacol., Kyoto Univ. Sch. of Med., Kyoto 606 and ¶Dept. of Neurosci., Osaka Bioscience Institute, Suita, Osaka 565, Japan.

Intracerebroventricular injection of 6R-L-erythro-tetrahydrobiopterin (BH_4), a cofactor for tyrosine hydroxylase, increases catecholamine (CA) synthesis (Miwa, S. et al., Arch.Biochem.Biophys., 239:234, 1985). In the present study, to clarify effects of BH_4 on CA release, we examined effects of BH_4 on in vivo dopamine (DA) release from the striatum of male Wistar rats using brain dialysis. DA in perfusates was assayed using HPLC with electrochemical detection after purification with alumina batch method. BH_4 applied in the perfusion fluid (0.1 mM - 5 mM) dose-dependently increased DA concentration in perfusates (2-fold increase for 0.1 mM BH_4, 5-fold for 0.5 mM, 10-fold for 1 mM and 60-fold for 5 mM), whereas biopterin had little effect. The increase was abolished by tetrodotoxin (10 μM in perfusion fluid) but was persistent after inhibition of tyrosine hydroxylase by α-methyl-p-tyrosine or inhibition of DA uptake by nomifensine. These results show that BH_4 enhances DA release in the brain and that this enhancement is not a result of an increase in DA synthesis or inhibition of DA uptake but a result of direct effects of BH_4 on the mechanism of DA release.

294.10

DIFFERENCES IN THE EFFECTIVE SURFACE AREA OF MICRODIALYSIS PROBES IN VIVO VERSUS IN VITRO. G.M. Alexander, J.R. Grothusen* and R.J. Schwartzman. Dept. of Neurology, Jefferson Medical College, 1025 Walnut St., Phila, PA 19107

The relative efficiency of microdialysis probes in vivo differs from that determined in vivo. The relative efficiencies were determined both in vitro and in vivo using tritiated water (THO). THO freely distributes throughout the fluid spaces of an experimental animal and, at equilibrium, the brain extracellular concentration of THO is the same as the plasma concentration. Microdialysis probes were inserted into the right caudoputamen of anesthetized rats. The rats were injected with THO and after one hour microdialysis samples were collected. The in vitro relative efficiency for THO was computed as the ratio of the THO concentration in the dialysate to that of the solution the probe was immersed in. The in vivo relative efficiency was computed as the ratio of the THO concentration in the brain dialysate to that measured in the plasma. The ratio of the in vivo to in vitro relative efficiencies is both flow and temperature dependent. This study demonstrates how the effective surface area can be computed at any probe flow rate and how it can be used as a correction factor.

TEMPERATURE EFFECTS ON THE CALIBRATION OF MICRODIALYSIS PROBES T. J. Parry* and J. G. McElligott (SPON: R. Murray) Temple University School of Medicine, Dept. of Pharmacology, Philadelphia, PA 19140.

Temperature, an often ignored variable, is important for *in vitro* calibration of microdialysis probes since thermodynamic principles dictate that the diffusion coefficient and percent recovery of analyte vary with temperature. This study illustrates the influence of temperature on percent recovery and stability of catecholamines and indolamines during microdialysis probe calibration. Standards containing norepinephrine (NE), dihydroxyphenylacetic acid (DOPAC), 5-hydroxyindolacetic acid (5-HIAA), dopamine (DA), and serotonin (5-HT) were prepared (1 to 0.1 μM) with a deaerated Krebs-bicarbonate buffer with glutathione and cysteine as antioxidants in open test tubes. Microdialysis probes (membrane size; 250 μm OD X 3mm length, total probe dead volume ≈7 μl), constructed in our laboratory, were immersed in the above standards and incubated at 21.5, 39, and 50°C for ten minutes. The dialysate (10 μl), collected at a flow rate of 1 μl/min, was placed in 5μl of 0.1M $HClO_4$ containing an internal standard (dihydroxybenzylamine DHBA) and was analyzed immediately by HPLC-EC. Percent recovery was calculated from temperature matched standards. The percent recovery of 5-HT and 5-HIAA rose in a non-linear fashion when compared to standards at 21.5 and 50°C (for 5-HT from 10.1% to 18% and for 5-HIAA from 15.8%, to 25%). The percent recovery of catecholamines also rose until a temperature of 39°C but then decreased at 50°C. We have subsequently found that the catecholamines in standard solutions even with antioxidants break down over the ten minute incubation time at elevated temperatures (20 to 50°C) while the indolamines remain stable. Results show that it is essential to calibrate microdialysis probes *in vitro* at brain temperature and to compare them with standards at the same temperature in order to minimize an underestimation of neurotransmitter and metabolite concentrations.

PHARMACOLOGICAL MODIFICATIONS OF CATECHOLAMINERGIC METABOLISM MEASURED BY IN VIVO VOLTAMMETRY AND MICRODIALYSIS IN THE ROSTRAL VENTROLATERAL MEDULLA OBLONGATA OF ANAESTHETIZED RATS. L.Lambás-Señas*, JY.Gillon*, JP.Bouilloux*, M.Seccia*, L.Quintin and B.Renaud. Neuropharmacologie, Univ. Claude Bernard and CNRS, Lyon, France.

Two recent in vivo techniques are available to measure central catecholaminergic (CA) metabolism: voltammetry and microdialysis. We used these two techniques to monitor the CA metabolism of the C1 adrenergic neurons located in the rostral ventrolateral medulla oblongata (RVL). In vivo voltammetry allowed the recording, every 2 min, of a catechol oxidation peak (CA.OC) (+55mV) in the C1 group. Microdialysis allowed the measurement (by HPLC-ED) of 3,4-dihydroxyphenylacetic acid (DOPAC) released in the RVL during 10 min periods. Pharmacological manipulations showed that: i) the tyrosine-hydroxylase inhibition(∝-MPT, 250 mg/kg,i.p.) and the MAO inhibition (pargyline, 75mg/kg, i.p.) suppressed both the CA.OC and the extracellular DOPAC, ii) the dopamine-β-hydroxylase inhibition (FLA 63, 30mg/kg, i.p.) doubled both the height of the CA.OC and the extracellular DOPAC. The changes in CA.OC (voltammetry) and extracellular DOPAC (microdialysis) exhibited very similar time courses in the 3 experiments. These results confirm that, as previously suggested, DOPAC is the catechol responsible for the in vivo oxidation current observed in the C1 group. Additional validation experiments are in progress to determine if the combination of in vivo voltammetry and microdialysis provide a useful approach of the CA metabolism of the C1 adrenergic neurons.

DIFFERENTIATION OF DOPAMINE OVERFLOW AND UPTAKE IN VIVO. L.J. May*, W.G. Kuhr and R.M. Wightman. Dept. of Chemistry, Indiana University, Bloomington, IN 47405.

Fast-scan cyclic voltammetry with Nafion-coated,carbon-fiber microelectrodes was used to measure the stimulated overflow of dopamine (DA) in vivo. DA concentrations in the extracellular fluid of the rat caudate nucleus were sampled in less than 10 ms at 100-ms intervals. Overflow of DA was induced by electrical stimulation of the medial forebrain bundle with 120-pulse trains of 300-uA biphasic pulses. Stimulated overflow was measured as a function of stimulus frequency both before and after administration of various pharmacological agents. The maximum DA observed at frequencies between 9 and 60 Hz was correlated with the maximum DA predicted by a simple uptake/overflow model. Observed overflow was assumed to be a function of DA overflow per stimulus pulse and the kinetics of cellular DA uptake. Correlation of experiment with simulation was obtained at 95% confidence for an increase in Km after administration of 20 mg/kg nomifensine or 25 mg/kg bupropion, whereas an equivalent increase in DA overflow per pulse did not. Results obtained following administration of 1-DOPA methyl ester were best modeled by an increase in DA overflow per pulse. Effects of GBR 12909 best fit an increase in DA available for overflow.

Supported by NSF BNS 86-06354.

ASCORBATE INTERFERES WITH DOPAMINE DETECTION AT NAFION-COATED ELECTRODES. D.J. Wiedemann, A. Basse-Tomusk, R.M. Wightman & G.V. Rebec, Dept. Chem. & Psychol., Indiana University, Bloomington, IN 47405. (SPON: R.S. Gurd)

Attempts to measure the low extracellular concentrations of dopamine(DA, 20 nM) using in vivo voltammetry have been hindered by the high levels of ascorbate (AA, 300-400 uM) present in DA terminal areas. The advent of nafion, a cation exchange polymer which can be used to coat electrodes, has greatly improved the ability to selectively detect DA under certain conditions (Gerhardt et al., Brain Res.,290: 390,1984).

In this study, the voltammetric response of nafion-coated microdisk electrodes to varying concentrations of DA and AA was measured (scan rate 812 mV/s or 100 mV/s). While many of these electrodes were able to detect extremely low concentrations of DA (20-50 nM), no electrode tested (n=20) was capable of rejecting 100 uM AA regardless of film thickness. In fact, current produced by 100 uM AA was of similar magnitude to that produced by 250 nM DA. Several of these electrodes were lowered into the striatum of urethane-anesthetized rats and the response to 2.5 mg/kg d-amphetamine monitored. In some cases, a peak resembling DA appeared during the first 10 min of the response but this was always subsequently overwhelmed by a peak resembling AA. Thus, these limitations must be considered when using this technique.

Supported by PHS RO1 NS15841 (RMW) and DA 0241/BNS-11240 (GVR).

INVERSE RELATIONSHIP BETWEEN ASCORBATE AND DIHYDROXYPHENYLACETIC ACID IN THE STRIATUM OF THE RAT. A. Basse-Tomusk & G.V. Rebec, Dept. Psychol., Indiana University., Bloomington, IN 47405

Accumulating evidence suggests that ascorbate (AA) modulates dopaminergic transmission in the striatum (Gardiner et al., Brain Res., 344:181, 1985). In this study in vivo voltammetry was used to study the regional distribution of AA as it relates to the distribution of the dopamine metabolite, dihydroxyphenylacetic acid (DOPAC). In each rat (n=20), an electrochemically modified carbon-fiber electrode was lowered through one of four regions which were selected to sample the entire extent of the striatum. During each dive, voltammetric scans were made at 1 mm increments to estimate extracellular DOPAC and AA concentrations at each dorsoventral level.

Within each striatal region, there was a large amount of variability in AA levels (200-500 µM) between animals. However, within individual animals, a consistent pattern emerged in all areas. AA levels were highest at the most dorsal and most ventral extent of the striatum. The opposite was true for DOPAC. Because DOPAC may serve as an index of dopamine turnover, our data suggest that AA levels are inversely related to dopamine turnover in the striatum.

SELF-STIMULATION OF THE VENTRAL TEGMENTUM AND CONCURRENT RELEASE OF DOPAMINE MEASURED BY IN VIVO ELECTROCHEMISTRY. **C.D. Blaha[1,2], A.G. Phillips[1], and H.C. Fibiger[2], Depts. of Psychology[1] and Psychiatry[2], University of British Columbia, Vancouver, BC, Canada, V6T 1Y7.**

Ex vivo studies of dopamine (DA) turnover and metabolism support the dopaminergic hypothesis of brain-stimulation reward in the VTA. We examined this hypothesis by monitoring extracellular DA concentrations during intracranial self-stimulation (ICS) using in vivo chronoamperometry (10-60 sec sampling rate). Male rats were implanted with a bipolar stimulating electrode in the VTA and a stearate-modified graphite paste recording electrode in the ipsilateral N. accumbens.

Initiation of ICS was accompanied by an immediate increase in the electrochemical DA signal. The DA signal remained elevated over the course of a 10 min period of ICS using a fixed current intensity (60Hz, 0.2s, 15-25uA test range) and returned to baseline levels within 5 min during extinction; a positive correlation was seen between changes in DA release and ICS response rates. Rate-intensity experiments also revealed a corresponding increase in both the ICS rates and DA release levels with each successive increase in current intensity (10-40uA, 5uA step/10 min). These data provide the first demonstration of DA release in the N. accumbens during ICS of DA cells in the VTA. Accordingly, these findings are consistent with a role for DA in brain-stimulation reward.

294.17

IN VIVO ELECTROCHEMICAL DETECTION OF DOPAMINE WITHIN THE NUCLEUS ACCUMBENS OF RATS SELF-ADMINISTERING COCAINE. J.M. Finlay, H.C. Fibiger, C.D. Blaha and A.G. Phillips. Div. of Neurol. Sci., Depts. of Psychiatry and Psychology, Univ. of British Columbia, Vancouver, BC, V6T 1W5.

Intravenous self-administration (SA) of cocaine is thought to be mediated by an increase in extracellular dopamine (DA) concentrations within the terminal regions of mesolimbic DA neurons. Lesions and pharmacological manipulations of mesolimbic DA neurons have been used to provide indirect support for this hypothesis. In the present experiment, in vivo electrochemistry was used to directly monitor extracellular DA concentrations within the nucleus accumbens of rats self-administering cocaine.

During daily 3-hr sessions rats were allowed to bar press for intravenous infusions of cocaine. When responding had stabilized, a stearate-modified carbon paste electrode was implanted within the anteromedial nucleus accumbens. Each rat was then given access to cocaine and DA concentrations were determined at 60 s intervals using chronoamperometry. Intravenous SA of cocaine was associated with a significant increase in extracellular DA concentrations within the nucleus accumbens.

The ability to monitor changes in extracellular DA concentrations associated with drug SA should permit the further characterization of mesolimbic DA neurons in reinforcement processes.

DOPAMINE DIFFUSION IN TURTLE BRAIN MEASURED WITH HIGH-SPEED VOLTAMMETRY. M.E. Rice and C. Nicholson. Physiology & Biophysics, NYU Med. Center, New York, NY 10016.

Dopamine (DA), besides acting as a classical neurotransmitter at discrete synapses, may also act as a neurohumoral agent on neurons distant from a release site. To estimate the range of DA influence, parameters affecting DA diffusion, including tortuosity (λ) and extracellular volume fraction (α) of the tissue, uptake and interactions with the extracellular matrix, must be determined. Previous work suggests that these factors may vary between brain regions, such that diffusion is less efficient in regions with high DA uptake like rat striatum (Rice et al., Neurosci., 15:891, 1985) compared to cortex (Dayton et al., J. Electroanal. Chem., 146:189, 1985). Using 8µm carbon fiber electrodes with fast-scan (300 V/s) cyclic voltammetry, we examined iontophoretically introduced DA diffusion in isolated regions of turtle (Pseudemys scripta and Chrysemys picta) brain, including cerebellum, olfactory bulb and frontal cortex. Curve-fitting based on simplex optimization of α, λ and concentration dependent uptake (k') revealed that DA diffusion was largely governed by the same parameters as the standard extracellular marker, tetramethylammonium (Nicholson & Phillips, J. Physiol. 321:225, 1981). These data imply that DA may diffuse relatively freely in turtle brain and hence may exert its influence over considerable distances. Supported by NS-13742.

WORKSHOP: CODING VISUAL SIGNALS AT THE PHOTORECEPTOR SYNAPSE. P. Sterling, UPenn and D. Copenhagen, UCSF (Co-chairmen); M. Wilson, UC Davis; A. Kaneko, Natl. Inst. Physiol., Okazaki; A. Stuart, UNC.

The photoreceptor axon terminal integrates neural signals from many sources: currents from the inner segment and adjacent photoreceptors, and feedback chemical signals from second order neurons. This complexity most likely relates to the problem of encoding an optical image whose intensity can vary over many log units using membrane potentials that can vary by only tens of millivolts. Wilson describes how electrically coupled photoreceptors filter voltage-gated photocurrents and suggests that feature extraction begins at the first synapse (salamander). Copenhagen treats the kinetics and gain of synaptic transfer from photoreceptors to second order neurons and explains the different issues in transmitting small and large signals (turtle, toad). Kaneko reports that the presumed photoreceptor transmitter (glutamate) itself excites cone terminals and suggests a possible role for this chemical signal in rod-cone interactions (fish). Stuart compares problems faced by an invertebrate visual system with those of the vertebrate and summarizes the physiological basis for their solution (barnacle). Sterling describes cone circuits to the ganglion cell and computations to suggest that the ganglion cell's contrast sensitivity originates in the cone axon terminal (cat).

SYMPOSIUM. SPECIFICITY IN THE CONTROL OF REGIONAL SYMPATHETIC OUTFLOW: PHYSIOLOGICAL, NEUROCHEMICAL AND ANATOMICAL APPROACHES. L.C. Weaver, Robarts Research Institute and Univ. of Western Ontario (Chairperson); R.M. McAllen*, Univ. of Melbourne; S.M. Barman, Michigan State Univ.; T.L. Krukoff, Univ. of Alberta; E.M. McLachlan*, Univ. of New South Wales.

The sympathetic nervous system provides discrete control of cardiovascular function by means which remain unknown. What characterizes a vasomotor sympathetic neuron? How can target organ specificity of central sympathetic neurons be determined? Do anatomical or neurochemical distinctions provide clues about the specificity of neuron function? Dr. McAllen will describe responses to stimulation of groups of brainstem neurons which demonstrate differential control of hindlimb skin and skeletal muscle vessels. Dr. Barman will discuss relationships between firing of brainstem neurons and different sympathetic nerves and selective medullo-spinal projection patterns. Dr. Weaver will provide evidence that visceral postganglionic neurons receive differential tonic and reflex inputs. Dr. Krukoff will correlate information about neurochemicals contained within sympathetic preganglionic neurons and terminal near them with possible functions of these neurons. Dr. McLachlan will demonstrate that characteristics of channels within postganglionic cell membranes provide these neurons with physiological properties that may distinguish them functionally.

VISUAL SYSTEM: DEVELOPMENT AND PLASTICITY IV

298.1

THE FATE OF THE SUBPLATE, A TRANSIENT STRUCTURE IN THE DEVELOPING NEOCORTEX. J.J.M. Chun and C.J. Shatz, Dept. of Neurobiology, Stanford Univ. Sch. of Medicine, Stanford, CA 94305.

During the development of the neocortex, the region of the future white matter directly beneath the cortical plate (CP) contains a subdivision called the subplate (SP). The SP includes a transient population of early-generated cells that are also immunoreactive (ir) for the neuron-specific marker MAP2, as well as for several neuropeptides (Chun et al.,1987, Nature 325, 617-620). Here, immunolabeling is used to examine the fate of this special population. The SP, as defined by MAP2-ir, increases in width relative to the CP between E46 and E56 and then decreases most rapidly during the first 4 postnatal weeks. Between P0 and P401, the density of MAP2-ir cells within the white matter of the lateral gyrus decreases by 5.5X. There is also a decrease in the density of peptide-immunoreactive cells within the SP during the same period: somatostatin (SRIF)- 5X; NPY-23X. SRIF-ir cells comprise a constant fraction of all MAP2-ir cells throughout postnatal life (22 to 23%), whereas the fraction of NPY-ir cells decreases between P0 and P401 (18 to 4%). These changes in cell density occur within a region of the white matter that increases in area by only 2X. Thus, the disappearance of the SP cannot be due to simple dilution. Cell death must also contribute significantly. (NIH Grants EY02858 to C.J.S. and GM07365 to J.J.M.C.)

RELATIONSHIP OF GENICULOCORTICAL AFFERENTS TO DEVELOPING NEURONS IN THE FERRET VISUAL CORTEX. Jean D. Peduzzi. Dept. of Physiol. Optics, School of Optometry, University of Alabama at Birmingham, Birmingham, AL 35294.

Previous studies (Jackson, Peduzzi & Hickey, 1984; Jackson & Hickey, 1986) described the position of neurons of a given birthdate in the developing and adult ferret visual cortex. In this study, the relationship of geniculocortical (GC) fibers (identified by a TMB reaction following embryonic or postnatal intraocular injections of WGA-HRP) to particular cortical neurons (identified by autoradiography after ^{3}H-thymidine injections) was examined. The GC afferents do not reach the area of the presumptive visual cortex until postnatal day 3 (P3). The pattern of GC fibers can be divided into 4 primary stages. The first stage is a "waiting period" (from P3-P7) where GC afferents are waiting or expanding in the intermediate zone but have not reached the cortical plate. The second stage is a "widely dispersed stage" (from P10-P15) where GC fibers are found throughout the primitive cortex. The widespread distribution of fibers affords the possibility of interaction with virtually all visual cortical neurons during this stage. The third stage is a "right place-wrong amount stage" (from P20-P36) where GC fibers are present in the normal geniculo-recipient layers but the projection to layer VI is much greater than that found in the adult. The fourth stage is the adult pattern where the major geniculate projection is to layer IV and minor projections to layers I and VI. (EY01338 and EY03039)

298.3

PRENATAL DEVELOPMENT OF AXONAL PROJECTIONS FROM THE CAT'S VISUAL CORTEX. S.K. McConnell and C.J. Shatz. Dept. of Neurobiology, Stanford Med. School, Stanford, CA 94305.

In the adult cat, neurons in the visual cortex project with remarkable specificity to cortical and subcortical targets. We have examined the development of these axonal projections, using either [3H]-leucine (injected into the visual cortex of living fetal or neonatal kittens) or the fluorescent tracer dil (placed in fixed prenatal brains).

The first cortical axons reach the thalamus by E39. Labeled axons have arrived in the vicinity of all cortical and subcortical targets by E52, at which time some axons (e.g., those to the superior colliculus and claustrum) have invaded their targets, whereas other sets of axons--most strikingly, those headed for the lateral geniculate nucleus and contralateral cortical areas--accumulate in regions just outside the target itself. Cortical axons invade the LGN at around E59, while both callosal axons and ipsilateral corticocortical axons continue to wait beneath the cortical plate well into postnatal life. A transient aberrant projection was observed prenatally, when some axons from visual cortex are misrouted from the corpus callosum into the fornix.

Cortical axogenesis in the cat thus shows three characteristic features: directed outgrowth to normal targets, early "waiting periods" in which axons accumulate outside the target, and early "exuberant" axonal projections that are eliminated in later life. (Supported by NIH EY02858 and EY06028.)

LOCALIZATION OF CYTOCHROME OXIDASE IN MACAQUE STRIATE CORTEX DURING PRENATAL DEVELOPMENT. M. Wong-Riley, T. Trusk, and D. Hoppe*. Dept. Anatomy & Cellular Biology, Med. Col. of WI, Milwaukee, WI 53226.

The mature pattern of cytochrome oxidase (C.O.)-rich laminae and supragranular puffs of macaque striate cortex is present with slight modifications at birth (Kennedy et al., '85). We sought to determine if C.O. is expressed in early prenatal development and whether the pattern changes over time. Twelve fetal macaque monkeys at 4 age groups were examined: (1) Embryonic day (E) 70, when layers V and IVC neurons had attained their final positions; (2) E101-103, when the last striate neurons had been generated; (3) E135, when most geniculocortical fibers had invaded the cortex (Rakic, '74;'76); and (4) E158-160, 1 week before birth. We found that at E70, the major site of high C.O. activity was in upper II, where small, spindle-shaped cells with darkly reactive mitochondria were aggregated. The outer half of I was moderately reactive, while the rest of the cortical plate was only lightly reactive. At E101, upper II retained its dark staining, and a moderately dark band appeared in VI and upper half of V. C.O. activity in the cell dense IV was quite low. By E135, however, IVA, IVCα and the lower border of IVCβ (IVCβ_{dark}) and VI were distinctly reactive, while the rest of IVCβ, II/III, and I were only lightly reactive. IVB and V were unusual in that IVB was wider at this stage, and both of these lightly reactive layers had aggregates of C.O. reaction product along their midportions. No distinct puffs were found at this age. Finally, between E158 and E162, the newborn pattern of C.O. was achieved with dense staining in supragranular puffs, IVA, IVCα, IVCβ_{dark}, and VI. Most neurons within puffs contained reactive mitochondria at this age. Since puffs are present at E143 (Horton, '84), they must have developed sometime between E135 and E143, approximately 3.5 weeks before birth. [Supported by NIH EY05439 to MWR. Fetal brains were gifts of Dr. S.A. Sholl (NIH HD18865 & RR00167)]

SENSITIVE EXTRACELLULAR RECORDINGS OF SPONTANEOUSLY ACTIVE PYRAMIDAL AND NONPYRAMIDAL NEURONS IN EMBRYONIC VISUAL CORTEX. M.G. Blanton and A.R. Kriegstein. Dept. of Neurology, Stanford University, Stanford, CA 94305-5300.

An understanding of normal and disrupted neuronal development requires information on the physiological behavior of individual developing neurons. Using a non-invasive extracellular patch clamp technique (Forda et al, Brn Res 249: 371, 1982), we obtained sensitive, high resolution unit recordings from slabs of embryonic turtle visual cortex, chosen for its simple cytoarchitecture and resistance to hypoxia. Our capacity to visualize the tissue allowed selection of specific neuronal types, permitting anatomical-physiological correlations. During early cortical plate formation, identified nonpyramidal cells fired periodic repetitive bursts of rapid action potentials (APs), while pyramidal units fired single, relatively slow APs. With development, AP duration shortened and firing patterns of the cell types became more distinct. Evoked activity patterns suggested that nonpyramidal GABA-mediated inhibition of pyramidal cells was functional early, when synapses were still sparse. Presumed synaptic currents, graded and often associated with APs, became more frequent during development. Similar spontaneous APs and synaptic currents were recorded in early developing rat neocortex, indicating that distinct patterns of nonpyramidal and pyramidal spontaneous electrical activity may be a general feature of early cortical development in higher vertebrates.

EFFECTS OF VISUAL DEPRIVATION ON SYNAPTIC ACTIVITY IN THE RAT VISUAL CORTICAL SLICE. R. L. Berry and T. J. Teyler. Dept. of Neurobiology, NE Ohio Univ. College of Medicine, Rootstown, Ohio 44272.

Visual deprivation effects, widely studied in intact cat cortex, have not been studied with in vitro slice techniques. The present study investigates the effects of monocular (MD) and binocular deprivation (BD) on the electrophysiology of rat primary visual cortical slices.

Long Evans hooded rats were given monocular or binocular lid suture (or no treatment) before natural eye opening and reared to 3-6 mos. Animals were then sacrificed and cortical slices were obtained and maintained in slice chambers where white matter (geniculocortical fibers) underlying cortical area OCl was stimulated and cortical field potential profiles were obtained. Integration of current sinks obtained by current source density analysis provided laminar estimates of synaptic activity. Slices from cortex opposite the sutured eye in MD rats demonstrated a marked reduction in multisynaptic (5-40 msec post stimulus) layer II-IV synaptic activity when compared with slices from the experienced cortex and from BD and normally reared rats. BD slices exhibited near normal patterns of responses. These results indicate that in rat, as in cat, MD is much more potent than BD in reducing responsivity of cortical neurons--a surprising finding considering that in cats this difference is attributed to binocular competition (in MD and not BD) not likely to play a major role in the much less binocular rat. This research was supported by ONR Grant #86K0664.

NMDA-EVOKED CALCIUM UPTAKE BY SLICES OF KITTEN VISUAL CORTEX MAINTAINED *IN VITRO*. J.E. Sherin*, D. Feldman* and M.F. Bear, Center for Neural Science, Brown University, Providence, RI 02912.

We have developed a neurochemical assay of NMDA receptor effectiveness in the visual cortex of kittens. Slices of visual cortex are prepared and maintained *in vitro*, and uptake of ^{45}Ca is monitored as different concentrations of NMDA are applied. We find that Ca uptake is saturated by a 2 minute exposure to 50 μM NMDA; the maximum value attained is ~5.4 nmoles Ca/ mg protein which is 145% of basal uptake (3.7 nmol/mg). NMDA-stimulated uptake is significantly reduced by the selective NMDA receptor antagonist AP5 in concentrations ≥ 50 μM. In contrast, Ca uptake evoked by 62.5 mM K (144% of control) is unaffected by 100 μM AP5.

Both norepinephrine (NE) and NMDA receptors are thought to contribute to the mechanisms underlying experience-dependent plasticity in the visual cortex during the critical period. We therefore examined the effects of NE on NMDA-evoked Ca uptake. Slices were pretreated for 5 min. with different concentrations of NE before NMDA and ^{45}Ca were added. 50 μM NE (in 0.5 mM ascorbate) doubled the Ca uptake evoked by 25 μM NMDA, from 113±2 % to 128±2 % of basal levels. These data support the hypothesis that NE exerts its effects on synapse modification, at least in part, by modulating the effectiveness of visual cortical NMDA receptors.

Rearing kittens in the dark from birth leaves the visual cortex largely unresponsive to retinal stimulation, but also highly modifiable by subsequent visual experience. To assess the functional state of NMDA receptors in striate cortex under these conditions, we assayed NMDA-stimulated Ca uptake in tissue taken from P31-40 dark-reared (DR) kittens. We found that Ca uptake evoked by 50 μM NMDA in slices from DR kittens was only ~1/3 that of control (116±4 % vs. 145±7 % of basal). These data suggest that the increased modifiability of DR cortex is not explained simply by an increase in the sensitivity or number of NMDA receptors. (Supported by ONR contract N00014-81-K0136 and NIH grant NS06929)

298.8

PHARMACOLOGICAL MODULATION OF LONG-TERM POTENTIATION IN SLICES OF VISUAL CORTEX. Barry W. Connors and Mark F. Bear, Section of Neurobiology and Center for Neural Science, Brown University, Providence, RI 02912.

Neocortex displays a remarkable degree of experience-dependent plasticity. Accumulated evidence suggests that some types of modification require the presence of noradrenergic or cholinergic inputs. In addition, cortical NMDA receptors and the general level of GABA-mediated inhibition have been implicated. A crucial issue concerns the mechanisms by which these variables interact to orchestrate synaptic modifications in visual cortex.

Slices of area 17 were prepared from kittens aged 32 to 56 days of age, or from adult rats, and maintained *in vitro*. Bipolar stimulating electrodes were placed at the white matter-layer VI border and field potentials were recorded in layer III. Baseline responses to stimulation in the range of 15 to 50 μA were collected every 30 sec. for ≥10 min., followed by conditioning stimulation applied at twice the test intensity. A wide range of stimulation parameters were tried, ranging from 2 Hz for 10 min. to repeated bursts of 50 Hz stimulation. In general, conditioning stimulation of any type was ineffective in eliciting potentiation unless a small amount of the $GABA_A$ receptor antagonist bicuculline methiodide (BMI) was added to the bathing solution. When BMI was present in concentrations ranging from 0.3 to 1 μM, conditioning stimulation of 4 Hz for 30-60 sec. was most effective in producing a lasting (>30 min.) potentiation (LTP). LTP always followed a period of post-tetanic depression that lasted several minutes. The induction of LTP was most probable when facilitation and afterdischarge occurred during the tetanus. Addition of 10 μM norepinephrine (NE; in 20μM ascorbate) to the bath had no effect on LTP induction in the absence of BMI. However, NE did reliably lower the threshold concentration of BMI required for conditioning stimulation to elicit potentiation. In two experiments, slices treated with BMI and NE were conditioned in the presence of 50-100 μM AP5, a selective NMDA receptor antagonist. No facilitation or afterdischarge occured during the tetanus and no LTP was induced. However, LTP could be induced after the AP5 was washed out.

Taken together, these results suggest that long-term, activity-dependent synaptic potentiation in neocortex requires activation of NMDA receptors that are relatively ineffective unless network inhibition is slightly suppressed. NE facilitates these modifications by reducing the requirement for disinhibition. (Supported by the Klingenstein Fund, and NS25983 and NS06929 from the NIH)

298.9

THE LOCATION AND FUNCTION OF NMDA RECEPTORS IN CAT AND KITTEN VISUAL CORTEX. K. Fox, H. Sato and N. W. Daw. Dept. Cell Biol., Wash. Univ. Med. Sch., St. Louis MO 63110. We studied the effects of NMDA antagonists in cat and kitten area 17 to assess the hypothesis that NMDA receptors play a role in cortical plasticity. Carbon fiber micro-electrodes were used to record from neurons and apply D-APV. The standard drug trial of 10nA for three minutes was ineffective on kainate responses but abolished equipotent NMDA induced excitation. Sensitivity to APV was correlated with cortical layer but not with receptive field type, stimulus evoked firing rate, or sequence within penetration, and with age only in layer IV. Layers II and III of 28-35 day kittens and adults were more sensitive to APV than were deeper layers: visual responses were reduced to 10-45% of control at all ages. Layer IV cells were insensitive to APV in adults but in kittens 57% showed small but significant reductions in response (55-70% of control). Preliminary results suggest layer IV may be more sensitive in 21 day kittens. Spontaneous activity was reduced more than visual response in both kittens and cats. Cells which showed no response to 10nA of APV were unaffected by higher doses. The developmental time course of NMDA receptor efficacy in layer IV more closely follows that of geniculo-cortical axon segregation than the critical period. The persistence of NMDA receptors in layers II and III of adult may indicate a role in the transmission of sensory input to these layers rather than plasticity.

298.10

POSTNATAL DEVELOPMENT OF GABAERGIC SYNAPSES IN THE VISUAL CORTEX (AREA 17) OF NORMAL AND DEPRIVED CATS. R.E. Kalil and A.N. Lies*. Dept. of Ophthalmology and Neurosciences Training Program. Univ. of WI, Madison, WI 53706.

GABAergic inhibitory mechanisms are thought to play an important role in molding the response selectivity of cortical neurons. With the light microscope, GABA+ cells are evident in area 17 of the newborn kitten, but their maturation, as gauged by cell body growth, is not complete until at least 8 weeks postnatal. At present there is little information available concerning the morphological development of GABA+ synapses in visual cortex. We have therefore combined electron microscopy with immunocytochemistry to study this problem directly.

Antibodies raised against GABA conjugated to bovine serum albumin were used to stain cortical neurons in normal cats that ranged in age from newborn to adult. Also studied were cats that had been reared from birth to adulthood with binocular eyelid suture. GABA+ cells and processes are present in the cortex of normal animals at all ages studied. In cats younger than 4 weeks, presynaptic GABA+ terminals are not prominent, although stained cell somas and dendrites often are postsynaptic. During the second postnatal month, GABA+ terminals increase in size and frequency. By 8 weeks, they are qualitatively similar to those in adult cats. Long-term deprivation appears to have no major effect, suggesting that normal visual experience is not essential for the development of GABA+ synapses in area 17.

298.11

Postnatal development of Substance P-ir structures in the cat visual cortex:neurons with ascending axons become less and less detectable. P.Wahle*,C.Sanides*,K.Albus, MPI fuer Biophysik. Chemie/110, Am Fassberg, 3400 Goettingen, FRG.

In 30 cats aged postnatal day (P) 0 to adulthood SP-ir was demonstrated using the PAP-method.SP-ir cells are first detected at P2 in early stages of morphological differentiation in layer V. During the following 2 weeks more and more neurons become SP-ir and differentiate. As a consequence SP-ir axons and terminals increase in density,and the staining intensity increases reaching a peak from P 12-20. Neurons now are completely labeled. The somata sit in layers V/VI, they are bitufted to multipolar. The axon arises from the upper pole,even from secondary dendrites.Initially issued recurrent collaterals form a dense terminal plexus in layer V, further collaterals ascend as a bundle to superficial layers , where a second terminal plexus forms in II/III. Fibers reach layer I. From P 15 onwards cells become lighter and lighter labeled and decrease in number. Until the end of the third month the innervation pattern has disappeared; only occasionally could a faintly labeled soma be detected in the 12 month old cat. The concurrent analysis of Somatostatin-ir structures, however, reveals the presence of a cell type that displays the same morphological variability, same axonal projection and postnatal chronology of appearance. It can be easily detected in the young and adult cat cortex.This suggests that a persisting cell type that uses SOM/GABA as transmitter expresses high amounts of SP during the first three postnatal month.

298.12

DEVELOPMENT OF ASTROCYTES IN THE CAT VISUAL CORTEX. C.M. Müller*, A.K. Engel* and W. Singer (SPON: European Neuroscience Association). Max-Planck-Institut für Hirnforschung, Frankfurt/M., F.R.G.

Neurones of the cat visual cortex acquire their response selectivity under the influence of visual experience. This process starts at three weeks of age, lasts for several weeks and coincides with an activity-dependent elimination of synaptic connections. Since astrocytes have been shown to participate in synapse elimination, we studied their development in the cat visual cortex by immunolabeling the astrocyte specific proteins GFAP and S-100. The distribution of immunopositive cells was similar with both markers. At all ages (1 week to adult) heavily labeled cells were present in the white matter. Developmental changes in the cortex followed the characteristic inside-out pattern. Initially (from 7-21 days postnatally) labeled cells were confined to infragranular layers and only increased in number. At 4 weeks they occured throughout all layers. Staining intensity in gray matter was weak at these developmental stages. Between the fifth and seventh week the adult pattern with heavily labeled cells in all layers was attained. Preliminary studies in dark reared animals revealed a reduced density and staining intensity, especially in supragranular layers. As dark rearing delayes also the decay of cortical susceptibility to experiential modifications there may be an inverse relation between the maturity of astrocytes and cortical malleability.

EXCITATORY AMINO ACIDS: EXCITOTOXICITY III

299.1

CHRONIC QUINOLINIC ACID LESIONS IN RATS CLOSELY MIMIC HUNTINGTON'S DISEASE. M. Flint Beal, Neil W. Kowall, Kenton J. Swartz, Robert J. Ferrante and Joseph B. Martin. Neurology Service, Mass. General Hospital, Boston, MA.

Our previous work has shown a relative sparing of NADPH-diaphorase neurons with preserved concentrations of somatostatin and neuropeptide Y following acute quinolinic acid (1 week) striatal lesions. These results are similar to those in Huntington's disease (HD) although in this illness there are 2-3 fold increases in striatal somatostatin and neuropeptide Y concentrations. In the present study we studied the effects of lesions at 1 year. Lesions were made by injecting 240 nmol of quinolinic acid in 1 ul into the anterior striatum. Neurochemical studies showed a significant decrease of GABA of 38% and substance P of 56% while somatostatin was significantly increased by 41% and neuropeptide Y by 74%. Histologic evaluation of the lesions was carried out using NADPH-diaphorase staining combined with enkephalin staining. The histologic staining showed a marked shrinkage of the striatum with reabsorbance of the acute lesion core. Neuronal counts showed marked approximately 3 fold significant increases in the numbers of NADPH-diaphorase neurons in regions in which there were significant 60% reductions in the numbers of enkephalin neurons. Chronic quinolinic acid lesions therefore closely resemble the neurochemical and histologic features of HD, since they result in significant increases in both somatostatin and neuropeptide Y concentrations and marked increases in the density of NADPH-diaphorase neurons.

299.2

GLUCOSE-DEPRIVATION CORTICAL NEURONAL INJURY IS STRONGLY INFLUENCED BY THE AVAILABILITY OF EXTRACELLULAR AMINO ACIDS. H. Monyer, M.P Goldberg, and D.W. Choi. Stanford Univ. Med. Sch., Stanford, CA 94305.

We developed a murine cortical cell culture model of glucose-deprivation neuronal injury (GDNI). In our initial experiments (Brain Res. 446:144), cultures were exposed for 3 - 6 h to Eagle's minimal essential medium (MEM) without vitamins or glucose, prior to the addition of glucose. By the next day, substantial amounts of neuronal injury developed, that could be attenuated by the addition of the NMDA antagonist APV. Here we explored the dependence of GDNI on the availability of the essential amino acids (AAs) normally present in MEM.

If all AAs were omitted from the glucose-deprivation medium, GDNI was usually somewhat reduced compared with that found in the standard MEM condition. Adding back AAs but not glutamine (Glut), the synthetic precursor for transmitter glutamate, resulted in GDNI which was both more extensive, and less sensitive to APV, than that found in the standard MEM condition. We conclude that: 1) GDNI is enhanced by the presence of extracellular essential AAs (not including Glut); and 2) in the presence of these AAs, Glut has a dual effect on GDNI, increasing a component mediated by NMDA receptors (possibly by serving as a substrate for glutamate synthesis in presynaptic terminals), but also decreasing another component not mediated by NMDA receptors.

299.3

DELAYED ANTAGONISM OF NMDA RECEPTOR-MEDIATED CORTICAL NEURONAL INJURY: AN IN VITRO MODEL. D.M. Hartley and D.W. Choi. Stanford Univ. Med. Sch., Stanford, CA 94305.

Present experiments explored the neuroprotective efficacy of manipulations performed "late" after excitotoxin-induced injury. Murine cortical cell cultures exposed to 500 μM NMDA for 3 min developed over the next day substantial neuronal cell loss. When added at t = 0 - 30 min after NMDA exposure, concentration-dependent neuroprotection was produced by the competitive NMDA antagonist D-APV (EC_{50} 10 μM) and the non-competitive NMDA antagonists MK-801 (EC_{50} 0.3 μM) and dextrorphan (EC_{50} 3 μM). Maximal benefit (at t = 0) was similar for all three drugs (50 - 80% reduction in neuronal damage) and somewhat less than the essentially complete protection afforded by these drugs if added during the toxic exposure. In contrast, little benefit was produced by late addition of 1 mM secobarbital, 100 μM phenytoin, 10 μM nifedipine, 3 μM TTX, or non-NMDA antagonists (1 mM GAMS, 1 mM GDEE, or 10 μM FG 9065). Rescue benefit could also be demonstrated by removing Ca but not Na from the medium for 30 min at t = 0; interestingly, if both Ca and Na were omitted for this period, neuronal injury could be essentially blocked. The ability of NMDA antagonists to rescue cortical neurons "doomed to die" by previous toxic exposure may be a basis for the protective efficacy of these drugs administered subsequent to ischemic insults in vivo.

299.4

CORTICAL NEURONAL INJURY IN VITRO FOLLOWING COMBINED GLUCOSE AND OXYGEN DEPRIVATION: IONIC DEPENDENCE AND DELAYED PROTECTION BY NMDA ANTAGONISTS. M.P. Goldberg, H. Monyer and D.W. Choi. Stanford Univ. Med. Sch., Stanford, CA 94305.

We have previously described NMDA receptor-mediated neuronal injury in cortical cell cultures deprived of either oxygen or glucose for 4 - 8 h. Combined removal of both oxygen and glucose resulted in more rapid neuronal injury, such that a 30 - 45 min exposure was sufficient to produce marked neuronal swelling, followed over 24 hr by widespread neuronal degeneration. Both acute swelling and delayed death were blocked by addition of the NMDA antagonist dextrorphan (DX, EC_{50} 3 μM) during exposure (D-APV, CPP, and MK-801 were also effective). DX reduced neuronal loss by 50 - 75% even when administered following completion of the deprivation insult.

Substitution of choline for Na in the exposure solution blocked acute swelling but not late neuronal cell loss. In this Na-free solution, removal of Ca substantially reduced, and excess Ca (5.4 mM) enhanced, subsequent injury; DX however still blocked injury. Removal of Ca in normal Na yielded destructive neuronal swelling, which could also be blocked by DX.

Neuronal injury in this in vitro model of ischemia may be due to an NMDA receptor-mediated influx of Ca and Na, in part occuring in a delayed fashion subsequent to the actual insult.

299.5

NON-NMDA RECEPTOR-MEDIATED NEUROTOXICITY IN CORTICAL CULTURES. J. Koh, D.M. Hartley, D.W. Choi, Stanford Univ. Med. Sch., Stanford, CA 94305.

The neurotoxicity of non-NMDA receptor agonists was quantitatively investigated in dissociated murine cortical cell cultures. 5 min exposure to 1 mM kainate produced acute neuronal swelling, but little in the way of neuronal loss by the next day. 5 min exposure to 1 mM AMPA produced neither acute neuronal swelling nor much late neuronal loss. With 24 h exposures, both kainate (EC_{50} 15 μM) and AMPA (EC_{50} 3 μM) produced concentration-dependent widespread neuronal loss; AMPA but not kainate toxicity was sensitive to attenuation by GAMS, whereas both AMPA and kainate toxicity were sensitive to attenuation by kynurenate (Kyn). Thus the non-NMDA agonists kainate and AMPA, which probably act on separate receptors, differ from NMDA agonists in requiring lengthy exposure to destroy most cortical neurons. Somewhat puzzling then is the ability of quisqualate (Quis) (30 μM - 1 mM) to produce widespread late neuronal loss with 5 min exposure. Since this toxicity is resistant to glutamate antagonists (APV, GAMS, GDEE, Kyn) added acutely during agonist exposure, but can be attenuated by Kyn (but not APV) added "late" to the medium after agonist washout, we speculate that Quis even upon brief application, may be taken up into neurons and released gradually, thus achieving in fact lengthy exposure (see Harris et al., Brain Res. 418:361).

BIPHASIC EFFECTS OF PURINES ON QUINOLINIC ACID NEUROTOXICITY. T.W. Stone, J.H. Connick* and C. Chumbley* (SPON: European Neuroscience Association) Departments of Physiology and Anatomy, St George's Hospital Medical School, University of London, London SW17 0RE.

The ability of the endogenous neurotoxin quinolinic acid to produce neuronal damage may involve presynaptic factors. We have recently shown that quinolinate can induce a release of glutamate and aspartate in vivo and we reasoned that compounds which suppress transmitter release might protect against quinolinate toxicity.

Male rats were anaesthetised with pentobarbitone and stereotaxic injections made into the dorsal hippocampus. Quinolinate was used at doses of 100 nmoles for a limited lesion, and 120 nmoles for an extensive lesion. Animals were killed 5 days later and the brain taken for histology. The extent of hippocampal damage was assessed blind on a 1-10 scale. The co-injection of R-PIA (100ng) reduced the amount to damage produced by quinolinate. Similarly the intraperitoneal administration of R-PIA (0.01mg/Kg) also afforded significant protection when injected at the same time as the intrahippocampal quinolinate. Higher doses of systemic R-PIA caused an enhancement of the toxic effects of quinolinate probably due to hypotension inducing a degree of hippocampal hypoxia.

RELATIVE RESISTANCE TO QUINOLINIC ACID TOXICITY OF NEURONS CONTAINING NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-d) IN CULTURES OF RAT CORTICOSTRIATAL SYSTEM. W.O. Whetsell, Jr., and B. Christie-Pope*. Neuropathology, Vanderbilt Univ. Sch. Med., Nashville, TN 37232

Mature (21 days *in vitro*) organotypic cultures of rat corticostriatal system (Whetsell & Schwarcz, J. Neural Trans. Suppl 19, 53, 1983) were used to investigate sensitivity of subpopulations of neurons to toxicity of the endogenous excitotoxin, quinolinic acid (QUIN). Specifically, the question of sensitivity of NADPH-d-containing neurons to QUIN toxicity was examined in this system. Corticostriatal (CXCA) cultures were exposed to a range of QUIN concentrations (10^{-3}M, 10^{-4}M, or 10^{-6}M) for different periods of time and compared by light microscopy to control (non-QUIN-treated CXCA cultures) after histochemical staining for NADPH-d activity (Vincent et al.,Comp. Neurol. 217:252, 1983). CXCA cultures exposed to QUIN 10^{-3}M showed generalized degeneration in the living state after 24 hours; NADPH-d positive neurons were either not present or were rarely found in these cultures. Identical sibling cultures incubated in QUIN 10^{-4}M showed vacuolization and destruction of many regions by 24 hours, but in those regions, the population of NADPH-d positive neurons was indistinguishable from control cultures. Other sibling CXCA cultures chronically exposed to QUIN 10^{-6}M for four-to-five weeks showed scattered focal degeneration similar to that reported previously (Whetsell & Schwarcz, Soc. Neurosci. Abstr., 1987), but NADPH-d-containing neurons were well-preserved. Results indicate that NADPH-d-bearing neurons appear to be relatively resistent to QUIN neurotoxicity at moderate to low concentrations of QUIN but susceptible to higher concentrations of QUIN in this paradigm. (Supported by USPHS grant NS-20509.)

ADENOSINE ANALOGUES PROTECT AGAINST KAINATE-INDUCED TOXICITY IN RAT STRIATUM AND HIPPOCAMPUS. B. Arvin*, L.F. Neville* and P.J. Roberts Dept. of Physiology and Pharmacology, University of Southampton, Southampton, U.K.

Kainate when administered intracerebrally or systemically in rats, produces well documented axon-sparing lesions, by a mechanism at least partially dependent on the presence of glutamate.

In this study, we have examined the effects of a number of adenosine analogues in relation to the possibility of modifying kainate-induced striatal or hippocampal damage. Co-injection of 2-chloroadenosine (3-25 nmol) with kainate (2.2 nmol intracerebrally) resulted in a dose-dependent protection in both rat striatum and hippocampus. The selective A1 agonist, CPA (1-5 mg/kg i.p.) prevented loss of hippocampal CA1 neurons following systemic kainate (8-12 mg/ kg i.p.). In contrast, the A1 antagonist CPT (5 mg/kg) enhanced kainate toxicity in the hippocampus.

These findings may lead to a better understanding of the mechanisms underlying excitotoxin cell loss and also suggests a potential anti-excitotoxic strategy directed at pre- rather than postsynaptic targets.

299.9

ROLE OF CALPAIN ACTIVATION IN THE MECHANISM OF EXCITATORY AMINO ACID NEUROTOXICITY. R. Siman, J.C. Noszek*, and C. Kegerise*, Neuroscience Group, The DuPont Company, Wilmington, DE. 19898.

Sustained stimulation of receptors for excitatory amino acids (EAAs) leads to the death of receptive neurons, and to activation of the calcium-dependent protease calpain I (Siman and Noszek, *Neuron*, in press). Here, we have investigated the relationship between the protease activation and neurotoxicity. Calpain activation was detected and quantified on immunoblots as increases in the levels of major proteolytic fragments of the calpain substrate spectrin. Intraventricular administration of NMDA (80 ug) or kainate (0.2-1 ug) produces hippocampal damage and calpain I-induced spectrin degradation. The NMDA antagonist CPP (2 ug) selectively blocks both NMDA-induced neurotoxicity and calpain activation. Only those doses of EAAs sufficient to cause neuronal damage also markedly activate calpain I. The calpain activation occurs over the course of the first day, temporally coincident with the onset of hippocampal neurodegeneration monitored by silver impregnation histochemistry. Colchicine lesions of hippocampus are not accompanied by calpain activation, indicating that protease stimulation does not occur simply as a secondary response to neuronal destruction. These results indicate that calpain activation can serve as an intracellular mediator of EAA action, and further support the hypothesis that calcium influx and calpain I activation are obligatory events in the initiation of EAA neurotoxicity.

MK-801 PRETREATMENT ENHANCES NMDA MEDIATED BRAIN INJURY AND ALTERS NMDA RECEPTOR AND PCP RECEPTOR BINDING CHARACTERISTICS IN PERINATAL RATS. M.V. Johnston, F.S. Silverstein and J.W. McDonald. MSTP and Neuroscience Programs and Departments of Pediatrics and Neurology, University of Michigan, Ann Arbor, MI. 48104.

MK-801, a non-competitive NMDA receptor antagonist, effectively reduces NMDA mediated brain injury in 7 day old rats when administered (i.p., 1 mg/kg) after an intrastriatal injection (25 nmol NMDA/0.5 ul; McDonald et al., 1988). NMDA mediated brain injury is markedly enhanced in 7 day old rats (*Brain Res.*, In press) which allows quantitation of injury by comparison of hemisphere weight disparities in pups that received unilateral injections. In this model, MK-801 (1 mg/kg, i.p.) antagonized NMDA mediated injury when administered 2, 6, and 12 hours before intrastriatal injection of NMDA. However, when MK-801 was given 24 hours prior to the NMDA injection, NMDA mediated injury was enhanced relative to NMDA injected controls as assessed by hemisphere weight disparities [% Damage (injected vs contralateral hemisphere) in controls (n=11) was 31.8±0.9 vs MK-801 pre-treated (n=6) 39.4±3.7, $p<0.05$ independent t-test].

To examine the mechanisms for this effect, in vitro quantitative autoradiography was carried out in 7 day old rats treated with MK-801 (1 mg/kg, i.p.) 24 hours before sacrifice. NMDA sensitive [3H]glutamate binding was enhanced relative to saline treated controls (130-140% of control) while [3H]TCP binding to the PCP receptor was reduced (60-80% of control): NMDA binding in CA_3 region of hippocampus (fmol/mg protein, mean±SEM), MK-801 treated (n=3) 1,092.9±81.0 vs control (n=3) 894.3±95.2, $p<0.01$; TCP binding in CA_3, MK-801 treated (n=3) 71.8±6.6 vs control (n=3) 114.9±6.3, $p<0.01$. The data suggest that pretreatment with non-competitive NMDA antagonists in vivo increases the ratio between NMDA receptors and PCP receptors on NMDA channels. This change may be associated with enhanced sensitivity to NMDA toxicity.

299.11

GANGLIOSIDES AND NMDA-SENSITIVE GLUTAMATE RECEPTOR ANTAGONISTS PREVENT GLUTAMATE NEUROTOXICITY VIA DIFFERENT MECHANISMS. H. Manev*, M. Favaron*, H. Alho, M. Bertolino*, A. Guidotti and E. Costa. FGIN, Georgetown Univ., Medical School, Washington, D.C. 20007.

In primary culture of rat cerebellar and cortical neurons excitatory amino acids regulate translocation of protein kinase C (PKC) and induce neuronal cell death. PKC translocation was assessed within 15 min by measuring ^{3}H-phorbol ester binding, while neuronal viability was measured 24 h later by staining with fluorescein diacetate/propidium iodide. The two noncompetitive allosteric antagonists of NMDA sensitive glutamate receptors (phencyclidine and MK-801) counteracted more effectively neuronal death and PKC translocation induced by glutamate than those induced by kainate. Pretreatment with gangliosides (GT1b, GD1b and GM1, 50 μM or lower) for two h followed by washing similarly prevented the action of the two excitatory amino acid agonists. Asialo ganglioside was inactive. In contrast to PCP and MK-801, the doses of gangliosides that counteracted glutamate-and kainate-induced neuronal death failed to change the agonist stimulation of ionotropic and metabolotropic responses. Probably, gangliosides protect from neuronal death by limiting the translocation of PKC and of other Ca^{2+} regulated enzymes. This action is unrelated to a modification of excitatory amino acid receptor mediated responses.

299.12

CORRELATION BETWEEN GANGLIOSIDE CONTENT AND PROTECTION OF GLUTAMATE-INDUCED NEUROTOXICITY IN CEREBELLAR NEURONAL CULTURE TREATED WITH GT_{1b}.
B. Ferret*, H. Manev*, A. Guidotti and E. Costa., (SPON: F. Vaccarino) FGIN, Georgetown Univ., Washington, D.C. 20007.

Cerebellar granule cells (8 days in vitro) have the following relative abundance of ganglioside: 0.24 GM3; 0.05 GM2; 0.22 GM1; 0.57 GD3; 1.8 GD1a; 0.39 GX; 0.84 GD1b; 0.93 GT1b O-Acetyl; 2.9 GT1b; 0.37 GQ- (μg neuraminic acid/mg protein). GX is a ganglioside tentatively identified as lactone of GT1b. In primary culture of rat neuronal cells, 2 hrs pretreatment with 10-50 μM GT1b, or GD1b or GM1 prevents the glutamate-induced neurotoxicity. Incubation of cells with GT1b (10-50 μM) for 2 hours induces a dose-dependent increase in cell content of GT1b (up to 5 fold) and a slight increase in GD1a and GM1. The increased GT1b content and the protection against glutamate-induced neurotoxicity appear to be related. The protective effect of gangliosides (10-50μM) lasts for 24-48 hours after their removal from the medium. Following incorporation of GT1b in the cell membranes, GT1b content declines at a rate of about 6% per hour. We conclude that the long lasting protective effect of gangliosides on glutamate-induced neurotoxicity is related to the presence of an increase in the sphingoglycolipid membrane content.

PROCESS OUTGROWTH, GROWTH CONES, AND GUIDANCE MECHANISMS V

300.1

VARIOUS THY-1 ANTIBODIES DIFFERENTIALLY ENHANCE OUTGROWTH BY RODENT RETINAL GANGLION CELLS. Stuart A. Lipton, Leonard A. Levin* and Colin J. Barnstable. Dept. of Neurol., Harvard Med. Sch., Boston, MA; Lab. of Neurobio., Rockefeller Univ., NYC 10021.

When immobilized, the Thy-1 monoclonal antibodies (MAbs) 2G12 and OX7 have been shown to promote the outgrowth of postnatal rat retinal ganglion cells in culture [Leifer, Lipton, Barnstable & Masland, *Science* 1984;224:303]. OX7 reacts with the allelic site at amino acid #89 while 2G12, although binding elsewhere, can compete for this site. In the present study we tested various Thy-1 MAbs that react with mouse including three developed by Tim Springer [*PNAS* 1981;78:4535]. We found that these MAbs bind differentially to various Thy-1 positive tissues, for example, to spleen and neurons but not thymocytes from the same animal. This finding suggests the possibility of binding to carbohydrate moieties, which vary among tissues, rather than solely to the amino acid residues, which are invariant. In contrast, other Thy-1 MAbs bind to all three tissues. Interestingly, despite approximately equal concentration and equal affinity for substrate, the MAbs with disparate binding patterns differentially affect process outgrowth by retinal ganglion cells. These findings confer an element of selectivity to the effect of Thy-1 MAbs. Explanations may include a conformational change or active site on Thy-1 that is affected by specific Thy-1 MAbs.

MONOCLONAL ANTIBODIES TO G4, A NEURAL CELL SURFACE GLYCOPROTEIN, INTERFERE WITH NEURITE EXTENSION ON AN AXONAL SUBSTRATE AND ON A G4 SUBSTRATE. S. Chang, F.G. Rathjen*, and J.A. Raper. Max-Planck-Institut für Entwicklungsbiologie, Spemannstr. 35, D-7400 Tübingen, FRG.

Embryonic neurons have been observed to elongate upon the surfaces of other axons in vivo. Thus axons are a natural substrate for neurite outgrowth, and could be an important source of information for growth cone pathfinding. In order to identify the molecules which promote neurite extension on axons, we have developed an assay which measures chick sympathetic neurite extension on chick sympathetic axons.

Polyclonal antibodies to G4, a recently identified cell surface glycoprotein, interfere with neurite extension in this assay. We have now tested eight monoclonal antibodies and all were effective in reducing the lengths of neurites growing on axons. The monoclonal antibodies reduced the average neurite length to about 60-70% of control values, which is the same result obtained with polyclonal antibodies to G4.

In addition, purified G4 is a potent promoter of neurite outgrowth from both central and peripheral neurons. This finding is in agreement with the recent report that 8D9, another glycoprotein related to L1, promotes neurite outgrowth as well (Lagenauer & Lemmon, Proc. Natl. Acad. Sci. USA 84:7753, 1987). Monoclonal antibodies to G4, when incubated on substratum bound G4 and washed off, can inhibit completely the neurite promoting activity of G4.

Our results identify G4 as one of the molecules on axonal surfaces which promote neurite outgrowth.

THE 8D9 ANTIGEN, A MEMBER OF THE NILE/L1/NgCAM CLASS OF CELL ADHESION MOLECULES, IS INVOLVED IN AXON OUTGROWTH ON GLIA. J. Drazba* and V. Lemmon (SPON: M. Ontell). Dept. of Neurobiology, Anatomy and Cell Science and Ctr. for Neuroscience, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

A novel assay for studying axon growth on glia has been developed. Confluent monolayers of chick retina Muller cells are prepared by culturing dissociated E13 retinae. Neurons are removed by treating the cultures with an anti-ganglioside MAb (8A2) and complement. Subsequently, strips of retina attached to nitrocellulose (after W. Halfter et al., Dev. Biol., 95:56, 1983) are placed on the Muller cells. Axons from the retinal ganglion cells grow out perpendicularly from the strips. The rate of outgrowth is rapid, up to 2 mm/24 hours, but varies depending on the substrate (matrigel>laminin>glia> collagen>polylysine). MAb JG22, which inhibits integrin function, did not inhibit axon outgrowth on glia; neither did polyclonal Fab' fragments to NCAM. In contrast, Fab' fragments to the 8D9 antigen inhibited neurite outgrowth by about 50%. These results strongly suggest that the 8D9 antigen is one of the molecules that mediates axon growth along glia. (Supported by NIH EY05285 and MOD 1-979)

ANTIBODIES TO L1 INHIBIT RETINAL NEURITE GROWTH ON SCHWANN CELLS. D.K. Simon*, N. Kleitman, M. Schachner+, R.P. Bunge. Dept. Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110; +Dept. Neurobiol., Univ. Heidelberg, FRG.

Embryonic rat retinal explants extend long neurites on Schwann cell surfaces in vitro. We have explored this interaction using antibodies to the cell adhesion molecule L1. Anti-L1 blocked outgrowth on Schwann cell surfaces in a dose dependent manner which was specific to neurite growth on Schwann cells. Hemi-retinas from day 15-16 rat embryos were plated on Schwann cell monolayers cultured on ammoniated type I collagen (AC). AC alone did not support retinal neurite outgrowth. Affinity purified polyclonal antibodies to L1 (400 μg/ml) or Fab fragments (50-200 μg/ml) were present in the culture medium from the time explants were plated onto the monolayers. Outgrowth was quantified by measuring the area covered by neurites. The intact polyclonal anti-L1 inhibited neurite outgrowth by 95% relative to control cultures. Fab fragments blocked growth in a dose dependent manner: 24% at 50 μg/ml, 85% at 100 μg/ml, and 90% at 200 μg/ml. At the 50 μg/ml dose, neurites were defasciculated. Anti-L1 Fab fragments did not appear to affect outgrowth on an air-dried collagen substratum, suggesting that L1 specifically affected the neurite-Schwann cell interaction. Other antibodies to Schwann cell or neurite surfaces tested (anti-laminin, anti-Thy-1, 217C) did not affect outgrowth in this system and anti-L1 appeared not to inhibit retinal outgrowth on astrocytes (Ard et al., this volume). Our results suggest that L1 is a mediator of retinal neurite outgrowth on Schwann cells and may prove important in supporting regeneration of these CNS neurons into a peripheral nerve environment. (Supported by NIH NS09923, NS08069.)

ISOLATED SCHWANN CELLS SUPPORT NEURITE REGENERATION FROM EXPLANTS OF ADULT RAT RETINA. J.M. Hopkins and R.P. Bunge. Dept. Anat., Washington U. Sch. Med., St. Louis, MO 63110.

The ability of sciatic nerve grafts to support regeneration of retinal ganglion cell axons in the adult rat raises the question of whether Schwann cells or extracellular matrix is primarily responsible for this phenomenon. We have used explants of adult rat retina, stimulated to regeneration by intraorbital axotomy, to explore this question in vitro. Primary cultures of isolated Schwann cells were prepared from embryonic day 15 rat dorsal root ganglion cultures which were denervated prior to addition of retinal explants (orphaned Schwann cells), or from postnatal day 1 rat sciatic nerves (sciatic Schwann cells). Ammoniated rat tail collagen served as a primary substratum for Schwann cells. Retinal explants were prepared from adult rats 7 days after crush of the optic nerve. Neurite growth from these explants was assessed by neurofilament immunofluorescence after 3 days in vitro. Air dried or ammoniated collagen alone did not support neurite growth. Explants seeded onto a bed of sciatic Schwann cells extended long neurites onto the cells but did not cross bare collagen between the cells. Orphaned Schwann cells supported growth of retinal neurites for distances up to 2 mm, in a pattern that closely paralleled the linear organization of the Schwann cells in these cultures. Since the Schwann cells prepared for these experiments do not produce basal lamina we concluded that the Schwann cell surface is a sufficient substrate for the growth of axons regenerating from adult rat retina. We are presently using this model to explore the molecular basis for the ability of Schwann cells to support regeneration of adult mammalian retinal axons. (NIH EY06073, NS09923.)

300.6

RETINAL NEURITE GROWTH ON ASTROCYTES AND OLIGODENDROCYTES IN CULTURE. M.D. Ard+, P. Wood, M. Schachner++, and R.P. Bunge. Dept. Anatomy, Washington Univ. Sch. Med., St. Louis, MO 63110; +M.D.A. currently at Dept. Anat., Univ. Mississippi Med. Ctr., Jackson, MS 39216; ++Dept. Neurobiol., Univ. Heidelberg, FRG.

In an effort to model conditions for CNS regeneration in vitro, we have cultured neonatal rat cortical astrocytes (method of McCarthy & de Vellis, 1980, J. Cell Biol. 85:890) as a substratum for neurite growth from embryonic day 15 rat retinal explants. Retinal neurites grew well (to an average length of 2 mm in 4 days) on the surfaces of astrocytes in various conditions, independent of the amount of extracellular matrix present in these experiments. By electron microscopy neurites were seen to grow in channels formed between layered astrocyte processes, often in contact with astrocyte surfaces. Antibody to the cell surface molecule L1 was added to cultures in preliminary experiments. Retinal neurite growth on astrocytes was not inhibited by anti-L1 at a concentration (100 μg/ml) which blocked retinal neurite growth on Schwann cell surfaces (Simon et al., this volume).

Recent reports (e.g., Caroni & Schwab, 1988, Neuron 1:85) have implicated mature oligodendrocytes in obstruction of axonal regeneration. To test whether oligodendrocytes could inhibit neurite growth on an otherwise permissive substratum, we added cultured oligodendrocytes derived from adult rat spinal cord and partially purified using fluorodeoxyuridine (Wood & Bunge, 1986, J. Neurol. Sci. 74:153) to our astrocyte preparations. After allowing one day for the mixed glial cells to attach, retinal explants were added. Neurite growth on oligodendrocytes plus astrocytes was not inhibited compared to neurite growth on astrocytes alone. (NIH NS09923; National Multiple Sclerosis Society.)

Identification of radial glial growth cones. JP.Misson*,P. Evrard*, JF. Gadisseux*,VS Caviness Jr.(Spon. M. Edwards)E.K. Shriver Center, Developmental neurobiology, Waltham MA 02254.

Radial glia are transiently present in the cerebral wall during neocortical histogenesis and are believed to serve as guides for neuronal migration. Radial glial cells have been demonstrated to be mitotically active and presumably are progenitors for new cells and radial fibers (Misson et al. Dev.Br.Res.1988,38, 183). The density of RGF appears to remain constant as the volume of the cerebral wall increases,implying that radial glial cells increase in number (Gadisseux et al. Neurosc. Abstr. 1987, 1117). The present analysis focuses on the shape transformation of the daughter cells, in particular on the manner in which newly formed radial processes are redeployed and incorporated into the transcerebral system of fascicles. RG are stained with RC2 (Misson et al. Neurosc. Abstr. 1987,1345) and for glycogen. Selectively stained growth cone at the outgrowing tips of newly formed RGF are found almost exclusively within the radial glial fascicles. The growth cones are of two forms: cylindric form or flattened form. The cylindric form,which is similar in shape to axonal growth cones within developing axonal fascicles are found within the glial fascicles. The flattened form which are similar to growth cones at the tips of terminal arborizations of axons are observed on RGF which are deflected singly from the glial fasicles suggesting a different mechanism of growth. These observations are consistent with the view that the radial glial cell population is dynamically increasing. At least some of the newly formed radial glial daughter cells are elaborating new growth-cone-tipped processes.The new processes become incorporated into the glial fiber system by fasciculation within the pre-existing fascicles. Their deployment behavior, and growth cone configuration are similar to those of axons. Supported by the Charles A King Trust and a NIH grant 12005.

RADIAL GLIA: A CELLULAR SOURCE FOR FIBRONECTIN DURING EARLY CORTICAL DEVELOPMENT A.L. Pearlman, J. Cohen* and W. Puckett*. Depts. of Cell Biology and Neurology, Washington Univ. School of Medicine, St. Louis, MO 63110

Fibronectin (FN) is transiently present in the developing cerebral cortex of the mouse (Stewart and Pearlman, 1987) and cat (Chun and Shatz, 1988) in a distribution that suggests an important role in cortical development. To determine the relationship between FN and the cellular elements of developing cortex, we double-labeled unfixed cryostat sections of murine cerebral cortex from embryonic day 11 (E11) through E13 with a polyclonal antibody to FN (provided by J. McDonald) and with the RC1 monoclonal antibody (provided by M. Yamamoto), which labels radial glia but not neurons. We found that FN is distributed along most of the length of the radial glia at early stages of cortical formation (E11-12). Slightly later (E12-13) the laminar distribution of FN (op. cit.) is reflected by discontinuous labeling along radial glial processes. To determine which cells of developing cortex produce FN, we cultured dissociated cortical cells from E13 embryos and 48 hours later treated them with monensin to block the export of FN. We found immunolabeling for FN within RC1+ cells with the morphology of radial glia, but not within RC1- neurons. Thus our evidence indicates that radial glia produce FN and distribute it along their processes in the zones involved in early axonal elongation and cortical plate formation. (Supported by NIH grant EY621).

300.9

A POSSIBLE ROLE OF GLIA IN THE DECUSSATION OF HINDBRAIN AUDITORY FIBERS IN THE DEVELOPING FERRET. J.K.Brunso-Bechtold and C.K.Henkel, Department of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103

At birth, the ferret lateral and medical superior olivary nuclei are extremely immature ultrastructurally as well as in their dendritic development. Somatic synapses which typify these nuclei in the adult are not common until 2 weeks of development and the mature dendritic morphology is not seen until the second postnatal month. The immature ferret hindbrain is also characterized by the presence of a midline glial structure which is similar to that described in the rat by Van Hartesveldt, et al. (1986). In the ferret, however, this structure reacts intensely with antibodies to GFAP as well as to S-100. It is comprised of large caliber, dense fibers and extends from the dorsal to the ventral surfaces of the hindbrain. The structure is evident at birth and is no longer present by the end of the first postnatal month. Despite the presence of what would seem to be a formidable barrier to growing axons, the midline trapezoid body is quite large at birth. In an effort to determine the manner in which developing axons might negotiate the midline glial barrier, we studied the midline in the developing ferret using immunocytochemical and electron microscopic techniques. Our results suggest that very fine caliber glial processes, some of which may be extensions of what had been radial glia, may be playing a role in guiding growing axons through the glial midline barrier present early in development. (Supported by NIH Grant NS23092-03.)

300.10

MECHANISM OF ACTION ON THE GROWTH CONE OF *APLYSIA* HEMOLYMPH IN PROMOTING NEURITE OUTGROWTH. D.J. Goldberg. Dept. of Pharmacology, Columbia U., New York, NY 10032.

Little is understood of how the binding to neurons of factors on the substratum promotes neurite outgrowth. I have used high-resolution video microscopy to examine how *Aplysia* hemolymph, which contains such a factor(s) (as yet unpurified), acts on the growth cone. Growth normally occurs by the extension of flat, organelle-free veils of membrane, followed by the engorgement of some of the veils with organelles and cytoplasm moving in from the central region of the growth cone and then the conversion of the engorged veils into cylindrical neurite. I find that a primary action of hemolymph is to promote the step of veil engorgement. In the absence of hemolymph, dihydrocytochalasin B, which weakens and depolymerizes networks of actin filaments, produces the same effect. This demonstrates that the actin filament network of the veil *resists* an intrinsic forward thrust of organelles and cytoplasm (presumably slow axonal transport). It may be that an important mode of action in promoting neurite growth for the factor(s) in hemolymph, and perhaps other substratum-bound factors, is weakening of the actin filament network of newly formed veils. Protein phosphorylation could be the route by which this is accomplished, in that stimulation of protein kinase A or C also causes veil engorgement, though inhibition of protein kinase C, at least, does not reduce the effect of hemolymph on the veil.

GLYCOPEPTIDES ON THE GROWTH CONE SURFACE: SPECIFIC INTERACTIONS WITH TARGET CELLS IN APLYSIA. R.T. Ambron, H. Den*, I. Protic*, C. Gabel*. Dept. Anatomy and Cell Biology, Columbia University, N.Y., NY 10032.

Neurons of *Aplysia* growing in vitro form specific chemical synapses on their follower cells, implying that macromolecules at the growth cones of these neurons recognize their target. To identify these constituents, we isolated growth cones from RUQ cells and identified several classes of glycopeptides, including one (GPwga) that is enriched and exposed on the surface. Studies now indicate that a GPwga is present at the growth cones of many neurons. To see if GPwga interacts with target cells, we isolated GPwga from the neurons of 180 abdominal ganglia. GPwga and ovalbumin glycopeptides (GPov), were each coupled to fluorescent beads and the beads were added in vitro to target cells known to be innervated by many neurons from the ganglion. We found that: 1) Beads containing GPwga, but not GPov, bound to muscle cells isolated from the circulatory system or the heart; 2) Binding depended on the glycopeptide since GPwga in the bath diminished binding of GPwga-beads; 3) GPrt, another class of glycopeptide at growth cones, did not bind to the cells. When added to neurons as targets, GPwga-beads bound to certain neurons; others not only failed to bind GPwga, but excluded the beads from the area around the cell. To see if the neurons release proteins, cells were exposed to ^{35}S-met for 24h. Autoradiography showed that each neuron is surrounded by labeled proteins bound to the substrate.

These results indicate that among the glycopeptides present at the growth cone, GPwga is involved in some aspect of neuron-target interaction and that this interaction may be modulated by material released from the neuron.

SELECTIVE SYNAPSE FORMATION IN VITRO BY NEURON L10 OF APLYSIA IS ASSOCIATED WITH SPECIFIC PATTERNS OF REGENERATION. D. Hawver* and S. Schacher (SPON: J.E. Goldman), Ctr. Neurobiol. & Behav., Columbia CPS & NYS Psych. Inst., New York, NY 10032

In cell culture, L10 forms specific connections with appropriate abdominal ganglion neurons. To explore the mechanisms underlying this specificity, we have combined phase contrast and fluorescent light microscopy to examine the pattern of neurite outgrowth by L10 after 4-5 days of co-culture with either target or non-target cells alone, or with both cell types simultaneously.

Action potentials in L10 evoke a dual-action (fast excitatory-slow inhibitory) response in RB cells. Injection of the fluoresscent dye 5(6)-carboxyfluorescein into L10 reveals many labeled processes extending along and in close apposition to the axons and processes of the RB cells (N=5). In contrast, when co-cultured with non-target right upper quadrant (RUQ) cells (N=3), the neurites of L10 generally form loops and only intersect the processes of the RUQ cells. These differences in the pattern of growth are also observed when L10 is co-cultured with both RB and RUQ cells (N=4). In addition, nearly all the neurites of L10 extend along RB cells when the processes of both the RB and the RUQ cells are in close proximity.

These results are consistent with the idea that synapse specificity may involve the activation of cellular mechanisms for both target selection and avoidance. We plan to examine the nature of the signals from the postsynaptic cells and how they influence neurite outgrowth from L10.

HUMAN BEHAVIORAL NEUROBIOLOGY II

SEX DIFFERENCES IN THE ANATOMY OF THE CORPUS CALLOSUM AND RELATION TO FUNCTIONAL ASYMMETRY AND COGNITION. S. F. Witelson. Department of Psychiatry, McMaster Univ., Hamilton, Canada. L8N 3Z5.

At least 15 studies have been reported in which gross anatomy of the human corpus callosum in midsagittal section was studied for possible sex differences. Almost all found that males either had or tended to have a larger callosal area and a larger splenium. Relative to brain size, females still did not have larger callosa. Only two studies reported opposite results: splenial breadth was larger in females in both, and splenial area tended to be greater in one. I now report a series of sex differences observed in callosal anatomy in a sample of 56 brain specimens when different subregions of the callosum and factors of hand preference and age were considered. In contrast to males, callosal size was not associated with hand preference in females. The genu was found to be significantly larger in males, but females had a larger relative posterior trunk region than males for consistent-right-handers. Callosal size decreased with age in men, but not in women. These results suggest that the biological rules governing hand preference and functional asymmetry may be different in the sexes; that the neurobiological basis of aging may be different in women than men, and that the sex difference in callosal proportional morphology may be related to the sex differences in brain lateralization and cognition. (Supported; Grant NS 18954)

301.2

SEX DIFFERENCES IN CORTICAL ACTIVATION PATTERNS DURING AN ORTHOGRAPHIC ANALYSIS TASK USING rCBF METHODOLOGY. C.E. Naylor and F.B. Wood*. Bowman Gray School of Medicine, Winston-Salem, NC 27103.

The present study examines rCBF findings on 52 normal readers, 30 females and 22 males, during an orthographic analysis task requiring subjects to identify words that were four letters in length. There were no sex differences in behavioral performance. The more accurate a subject's performance, the greater was the relative activation in Wernicke's area compared to activation in the left angular gyrus region.

A unique relationship between the probe over the left temporal region and several other probes (holding all other probes constant) was found, yet the pattern differed depending on sex. For females, significant unique partial correlations were found between the probe over the left temporal region and numerous intra- and interhemispheric sites. For males, there was a signifiaant positive correlation between Wernicke's area on the left and the homologous region in the right hemisphere.

These results suggest that Wernicke's area serves to "drive" a greater number of other cortical regions in females compared to males. In other words, there may be more language "driving" in females due to more extensive unique linkages both within and between the hemispheres.

301.3

NEURAL CORRELATES OF HUMAN ATTENTION TO TOUCH AND FLUTTER J.V. Pardo, P.T. Fox, and M.E. Raichle. Depts. of Psychiatry, Neurology and Neurological Surgery, and Radiation Sciences, Washington University School of Medicine, and the McDonnell Center for Studies of Higher Brain Function, St. Louis, Mo. 63110

The regional cerebral blood flow responses to touch and flutter were measured using PET in normal right handed subjects performing somatosensory tasks requiring attention. Three task conditions were compared to the control state (eyes closed, rest): count pauses in a volley (3-5 Hz) of suprathreshold touches applied using a von Frey hair to the pad of either the left (A; nine subjects) or the right great toe (B; 10 subjects), or monitor the right great toe for changes in flutter (35 Hz) amplitude (C; 14 subjects). In contrast to the predominantly Rolandic responses observed when potent vibrotactile stimuli (130 Hz, 2mm) are applied to subjects in a passive (no task) state, these tasks recruited a major response in the contralateral supramarginal gyrus (Brodmann 40). In fact, monitoring for changes in flutter did not activate Rolandic toe cortex. Response location was asymmetric; the left response was about 1 cm anterior to the right. Additional studies indicated that neither the somatosensory stimulus without attention, nor the attentional task without a stimulus, activated the supramarginal gyrus.

301.4

SYNTACTIC AND SEMANTIC CONTRIBUTIONS TO SENTENCE COMPREHENSION IN ALZHEIMER'S DISEASE (AD). J. Sherman*, J. Schweickert*, J. Growdon, S. Corkin. Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

A sentence-picture matching task was presented to 12 AD patients and 8 age-matched healthy control subjects (HCS). The subjects heard sentences that varied in syntactic complexity, semantic constraint, and plausibility, and were asked to choose which of two pictures matched each sentences' meaning. The incorrect picture violated either a lexical or syntactic property of the sentence. HCS performed almost perfectly on the task, whereas 10 of the 12 AD patients performed below the normal range. The 10 impaired patients were worse on sentences paired with pictures that violated syntactic properties rather than lexical properties. Further, syntactic complexity hindered their sentence interpretation irrespective of semantic constraint and plausibility. Sentence interpretation was also affected by semantic constraint and plausibility: For all sentence types, patients performed better on constrained than unconstrained sentences, and better on plausible than implausible sentences. The results indicate that AD patients attempted to apply independent syntactic and semantic analyses in their sentence interpretation, but were often unsuccessful at both. The findings suggest that syntactic and semantic processing are compromised in AD patients' sentence comprehension and contrast with the general characterization of the language function in AD as showing preserved syntactic knowledge.

301.5

ACTIVATION OF THE TEMPORAL POLES IN NORMAL AND PATHOLOGICAL FORMS OF HUMAN ANXIETY, EM Reiman, ME Raichle, E Robins, MJ Fusselman, PT Fox, MA Mintun, and JL Price Washington Univ. Schl. of Med., St. Louis, MO 63110

Positron emission tomographic (PET) measurements of regional blood flow were used to investigate the neuroanatomical correlates of anticipatory anxiety. Eight normal volunteers were studied with and without the anticipation of a painful electric shock. In anticipation of the shock, the subjects had significant increases in subjective and physiological measurements of anxiety; they also had significant increases in blood flow in the region of the right and left temporal poles.

In a separate study, PET was used to investigate the neuroanatomical correlates of experimentally induced anxiety attacks in patients with panic disorder. Patients with panic disorder and normal control subjects were studied before and during the infusion of sodium lactate. The production of lactate-induced panic was associated with blood flow increases in the same bilateral regions of temporopolar cortex; bilateral regions corresponding to the lateral putamen, claustrum or insular cortex; bilateral regions corresponding most closely to the superior colliculus; and a region corresponding most closely to the left side of the anterior cerebellar vermis. Lactate was not associated with significant blood flow changes in non-panicking patients or controls.

These studies demonstrate activation of the temporal poles in normal and pathological forms of human anxiety.

301.6

PET SCAN CHANGES IN CORTICAL (3-N-[11-C] METHYL) SPIPERONE BINDING FROM DEPRESSED TO NON-DEPRESSED STATES IN POST-STROKE DEPRESSION. R.M. Parikh,* R.G. Robinson, H.S. Mayberg, D.F. Wong,*, T.R. Price,*, E.P. Brousolle,* J.M. Links,* R.F. Dannals,* H.N. Wagner,* (SPON: A. Justice) Johns Hopkins Univ. Sch. Med. Baltimore, Md 21205.

In a previous PET study, we reported that spiperone (NMSP) binding in the temporal cortex of stroke patients with left hemisphere lesions was highly correlated with severity of depression (r=.92). This case study reports the effect of treatment of depression on NMSP binding in the temporal cortex in one patient. The patient, a 60 year old right-handed black female had sudden onset of right hemiparesis. CT and MRI scans demonstrated a lacunar infarct of the left caudate nucleus. At one week post stroke, she was found to have a major depression (Hamilton score 22) and after undergoing an NMSP PET scan, was started on a double-blind treatment study using nortriptyline and placebo. Her depression improved dramatically on placebo over the 6 week study (Hamilton score became 0). Her NMSP binding ratio in the ispsilateral to contralateral frontal and temporal cortex changed from .91 and .92 respectively before treatment to 1.20 and 1.17 respectively after treatment. This increased NMSP (primarily 5HT2 receptor binding) over the course of treatment could not be attributed to a drug effect and is to our knowledge, the first known case of a patient with post-stroke depression showing a commensurate change in in vivo chemistry.

301.7

CSF MONOAMINE METABOLITE MEASURES IN POST-STROKE DEPRESSION R.G. Robinson, R.M. Parikh,* R.A. Rodriguez,* G.M. Greene* and T.R. Price*. Johns Hopkins Univ. Sch. Med. and Univ. of Maryland Sch. Med. Baltimore, Md 21205.

Acute stroke patients (n=21) and non-stroke neurologic controls (n=9) were examined for cerebro-spinal fluid (CSF) concentrations of monoamine metabolites MHPG, 5-HIAA and HVA. The CSF collection was controlled for lumbar gradient, time of day, diet, exercise and time since stroke. Measurements of CSF MHPG, 5-HIAA and HVA were carried out using a high pressure liquid chromatography (HPLC) assay. CSF MHPG levels were significantly lower in patients with left compared with right hemisphere lesions (19.0 ng/ml± 7.3 vs 28.2 ng/ml±8.2, t=-2.5, df=17, p<.02) or control patients (27.0 ng/ml±5.8, t=-2.5, df=15, p<.05). There were no significant differences in MHPG between right lesion and control groups or among right, left and control groups in 5-HIAA or HVA levels.

Mean Hamilton Depression Scores were significantly higher in the left compared to control group (10.5±8.9 vs 2.4±5.9, t=-2.1, df=13, p<.05) and for the entire study group, CSF MHPG levels were inversely correlated to Hamilton scores (r=-.61, df=23, p<.01). These findings are consistent with our previous hypothesis that noradrenergic dysfunction may play a role in post-stroke depression.

301.8

MAPPING TWO VISUAL PATHWAYS IN MAN WITH REGIONAL CEREBRAL BLOOD FLOW (rCBF) AS MEASURED BY POSITRON EMISSION TOMOGRAPHY (PET) AND $H_2{}^{15}O$. J.V. Haxby*, C.L. Grady, B. Horwitz, M.B. Schapiro, R.E. Carson*, L.G. Ungerleider, M. Mishkin, P. Herscovitch, R.P. Friedland, S.I. Rapoport. Lab. of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

The presence and neuroanatomical location of separate visual pathways for processing spatial location and object identity were investigated by measuring rCBF with PET in 4 healthy young men during visual processing and sensorimotor control tasks. Visual processing was induced with two-choice, match-to-sample visual discrimination tasks. The object identity task involved face recognition. The spatial location task involved perceiving the location of a dot in a square with the sample and choice stimuli rotated relative to each other. PET rCBF measurements were obtained using bolus injections of $H_2{}^{15}O$ and the weighted integration method. Difference images contrasting each visual processing task to the sensorimotor control task were obtained and smoothed, the latter resulting in an in-plane resolution of 9 mm.

Each subject demonstrated a double dissociation between regions activated by the two visual tasks. Areas consistently activated during the spatial but not the face recognition task were in the superior parietal lobule, bilaterally. Areas consistently activated more by the face recognition than by the spatial vision task were in the region of the occipitotemporal junction, bilaterally, just inferior to the angular gyrus. These results demonstrate two distinct visual processing pathways at work in humans. These human neural systems are similar to visual pathways in nonhuman primates, though there seem to be cross-species differences in their anatomical location.

301.9

LATERALITY PATTERNS IN TWO COGNITIVE ACTIVATION TASKS USING THE rCBF METHODOLOGY. F.B. Wood* and C.E. Naylor (SPON: I.Brown). Bowman Gray School of Medicine, Winston-Salem, NC 27103.

Regional cerebral blood flow was measured during an orthographic analysis task and a recognition memory task. The subjects were 52 normal readers, 30 females and 22 males, with no history of physical or emotional illness.

The difference between the activation at homologous probes was calculated. These difference scores were then subjected to a principal components analysis. Two major factors emerged. The first involved a reciprocal pattern of activation between frontal and posterior regions. Greater activation in the frontal regions of one hemisphere was associated with a pattern of greater activation in posterior regions of the opposite hemisphere around the angular gyrus and a relative reduction of activation in the ipsilateral posterior region. A second factor involved a similar reciprocal relationship between central regions and more inferior temporal flow. Increased flow in central regions of one hemisphere was related to a relative increase in flow in the inferior temporal region of the opposite hemisphere.

The relative weighting of these two factors was found to vary depending on the task. The anterior-posterior factor was found to be the principal component in the memory task, while the second factor involving laterality patterns in central regions accounted for most of the variance in the orthographic analysis task.

301.10

SOURCE LOCALIZATION OF COMPONENTS OF THE VISUAL-EVOKED NEUROMAGNETIC RESPONSE. C. J. Aine, J. S. George*, M. T. Oakley, P. A. Medvick*, and E. R. Flynn. Neuromagnetism Laboratory, MS M882, Los Alamos National Laboratory, Los Alamos, NM 87545.

Neural sources were determined from neuromagnetic field distributions recorded in humans for each temporal component of an evoked response elicited in a visual attention task. The dipole-like current sources of the magnetic components were then located on anatomical images of the subjects' brains produced by Magnetic Resonance Imaging. The results demonstrated a strong correlation between magnetic waveform morphology and simultaneously recorded electrical responses. Computer modeling experiments were performed to aid in determining whether the time-series of field patterns reflected a single source with a location and orientation that changed with time or two independent sources. In another case, the field distribution was fit by a linear combination of two discrete dipole sources. The two dipoles were modeled by first fitting one dipole and then fitting a second dipole to the residual field distribution; the predicted field patterns were then summed and compared to the empirical field distribution. Some electrical/neuromagnetic "components" apparently reflect focal activation of discrete cortical loci; however, other "components" may reflect extremes of a spatial-temporal path of cortical activation. These results demonstrate the value of combining several complementary methodologies for mapping brain function onto structure.

301.11

"HORIZON OF SIMULTANEITY" FOR AUDITORY AND VISUAL STIMULI - AND HOW THE BRAIN MAY GET RID OF IT: E. Pöppel, K. Schill, N. von Steinbüchel. Dept. of Medical Psychology, Goethestr. 31, 8000 München 2, FRG

Reaction time (RT) to auditory stimuli is shorter than to visual stimuli (130 ms to auditory vs. 160 ms to visual stimuli under optimal conditions). This difference is mainly due to principally different transduction mechanisms in the two sensory systems. A transduction time of at least 30 ms even under high contrast conditions has to be assumed for the visual system, whereas in the auditory system it is well below 1 ms. This temporal difference implies that an object which is defined in visual and auditory space will be available centrally with a considerable temporal difference. We have studied whether the difference in transduction is compensated by the time that sound travels through space. Auditory stimuli were systematically removed from subjects and it was tested whether RT to these stimuli increased accordingly. This was the case and it was found that at approximately 10 m distance RT to visual and auditory stimuli was about equal. Thus, at 10 m we observe a "horizon of simultaneity" for these two sensory channels. These facts pose a particular problem for sensory integration: How is object identity possible if there is a temporal delay in central availability? One solution could be that one channel is disregarded altogether. We would like to suggest, however, that the brain solves this temporal problem by a mechanism that allows to disregard non-simultaneity within a certain range. This could be done by using neuronal oscillators that define system states. If these are relaxation oscillators that are entrained by either sensory system, the other system could be linked to defined system states. If a system state means that within one period of an oscillation no before-after relationship is defined, temporal differences within the two sensory systems would be disregarded. Experimental evidence for oscillatory processes and order threshold with 30-40 Hz support experimentally this hypothesis. Supported by DFG PO 121/13-1

301.12

TOPOGRAPHIC BRAIN MEASURES OF HUMAN PAIN AND PAIN RESPONSIVITY. A.C.N. Chen, S.F. Dworkin,* and J. Gehrig.* Lab. of Brain/Pain Research SC-63, Univ. of Washington, Seattle, WA 98195.

We have been analyzing ongoing EEG activities based on Fast-Fourier Transform under naturalistic pain states. In this research, we have a) quantified topographic brain activities by computer analysis of the ongoing EEG cortical spectrum in relation to a longer lasting, more diffuse type of tonic pain, the cold-pressor test (CPT); and b) assessed neurophysiological correlates of individual differences in pain responsivity which we have observed consistently.

EEG was recorded bilaterally at F3, F4, T3, T4, P3, P4, and O1, O2 with linked-ears reference for 42 normal healthy male subjects (mean=24.7years, s.d.=5.8). Psychological and physiological data were gathered in three experimental stages: Baseline, Noxious Stimulation (Pain), and Post Test. EEG sampling rate and filter setting were at 250 Hz and 0.5-70 Hz, respectively. Pain was assessed by endurance time to withdrawal from the 1±0.3°C icewater, and by subjective ratings of pain intensity and aversiveness.

A dichotomy of pain responsivity was observed: A pain-tolerant group (PT) tolerated the required 3 min of cold pressor, while the pain-sensitive group (PS) tolerated a mean of only 57 sec ($t=16.7$, $p<10^{-9}$). The PS (n=13) group reported significantly higher pain ratings than the PT (n=29) subjects. State anxiety was heightened equally for both PS and PT subjects under the CPT. For all subjects, pronounced topographic changes in specific band densities were demonstrated for both hemispheres during the CPT pain condition. Greater changes occurred in the delta band power density at all topographic loci. Neither theta nor alpha activities changed under CPT pain state, specifically. However, the higher frequency beta-1 and beta-2 power densities increased significantly under CPT pain, especially at the temporal loci. Comparing PS and PT groups, both showed no discernible differences at Baseline in EEG findings. During the CPT, PS exhibited clearly greater reactivity in the delta band than PT. In contrast, both groups exhibited an equal degree of heightened power density for the high frequency beta bands. These results indicate that even though both delta and beta band power densities increased under the pain state for PS and PT groups, differences in the delta band, only, distinguished between these two groups.

The topographic activation of delta activity in the anterior-posterior loci for both hemispheres may be interpreted as global activation of the protocritic sense/feelings of pain and discomfort. By contrast, the enhancement of beta activity may be interpreted as heightened vigilance related to scanning mechanisms that govern both perceptual and cognitive functions.

MESSENGER RNA REGULATION II

302.1

CHANGES OF TYROSINE HYDROXYLASE mRNA IN DOPAMINERGIC NEURONS OF RAT SUBSTANTIA NIGRA DURING RETROGRADE DEGENERATION. *T. Shirao, M.J. Evinger, L. Iacoviti and D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Tyrosine hydroxylase (TH) is the initial and rate-limiting enzyme necessary for catecholamine biosynthesis in dopaminergic neurons. In this study we analyzed changes of TH mRNA in dopaminergic neurons of rat substantia nigra (SN) during retrograde degeneration. Axons of the unilateral nigrostriatal pathway were transected by a small knife cut placed stereotaxically at the level of posterior lateral hypothalamus. At various times after placement of lesions, total RNA was extracted from SN tissue using the guanidine monothiocyanate-lithium chloride method. Total RNA content was determined spectrophotometrically. TH mRNA levels were quantitated by Northern blot and slot blot analyses using TH cRNA (380 ntd.) (T.H. Joh) as a probe. Bovine adrenal medulla RNA served as a standard. Some brains were processed for *in situ* hybridization analysis. On Northern blots a single mRNA band of 1900 bases was detected in both ipsilateral and contralateral SN during retrograde degeneration. In the ipsilateral SN, the TH mRNA level was not changed at postoperative days 2 and 3. However, by postoperative day 14, the TH mRNA level was reduced to less than 10% of unoperated control. No change in TH mRNA level was detected in the contralateral SN. Our previous immunohistochemical studies have demonstrated a cell loss of dopaminergic neurons maximal at 12 days following transection of the nigrostriatal tract with survival of only 30% of dopaminergic neurons in the SN pars compacta (Saji and Reis, 1985). In our studies TH activity in the ipsilateral SN was 40% of control at postoperative day 14. Therefore, TH activity in those surviving neurons appeared unchanged. *In situ* hybridization analyses with ^{35}S-labelled TH cRNA showed a reduced number of dopaminergic neurons in the ipsilateral SN at postoperative day 14. Furthermore, reduced grain density over those surviving neurons was observed in the ipsilateral SN compared with the contralateral SN. Therefore, we conclude that TH mRNA levels within the surviving dopaminergic neurons in the ipsilateral SN are decreased, although the levels of TH activity within those neurons remain similar to control.

302.2

NEURAL MODULATION OF PHENYLETHANOLAMINE N-METHYL-TRANSFERASE mRNA IN BOVINE CHROMAFFIN CELLS. *M.J. Evinger, P. Ernsberger, B.N. Reynolds*, D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Phenylethanolamine N-methyltransferase (PNMT), the enzyme catalyzing the synthesis of epinephrine from norepinephrine, is regulated in the adrenal medulla by hormonal and neural stimuli. Previously, we demonstrated a 5-8 fold increase in PNMT mRNA levels in response to depolarization by potassium (50 mM). In this study, we sought to resolve whether neurotransmitters which bind to defined adrenal medullary cell receptors are able to influence expression of the PNMT gene. Primary cultures of dispersed bovine chromaffin cells were established following collagenase digestion of adrenal medullary tissue. After 48 hr, cells were incubated 18-24 hr in fresh media containing agents known to influence PNMT enzymatic activity or catecholamine release from chromaffin cells. Total RNAs were prepared from harvested cells disrupted by treatment with 0.5% NP-40, then fractionated on denaturing agarose gels for Northern blot analyses by hybridization with PNMT (T.Joh) and 18 S rRNA (R. Guntaka) cDNAs. The cholinergic agonists nicotine (10 μM) and carbachol (200 μM) elicited increases in the steady state levels of PNMT mRNA relative to untreated control cultures. The stimulatory effect of carbachol could be partially blocked by incubation with the nicotinic antagonist hexamethonium (0.5 mM), thereby implicating nicotinic receptors in the response. Reversal of carbachol stimulation by the muscarinic antagonist atropine (1 μM) was considerably smaller in magnitude although radioligand binding assays using ^{3}H-quinuclidinyl benzylate reveal that both M1 and M2 receptor subtypes are present on chromaffin cells in moderate abundance (B_{max} = 58 ± 9 fmol/mg protein; or 7600 ± 1200 sites/cell) and exhibit very high affinity (K_d = 300 ± 73 pM). The ability of other neurotransmitters to regulate PNMT gene expresssion is suggested by the increase in PNMT mRNA using histamine at concentrations up to 10 μM. We therefore conclude that, in addition to hormonal regulation, the PNMT gene is responsive to neural stimuli and can be modulated by specific neurotransmitters.

302.3

SHORT- AND LONG-TERM EFFECTS OF ANGIOTENSIN ON CATECHOLAMINE SYNTHESIZING ENZYMES IN CULTURED BOVINE ADRENAL MEDULLARY CELLS (BAMC). M.K. Stachowiak, A. Poisner*, H.K. Jiang*, P. Hudson*, V. Owyang* and J.S. Hong. LMIN, NIEHS, Res. Triangle Pk., NC 27709.

Renin-angiotensin and adrenal medullary (AM) catecholamines are two major hormonal systems controlling circulation. The presence of renin in the adrenal cortex suggests paracrine functions of angiotensin in AM. In this report, we have examined effects of angiotensin on cultured AM cells. Exposure of BAMC for 10-30 min to 200 nM sar^{1}-angiotensin II (ANG) produced transient increase in the affinity of tyrosine hydroxylase (TH) to BH_4 cofactor. No change in the activity of PNMT was found at 30 min; however, 48 hrs exposure produced a 2-fold increase and also elevated total met-enkephalin content. 24 hrs incubation with ANG produced increases in TH, PNMT, and proenkephalin (pEK) mRNA levels (ED_{50} 1.2 nM), which were additive with the increases produced by forskolin or veratridine. Induction of mRNAs by ANG was inhibited by nifedipine, calmidazolium and TPA indicating involvement of calcium channels, calmodulin and protein kinase C. Thus, the adrenal medulla appears to be a locus of the interactions between the renin-angiotensin and sympathoadrenal systems. In addition to modulating secretion of catecholamines and enkephalins, angiotensin could be involved in the short-term regulation of TH activity and the expression of TH, PNMT and pEK genes.

302.4

DETECTION OF TRYPTOPHAN HYDROXYLASE mRNA IN RAT CNS. T.L. Green*, P.D. Walker, L. Ni*, G.M. Jonakait and R.P. Hart (SPON: H.H. Feder). Dept. of Biol. Sci., Rutgers University, Newark, NJ 07102.

We have devised an assay for tryptophan hydroxylase (TPH) mRNA that is quantitative and detects tissue-specific messages. This assay utilizes a radiolabeled 69 nt synthetic TPH oligonucleotide primer hybridized with mRNA in a reverse transcriptase-catalyzed extension reaction. The size of the cDNA product, measured by gel electrophoresis, indicates the distance between the priming site and the 5' end of the mRNA. The amount of cDNA product is linear with respect to RNA added to the reaction.

The primer extension assay reveals two species of TPH mRNA in pineal and one in the CNS. The larger, pineal-specific species yields a cDNA size (738 nt) by primer extension that would be predicted from the sequence of the rabbit pineal cDNA that has been cloned[1]. A smaller TPH mRNA (producing a 550 nt extended cDNA) was found in pineal and in midbrain and medullary raphe nuclei, but not in the cerebellum or the superior cervical ganglia (SCG). The absence of signal in a catecholaminergic region (SCG) argues against detection of the highly homologous tyrosine hydroxylase mRNA. In order to demonstrate this specificity further, rat serotonergic neurons were lesioned at birth with 5,7-dihydroxytryptamine following protection of catecholaminergic neurons with desmethylimipramine. Lesioned adult rats had depleted TPH mRNA in brainstem nuclei, but little mRNA depletion in the pineal. (Supported by NS 23687. GMJ and RPH are Johnson & Johnson Discovery Research Fellows.)

302.5

REGULATION OF TRYPTOPHAN HYDROXYLASE mRNA IN RAT CNS FOLLOWING pCPA ADMINISTRATION. R.P. Hart, T.L. Green*, P.D. Walker, L. Ni*, S. Schotland*, and G.M. Jonakait. Dept. of Biol. Sci., Rutgers University, Newark, NJ 07102.

Inhibition of tryptophan hydroxylase (TPH), the rate-limiting enzyme in 5-HT biosynthesis, occurs following administration of *p*-chlorophenylalanine (*p*CPA). In order to determine effects of enzyme inhibition on subsequent biosynthesis of TPH, we assayed TPH mRNA levels following chronic *p*CPA administration.

Adult rats were injected with 300 mg/kg s.c. *p*CPA prior to implantation of Alzet minipumps containing sufficient *p*CPA to deliver 100 mg/kg/day for 14 days. At various times after implantation, dorsal raphe nuclei were assayed for TPH enzyme activity. TPH mRNA from medullary raphe was assayed using a radiolabeled 69 nt synthetic TPH oligonucleotide primer that hybridized with total RNA in a reverse transcriptase-catalyzed primer extension reaction[1].

During the first week of *p*CPA infusion, TPH enzyme activity was 77% inhibited. By contrast, TPH mRNA levels increased relative to control rats receiving sham surgery. TPH activity remained inhibited to the same extent 2 and 3 weeks after implantation. TPH mRNA levels, however, approached control levels at 2 weeks and dropped below control at 3 weeks.

These results are consistent with an end-product regulation of TPH biosynthesis via control of specific mRNA levels. (Supported by NS 23687. GMJ and RPH are Johnson & Johnson Discovery Research Fellows.)

Transneuronal alterations of nigral GAD mRNA containing neurons following long term striatal lesions. G.M. Pasinetti, D.G. Morgan, S.A. Johnson, M.M. Meyers* and C.E. Finch, Gerontology Ctr. and Dept of Biological Sciences USC, Los Angeles, CA 90089

Neostriatal injection of ibotenic acid (IBO) elicits transneuronal degeneration of neurons in s. nigra (SN) reticulata (Saji and Reis, Science 1987). We extended these findings in adult Fisher 344 male rats, unilaterally injected (4 µg IBO in 1 µl) in three different striatal sites. GAD mRNA containing neurons (GABAergic neurons) were identified by in situ hybridization; tyrosine hydroxylase (TH) immunopositive neurons (dopaminergic neurons) were identified using a primary antibody to TH (Eugene Tech). In situ hybridization and immunocytochemistry were performed on 10 µm paraffin sections, GAD (Sal I/Eco RI, 1.3 Kb) cDNA fragment (A.Tobin), was recloned into Bluscribe M13 vector to produce single strand cRNAs. Three months after striatal IBO lesions there was a 50% loss of GABAergic neurons throughout the rostral-caudal extent of the striatum. The striatal cross-sectional area on the lesioned side was a 30% less than the contralateral side. SN reticulata cross-sectional area, ipsilateral to the IBO lesions showed 30% reduction. None of these alterations were evident in the vehicle injected group. The SN pars compacta dopaminergic neurons on the lesioned side showed small apparent cell loss (10-15%), compared to the contralateral side; similar neuron loss was observed in the vehicle injected group. GABAergic neurons in SN reticulata ipsilateral to the lesioned side showed a 40% loss in the central and ventromedial portions, with no apparent loss in the dorsolateral portion. GABAergic neurons were unchanged in the vehicle injected group. Experiments are in progress to determine the long term effect of striatal excitatory lesions on TH mRNA prevalence in the remaining SN dopaminergic neurons. (Supported by John D. and Katherine T. CARBOXYPEPTIDASE E EXPRESSION IN RAT BRAIN, STUDIED WITH IN SITU HYBRIDIZATION. C.A. Ross, L. Fricker and S.H. Snyder (SPON: G. Pearlson). Johns Hopkins University School of Medicine, Department of Neurosci., Baltimore, MD 21205.

Carboxypeptidase E (CPE, also called enkephalin convertase) is believed to participate in the processing of enkephalins, as well as possibly other neuropeptides. In order to map its expression in brain, we synthesized and labelled three antisense and two sense orientation 45 base oligodeoxynucleotides, and performed in situ hybridization. All three antisense probes yielded similar patterns of label, while sense strand probe labelling was negligible. Antisense labelling was highest in amygdala, paraventricular hypothalamus, cerebral cortex, and nucleus of the tractus solitarius--areas known to contain enkephalins. Label was also dense in hippocampus and cerebellar granule cell layer--areas not known to contain enkephalins. Label was present at lower levels in many other areas of brain. We conclude that CPE is expressed in widespread regions of the brain, and is probably involved in processing of a number of neuropeptides.

302.8

MULTIPLE PATHWAYS MEDIATE c-fos INDUCTION BY NGF IN PC12. R. C. Armstrong* and S. Halegoua* (SPON: A. Carlson). Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook N.Y. 11794

In PC12 cells, NGF stimulates transcription of the proto-oncogene c-fos. We have investigated the molecular mechanisms underlying this transcriptional activation. In PC12 cells c-fos mRNA is induced by cAMP activated A-kinase, phorbol ester (PDBU) activated C-kinase, or increased intracellular Ca^{++}. Since each of these pathways is thought to mediate NGF action, we questioned whether any of these pathways mediate c-fos induction by NGF. A reinduction strategy was employed that takes advantage of the transient nature of c-fos induction. After c-fos is induced by PDBU, it cannot be reinduced by either PdBu or Ca^{++} for at least four hours after the primary event. However reinduction can occur by dbcAMP or NGF (~50% of non-preinduced level) after a primary induction by PDBU. Similarly, if c-fos is first induced by Ca^{++}, reinduction by Ca^{++} or PDBU is blocked, however, dbcAMP and NGF can reinduce c-fos (~50% of non-preinduced level). With both dbcAMP and NGF, an initial induction of c-fos blocks reinduction by the same agent. In contrast, when cells are pretreated with dbcAMP, a rechallenge with PDBU or NGF results in a level of c-fos mRNA which is similar to that observed in non-pretreated cells. In an A-kinase deficient PC12 mutant, c-fos can be initially induced by PDBU or Ca^{++} and then reinduced by NGF (~50% of non-preinduced level). These data suggest a complex regulation of c-fos induction by NGF using both novel and established pathways.

MORPHINE INCREASES c-fos mRNA IN RAT CAUDATE-PUTAMEN. S.L. Chang* and R.E. Harlan (SPON: C. Dempsey). Dept. of Anatomy, Tulane University Medical Center, New Orleans, LA 70112; S.P. Squinto*, Dept. of Biochemistry and Molecular Biology, Louisiana State University Medical Center, New Orleans, LA 70119.

The c-fos is the cellular homologue of the oncogene v-fos carried by FBJ and FBR murine osteosarcoma viruses (J. Virol., '82, 114). The role of c-fos is postulated to be responsible for transduction of signal from cell surface to nucleus. Our preliminary results suggest that c-fos mRNA in rat caudate-putamen in vivo was increased by morphine administration to maximum at 36 min. and dropped back to control level at 49 min. A further confirmative study was then performed. A significant induction of c-fos mRNA (60%, $p < 0.05$) was observed by slot-blotting analysis after acute morphine treatment (10 mg/kg, 30 min). This effect was blocked completely by naloxone, the opiate antagonist, (10 mg/kg) simultaneously injected along with morphine. Naloxone alone did not have a significant effect on c-fos mRNA levels. Both morphine and naloxone are assumed to have high affinity for the μ-type opioid receptor. The caudate-putamen has been shown to have patches of μ-type receptor. We now are studying the cellular localization of the morphine inducible c-fos protein in the rat brain.

ESTROGENS MODULATE C-FOS AND PARVALBUMIN GENE EXPRESSION IN THE RAT CNS. E. Cattaneo*, M. Berchtold* and A. Maggi. M.P.L., Inst. of Pharmacol. Sciences U. of Milan I-20131 Milan Inst. Pharmacol. Biochem. U. of Zurich-Irchel CH-8057, Zurich.

A computer analysis of the rodent c-fos proto-oncogene indicates at 175 bps upstream from the TATA box the presence of the sequence GGTCCTAGGAGACC highly homologous to the reported "ERE" consensus sequence (GGTCAXXXTGACC). The measure of c-fos mRNA accumulation in the rat uterus and midbrain after estrogen (E) administration (75 µg/rats s.c.) at different times indicates an increase of c-fos mRNA within 24 hours. Since it has been reported that GABAergic neurons are a target for estrogens in the brain and that parvalbumin is a Ca^{++} binding protein tipically associated with these neurons, the time course of parvalbumin mRNA accumulation after E administration was observed. Preliminary results indicate a different profile of parvalbumin and c-fos induction. On the bases of the data obtained it is hypothesized that parvalbumin mRNA accumulation is secondary to c-fos induction. Therefore, parvalbumin could be involved in a feed back regulative mechanism preventing Ca^{++}-dependent c-fos stimulation.

302.11

EXPRESSION OF BRAIN SPECIFIC SRC(+) ONCOGENE IN RAT BRAIN, STUDIED WITH IN SITU HYBRIDIZATION. C.A. Ross, R.C.A. Pearson, G. Wright and S.H. Snyder. Johns Hopkins University School of Medicine, Department of Neurosci., Baltimore, MD 21205.

Brain Src proto-oncogene product (termed Src (+)) contains an 18 nucleotide insert not present in other tissues. In order to map its expression with in situ hybridization, we labeled antisense and sense 60 base oligonucleotide probes (to the 18 base insert plus 21 nucleotides on either side). Antisense labeling in brain could be blocked by pretreatment of sections with RNase, and could be predominantly blocked by coincubation with excess cold probe. By contrast, antisense labelling in peripheral tissues was fainter than in brain, and was little changed by coincubation with excess cold probe. Thus antisense labelling in brain appeared to be predominantly specific. Sense strand labelling was very faint. Antisense labelling in CNS was high at E 15, but still present at E 19 and in adult. In adult brain, antisense label was most dense in the cerebellar granule cell layer, hippocampal pyramidal layer and dentate gyrus, and olfactory bulb, with lower densities elsewhere. These studies suggest a general role for src(+) expression in nervous tissue, perhaps in maintainance of the neuronal differentiated state.

302.12

TEMPLATE SEQUENCE-DEPENDENT TERMINATION OF IN SITU TRANSCRIPTION. L.H. Tecott and J.H. Eberwine*. Nancy Pritzker Lab., Dept. of Psychiatry and Behavioral Sciences, Stanford University, Stanford, California 94305.

We have described a novel method, in situ transcription (IST), involving the oligonucleotide-directed reverse transcription of specific mRNAs within fixed tissue sections (Tecott, L.H., et al., Science, in press). Gel electrophoresis of radiolabeled IST transcripts primed by a 36mer (P1) complementary to rat proopiomelanocortin (POMC) mRNA in fixed pituitary sections revealed a complex pattern of bands. To determine whether the bands resulted from priming at a single site along POMC mRNA or at multiple messages, P1-primed IST transcripts were compared with those primed by P2, an overlapping POMC oligonucleotide. The P2-primed bands were shifted, but in register with the P1-primed bands, consistent with the relative positions of these primers along POMC mRNA. This suggested that the oligonucleotides primed single sites on POMC mRNA and that the bands resulted from termination of reverse transcription at discrete sites along the message. Further analysis revealed a striking correspondence between IST banding patterns and template sequences. Transcription terminated predominately at guanine residues. The IST banding patterns of 90% homologous regions of rat and mouse POMC mRNA were clearly distinguishable, demonstrating the specificity provided by banding pattern analysis. Such "fingerprints" of template sequences may aid in distinguishing among members of gene families, viral subtypes and alternate splice species of mRNA.

302.13

DEVELOPMENTAL EXPRESSION OF THE NEURON-SPECIFIC MuBr8 mRNA AND PROTEIN. M.C. Wilson,[1] G A. Oyler,* J.W. Polli,* G.A. Higgins,[1] and M.L. Billingsley. Hershey Medical Center, Hershey PA 17033; and Scripps Clinic and Res. Foundation[1], La Jolla, CA 92037.

The developmental expression of the neuron-specific gene product MuBr8 in rodent brain was studied using Northern and Western blots, in situ hybridization and immunocytochemistry. In situ hybridization detected MuBr8 in entorhinal and neocortex, olfactory bulb, and cerebellum at embryonic day 15 (E15); in adults, MuBr8 was highest in hippocampus and neocortex. Immuno-reactivity to MuBr8 synthetic peptide antisera was detected from E6 to adult in rat brain synaptosomes and cytosol; immunoreactivity increased 10-fold during this period, with the greatest changes occurring between postnatal day 3 and 11. MuBr8 mRNA and protein were expressed at low levels in PC-12 rat pheochromocytoma and human SMS-KCNR neuroblastoma. The regulation and posttranslational modification of MuBr8 protein in response to differentiating agents is being examined in these cell lines. These results suggest that MuBr8 is regulated during development, and may be a marker of neuronal differentiation. Supported by grants from March of Dimes (GAO) and PHS (M.C.W. and M.L.B).

ION CHANNELS: MODULATION AND REGULATION IV

303.1

ELECTROPHYSIOLOGY OF FOUR CLONED MUSCARINIC RECEPTOR SUBTYPES EXPRESSED IN A9 L CELLS. S.V.P. Jones*, J.L. Barker, N.J. Buckley*, T.I. Bonner*, R. Collins* and M.R. Brann* (SPON: R. Nelson). Lab. Neurophysiology, Lab. Molecular Biology, NINCDS, Lab. Cell Biology, NIMH, Metabolic Diseases Branch, NIDDK, NIH, Bethesda MD 20892. The function of four cloned muscarinic receptor subtypes (m1-m4) were investigated in A9 L cells transfected with each of the different muscarinic receptor subtypes. Electrophysiological responses to cholinergic stimulation of each muscarinic receptor subtype were recorded using the tight-seal whole-cell recording technique. Cells transfected with m1 and m3 muscarinic receptors were hyperpolarized by acetylcholine (ACh), while m2- and m4- transfected cells did not respond to ACh concentrations of up to 1mM. ACh induced outward currents in m1- and m3-transfected cells voltage-clamped at -50mV, that were blocked by the muscarinic receptor antagonist, atropine (1μM), but not by the nicotinic receptor antagonist, tubocurarine (50μM). Reversal potentials of ACh-evoked currents in m1- and m3-transfected cells, changed about 50mV per 10-fold increase in K^+ concentration, indicating a Nernstian dependence on K^+. In K^+-free solutions, outward responses to ACh stimulation in m1- and m3-transfected cells could still be detected, showing the response was also contributed to by Cl^-. The Cl^--dependent conductance was consistently smaller than that recorded in K^+ containing solutions. Responses to ACh in m1- and m3-transfected cells were blocked by barium (1mM) and cobalt (5mM) applied extracellularly and by buffering the intracellular Ca^{2+} to low levels with 5mM BAPTA. Thus a role for intracellular Ca^{2+} may be indicated in the generation of the m1- and m3-evoked K^+ and Cl^- conductances. m3-transfected cells respond to ACh in a manner that is qualitatively similar to that seen in m1-transfected cells, whilst m2- and m4-transfected cells are not coupled to electrically detectable responses in A9 L cells.

303.2

MUSCARINIC RECEPTOR SUBTYPES MEDIATE SEPARATE COMPONENTS OF CHOLINERGIC RESPONSES IN HIPPOCAMPAL PYRAMIDAL CELLS. T.A. Pitler and B.E. Alger. Dept. of Physiol., Univ. of Maryland School of Medicine, Baltimore, MD 21201.

Using intracellular techniques in the rat hippocampal slice we examined several components of muscarinic receptor activation, including the rate of rise of the carbachol induced depolarization, the maintained depolarization, the increase in input resistance, and the ability of carbachol to inhibit the action of the G-protein associated neurotransmitter adenosine. Using the specific M_1 receptor antagonist pirenzepine (PRZ), and the M_2 receptor antagonists AF-DX 116 and gallamine, we attempted to determine if different aspects of carbachol's action were mediated by the separate muscarinic receptor subtypes.

The M_1 antagonist PRZ blocks the fast rate of rise of the carbachol induced depolarization and blocks the ability of carbachol to inhibit the adenosine response, but does not affect the maintained depolarization or the increase in input resistance. On the contrary, the M_2 receptor antagonists both reduced the maintained depolarization and increase in input resistance, while having little effect on the rate of rise of the muscarinic depolarization or the ability of carbachol to block the adenosine response. AF-DX 116 was more consistent and selective than gallamine. Experiments are underway to identify the intracellular second messenger systems related to activation of each of the receptor subtypes.

NON HYDROLYSABLE GTP-ANALOGUES MAY FAVOUR AGONIST CONFORMATION OF DIHYDROPYRIDINE BINDING SITES.

S.Bergamaschi*, M. Parenti, S. Govoni*+, P.Cominetti*, M.Trabucchi^, and L.Lucchi*
Inst. of Pharmacol., Univ. of Milano, ^Chair of Toxicology, II Univ. of Rome, +Dept. of Pharmacobiology, Univ. of Bari, Italy.

Recent studies hypothesize a direct coupling of G-proteins to ion channels including voltage-dependent calcium channels. The present work studies the effect of non-hydrolysable GTP-analogues on [3H]-PN 200-110 binding to rat cortex membranes. GTP- -S and GMP-PNP increased the amount of PN 200-110 displaceable by BAY K 8644 but not by nitrendipine.Using 0.3 nM ligand and 0.6 uM BAY K 8644 as competing drug the binding was 140±12 and 99.7±9 fmoles/mg protein, respectively in presence or absence of GMP-PNP. GTP exerted similar effects but at higher concentrations. Other nucleotides did not modify the binding significantly.Qualitatively different results were obtained when using [125 I]-omega-Conotoxin as ligand and the cold toxin as displacer. The effect of GTP-analogues on PN 200-110 binding, when an agonist dihydropyridine is used as displacer, is reminiscent of electrophysiological data indicating that activation of G-proteins may promote agonist responses to calcium channel ligands.

303.4

MUSCARINIC MODULATION OF Ca CURRENT IN A PARASYMPATHETIC NEURON.

A.Tse, R.B. Clark and W. Giles, Dept. of Physiology, Faculty of Medicine, University of Calgary, Calgary, Canada.

Bullfrog (Rana catesbeiana) intracardiac parasympathetic neurons were isolated with an enzymatic dispersion procedure (Tse et al, Soc. Neurosci. Abst. 13, 535). The Ca currents of these neurons were recorded with the whole cell variant of the gigaohm seal method. Voltage-clamp results suggested the presence of L-type and possibly N-type Ca currents. Since these neurons are known to receive cholinergic input from the vagus nerve, the effect of ACh on the total Ca current was investigated. ACh (0.2-5 μM) or carbachol (1-5 μM) caused a reversible, 30-50% decrease of the Ca current amplitude at depolarizations to about +10 mV, near the peak of the Ca current-voltage relation. Two lines of evidence suggested that this was a muscarinic effect: (1) dl-muscarine (0.5-2 μM) mimicked the ACh response. (2) atropine (10-50 uM) antagonized the ACh effect. Since the inclusion of the non-hydrolysable GTP analog, GTPγS (50-100 μM) in the pipette mimicked the ACh response, a GTP-binding protein is likely to be involved.

The action potential afterhyperpolarization (AHP) in these neurons was generated mainly via a Ca dependent K current. Muscarine (1-2 μM) reduced the AHP amplitude by 4.4 ± 1.6 mV (n=7). When 2-3 ms voltage clamp steps (from -60 to +10 mV) were used to simulate action potentials, muscarine reduced the magnitude of the Ca current and the Ca-dependent K tail current concomitantly. This suggested that the reduction of AHP by muscarine in these cells was at least partly a secondary effect of the muscarinic modulation of Ca current.

303.5

ACETYLCHOLINE ENHANCES CALCIUM CURRENT IN A SINGLE IDENTIFIED SNAIL NEURON.

H.M. Gerschenfeld* and D. Paupardin-Tritsch* (SPON: European Neuroscience Association). Lab. Neurobiol., Ecole Normale Supérieure, 75005 Paris, France.

In cell F1 of the right parietal ganglion of Helix aspersa bathed in a TTX/Ba-containing saline, acetylcholine or carbachol (CCh, 10 uM) induces an increase in inward current. This is an enhancement in Ca current because: 1) CCh does not affect any outward currents in F1 neurons bathed with Co-containing saline and 2) the response to CCh is not affected by intracellular Cs-loading which blocks the outward currents. This CCh effect shows marked desensitization. It is not altered either by D-tubocurarine or hexamethonium application (20 uM), but is blocked by atropine (5 uM). Extracellular application of either forskolin or zaprinast,a cGMP-dependent phosphodiesterase inhibitor, does not affect the Ca current in the F1 neuron. In contrast, intracellular injection of EGTA prior to CCh application blocks the CCh-induced increase in Ca current.

It is concluded that CCh enhances the Ca current of neuron F1 by activating a muscarinic-like receptor different from the three types of ACh receptor described in molluscan neurons (Kehoe, 1972). Moreover, this response is not mediated by cAMP or cGMP but cytosolic Ca appears to play a role in its intracellular mechanism.

303.6

APLYSIA NEURONS POSSESS A FAMILY OF G PROTEIN-LINKED NEUROTRANSMITTER RECEPTORS MEDIATING BOTH ACTIVATION OF 'S'-LIKE K CURRENT AND SUPPRESSION OF Ca CURRENT.

V. Březina* (SPON: P. O'Lague), Dept. of Biology, UCLA, Los Angeles, CA 90024.

Aplysia neurons exhibit three principal types of response to many transmitters: 'fast' Na and Cl currents, and a 'slow' K current. The K-current responses to acetylcholine, histamine and the neuropeptide FMRFamide are mutually non-additive; all represent activation of the same K current identical or similar to the 'S' current[1-5] The transmitters act at separate receptors (distinct from those responsible for the 'fast' responses), each of which also mediates suppression of the voltage-dependent Ca current[4-6]. These 'slow' (but not the 'fast') effects are mimicked by GTP-γ-S[3,6,8] and blocked by pertussis toxin[3,7], suggesting involvement of G protein(s). It has been suggested that these activate a phospholipase to generate metabolites of arachidonic acid which act as second messengers mediating the responses[9,10]. Synergistic activation of 'S'(-like) K current and suppression of Ca current by members of this family of receptors may underlie presynaptic inhibition in Aplysia[2,5].

303.7

G PROTEINS RECONSTITUTE INHIBITION OF Ca^{2+} CURRENTS BY BRADYKININ (BK) IN PERTUSSIS TOXIN-TREATED RAT DORSAL ROOT GANGLION (DRG) NEURONS

D. A. Ewald[1], R. J. Miller[1] and P. C. Sternweis[2]
[1]Dept. of Pharm. & Physiol. Sci., U. of Chicago, Chicago IL 60637
[2]Dept. of Pharm., U. of Texas Health Sci. Cntr., Dallas TX 75234

Using the whole-cell patch clamp technique on cultured rat DRG neurons, Ca^{2+} currents were evoked at 0 mV from -40 mV (sustained current) and from -80 mV (sustained plus transient currents). 100 nM BK inhibited both sustained and transient currents (% inhibition ± S.E.: 66.4 ± 7.6 and 66.6 ± 5.2, n=7). Pretreatment with pertussis toxin (PTX) blocked this inhibition (3.0 ± 6.9 and 0.6 ± 8.1, n=5). We tested the ability of the alpha subunits of three PTX-substrate G proteins isolated from brain to reconstitute the inhibitory effects of BK in PTX-treated cells by including 100 nM alpha subunit plus 1 mM GTP in the normal intracellular solution. Partial reconstitution of BK inhibition was achieved with all three. The alpha subunit of G_o (39 kD) was most effective (50.0 ± 3.4 and 48.0 ± 5.2, n=5) and that of G_i (41 kD) was least effective (36.8 ± 2.5 and 34.8 ± 6.7, n=4). The 40 kD alpha subunit of a G protein of unknown function was intermediate (39.8 ± 3.1 and 43.3 ± 2.5, n=7). This lack of specificity for a particular G protein was in contrast to our results with neuropeptide Y (NPY) in which reconstitution of Ca^{2+} current inhibition was selective for the alpha subunit of G_o. Unlike reconstitution of BK inhibition, the inhibition of Ca^{2+} currents by NPY was completely reconstituted (45.1 ± 5.1 and 54.4 ± 5.8, n=10) compared to that of untreated cells (51.1 ± 3.1 and 61.4 ± 5.7, n=8). We are investigating the dose dependence of reconstitution of BK inhibition to determine whether the relative lack of specificity and efficacy are due to less selective and lower affinity binding of the alpha subunits to the BK receptor or due to the presence of multiple G protein pathways in untreated cells.

303.8

AGONISTS THAT SUPPRESS M-CURRENT IN FROG SYMPATHETIC NEURONS INCREASE PHOSPHOINOSITIDE TURNOVER.

Mark D. Leibowitz, and Emily M. Subers*. Dept. Physiol. & Biophys., (SJ-40) and Dept. Pharmacol.*, (SJ-30), Univ. of Washington, Seattle, WA 98195.

Acetylcholine (ACh), substance P (SP), and teleost luteinizing hormone releasing hormone (t-LHRH), acting at distinct receptors all suppress the voltage dependent, non-inactivating potassium current I_M. Previous work has suggested that products of PI turnover may be involved in this suppression. Although ACh and numerous other neurotransmitters have been shown to increase PI turnover in mammalian neurons, this has not been shown in the frog. Using whole, desheathed frog (*Rana pipiens*) sympathetic chains preincubated in [^{3}H]myo-inositol we show that muscarine, SP, and t-LHRH all stimulate the formation of inositol phosphates, when compared to paired, untreated control chains.

TREATMENT	% OF CONTROL	N	
1 mM muscarine	181*	4	
+ 10 μM atropine	103	2	
10 μM t-LHRH	154*	8	
0.3 μM SP	126*	5	(* $p < 0.05$)

Neither increased intracellular calcium, nor phorbol ester-induced activation of protein kinase C, can fully mimic the agonist-mediated suppression of I_M (Pfaffinger, et al. Biophys. J. 53:637a). Thus, while activation of phospholipase C does not mediate suppression of I_M by agonists, it could play a role in modulating other currents (e.g. $I_{K(Ca)}$) or in other receptor mediated phenomena. Supported by NIH grants NS08174, HL30639, and training grant GM07270. M.D.L. is an FESN scholar in "Transduction of neuronal signals".

303.9

THE ROLE OF PROTEIN KINASE C IN DESENSITIZATION OF PEPTIDE RECEPTORS INVOLVED IN M-CURRENT SUPPRESSION. Martha Bosma* and Bertil Hille (SPON: M. Spencer). Dept. of Physiol. Biophys., Univ. of Wash., Seattle, WA 98195.

We have studied suppression of M-current (I_M) by peptide agonists and desensitization of peptide receptors in isolated internally dialyzed frog (Rana pipiens) sympathetic neurons using whole-cell voltage clamp. 1 uM substance P (SP) or chicken II LHRH (cII-LHRH) suppresses I_M, and in the continued presence of agonist, the receptors desensitize and I_M recovers within 1-3 min. After agonist washout, the receptors are refractory to a second application of the same peptide for at least 30 min. There is no cross-desensitization between the two peptides. 10 nM of either peptide suppresses I_M without receptor desensitization. 1 uM teleost LHRH suppresses I_M but desensitizes LHRH receptors only slightly in 3 min. It does not suppress I_M after a desensitization by cII-LHRH. Some of these agonist actions are altered by activators of protein kinase C (PKC). Addition of phorbol ester (1 uM PMA) causes a partial (60%) reduction of I_M by itself, after which the agonist actions of SP are occluded. However, cII-LHRH can still suppress I_M and desensitize its receptor. We investigated the role of PKC using two inhibitors. First we added to the pipette solution a peptide that acts as a pseudosubstrate of PKC and inhibits its phosphorylating activity (kindly provided by Dr. Bruce Kemp of Melbourne). Second, we used bath application of H7, which reversibly inhibits PKC. In experiments with either of these inhibitors, SP and cII-LHRH were still able both to suppress I_M and to desensitize their receptors fully. Apparently the inhibitors did block PKC since PMA reduced I_M less under these conditions and no longer diminished the response to SP. Hence, PKC is not an essential mediator either in agonist-induced suppression of I_M by these two agonists, or in desensitization of the receptors by the agonists. Supported by NS08174. MB is an MDA fellow.

G_o DIRECTLY ACTIVATES K^+ CHANNELS IN HIPPOCAMPAL NEURONS. A.M.J. VanDongen*, J. Codina*, L. Birnbaumer*, and A.M. Brown, Physiology and Molecular Biophysics, Cell Biology, Baylor College of Medicine, Houston, Texas 77030.

Guanine nucleotide binding (G) proteins couple numerous neurotransmitter-activated receptors to K^+ and Ca^{2+} channels in neurons. G_o is the major G protein in brain and its function is unknown although it can reconstitute opioid inhibition of Ca^{2+} channels (Nature 325:445, 1987). We tested whether G_o gates neuronal channels directly. G proteins purified from bovine brain (J. Biol. Chem. 261:8182, 1986) and preactivated with GTPγS were applied to inside-out patches of membrane excised from neonatal rat hippocampal neurons. The patch pipette contained (in mM): K or Na MES 130, $MgCl_2$ 1, EGTA 5, HEPES 10, and Tris to pH 7.4. KMES was used in the bath. G_o activated K^+ channels having a conductance of about 40 pS and, in some cases, the channels were inwardly rectifying. This activation began at picomolar concentrations and was concentration-dependent. AMPpnP at 100 μM had no effect, ruling out G_o-mediated phosphorylating mechanisms. Activation of these channels by G_o was specific because pre- or post-G_o, 2 G_o-poor fractions purified from bovine brain, either had no effect or were effective only at much higher concentrations. G_o also activated cation-conducting channels having a smaller conductance of 10-20 pS. We conclude that G_o directly activates a variety of neuronal K^+ channels and we propose that membrane channels are the main targets of G_o. (Supported by NIH-HL37044 to A.M. Brown and L. Birnbaumer)

SUBSTANCE P MODULATES POTASSIUM CHANNELS ON T-LYMPHOCYTES THROUGH A GTP-BINDING PROTEIN. M.A. Schumann* and P. Gardner. Department of Medicine, Stanford University School of Medicine, Stanford, CA 94305.

Substance P (SP) is implicated in the mediation of hypersensitivity reactions, but its molecular mechanism of action on T-lymphocytes has not been established. We have used a tight seal-whole cell patch-clamp recording to investigate the action of SP on Jurkat cell line with voltage-dependent K^+ channels. Perfusion of the bathing medium with SP (1 nM-10 μM) induced in 1-3 mins a dose-dependent depression (2.4±1.7%-44.7±6.7%, n=30) of the K^+ current peak amplitude elicited by depolarizing pulses. The relative magnitude of the effect was greater with 11 mM than 1.1 mM EGTA in the pipette. The latter revealed an apparent Ca^{2+}-dependent desensitization. In all cases, SP produced in 1-3 mins a nearly irreversible increase (70 ± 20.3%, n=10) in the rate at which the current inactivates. Substance P antagonist [D-Arg^1,D.phe^5,D-$Trp^{7,9}$,Leu^{11}]-SP at 50 μM blocked SP (10 nM) action by 50%. When the cells were dialysed for 5 mins with Guanosine-5-O (2.thiodiphosphate) (GDP-β-S) which competitively inhibits the binding of GTP to G protein, SP action was blocked in a dose-dependent fashion. 500 uM GDP-β-S produced a more than 3-fold reduction in SP (5 μM)-induced depression of current amplitude. Our findings provide a direct demonstration of the G-protein-mediated inhibition by SP of voltage-dependent potassium channels in T-cells. NIH Grant #R01 EY06478.

RAS CHANGES TTX SENSITIVITY OF VOLTAGE-DEPENDENT NA^+ CURRENT IN AtT-20 CELLS. R.E. Flamm, N.C. Birnberg*, and L.K. Kaczmarek. Depts. of Pharmacol. and Cell. Molec. Physiol., Yale Univ. Sch. Med., New Haven, CT 06510.

Transfection of the cHa-ras oncogene into the mouse anterior pituitary cell line, AtT-20, results in morphological and electrophysiological changes in cell phenotype. Transformed cells (ras-AtT-20) are larger and have more extensive neurite growth than untransformed (AtT-20) cells. AtT-20 cells fire spontaneously with prolonged (200-400 msec) action potentials, whereas only short-duration (10 msec), stimulus-evoked spikes are recorded in ras-AtT-20 cells. We report that ras-induced transformation generates changes in the tetrodotoxin (TTX) sensitivity of the voltage-dependent Na^+ current. TTX sensitivity in untransformed AtT-20 cells is biphasic. 10 nM TTX produces a 60% reduction in mean Na^+ current and no further reduction is observed until cells are exposed to 5 uM TTX. In contrast, in ras-AtT-20 cells (3 different clones) a 70-95% reduction in mean Na^+ current is observed with 100 nM TTX and Na^+ current is entirely abolished with 1 uM TTX. These results indicate that the introduction of activated ras causes the disappearance of TTX-insensitive Na^+ channels. Whether ras modifies the expression of different Na^+ channel species or alters post-translational modifications of the Na^+ channels in AtT-20 cells is currently under study.

NEURAL CONTROL OF IMMUNE SYSTEM II

304.1

DIFFERENT IMMUNE COMPETENCE AND "ANXIETY LEVEL" IN LATERALIZED MICE. **E. Fride, R.L. Collins & P. Arora (SPON:P. Skolnick). NIDDK/LN, NIH, Bethesda MD 20892 and Jackson Laboratory, Bar Harbor ME 04609.**

Previous studies have found a relationship between lateralization of the left and right cortex and both response to stress and modulation of immune function. Hence, the level of anxiety, cerebral asymmetry and regulation of the immune system may all be interrelated. Mice of the high (HI), low (LO) and heterogeneous (HET) lines were examined for both handedness and performance in a "plus-maze". Less time spent in the open as opposed to that in the closed arms was taken as an indication of a higher level of anxiety. Three weeks later, the animals were sacrificed and single cell suspensions from spleens prepared. The immune functions studied were: CTL response, MLR and mitogen-stimulated T and B lymphocyte proliferation. HI mice spent less time in the open arms of the plus-maze than did LO or HET mice ($p<0.01$). CTL response and MLR of the HI mice were lower ($p<0.03$) compared to both HET and LO lines. Further, the proliferative response to PHA was reduced in the LO mice. Low cell numbers in the spleens of HI and LO mice were found, whereas basal [^{3}H]thymidine uptake of these cells was much higher compared to HET mice. Although the degree of paw preference correlated positively with the level of "anxiety" in the plus-maze ($p<0.002$), it did not correlate with immune function. In summary, we found that strongly lateralized mice were more "anxious" and displayed lower immune competence than weakly lateralized mice.

304.2

MATERNAL SEPARATION ALTERS PERIPHERAL BLOOD LYMPHOCYTE CD4/CD8 RATIOS AND POKWEED MITOGEN (PWM) BUT NOT PHYTOHEMAGGLUTININ (PHA) RESPONSES IN JUVENILE BONNET MACAQUES. L. Bostom*, G. Sunderland*, H. G. Durkin*, M. R. Murali*, L. Rosenblum* and A.R. Gintzler (Spon. K. Fukada). SUNY Health Science Center at Brooklyn, N.Y. 11203, U.S.A.

The effects of maternal separation on juvenile Bonnet Macaque (female, 9-14 months) CD4/CD8 ratios and mitogen responses were determined (PHA,.125-1.0 ug/ml; PWM, 1:50-1:400)using immunofluorescence (FACS) and ^{3}H-thymidine uptake, respectively. Prior to the 14 day separation, 4-5 baseline values were obtained from each of six primates. Thereafter, the offspring continued to be housed together during the separation. Increased CD4/CD8 ratios were evident within 24h of separation and progressively increased reaching maximal values (2-3 fold) at day 10-14 of separation. Ratios returned to pre-separation values within 14 days after reunion. PHA responses during separation did not differ from control values. In contrast, PWM responses became substantially depressed (3-5 fold) 7-14 days into separation and did not return to pre-separation values through day 14 after reunion. These data suggest that maternal separation selectively affect certain aspects of immune competence in primates and support the use of these animals to investigate the psychosocial parameters of immune function and their neural and hormonal mediators.

304.3

THYROTROPIN RELEASING HORMONE (TRH) RECEPTORS IN THE IMMUNE SYSTEM. D.V. Harbour*, E.M. Smith*, and W.J. Meyer, III* (SPON: J. Calverley). Dept. of Psychiatry, Univ. of Texas Medical Branch, Galveston, TX 77550

We have identified TRH receptors on T cells of the immune system. Scatchard analysis of competetive binding studies show two specific binding sites: a unique high affinity binding site with approx. Kd 4 X 10-11 M and Bmax of approximately 35 fmol/mg membrane protein and a lower affinity binding site that is similar to the pituitary with approx. Kd of 2 x 10-8M and Bmax of approximately 4 fmol/mg membrane protein. The receptors are presumed to be bioactive since release of immunoreactive (ir)-Thyrotropin (TSH) occurs after treatment of the cells with TRH. We are currently conducting calcium uptake studies to determine the second messenger pathway of the receptors. Preliminary studies incubating the Molt4 cells with the thyroid hormone T3 show a 32-60% downregulation of the TRH receptor number. This cell line is a model to study regulation of the TRH receptor on the cells of the immune system. In addition, the finding of these receptors on normal peripheral blood mononuclear cells provides a mechanism of interaction between cells of the immune system and peripheral sources of TRH which may result in modulation of a local immune response.

304.4

CNS LOCALIZATION OF THE IMMUNOSUPPRESSIVE EFFECT OF OPIATES. R.J. Weber* A. Hagan, and A. Pert. (SPON: D. Lozovsky). LN, NIDDK, NIH, and BPB, NIMH, Bethesda, MD 20892.

Central administration of neuroactive substances such as morphine and CRH result in alterations of immune function, and have provided strong evidence for a role of the CNS in control of immunity. In order to determine the origin of the CNS effects of morphine on immune function, rats were implanted with bilateral cannulae guides aimed for various brain structures. One week following surgery the animals received bilateral injections of morphine (5 ug in 1 ul saline) in each structure. Three hours following administration of morphine the rats were sacrificed, spleens removed, and natural killer(NK) cell activity measured. Injection of morphine into the periaqueductal gray matter (PAG), but not other brain regions, produced a rapid and dramatic suppression of NK cell activity, when compared to saline injected animals, and this suppression was blocked by prior peripheral administration of naltrexone. Electrical stimulation of the PAG reveals similar effects on immune function. The activation of in the PAG may be relevant for understanding the ability of certain forms of stress to alter immune function through opiate- dependent mechanisms.

304.5

MURINE SPLENIC LYMPHOCYTES DEMONSTRATE CON-A-INDUCIBLE PROLACTIN-LIKE IMMUNOREACTIVITY AS DETERMINED BY IMMUNOCYTOCHEMISTRY (ICC). J.R. Kenner*, P.F. Smith*[1], E.W. Bernton*, D. Hartmann*[2] and J.W. Holaday, Dept. Med. Neurosci., WRAIR, Wash., DC 20307; [1]Dept. of Anatomy, USUHS, Bethesda, MD 20814 and [2]Dept. of Pathology, Georgetown Univ. Sch. Med., Wash., DC 20007.

Circulating pituitary prolactin (PRL) has been implicated as a critical modulator of humoral and cellular immune function (Bernton et al. Science, 239:401,1988). An extra-pituitary source of PRL may also have an immunological role, as suggested by in vitro studies demonstrating inhibition of mitogen-induced lymphocyte proliferation by anti-PRL antibodies (Hartmann et al. J. Lympho. Biol., 42:335,1987). The present study demonstrates that mouse splenic lymphocytes contain immunoreactive PRL (IR-PRL) as measured by ICC, and that the quantity of IR-PRL is increased by T- [Concanavalin-A (Con-A)], but not B- [lipopolysaccharide (LPS)] cell mitogens. Spleen cells from 5-6 wk old C3H/HeN male mice were incubated 48 hrs in control media or mitogen and fixed with B-5. ICC was performed using both polyclonal and monoclonal anti-PRL antibodies and detected with horseradish peroxidase via the ABC method. 37% of unstimulated lymphocytes exhibited a lactotrope-like characteristic unipolar immunoreactivity which was increased to 87% by Con A- (but not LPS-) mitogen. Presorption of the monoclonal antibody by 24Kd PRL prevented detection by ICC. IR-PRL was also detected in lymphocytes stimulated 48 hrs in serum-free medium, and in EL4 (mouse) and H9 (human) T-cell lymphoma lines. Results indicate that lymphocyte expression of IR-PRL is enhanced by T-cell mitogens.

304.6

TUMOR NECROSIS FACTOR-α STIMULATES CORTICOTROPIN RELEASING HORMONE SECRETION BY EXPLANTED RAT HYPOTHALAMI IN VITRO. R. Bernardini§, A.E. Calogero§*, T.C. Kamilaris*, P.W. Gold* and G.P. Chrousos§ DEB§, NICHD and PBP, NIMH, NIH, Bethesda, MD 20892

The hypothalamic-pituitary-adrenal (HPA) axis is activated during the inflammatory/immune response. Interleukin (IL)-1, -2 and -6 have been shown to act as HPA axis activators in vivo. We have shown that this effect of IL-1 and IL-2 is directed towards the CRH neuron. In this study we examined the ability of tumor necrosis factor-α (TNF-α), a major macrophage-derived cytokine secreted following macrophage activation, to stimulate CRH secretion by in vitro cultured rat hypothalamic explants.

After explantation and overnight incubation in medium 199 (M199), single hypothalami were incubated for 60 min with M199, followed by a 40 min stimulation with graded concentrations of TNF-α (Dr. M. Palladino, Genentech, South San Francisco, CA) ranging between 10^{-13}M and 10^{-7}M. The viability of each explant was tested in a final step of the experiment, examining the CRH response to 60mM KCl-induced depolarization. Immunoreactive rat corticotropin releasing hormone (iCRH) was assayed directly in the media by a specific radioimmunoassay. Statistical analysis was performed by ANOVA followed by Duncan multiple range test. TNF-α stimulated iCRH secretion by explanted rat hypothalami at doses ranging between 10^{-11}M and 10^{-7}M ($p<0.01$; $ED_{50}=2x10^{-11}$M).

We conclude that TNF-α stimulates rat hypothalamic CRH secretion in vitro. Thus, this cytokine may be included in the glucocorticoid-mediated counterregulatory mechanism via which the immune system restraints its own response.

INTERLEUKIN-1 AS AN IMMUNOTRANSMITTER: PERIPHERAL IL-1 ADMINISTRATION ACTIVATES BRAIN NOREPINEPHRINE METABOLISM Adrian J. Dunn
Dept of Neuroscience, Univ of Florida, Gainesville, FL 32610-0244

Immunologic activation is associated with increased concentrations of plasma corticosterone, as well as increases in the firing rate and norepinephrine (NE) metabolism of hypothalamic neurons. Interleukin-1 (IL-1) is a cytokine produced by macrophages after antigen presentation. Recent reports indicate that IL-1 administration elevates plasma corticosterone, which may account for the elevation of plasma glucocorticoids observed following antigenic stimulation.

Purified recombinant IL-1 injected intraperitoneally (ip) markedly activates cerebral noradrenergic systems as indicated by increased concentrations of the NE catabolite, 3-methoxy,4-hydroxyphenyl-ethyleneglycol (MHPG) in several brain regions. The increase of MHPG is largest in the hypothalamus. Tryptophan concentrations are also increased throughout the brain. These effects are dose-dependent with a minimum effective dose of 25 ng. They peak 2-4 hours after IL-1 administration, roughly parallelling the increased plasma corticosterone. The activity of IL-1 is lost after heating. Several different preparations of both IL-1α and IL-1β are effective. These changes resemble those observed following infection of mice with Newcastle disease (NDV) or influenza viruses, or endotoxin administration.

Because noradrenergic neurons with terminals in the paraventricular hypothalamus are known to regulate the release of corticotropin-releasing factor (CRF), these results suggest that IL-1 stimulates the hypothalamic-pituitary-adrenal (HPA) axis by activating these neurons. The effect of IL-1 on hypothalamic MHPG explains both the activation of hypothalamic NE metabolism and that of the HPA axis during immune responses.

[Supported by the National Institute of Mental Health (MH25486)].

THE ORGANUM VASCULOSUM LAMINA TERMINALIS (OVLT) AND THE PREOPTIC ANTERIOR HYPOTHALAMUS AREA (POA) ARE PRIMARY SITES FOR INTERLEUKIN-1-INDUCED ACTH RELEASE. G. Katsuura*, K. Koves*, P.E. Gottschall* and A. Arimura (SPON : P. Guth), US-Japan Biomed. Res. Labs, Tulane Univ. Hebert Center, Belle Chasse, LA 70037.

We recently demonstrated that both systemic and central administration of interleukin-1 *beta* (IL-1 *beta*) induced ACTH release in conscious rats which appears to be mediated by an increased release of endogenous CRH. The present study was conducted to examine the primary site of action of circulating IL-1 *beta* in the brain. The OVLT, which has fenestrous endothel, was first examined as the possible port of entry of circulating IL-1 into the brain. Adult male rats were lesioned in the OVLT by high frequency current. Sham-operated animals served as the control. The magnitude of ACTH response to *iv* administration of IL-1 *beta* increased 1.5 ~ 1.7 times one week following lesion and returned to the control levels 3 weeks later. Lesion of the subfornical organ (SFO), another circumventricular organ, did not alter the magnitude of the response. On the other hand, bilateral lesion in the POA diminished ACTH response by 50%, as compared with sham-operated animals. These findings may be interpreted as follows: Lesion of the OVLT may have caused a post-surgical inflammatory reaction which resulted in an increased entry of IL-1 *beta* into this area, thereby eliciting a greater response. Three weeks post-surgery such inflammation may have subsided and the amount of IL-1 *beta* which had entered into the brain returned to the pre-surgical level. Lesion of the SFO may also have resulted in the increased entry of IL-1 *beta* into this area which, however, lacks the neuronal components which respond to IL-1 *beta*. The POA appears to contain the critical neuronal elements which convey the signal of IL-1 *beta* to the CRH neurons. (Supported by NIH grant DK09094).

ASTROCYTE-MEDIATED IMMUNOSUPPRESSION. M. Borgeson* and R. W. Keane. Department of Physiology and Biophysics, University of Miami School of Medicine, Miami, FL 33101.

Using primary cultures of murine central nervous system (CNS) cells, we demonstrate that astrocytes suppress antigen-stimulated T helper cell proliferation and alloantigen- or mitogen- (Concanavalin A, phytohemagglutinin (PHA), lipopolysaccharide) stimulated spleen mononuclear cell (SMC) proliferation by 70-100%. As few as 0.4 % astrocytes present in the total cell population of proliferation assays suppressed PHA-stimulated lymphocyte proliferation by 65-70%. Astrocytes did not suppress the proliferation of a cytotoxic T cell line (CTLL-2), but did suppress the formation of alloantigen-reactive cytotoxic T cells in a mixed lymphocyte culture. Astrocyte-mediated suppression was not sensitive to indomethacin, a blocker of prostaglandin E production, and was not species-specific. Pure cultures of CNS microglia also suppressed mitogen-stimulated SMC proliferation, but microglial-mediated suppression was completely reversed by indomethacin treatment. Neither CNS neurons nor C3H fibroblasts suppressed lymphocyte proliferation. Astrocyte-mediated immunosuppression may limit immune reactions in the CNS and thus contribute to the maintenance of the immune privileged status of the CNS. INNERVATION OF T-CELL COMPARTMENTS IN *XENOPUS LAEVIS* SPLEEN. S.Y. Felten and N. Cohen * Depts. of Neurobiology and Anatomy & Microbiology and Immunology, Univ. of Rochester Sch. Med., Rochester, NY 14642.

Studies of sympathetic postganglionic innervation of rodent spleen from our laboratory and others have described innervation of specific lymphoid compartments in addition to extensive innervation of the vasculature, capsule, and trabeculae. In rodents, this non-vascular innervation is found in the periarteriolar lymphatic sheath (PALS), a T-cell compartment, at the inner edge of the marginal zone among T- and B- cells and macrophages, in the parafollicular zone, with occasional fibers entering the follicle itself. In the PALS, direct contacts between tyrosine hydroxylase (TH) positive nerve terminals and lymphocytes have been noted.

The Xenopus spleen has a different arrangement of immune cells than the rodent since germinal centers are generally absent, and the T-dependent area is analogous to the marginal zone of the rodent. We examined the adult Xenopus spleen using glyoxylic acid histofluorescence (HF) to demonstrate catecholamine innervation patterns and HPLC to determine whether the postganglionic sympathetics innervating the spleen were adrenergic as has been reported in other anurans or noradrenergic as in rodents.

HF staining showed specific compartmentation of CA containing nerve fibers in the white pulp areas. There was little or no staining in any other compartment. Within the white pulp, there was prominent staining around the edge, associated with the marginal zone. In addition, there were fibers associated with the blood vessels that branched into the parenchyma of the PALS. HPLC with electrochemical detection for monoamines and their metabolites showed only norepinephrine (2.54 pMol/mg wet wt.). Epinephrine and serotonin were not present in measurable amounts.

THE ADRENAL MEDULLA AND SYMPATHETIC β_2-ADRENOCEPTORS INFLUENCE THE SEVERITY OF EXPERIMENTAL ARTHRITIS (EA) IN THE RAT. T.J. Coderre, M.F. Dallman*, A.I. Basbaum, and J.D. Levine*. Division of Neurobiology, UCSF, San Francisco, CA 94143.

In previous studies we demonstrated that β_2-adrenergic antagonists attenuate the severity of EA in the rat (Levine et al., PNAS 1988, in press). This study addressed the β_2-agonist contribution of the adrenal medulla to the severity of EA. Arthritis was induced by intradermal tail injection of 0.1 ml of 10 mg/ml Mycobacterium butyricum in mineral oil, and joint injury was assessed radiologically 28 days later. Bilateral adrenal medullectomy (ADMX) was performed 3 weeks prior to the induction of EA, and/or reserpine (0.25 mg/kg, i.p.) was given every 2 days, to produce a chemical sympathectomy (SYMX). Both ADMX and SYMX significantly attenuated EA compared to no treatment or sham-ADMX controls. Another group of ADMX rats received a slowly released preparation of either epinephrine (0.5 µM/kg) or the β_2-agonist, salbutamol (0.165 µM/kg). The drugs were dissolved in 0.2% ascorbic acid and mixed with paraffin oil and arlacel (4.25:5.0:0.27 v/v) and were administered s.c. every 3 days to restore the β_2-agonist effect of epinephrine normally secreted by the adrenal. Chronic treatment with salbutamol, but not epinephrine, produced a significant increase in EA (compared to untreated, ADMX rats). Salbutamol, however, did not increase EA in ADMX rats which were also SYMX. We conclude that EA is influenced by catecholamines which are released by the adrenal medulla. The catecholamines act, in part, at β_2-adrenergic receptors located on sympathetic postganglionic neurons. Supported by NIH grants AR32634, NS14627, 1F05TW03980 and the Arthritis Foundation.

THE DISTRIBUTION OF ANS RECEPTORS ON CELLS OF THE IMMUNE SYSTEM. K. Bulloch and T. Radojcic. Neuroimmune Physiology Lab., Wellcome Foundation/Depts. of Psychiatry and Pediatrics, University of Cal. San Diego, CA 92093

Lymphoid tissues and organs receive a rich ANS innervation. In order to determine the role of the ANS with regard to immune function we are now evaluating the temporal distribution of the ANS receptor fields within the lymphoid tissues. Herein we report the pattern of ANS receptors on isolated thymocytes and splenocytes as well cloned cell lines of the immune system. Our results show binding of both adrenergic and muscarinic antagonists to an immature thymocyte cell line are comparable to those seen in isolated thymocytes. A mature activated T-helper cloned cell line had a greater number of B-AR receptors than did immature cloned or normal thymocytes, but did not express any m-ACH receptors. However, T-killer cells are known to bear functional m-ACH receptors. These data are consistent with reports that ANS receptors vary in number with functional maturity of different subtypes of T lymphocytes. A cloned B cell line expresses a unique type of m-ACh receptor. Several reports have demonstrated that cholinergic agonists increase the secretion of immunoglobulins. Our data supports these findings and indicate that cholinergic agents may mediate their effect directly on B cell muscarinic receptors. The effect of ANS agonists on second messengers on immune function will be discussed. Supported by: grant #N00014-85K-0528 ONR and a grant from Joan B. Kroc Foundation of Psychoneuroimmunology.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CEREBELLUM II

305.1

INTERCONNECTING AN ANALOG SIMULATOR WITH AN OLIVARY NEURON. Y. Yarom* and A. Adan* (SPON: I. Parnas). Dept. of Neurobiology, The Hebrew University of Jerusalem, Israel.

The membrane potential of inferior olivary neurons occasionally oscillates with an almost sinusoidal waveform (Llinas & Yarom, 1986). An analog simulator consisting of four similar interconnected units was constructed. When one of the units receives a trigger signal, the system can either generate sustained oscillations or briefly oscillate and then slowly relax to resting conditions. This behavior is determined by the degree of coupling between the elements. Once the system is oscillating it will remain in this state, independent of any external inputs. In order to stop the oscillations, one or two of the units has to be disconnected from the rest. Thus, the four damped oscillators can generate sustained oscillations provided that they are interconnected. In order to test the hypothesis that olivary neurons function similarly to the simulator, the four units were interconnected to an olivary neuron in a slice preparation. Under these conditions the hybrid system behaves in the same way as the 4 units by themselves; it can generate sustained oscillations only when all 5 elements are connected. The simulator and the hybrid system differ in that a lower gain setting is sufficient in the hybrid system to generate sustained oscillations. Furthermore, in the hybrid system, briefly depolarizing the olivary neuron to a level which completely inactivates the somatic Ca spike turns off the sustained oscillations. The same effect can be generated by briefly hyperpolarizing the olivary neuron to below the threshold of the somatic Ca spike. We conclude that olivary neurons operate on principles similar to those characterizing the oscillating units of the simulator and that the somatic Ca spike is the main factor responsible for generating the sustained oscillations in olivary neurons.

305.2

DOES STIMULATION OF THE INFERIOR OLIVE PRODUCE MOVEMENT? Alan R. Gibson and Richard Chen*, Barrow Neurological Inst., Phoenix, AZ 85013. Production of movement by climbing fiber activity has important implications for models of cerebellar function. Mauk et al. (Proc. Natl. Acad. Sci. 83, 1986) report that stimulation of the rabbit rostral dorsal accessory olive (rDAO) in the face region produces blinks whereas stimulation in other rDAO regions produces head movements. Three cats were prepared for chronic recording and stimulation. Eyelid movements were monitored photoelectrically and limb movements were monitored with accelerometers. We identified regions of rDAO by mapping cutaneous receptive fields. The peak neural response of eye rDAO to an air puff occurred after the onset of the blink. Stimulation in rDAO could produce a blink, but thresholds decreased by more than 50% 1.0 mm below rDAO. Blinks were as easily elicited from limb rDAO as from eye rDAO, and none of the lowest threshold points for blinking were in the IO. Limb movements elicited by olivary stimulation showed no specificity for the region of the olive being stimulated and required 2 to 3 times as much charge as .9 to 1.8 mm above rDAO. No qualitative differences could be discerned between movements elicited within IO and the lower threshold movements elicited near IO. Our results do not support the concept that electrical activation of the inferior olive produces movements.

305.3

CELLS IN THE INFERIOR OLIVE, BUT NOT THE CEREBELLAR VERMIS, ARE RHYTHMICALLY ACTIVATED BY HARMALINE IN THE GENETICALLY DYSTONIC RAT. S.E. Stratton and J.F. Lorden, Dept. of Psychology, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

The genetically dystonic (dt) rat fails to develop a tremor following administration of harmaline. Because this mutant responds to other tremorogenic agents, an abnormality has been sought in the olivo-cerebellar pathway activated by harmaline. Single unit recordings in the cerebellar vermis showed that in normal animals, harmaline produced a sustained, rhythmic increase in complex spike activity in 67% of the cells. In the dt rat, only 9% of the cells showed this response. The present study was conducted to determine whether the reduced effectiveness of harmaline in the dt rat was due to a failure to activate the inferior olive, the site thought to be the pacemaker for the harmaline tremor. Pre- and post-harmaline (10 mg/kg, i.v.) single unit activity was recorded in 6 normal and 12 dt rats anesthetized with urethane (1.9 g/kg). In all cells recorded in the subnucleus b of the medial accessory olive (5 normal and 11 dt), a sustained, rhythmic increase in frequency from about 1 Hz to 4 Hz was obtained. Two cells that did not respond were located outside the inferior olive. These results suggest that the failure of the dt rat to show harmaline tremor is the result of a cerebellar defect. (Supported by NS18062).

305.4

SENSORY INPUT TO THE FORELIMB INFERIOR OLIVE AND ITS RELATIONSHIP TO MOTOR PATHWAYS. M.L. McCurdy*, C. Melton*, J.C. Houk and A.R. Gibson. Dept. of Physiology, Northwestern Univ. Med. Sch., Chicago, IL 60611 and Division of Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85013

Stimulation of cat magnocellular red nucleus (RNm) inhibits responses of rostral dorsal accessory olive (rDAO) neurons to peripheral input (Soc. Neurosci. Abs.11:182,1985). Since the RNm does not project directly to rDAO, the neural connections subserving the olivary gating may involve sensory pathways to the rDAO. Our studies show that afferent input to the forelimb region of rDAO arises from a column of cells in the caudal cuneate nucleus and cervical spinal cord (Soc. Neurosci. Abstr. 12:326, 1986). We determined whether this column receives input from RNm by injecting WGA-HRP into the forelimb areas of both RNm and rDAO.

The dual injection protocol demonstrated that labeled column cells were within a larger zone comprising the rubral terminal field. Branches of rubrospinal tract axons were seen coursing toward the area of the column. The results identify a likely collateral pathway that could gate rDAO activity. Motor cortex projects to similar cuneate and spinal regions and is also reported to gate olive activity (Somatosens. Res 1:169,1983; J. Physiol. 228:619,1973).

A second question we addressed was whether the RNm-column-rDAO pathway was topographically organized. Topographic specificity could provide a basis for somatotopic specificity in the gating mechanism. Injections in spinal or cuneate parts of the column revealed no specific topography for RNm cells that project to the column. Small injections in somatotopic regions within the forelimb area of rDAO and in trunk rDAO demonstrate that the trunk and proximal forelimb are represented in the cuneate part of the column and the distal forelimb is represented in both spinal and cuneate parts. Although the somatotopy in rDAO is more detailed than that in the column, both nuclei emphasize the distal forelimb.

305.5

OPTOKINETIC STIMULATION INCREASES CORTICOTROPIN RELEASING FACTOR mRNA IN INFERIOR OLIVARY NEURONS OF RABBITS. N.H. Barmack and W.S. Young, III. R.S. Dow Neurol. Sciences Inst., Good Samaritan Hosp. & Med. Ctr., Portland, OR 97209 and Lab. Cell. Biol., NIMH, Bethesda, MD 20892.

Neurons located in the caudal dorsal cap of the inferior olive are excited by low velocity optokinetic stimulation in the posterior-anterior direction of the contralateral eye. These visual olivocerebellar neurons have been implicated in the regulation and possible plasticity of eye movements. A neuropeptide, corticotropin releasing factor, CRF, has been identified in all olivary neurons. Using in situ hybridization histochemistry we have examined the influence of prolonged, unidirectional, binocular opto-kinetic stimulation on the level of CRF mRNA in neurons of the caudal dorsal cap. Rabbits were partially restrained within an optokinetic drum which rotated at an angular velocity of 5°/sec for 6-150 hr. Frozen brain sections were hybridized with an S^{35}-labelled oligonucleotide probe for CRF. The x-ray film images of these sections were subsequently analyzed with a computer-based microdensitometer. Six hours of optokinetic stimulation was sufficient to cause an increase in CRF mRNA in neurons of the "stimulated" dorsal cap relative to the background activity of the rest of the inferior olive. After 140 hours of optokinetic stimulation there was a 10-fold increase in the level of CRF mRNA. This elevated level of CRF mRNA lasts 24 hours. These data suggest that CRF may play an important role in olivocerebellar function.

305.6

DEVELOPMENT OF THE OPTOKINETIC REFERENCE FRAME OF FLOCCULAR PURKINJE CELLS IN RABBIT. R. E. Soodak*, L. J. Croner* and W. Graf. The Rockefeller University, New York, NY 10021.

Purkinje cells of the rabbit flocculus encode retinal slip velocity with an internal coordinate system roughly aligned with the axes of the semi-circular canals and extra-ocular muscles. In addition, the simple and complex spike responses of a given purkinje cell are usually reciprocally related, with the simple spikes increasing in activity when the complex spikes decrease, and vice-verca. To examine the role of visual experience in the development of these highly specific neuronal responses, we recorded simultaneously the simple and complex spike activity of floccular purkinje cells from dark-reared rabbits. Recordings were made from adult animals that had been reared in total darkness from before eye opening. Our visual stimulus was a planetarium projector that simulated the retinal slip resulting from rotational self-motion.

As in normal rabbits, purkinje cells of dark-reared rabbits encoded rotational self-motion with an approximately sinusoidal tuning curve, similar to the encoding of angular acceleration by the semi-circular canals. In addition, all three visual response types found in normal animals, i.e., Vertical Axis, Anterior (45 deg) Axis and Posterior (135 deg) Axis, were found in dark-reared rabbits as well.

The reciprocal relationship between simple and complex spike activity was also observed in dark-reared rabbits. This suggests that simple spike-complex spike reciprocity is not the result of an instructive process in which the climbing fiber "teaches" the parallel fiber inputs through a mechanism of heterosynaptic plasticity.

KINEMATIC ANALYSIS OF NICTITATING MEMBRANE RESPONSES IN CEREBELLAR LESIONED RABBITS. J. P. Welsh. Dept. of Psychology, University of Iowa, Iowa City, IA 52242

Cerebellar lesions reduced the frequency and amplitude as well as increased the rise time of nictitating membrane extensions (NMEs) elicited by tones or low intensities of corneal air puff. These deficits were most prominent after lesions in the anterior interpositus nucleus (aINT). Over a range of air-puff intensities, the NME of normal rabbits consists of one peak of velocity and acceleration. The tone-elicited NME of normal rabbits consists of one peak of velocity but consists, however, of 2 peaks of acceleration. Cerebellar lesions producing a continuum of deficits in frequency, amplitude and rise time of tone-elicited NMEs progressively reduced the peak velocity and acceleration as well as increased the time of peak velocity and acceleration of tone-elicited NMEs. In contrast to the normal NME elicited by a tone, only one peak of acceleration was observed in NMEs following cerebellar lesions that reduced NME amplitude. Lesions of aINT reduced peak velocity and latencies to peak velocity and peak acceleration of the NME elicited by air puff, especially at low intensities. The different acceleration profiles of tone-elicited and air puff-elicited NMEs may be a function of differential patterns of motoneuronal excitation for this behavior. These analyses suggest that cerebellar lesions may disrupt NME performance by fundamentally disrupting patterned motoneuronal activity. Supported by USPHS MH Grants 16841 & 15773.

SPATIAL AND TEMPORAL PATTERNS OF SPONTANEOUS AND EVOKED CALCIUM DEPENDENT EVENTS IN THE DENDRITES OF GUINEA PIG CEREBELLAR PURKINJE CELLS IN VITRO. W.N.Ross and R.Werman* Dept. Physiology, New York Med.Coll.,Valhalla,NY 10595 and Dept. Neurobiology, Hebrew Univ., Jerusalem, Israel.

We have used the indicator dye arsenazo III in conjunction with a 64 element photodiode array to measure dendritic calcium changes induced by spontaneous or somatically-stimulated electrical events. The recording system had a time resolution of 1 msec and sufficient sensitivity to detect calcium changes at each location without signal averaging. Calcium transients corresponding in time with somatically recorded action potentials could be detected from all locations on the dendritic arborization. Individual calcium action potentials in a burst often had different spatial distributions. In general, transients that were only detected from secondary branches were associated with small electrically recorded events in the soma. Calcium transients which were detected from the main trunks had large somatic electrical potentials whether or not there were corresponding transients over the finer dendritic branches. Somatically stimulated transients were larger in the proximal dendritic region while spontaneous events were larger distally. Calcium increases corresponding to plateau potentials were also detected without averaging. These had a heterogenous spatial distribution, but were generally larger nearer to the soma. Supported by USPHS grant NS16295 and the U.S.-Israel Binational Foundation.

305.9

SYNAPTICALLY EVOKED CALCIUM TRANSIENTS IN THE DENDRITES OF CEREBELLAR PURKINJE CELLS IN VITRO. H. Miyakawa*, V. Lev-Ram*, and W.N. Ross. (SPON: F. Horvath). Dept. of Physiology, New York Medical College, Valhalla, NY 10595.

We have used the same preparation and optical recording apparatus as Ross and Werman (preceding abstract) to record calcium increases in the dendrites of Purkinje cells in response to white matter stimulation which predominantly activates the climbing fiber synapse. These calcium transients could be detected in a single trial from all locations in the dendritic field, but were usually distributed closer to the soma when compared with transients evoked by spontaneous calcium-dependent action potentials in the same cell. No signals were detected from the soma. The amplitudes of the synaptically activated and action potential activated transients were of the same order of magnitude. When the two potentials were activated at about the same time their transients did not sum. The recovery time course of the transients was complex but the initial component was rapid, often having a time constant of less than 100 msec. Repetitive stimulation could increase this recovery time but the increase was not uniform at all dendritic locations.

Supported by USPHS grant NS16295. V. Lev-Ram is a Chiam Weizmann Postdoctoral Fellow.

305.10

DENDRITIC CALCIUM-DEPENDENT EVENTS IN PURKINJE CELLS DETECTED WITH FURA-2. V. Lev-Ram, H. Miyakawa, and W.N. Ross. (SPON: K. Hubbard). Dept. of Physiology, New York Medical College, Valhalla, N.Y. 10595.

Purkinje cells in sagittal cerebellar slices were injected with the impermeant calcium indicator fura-2 and excited at 395±20 nm with a xenon lamp. Epifluorescence at >510 nm from a 70 um diameter spot in the dendritic field was measured with a photodiode. When the cell fired a series of calcium-dependent action potentials, each spike caused a transient reduction in fluorescence which could be detected without averaging. Climbing fiber synaptic activation also caused a reduction in fluorescence detected in a single trial. A burst of action potentials often caused a reduction in fluorescence of over 35%. The time course of these transients was approximately the same as those recorded from similar cells using absorbance changes of arsenazo III. These experiments show that fura-2 and a photodiode array could be used to measure the spatial, temporal, and amplitude characteristics of calcium-dependent dendritic events in Purkinje cells.

SPATIAL AND TEMPORAL PATTERNS OF PURKINJE AND GRANULE CELL ACTIVITY RECORDED SIMULTANEOUSLY IN THE RAT CEREBELLUM USING SILICON MICROELECTRODES. M.E. Nelson[1], B. Rasnow[2], J.J. Banik*[3], and J.M. Bower[1]. Depts. of Biology[1], Physics[2], and Electrical Engineering[3], Caltech, Pasadena, CA 91125.

We have developed a technique which allows us to make simultaneous extracellular recordings from a planar array of cerebellar locations using a multiprong, multisite, silicon-based recording probe. This new technique is more powerful than earlier multi-single neuron recording methods (Bower and Llinas, Soc. Neurosci. Abstr., 9: 607, 1983) which were limited to recording one site per inserted probe and which did not provide a constrained and easily reproducible geometry between recording sites. The key to the new technique is our development of a miniature 30-channel silicon-based microelectrode with excellent recording characteristics. Using photolithography and anisotropic etching techniques, we are able to shape the silicon substrate into a structure which supports a high density of recording sites while at the same time being no larger than standard glass pipettes. The probes are a comb-like structure with 10 teeth per comb. At its widest point, the shank of each tooth is approximately 24μ x 12μ in cross-section and tapers to a sub-micron point at the end of its 1.5 mm length. The teeth are spaced 150μ apart and there are 3 recording sites on each tooth. For these cerebellar studies, we have positioned the recording sites on each individual tooth to simultaneously recording climbing fiber responses at the dendritic level, simple spikes at the somatic level, and granule cell responses in the underlying granule cell layer. We have used the probes in Crus IIa of the rat cerebellar cortex to record spontaneous activity and responses to tactile stimulation of the face. (This work supported by NIH Grant NS22205, the Joseph Drown Foundation, and the Whitiker Foundation.)

SPATIAL PATTERNS OF CEREBELLAR CORTEX ACTIVITY IN VIVO USING VOLTAGE SENSITIVE DYES AND IMAGE ANALYSIS. S.A. Elias, H. Yae*, J.H. Kim and T.J. Ebner. Depts. Neurosurgery and Physiology, Neuroscience Grad. Prog., Univ. of MN, Mpls., MN 55455.

We recently reported that voltage sensitive dyes and image processing can be used to investigate the spatial features of cerebellar circuitry. This technique has been further used to study (1) the three-dimensional nature of parallel fiber activation and (2) the spatial activation of the cortex to peripheral input. Rats were anesthetized with ketamine and the cerebellar cortex stained with RH414. Using a epifluorescence microscope, images were recorded using a CCD video camera. The video signals were filtered, windowed and the control/stimulus averaging and subtraction (up to 1000 times) performed on line. Using a microelectrode to provide surface stimulation, the evoked optical images were recorded at depths of focus from surface to 500 um. The resulting images were organized longitudinally, and at greater depths showed increasing parasagittal spread. Images to repetitive stimulation of the face and forelimb were made up of two components (1) areas of cortical activation and (2) increased blood flow in the surface blood vessels. The preliminary data suggests that this technique will be useful for the study of somatosensory input and properties of intrinsic cortical activity. Supported by Minnesota Med. Found. and NIH/NS-18338.

SOMATOSENSORY CORTEX III

306.1

EFFECTS OF SELECTIVE REMOVALS OF THE POSTCENTRAL HAND REPRESENTATIONS ON THE RESPONSIVITY OF NEURONS IN THE SECOND SOMATOSENSORY AREA (SII) OF RHESUS MONKEYS. T.P. Pons, P.E. Garraghty and M. Mishkin, Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

We previously reported that elimination of all four hand representations in the postcentral strip (i.e. areas 3a, 3b, 1, and 2) eliminated the hand representation in SII. Two of these postcentral areas (3b and 1) process predominantly cutaneous inputs, whereas the other two (3a and 2) process mainly "deep" somatic inputs. We have now found that following selective removal of the 3b and 1 hand representations the SII hand representation remains intact, but activation of its neurons requires a substantially higher-than-normal amplitude of somatic stimulation. We used a pressure aesthesiometer to quantify the force required to elicit a consistent neuronal response from recording sites in different representations in SII 6-8 weeks after the selective ablations. Whereas a stimulation force of < 0.5 gr was adequate to produce a response at a majority of recording sites outside the hand region of SII, a stimulation force of $>$ than 2 gr was necessary to evoke a response at sites within it, presumably because of the need to activate "deep" somatic inputs from the hand. These findings suggest that modality-specific information is relayed from the postcentral strip to SII along parallel channels, with cutaneous inputs being transmitted via areas 3b and 1 and "deep" inputs via areas 3a and 2.

306.2

CORTICAL RESPONSES TO PARESTHESIAS. C.N. Applegate* and P.T. Fox SPON:(S.G. Eliasson) Washington University School of Medicine, St. Louis, MO 63110

Paresthesias are associated with ectopic impulses in peripheral and spinal axons, but the role of cortex is not known. Using positron emission tomography (oxygen-15 water), we identified multiple areas of cortical activity during paresthesias that follow prolonged (60 min) hand vibration. Three conditions were aquired in each of 6 subjects: rest, hand vibration, and paresthesias (after stimulus termination). Image analysis used paired subtraction (stimulus - rest, paresthesias - rest), inter-subject averaging and a search routine that identified foci of blood flow change. Left hand vibration increased blood flow in: right post-central ("S1"), 23%; right medial frontal ("SMA"), 12%; right parietal opercular ("S2"), 8%; left superior lateral parietal ("S3") 7%, right insular ("S4"), 7%; and bilateral orbitofrontal, 8% cortices. During paresthesias the blood flow increases were: right S1, 12%; right S2, 8%; left S3, 6%; right S4, 9% and bilateral orbitofrontal, 8%. SMA was not active during paresthesias. Thus cortical areas activated by a physiologic stimulus were also actived during paresthesias. In fact, extraprimary responses were of equal or even greater magnitude during paresthesias than during vibration.

306.3

RIGHT-HEMISPHERIC DOMINANCE FOR SOMATOSENSORY PROCESSING IN HUMANS. P.T. Fox, C.N. Applegate* Washington University Medical School, St. Louis, MO 63110

Human hemispheric specialization for language, skilled movement, and attention is well known. Hemispheric domiance for modality-specific sensory processing is not well described. Studying right-handed normal volunteers with positron emission tomography (oxygen-15 water), we found a right-hemispheric response predominance in 3 extraprimary somatosensory areas.

A vibratory stimulus was applied bilaterally to lips, fingers, and toes and also unilaterally (right and left) to fingers on separate trials in 9 subjects. The control state was eyes-closed rest. Images of average blood-flow change were formed using paired-image subtraction and intersubject averaging.

No evidence of lateral dominance was found for responses in primary somatosensory cortex or supplementary motor area. Right-hemispheric dominance was found for three extra-primary somatosensory responses: buried posterior sylvian ("S2"), lateral superior parietal ("S3"), and anterior insular ("S4") cortices. This effect was most clearly demonstrated with bilateral stimuli. Responses to bilateral stimuli were predominately or exclusively on the right. Responses to unilateral stimuli were contralateral, but were weaker or absent on the left.

306.4

THE SPATIAL AND TEMPORAL ORGANIZATION OF THE PRIMARY SOMATOSENSORY EVOKED POTENTIAL P.B. Hoeltzell*, R.W. Dykes, C.E.Chapman Dept. Physiol. McGill Univ., Mtl. QU.

The primary somatosensory evoked potential consists of a biphasic waveform that is initially positive at the surface. With increasing depth, this potential reverses polarity, becoming initially negative. Traditionally it is modelled by current dipole.

Data was obtained from pentobarbital anesthetized cats. A computer-controlled punctate mechanical stimulus was delivered to the cat forepaw. Recordings were made using 200 um steps in the AP and Ml planes. Vertical data were collected using 100 um steps. The waveform profiles were analyzed both as a function of time and space. A current source density (csd) analysis was also performed.

Three distinctly different waveform profiles were found. The first consisted entirely of initially negative, non-inverting waveforms. The second profile was composed of initially positive waveforms. Waveforms found at the evoked potential focus were more complex and followed the classic description.

Laminar analysis in conjunction with the csd data showed that one waveform produced a strong source-sink couplet in layer II and another produced a weak sink-source couplet in layer IV. The classical evoked potential was shown to be the result of the summation of these two separate neuronal populations.

306.5

AN HYPOTHETICAL MODEL OF CORTICAL SENSORY PROCESSING BASED UPON STUDIES OF THE SOMATOSENSORY-EVOKED RESPONSE IN AWAKE MONKEYS AND CONSIDERATION OF CORTICAL CONNECTIVITY.

L.J. Cauller*, A.T. Kulics* and T.J. Teyler (SPON: T.J. Voneida). Department of Neurobiology, Northeastern Ohio Universities' College of Medicine, Rootstown, OH 44272.

A series of experiments has been undertaken to identify the neural events underlying N1, the surface-negative component (50ms poststimulus) of the somatosensory-evoked potential (SEP) (Kulics,A.T. and Cauller,L.J. *Exp. Brain Res. 62*:46, 1986). The amplitude of N1 predicts the discrimination response of behaving monkeys (Kulics, A.T. *EEG Clin. Neurophysiol. 53*:78, 1982). Current source-density analysis has identified current sinks in superficial layers I/II of postcentral Area 1 associated with multiple unit activity (MUA) in layers II-V. The excitatory nature of N1 is indicated by the prominence of late MUA which extends into subcortical white matter. In contrast to the awake response, the N1 interval of the response during slow-wave sleep is associated with MUA inhibition and large current sources through layer III. As the principal source of excitatory input to superficial layers, the "backward" projection which converges upon Area 1 from secondary somatosensory areas is thought to be the origin of N1 input (Pandya D.N. and Seltzer B., *J. Comp. Neurol. 204*:196, 1982). A model is developed which considers the functional significance of the "backward" cortical system for conscious sensory processing that emphasizes the role of distal apical dendrites of the population of pyramidal neurons which engage superficial layers I/II. The unconscious state of cortical sleep is viewed as the blockade of superficial inputs.

306.6

INTRAHEMISPHERIC CORTICO-CORTICAL AFFERENTS TO AREA 5 AND SsA IN THE CAT. C. Avendaño, E. Rausell* and A. Verdú*. Dept. Morphology, Medical School, Autónoma Univ., 28029 Madrid, Spain.

The intrahemispheric cortical afferent connections of area 5 and the adjoining "anterior suprasylvian area" (SsA) were studied in the cat by placing single or multiple injections of retrograde tracers (HRP, WGA-HRP or fluorescent dyes) into different divisions of areas 5a, 5b, 5m and SsA. Labeled cells were plotted on projection drawings of coronal sections of the brain, and on two-dimensional "maps" of the cerebral cortex.

The major findings of this study are: 1. Areas 3a, 3b, 1 and 2 project to area 5 and to SsA. These projections, however, show marked differences in amount and topographical distribution depending on the medio-lateral and rostro-caudal location of the injections. 2. Areas 4 and 6 also project heavily to area 5 and SsA in a well organized topographic fashion: Area 4 projects mainly upon areas 5a, 5m, SsA, and the medial part of 5b; area 6 projects mainly upon the lateral part of 5b, and SsA. Moreover, the upper bank of the cruciate sulcus (areas 4β and 4δ) projects to medial parts of area 5, and the lower bank (areas 4β, 6aα and 6aβ) projects to lateral parts of area 5. 3. SIIm, SII and SIV are connected mainly with medial parts of area 5 (particularly 5a), and SsA. 4. Areas 7 and 7m, and a number of visual areas (19, SVA, AmLS, PmLS, 21, 20, 18, AILS and PILS) project in varying degrees to lateral parts of area 5b. Some of these areas also send weak to moderate projections to the medial part of 5b and the lateral part of 5a. 5. Sparse projections arising from the dorsolateral prefrontal, cingular, retrosplenial, granular insular, and suprasylvian fringe cortices were found to distribute particularly in lateral portions of 5b. 6. Quite abundant intrinsic connections were also found, which were loosely organized according to a complex topographic pattern.

CELLULAR LOCALIZATION OF CHOLINERGIC AND OPIATE RECEPTORS IN RAT SENSORIMOTOR CORTEX. M. Sahin*, W.D. Bowen and J.P. Donoghue. Div. of Biology and Medicine and Center for Neural Science, Brown University, Providence RI 02912.

Both cholinergic and opiate systems are thought to be modulators of synaptic function in cerebral neocortex. In the present study, we sought to dissociate those receptors which are localized to afferent fibers from those that are on intrinsic cortical elements. We examined the cellular location of nicotinic and muscarinic cholinergic and μ-opiate receptors by combining *in vitro* receptor binding techniques with lesions of thalamic or cortical neurons. Lesions were made electrolytically or by injecting kainic acid (KA) in the thalamus or by injecting quinolinic acid (QA) into the cortex. Ligands to each receptor type (tritiated nicotine, QNB, DAGO, muscimol) were applied to adjacent sections taken from these animals. Autoradiograms were analyzed using a computer densitometry system.

In controls, *nicotinic* receptor labeling was most dense in mid-cortical layers where thalamic fibers terminate. Following thalamic lesions, labeling within the cortical projection zone of the damaged thalamic neurons decreased 50% compared to the contralateral control side. In contrast, normal labeling remained after cortical lesions. Together, these results suggest that nicotinic receptors are largely located presynaptically on thalamo-cortical fibers. *Muscarinic* receptors were dense throughout cortex except for layer V. This normal pattern was unchanged by thalamic lesions, but was reduced up to 85% after cortical QA lesions, indicating that muscarinic receptors are located on cortical neurons. In sensorimotor cortex, *μ-opiate* labeling resembled the projection pattern from the posterior nucleus (PO). Opiate labeling decreased significantly after thalamic lesions, but a considerably greater decline (up to 75%) was observed after cortical QA lesions. Thus, μ-opiate receptors appear to be located both presynaptically on PO fibers, and postsynaptically on cortical neurons.

Based on iontophoretic studies, presynaptic nicotinic receptors may account for suppression and postsynaptic muscarinic receptors may account for enhancement of thalamic transmission observed after ACh applications in rat sensorimotor cortex (Donoghue and Carroll, '87). The role of μ-opiate receptors in cortex is not clear, but may have diverse functions based on their separate locations. Supported by NIH NS22517 and March of Dimes.

CENTRAL, NOT PERIPHERAL, ANGIOTENSIN II SYNERGIZES WITH ALDOSTERONE IN RAT SALT APPETITE. A.N. Epstein & R.R. Sakai*, Dept. of Biology & Institute of Neurological Sciences, Univ. of Pennsylvania, Phila. Pa. 19104-6018.

Rats that were pretreated with systemic DOCA (5 days at 500 µg/rat) and then received 6 hr of intravenous angiotensin II (ANG II) at a dipsogenic dose (64 ng/min/rat) did not drink 3% NaCl, in contrast to others that were also pretreated with a mineralocorticoid but were given intracerebroventricular ANG II (0.6, 6.0, or 60 ng by pulse injection) which evoked reliable and conspicuous salt intake. The failure of peripheral ANG II to evoke salt intake in synergy with aldosterone (ALDO) is consistent with our report at last year's meeting (Epstein, et al; Soc. Neurosci. Abst., 13, 1168, 1987) of the contrast between the effects of central and peripheral ANG II receptor blockade on depletion-induced salt appetite. Sarile (a specific ANG II receptor antagonist) reduced salt intake generated by sodium depletion in a dose-related fashion when it was given into the rat's cerebral ventricles, but had no effect on the same behavior when it was given intravenously.

Thus, these data suggest that peripheral ANG II of renal origin does not participate directly in the arousal of the rat's salt intake. It contributes to the behavior by releasing ALDO which then synergizes within the brain with ANG II of cerebral origin.

FOURTH VENTRICULAR (4V) EFFECTS OF PEPTIDE YY (PYY) AND NEUROPEPTIDE Y (NPY) ON INGESTIVE BEHAVIORS. ES Corp*, LD Melville*, D Greenberg, J Gibbs and GP Smith. Dept. Psychiatry, NYH-Cornell Med Ctr, White Plains, NY 10605

PYY and NPY produce dose-related increases in food intake after 4V injections. We now report that these peptides act with different potencies and different effects on feeding and non-feeding behaviors. PYY was about 4X as potent as NPY for eliciting a half-maximal feeding response (1.25 ug PYY vs. 5ug NPY). Moreover, PYY elicited eating after a shorter latency (4±1 min and 10±2 min for PYY 5 and 10 ug, respectively vs. 19±1 min for both NPY 5 and 10 ug). A dose (10 ug) of PYY and NPY that produced equivalent, maximal food intakes produced differential behavioral effects (Table of mean % time, 60-min test, n=4).

	VEH	PYY10	NPY10
FEEDING	8.5	45.0*	52.5*
GROOMING	9.8	2.1*	1.1*
RESTING	26.7	30.0	7.9*#
SLEEPING	42.3	0.0*	27.8*#
EXPLORING	11.9	17.3	10.2
DRINKING	0.8	5.5	0.5

*p<.05 compared with VEH # p<.05 compared with PYY.

The differences in potency and behavioral effects suggest PYY and NPY are not acting through identical sites and/or receptor mechanisms in the hindbrain.

307.3

NEUROPEPTIDE Y (NPY) INCREASES FOOD INTAKE COMPARABLY WHEN RATS RECEIVE FOOD EITHER IMMEDIATELY OR AFTER 4-HR OF FOOD DEPRIVATION. Pamela K. Green*, Alfred J. Sipols, Paige Israel* and Stephen C. Woods. Dept. of Psychology, NI-25, Univ. of Washington, Seattle, WA 98195.

NPY, like insulin, causes increased food intake when administered acutely to rats. Rats given insulin and food-deprived for several hours show comparably increased food intake as when given immediate access to food. The present study sought to determine whether NPY has a similar latent effect on food intake. Six naive male Long-Evans rats (260-380 g) were maintained on ad lib food (pelleted chow) and water. Each animal received an intraventricular (ivt) cannula aimed at the lateral cerebral ventricle. After recovery, rats were given ivt injections (1 ul) of saline or 9.5 ug NPY in saline during the light portion of the day. One-hr food intake was measured either immediately after the injection, or else after a 4-hr interval with no food. Each rat was run in 3 of the 4 conditions (ie, saline vs NPY, and 0 vs 4-hr deprivation). Mean food intake was increased following NPY when animals had immediate access to food (saline = 0.4 ± 0.7 g; NPY = 2.7 ± 1.2 g). After 4-hr food deprivation, saline animals ate slightly more (ns) food (1.4 ± 1.4 g). NPY injected animals, however, again ate increased food (2.5 ± 1.4 g), the amount being comparable to that consumed with immediate access tp food. These findings suggest that NPY causes long-term changes in the neural mechanisms that regulate food intake.

307.4

NEUROPEPTIDE Y PRODUCES CONDITIONED TASTE AVERSIONS IN LEAN BUT NOT OBESE ZUCKER RATS. A. J. Sipols, D. Figlewicz Lattemann*, and S. C. Woods. Department of Psychology, University of Washington NI-25, Seattle, WA 98195.

Neuropeptide Y (NPY) elicits large and rapid increases of food and water intake when administered in microgram quantities into either the cerebrospinal fluid or the paraventricular nuclei of many animals. We previously found that obese (fa/fa) Zucker rats display a diminished food intake response to intraventricular (IVT) NPY in comparison to that of their their lean (Fa/Fa) and heterozygous (Fa/fa) siblings. We have also described the formation of conditioned taste aversions to novel flavors following IVT NPY in Long-Evans rats. The present experiment examined the possible association of Zucker rat genotype with susceptibility to NPY-induced taste aversions. Female Zucker rats were surgically implanted with cannulas aimed at the third cerebral ventricle. The animals were adapted to a schedule of ad lib food with water available only 20 min/day. Following stabilization of daily water intake (8 days), a novel aqueous solution of non-caloric lime-flavored Kooladid was offered instead of water. After 20 minutes, half the rats of each genotype were injected IVT with saline (1 µl) and half with 9.5 µg NPY. On the following day, all subjects were presented with a two-bottle choice of lime Kooladid vs. water. Lean (Fa/Fa) animals receiving NPY drank significantly less Kooladid (24.8 +/- 13.7%) than lean animals receiving saline on the previous day (58.1 +/- 9.6%, p<.05). Total liquid intake was comparable for the two groups. Kooladid intake of obese Zucker rats receiving NPY did not differ significantly from that of their saline controls (36.8 +/- 17.4 vs. 46.2 +/- 8.3%). This was also true of the heterozygous rats. Therefore, obese Zucker rats neither eat more food nor form conditioned taste aversions in response to IVT NPY.

307.5

THE KAPPA OPIOID ANTAGONIST, NOR-BINALTORPHIMINE, DECREASES STARVATION- AND OPIOID-INDUCED FEEDING. A.S. Levine, M. Grace, W. Welch, C.J. Billington and P.S. Portoghese. VA Medical Center and Univ. of Minn., Minneapolis, MN, 55417.

Agonists of the mu, delta and kappa opioid receptors increase short term feeding and blockade of the opioid receptor with non-selective antagonists decreases feeding. Recently, the highly selective kappa opioid antagonist, nor-binaltorphimine (nor-BNI) has been reported. In the present study, 50 male rats were injected with nor-BNI (100 nmol) or vehicle intraventricularly (ICV) following a 24 hour starvation period. Nor-BNI was injected either two hours, one hour, or immediately prior to placement of food in the home cage. There was a main effect of nor-BNI ($F(2,44)=4.60$, $p<0.05$) on food intake, but no main effect of time of injection of nor-BNI. Nor-BNI decreased food intake (3.8±0.6 g/hr and 3.9±1.9 g/hr) compared to vehicle control rats (5.5±.5 g/hr and 6.9±.6 g/hr, $p<0.05$) when the drug was injected immediately before access to food. Twenty-four hour food intake was similar in the nor-BNI group (19.4±3.1 g) and the vehicle group (23.6±2.2 g). The kappa agonist U-50,488H (100 µg) was administered ICV to 7 rats and increased feeding (2.9±.9 g/hr) compared to 6 rats receiving the vehicle (.8±.5 g/hr, $p<0.05$). ICV injection of nor-BNI (100 nmol) + U-50,488H blocked the ability of the kappa agonist to induce feeding (.3±.2 g/hr). These data indicate that the kappa antagonist nor-BNI decreases food intake induced by food deprivation and by administration of a kappa agonist.

307.6

NEUROPEPTIDE K SUPPRESSES FEEDING IN THE RAT. S.P. Kalra, A. Sahu*, M.G. Dube* and P.S. Kalra (SPON: M.F.NOLAN). OB/Gyn, Univ. Fla. Col. of Med., Gainesville, FL 32610

Neuropeptide K (NPK), a 36 amino acid residue peptide belonging to the tachykinin family is localized immunocytochemically in the rat brain, especially in hypothalamic sites implicated in the control of ingestive behavior in the rat and in many neurons in the gastrointestinal tract. In addition, high concentrations of NPK and other tachykinins have been detected in plasma and tumor tissue from patients with carcinoid tumors. We studied the effects of NPK on feeding behavior in 3 experimental paradigms. In Expt. 1, intraperitoneal (i.p.) injection of NPK (1.25 and 3.14 nmols) to food-deprived (24 h) rats significantly delayed the onset of feeding and decreased 1 and 2 h cumulative food intake. Similarly in Expt. 2, NPK (3.14 nmols, i.p.) 15 min before onset of the dark phase (lights on 0500-1900 h) significantly delayed the occurrence of ingestive behavior and cumulative food intake was markedly suppressed. Since intraventricular (Ivt) injection of neuropeptide Y (NPY) stimulates feeding in rats, in Expt. 3 the effects of NPK on NPY-induced feeding in satiated rats were assessed. NPY (0.47 nmol, Ivt) elicited a vigorous feeding response while NPK treatment i.p. 15 min prior to NPY, significantly suppressed food intake and delayed the onset of ingestive behavior. Thus, NPK can acutely and consistently suppress normal as well as evoked feeding behavior. These findings suggest that NPK may play a role in the control of feeding behavior in rats and some of the clinical gastrointestinal tract symptoms may be mediated by the reportedly high circulating concentrations of NPK in carcinoid patients. (NIH DK 37273).

307.7

CIRCADIAN RHYTHM OF PLASMA CORTICOSTERONE IN DIABETIC RATS. **M.H. Oster*, T.W. Castonguay, C.L. Keen*, and J.S. Stern*. (SPON: B. Wong). Dept. of Nutrition and Food Intake Laboratory, Univ. of Calif-Davis. Davis, CA 95616.**

Abnormal corticosterone rhythms have been implicated in several models of hyperphagia. We hypothesized that the circadian rhythm of corticosterone in diabetic (DIAB) rats would have a different pattern than that of non-DIAB, control rats. To test this hypothesis, 20 Sprague-Dawley male rats (mean body wt.:118g) were given ad libitum access to a stock diet (Purina rat chow) and housed individually in a light and temperature controlled room (14/10 l/d: 22°C). Rats were made diabetic by 2 subcutaneous injections of streptozotocin (40 mg/kg). Rats which were not injected served as controls (CON). Ten days after induction of the diabetes, tail blood samples were taken every 4 h for 24 h. Plasma corticosterone levels (determined by RIA) were significantly higher in DIAB rats than in CON rats during the light cycle; however, concentrations were similar during the night cycle. To determine if the altered corticosterone rhythm of DIAB rats was a function of hyperphagia, rats were divided into two groups and fed either a diet with 21% of calories from fat (low fat or LF) or a diet with 64% of calories from fat (high fat or HF). Food intake of DIAB rats fed the HF diet was not different from controls. While the peak level of plasma corticosterone achieved was comparable in these 3 groups, the high level was maintained over a longer period of time in the DIAB-HF rats. (DK/HL07355, DK35747)

FEEDING PATTERNS IN YOUNG ANIMALS IN RELATION TO BODY WEIGHT AND SEX. G. Shor-Posner, G. Brennan*, R. Jasaitis*, B. Leibowitz* and S.F. Leibowitz. The Rockefeller University, New York, N.Y. 10021

Our understanding of eating patterns in young animals may help us to identify predisposing factors in the development of eating disorders. In this study, the natural feeding behavior and dietary selection patterns of 20 weanling rats, maintained on pure macronutrients, were examined.

Analyses revealed striking differences in diet selection as a function of sex and age. In weanling animals: females tended to consume more of the carbohydrate diet than did the males (27 vs 21 Kcal), who ate significantly more fat (16 vs 8 Kcal). During puberty and adolescence: an early rise in protein intake was observed, followed by a sharp decline in young adults of both sexes. Fat intake increased over time and preference for this diet was positively related to body weight. Rats heavy initially (82g at 28 days) ate 54% of their diet as fat 6 weeks later; this is compared to leaner rats (68g at 28 days) that subsequently ate only 38% as fat. A similar correlation became apparent in females only after the onset of puberty. These findings indicate that initial body weight and sex of the young animal may be critical factors in determining natural patterns of eating and body weight gain.

EFFECTS OF GOSSYPOL ON FOOD INTAKE AND BODY WEIGHT M.Chitcharoenthum* and J.E.Cox.(SPON:S.Mangel) Dept. Psychol.Univ.Alabama at Birmingham,Birmingham Al 35294.

Decreases in food intake (FI) and body weight (BW) are side effects of chronic treatment with gossypol,a polyphenolic compound from cotton plant. We examined how gossypol depresses BW. In the first experiment, gossypol acetic acid (GAA) was injected (10 mg/kg BW;sc) into young 5-wk old rats daily for 6 days. BW and FI were decreased significantly. BW remained depressed after the termination of treatment even though FI recovered. Carcass analysis showed that body fat content of GAA-rats was less than half that of controls. Behavioral observations of young rats during feeding (three meals/day and 2h/meal) showed that the GAA- and control rats had similar feeding latency and duration but differed significantly in daily FI within the first week of treatment. In young rats, GAA and thyroidectomy depressed basal oxygen consumption similarly (measured at 0,4,and 8 days of treatment). Free thyroxine levels in GAA-rats were significantly lower than in controls within 2 days of treatment. These results suggest that gossypol affects metabolism by depressing thyroid function and this action may be responsible for the effect of GAA on BW. However, daily sc injection of T4 (800 ng/rat) or T3 (3 ng/rat) did not prevent the effect on BW. This suggests the involvement of other mechanisms in the BW-depressant effect of gossypol. Similar results were also observed in adult rats.(supported by NSF BNS-8606768)

RELATIONSHIP BETWEEN PLASMA OSMOLALITY AND EXTRACELLULAR FLUID NEUROCHEMICAL CONCENTRATIONS IN THE LATERAL HYPOTHALAMUS AS MEASURED BY IN VIVO DIALYSIS. P.A. Mason, D. Bhaskaran, and C.R. Freed. Depts. of Med. and Pharm., Univ. Colo. Health Sci. Ctr., Denver, CO 80262.

Previously, we have reported that plasma osmolality is inversely related to extracellular fluid catechol concentration in the lateral hypothalamus (LH) as measured by in vivo electrochemistry (EC) (J. Neurochem., June 1988). Since the composition of the EC signal is ambiguous, we have repeated the experiments using in vivo dialysis. Male Sprague-Dawley rats had guide cannulae implanted above the LH. One week after surgery, rats were water-restricted for 48 hr. On the test day, a 300 u x 1.5 mm dialysis probe was inserted and perfused with Ringer's solution (1.5 µl/min) as the rats drank distilled water or 0.9% saline. Dialysate was assayed by microbore HPLC to determine the concentrations of ascorbic acid, uric acid, epinephrine, norepinephrine, and dopamine. Results showed that the ascorbic acid concentration increased in response to drinking distilled water, but not 0.9% NaCl. No consistent change was observed in the uric acid concentration. Results for epinephrine, norepinephrine, and dopamine are pending. These data suggest that ascorbic acid release from the LH is related to changes in plasma osmolality.

POTENTIATION OF TRANSMITTER-RELATED FOOD INTAKE REDUCTION BY CYCLO(HIS-PRO). L.-M. Kow, K. Shiosaki,* A. Nadzan* and D.W. Pfaff. The Rockefeller University, New York, N.Y. 10021, and Abbott Laboratories.

Our electrophysiological evidence suggests that cyclo(His-Pro) [cHP], a metabolite of TRH, can inhibit food intake (FI) by modulating actions of neurotransmitters (Exp Brain Res 67:93, '87). To test this, we investigated effects of intracerebroventricular infusion of cHP or saline combined with IP injection of d-Amphetamine (Amph. 0.4 mg/kg), d-Fenfluramine (Fenf. 3.0, 1.5, or 0.75 mg/kg) or saline on the FI of food-deprived male rats. Amph treatment inhibited FI to 56, 73, and 94% of the baseline level at 1, 2, and 7 hrs, respectively, after food presentation. cHP alone at 1 umole/rat had no effect on FI, but when combined with Amph, potentiated the inhibition of FI to 28%, 40%, and 70% respectively. Such a potentiation was also observed, in a dose-dependent fashion, with cHP at 0.5 and 0.05 umole/rat. Similarly, combined cHP (1 umole/rat)-Fenf caused twice as much inhibition of FI as saline-Fenf treatment at every Fenf dose and time point. Thus, cHP potentiates FI reduction by Amph and Fenf, probably by modulating neurotransmitters released with Amph or Fenf treatment.

DEFECTIVE BRAIN GLUCOSE UTILIZATION IN OBESITY-PRONE RATS. B.E. Levin and A.C. Sullivan*. Neurology Svc., VA Med. Ctr., E. Orange, NJ 07019, and Dept. Pharmacol. and Chemotherapy, Hoffmann-LaRoche, Nutley, NJ 07110.

Only half the male Sprague-Dawley rats develop diet-induced obesity (DIO) when fed a high energy (HE) diet. Resistance to developing DIO can be predicted before exposure to the HE diet by the presence of lower glucose-induced plasma norepinephrine (NE) levels (AJP 253:R476, 1987). Here, chow-fed diet resistant (DR; n=10) and DIO-prone (n=10) male rats were prospectively identified by the areas under their glucose-induced (1g/kg, i.v.) NE curves (DR<4000 and DIO>4000 pg/ml/60min). DR- and DIO-prone rats (4h) were then trained to drink 1ml of 50% glucose in 1min and then were tested for local cerebral glucose utilization (LCGU). Rats were fasted for 4h and then given a bolus of ^{14}C 2-deoxyglucose (30µCi, i.v.). Control rats (C) received no solution while S rats received 1ml of oral 0.15% saccharin in place of glucose. Cerebral autoradiograms of DR-prone rats showed 60-190% increases in medullary (a. postrema, n. tr. solitarius, dorsal motor n. X) LCGU in the S versus C conditions. This increased forebrain LCGU to S but DR-prone rats had 25% greater LCGU in the ventromedial hypothalamus than DIO-prone rats. Thus, DIO-prone rats had specific defects in brain LCGU which might be associated with their tendency to become obese on HE diets.

ANGIOGENESIS IN INTRACEREBRAL GRAFTS OF CNS AND PITUITARY TISSUES.
R. Broadwell, W. Hickey*, and A. Wolf*. Univ. Maryland Sch. Med., Balto., MD 21201 and Washington Univ. Sch. Med., St. Louis, MO 63110

The vascularization of solid grafts from Lewis rat fetal CNS and adult anterior pituitary tissues placed stereotaxically into the third cerebral ventricle of AKR nude mice was investigated immunohistochemically with biotinylated primary antisera against rat or mouse class I major histocompatibility complex (MHC). HRP conjugated to avidin was used to localize and identify the antigen-antibody reaction. Host mice were given intraperitoneal injections of gamma interferon (50,000 units) for 3 days before sacrifice. Brains of host mice were frozen, and 5u-thick cyrostat sections were prepared for immunostaining. Both types of donor tissue contained blood vessels at the time of grafting; however, blood vessels supplying CNS grafts were not perfused with host blood until after 7 days post-transplantation, whereas blood vessels of anterior pituitary grafts received host blood prior to 3 days post-transplantation. H & E stained sections contained cells within grafts. At 21 days, immunostaining for rat class I MHC revealed that vessels indigenous to the donor tissues were sustained within the grafts and that these graft vessels failed to enter host mouse brain parenchyma. Immunostaining for mouse class I MHC demostrated HRP-reactive blood vessels throughout the host brain and within the grafted rat tissues. The grafted CNS tissue exhibited a blood-brain barrier to blood-borne HRP; grafted anterior pituitary tissue did not. Ultrastructural inspection of blood vessels supplying CNS grafts disclosed typical blood-brain barrier endothelia; endothelia in anterior pituitary grafts were fenestrated. The results suggest that blood vessels supplying intracerebral grafts of CNS and peripheral tissues are derived from both the host and donor and that the grafted tissue dictates the type of endothelial cell inhabiting the graft.

308.2

CHARACTERIZATION OF THE ENDOTHELIAL BARRIER IN NEURAL TRANSPLANTS AND RELATED TISSUES.
J.M. Rosenstein, L.A. Sternberger and N.H. Sternberger. (Spon. J. Bernstein). Depts. of Anatomy, George Washington Univ., Wash.,D.C. 20037 and Univ. of MD Sch. of Med., Baltimore, MD 21201.

A monoclonal antibody, endothelial barrier antigen (EBA) recently described (PNAS 84:8169) can be used to determine both the location and morphology of blood-brain and blood nerve barriers in vivo and has the potential for elucidating the biochemical basis of the endothelial cell barrier. We have utilized anti-EBA to characterize barrier properties during neovascularization of neural transplants and correlated observed barrier dysfunction as depicted by protein exudation with potential vascular changes. Normally, in aldehyde fixed paraffin sections all microvessels, including pial, not related to permeable regions stain strongly with anti-EBA. Fetal CNS grafts in lateral or IV ventricle are vascularized by choroidal vessels which did not stain for anti-EBA and neither did many pial vessels incorporated into CNS grafts. Vessels within autonomic tissue grafts as expected did not stain since they are rarely invaded by CNS vessels. Interestingly, vessels of the iris, like pial vessels which are barrier-competent lacking direct astrocytic contact, stained strongly for anti-EBA. The EBA antibody can be a useful probe for determining barrier properties in neural grafts and adjacent host tissues. (Supported by NS-17468 and NS-24185).

THE BLOOD-BRAIN BARRIER IN INTRACEREBRAL ALLOGRAFTS OF HYPOTHALAMUS AND NEOCORTEX.
S.J. Wiegand and J.T. Hansen. Dept. of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, NY 14642.

Recently, it has been reported that grafts of fetal neocortex exhibit a marked and essentially permanent blood-brain barrier (BBB) dysfunction (Science, 235:772, 1987). Longstanding disruption of the BBB could adversely affect the function, and ultimately the survival of CNS allografts. Therefore we have reexamined this issue using our standard grafting protocol. Donor tissues were obtained from the neocortex or anterior hypothalmus of Long-Evans fetuses (E17) and transplanted to the periventricular hypothalamus/third ventricle of adult male Long-Evans rats. Experimental and control animals received an injection of horseradish peroxidase (HRP, 200 mg/kg, IV) between 15 min. and 12 hrs. prior to sacrifice. Light microscopic analysis of TMB and DAB reacted sections revealed that the parenchyma of the transplants were largely free of diffusely distributed HRP reaction product, except where the grafts were adherent to the median eminence or subfornical organ of the host brain, or where other host tissues having a 'leaky' vasculature (choroid plexus, dura mater) became intimately associated with the transplants. Diffuse labeling, similar in extent and intensity to that observed within the grafts, also was noted in areas of host and control brains that were contiguous with circumventricular organs (eg basal hypothalamus), suggesting that intravenously injected HRP entered the grafts only by way of the host brain and not by extravasation from vessels inherent to the transplants. Ultrastructural analysis confirmed that capillaries in all regions of the transplants exhibited features of normal CNS vasculature (non-fenestrated endothelia with occluding junctions and low to moderate levels of endocytosis). These observations support the contention that CNS allografts develop a characteristic and competent BBB.

VASCULAR MORPHOLOGY AND PERMEABILITY IN FETAL CNS GRAFTS TO THE SUBCAPSULAR KIDNEY SPACE.
J.F. Naradzay and J.M. Rosenstein. (Spon. K. Peusner). Department of Anatomy, George Washington Univ. Sch. of Med., Wash. D.C. 20037.

Recent studies have shown that the BBB to protein in fetal neocortical tissue is altered when grafted into the brain ventricle. According to conventional neovascularzation theory, due to local tissue factors, any CNS graft would be expected to have a blood-brain barrier (BBB). In order to determine if grafted CNS would alter the phenotype of ingrowing peripheral vessels we have utilized a relatively uncomplicated model. We transplanted rat fetal cortex which already has a BBB to protein, to the subcapsular space of the rat kidney. After postoperative times between 2 weeks and 3 months HRP was injected systemically for periods between 1 and 4 minutes to determine permeability characteristics. Correlative EM depicted vascular morphology. Each graft contained protein exudate particularly around large vessels in the neuropil. At the EM level these vessel endothelium had fenestrations, were invested with collagen and were not contacted by glia; capillaries indigenous to the CNS graft were also found. The presence of non-CNS blood vessels with certain peripheral vessel ultrastructural and permeability characteristics would appear to contradict angiogenesis dogma in that CNS grafts can receive and do not alter vessels of a different phenotypic or physiologic nature. (Supported by NS-17468).

EFFECTS OF HIPPOCAMPAL TRANSPLANTS WITH OR WITHOUT NERVE GROWTH FACTOR (NGF) ON SEPTAL CHOLINERGIC NEURON SURVIVAL.
G.V. Smith & L.F. Kromer, Dept. of Anat. & Cell Biol., Georgetown Univ., Washington, D.C.

Previous studies have demonstrated that implants of fetal hippocampal (HPC) tissue can promote the regeneration of injured axons in the septohippocampal pathway and that intraventricular infusions of NGF prevents the death of medial septal neurons following transection of the fornix-fimbria (F/F). Thus, the present experiments were conducted to determine whether the combined use of NGF infusions plus embryonic transplants optimizes the long-term survival of septal neurons after axotomy. For these studies adult rats were randomized into 4 experimental and 2 control groups. Group I received a simultaneous F/F lesion and HPC transplant. Group II received NGF for 2 weeks following the F/F lesion. Group III received both NGF for 2 weeks and was also given a HPC transplant 1 week following the lesion. Group IV was lesioned 1 week prior to receiving the HPC transplant, but was not given NGF. Group V received only the F/F lesion. Group VI received a simultaneous F/F lesion and an "inappropriate" neural transplant. Eight weeks after the F/F lesion the specimens were evaluated for the survival of choline acetyltransferase-positive cells. Statistical analyses of our preliminary data suggest several interesting findings. Most importantly, there were no differences between groups receiving NGF alone or in combination with a HPC transplant. However, both of these groups differed from control groups and groups receiving only HPC transplants. These preliminary results support earlier reports that NGF may be critical for septal cholinergic neuronal survival following axotomy and suggest that embryonic transplants alone may not provide as strong a survival effect. (Supported by NIA grant #AG-06648)

MODULAR ORGANIZATION OF FETAL STRIATAL GRAFTS
F.-C. Liu*, A. M. Graybiel and S. B. Dunnett. (SPON: B. Seltser) Dept. Brain & Cognitive Sciences, MIT, Cambridge, MA 02139

Intrastriatal grafts were made by injecting dissociated cells of E15 ganglionic eminence into adult rat striatum pretreated 7 days before with ibotenic acid. Some donors had been exposed to 3H-thymidine at E11-E15. After 9-16 month survivals, the grafts, as reported by Walker et al '87, Isacson et al '87 and Graybiel et al '87, displayed a modular organization in which acetylcholinesterase (AChE)-positive patches (P) appeared in an AChE-poor surround (nonpatch, NP). We tried to determine whether (a) both P and NP were donor tissue; (b) both P and NP were striatal tissue; (c) the P regions resembled striosomes, matrix or both. The 3H-thymidine study showed that the graft tissue was donor tissue. Many markers characteristic of normal striatum were expressed in the P regions: tyrosine hydroxylase, perikaryal met-enkephalin (ENK) and calcium binding protein (CaBP, Gerfen et al, PNAS '85) immunoreactivities, dopaminergic and muscarinic binding and binding for choline uptake sites. None of these markers were expressed strongly in NP regions. By contrast, cells uncharacteristic of striatum were found in the NP regions: large CaBP-positive neurons and similar large somatostatin-positive neurons. These findings raise the possibility that the NP regions were not striatal. The NP regions were probably not pallidal either because they lacked epidermal growth factor-like immunoreactivity (Fallon et al, '84). Most of the P tissue resembled striatal matrix in having CaBP- and ENK-positive medium size neurons and (2 cases) lacking high 3H-naloxone binding. We conclude that the modular organization of the grafts may represent a modular admixture of striatal and nonstriatal tissue. *We thank Drs. Gerfen, Fallon and Loughlin for antisera, and NSF BNS83-19547 & BNS-8720475.*

TRANSPLANTS OF FETAL HIPPOCAMPAL TISSUE IMPAIR ACQUISITION OF THE MORRIS WATER MAZE BY RATS WITH HIPPOCAMPAL ABLATIONS. M.L. Woodruff, A.J. Nonneman, R.H. Baisden and D. L. Whittington*. Dept. of Anatomy, Col. of Med., East Tenn. St. Univ., Johnson City, TN 37614 and Dept. of Psych., Univ. Kentucky, Lexington, KY 40506.

Transplantation of fetal hippocampal tissue produces recovery of behavioral function in hippocampal damaged rats in the Rabinovitch-Rosvold mazes (Kimble et al. Brain Res. 363:356, 1986) and in the DRL task (Woodruff et al. Brain Res. 408:97, 1987). This study was conducted to determine whether such transplants would also reduce the impairment in acquisition of the Morris water maze that follows hippocampal lesions in rats. Rats with hippocampal lesions were compared to normal rats or rats with either grafts of fetal hippocampus or cerebellum/brainstem. Testing in the water maze began 120 days postoperatively. The dependent variables included the swim time to find a submerged platform over 10 daily trials and the amount of time spent in the area of the platform on two probe trials with no platform in the tank. Statistical analysis indicated that the rats with hippocampal lesions were impaired in the water maze relative to normals, but that the transplanted rats were more impaired than the rats receiving just hippocampal lesions. These results indicate task differences in the ability of transplants to produce recovery. (Supported by USPHS Grant #ES04070 to MLW.)

FETAL NEOCORTICAL TRANSPLANTS IMPROVE SPATIAL BEHAVIOR IN OLD MICRENCEPHALIC RATS. M.H. Lee, A. Rabe and P. Wang*. New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314

Transplantation of fetal brain tissue has been shown to partially restitute impaired function associated with aging. Using an animal model of micrencephaly, we sought to determine whether functional deficits associated with congenital brain abnormalities could also be ameliorated by neural transplants. Transplants consisted of solid neocortical tissue (10-20 mm^3) of normal E18 fetuses, grafted onto the posterior neocortex of 10-day old micrencephalic rats. Micrencephaly was induced during fetal development by injecting the pregnant dam with methylazoxymethanol acetate (30mg/kg, E15). The offspring has been shown to be permanently impaired on a variety of spatial problems, including Morris water maze in which both immature (1 mo) and mature (6 mo) micrencephalic rats showed profound deficit in locating a hidden platform. At 2 years of age, transplant-bearing micrencephalic (MT) rats were tested in the Morris maze with micrencephalic (MC) and normal (NC) controls. As compared to the NC, the MC rats were again impaired in terms of both the time spent to locate the platform ($p<.01$) and the number of trials required to reach the criterion (10 sec) performance ($p<.01$). The transplants did help the MT rats improve their performance: they were not only significantly superior to the MCs on both measurements ($p<.05$), but also indistinguishable from NC rats on the criterion measure.

Polymer Brain Implants for Controlled Release of Dopamine: in vitro and in vivo observations.

B.A. Sabel, A. Freese[1], M. During[2], M. Saltzman[1] and R. Langer[1]. Dept Med Psychol, Univ Munich Medical School, Fed. Rep. Germany; Dept Chem Eng, M.I.T., Cambridge[1]; Dept Pharmacol, Yale Univ, New Haven, USA[2].

Brain tissue implants can reverse some of the behavioral and biochemical deficits associated with brain lesions. It has been proposed that these effects may be in part due to a non-specific release of neurotransmitters. Therefore, as an alternative to tissue implants, we have developed a controlled-release polymer matrix which can release a neurotransmitter, dopamine (DA), at a controlled rate for an extended period of time.

A variety of DA-containing matrices were prepared and release kinetics were studied in vitro. DA-release was monitored by spectophotometry (280 nm) and confirmed by HPLC. The release in vitro depended on the geometry and loading of the polymer matrix, and in some configurations, linear release of DA occured for at least 65 days.

Matrices were then implanted unilaterally into the brain of rats onto the dorsal surface of the caudate nucleus after aspiration of overlying neocortex. Intrastriatal microdialysis revealed that DA-levels in extracellular fluid (ECF) were constant from 20 days throughout the length of the experiment (65 days) and reached unprecedented elevations to 7.2 µM of DA (normal is 26 nM).

The possibility that these polymers may be effective in reversing some of the behavioral deficits associated with brain lesions is now under study. However, we believe that the controlled release polymer technology provides a novel method for delivering substances into the brain.

308.10

IMPLANTABLE MICROENCAPSULATED DOPAMINE (DA): A NOVEL MEANS FOR SLOW-RELEASE OF DA INTO BRAIN TISSUE. A.McRae[1], S.Hjorth[2], L.Dillon[3]*, D.Mason[3]* & T.Tice[3]*. University of Göteborg, Departments of [1]Histology and [2]Pharmacology, S-40033 Göteborg, Sweden, and [3]Southern Research Institute, Birmingham, AL 35205, USA.

Biodegradable controlled-release systems constitute an exciting new technology for drug release in the CNS. DA was encapsulated in a thermoplastic polyester excipient: poly [DL-lactide-co-glycolide], which is of the same class of material used to make resorbable sutures. Ten male rats were unilaterally lesioned in the ascending median forebrain bundle using 6-OHDA (8µg/4µl). When a stable baseline apomorphine rotational response for all rats was established - 4-7 weeks after 6-OHDA lesion - they were sterotaxically injected under ether anaesthesia with 3µl of a DA microcapsule suspension into 2 sites in the denervated lateral striatum. Controls received empty capsules. Thirty minutes following the injections rats were placed into the rotometers and their behavior was recorded for the subsequent 2-4 hours. Rats with DA microcapsules exhibited contralateral rotation with an amplitude comparable to that of apomorphine. Control rats did not show any rotational behavior. Furthermore, preliminary results indicated that rats receiving DA microcapsules showed attenuated rotational responses to apomorphine (mixed D1/D2 agonist) and (-)-3PPP (D2 agonist/antagonist) up to 3 weeks following implantation. Histological analysis with anti-DA antiserum confirmed the presence of DA in the capsules 3-4 weeks following the injection. The present data indicate that it is possible to attain functional significant amounts of DA for prolonged periods of time by injecting microencapsulated DA directly into brain tissue. This novel "slow-release" approach may become useful not only in basic neuroscience research but also in the clinical management of neurodegenerative disorders.

308.11

MAGNETIC RESONANCE IMAGING OF RAT BRAIN FOLLOWING FETAL STRIATAL TISSUE TRANSPLANTS. A.B. Norman, S.R. Thomas*, R.G. Pratt*, R.C. Samaratunga*, M. Kolmonpunporn and P.R. Sanberg. Lab. of Behavioral Neuroscience, Depts. of Psychiatry and Radiology, University of Cincinnati College of Medicine, Cincinnati, OH 45267-0559.

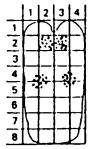
Magnetic resonance imaging (MRI) provides an excellent method for visualizing brain pathologies. Kainic acid (KA) lesions of rat striatum produce a degeneration of the striatum with a concomitant dilation of the lateral ventricles. Fetal striatal tissue transplants into the KA-lesioned striatum reverse the functional deficits produced by the lesion. However, it is generally necessary to kill rats in order to correlate the survival, growth and location of the transplants with functional recovery. We examined the ability of MRI to visualize lesions and transplanted tissues in vivo.

Twelve male rats received unilateral striatal KA lesions (5 or 10 nmol). Four weeks later rats were anesthetized, their heads placed into a 5.1 cm diameter radio frequency coil for subsequent imaging at 0.15 Tesla. T_1 weighted scans using 3.5 mm coronal sections clearly showed the enlarged ventricles on the lesioned side. Hippocampal damage was also observed in some of the rats. These lesions were confirmed by histological techniques in five rats. T_2 weighted scans demonstrated that the remaining lesioned striatal tissue was abnormal compared to the contralateral side. Four weeks following transplants of E17 fetal striatal tissue in the lesioned striatum, two rats were imaged. Changes were evident in the MR images, possibly as a result of the transplanted tissue. Histological verification will be necessary to confirm this conjecture. MRI with its excellent discrimination of tissues and CSF appears to provide a non-invasive method for monitoring lesions and subsequent transplants in vivo.

308.12

FETAL (E.17) CATECHOLAMINERGIC BRAINSTEM NEURONS FOR GRAFTING: LOCALIZATION, CHARACTERIZATION AND VIABILITY. Yves Sauvé*, J.W. Commissiong & G. Toffano (Spon. D.G. Watt). Dept. of Physiol., McGill Univ., Montreal, Canada H3G 1Y6 and Fidia Res. Lab. 35031 Abano Terme, Italy.

The present report deals with the characterization of fetal (E.17) rat catecholaminergic (CA) neurons used for grafting in the CNS. The fetal brainstem was dissected as illustrated (32 x by 1.0 mm^3), and cell suspensions prepared from the shaded areas, were smeared on coated slides (1% gelatin, 1% albumin), and then processed for histofluorescence. A high population of CA neurons was found in 2-2/2-3 (MES) and 4.5-1.5/4.5-2.5 (LC) (Brain Res. 380: 205-215, 1986). A high proportion of the neurons from the MES were morphologically intact with somatic dendrites and complete axons. The brainstem was perfused with a 0.1% paraformaldehyde solution and 16 µm sections processed for histofluorescence. The MES appeared as two cell clusters located medially and rostrally (2-2, 2-3) and the LC was located more caudally (4.5-1.5, 4.5-2.5). The viability of both the MES and LC cells in suspension, as assessed by the vital stains acridine orange and ethidium bromide (in a 0.8% NaCl/0.6% glucose; 307 mOsm), was > 60% for up to 24 h. These results provide reproducible methods for obtaining brainstem catecholaminergic cells for grafting.



309.1

THE EFFECT OF COCAINE AND SCH 23390 ALONE AND IN COMBINATION ON MILK INTAKE IN RATS. D. Rapoza* and W. L. Woolverton. Drug Abuse Research Center, The University of Chicago, Chicago, IL 60637

Recent research suggests that D1 dopamine (DA) receptors may play an important role in the behavioral effects of psychomotor stimulants. The present study examined the effects of cocaine and the D1 DA antagonist SCH 23390, administered alone or in combination, on milk intake in rats. Ten male Sprague-Dawley rats were given access to a milk solution (2:1 tap water:Bordens sweetened condensed milk) for 15 min each day. When intake was stable, dose-response functions were determined for cocaine (4.0 - 32 mg/kg, i.p., 10 min pre-session) administered alone or in combination with SCH 23390 (0.12 - 0.5 mg/kg, i.p., 30 min pre-session). The mean baseline intake was 95 ml/kg. Both cocaine (4.0 - 32 mg/kg) and SCH 23390 (0.12 - 0.5 mg/kg) caused dose-dependent decreases in milk intake. Intake that had been reduced to 7 ml/kg by 16 mg/kg cocaine was restored by SCH 23390 (0.12 [N=7], 0.25 [N=6], and 0.5 [N=5] mg/kg) to 42, 37, and 50 ml/kg, respectively. Similarly, intake that had been reduced to 43 ml/kg by 0.5 mg/kg SCH 23390 was restored by cocaine (4.0 or 8.0 mg/kg) to 65 or 62 ml/kg, respectively. Thus, there was a mutual attenuation of the effects of cocaine and SCH 23390 on milk intake when the two drugs were combined. These results suggest that D1 receptors play a role in the effects of cocaine on milk intake in rats, and are consistent with the hypothesis that D1 receptors are permissive in the expression of the behavioral effects of cocaine. (Supported by NIDA grant DA-00250)

309.2

EFFECTS OF (+)-MDMA AND (-)-MDMA ON THE THRESHOLD FOR REWARDING BRAIN STIMULATION: FURTHER EVIDENCE FOR DOPAMINERGIC MEDIATION OF MDMA'S REINFORCING EFFECTS. M. Bird and C. Kornetsky. Laboratory of Behav. Pharmacol., Boston University School of Medicine, Boston, MA 02118.

We recently reported inhibition of the threshold lowering effects of rewarding brain stimulation of (+,-)-MDMA (3,4-methylenedioxymethamphetamine) by D2 but not 5-HT2 antagonist, and that reinforcing doses of (+,-)-MDMA (ED50=0.70 mg/kg) increased striatal dopamine (DA) turnover without significantly altering 5-HT metabolism (Soc. Neurosci. Absts. 13:1323, 1987). Current evidence indicates 5-HT stereoselectivity for (-)-MDMA, (Psychopharmacol. 88:525, 1986), while (+)-MDMA has comparatively greater DA releasing activity (Eur. J. Pharmacol. 132:269, 1986). The relative effects of MDMA's enantiomers on the reward threshold in F-344 male rats with electrodes in the medial forebrain bundle were determined to further assess the contribution of 5-HT and DA in (+,-)-MDMA's euphoriant properties. Although both isomers lowered the threshold, (+)-MDMA had greater efficacy and potency than (-)-MDMA (ED50=0.30 and 1.70 mg/kg, respectively). These results offer additional evidence that (+,-)-MDMA activates central reward pathways via dopaminergic processes. GBR BINDING IN THE NUCLEUS ACCUMBENS. P.S. Berger*, J.D. Elsworth, J. Arroyo*, and R.H. Roth. (Spons: D.L. Rosin). Depts. Pharmacol. & Psychiat., Yale Univ. Sch. Med., New Haven, CT 06510.

Some of the behavioral actions of cocaine may be dependent on dopaminergic activity in the nucleus accumbens (NAc), since 6-hydroxydopamine lesions of this area abolish both the reinforcing effects of cocaine in the self administration paradigm and the increase in locomotor and rearing behaviors produced by low doses of cocaine. However, it has been reported (J. Neurochem., 1985, 45: 51-56) that cocaine does not inhibit dopamine (DA) uptake in the NAc and that Na^+-dependent ^{3}H-cocaine binding is absent in the NAc. In striatum GBR-12935 has a much higher affinity for the DA uptake carrier (Kd=1 nM) than cocaine (Kd=400 nM). Therefore we have characterized ^{3}H-GBR binding in the NAc and re-examined the effect of cocaine on DA uptake in the NAc. ^{3}H-GBR was found to bind with high affinity in the NAc with an apparent Kd of approximately 1 nM. The IC50 values for the displacement of ^{3}H-GBR by a series of compounds including cocaine, methylphenidate, DA, nomifensine, GBR-12935, phenylcyclidine, mazindol and benztropine in the NAc correlates well with their IC50 values in striatum (r=.99). In a P2 preparation of NAc, cocaine inhibited DA uptake potently with an IC50 value of 400 nM. These biochemical data are consistent with the hypothesis that interaction of cocaine with the DA uptake carrier in NAc may be involved in the reinforcing effects of cocaine. Supported by NIH Grant DA 05119.

$5HT_3$ ANTAGONIST SPECIFICALLY BLOCK MORPHINE AND NICOTINE-REWARD. G.Di Chiara, E.Acquas, P.Leone and E.Carboni. Inst. of Exp. Pharmacology and Toxicology, Univ. Cagliari, 09100 Cagliari, Italy.

The effect of two potent and specific antagonists of $5HT_3$ receptors, ICS 205-930 and MDL 72222, on the reinforcing properties of amphetamine, morphine and nicotine was studied in rats. Drug-induced reinforcement was assessed by measuring drug-conditioned place-preference. ICS 205--930 and MDL 72222 dose-dependently reduced the place-preference induced by morphine (1.0 mg/kg s.c.). At doses of 30 μg/kg s.c. the two antagonists completely blocked morphine-induced place-preference while doses of 15 μg/kg s.c. significantly reduced it. ICS 205-930 and MDL 72222, at doses of 30 μg/kg s.c. also prevented the place-preference induced by nicotine (0.6 mg/kg s.C.). In contrast, ICS 205-930 and MDL 72222, up to doses of 30 μg/kg s.c. failed to modify the place-preference conditioning elicited by amphetamine (1.0 mg/kg s.c.). The results indicate that $5HT_3$ receptors are specifically involved in the reinforcing properties of morphine and nicotine.

309.5

THE EFFECTS OF NICOTINE ON BRAIN-STIMULATION REWARD. D.J. Lyons, G.T. Bain and C. Kornetsky Laboratory of Behavioral Pharmacology, Boston Univ. Sch. Med., Boston, MA 02118.

The purpose of this experiment was to determine if nicotine increases sensitivity of animals to rewarding electrical intracranial stimulation, a model of drug-induced euphoria. Bipolar electrodes were stereotaxically implanted into the medial forebrain bundle-lateral hypothalamic area of male F344 rats. Doses of nicotine from 0.25 to 0.75 mg/kg consistently increased the subject's sensitivity to electrical stimulation, i.e., lowered the threshold, in a fashion similar to that seen with other drugs of abuse. In addition, co-administration of a low, ineffective dose of nicotine with an ineffective dose of morphine (0.25 mg/kg) or amphetamine (0.06 mg/kg) resulted in significant increases in sensitivity to the stimulation. These results suggest that the reinforcing effects of nicotine acts through the same neural systems as these other drugs. However, in striking contrast to naloxone's ability to block the threshold lowering effects of morphine, cocaine or amphetamine, naloxone failed to attenuate the threshold lowering effects of nicotine in 3 of 4 animals. These results suggest that although nicotine may act in part through neural systems that support opiate and psychomotor stimulant reward there also may be important differences. [(Support in part by NIDA grant DA 02326 and Research Scientist Award DA 00099 (CK)].

309.6

RIMCAZOLE (RMZ), A NOVEL ANTIPSYCHOTIC, BLOCKS THE ACTIVATION OF A_{10} DOPAMINE NEURONS BY PHENCYCLIDINE AND (+)SKF 10,047, A σ-AGONIST. E.D. French, M. Smith* and A. Ceci*, Dept. Pharmacol., Univ.Arizona, Coll.Med., Tucson, AZ. 85724

RMZ's preclinical and clinical antipsychotic profile has been suggested to be due to its selective affinity for central σ-binding sites. Since both σ-agonists and PCP activate the mesocorticolimbic dopamine neurons, we assessed the ability of RMZ to attenuate these actions.

Single-unit extracellular recordings from VTA A_{10} neurons in chloral hydrate anesthetized rats showed that RMZ pretreatment (2.5 or 10 mg/kg) significantly attenuated the approximate 43% increase in firing rate elicited by both PCP and (+)SKF; the former appearing more sensitive to antagonism. RMZ did not alter spontaneous activity or apomorphine-induced slowing of these dopamine cells. Also, the naloxone-sensitive activation of A_{10}'s by morphine was not affected by RMZ, nor did naloxone affect the stimulatory effects of either PCP or SKF, thus indicating an apparent selective blockade of PCP and SKF by RMZ. Interestingly, in behavioral studies RMZ effectively antagonized only the locomotor stimulatory effects of (+)SKF, but not PCP. These latter findings might best be explained by the fact that PCP's behavioral effects, unlike those of (+)SKF, are preferentially mediated through presynaptic dopamine mechanisms. Notably, RMZ also did not attenuate morphine- or d-amphetamine-induced hyperactivity. Moreover, the electrophysiological and behavioral effects of (+)SKF were antagonized by the selective σ-agonist, DTG.

These results suggest that RMZ's moderate efficacy in ameliorating schizophrenic symptoms may be related to its ability to antagonize PCP &/or σ-sites on mesocorticolimbic dopamine neurons.

309.7

ACUTE NEUROENDOCRINE RESPONSE TO CANNABINOID TREATMENT IN THE MALE RAT. L.L. Murphy*, R.W. Steger*, M.S. Smith* and A. Bartke* (SPON: P. Consroe). Depts of Physiology, Southern IL Univ Sch of Med, Carbondale IL 62901 and Univ of Pittsburg, Pittsburg, PA 15261.

The acute neuroendocrine responses to low doses of delta-9-tetrahydrocannabinol (THC), cannabinol (CBN) and cannabidiol (CBD) administered alone or in combinations were evaluated by measuring plasma luteinizing hormone (LH) and prolactin (Prl) levels and norepinephrine (NE), dopamine (DA) and serotonin (5-HT) dynamics within the hypothalamus at specific times after oral cannabinoid treatment. Adult male Sprague-Dawley rats were given p.o. a sesame oil vehicle (controls) or a low dose (0.5 mg /kg b.w.) of THC, CBN, CBD, THC+CBN or THC+CBD and were sacrificed by decapitation 30, 60 or 120 min after treatment. Only the dosing regimens of THC+CBN and THC+CBD significantly reduced plasma LH at every interval tested to 50-60% of values measured in vehicle controls (30 min, $p<0.05$; 60 min, $p<0.05$; 120 min, $p<0.01$). In addition, plasma LH levels were reduced to 55% of control values 60 min after THC administration ($p<0.05$). There were no changes in plasma Prl in response to cannabinoid treatments. All the cannabinoid treatments dramatically affected NE turnover in the median eminence (ME) and medial basal hypothalamus (MBH). There was complete suppression of NE turnover at 30 min post-THC and 120 min post-THC+CBN in the ME and 120 min post-THC+CBD in the MBH. Cannabinoids did not significantly affect MBH-DA turnover or 5-HT content. These data demonstrate that treatment with a low dose of THC alone or in combination with CBN or CBD suppresses LH secretion and further suggests that alterations in hypothalamic noradrenergic activity may be the mechanism of cannabinoid action. CHRONIC COCAINE REDUCES ALPHA-2 RECEPTOR ELICITED MYDRIASIS AND INHIBITION OF LOCUS CERULEUS. J. Marwah, A. L. Curtis and D. Pitts. Wayne State University, Detroit, MI 48202.

The effects of chronic cocaine (50 mg/kg/day for two weeks) administration on alpha$_2$ adrenoceptor mediated responses were studied in rats. Chronic administration of cocaine significantly (compared to sham controls) attenuated the alpha$_2$ adrenoceptor mediated inhibition of noradrenergic locus ceruleus (LC) neurons as well as alpha$_2$ adrenoceptor elicited mydriasis. Noradrenergic LC neurons from the cocaine treated and sham groups differed significantly in their responsiveness to the inhibitory effects of clonidine (ED_{50} values ug/kg were sham 7.35 +/- 1.13 and cocaine treated 17.17 +/- 4.40 $p < 0.05$). The ED_{50} values for the mydriatic response were sham 5.71 +/- 0.49 and cocaine treated 16.42 +/- 0.69 ug/kg respectively $p < 0.001$. No differences in cardiovascular responses to systemically injected clonidine between the chronic cocaine and sham treated groups were observed. Chronic cocaine treatment attenuates the two alpha$_2$ adrenoceptor mediated responses most likely via an interaction with central catecholaminergic neurotransmission. (Supported in part by a NIDA grant DA 04158.)

EFFECTS OF COCAINE ON ACQUISITION AND RETENTION OF ETHANOL TOLERANCE. D.L. Hjeresen. Life Sciences Division, Los Alamos National Laboratory, Los Alamos, NM 87545

The frequent combined use of abused substances remains a significant drug abuse treatment problem. Due to the complexity of multiple drug interactions, little research exists to indicate the effects of various drugs on the development of tolerance, a key measure of drug dependence. Recent research has demonstrated that nicotine accelerates and maintains tolerance to the hypothermic and ataxic effects of ethanol (EtOH) *(Hjeresen & O'Donnell, Neurosci Abst 12:49, 1986)*. The present research was conducted to determine the effects of cocaine (Coc) on these same measures.

Male Long-Evans rats (mean body weight=332.1± 3.8 g) were tested in four treatment groups (N=6 ea): 1) EtOH (2.5 g/kg, 15% v/v, i.p.) and Coc (1.0 mg/kg in NaCl vehicle), 2) EtOH and NaCl (1 ml/kg), 3) NaCl (equivalent in volume to EtOH injections) and Coc and, 4) NaCl and NaCl. For 11 consecutive days a colonic temperature was taken, rats were injected with both drugs and returned to their home cages for 10 min. Rats were then tested in a locomotor activity apparatus for 30 min. Additional colonic temperatures were taken 40, 70 and 100 min following drug injections. Rats treated with NaCl+Coc had significantly higher colonic temperatures and locomotor activity than NaCl+NaCl rats. Rats treated with EtOH+Coc had significantly higher locomotor activity but lower colonic temperatures compared to EtOH+NaCl treated rats. The EtOH+Coc treatment delayed acquisition of tolerance to the hypothermic but not ataxic effects of EtOH. On Days 12 to 17, rats were all treated with NaCl+NaCl to extinguish tolerance. On Day 18, all rats were tested with an EtOH+NaCl injection to determine any retention of tolerance. Groups previously treated with EtOH were significantly more tolerant to the hypothermic effects of EtOH than NaCl rats regardless of previous Coc treatment. Rats in the NaCl+Coc group were more active than rats in all other groups. Thus, Coc appears to interact differently with independent effects of EtOH.

DESIPRAMINE ENHANCES BROMOCRIPTINE BUT NOT AMANTADINE IN COCAINE WITHDRAWAL. A. J. Giannini. Department of Psychiatry, Ohio State University and Northeastern Ohio Medical College, Youngstown, Ohio 44504.

Fifty cocaine abusers were divided into 5 groups of 10 volunteers each. The first group was treated with placebo (P), the second with bromocriptine 2.5 mg. q.i.d. (B), the third with amantadine 100 mg. q.i.d. (A), the fourth with desipramine 200 mg. q d and bromocriptine 2.5 mg. q.i.d. (DB), the fifth with desipramine 200 mg. q d and amantadine 100 mg. q.i.d. (DA). All groups were superior to placebo ($p < .01$) after 20 days. There was no difference between B and A after 30 days. DB, however, was superior to DA after 30 days ($p< .02$) as well as B ($p <.05$) and A ($p < .05$).

It is hypothesized that desipramine enhances the catecholamine agonist effects of bromocriptine by changes in the presynaptic auto-receptor.

309.11

FLUOXETINE BLOCKS DEPRESSION IN PHENCYCLIDINE BUT NOT COCAINE WITHDRAWAL. R.H. Loiselle, A. James Giannini. Dept of Psychiatry, Northeastern Ohio Medical College and Ohio State University, Youngstown, OH 44504

Fluoxetine 20 mg. was given to 10 male cocaine and 10 male phencyclidine abusers in withdrawals. Placeboes were given to age matched controls also in withdrawal. Fluoxetine was more effective than placebo ($p < .01$) in phencyclidine but not cocaine ($p > .10$) withdrawal. This supports a serotonergic role for phencyclidine but not cocaine withdrawal.

309.12

ELEVATED SERUM PROLACTIN LEVELS IN NEWLY ABSTINENT MALE COCAINE ABUSERS. J.N.Wilkins*, D.A. Gorelick, B.R. Bamshad*, D.Y Setoda*, Research Service, W.L.A. V.A. Medical Center, Brentwood Divn., 11301 Wilshire Blvd., Los Angeles, CA 90073.

We measured serum prolactin (HPrl), as a peripheral marker of central nervous system (CNS) dopamine (DA) activity, by radioimmonassay, and cocaine and benzoylecgonine (BE) levels by high pressure liquid chromatography, with diode array detection, in 23 male inpatients receiving treatment for cocaine dependence (DSM IIIR) at various stages of abstinence (from 0 to 25 days). Four subjects (group 1) were positive for blood BE and urinary cocaine, evidence of very recent exposure to cocaine, in addition to being positive for urinary BE. Fifteen subjects were positive only for urinary BE, and 4 subjects were negative in the blood and urine tests (group 2). The mean admission HPrl level for group 1 was 13.7 ± 1.9 ng/ml (± S.D.; mean self-reported last cocaine use of 0.75 days), compared to a mean of 11.93 ± 2.6 for group 2 (mean self-reported last cocaine use of 18.25 days). Both groups were elevated above our laboratory mean for similarly aged-matched drug-free controls (6.8 ± 1.5 ng/ml). After 1 week of inpatient treatment, HPrl levels for both groups fell approximately 20 to 25%, while after 2 weeks of inpatient treatment HPrl levels in group1 became normal (7.3 ± 4.8 ng/ml) while HPrl levels from group 2 rose to levels slightly higher than on admission (12.6 ± 3.7 ng/ml). Although preliminary, these results are consistent with decreased CNS DA activity in newly abstinent cocaine abusers, possibly lasting as long as 2-5 weeks.

TROPHIC ACTIVITIES OF BRAIN MACROPHAGES. M. Mallat*, E. Hétier*, R. Houlgatte*, P. Denèfle*, J. Ayala*, A. Bousseau*, P. Brachet* & A. Prochiantz. U.114 INSERM, Collège de France, 11 pl.M.Berthelot, 75231 Paris cedex 05, France.

Amoeboid microglial cells have been purified from rodent brain primary cultures. Cell purity has been estimated to 95% with the help of specific biochemical markers such as:

1. Presence of iC3b receptor and CD4 antigen.
2. Activity of non-specific esterases.
3. Expression of MHCII antigens.
4. Strong phagocytic behaviour.

These amoeboid microglial cells, when stimulated with LPS in vitro, synthesize high amounts of interleukine 1 and TNF mRNAs. In addition, LPS stimulation provokes the release of Nerve Growth Factor. These findings confirm the hypothesis that amoeboid microglial cells constitute an important source of trophic and neurotrophic molecules in the mammalian brain.

310.2

NON-NEURONAL CELLS REGULATE SOMATOSTATIN EXPRESSION IN CULTURED SYMPATHETIC NEURONS. L.A. Kessler, Y. Wong and K. Spiegel. Depts. Neurology & Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Neuronal interactions with non-neuronal cells may influence neurotransmitter phenotypic expression. The present study examines the role of non-neuronal cells in regulating somatostatin (SS) expression in cultured sympathetic neurons of the neonatal rat superior cervical ganglion (SCG). SS levels were unchanged or reduced when SCG neurons were co-cultured with ganglion non-neuronal cells. Further, the amount of SS released into the medium remained unchanged or only slightly increased in co-cultures. Surprisingly, however, levels of SS mRNA were significantly increased in co-cultures, suggesting that post-transcriptional mechanisms prevented a concomitant increase in peptide levels.

Effects of non-neuronal cells could be mediated by either the release of soluble factors or by direct cell-cell contact between non-neuronal cells and neurons. To study the role of non-neuronal cell derived soluble factors, SCG neurons were treated with medium conditioned by exposure to ganglion Schwann cells, ganglion fibroblasts, RN22 Schwannoma cells or rat skin fibroblasts (RFCM). Treatment with any of these conditioned media increased levels of both SS mRNA and SS peptide. However, when neurons were co-cultured with non-neuronal cells, treatment with RFCM incresed SS mRNA levels but not levels of the mature peptide. Thus the presence of non-neuronal cells prevented an increase in SS peptide concomitant with the increase in mRNA.

To study the role of cell-cell contact, neurons were either cultured on top of non-neuronal cells which had been lightly fixed with 10% trichloroacetic acid or were treated with a preparation of non-neuronal cell membranes. Each of these treatments increased SS mRNA levels. Our observations suggest that non-neuronal cells may influence SS expression both by the release of soluble factors and by contact-mediated mechanisms. Although non-neuronal cells regulate levels of SS mRNA, post-transcriptional regulation may be rate-limiting so that peptide levels remain unchanges even though mRNA levels are greatly increased.

310.3

DEPOLARIZATION AND INSULIN-LIKE GROWTH FACTOR-I (IGF-I) DIFFERENTIALLY REGULATE PRESUMPTIVE NEUROBLAST MITOSIS E. DiCICCO-BLOOM and I.B. BLACK. Div. of Developmental Neurolory, Cornell Univ. Med. Coll.,New York, NY 10021

The process of neurogenesis has been studied descriptively, yet regulatory mechanisms are unknown. Employing a recently developed, virtually pure neuronal culture system, we found that insulin growth factors specifically regulated entry of neuroblasts into the cell cycle (PNAS, in press). We now compare a wholly different signal, neuronal depolarization, with growth factor stimulation of mitogenesis.

Dissociated embryonic rat sympathetic neuroblasts were cultured for 48 hrs in fully-defined medium. [^{3}H]thymidine incorporation was assessed by scintillation spectroscopy (Inc) or by determination of the labeling index (LI), i.e. the percentage of identified neuroblasts incorporating nuclear thymidine, defined by autoradiography.

Neuronal depolarization mediated by elevated extracellular K^+ (30mM) or by the specific Na^+ channel agonist, Veratridine (Ver), both stimulated neuroblast Inc. This stimulation reflected an increased proportion of neuroblasts entering the cell cycle, since the LI increased from approximately 12% in controls to 21% and 30% after K^+- and Ver-induced depolarization respectively. In contrast, equimolar Na^+ addition decreased Inc slightly.

To examine potential relationships between IGF-I and depolarization-induced DNA synthesis, we defined the role of the Na^+ channel by using the specific antagonist, Tetrodotoxin (TTX). Whereas Na^+ channel blockade completely prevented Ver stimulation, TTX had no effect on IGF-I-induced mitosis. We tentatively conclude that depolarization and growth factors mediate neuroblast mitosis via different mechanisms. (Supported by NIH Grants HD 00676, BRSG S07 RR05396, the Mellon Fdn. and a McKnight Research Project Award).

310.4

ROLE OF VOLTAGE SENSITIVE CALCIUM CHANNELS (VSCC) IN MITOGENIC STIMULATION OF NEUROBLASTS D.W. PINCUS, E. DICICCO-BLOOM, and I.B. BLACK Div. of Developmental Neurology , Cornell University Medical College, New York, NY 10021.

We have recently found that insulin growth factors (IGF) and depolarization differentially stimulate neuroblast mitosis *in vitro* (previous abstract). We now define the role of VSCC in this differential regulation.

Dissociated embryonic rat sympathetic neuroblasts were cultured for 48 hrs in fully-defined medium and assayed for [^{3}H]thymidine incorporation (Inc) by scintillation spectroscopy.

Depolarization by elevated extracellular K^+ (30mM) or the specific Na^+ channel agonist, Veratridine (Ver), increased Inc more than 2-fold. Increased Inc elicited by Ver was prevented by the specific Na^+ channel blocker Tetrodotoxin (TTX). In contrast, K^+ stimulation of Inc was unaffected by TTX, suggesting a Na^+ channel-independent mechanism. To determine whether Ca^{++} entry mediated the depolarization effect, cells were cultured in the presence of K^+ and the specific VSCC blocker, Nitrendipine. The drug preferentially blocked the K^+-induced increase in Inc, while having little effect on baseline or IGF-induced mitosis. To further elucidate the role of Ca^{++} entry, cells were cultured with or without the VSCC agonist, Bay K 8644, in the presence of submaximal doses of Ver or IGF. While BAY and Ver alone had little effect, the two combined significantly increased Inc, suggesting that Ca^{++} fluxes via VSCC mediate depolarization effects. Conversely, Bay did not augment IGF mitogenesis, indicating different underlying mechanisms. (Supported by NIH Grants HD 00676, HD 23315 and a McKnight Research Project Award).

310.5

PRODUCTION OF NERVE GROWTH FACTOR RECEPTOR IN RECOMBINANT EXPRESSION SYSTEMS. Alonzo H. Ross[1], Usha R. Reddy[2], V. Prabhakar[1], and G. Venkatakrishnan[1]. [1]Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545; [2]Childrens Hospital of Philadelphia, PA 19104.

The nerve growth factor receptor (NGF-R) is a 75,000-dalton glycoprotein with an N-terminus signal sequence and a single transmembrane domain. The availability of the receptor cDNA has allowed us to express recombinant receptor in several systems. NGF-R was prepared in bacteria as a fusion protein with B-galactosidase, but this material did not bind NGF, possibly because of incorrect disulfide bonding. The receptor was then expressed in monkey COS cells using a vector with a cytomegalovirus early promotor and an SV40 origin of replication which allows amplification of the plasmid in COS cells. The full-length receptor is strongly expressed and is transported to the cell surface. The extracellular domain of the NGF-R was also expressed in COS cells, but even though the signal sequence was correctly cleaved, this protein was inefficiently transported through the endoplasmic reticulum and, hence, poorly secreted. Both the extracellular domain and the full-length NGF-R bound NGF and were bound by a conformation-dependent anti-NGF-R monoclonal antibody. These studies suggest that there are multiple signals for the subcellular localization of NGF-R. We are also constructing plasmids for the preparation of large quantities of NGF-R using the recombinant Baculovirus system.

310.6

NERVE GROWTH FACTOR (NGF) REGULATES SYNAPTIC MOLECULES IN THE DEVELOPING RAT SUPERIOR CERVICAL GANGLION (SCG). K. Wu* and I.B. Black. Division of Devel. Neurology, Cornell Univ. Med. Coll., N.Y., NY 10021.

Our previous work indicated that presynaptic innervation is necessary for both the normal development of the ganglionic postsynaptic density protein (PSDp) and the normal maintenance of the protein in the adult SCG. Subsequent experiments suggested that sympathetic impulse activity itself regulates the adult rat ganglionic PSDp. In the present study, we examined the effect of NGF on the PSD protein in SCG. Treatment of neonates with NGF (daily dose of 10 g/g body weight) for 10 days increased calmodulin binding to the PSDp by 4.5-fold. The treatment elicited only a 1.8-fold increase in total synaptic membrane protein, suggesting that the effect on the PSDp was highly selective. The effect of NGF appeared to be highly specific since Cytochrome C, structurally similar to NGF, had no effect on the PSD protein. Finally, NGF treatment elicited a 7-fold increase in the PSDp in unilaterally denervated ganglia, indicating that the synaptic effects of NGF did not depend on the presence of presynaptic cholinergic nerve terminals. Our results suggest that the trophic protein NGF as well as impulse activity, may regulate synaptic function. (This work was supported by NIH Grants NS 10259 and HD 23315, IBB is the recipient of a McKnight Research Project Award).

310.7

NEURAL REGULATION OF MUSCLE GLUTAMINE SYNTHETASE EXPRESSION. S. R. Max, B. Feng*, C. Banner*, M. Konagaya*, Y. Konagaya*, and J. W. Thomas. Dept. of Neurology, Univ. of Md. Sch. Med., Baltimore, MD 21201 and Lab. of Molecular Biology, NINCDS, NIH, Bethesda, MD 20892.

The mechanism of glutamine synthetase induction in rat skeletal muscle following denervation (Soc. Neurosci. Abs. 12:1107, 1986) was investigated. Adult male rats were subjected to mid-thigh section of the sciatic nerve. At 1, 2, and 5 hours and 1, 2, and 7 days after denervation, rats were sacrificed, and denervated and contralateral control soleus and plantaris muscles were excised, weighed, homogenized and assayed for glutamine synthetase. Glutamine synthetase activity increased about 2-fold 1 hour after denervation in both muscles. This increase in enzyme activity was maintained for up to 7 days post-denervation. Immunotitration with an anti-glutamine synthetase antibody suggested that denervation causes an increase in the number of glutamine synthetase molecules in muscle. Nevertheless, enhanced enzyme activity probably does not reflect increased synthesis of glutamine synthetase molecules; cycloheximide did not block the denervation-mediated increase in enzyme activity, and Northern blot analysis revealed no increase in glutamine synthetase mRNA following denervation. A combination of denervation and dexamethasone injections resulted in additive increases in glutamine synthetase activity. Thus, the mechanism underlying increased glutamine synthetase following denervation appears to be post-transcriptional and is distinct from that of glucocorticoid-mediated glutamine synthetase induction previously described by us (Endocrinology 120:1179, 1987). (Supported by NIH, HD-16596).

310.8

GANGLIOSIDE GM1 MODULATION OF PROTEIN KINASE ACTIVITY IN PC12 CELLS. B.S. Hilbush and J.M. Levine, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794

Exogenous gangliosides exhibit neurotrophic effects, enhancing regeneration *in vivo* and neurite outgrowth *in vitro*. Ganglioside GM1 can potentiate the response to nerve growth factor (NGF) in the PC12 cell line, thereby enhancing neurite outgrowth (Dev. Brain Res. 8:215-221,1983).The molecular mechanisms responsible for GM1 action are unknown; however, a modulation of NGF-induced protein kinase activity might account for the trophic effects of exogenous gangliosides. Therefore, we have investigated the effects of exogenous GM1 ganglioside on protein kinase activity in PC12 cells.

The extent of ^{32}P incorporation into tyrosine hydroxylase (TH) was used to assess the effects of GM1 on kinase systems. Treatment of PC12 cells with GM1 alone resulted in no changes in basal levels of TH phosphorylation. GM1 together with NGF (50ng/ml) caused a 30-40% increase in TH phosphorylation compared to treatment with NGF alone. These stimulatory effects were maximal at concentrations of 1-10μM, while higher concentrations ($\geq$ 100 μM) were inhibitory. Pulse-chase studies demonstrated that the increases in TH phosphorylation were due to kinase activation rather than inhibition of phosphatase activity.

Two-dimensional tryptic peptide mapping of TH demonstrated that phosphopeptide T_2 undergoes a 2-fold increase in labeling upon treatment with GM1 and NGF. T_2 is phosphorylated in response to agents known to raise intracellular Ca^{2+} levels, suggesting that this phosphopeptide is a substrate for a Ca^{2+}/calmodulin-dependent protein kinase (J.B.C. 260:9047-9056,1985). Thus, GM1 may act synergistically with NGF to activate Ca^{2+}/calmodulin -dependent protein kinase. NGF has been shown to activate cAMP-dependent protein kinase and C kinase. The ability of exogenous GM1 ganglioside to recruit an additional protein kinase to the NGF response may provide a mechanism responsible for its neurotrophic effects.

310.9

INTRAOCULAR TRANSPLANTATION OF AN ENRICHED SCHWANN CELL SUSPENSION FACILITATES THE SURVIVAL OF RAT RETINAL GANGLION CELLS FOLLOWING OPTIC NERVE SECTION. L. Maffei*[1], G. Carmignoto*[2], G. Ferrari*[2], P. Candeo*[2] and R. Canella*[2] (SPON: J. Paolicchi). [1]Institute of Neurophysiology, CNR, Pisa, Italy and [2]Fidia Research Laboratories, Abano Terme, Italy.

Schwann cells (Scs) are known to play an essential role for the regeneration of mammalian peripheral nerves. The results here reported show that Scs transplanted intraocularly improve the survival of rat retinal ganglion cells following optic nerve section. Scs were derived from neonatal rat sciatic nerves. A single intraocular injection of a cell suspension containing at least 80% of Scs (about 10^6 Scs) was performed at the time of the optic nerve section. Surviving retinal ganglion cells were retrogradely labelled with HRP applied to the proximal stump of the optic nerve. In the retinae which received Scs, surviving retinal ganglion cells were much more numerous with respect to controls. Approximately 25% of the normal ganglion cell population was still viable 9 weeks after axotomy. Even 12 weeks after section, numerous viable retinal ganglion cells were present. The properties which make Scs active in peripheral nerve regeneration (source of trophic factors and/or supporting substratum for axon regeneration) could also be responsible for the survival of retinal ganglion cells after optic nerve section.

CONCENTRATION DEPENDENCE OF A NEURON SURVIVAL FACTOR FOR DORSAL LATERAL GENICULATE NUCLEUS (dLGN) NEURONS IN VIVO. K.L. Eagleson*, F. Haun, and T.J. Cunningham, Dept. of Anatomy, Med. Coll. of Pa, Phila., PA 19129,

Occipital cortex ablation in newborn rats produces near complete degeneration of the dLGN in 5 days. This degeneration is attenuated when embryonic cortical cells, first maintained in explant co-culture with embryonic diencephalon for 5 days, are transplanted into the lesion cavity. These transplants prolong for about a week the survival of a population of host dLGN neurons generated on embryonic days 15 and 16 (E15, E16). Cells generated earlier (on E14) are unaffected. A similiar effect is obtained when a macromolecular fraction of the culture medium conditioned by the transplant cells is entrapped in gel beads and then implanted into the lesion cavity. In this study we tested the effect of varying the concentration of this medium fraction, with the starting concentration of the fraction designated X. Increasing concentrations produced a progressive fall-off of trophic activity such that at 200X neuron survival was identical to unconditioned medium controls. Diluting the medium had the opposite effect, but largely due to increased survival of E14 generated neurons (e.g., 26% remain at 0.05X, compared to 5% in lesion only animals). The results may reflect the separate operation of neurotrophic and neurotoxic factors at different concentrations for different dLGN neuron populations. Or, it may be that the production of a single cortically-derived neurotrophic factor is controlled strictly during development such that the low concentrations required by E14 thalamic neurons are available early in development and the higher concentrations required by E15,E16 thalamic neurons are available later. Supported by NIH grant NS16487 (TJC).

PARTIAL NEUROTROPHIC MAINTENANCE OF FUNGIFORM TASTE BUDS. D.R. Riddle* and B. Oakley. (SPON: E. Valenstein). Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109.

Recent evidence indicates that fungiform taste buds are not completely dependent upon their nerve supply. We examined fungiform taste buds in rats 8, 23 and 180 days after unilateral transection of the chorda-lingual nerve. All fungiform taste buds deteriorated with time; 45% disappeared completely. However, some small remnants remained; many of the distorted remnants disappeared or regulated into well-shaped atrophic taste buds (small, generally lacking a taste pore: mean of 55% of the normal volume). Comparison of three rodent genera revealed the neurotrophic dependence of fungiform taste buds is least in golden hamsters (*Mesocricetus auratus*), intermediate in albino rats (*Rattus norvegicus*) and greatest in mongolian gerbils (*Meriones unguiculatus*).

The following data suggest that taste buds toward the front of the tongue are the least susceptible to denervation---apparently their stem cell progeny can differentiate and either form taste bud remnants or regulate into atrophic buds. Among fungiform taste buds, those at the tip of the tongue are twice as likely to survive denervation for months. In 10 rats the chorda-lingual nerve was transected unilaterally and the IX nerve bilaterally. By 8 days all vallate taste buds had completely disappeared, whereas 6% of the foliate and 71% of the fungiform taste buds were still present in some form. Thus, fungiform taste buds may survive denervation to a degree that depends upon the genera of the rodent and the locus on the tongue. Supported by NIH Grant NS-07072.

310.12

THE TRIGEMINAL NERVE LACKS THE NEUROTROPHIC CAPACITY TO MAINTAIN TASTE BUDS. B. Oakley and D.R. Riddle*. Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109.

We have tested the proposition that branches of the trigeminal (Vth) cranial nerve can maintain fungiform taste buds in rats. This is a sequel to a companion study on the effects of denervation upon rodent fungiform taste buds. We transected the chorda tympani nerve and caused the anterior part of the rat tongue to be innervated by the a) lingual nerve alone, b) mylohyoid nerve alone, c) lingual and mylohyoid nerves, or d) lingual and auriculotemporal nerves. We determined the number of missing taste buds and the number and volume of remnants of taste buds and atrophic buds (small, but well-shaped). Except for a small decrease in the number of missing taste buds, Vth nerve innervated taste buds fared little better than denervated controls (chorda-lingual nerve transected). However, Vth nerve innervation significantly decreased the marked tendency of a large filiform papilla to emerge from an empty fungiform papilla in denervated controls, suggesting that trigeminal axons suppressed the formation of ectopic filiform papillae.

Thus, the various branches of the Vth nerve showed no specific neurotrophic capacity to support fungiform taste buds, the number and size of which did not differ from denervated controls. These results extend to fungiform taste buds our conclusion from studies of vallate and foliate taste buds: only chemosensory axons will support taste buds on the tongue. This specificity of neurotrophic support of mammalian taste buds raises the possibility of specific neurotrophic agent(s) in chemosensory axons. Supported by NIH Grant NS-07072.

311.1

ADHESION MOLECULE BOUNDARIES DURING CNS PATTERN FORMATION AND SYNAPTIC STABILIZATION. D. Steindler, N. Cooper, A. Faissner* and M. Schachner. Dept. of Anat. and Neurobiol., Univ. of Tenn., Memphis, and Dept. of Neurobiol., Univ. of Heidelberg.

Previous lectin binding and GFAP immunocytochemistry (ICC) studies during postnatal development in the mouse CNS have shown that "hidden" boundaries exist around developing functional cytoarchitectonic arrangements during a critical period in the first postnatal week (Cooper and Steindler, J. Comp. Neurol. 249:157, 1986; Brain Res. 380:341, 1986; Steindler and Cooper, Dev. Brain Res. 36:27, 1987). Transient glial-glycoconjugate boundaries cordon off cortical layers, nuclei, and functional units (e.g. somatosensory barrels and barreloids, neostriatal striosomes), and they may be involved in specific pattern formation events including neuron and afferent sorting. In the present study, we have begun to characterize boundary constituents using nine different monoclonal antibodies directed against putative cell or substrate adhesion molecules, including the J1 glycoprotein, L2, and AMOG, in LM and EM ICC studies in the CNS of mice ranging in age from E18 to adult. LM ICC of the J1 glycoprotein, for example, reveals boundaries around developing barrels during the first postnatal week. Coincidental with the disappearance of these tissue boundaries in the second postnatal week, several of the Mabs reveal an intricate network on the surface of neurons that surrounds axosomatic and axodendritic synapses. We believe that glia and associated adhesion molecules may serve to sort and later corral young neurons within functional arrangements. Greater concentrations of glial processes and their increased expression of certain adhesion molecules within boundary sites actually bog down the young neurons, thus preventing their extension into adjacent, functionally different zones. Tissue boundaries disappear, and cell surface boundaries appear during synaptic stabilization when the business of the brain evolves from pattern formation to information processing and transfer. Supported by NIH grant NS 20856.

Development of Cat-301 expression on motor neurons requires muscle afferents. R. Kalb and S. Hockfield Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT

Previously we found that monoclonal antibody Cat-301 recognizes a postnatally expressed neuronal surface antigen on hamster spinal motor neurons. Motor neurons do not develop Cat-301 immunoreactivity following neonatal lesions which disrupt their normal pattern of activity, such as sciatic nerve crush or thoracic hemicordotomy. Other motor neuron antigens recognized by monoclonal antibodies are unaffected by these procedures. The same lesions in adults have no effect on Cat-301 immunoreactivity. In an attempt to determine what component of the segmental reflex arc is necessary for Cat-301 expression, we performed dorsal rhizotomies on hamster pups. The extent of deafferentation was assayed using calcitonin gene related peptide (a primary afferent marker). In neonatally deafferented cord segments Cat-301 immunoreactivity does not develop on motor neurons, while deafferentation in adults has no effect on Cat-301 expression. Neonatal or adult rhizotomy does not inhibit the expression of other motor neuron antigens. Next, to determine which dorsal root afferents stimulate Cat-301 development we depleted small diameter afferents by neonatal capsaicin treatment. The efficacy of capsaicin was assayed by the loss of dorsal root ganglia substance P immunoreactivity. Depletion of small diameter afferents has no effect on the development of motor neuron Cat-301 expression in neonates or adults. These results suggest that the development of motor neuron Cat-301 depends on non-nociceptive afferents, including larger diameter muscle afferents conveying muscle tension or joint position sense of normally active muscles

311.3

A POSITIONAL MARKER IN THE DORSAL EYE OF THE EMBRYO. Ursula C. Dräger and Sylvia A. Rabacchi. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

We are trying to identify molecules involved in the establishment of positional information in the eye of the early mouse embryo. In independent fusions we found two monoclonal antibodies that label strongly the dorsal retina in mouse, rat, chick and xenopus embryo; in addition, most cells in the body are weakly labeled. The two antibodies appear to recognize the same antigen but different epitopes on it. In the mouse embryo, strong labeling of the dorsal eye begins at the optic vesicle stage; at the early eye-cup stage the antigen becomes very abundant, filling diffusely the cytoplasm of all cells in the dorsal one-third of the neural retina. As differentiation advances from center to periphery, the dorsal eye antigen recedes toward the dorsal edge of the retina. Besides its presence in undifferentiated retina, the antigen appears transiently at high levels in axons originating from dorsal retina, and this dorsal bundle can be followed to the lateral geniculate nucleus. In addition to strong expression in the dorsal eye, high levels of the antigen are seen in various other places including the inner ear, early motor neurons and muscle.

Western blot analyses show a major band at 44kd and several minor bands; the antigen is present in all tissues and in all species we tested, including human, rodents, fish, lobster, drosophila and flat worms.

From these morphological and biochemical observations we conclude that we have identified a very conserved and widely distributed antigen; its very high expression in the embryonic dorsal retina suggests that it may be involved in the determination of the dorso-ventral axis of the embryonic eye. (Supported by EY01938)

311.4

MOLECULAR CLONING OF THE 'DORSAL EYE ANTIGEN': HOMOLOGY TO THE HIGH-AFFINITY LAMININ RECEPTOR. Sylvia A. Rabacchi, Rachael L. Neve and Ursula C. Dräger. Department of Neurobiology, Harvard Medical School and Department of Clinical Genetics, Children's Hospital, Boston, MA 02115.

Using a monoclonal antibody against an antigen expressed at high levels in the dorsal retina of the vertebrate embryo we isolated a cDNA clone from an embryonic rat brain library in λgt11. When this clone was used to probe RNA from embryonic mouse heads, it hybridized to a single prominent 1.3kb RNA species. Sequence analysis revealed a partial clone coding for the COOH-terminal portion of a protein with very strong homology to the partial sequence of the human laminin receptor described by Sobel et al. (PNAS, 1986). Antisera to purified laminin receptor and to a synthetic peptide from the COOH-terminal portion of the protein (generous gifts from L. Liotta), and an antiserum to the laminin-receptor β-galactosidase fusion protein (a generous gift from B. Segui) recognized in Western blots of our preparations the same bands as our monoclonal antibody, i.e. a prominent band at 44kd and weaker bands including one at 67kd; these bands were present in blots of whole tissue extracts as well as crude membrane preparations and high-speed supernatants. In addition, our monoclonal antibody reacted strongly with the fusion protein (courtesy of B. Segui). On sections through embryonic mouse eyes the antiserum to the purified receptor labeled the dorsal retina in a fashion similar to but weaker than our monoclonal antibody.

From these observations we conclude that the "dorsal eye antigen" is either identical or closely related to the high-affinity laminin receptor. (Supported by EY01938)

311.5

TRANSIENT PATTERNED EXPRESSION OF THE 1F8 ANTIGEN DURING DEVELOPMENT OF THE GRASSHOPPER NERVOUS SYSTEM. E.E.Ball, M.J.Bastiani#, H.G.deCouet*, J.M.A.Quinn*. Molecular Neurobiology, Res. School Biol. Sci., Australian National Univ. PO Box 475, Canberra City, ACT 2601, Australia; #Biology Dept., Univ. of Utah, Salt Lake City, Utah 84112, USA

The 1F8 MAB recognizes a cell surface protein (1F8a) of molecular weight ~105kD which is expressed with changing temporal and tissue specificity during the embryonic development of grasshoppers (Locusta, Schistocerca). The neuroepithelium first expresses 1F8a at the borders of thoracic segments 2-3 at 26-27% of embryonic development. Expression then spreads both anteriorly and posteriorly, beginning first at the margin of the neuroepithelium of each segment. Midline staining becomes less intense as the neuroepithelium begins to stain. By 30% most thoracic neuroepithelial cells express 1F8a. From 30-35% staining of the abdominal nervous system spreads posteriorly and the entire neuroepithelium stains by the end of this period. By 40% multiple transverse stripes in the dorsal part of each ganglion begin to stain, giving the CNS a ladder-like appearance. Each stripe consists of the progeny of only a few cells. At ~40% expression of 1F8a begins to disappear from the neuroepithelium in the same order as it appeared, and from 45-60% it is limited to a thin layer in the midline of each ganglion and to the median neuroblast. At 60% staining of the CNS again becomes widespread for a short time before becoming restricted to a smaller, segmentally repeated set of cells, some or all of which are glia.

311.6

ISOLATION OF A GENE EXPRESSED IN NEURONAL STEM CELLS. U. Lendahl*, L. Zimmerman*, K. Frederiksen and R. McKay. Depts. of Brain and Cognitive Science, Biology, Mass. Inst. of Technology, Cambridge, MA 02139, U.S.A.

The Rat.401 protein is a 200 kD protein specifically found in neuronal stem cells in the rat CNS, but absent from adult CNS. Immunostaining reveals an intermediate filament-like cytoplasmic distribution.

We here report the cloning of the gene encoding the Rat.401 protein. Immunopositive clones were obtained from a lambda gt11 cDNA expression library made from embryonic day 15 rat poly(A)$^+$ RNA. We now have cDNA clones spanning more than 4 kb (kilobase pair) of the Rat.401 gene. The size of the mRNA is approximately 6 kb. Rat.401 mRNA is found only in developing CNS regions and in amounts proportional to the protein levels. The close correlation between amounts of mRNA and protein suggests that Rat.401 gene expression is regulated at the mRNA level.

Preliminary DNA sequence analysis indicates that portions of the Rat.401 protein are repetitive, displaying a 9 amino acid motif of predominantly negatively charged amino acid residues. A search in the EMBL data bank reveals no significant homologies to other characterized genes.

Supported by grants from NIH, Whitaker Health Science Fund, the Rita Allen Foundation and an EMBO Fellowship to UL.

311.7

MOLECULAR CLONING OF A HOMEOBOX FROM THE LAMPREY. J.W. Pendleton, S. Chang*, M.J. Cohen, and F.H. Ruddle*, Department of Biology, Yale University, P.O. Box 6666, New Haven, CT 06511.

The CNS of the larval sea lamprey, Petromyzon marinus, has many advantages for the study of neural phenomena - large identified neurons, a hardy in vitro preparation, and well-characterized growth after CNS injury. Because of these attributes, studies of homeobox-containing genes and their expression in the lamprey CNS may be of interest.

We screened a lamprey genomic library (kindly provided by R. Doolittle) with probes containing the homeobox from the Drosophila antp and mouse Hox1.5 loci. Preliminary sequence analysis indicates that this lamprey homeobox is a member of the highly conserved antp group. Furthermore, the deduced amino acid sequence suggests that this homeobox shares a high degree of homology with the following class of homeoboxes: human Hu1, mouse Hox1.3 and Hox2.1, Xenopus XHox1B, and salmon pS12B (Hart et al 1987, Fjose et al 1988). This class of homeobox-containing genes is known to be expressed in the CNS, and we are currently examining expression of this homeobox-containing gene in the lamprey. From an evolutionary perspective, the lamprey is the most primitive vertebrate from which a homeobox has been cloned and sequenced.

311.8

THE LOCUS *ELAV* OF *D. MELANOGASTER* ENCODES AN RNA BINDING PROTEIN. S. Robinow*, A. R. Campos*, K.-M. Yao* and K. White* (SPON: L. I. Mortin). Department of Biology, Brandeis University, Waltham, MA 02254.

We are interested in the genetic basis which underlies the maturation of a neuron from its birth to its terminally differentiated state. In the fruit fly, *Drosophila melanogaster* a region at the tip of the X chromosome is required for the proper development of the nervous system. The locus *embryonic lethal-abnormal visual system* (*elav*) is one of at least two loci which map within this region that are required for proper neural development (Campos, A. R., *et al., J. Neurogenet.*, 2:197-218, 1985; Homyk, Jr., T., *et al., J. Neurogenet.*, 2:309-324, 1985; Jiménez, F. and J. A. Campos-Ortega, *J. Neurogenet.*, 4:179-200, 1987). This locus has been cloned and molecularly characterized (Campos, A. R., *et al., EMBO J.* 6:425-431, 1987). Transcripts from this locus are found in most, if not all neurons at all developmental stages while they are not found in neuroblasts and at least one class of glial cell (Robinow, S. and White, K., *Dev. Biol.*, 126:294-303, 1988).

We have identified the transcriptional and translational start sites for at least one of the three embryonic transcripts. A protein sequence homology search of the conceptual translation of the open reading frame found within an embryonic cDNA suggests that this locus encodes an RNA binding protein. However, at present we have no direct evidence that the *elav* gene product can bind RNA. We are in the process of raising antibodies against a series of *elav* fusion proteins. Antibodies will be used to test directly for the ability of this protein to bind RNA. We will also approach the question of whether this protein binds all or only a subset of transcripts.

311.9

POSITION-DEPENDENT EXPRESSION OF PEPTIDERGIC PHENOTYPE IN POST-MIGRATORY NEURONS OF THE INSECT ENTERIC NERVOUS SYSTEM. P. F. Copenhaver and P. H. Taghert. Anatomy & Neurobiology 8108, Washington University Medical School, St. Louis, MO 63110.

We have been examining the developmental regulation of peptidergic phenotype within the Enteric Plexus, a discrete region of the enteric nervous system (ENS) of the moth, Manduca sexta. Unlike many neurons in the insect CNS, the ~400 neurons of the Enteric Plexus (EP cells) do not appear to be uniquely identifiable but can be categorized by morphological and biochemical subtype: they arise by a process of placode evagination from the foregut epithelium and acquire their mature positions (along the foregut and midgut) by a multiphasic sequence of cellular migration via stereotyped pathways. The behavior of the EP cells during migration appears probabilistic and results in significant variability in their post-migratory distributions. However, the expression of substances related to the molluscan peptide Phe-Met-Arg-Phe-amide (FMRFamide) commences in the Enteric Plexus only after migration is complete, and then only in a subset of the EP cells that have successfully navigated onto the midgut surface. To test the role of this migratory process in regulating peptidergic phenotype, we have begun to manipulate the developing ENS in embryo culture. Animals isolated from their eggshells and embryonic membranes will nevertheless exhibit the normal sequence of cell migration and position-dependent expression of FMRFamide-like substances in vitro. If a subset of the EP cells are surgically prevented from contacting the midgut migratory pathways, none of these neurons successfully navigate onto the midgut. In addition, no detectable levels of FMRFamide-like material is found within this stranded group, suggesting a lack of peptidergic expression in the absence of the normal migratory process. We are currently testing the relative importance of specific migratory pathways and post-migratory environments in regulating peptidergic phenotype within this cell population both in situ and in primary culture. Supported by an NIH postdoctoral fellowship to P.F.C. (F32NS07957) and NIH grant # NS21749 (to P.H.T.).

CHANGES IN THE EXPRESSION OF A FMRFAMIDE-LIKE PEPTIDE IN THE PERIPHERAL NEURON L1 IN *MANDUCA* EMBRYOS J. B. Wall* and P. H. Taghert (SPON: A. Loewy) Dept. of Anatomy and Neurobiology, Washington University Medical School, Saint Louis, MO 63110

We are studying a peripheral neuron (L1) to ask what factors influence the biochemical differentiation of a neuron during development. The segmentally repeated cell called L1 extends a distal process towards the heart, and in posterior segments (A2-A8), contacts it. The L1 neuron also projects a varicose and highly branched process medially in the Transverse Nerve. The morphology and disposition of the axon suggests a neuroendocrine function. The cell is both SCP_B and FMRFamide immunoreactive (IR): such labelling is specifically associated with large (~200 nm) secretory granules. Using single cell dye fills and the anti-peptide antibodies, we have compared morphological growth with levels of IR material. There are two phases to the pattern. Peptide-IR is first detectable shortly after L1 extends its initial growth cone at 41% of embryogenesis. At this stage, IR is seen in the cell body, axon, growth cone and filopodia. L1 cells in all segments simultaneously begin such expression and no segment-specific differences are noted. Other neurons in *Manduca* embryos are also labeled by these same antibodies, but their initial expression follows that of L1 and they have extended considerably longer axons at these times. The L1 pattern changes when, at ~60%, L1 cells in anterior segments increase in IR levels, while the levels in homologous cells in the posterior segments gradually decline. These differences are not the result of cell death. We are currently studying the mechanisms that underlie this early cell-specific initial expression, and later segment-specific transient expression.
Supported by NIH Grant # NS21749 (PHT).

311.11

ISOLATION OF A GENE THAT IS SPECIFICALLY EXPRESSED IN A SUBSET OF GLIA FROM THE MOTH *MANDUCA SEXTA*. N. Plaut*, P.F. Copenhaver and P.H. Taghert (SPON: I.A. Ferguson). Dept. of Anatomy & Neurobiology,Washington Univ. Med. School, Saint Louis, MO 63110.

Whereas insect neuronal development has been extensively analysed in recent years, relatively few modern studies of insect glia have been reported. By means of a differential screen between distinct regions of the larval *Manduca* nervous system, we have isolated a cDNA clone of a gene (NPF) that is specifically expressed in a sub-class of glia. The clone is 450bp in length and about two thirds the size of the smallest transcript detectable with northern analysis. The DNA sequence reveals a single long open reading frame whose initial regions are not represented in the isolated clone; neither the nucleotide nor predicted protein sequence is homologous to any recorded sequences in the Genebank database.

NPF transcripts are expressed exclusively in the nervous system and at least two transcripts (~0.7 & ~1.0 kb) are present; the ratio of these vary during post-embryonic development. NPF transcripts are first detected during the latter half of embryogenesis. In larval stages, there are quantitative differences in NPF expression between the various ganglia of the CNS. In situ hybridisation with both DNA and RNA probes indicates that the NPF gene is abundantly expressed in those glial elements that separate the nerve cell bodies from the neuropil. Glial elements that constitute the neural sheath and that populate the neuropil do not express the gene. Weaker signals are also detected in the cell body layer of ganglia although these also appear due to non-neuronal cells. With a view to pursuing a genetic analysis of potential NPF function, we are cloning a *Drosophila* homologue of NPF. Supported by NIH grant NS 21749 (PHT).

311.12

CULTURED DROSOPHILA NEUROBLASTS USED TO IDENTIFY GENES IMPORTANT DURING NEUROGENESIS. L.A. Perkins, K. Zhang,* A.P. Mahowald,* and N. Perrimon* Case Western Reserve U., Cleveland OH 44106 & Harvard Med. School, Boston, MA 02115.

Utilizing a unique approach to isolate large populations of neuroblasts from early gastrula stage embryos it was possible to obtain RNA from undifferentiated neuroblasts and differentiated neurons. These RNAs were used to generate cDNA probes for differential screening of 2 embryonic cDNA libraries. Clones were selected if no hybridization was observed with the cDNAs derived from differentiated neurons and if hybridization was observed with the cDNAs derived from undifferentiated neuroblasts. One of our cDNA clones identifies the previously described neurogenic gene Delta. Northern analysis reveals 3 developmentally regulated transcripts; 2 of which are expressed during neuroblast segregation. In situ hybridization to sectioned embryos shows strong labelling over neuroblasts. Another of our clones identifies the heat shock cognate gene, hsc-4. Developmental Northern analysis reveals one major transcript not developmentally regulated, in situ hybridization to sectioned embryos shows an intricate pattern of tissue enriched expression. Segregating neuroblasts are particularly enriched for this transcript. Other of our cDNA clones do not identify previously described loci and reveal interesting temporal and spacial developmental profiles. From among these clones we hope to identify new loci important during neurogenesis.

312.1

APPLICATION OF A NEW AUTOMATED METHOD OF SCALING SOMATOSENSORY EVOKED POTENTIALS IN SEVERELY BRAIN INJURED PATIENTS. C.E. Dixon, S. Choi*, W. Burton*, C. Chan*, A. Marmarou*, P.G. Newlon, H. Lutz*, H.F. Young*. Div. of Neurosurgery and Dept. of Biostatistics, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

Abnormalities in somatosensory evoked potentials (SEP's) are known to provide a powerful prognostic tool in severe human head injury. However, evaluation of an abnormal SEP had previously been dependent on human inspection. We describe herein the computerized application of a simple scale for analysis of SEP waveforms. The scale is based on the sum of the amplitudes of all the peaks occurring between 20-250 msec after stimulus. A total of 135 SEP waveforms were collected from 53 severely brain injured patients within 1 day post-injury. Each digitized waveform consisted of 512 sample points and was first processed through a peak detection program, then, a scaling program which provided a "grade" from I-III (Greenberg et al., 1977) and the probability of the waveform belonging to that grade. Grades produced by the automated technique were highly correlated with grades produced by human inspection. Differences between the two techniques were primarily attributable to errors of peak detection and may be resolved with further refinement. This method can be easily applied to computerized serial on-line monitoring of patients. Supported by NIH NS 12587.

312.2

Lower Limb Motor Evoked Potentials Elicited in Humans With a Magnetic Stimulator. I.Bell, R.D.Linden, C.H.Tator, R.D.G.Blair.

To determine the optimal scalp location for eliciting motor evoked potentials (MEP) with a magnetic stimulator, 11 normal subjects were stimulated at nine different sites on the scalp. The stimulation sites were: Cz; the midpoints between Fz-Cz, Cz-Pz, C3-Cz and Cz-C4; anterior and posterior to the midpoints of C3-Cz and Cz-C4 at 10% of the nasion-inion distance. Electromyographic activity was recorded from the extensor digitorum brevis muscles. The sweep time was 150 ms with a 30 ms delay (filter settings 10 Hz and 2000 Hz) and the interstimimulus interval was 10 sec. Stimulus intensity was set at threshold and 20% above threshold. Stimulation at each site was performed with the current flowing through the coil in a clockwise direction and in a counter clockwise direction.

MEPs elicited when the coil was placed over the anterior and central scalp locations elicited the largest responses. Threshold responses were recorded to stimulation at anterior locations in eight subjects (three left-sided, one central and four right-sided) and at central locations in three subjects (two left-sided and one right-sided). Responses could not be obtained from all 9 sites in each subject and the effect of current direction in the coil varied between subjects. This study demonstrates for the first time that MEPs can be easily recorded from the lower limbs in humans. Further, the optimal coil orientation to elicit a response from the lower limbs requires careful positioning.

312.3

ABNORMAL P1 POTENTIALS IN AUTISTIC SUBJECTS. *J.BUCHWALD, R.ERWIN, J.SCHWAFEL* AND P.TANGUAY*, (SPON: R. STRANDBURG. Dept. of Physiol.,Brain Res.Inst. and Ment.Ret.Res.Ctr., UCLA Med.Ctr.,Los Angeles, CA 90024.*

Previous work on the cat and the human has closely linked the generator substrate of the P1 potential to the ascending reticular activating system(ARAS) and to its relays in the intralaminar thalamus. A current theory of autism postulates that dysfunction of the ARAS may be fundamental to this syndrome. Thus we hypothesized that P1, a putative electrophysiological probe of the ARAS, might be abnormal in autism. To test this hypothesis, middle-latency responses(MLRS) were recorded in a group of 11 autistic subjects (mean age 25.7 years) with mean full scale IQ of 97. Each had a history of childhood autism and prior to recording was rediagnosed as autistic, utilizing DSM III criteria, by a UCLA child psychiatry team. A group of 11 normal adults (mean age 20.5 years) served as controls. MLRs from midline (Cz) electrodes were evoked by click stimuli presented at rates of 0.5,1,5,8, and 10/sec. Computer averages of 500 trails were analyzed for peak-to-peak Pa-Nb and P1-Nb amplitudes; Pa, the maximum 25-40 msec positive peak, Nb the maximum 40-50 msec negativity, and P1 the maximum 50-65 msec positivity. While Pa showed no difference between the two groups, the autistic P1 was significantly smaller at slow click rates and did not change with increasing rates. This is the first report of abnormal P1 responses in autism and indicates functional abnormality in the generator substrate of this component, postulated to be the ARAS.(Supported by HD05958 and HD04612.)

312.4

PONTINE RETICULAR FORMATION LESIONS IN THE CAT:EFFECTS ON P1 POTENTIAL AND BEHAVIOR. *J.Harrison, J.Buchwald, S.Song*, N.Woolf, L.Butcher. Brain Res.Inst.,Ment.Ret.Res.Ctr.,Dpts.of Physiol. and Psychol.,UCLA Med.Ctr.,Los Angeles, CA 90024.*

The midlatency auditory P1 evoked potential seems to reflect activity of the reticular formation(RF). It is present during wakefulness and REM sleep but absent during slow-wave sleep in cats and humans(Chen & Buchwald, Erwin & Buchwald). The cat P1 is positive with 20-30 msec latency, present at slow but not rapid click repetition rates and absent with barbiturate anesthesia. It is eliminated by scopolamine, a cholinergic antagonist (Dickerson & Buchwald). These features led us to propose that P1 is dependent on cholinergic neurons of the RF. With radio-frequency lesions we destroyed large cholinergic cells in the pedunculo-pontine tegmental nucleus in the cat RF. Early RF-lesion studies in cats resulted in a permanent sleep state(Lindsley et al.). Our cats with somewhat more posterior lesions were awake the day after surgery, but had behavioral deficits: lack of grooming, biting objects, circling to one side, tendency to bump into walls, and sometimes pain insensibility. Sham operations did not result in these effects, which are similar to deficits from lemniscal damage(Sprague et al.), although we did not lesion the lemnisci. The largest lesions resulted in permanent loss of P1. In some cases P1 remained, and some cholinergic neurons were spared. Post-lesion P1 potentials were eliminated by scopolamine and enhanced by physostigmine. These data support our hypothesis that P1 is dependent on cholinergic neurons of the RF.(Supported by USPHS Grants HD05958, and NS25400.)

THE PROPAGATION POTENTIAL. A.P. Rudell* and S.E. Fox. Dept. of Physiology, SUNY Health Sci. Ctr., Brooklyn, NY 11203.

Experiments with earthworm giant axons and bullfrog sciatic nerves have convinced us that there is a net longitudinal current flow so long as an action potential (AP) is propagating in an axon. Its extracellular component flows in a direction opposite to AP propagation. When recorded differentially from electrodes separated several cm along the outside of the axons, a negative peak appeared at the time the AP reached the first electrode and a positive peak when it reached the second. Between these events was a negative plateau (with respect to the first electrode), the propagation potential, averaging about one-third the magnitude of the peaks in the earthworm. The plateau in the earthworm was not absolutely flat, but had ripples, possibly due to differences in extracellular resistance along the nerve and to variation in its diameter. The ripple pattern was not the same for each preparation, so that an average response of 25 different axons approached absolute flatness for the duration of AP propagation. Differential intracellular recordings from giant axons with micropipets inserted in the head and tail regions showed depolarizing afterpotentials, but their decay was too rapid to account for the propagation potential. Several other hypotheses have been considered as possible explanations for the plateau, but the mechanism has not yet been established.

The implication of the findings for EEG and evoked potentials in humans is that axonal activity may be responsible for a larger portion of such recordings than previously supposed. Slowly conducting axons should produce long duration propagation potentials, which could summate to large values in spite of significant temporal dispersion.

312.6

AGE-RELATED CHANGES IN AUDITORY EVENT-RELATED POTENTIALS AS A FUNCTION OF TASK DIFFICULTY IN NORMAL HUMAN SUBJECTS. V.L. Rothenberger*, N.K. Squires*, and D.T. Arcieri*. (SPON: John Stamm). Psychology Dept., S.U.N.Y. Stony Brook, Stony Brook, NY 11794.

Event-related potential (ERP) studies have described consistent age-related changes in the P300 component, with older subjects having longer latencies than younger subjects. The current literature is inconsistent in reporting the nature of the aging/latency relationship; several studies report a linear relationship, while other studies describe a non-linear function. The current project addressed the problem of whether variation in task difficulty may explain the form of the aging/P300 latency relationship. Auditory ERPs were recorded in two three-tone auditory oddball tasks where subjects attended to two rare tones differing in the difficulty of the discrimination. Results indicated significant correlations between age and latency in the easy discrimination (r=.51) and the difficult discrimination (r=.49). Regression analyses revealed linear relationships in all task conditions. The slope of the regression line appears to increase as a function of task difficulty.

VEP CHANGES IN MS PATIENTS IN CORRELATION WITH THE STAGE OF THE DISEASE AND OTHER CLINICAL DATA. M. Ejma*, R. Podemski*, P. Olejniczak. Dept. of Neurol. Med. Sch. in Wroclaw, Poland.

Whole visual fields of each eye separately were stimulated with a reversible checkerboard pattern in 205 MS patients and 100 controls. The latencies of the P100 and amplitudes of the P100/N120 were analyzed with the Nicolet CA-1000 averager.

MS patients showed significant elongation of the latencies and reduction of the VEP amplitudes compared to the control group. VEP latencies' duration correlated positively with the certainty of the diagnosis, stage and duration of the disease. It did not depend on the actual patient's age, age at the onset of the disease or improvement obtained in the course of treatment. More marked elongation of the P100 latencies was accompanied by the fall of the amplitudes of the P100/N120 complex. Significant VEP changes were found not only in patients with optic disc decolorization, but also in cases with normal eye bottom pictures.

312.8

RELATIONSHIPS BETWEEN INTRA- AND EXTRACRANIAL RECORDINGS OF HUMAN EVENT-RELATED POTENTIALS. I. Kiss, P. Lordeon*, R. Brenner* and R. Dasheiff University of Pittsburgh Epilepsy Center and Western Psychiatric Institute and Clinic, Pittsburgh, PA 15213

Candidates for surgical treatment of epilepsy received bilateral frontal and temporal implants of 8-contact intracranial electrodes. Event-related potentials were generated using an auditory "oddball" paradigm and recorded simultaneously from sets of 16 intracranial and 4 surface midline sites.

ERP's recorded from frontal and scalp electrodes contained features of similar latency but opposite polarity. Recordings from temporal lobes were remarkable for their lack of N1-P2-like features despite the presence of N2-P3-like activity. In addition, anomalous features were recorded at intracranial regions shown to produce epileptiform discharges.

These preliminary results suggest that components of ERP's recorded at the scalp may be reflected in intracranially recorded ERP's and that N1-P2 and N2-P3 are generated in separate regions. It is also possible that intracranially recorded ERP's may aid in the location of seizure foci.

BIOMAGNETIC STUDIES FOR THE LOCALIZATION AND CLASSIFICATION OF CNS DISFUNCTION IN CHILDREN. N.C.Rasis and P.A.Anninos. Lab. of Med. physics and Neurophysiology,Univ. of Thrace, sch. of Med. Alexandroupolis,Greece.

Using the Biomagnetometer SQUID (Superconducting Quantum Interference Devise) we studied various CNS disfunctions in children and compared and classified them according to the different types that we found.With the above instrument,due to its better spatial resolution,we can localize different CNS disfunctions by measuring separetely the emitted magnetic field from 32 points in each hemisphere from the skull. These points were chosen around specified standart EEG origin positions as defined by the international 10-20 system from electrode placement.The emitted magnetic field from each measuring point is measured from a distance of 3 mm from the skull thus avoiding the junction potentials which usually develop with the use of electrode contacts.Our results were expressed in terms of "Iso-Spectral Amplitude" maps(ISO-SA)for band frequencies between 2-7Hz.In these studies we examined three groups of children.In each of these three groups we concerned with identified clinical general epilepsy,post-traumatic epilepsy and febrile convulsions respectively.In the first group using the above mapping technique we were able to indentify well extented regions of high magnetic emitted energy in the 2-7Hz band frequencies,whereas in the second ,we had focal regions near the traumatic area.Finally in the third ,we found for first time diffused regions of high emitted magnetic energy in the 2-7Hz band range located in the temporal hemispheres.

INTERLEUKIN-1 INDUCED INFLAMMATION IN THE CENTRAL NERVOUS SYSTEM: PHYSIOLOGICAL AND PATHOLOGICAL CORRELATES. M. Litwak*, C. Brosnan*, C. Schroeder and J. Arezzo, (SPON: M. Schroeder). Dept. of Neuroscience, Neurology and Pathology, Albert Einstein Coll. of Med., Bronx, N.Y. 10461

Interleukin 1 (IL1) is a protein secreted by activated macrophages. In vitro studies with endothelial cell cultures show IL1 to be involved in binding of T and B-lymphocytes and to act synergistically with interferon -gamma and tumor necrosis factor to promote migration of lymphocytes and neutrophils to the focus of inflammation. To evaluate IL1 induced inflammation on CNS function, we tested the effects of monocular injections of IL1 upon the latency and amplitude of visual evoked potentials (VEP) in 5 normal rabbits. Intraocular injection allows IL1 direct access to the myelinated fibers of the retina. The nearly complete crossing of the visual pathways permits the saline treated eye to function as an internal control.

IL1 induced an initial slowing of conduction at 3.0 hours which returned to normal by 72 hours. The effects were limited to the retina and distal portions of the optic nerve of the treated eye. At 3 hours the onset and peak of the cortical VEP were delayed by approximately 2.0 msec (10%). Histology revealed that IL1 affects the vasculature, altering the blood brain barrier resulting in the infiltration of inflammatory cells and fluids; there was no evidence of myelin pathology. Other cyokines, including: interleukin-2, interferon-gamma and tumor necrosis factor, produce similar alterations in conduction. These alterations differed principally in timing of the onset, the magnitude of the alteration and degree of reversibility. These results indicate that inflammatory mediators have an acute and direct effect on conduction within CNS pathways that may underlie the exacerbating/remitting characteristics of demyelinating diseases. Supported by NS-11920-14.

PEAK LATENCIES OF FELINE SPINAL CORD MOTOR EVOKED POTENTIALS IN RESPONSE TO ELECTRICAL, TRANSCRANIAL BRAIN STIMULATION. P.E. Konrad, W.A. Tacker, Jr.,* and D. Schooler.* Hillenbrand Biomed. Eng. Ctr., Purdue Univ., W. Lafayette, IN 47904.

Motor evoked potentials (MEPs) are bioelectrical potentials originating in efferent pathways as a result of brain stimulation. They can be used to diagnose brain or spinal cord injury which may result in motor dysfunction. The development of a standard feline model of the MEP test requires characterization of peak latencies at standard recording locations and under a variety of stimulus intensities and modalities likely to be used by investigators. To this end, 10 cats were anesthetized and prepared for paraspinal recording of MEPs at the level of $T_{9/10}$. Peak latencies of spinal cord MEPS were recorded in response to scalp-, dura- and cortex-to-palate transcranial stimulation. A broad range of stimulus intensities and durations (0 - 80 mA; 50 - 1000 μsec; 21 Hz; 200 repetitions per average) were used for each stimulus modality resulting in the genesis of nine distinct peaks. The range of average peak latencies was 1.57 - 9.75 msec. Statistical analysis using a general linear model procedure and studentized Newman-Keuls test showed that the average latency for each peak is statistically different ($p < 0.05$) from each other, independent of the effect of stimulus modality or cats. The results emphasize the absence of overlap of latencies for the peaks. The first four peaks occurred with relatively high frequency (>41%) within the range of stimulus intensities tested.

313.1

OXIDATION PRODUCT OF SEROTONIN: NEUROTOXIC PROPERTIES. E.P.Crino, E.A.Vogt, J-C.Chen, and L.Volicer. Dept. of Pharmacology, Boston Univ. Sch. of Med., Boston, MA. 02118 and GRECC, E.N.Rogers Mem. Vet.Hosp., Bedford, MA 01730.

Electrochemical oxidation of serotonin has yielded a partially oxidized compound (5HTe-) which is similar chromatographically to one found in Alzheimer patient cerebrospinal fluid. To assess its toxicity, 5HTe- (80ug in 20ul buffer) was injected into the lateral ventricles of rats. Animals were sacrificed at 6 days post-injection and stained with the Fink-Heimer method for nerve terminal degeneration. Cell death and terminal degeneration was evident in superficial layers of prefrontal, insular, and posterior cingulate cortices, and in CA1, CA3, and dentate gyrus sectors of hippocampus. 5HTe-injection (5ug in 5ul buffer) into cingulate and hippocampal cortices resulted in cell death and terminal degeneration. In hippocampus, degeneration was prominent in CA1 and dentate gyrus. Projection areas of cingulate cortex such as anterodorsal thalamic nucleus and contralateral cingulate cortex also showed terminal degeneration. Thus, 5HTe- is neurotoxic and may contribute to the pathogenesis of Alzheimer's disease. (Supported by USPHS AG06419 and the Veterans Administration).

313.2

ENDOGENOUS NEUROTOXIN FORMATION IS DUE TO NON-ENZYMATIC OXIDATION OF MONOAMINES. K.J. Axt and L.S. Seiden. Dept. Pharm/Phys. Sci., Univ. of Chicago, Chicago, IL 60637.

We have previously reported the formation of endogenous neurotoxins in the rat brain shortly after a single high dose of methamphetamine (MA) and p-chloroamphetamine (pCA). We have speculated that MA and pCA neurotoxicity are mediated by these neurotoxins (Seiden & Vosmer, 1984; Commins et al., 1987a,b). We now report that the endogenous formation of 6HDA and 5,6-DHT likely result from autoxidation of monoamines and not through the action of a hydroxylase. Evidence includes 1) the inability of hydroxylase inhibitors, other than a-methyl-p-tyrosine (AMT), to prevent the MA-induced long-term depletions of DA and 5HT; 2) the ability of aminotriazole, a catalase inhibitor, to enhance MA-induced DA depletions and 6HDA formation (in vivo and ex vivo). Aminotriazole pretreatment does not enhance MA-induced 5HT depletions nor formation of 5,6-DHT from 5HT ex vivo using a Fenton reaction system. This latter result may be explained by in vitro studies using a Fenton reaction system in which excess hydrogen peroxide markedly enhances degradation of 5,6-DHT. This research was supported by PHS MH-14274 Training Grant; RSA MH-10562 (L. Seiden) and NIDA DA-00250.

313.3

TOXICITY OF 6-OHDA IN THE HUMAN NEUROBLASTOMA CELL LINE SH5Y5Y IS INDEPENDENT OF DOPAMINE UPTAKE. D.E. Decker*[1], S.E. Buxser*[1], J.S. Althaus*[2] and P.F. VonVoigtlander[2] (SPON: K. Lookingland). [1]Cell Biology and [2]CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Toxicity of 6-hydroxydopamine (6-OHDA) in vivo has been shown to be dependent on the competitive binding of 6-OHDA to norepinephrine (NE) and dopamine (DA) uptake systems in both peripheral and central catecholamine (CA) containing neurons. The human neuroblastoma cell line SK-NSH-SY5Y (SY5Y) also shows toxicity to 6-OHDA (Castiglioni et al. 1982, Biochem. Pharm. 31:181). This toxicity could be neutralized by catalase and was thought to be dependent upon the generation of H_2O_2. We examined 6-OHDA toxicity in the SY5Y to determine if specific toxicity occurring through a DA dependent uptake mechanism could be demonstrated. As a measure of 6-OHDA toxicity, uptake of the nonmetabolizable amino acid alpha amino isobutyric acid (AIB) was measured after treatment with 6-OHDA for 1 hr at 37°. The IC_{50} value for 6-OHDA in inhibiting AIB uptake in SY5Y cells was 50 µM. Toxicity of 6-OHDA was prevented in the presence of 3 U/ml of catalase. Since catalase alone could prevent toxicity of 6-OHDA, toxicity occurring through a CA uptake system under these conditions was doubtful. HPLC analysis using electrochemical detection showed that less than 10% of the 6-OHDA was detectable after incubation at 37° for 1 hr. However, inclusion of 1 mM ascorbate (ASC) under these conditions stabilized the 6-OHDA. When 1 mM ASC was included in the incubation medium and AIB uptake measured, an increase in the toxic potency of 6-OHDA was observed, and this could not be completely blocked with 3 units/ml of catalase. Initially it was presumed that the increased toxicity of 6-OHDA in the presence of 1 mM ASC reflected the stabilization of 6-OHDA and subsequent toxicity through a CA specific uptake system. However, when 1 mM DA was included in the incubation medium to block 6-OHDA uptake, toxicity still occurred. Alternatively the increased toxic potency of 6-OHDA in the presence of 1 mM ASC may result from an increased concentration of H_2O_2 liberated by 6-OHDA through a redox-recycling mechanism in the presence of ASC. This hypothesis was supported by the result that the toxicity of 6-OHDA in the presence of 1 mM ASC could be blocked by increasing the catalase concentration to 30 units/ml. Although we showed that SY5Y cells possess a DA uptake system that was specifically blocked by 1 µm nomifensine, toxicity of 6-OHDA did not appear to occur as the result of 6-OHDA uptake into cells via the DA uptake system.

313.4

MECHANISM OF METHAMPHETAMINE-INDUCED NEURONAL DAMAGE: A POSSIBLE ROLE FOR FREE RADICALS. G.C. Wagner and M.J. DeVito* Depts. of Psychology and Toxicology, Rutgers Univ. New Brunswick, NJ 08903

The hypothesis that methamphetamine-induced neuronal damage is mediated by free radical production was evaluated by pretreating rats with either antioxidants or a superoxide dismutase inhibitor. Methamphetamine (6.25 - 25mg/kg delivered four times at 2 h intervals) or saline was administered to rats pretreated with ascorbic acid (10 - 1000 mg/kg), ethanol (1 g/kg), vitamine E (2 g/kg), mannitol (2 g/kg) or diethyldithiocarbamate (200 - 800 mg/kg). Rats were sacrificed two weeks later, striatal tissue was removed and dopamine and serotonin levels determined.

Administration of methamphetamine resulted in significant depletions of striatal dopamine (to 50% of control) and serotonin (to 50% of control). Pretreatment with any of the antioxidants significantly attenuated or completely eliminated the long-lasting monoaminergic depletions while pretreatment with DDC increased the magnitude of these depletions by approximately 20%.

These observations indicate that the repeated administration of methamphetamine results in long-lasting depletions of striatal dopamine and serotonin. The attenuation of this toxicity by three different antioxidants indicates that oxygen free radicals may have a role in the methamphetamine-induced neuronal damage.

313.5

TYRAMINE-INDUCED ALTERATIONS IN STRIATAL MONOAMINES. S.L. Walsh and G.C. Wagner. Department of Psychology, Rutgers, The State University, New Brunswick, NJ 08903

Tyramine, a potent releaser of catecholamines, is found endogenously in the central nervous system as well as exogenously in several food products. In an effort to determine if exposure to high doses of tyramine would result in altered striatal metabolism and/or cause long-lasting monoaminergic depletions, the following studies were conducted.

Swiss-Webster male mice were treated (s.c.) with 100 mg/kg tyramine HCl, sacrificed and striata dissected 20, 40, or 80 minutes later. It was observed that there were significant increases in the DOPAC/DA ratio at forty minutes which returned to baseline by 80 minutes, as well as increases in serotonin (50%) and 5HIAA (86%) at each time tested.

Swiss-Webster male mice were treated (s.c.) with 20, 40 or 80 mg/kg of tyramine HCl four times at two hour intervals then sacrificed one week later. It was observed that there was a significant decrease in striatal dopamine concentration at each dose with the greatest loss observed (35%) at the highest dose.

These observations indicate that peripheral administration of tyramine at high doses may result in both acute and long-lasting alterations in striatal neurotransmitter systems.

TRIADIMEFON INDUCES SEX-DEPENDENT CHANGES IN STEREOTYPED BEHAVIOR AND BIOGENIC AMINE ACTIVITY. O.D. Walker*, M.H. Lewis, K.C. Crofton, and R.B. Mailman (SPON: R.C. MacPhail). Curriculum in Toxicology and Biological Sciences Research Center, UNC, Chapel Hill, NC, and US-EPA, RTP, NC.

Triadimefon, [1-(4-chlorophenoxy)-3,3-dimethyl-1-(1H-1,2,4-triazol-1-yl)-2-butanone], is a triazole fungicide that has been observed to induce hyperactivity in mice and rats, and stereotyped behavior in female rats. The present study contrasted the behavioral effects produced by triadimefon in male and female Sprague-Dawley rats using a computer-supported observational method. Triadimefon was administered i.p. (0, 50, 100, or 200 mg/kg) in corn oil (2 ml/kg) four hours prior to behavioral assessment (n=10). Results indicated a highly significant dose-dependent change in stereotyped behavior in both sexes, with the highest dose producing increases in head weaving, circling, and a six-fold increase for females in backward locomotion. Sex differences were also observed in gnawing, rearing, locomotion, and inactivity. Concentrations of dopamine (DA), serotonin (5-HT) and their metabolites were determined by HPLC in nigrostriatal and mesolimbic terminal areas. In corpus striatum, triadimefon produced decreases in DOPAC at all three doses, but increases in 5-HIAA at the two highest doses. At the highest dose, DA concentrations were decreased while HVA was doubled. Dopamine utilization in the olfactory tubercles was much less altered by the fungicide with an increase in HVA observed only at the highest dose. Sex differences in monoaminergic activity were also examined and related to behavioral effects. (Supported in part by ES07126)

313.7

THE NE DEPLETING EFFECTS OF DSP-4 ARE NOT MAO B DEPENDENT AND DO NOT INCREASE WITH AGE. K. T. Finnegan*, L. E. DeLanney, I. Irwin*, G. A. Ricaurte, and J. W. Langston. *Institute for Medical Research, San Jose, CA 95128; Johns Hopkins Univ Sch of Med, Baltimore, MD 21205.* Age-related increases in MAO B activity may play an important role in the age-dependent effects of toxins that employ this enzyme for their bioactivation. The toxicity of the noradrenergic toxin, DSP-4, is reported to be prevented by the MAO inhibitors pargyline and deprenyl, suggesting that DSP-4 is metabolized by MAO B to a toxic metabolite (Gibson, 1987). Therefore, we examined the age-dependent hippocampal NE depleting effects of DSP-4 in 2 month and 10 month old C57BL/6 mice 1 week after DSP-4 administration. DSP-4 produced equivalent, dose-related depletions of hippocampal NE in the 2 age groups, suggesting that either: 1) other factors besides MAO B dependent activation are necessary for a toxin to produce age-related toxic effects; or 2) the ability of deprenyl to prevent NE toxicity may not be related to MAO B inhibition, but rather its ability to block NE reuptake. To test the latter possibility, we pretreated mice with deprenyl either 1 hr or 24 hrs before DSP-4. Deprenyl protected NE neurons when given 1 hr before DSP-4, but at the 24 hr pretreatment interval protection diminished significantly. Since MAO B is still completely inhibited 24 hrs after deprenyl, it seems unlikely that the protective effects of deprenyl can be solely attributable to MAO B inhibition. Thus the protection afforded by the 1 hr pretreatment interval may, at least in part, be due to NE reuptake blockade, mediated by the transient presence of deprenyl or its metabolites meth-amphetamine and amphetamine. These results may explain the inability of DSP-4 to cause increased toxicity with age.

313.8

ACUTE THIAMINE DEFICIENCY IN THE RAT: BRAIN LESIONS, AMINO ACID CHANGES AND MK-801 PRETREATMENT. P.J. LANGLAIS, R.G. MAIR, & W.J. MCENTEE, Research Service 151C, VA Med. Ctr., Brockton, MA 02401.

We have observed permanent tissue loss and amino acid reductions within thalamus, and learning-memory deficits in a rat model of Korsakoff's disease produced by an acute bout of pyrithiamine-induced thiamine deficiency (PTD). In the present study, rats were sacrificed at two stages of acute PTD to determine the progression and extent of pathological and amino acid changes. In an early acute group, a selective and marked loss of neurons was observed within intralaminar and posterior thalamic nuclei. At a later stage, severe neuronal and tissue loss and gliosis were present throughout the entire thalamus and to a lesser degree within hypothalamus, central and periacqueductal grey. In the late acute group, hemorrhagic lesions were present within the mammillary body (MB), geniculate (MG-LG) nuclei and thalamus. Affected areas were marked by large reductions of glutamate and aspartate and a 2-3 fold increase of glycine. Pretreatment with the NMDA antagonist MK-801 markedly attenuated the extent of cell loss, hemorrhages, and amino acid changes. These observations suggest that in PTD: i) a neurotoxic process originates within intralaminar nuclei and spreads into remaining thalamic and surrounding tissue; ii) damage to MB and DG-LG is primarily hemorrhagic and a later event; and iii) NMDA receptors play a role in the pathophysiological processes.

Supported by Veterans Administration research grant.

DETECTING CIRCUMVENTRICULAR ORGAN (CVO) TOXICITY. A. C. Scallet, J. W. Bryan, IV*, R. Rountree* and A. Andrews*. National Center for Toxicological Research, Jefferson, AR 72079.

The CVOs (arcuate nucleus, area postrema, and others) are preferentially exposed to blood-borne neurotoxicants since they lack the protection of a blood-brain barrier. Various chemicals produce necrosis of CVO cells, but monosodium glutamate (MSG) has most often been used experimentally. To compare methods to detect altered CVO function, male rats (n=17-23) received subcutaneous MSG on postnatal days 2, 4, 6, 8, and 10 (4 mg/g/day, group SC4) or orally by gavage (4 mg/g, group PO4 or 2 mg/g, group PO2) according to the same schedule. Controls (Cs) received SC or PO saline. PO2 and PO4 rats showed a dose-related decrease in body-weight through 3 mo of age. SC4 rats weighed the least until 13-14 wk, when their weight-gain accelerated markedly. At 8 mo, the nose-to-anus length of PO4s was less than Cs ($p < 0.01$), and SC4s were shorter than either PO4s or Cs ($p < 0.01$). On a hotplate analgesia test, SC4s and, to a lesser extent, PO4s had longer baseline latencies and greater response to morphine than Cs. The results signify that oral dosing of neonates with MSG may have prolonged effects on their growth and development. Immunohistochemical evaluation of the CVOs of these animals is underway.

313.10

EXCITOTOXIC MEDIATED SPINAL CORD DAMAGE: POSSIBLE ROLE OF THE NMDA RECEPTOR. V.Q. Gardner, V.J. Caiozzo, S. Munden, and R.J. Bridges. (SPON: S. van den Noort). Div. Orthop. and Dept. of Neurol., Univ. California, Irvine, CA 92717

Glutamate has been identified as a major excitatory transmitter in the mammalian CNS and, when present in excessive amounts, a potent neurotoxin. Recent studies have implicated NMDA (N-methyl-D-aspartate) receptor activation and increased intracellular Ca^{++} concentrations as mechanisms involved in this excitatory mediated cell death. In the present study, we have examined the effects of Ca^{++}, glutamate, and NMDA receptor antagonists on protein degradation in the spinal cord.

Spinal cords were rapidly removed from male Sprague-Dawley rats and divided into 4 segments. These segments were then either frozen immediately (time 0 control) or allowed to incubate for 3 hours at 23° C in physiological buffer with or without: 1) Ca^{++}, 2) glutamate, or 3) a noncompetitive antagonist of the NMDA receptor. The tissue samples were homogenized and the proteins were separated by gradient SDS-polyacrylamide gel electrophoresis and stained with Coomassie brilliant blue R-250.

Spinal cords incubated in buffer containing Ca^{++} or Ca^{++} plus glutamate consistently exhibited a dramatic decrease in band density at molecular weights of 200, 150, and 68 kDa. These bands correspond to the known molecular weights of proteins that make up the neurofilament triplet. Importantly, this degradation could be attentuated by the inclusion of ketamine (i.e., a noncompetitive inhibitor of the NMDA receptor). These findings demonstrate increased protein degradation in spinal cord in response to high levels of glutamate and suggest that the NMDA receptor may be involved in excitatory mediated spinal cord injury.

Supported in part by a grant from the American Paralysis Association and the Irvine Community Foundation.

SOMAN IN MULTIPLE LOW DOSES: DAMAGE TO SELECTED POPULATIONS OF NEURONS IN RAT BRAIN. R.C.SWITZER III[+], M.R.MURPHY^ S.K.CAMPBELL*, S.Z.KERENYI[#*], S.A.MILLER[#*], & S.L.HARTGRAVES[#]. [+]University of Tennessee, Med. Ctr., Knoxville TN 37920; ^Systems Research Lab., & [#]Radiat. Sci. Div., USAF Sch. Aerosp. Med., Brooks AFB, TX.

Soman is a fast acting, irreversible anticholinesterase organophosphate neurotoxin present in the chemical arsenals of a number of countries. Until recently sensitive methods had not been applied to show that single, severe symptom-producing doses cause CNS degeneration. We sought to determine if multiple exposures to single doses, each of which produce no anatomical or severe clinical symptoms, could result in CNS degeneration. Rats were given 54 μg/kg/day of soman for 5 days. Rats surviving the initial effects were allowed to survive from 7 to 35 days. Degeneration in 40μ freeze-cut sections was assessed using the cupric-silver staining method of de Olmos. Rats recovering rapidly from loss of weight showed no brain degeneration, but rats requiring extra care to recover from severe dehydration and weight loss displayed extensive degeneration in specific areas, including specific regions and layers of cortex, select thalamic nuclei, septum, amygdala, hippocampus and olfactory bulb. Hypothalamus, brain stem and cerebellum were devoid of degeneration.

Performed under USAF Contract F33615-85-D-0659 with Naval Medical Research and Development Command funding under project MF4561.001.

313.12

SOMAN TOXIC SYNDROME: PERFORMANCE, PHYSIOLOGY, BIOCHEMISTRY, AND NEUROPATHOLOGY. M. R. Murphy[+], S. Z. Kerenyi*†, S. A. Miller*†, R. C. Switzer III‡, D. W. Blick*†, & S. L. Hartgraves* *Systems Research Laboratories, ‡U. Tenn., & †Radiation Sci. Div., USAF School of Aerospace Medicine, Brooks AFB, TX 78235-5301.

Rats exposed for 5 days to 54 μg/kg/day of soman, an organophosphate that irreversibly inactivates cholinesterase (ChE), showed brain and blood ChE inhibition, weight loss, and variable motor symptoms (including convulsions). After soman administration ceased, surviving rats fell into dichotomous groups: 1) those recovering lost weight rapidly and showing no brain degeneration or abnormal behavior; and 2) those requiring extra care to recover from profound dehydration and weight loss, and, after recovery, displaying spontaneous, recurrent convulsions, hyperreactivity, changes (not necessarily deficits) in learning and performance of two-way shuttle avoidance, and extensive but localized brain degeneration.

This research was performed under USAF Contract F33615-85-D-0659, with funding from the Naval Medical Research and Development Command, project MF4561.001.

313.13

PROTECTIVE EFFECT OF BOTULINUM TOXIN ON MUSCLE TOXICITY OF SOMAN. M.E. Clinton, K.E. Misulis, W-D. Dettbarn. Neurology & Pharmacology Depts. Vanderbilt Univ., Nashville, TN 37212.

Acetylcholinesterase (AChE) inhibitors induce fasciculations and necrosis of skeletal muscle, which is presumed to be due to excess of acetylcholine (ACh), although this has not been proven. Botulinum toxin (BTX) a presynaptic inhibitor of acetylcholine release, was injected directly into the hindlimb of rats. Two days later the rats were given soman. One group was studied by electromyography (EMG) during the acute intoxication and a second group histologically with muscle taken 24 hours later.

Motor unit firings were recorded and digitized. In the acute group, within 60 min of receiving soman, controls had 584/min motor unit firings compared with 44.7/min in those with soman plus BTX. In the second group rats were sacrificed after 24 hours, and the left extensor digitorum longus was taken for histological staining. Those with soman alone had 35.3 lesioned muscle fibers per cross section compared with 3.8 for the BTX group.

Inhibition of ACh presynaptically prevents both fasciculations and the myopathy due to soman poisoning, further evidence that ACh excess is the responsible factor in soman induced myopathy and likely similar myopathies seen with other AChE inhibitors.

313.14

INFLUENCE OF PRETREATMENT AND THERAPEUTIC COMPOUNDS ON THE MORPHOLOGIC EFFECTS OF ACUTE SOMAN INTOXICATION IN THE RHESUS MONKEY. I. J. Hayward*, H.G. Wall*, N.K. Jaax*, J.V. Wade, J.B. Nold*, and D.D. Marlow*. US Army Medical Research Institute of Chemical Defense, APG, MD 21010-5425

The potential of anticonvulsant treatment to ameliorate brain lesions induced by the irreversible organophosphorus cholinesterase inhibitor soman (pinacolyl methylphosphonofluoridate) was examined in rhesus monkeys. Monkeys were pretreated with pyridostigmine (1.2 mg/kg, q8hr x 4, p.o.), injected 4.5-5 hr later with soman (76.5 ug/kg, i.m.), and then treated 1 min post-soman with atropine (0.4 mg/kg, i.m.), pralidoxime chloride (2-PAM, 25.71 mg/kg, i.m.), and diazepam, midazolam (1 mg/kg, i.m.), or sterile water. Treatment with diazepam or midazolam hastened recovery following soman challenge, when compared to animals receiving atropine and 2-PAM without an anticonvulsant. At 48 hr, tissues were prepared for routine histopathology with emphasis on brain, in particular frontal and entorhinal cortex, amygdala, caudate, and hippocampus. Neuronal lesions were generally minimal to mild regardless of treatment, except for occasional moderate lesions in animals that did not receive an anticonvulsant. Neuronal degeneration and necrosis were decreased significantly in the highly vulnerable entorhinal cortex, caudate nucleus, and hippocampus of anticonvulsant-treated animals. Thus, anticonvulsant therapy ameliorated brain lesion development in some areas and hastened the time to recovery post-soman challenge.

ORGANOPHOSPHATE INTOXICATION ALTERS DISTRIBUTION OF ELEMENTS IN CHICKEN PERIPHERAL AXONS. R. M. LoPachin, D. M. Lapadula* and M. B. Abou-Donia. Dept. of Anesthesiology, SUNY, Stony Brook, NY 11794 and Dept. of Pharmacology, Duke Medical School, Durham, NC 27710

Alterations in subcellular distribution of Na, Ca and other elements appear to play an important role in mediating cellular damage induced by a variety of injurious processes. We have used x-ray microprobe analysis to investigate the possibility that delayed nerve damage caused by organophosphates involves a perturbation of axonal elemental homeostasis. Leghorn Chickens were given a single oral dose of either tri-o-cresyl phosphate (TOCP, 750 mg/kg) or control solution. Fourteen days later control and treated chickens were sacrificed and mid-thigh sections of sciatic nerve were frozen in situ and removed for analysis. Concentrations (mmol element/kg dry wt) of Na, P, Cl, K and Ca were determined in frozen, unfixed, ultrathin (<200 nm) sections of nerve. Four sciatic nerve compartments were examined; axoplasm, mitochondria, myelin and ECF. In both axoplasm and mitochondria from control chickens K was the most abundant element whereas Na and Ca were present in very low concentrations. In myelin, P was most prominent with other elements being present at concentrations <200 mmol/kg dry wt. The ECF exhibited relatively high concentration of Na, Cl and Ca. These results are quantitatively similar to those from rat sciatic nerve (LoPachin et al., *J. Neurochem.*, 1988). TOCP intoxication was associated with a marked derangement of intracellular elemental distribution. Sodium levels increased 2-3 fold in both mitochondria and axoplasm whereas K concentrations decreased by one-third. In axoplasm, Ca levels increased only slightly, while mitochondrial levels of this element arose substantially. Changes in myelin or ECF were not observed. These results suggest that changes in intra-axonal levels of Na, K and Ca are involved in the mechanism of organophosphorous compound-induced delayed neurotoxicity. Supported by NIH Grants ES03810, OH02003 and ES02717.

NEUROBEHAVIORAL EFFECTS OF TRICHLORFON IN B6C3F1 MICE DURING A SUBCHRONIC DOSED FEED STUDY. G.B. Freeman, J. Killinger*, R. Trejo*, P.C. Chan*, A. C. Peters*. Battelle Columbus Division, Columbus, OH and NIEHS, Research Triangle Park, NC.

Trichlorfon is an organophosphate used commercially as an insecticide. In this 13-week subchronic dosed feed study, male and female B6C3F1 mice were administered trichlorfon in the diet for 13 weeks at dose levels of 0, 62, 185, 555, 1666 and 5000 ppm. Neurobehavioral evaluations were performed after 6 and 12 weeks of dosing. Total motor activity was reduced compared to control in both sexes at both study intervals in the 1666 and 5000 ppm dose groups. Female mice in the 1666 ppm group showed a 17% decline at 6 weeks and a 16% decrease at 12 weeks. The 5000 ppm female group demonstrated a 24% and 30% reduction at 6 and 12 weeks, respectively. Similar declines were reported for male mice; however, decrements became more severe at 12 weeks (1666 ppm at 6 weeks = 17%, 1666 ppm at 12 weeks = 27%, 5000 ppm at 6 weeks = 22%, 5000 ppm at 12 weeks = 39%). While the two sexes showed similar changes in motor activity, significant differences in grip strength were reported only for the 5000 ppm female group at 12 weeks. The lack of body weight reductions in mice suggested that grip strength deficits were not related to body weight. The results of the subchronic study indicated potential neurotoxic effects of trichlorfon, and that 5000 ppm was the apparent Maximum Tolerated Dose (MTD) in mice.

313.17

DISTINCT TOXICITIES OF INSECTICIDE PARATHION AND PARAOXON. K.-P. Shaw and J.C. Liu.* Dept. Biol. Anat., Natl. Def. Med. Ctr. Taipei, Taiwan, ROC

The purpose of these experiments was to characterize the mechanism of protection and therapy of organophosphate poisoning produced by insecticide parathion (IP) and its metabolite paraoxon (PO) which are widely used in many countries. PO (3-8 mg%) can potentiate indirect nerve twitch of sartorius muscle of frog, Rana catesbeiana to 126% of control value. PO (10 mg%) can completely abolish the direct muscle twitch and indirect twitch without potentiation. After washing for 1 hour, recovery of indirect twitch to 48% was observed. The commercial insecticide IP (8 mg%; contains organic solvent 3.5% xylene) induces depolarization and blocks indirect twitch completely without potentiation. After washing for 3 hours an 8% recovery of the indirect twitch was recorded. 3.5% xylene alone depolarizes and depresses the direct and indirect muscle twitch within 20 minutes. Pretreatment with atropine sulfate (1 mg/kg) and physostigmine salicylate (0.1 mg/kg) 10 minutes prior to PO (but not IP) exposure increases LD_{50} by 8 times in Balb/C mice. In conclusion, the distinct toxicities may relate more to the solvent than to the cholinergic effect of the insecticide. (Grant NSC 77-0412-B016-32, ROC)

NTE INHIBITION IS NOT FOLLOWED BY RETROGRADE AXONAL TRANSPORT DEFICIT AND POLYNEUROPATHY IN CHICKS. A. Moretto*, M. Lotti*, P.S. Spencer and M.I. Sabri. Institute of Neurotoxicology, Albert Einstein College of Medicine, Bronx, NY and Istituto di Medicina del Lavoro, Universita' di Padova, Italy.

Some organophosphorus esters induce central-peripheral distal axonopathy in sensitive species. The initiation mechanism is related to the inhibition and aging of more than 70% of axonal neuropathy target esterase (NTE) within hours of dosing. A progressive deficit of retrograde transport (RT) of I125-tetanus toxin along sciatic nerve follows with a peak inhibition 7 days after treatment. Clinical and morphological signs of neuropathy appear 10-14 days later. Morphological feature of this neuropathy is the degeneration of the distal, non terminal parts of the long and large-diameter axons in both spinal cord and peripheral nerves. Young animals are resistent to this toxicity despite the fact that nervous system NTE is inhibited by organophosphates. We treated 19-day old chicks with di-n-butyl-dichlorovinyl phosphate (DBDCVP;1mg/kg,s.c.), a neurotoxic dose for hens. Twenty four hours after dosing, NTE was inhibited more than 70% in chick brain, spinal cord and peripheral nerve. NTE in the nervous system of chicks was higher than the activity in hen nervous system. Seven days after DBDCVP treatment, accumulation in dorsal root ganglia and ventral spinal cord of retrogradely transported I125-tetanus toxin in treated animals did not significantly differ from that of vehicle-treated animals. Morphological examination on day 7, 14 and 21 after dosing showed no damage to either spinal cord or peripheral nerve axons. These data show that DBDCVP does not inhibit RT and cause neuropathy in chicks. Supported by NS19611.

TREMOR AND GRAIN PESTICIDES. L.J. Chapman*, Sauter S.L.*, Henning R.A.*, Matthews C.G.*, Levine R.L.*, Peters H.A.* (SPON: R. Daly). Speech Motor Control Labs., Neurology Department, University of Wisconsin, Madison, WI 53705-2280.

Although most tremor diagnoses are personal judgements based on visual observations, the unassisted clinician's eye can detect only gross differences in tremor amplitude and frequency. In the present study, computer-monitored strain gauge measurement of index finger tremor was able to demonstrate significant tremor amplitude and frequency differences between 19 grain industry employees and 19 controls. All the grainworkers were exposed to fumigant pesticides containing carbon disulfide, a known parkinsonian neurotoxicant and chronic tremorogen. Discriminant function analyses determined that computerized tremor measurement was more sensitive than conventional clinical tremor examination and did not misclassify any of the normal controls. Tremor power spectra in the grainworker group were abnormally shifted toward the lower frequencies and compressed into sharp frequency peaks. These results suggest that computerized finger tremor measurement may provide an indication of adverse neurotoxic effects prior to clinical diagnoses of a functional parkinsonian syndrome or a manifest overt disease state.

REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS III

314.1

AUTORADIOGRAPHIC EVIDENCE THAT SPINOTHALAMIC TRACT NEURONS POSSESS ADENOSINE RECEPTORS. J. I. Choca, R. D. Green*, and H. K. Proudfit. Dept. of Pharmacology, University of Illinois at Chicago, College of Medicine, Chicago, IL. 60612.

The purine nucleoside, adenosine, modulates pain transmission at the spinal cord level by interacting with adenosine A_1 and A_2 receptors, which are located predominantly on intrinsic neurons. We investigated the possibility that some of these spinal cord adenosine receptors may be localized on neurons of ascending somatosensory pathways. The spinothalamic tracts were lesioned by unilateral injections of the fluorescent, retrogradely-transported neurotoxin, doxorubicin, into the thalamic nuclei of rats. Autoradiographic studies were performed on paired spinal cord sections using the A_1-selective agonist, [^{3}H]R-PIA, and [^{3}H]NECA, an adenosine agonist that binds with equal affinity to A_1 and A_2 receptors. These lesions of the spinothalamic tract differentially decreased the [^{3}H]R-PIA and [^{3}H]NECA binding densities in the substantia gelatinosa. The results suggest that some spinal cord adenosine receptors are located on the cell bodies or dendritic branches of the spinothalamic tract neurons. Analgesia, which is produced by adenosine, may result from an adenosine-mediated inhibition of the spinothalamic tract neuron's response to painful stimuli. (Supported by USPHS Grant DA 03980)

314.2

MULTIPLE GRADIENTS OF ADENOSINE A_1 RECEPTORS IN THE CA1 REGION OF THE HIPPOCAMPUS. K.S. Lee. Dept. of Anatomy, Thomas Jefferson University, Philadelphia, PA 19107

Adenosine A_1 receptors are highly concentrated in the CA1 region of the hippocampus and exhibit a gradient of density along the longitudinal or septo-temporal axis of the hippocampus. Receptor localization studies utilizing autoradiographic techniques were undertaken to study the possibility of an additional gradient within the CA1 region along the transverse axis of the hippocampus. ^{3}H-cyclohexyladenosine (CHA) was utilized as a ligand for labeling A_1 receptors in cryostat sections as previously described (Lee and Reddington, Neurosci. 19: 1986). Quantitative densitometric measurements of CHA binding to coronal sections of rat and gerbil brains were performed using an Analytical Imaging Concepts system. The strata radiatum and oriens were measured in areas CA1a, CA1b and CA1c at a point approximately one-third of the distance from the septal pole along the longitudinal axis of the hippocampus. The relative densities of CHA binding can be summarized as follows: CA1a > CA1b > CA1c. Thus, two gradients of adenosine A_1 receptors are observed within the CA1 region, one oriented along the longitudinal axis of the hippocampus and a second along the transverse axis. The physiological impact of the differential distribution of A_1 receptors will be discussed as will the potential relevance of this pattern of distribution for the selective vulnerability of CA1 subpopulations.

314.3

AUTORADIOGRAPHIC LOCALIZATION OF ADENOSINE A-2 RECEPTORS IN THE RAT BRAIN. M.F. Jarvis, R.H. Jackson* and M. Williams Research Dept. Pharmaceuticals Div. CIBA-GEIGY Corp. Summit, NJ 07901

Purinergic neuromodulation appears to be mediated through pharmacological activity at two cell surface receptors, adenosine A-1 and A-2. While A-1 receptors have been well characterized, the study of A-2 receptors has been limited by the lack of appropriate ligands. In the present study, quantitative receptor autoradiography was used to localize binding sites for the nonselective agonist [^{3}H]NECA in the rat brain. The regional distribution of [^{3}H]NECA binding was similar to that for [^{3}H]CHA binding to A-1 receptors with the exception that the greatest density of binding was found in the striatum. When 50 nM CPA was included in the assay to block binding to A-1 receptors (Bruns et al., 1986; Mol. Pharmacol. 29: 331), [^{3}H]NECA binding sites (Kd = 9 nM and Bmax = 230 fmol/mg tissue) were exclusively concentrated in the striatum and olfactory tubercle. Pharmacological analysis of [^{3}H]NECA binding (+ 50 nM CPA) in striatum revealed a selective labeling of A-2 receptors (i.e. NECA showed the greatest activity in inhibiting [^{3}H]NECA binding (IC_{50} = 4 nM) followed by 2-CADO > R-PIA > CPA > S-PIA). These results indicate that some of the neuromodulary actions of adenosine may be mediated, at least in part, by A-2 receptors in the basal ganglia.

314.4

DOPAMINE D-2 RECEPTOR AUTORADIOGRAPHY IN THE FOREBRAIN OF BALB/cJ AND CBA/J MICE. K. Ozsvath* and D.C. German. Depts. of Psychiat. and Physiol., UT Southwestern Med. Cntr., Dallas, TX 75235-9070.

BALB/cJ mice exhibit greater spontaneous locomotor activity, possess 20% more midbrain dopaminergic neurons and 33% more D-2 receptor sites in the striatum than CBA/J mice (Baker et al. PNAS, 77:4369-4373, 1980; Boehme & Ciaranello PNAS, 78:3255-3259, 1981). Because of the important role of the nucleus accumbens in locomotion, we sought to measure the densities of D-2 receptors in this structure using receptor autoradiography techniques with ^{3}H-raclopride. In preliminary studies using scintillation counting of coronal sections through the forebrain, the specific binding of ^{3}H-spiperone was saturable with a Bmax = 148 ± 8 fmole/mg protein for the BALB/cJ mice and 194 ± 15 for the CBA/J mice (mean ± S.E.M., n = 6, $p < 0.05$). The Kd values were the same for both strains (1 nM). The autoradiographic experiments will reveal which forebrain nuclei (striatum, nucleus accumbens, etc.) are responsible for the overall greater number of binding sites in the CBA/J strain. ANATOMICAL AND ELECTROPHYSIOLOGICAL EXAMINATION OF A10 DOPAMINERGIC NEURONS IN INBRED MOUSE STRAINS. G.L. Bernardini, K.F. Manaye and D.C. German. Depts. of Physiol. and Psychiat., UT Southwestern Med. Cntr., Dallas, TX 75235.

The A10 dopamine (DA)-containing neurons, of the ventral tegmental area, play a role in locomotion and motivation. BALB/cJ and CBA/J mice have been shown to differ in A10 cell numbers and DA-related behaviors. The purpose of the present experiment was to determine whether the number of cells influences the firing properties of the cells. The locations and sizes of tyrosine hydroxylase immunohistochemically stained A10 neurons were entered into a computer from BALB/c, CBA, C3H/He and DBA/2 mouse strains (n = 5/strain). Single cell recordings from A10 neurons were made in the in vitro slice preparation (n > 15/strain). Although there were 25% more cells in the BALB/c mouse than in mice with the smallest number of cells, there was no significant difference in the baseline firing rates of cells among the four strains (3.0 ± 0.3 impulses/sec./strain). These data suggest that the baseline firing rate is not dependent upon total cell number in the nucleus. Research supported by MH-30546.

314.6

ANATOMICAL AND NEUROCHEMICAL DIFFERENCES IN THE MESOTELENCEPHALIC DOPAMINERGIC SYSTEMS OF INBRED MOUSE STRAINS. S.G. Speciale, B.E. Gonzalez*, K.F. Manaye and D.C. German. Depts. of Psychiat. and Physiol., UT Southwestern Med. Cntr., Dallas, TX 75235-9070.

Inbred mouse strains possess different numbers of midbrain dopamine (DA)-containing neurons and exhibit different motor behaviors (Fink & Reis, Brain Res. 222:335-349, 1981). We examined the relationship between the number of midbrain DA neurons and the concentrations of DA and its metabolites (DOPAC and HVA) in the cell body (nuclei A8, A9 and A10) and axon terminal (striatum and n. accumbens) regions of BALB/c, CBA, C3H/He and DBA/2 mice. The locations and sizes of tyrosine hydroxylase-positive neurons were entered into a computer, and DA and DA metabolite concentrations were measured with HPLC from micropunches from the mesotelencephalic regions. BALB/c mice had 19% more midbrain DA neurons than the strain with the fewest cells (C3H/He), but there was no correlation between the number of neurons and the biochemical measures in the midbrain or forebrain. These data suggest that differences in these neurochemical indices depend upon factors other than cell number. Research supported by MH-30546.

314.7

LOCALIZATION OF OPIOID RECEPTOR SUBTYPES IN THE DOPAMINE MESOCORTICOLIMBIC SYSTEM R.P. Dilts and P.W. Kalivas Dept. of VCAPP, Washington State Univ., Pullman, WA 99164

It has been demonstrated that opioids produce both a dopamine dependent and dopamine independent increase in locomotor behavior (Kalivas et al., J. Pharm. Exp. Ther. 227:229, 1983). In an effort to discern if opioid peptides modulate the mesocorticolimbic system through one or more receptor subtypes we have employed receptor autoradiography using selective ligands. DAGO, DPEN^{2,5}-enkephalin, and D-Pro^{10} dynorphin 1-11 were iodinated using the lactoperoxidase method to label mu, delta, and kappa receptors, respectively. Additionally, localization to dopaminergic or non-dopaminergic neurons has been studied utilizing the selective neurotoxins 6-hydroxydopamine and quinolinic acid administered within the ventral mesencephalon. Preliminary observations suggest that iodinated DPEN selectively labels delta receptors which are present in very low density within the mesolimbic projections. The binding of DPEN was resistant to either neurotoxin suggesting these receptors are not on neurons emanating within the A10 dopamine region. Kappa receptors labeled with the dynorphin analog are present within the mesolimbic projections but their anatomical locus is still under study. These results suggest a differential distribution of opioid receptor subtypes within dopaminergic systems. Furthermore, they provide a functional significance to differential processing of the pre-pro parent peptides.

VARIATIONS IN THE RATIO INDEX MEASUREMENT OF [^{18}F]-N-METHYLSPIROPERIDOL BINDING IN HUMAN BRAIN USING PET. S.L. Dewey, D.J. Schlyer*, A.P. Wolf*, N. Volkow, J. Brodie*, J.S. Fowler, C.-Y. Shiue*, D.R. Christman*, Brookhaven National Laboratory, Upton, NY 11973.

Quantitative measurements of Dopamine (D2) receptor binding can be obtained in the living human brain with Positron Emission Tomography (PET) by utilizing the selective D2 receptor ligand [^{18}F]-N-methylspiroperidol (NMSP). The ratio index (defined as the slope of the least squares fit through the ratio of Striatal activity/Cerebellar activity versus time, Wong, et al., 1986) in a group of normal male volunteers (n=12) was examined in order to determine the biological and methodological variability. In the first group (n=5) the ratio index was obtained by selecting the striatal region of interest as the four contiguous pixels with the highest activity. This method produced a ratio index of 3.65 ± 0.68. In the second group of subjects (n=7) the striatal region of interest was selected based upon the known anatomical structure of the human striatum. In this case, the ratio index was 3.52 ± 0.81. Thus the ratio index approach to receptor availability in linear studies is relatively insensitive to the method of striatal analysis. Slope variability using the subject as his own control is negligible (<2.0%). We conclude that the ratio index method is a valid approach to probing the effect of pharmacological intervention. Research supported by USDOE, OHER, NIH NS-15638.

CNS RECEPTOR TOPOGRAPHY IN THREE STRAINS OF RAT AND THE DOMESTIC CAT.

B.S. Neal, M.S. Bauer and J.N. Joyce. Dept. of Psychiatry and Pharmacology, Univ. Pennsylvania School of Medicine, Philadelphia, PA

We have utilized quantitative autoradiography to map receptor systems in 3 strains of rat and the cat. Long-Evans (LE), Sprague-Dawley (SD) and Wistar (W) rats were housed in Wahmann running wheels and entrained to a 12:12 hr light:dark cycle. Total daily wheel revolutions were recorded for 2 weeks. LE rats ran more than SD (25% of LE) or W (59% of LE) rats. There is evidence that the striatum (an area rich in DA) is functionally and anatomically organized into a lateral motor and a medial nonmotor region. Thus, we first chose to examine the topography of DA D1 and D2 receptors, and DA uptake sites in this region. We compared the striatal organization of rats with the cat, as the cat has a differentiated caudate and putamen made up uniformly of gray matter, while the rat caudatoputamen (CPU) is a single structure widely dispersed with white matter. DA receptors, D1 (labeled with [^{3}H]SCH23390) and D2 (labeled with [^{3}H]spiperone), show lateral-to-medial gradients in rat CPU, as do DA uptake sites (labeled with [^{3}H]mazindol). CPU from LE rats had more pronounced gradients (1.2-1.5-fold greater) compared to SD and W rats, due to fewer binding sites medially. The cat striatum does not show lateral-to-medial gradients, but has highly compartmentalized binding. High-density zones of DA D2 receptors and DA uptake sites were found in the dorsolateral head of the caudate, while DA D1 zones were more dispersed. Further studies are currently underway to examine other brain regions and receptor populations. **Supported in part by AFAR and Scottish Rite Foundation grants to JNJ.**

314.10

RESPONSE OF STRIATAL DOPAMINERGIC AND CHOLINERGIC RECEPTORS TO DOPAMINERGIC DENERVATION: EVIDENCE FOR A ROLE FOR A NEUROTROPHIC SUBSTANCE

D. L. Schambron, P.B. Molinoff and J. N. Joyce. Departments of Pharmacology and Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA.

Striatal dopamine (DA) D1 and D2 receptor subtypes appear to be regulated independently. In order to examine this furter, various methods of DA denervation were compared in their ability to modulate dopaminergic and cholinergic systems. Rats were prepared with a unilateral 6-OHDA lesion of the substantia nigra (SN), chronically treated with reserpine or saline, or injected with colchicine in the SN. Two weeks later the brains were removed and processed for quantitative autoradiography. The loss of DA and DA uptake sites (visualized with [^{3}H]mazindol) in the striatum was virtually complete on the side of the 6-OHDA lesion and resulted in an increase in the density of DA D2 receptors ([^{3}H]spiroperidol) in the lateral portion of the caudate-putamen. The increase in D2 receptors was topograph-ically correlated with an increase in choline uptake sites (visualized with [^{3}H]hemicholinium-3). There was an apparent reduction of D1 receptors ([^{3}H]SCH-23390) and both M1 ([^{3}H]pirenzepine) and M2 ([^{3}H]N-methylscopolamine) muscarinic receptors. In contrast to the 6-OHDA effect, reserpine treatment produced an up-regulation of both D2 receptors and D1 receptors. There was a down-regulation of muscarinic receptors. Injection of colchicine in the SN produced no significant up-regulation of striatal D2 receptors, but did produce both a loss of D1 and muscarinic receptors. **Supported by a grant from the American Federation for Aging Research to JNJ and GM 34781 to PBM.**

314.11

A METHOD FOR THE SIMULTANEOUS AUTORADIOGRAPHIC LOCALIZATION OF DOPAMINE RECEPTORS AND DEGENERATING FIBERS. L.D. Loopuijt*, L.Rotgers* and J. Korf* (SPON: ENA). Dept. Biol. Psychiatry, Univ. Groningen, Groningen, the Netherlands.

In order to compare the heterogeneous distributions of corticostriatal afferents and striatal dopamine receptors in detail, a convenient method for simultaneous localization of degenerating fibers and dopamine receptors was developed.

Solid kainic acid was apposed to the dura of somatosensory cortex of rats. After 5 or 6 days the rats were injected i.v. with 100 uCi (^{45}Ca)CaCl$_2$ and 20 h later with 100 uCi (^{3}H)N-n-propylnorapomorphine ((^{3}H)NPA, a dopamine agonist). They were sacrificed 1 h later. For the detection of ^{45}Ca, sections were covered with emusion (Ilford G5) coated coverslips, exposed, developed and counterstained. For the detection of (^{3}H)NPA, sections were rinsed in distilled water, defatted in xylene, dipped in nuclear emulsion (Ilford G5), exposed, developed and counterstained. This procedure results in a detailed localization of ^{45}Ca accumulating degenerating fibers at exposure times of 1-2 weeks, and, in adjacent sections, detailed visualization of in vivo labeled dopamine receptors at exposure times of 6-8 weeks.

NEUROLEPTICS HAVE HIGH AFFINITY FOR BOTH SEROTONIN AND DOPAMINE SITES LABELED BY ^{3}H-SCH-23390 IN HUMAN CHOROID PLEXUS. S.J. Boyson and L. O'Keefe*. Departments of Neurology & Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262.

A high density of binding sites in the choroid plexus was found in studies using the related isomers ^{3}H-SKF-83566 in rats (Boyson *et al.*, *J. Neurosci.* 6:3177-3188, 1986) and ^{3}H-SCH-23390 in humans (Boyson & O'Keefe, *Soc. Neurosci. Abs.* 13(1):711, 1987). Subsequent studies in pig and dog showed displacement of this binding by the 5HT$_{1c}$-selective ligand mesulergine (Nicklaus *et al.* *Soc. Neurosci. Abs.* 13(2):1197, 1987).

The pharmacological profile of neuroreceptor binding sites labeled by ^{3}H-SCH-23390 in human choroid plexus was investigated in membranes prepared from tissue collected postmortem; binding in human caudate/putamen, which contains a high density of D_1 and D_2 receptors, was compared. When choroid plexus membranes were incubated in 2 nM ^{3}H-SCH-23390, 2 sites ($p<.001$) were identified with virtually all ligands studied, including the neuroleptics α-flupenthixol, fluphenazine, SKF-83566, and SCH-23390; mesulergine; and the agonists serotonin and dopamine; these sites were split approximately 70:30. The larger site appears to be the 5HT$_{1c}$ receptor, because this is the site for which 5-HT has the higher affinity. All of the neuroleptics examined also showed higher affinity for this site. Mesulergine showed nanomolar affinity for this site. The smaller site, for which mesulergine shows an even higher affinity, is a dopamine receptor, as evidenced by sub-micromolar affinity for this site of dopamine. Supported by USPHS NS01195.

314.13

REGIONAL AND LAMINAR DENSITY OF THE NORADRENALINE INNERVATION IN ADULT RAT HIPPOCAMPUS. Sharon Oleskevich and Laurent Descarries, Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal, Québec, Canada H3C 3J7.

We used a recently developed radioautographic technique, based on the uptake labeling of monoamine terminals (axonal varicosities) in vitro, to quantify the noradrenaline (NA) innervation in adult rat hippocampus. After incubation of brain slices with 1µM [^{3}H]NA, the labeled varicosities were visualized as small aggregates of silver grains, in light microscope radioautographs prepared at 3 equidistant horizontal levels across the ventral 2/3 of the hippocampus. Using a computer-assisted image analyzer, counts were obtained from the subiculum (SUB), 3 sectors of Ammon's horn (CA1, CA3a, CA3b) and 3 sectors of the dentate gyrus (DG-medial blade, crest and lateral blade), every lamina being sampled in each of these regions. Based on initial results expressed in number of varicosities per mm^2 of section, the NA innervation of the hippocampus appeared generally denser and less uniform than that of the cerebral cortex. Its average density was 20% higher ventrally than dorsally. Both SUB and DG were more strongly innervated than Ammon's horn, in which CA1 showed the lowest overall density. In terms of laminar distribution, there was a clear predilection of the NA innervation for the stratum moleculare in SUB and CA1. In CA3, there was also a narrow band of even stronger innervation in the stratum radiatum, near the apical border of the stratum pyramidale, contrasting with the 3 times lower density in this cell layer and the stratum oriens. In DG, the innervation was again the weakest in the cell layer (granule), but exhibited an almost threefold greater density in the polymorph layer, the highest of all hippocampus. After correction for incomplete detection and measurement of varicosity diameter in EM radioautographs, it will be possible to express these quantitative results in number of terminals per volumetric unit of tissue. (Supported by MRC grant MT-3544).

314.14

THE PROJECTION OF NORADRENERGIC NEURONS IN THE KÖLLIKER-FUSE NUCLEUS (A7) TO THE SPINAL CORD DORSAL HORN. F.M. Clark and H.K. Proudfit. Dept. of Pharmacol., Univ. of Ill. at Chicago, Chicago, Il 60680.

Catecholamine neurons in the Kölliker-Fuse (A7) nucleus project to the spinal cord. However, the specific areas of termination are not known. The following two studies were done to determine the projection of A7 catecholamine neurons to the spinal cord dorsal horn. The first experiment involved unilateral lesions of the A7 nucleus. Cervical and lumbar spinal cord sections were processed for dopamine beta hydroxylase immunocytochemistry. We observed a marked (50-70%) decrease of DBH positive terminals in the ipsilateral spinal cord dorsal horn in both cervical and lumbar spinal segments. To further investigate the A7 spinal projection, a unilateral iontophoretic injection of the anterograde tracer, phaseolus vulgaris leucoagglutinin, was made into the A7 region. A large ipsilateral projection was observed in laminae 1 and 2 in both the cervical and lumbar spinal cord. There was a moderate projection to the contralateral dorsal horn comprising 10-20% of the total spinal projection. These results indicate that there is a substantial spinal projection of the A7 catecholamine cell group to the ipsilateral superficial dorsal horn and a moderate contralateral projection. HETEROGENEOUS DISTRIBUTION OF 3H-DPAT AND 3H-CYANOIMIPRAMINE (CN-IMI) BINDING SITES IN RAT DORSAL RAPHE NUCLEUS (DRN) J. Hensler, G. Kovachich, C.E. Aronson* & A. Frazer; VA Med. Ctr. & Univ. of Pennsylvania Sch. of Med., Philadelphia PA 19104.

The distribution of 5HT-1A receptors within the rat DRN as measured by quantitative autoradiography using 3H-DPAT (1.5 nM+2uM serotonin) was compared with the distribution of serotonin (5-HT) uptake sites in adjacent sections labeled with 3H-CN-IMI (03.nM+ 1uM sertraline). At the level of plate 50 of the atlas of Paxinos and Watson (1986), specific binding of 3H-DPAT in the DRN was 378 +23 fmol/mg protein and in DRN subregions was: ventromedial, 468+ 32; dorsomedial, 407+35; lateral, 274+42. A heterogeneous distribution of 3H-CN-IMI binding was also seen (fmol/mg protein): ventromedial, 3640+106, dorsomedial, 1855+86; lateral, 2473+214. 3H-CN-IMI binding in the entire DRN was 2565+97. In rats sacrificed 3 weeks after i.c.v. injections of 5,7-dihydroxytryptamine, the binding of 3H-DPAT (62+5 fmol/mg protein) or 3H-CN-IMI (357+44 fmol/mg protein) in the DRN was reduced. There was an essentially uniform reduction in 3H-DPAT binding in the different DRN subregions. 3H-CN-IMI binding was reduced significantly less in the ventromedial area (68+4%) than in either the lateral or dorsomedial areas, 87-93%. 3H-DPAT binding sites were not reduced in entorhinal cortex whereas 3H-CN-IMI sites were reduced markedly in this terminal field area. It may be inferred that 5HT-1A receptors and 5-HT uptake sites are located on serotonergic cell bodies and/or dendrites. The hetergeneous distribution of 5HT-1A sites in the DRN should be considered when investigating regulatory influences on 5HT-1A receptors in the DRN. Supported by Research Funds from the Vet. Admin. and USPHS GM34781.

AUTORADIOGRAPHIC LOCALIZATION OF DISTINCT SEROTONERGIC AND NONSEROTONERGIC [^{3}H]KETANSERIN BINDING SITES. S.J. O'Dell and J.F. Marshall. Dept. of Psychobiology, University of California, Irvine, CA. 92717.

Since its introduction as a radioligand for labeling 5-HT2 recognition sites, [^{3}H]ketanserin has been used extensively to define binding characteristics, quantify, and map the distribution of this serotonin receptor. Autoradiography of [^{3}H]ketanserin binding in rat brain shows high densities of binding sites in distinct cortical layers and in the striatum. Formerly, this binding was assumed to reflect the distribution of a pharmacologically uniform population of 5-HT2 receptors.

Recently, homogenate binding studies have shown that [^{3}H]ketanserin binds to two distinct populations of sites in rat brain. We have confirmed that one site has a high affinity (ca. 1 nM) for [^{3}H]ketanserin and binding to this site can be displaced by a variety of 5-HT2 antagonists. The second site has a lower affinity (ca. 20 nM) for [^{3}H]ketanserin and radioligand binding is displaced by the catecholamine-depleting drug tetrabenazine (TBZ), but not by serotonergic agents. Autoradiographic localization of this TBZ-displaceable site shows high binding in areas with significant dopaminergic innervation: caudate-putamen, nucleus accumbens, olfactory tubercle, lateral septum, etc. Lesions of the mesostriatal dopamine fibers with 6-hydroxydopamine cause massive decreases in TBZ-displaceable [^{3}H]ketanserin binding, confirming that the site is associated with dopaminergic nerve terminals.
