We have previously shown an inhibition of MAO-A activity with MDMA at an IC-50 of $5x10^{-5}$M in rat brain stem and hippocampus in both mature and immature rats (Kokotos and Azmitia, 1990). We also observed an increase in MAO-A activity at lower concentrations of the drug in two month old rat brain stem and hippocampus. As the primary monoamine oxidase present in serotonergic terminals is MAO-B, we sought to assay the effects of MDMA on MAO-B actvity in immature (one month old) rat brain stem and hippocampus as well as mature (two month old) rat brain stem and hippocampus. In brief, rat brain stems and hippocampi were dissected from one month- and two month old rats and homogenized 10x v/w in ice cold 0.01M PB for 10 strokes. The homogenates were centrifuged to obtain a mitochondrial-rich fraction. MDMA was added to homogenates at concentrations ranging from 10^{-4}M to 10^{-9}M. MAO-B activity was assayed by measuring 3H-DA degradation product by scintillation counting. An inhibition of MAO-B activity was observed in both age groups with an IC 50 of $5x10^{-5}$M. A stimulation of MAO-B activity was observed in one month old hippocampus in nanomolar concentrations ($p<0.001$). These results may explain some of the actions of MDMA on brain serotonergic function. Supported by NIDA contract 271-87-8144.

5-HT AND 5-HIAA LEVELS ARE INCREASED FOLLOWING MDMA IN RAT FETAL CULTURE MEDIA. X. F. Gu, AND E. C. Azmitia. Dept. of Biology, New York University, New York, NY 10003.

A method was developed to determine the levels of serotonin (5-HT) and its metabolite 5-hydroxyindoleacetic acid (5HIAA) in medium conditioned by cultured rat (Sprague-Dawley) fetal serotonergic neurons.

A raphe slice from 14-day-old fetal brain was dissected and dissociated. The cells were plated onto 96-well plates with an initial plating density of 0.9 x 10^6 cells/cm^2 in a volume of 200µl per well. Since there is a significant level of 5-HT in serum contained in complete neuron medium (CNM) which is necessary for the growth of fetal cells, a serum-free medium was required to detect the absolute level of 5-HT. Cells were cultured at 37°C for 1 day with CNM and then for 2 days with serum-free CNM. Medium (160µl) was then collected from each well and analyzed by reversed-phase high-performance liquid chromato-graphy with electrochemical detection. The mobile phase containing 60% acetonitrile was delivered at a flow rate of 1.0 ml/min onto a 10 cm x 3.2 mm column with ODS 3µm packing size. Samples (20µl) were automatically injected and analyzed by using a dual potentiostat electrochemical detector. The peak sizes were integrated using BASELINE 810 software. The lower limit of peak detection in this study was 0.2pmol for 5-HT and .1pmol for 5-HIAA per 20µl injection. This method was used to study the effects of 3,4-methylenedioxymethamphetamine (MDMA) on levels of 5-HT and 5-HIAA of fetal serotonergic neurons. There is no detectable level of 5-HT and 10^{-9}moles of 5-HIAA per well of control. After MDMA 10^{-5}M application, there is 10^{-7} moles of 5-HT and $5x10^{-9}$ moles of 5-HIAA. These results demonstrate that MDMA induces release of endogenous 5-HT from fetal serotonergic neurons. (NIDA contract, 271-87-8144)

SUBSTITUTED AMPHETAMINES CAUSE SEROTONIN RELEASE *IN VITRO* VIA A COMMON MECHANISM. U.V. Berger, X.F. Gu and E.C. Azmitia. Dept. of Biology, NYU, New York, NY 10003.

The neurotoxic amphetamine derivatives p-chloroamphetamine (PCA), 3,4-methylenedioxymethamphetamine (MDMA), methamphetamine (METH) and fenfluramine (FEN) cause release of serotonin (5-HT) from presynaptic nerve terminals. This release is primarily Ca-independent and blocked by 5-HT uptake inhibitors, suggesting that it proceeds via the uptake carrier. Yet, it is unknown whether this uptake carrier-mediated release is the same for all of these compounds. In this study, we tested the hypothesis that if these drugs had different mechanisms of causing release, then their effects would be additive when used in combination. Thus, we determined whether a combination of two drugs releases more 5-HT than either drug alone at an equivalent concentration. Drug-induced 5-HT release was studied using crude rat brain synaptosomes preloaded with ^{3}H-5-HT (100 nM). First, dose-response curves were determined, then two drugs were combined at their approximate EC_{50} concentration. EC_{50}'s for the different drugs ranged from 3 µM to 11 µm with PCA > FEN > MDMA > METH. The release caused by all four drugs was significantly attenuated by the 5-HT uptake blocker fluoxetine (80 nM). In no case did the combinations of two drugs at the EC_{50} exceed the releasing effect of the single drugs at the equivalent (i.e. $2xEC_{50}$) concentration. This lack of a synergistic effect of the drug combinations suggests that all of these amphetamine compounds compete for the same site(s) when causing release, implying that they act via a common mechanism. Currently, we are using the same experimental approach to determine whether these drugs share a common mechanism when causing toxicity to primary cultures of serotonergic neurons. METHYLENEDIOXYAMPHETAMINE (MDA) DESTROYS 5-HT AXONS AND TERMINALS IN BRAINSTEM NUCLEI OF RAT. J.A. Harvey, P. Iannuzzelli, A.G. Romano and S.E. McMaster. Depts. Anatomy & Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Although MDA is well known to selectively destroy 5-HT axons and terminals in forebrain, its possible actions on brainstem have not been examined. Therefore, we have compared the effects of MDA on serotonergic projections in both forebrain and brainstem. Animals were injected twice a day, for four consecutive days, with MDA (40 mg/kg per day, s.c.) or saline. Brains were obtained two weeks after the last injection and processed for 5-HT immunocyto-chemistry. MDA produced a severe loss of 5-HT immunoreactive fibers and terminals throughout the trigeminal sensory nucleus, vestibular nucleus, and superior olivary nucleus of the brain stem which was comparable to effects in forebrain structures such as neocortex and hippocampus. Fluoxetine (10 mg/kg, injected i.p., 20 min prior to MDA) blocked all evidence of neurotoxicity in forebrain and brainstem. Our results indicate that the ablation of 5-HT axons and terminals produced by MDA is more extensive than previously reported. (Supported by NIDA Grant DA04944-04).

CELL BODY LOSS UNDERLIES PERSISTENT SEROTONERGIC DEFICITS INDUCED BY (±)3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) IN PRIMATES. G. A. Ricaurte, J. L. Katz, and G. Hatzidimitriou*. Department of Neurology, Francis Scott Key Med. Ctr., Johns Hopkins School of Medicine and NIDA Addiction Research Center, Baltimore, MD. 21224

This study examined the basis for the lasting serotonin (5-HT)-depleting effects of (±)3,4-methylenedioxymethamphetamine (MDMA) in the primate. Six adult squirrel monkeys (*Saimiri sciureus*) were used. Three animals were administered MDMA (5 mg/kg, s.c., twice daily for 4 days); three saline-treated animals served as controls. Eighteen months later, immunocytochemical studies were performed using an antibody directed at 5-HT. Sections through the forebrain of MDMA-treated animals showed a marked reduction in the number of 5-HT axons in cortical and subcortical regions. Counts of neurons in the dorsal, median and B9 raphe cell groups revealed a concomitant loss of 5-HT-immunoreactive cell bodies. Each of the raphe nuclei examined was comparably affected. These findings indicate that the toxic effects of MDMA in the primate are not limited to axons but involve neuronal perikarya as well. Further, they suggest that cell body loss forms the basis for the persistent 5-HT deficits induced by MDMA in nonhuman primates. Possible permanent effects in humans using MDMA ("Ecstasy") recreationally need to be considered. [USPHS DA05707]

469.16

3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) DOES NOT ALTER RAT PINEAL SEROTONIN CONTENT. T.H. Champney and R.T. Matthews. Dept. of Anatomy, College of Medicine, Texas A&M University, College Station, Texas 77843-1114.

The illicit drug, MDMA (ecstasy), produces a sustained depression in serotonin (5HT) content in many brain regions of rats. This depression is presumably produced by a neurotoxic effect of MDMA at the nerve terminal utilizing a presynaptic 5HT reuptake system. The pineal gland contains large quantities of intracellular cytosolic 5HT without nerve terminals or well characterized 5HT reuptake systems. By determining MDMA's effects on pineal 5HT content, the mechanism of MDMA's neurotoxicity can be investigated. Male albino rats have been injected with MDMA acutely (ip) using several dose and time response protocols or have received MDMA subchronically (sc) to determine if MDMA alters pineal 5HT content. A significant dose dependent decline ($p<0.05$) in 5HT content 2 h after MDMA administration (10 and 30 mg/kg) is observed in the frontal cortex, the hypothalamus and the striatum, but not in the brain stem or pineal gland. Likewise, the decline in 5HT content after MDMA (10 mg/kg) is maximal 2 h after injection in the frontal cortex (73%), the hypothalamus (48%) and the striatum (53%), but is unaffected in the brain stem or the pineal. Two weeks after 8 MDMA injections (12 h apart, 10 mg/kg/injection) or a single para-chloroamphetamine (pCA, 10 mg/kg, ip) injection, 5HT levels are significantly reduced ($p<0.05$) in the frontal cortex (38% and 88%), the hypothalamus (21% and 41%) and the striatum (22% and 84%). Brain stem 5HT content falls 60% after pCA, but is unaffected by MDMA. Pineal 5HT content is unaltered by MDMA or pCA administration. These results suggest that the pineal is resistant to the neurotoxic effects of MDMA or pCA. This resistance may be due to different membrane properties of pinealocytes when compared to serotonergic neurons or to the intracellular localization of 5HT in pinealocytes.

PRENATAL COCAINE AND FENFLURAMINE ADMINISTRATION INHIBIT SEROTONIN AND DOPAMINE FIBER OUTGROWTH.

H.M. Akbari, H.K. Kramer, and E.C. Azmitia.

Dept. of Biology, New York Univ., Washington Sq. East, NY, NY 10003.

Prenatal cocaine exposure has been found to disrupt the development of the serotonin (5-HT) and catecholamine systems as assessed by immunocytochemical methods (Akbari et al., 1990). In this study, we examined the effects of prenatal cocaine and fenfluramine exposure on the development of cortical 5-HT and dopamine (DA) innervation.

Cocaine (40mg/kg s.c.), fenfluramine (5mg/kg s.c.) or vehicle was administered to pregnant Sprague-Dawley rats from gestational day 13 to partuition. Cortical 5-HT and DA fiber densities were assessed on postnatal days (PND) 1, 7, and 28 using high affinity ^{3}H-5-HT and ^{3}H-DA uptake. Prenatal cocaine exposure resulted in a decrease in the 5-HT and DA high affinity uptake on PND 1 and PND 7. On PND 1, forebrain 5-HT uptake levels were decreased to 84% of control and DA levels to 75% of control. On PND 7, ^{3}H-5-HT cortical uptake was reduced to 64% and ^{3}H-DA to 51% of control. By PND 28, ^{3}H-5-HT uptake had returned to control levels. ^{3}H-DA uptake was increased to 135% of control in cocaine-treated animals by PND 28. A similar pattern was observed following gestational fenfluramine exposure. On PND 1 and 7, ^{3}H-5-HT uptake was reduced to 68% and 58% of control and ^{3}H-DA uptake to 73% and 50% of control. By PND 28, 5-HT and DA uptake had returned to control levels in the fenfluramine-treated group.

Our results indicate that both prenatal cocaine and prenatal fenfluramine disrupt the normal development of cortical 5-HT and DA fiber systems. Although the decreases are observed only in the early postnatal period, they may cause behavioral deficits in the adult by disrupting the normal "chemical imprinting" process. Supported by NIDA contract # 271-A7-A144.

EARLY POSTNATAL COCAINE EXPOSURE FAILS TO MODIFY CORTICAL SEROTONIN AND DOPAMINE INNERVATION.

H. K. Kramer, E. C. Azmitia, and H. M. Akbari.

Dept. of Biology, New York University, NY, NY 10003.

We have previously shown (Akbari et al., 1991) that prenatal exposure to cocaine decreases serotonin (5-HT) fiber density postnatally. These changes were attenuated by continued cocaine administration through the early postnatal period. This study examines the effects of early postnatal exposure to cocaine on the 5-HT and dopamine (DA) systems.

Newborn Sprague-Dawley pups were injected with either cocaine (10mg/kg s.c.) or vehicle on postnatal days (PND) 1-5. Cortical 5-HT and DA fiber densities were quantified on PND 7 and PND 28 with high affinity ^{3}H-5HT and ^{3}H-DA uptake. No significant differences were observed in DA uptake on either PND 7 or PND 28. No differences in 5-HT uptake were seen on PND 7; however, on PND 28 a 23% increase in ^{3}H-5-HT uptake was seen in the cocaine group. Although this result was not statistically significant, it raises the possibility that early postnatal cocaine treatment may stimulate 5-HT fiber outgrowth.

Our results indicate that postnatal cocaine administration in the rat does not cause developmental changes in the 5-HT and DA systems comparable to those seen following prenatal cocaine exposure. As with the adult rat brain, early postnatal cocaine exposure does not seem to significantly alter fiber density in these two systems. We are currently studying the effects of higher doses of cocaine (20 and 30mg/kg), and the noradrenergic system's contribution to this developmental question. NEUROTRANSMITTERS: MOLECULAR NEUROBIOLOGY

470.1

NEURONAL GABA TRANSPORTER: IN VITRO PHARMACOLOGY AND DISTRIBUTION OF GENE EXPRESSION IN RAT AND HUMAN BRAIN. Y. Xia, C. Whitty, M. Poosch, G. Kapatos, M. Bannon. Dept. of Psychiatry, Wayne State University, Detroit, MI 48201.

The γ-aminobutyric acid (GABA) transporter is important in the regulation of GABAergic synaptic transmission. A rat neuronal GABA transporter clone (GAT-1; obtained from J. Guastella and colleagues) was calcium phosphate transfected into COS-7 cells. After 48 hrs, ^{3}H-GABA uptake was analyzed. The effects of various GABA transporter inhibitors were assessed. Nipecotic acid, a nonselective but potent inhibitor of GABA transporter and 2,4-diaminobutyric acid, which selectively inhibites the neuronal type GABA transporter, exhibited IC_{50}s of 10 μM and 300 μM, respectively. β-alanine and 4,5,6,7-tetrahydroisoxazolo[4,5-c]pyridin-3-ol, which are selective for the glial type of GABA transporter, inhibited GABA uptake by 10-20% at 1 mM. These results agree with the initial observations on this clone (Science 249:1303-1306, 1990) when expressed in Xenopus laevis oocytes. A BstXI-derived subclone corresponding to the 5' 333 bp of GAT-1 is being used for quantitation of GAT mRNA by nuclease protection assay. The GAT gene mRNA expressed in rat cortex, cerebellum, hippocampus, striatum, hypothalamus, and olfactory bulb are in the range of several pg/ng total RNA. Studies of the developmental profile of GAT gene expressed in these tissues are currently underway. A 276 bp human GAT-1 subclone corresponding to the 3rd transmembrane region and the 2nd external loop of the full length clone was obtained by PCR amplification using human putamen cDNA. This subclone is currently being used to quantitate the regional distribution of the GABA transporter in various human brain regions. Supported by: NIDA 06470.

470.2

DIVERSITY OF NEUROTRANSMITTER TRANSPORTER cDNAs IN BRAIN LIBRARIES. S. Shimada, S. Kitayama*, C.-Liang Lin*, A. Patel#, M. Kuhar#, P. Gregor and G.R. Uhl. Lab. Mol. Neurobiol., #Lab. Mol. Pharm., NIDA/ARC, Dept. of Neurol., Nsci., JHU Sch Med, Box 5180, Balto., MD 21224.

Recent cloning of cDNAs encoding GABA and norepinephrine transporters (GABAT and NET) reveals areas of high sequence homology. This family may also include the dopamine transporter that is a key molecular target for cocaine and MPTP, as well as the glutamate and serotonin transporters. We have used oligo-nucleotides corresponding to the 1st, 2nd, and 6th putative GABAT/NET transmembrane regions to clone PCR product cDNAs from brain libraries.

PCR product TM111 displays 52% amino acid identity with rat GABAT and 54% with NET; this also contrasts with a partial mouse GABAT cDNA which shows 95% identity with the rat sequence. Northern analyses show a 4 kb major band that hybridizes with TM111 and is present in mRNA from several brain regions but not from liver, pancreas or eye.

Screening a ventral midbrain library with oligo-nucleotide sequences conserved in GABAT, NET and TM111 reveals 0.005% positives; TM111 sequences are present in 0.001% of plaques from a whole brain library. Neuro-transmitter transporter cDNAs are thus individually rare, but members of a family of related genes with sequence conservation in putative transmembrane regions.

470.3

A cDNA ENCODING A NOVEL NEUROTRANSMITTER TRANSPORTER IS SELECTIVELY EXPRESSED IN SUBSTANTIA NIGRA. J. Kilty and S.G. Amara Section of Molecular Neurobiology, Howard Hughes Medical Institute, Yale University School of Medicine, New Haven , CT 06510

Degenerate oligonucleotides based on regions of amino acid sequence similarity between the cloned norepinephrine (NE) and GABA transporters were used in a polymerase chain reaction (PCR) with rat midbrain cDNA. The sequence of one of the cDNAs amplified in this reaction diverges significantly from the NE and GABA transporter cDNAs, but predicts a protein with extensive amino acid identity with the NE transporter. When used as a hybridization probe this 684 basepair PCR product detects a single 4.4 kilobase mRNA on Northern blots. On blots containing RNA isolated from a variety of specific brain regions, the intensity of this band was strongest in the substantia nigra, with faint signals in the brainstem and olfactory bulb. No hybridizing band could be seen in RNA from cortex, cerebellum, basal ganglia, kidney, lung, adrenal, or PC12 cells. The predicted sequence and tissue distribution of this mRNA identifies this clone as a likely candidate for a dopamine transporter.

470.4

ISOLATION OF NEW MEMBERS OF A TRANSPORTER GENE FAMILY BY SEQUENCE HOMOLOGY BASED PCR. J. A. Clark, A. A. Fluet, and S. G. Amara. Department of Molecular Neurobiology, HHMI, Yale University School of Medicine, New Haven, CT 06510.

Comparison of the amino acid sequences of clones encoding a GABA transporter from rat brain and a norepinephrine transporter from human neuroblastoma cells has led to the identification of regions of sequence with significant homology. Degenerate oligonucleotides were designed based on three of these conserved regions. Using the polymerase chain reaction along with these oligos we have isolated several novel DNA fragments from midbrain, spinal cord, C6 neuroblastoma cell, and retinoblastoma Y79 cell cDNA's. Sequencing these cloned PCR fragments has revealed a family of genes which are related to both the GABA and norepinephrine clones, but are clearly new members of this sodium-dependent transport family. Northern analysis has shown that each of these potential transporters has its own unique distribution throughout the rat CNS and peripheral tissues. Several of these fragments are presently being cloned in order to obtain full length sequences and allow complete characterization of these transport proteins.

470.5

UPTAKE, TRANSPORT AND TRANSLATION OF EXOGENOUS VASOPRESSIN (AVP) mRNA IN BRATTLEBORO RAT HYPOTHALAMO-NEUROHYPOPHYSIAL SYSTEM

G. F. Jirikowski, P. P. Sanna, D. Maciejewski-Lenoir* and F. E. Bloom. Dept. of Neuropharmacology, Scripps Clinic and Res. Fdn., La Jolla, CA 92037.

Following our recent detection of oxytocin mRNA in hypothalamic axons by in situ hybridization (Jirikowski et al, 1990) we have extended our studies to AVP mRNA, and have employed Brattleboro rats, genetically incapable of AVP expression, as a means to detect the metabolic fate of exogenous AVP mRNA injected intracerebrally. RNA extracted from hypothalami of osmotically challenged rats as well as synthetic riboprobes coding for the Arg-vasopressin (AVP) precursor were injected into the hypothalamo-neurohypophysial tract of homozygous Brattleboro rats. A radiolabelled riboprobe coding for AVP was found to be selectively accumulated and transported in axons to magnocellular perikarya within 2 h, while the antisense sequence failed to show cellular accumulation. Brattleboro rats injected with either the natural RNA preparations or with the synthetic sense probe showed immunoreactive AVP in magnocellular neurons and their distal axons by 18h and a temporary (1-5 days) significant increase in urine osmolarity. Our results suggest that magnocellular hypothalamic neurons are capable of uptake, axonal transport and translation of certain natural and synthetic mRNA sequences. This may reflect a novel means of interneuronal communication generally. Supported by grants AA06420 and NS22347. GFJ is a Heisenberg Fellow.

470.6

IMPORTANCE OF POLY-A TAILS FOR EXPRESSION OF EXOGENOUS RNA IN BRATTLEBORO RAT HYPOTHALAMO-NEUROHYPOPHYSIAL SYSTEM

D. Maciejewski-Lenoir*, P.-P. Sanna, G. F. Jirikowski, F.E. Bloom
Dept Neuropharm, Scripps Clinic & Research Fdn., La Jolla, CA 92037

Poly A(+) and poly A(-)RNA fractions, obtained from the hypothalami of osmotically challenged Lewis rats as well as cRNA coding for Arg-Vasopressin (AVP) were injected unilaterally into the hypothalamo-neurohypophysial tract of young homozygous Brattleboro rats. After 2 hours survival, the magnocellular hypothalamic nuclei of animals injected with 1 µg poly A(-) RNA contained Arg-Vasopressin immunostaining and immunoreactive peptide, ipsilateral to the injection site. After 18 hours, the Brattleboro rats injected with poly A(-) contained immunoreactive AVP in the median eminence and in the posterior pituitary lobe. Plasma AVP levels and urine osmolarity of animals injected with poly A(-) and synthetic AVP RNA were significantly increased within 120 minutes and remained elevated for up to 6 days after the injection. Similar effects could be observed with 50 ng of AVP-cRNA. The injection of 1µg poly A(+) RNA proved to be less effective, despite the presence of much more mRNA coding for AVP. To assess further the importance of the poly A tail in this process, we annealed the poly A(+) fraction with synthetic poly T tails and then treated with RNAse H in order to remove partially the poly A tails. The detailed poly A(+) fraction also significantly increased the urine osmolarity of injected Brattleboro rats, suggesting that the absence of poly A tail is of functional importance for the uptake, transport and translation of RNA by magnocellular hypothalamic neurons. Supported by grants AA06420 and NS22347.

470.7

REGULATION OF GAD PROTEIN LEVELS AND GENE EXPRESSION IN RAT CORTEX IN VITRO AND IN VIVO. K. Rimvall and D.L. Martin. Wadsworth Center for Labs. and Res., NY State Dept. Health, Albany, NY 12201.

We have previously shown that the two GAD proteins, GAD65 and GAD67, are present in cultures of prenatal rat cortex enriched in GABAergic neurons. Total GAD activity was reduced by 60% in cultures and 30% in vivo when intracellular GABA levels were increased >300% by chronic treatment with the GABA-transaminase inhibitor γ-vinylGABA (GVG). Levels of other amino acids (glutamate, glutamine, aspartate and alanine) changed only slightly. In cultures, the effects of GVG were mimicked by adding GABA to the medium, indicating a negative feedback mechanism. Immunoblotting experiments showed that the level of GAD67 protein was reduced by 76% in cultures and 79% in vivo, but the level of GAD65 protein was unchanged by GVG treatment. The possibility that the decrease in GAD67 is due to selective changes in gene expression was investigated. Total RNA and mRNA were extracted from rat brains and cultured neurons. Northern blotting with ^{32}P-labeled cDNA's from the genes coding for GAD65 and GAD67 (Erlander et al., Neuron, in press), showed that the cerebellum and cortex of adult rats and cultured GABAergic cells contain a 3.7 kb GAD67-mRNA. The effect of manipulating GABA levels on the levels and stability of GAD mRNA in cultures and in vivo are under study. Supported by Grants MH35664 and NS853102 from USPHS-DHH.

471.1

S-ANTIGEN (ARRESTIN) FAMILY: EXPRESSION AND IDENTIFICATION OF MULTIPLE FORMS IN RAT AND BOVINE TISSUES WITH SYMPATHETIC INNERVATION. C.M. Craft, D.H. Whitmore*#, R. Gonzalez*, T.H. Thai*. Lab. Mol. Neurogen., Dept. of Psychiatry, UT Southwestern Med. Sch., and VA Med. Ctr., Dallas. TX, 75235 and #Dept. of Biology, Univ. Texas, Arlington, TX.

Specific desensitization of activated receptors is mediated through kinases (K) and other cofactors to impair the capacity to activate guanine nucleotide binding proteins (Gs, Gi, Go) in the signal transduction cascade. In the retina, S-antigen (SAG) enhances inhibition of light-activated rhodopsin (R*) after phosphorylation by RK. In neuronal tissues with adrenergic receptors, an analogous protein, beta-arrestin (BAR), participates with BARK in homologous desensitization of B-adrenergic receptors (Lohse et al., 1991, Science 248:1547). Expression of mRNAs and proteins encoding SAG and BAR are detectable in mammalian retina and pineal gland (Craft et al., 1991, J. Neurochem. 55:1461). Antigenic epitopes are shared and highly conserved between members of the arrestin family; however, multiple genes encode the different members. With labeled polymerase chain reaction (PCR) and specific primers designed for regions for either SAG or BAR, we examined mRNA distribution. Total RNA was isolated from rat or bovine tissues and first strand cDNA synthesized with reverse transcriptase. We sequenced gel-purified PCR fragments with either the primers used for amplification or internal, shared primers. The labeled PCR products were further analyzed with restriction endonucleases that cut either SAG (Sst 1/ Rsa1) or BAR (Sau1/ Hpa II). SAG was detected in rat pineal, retina, Hardarian gland, and ciliary processes but none in heart, cerebrum, cerebellum or adrenal. BAR was expressed in all of these. Several PCR products analyzed from the pineal, cerebellum and adrenal were neither SAG or BAR; however, each had conserved arrestin-like domains, suggesting alternative arrestins for specific G-protein coupled receptors. Grant support: NINDS/NIH and VA Med.

471.2

MECHANISM OF RECEPTOR DYSFUNCTIONS IN HYPERREACTIVE AIRWAYS

J. Y. Lee*+, Z. Annau+, Y. Uchida*# and F. Hirata*+#. +Dept. of Environmental Health Sciences, The Johns Hopkins Univ., Baltimore, MD 21205 and #Depts. of Pharmaceutical Sciences and Pharmacology, and Institute of Chemical Toxicology, Wayne State Univ., Detroit, MI 48202

Hyperreactive airways (Asthma) have been proposed to be a disease of hypermuscarinic and hypo-ß-adrenergic functions. In order to study its mechanism, we employed an animal model of guinea pigs sensitized with ovalbumin and subsequently challenged by a single and multiple exposures to the antigen. When their tracheal responses to acetylcholine and isoproterenol were measured in vitro, the tracheas isolated after multiple challenges were more sensitive to acetylcholine but less sensitive to isoproterenol. However, the binding studies with [^{3}H]QNB and [^{125}I]CYI showed no changes in the number and affinity of M_3-muscarinic and β_2-adrenergic receptors. These observations suggest that inflammatory reactions occurring in the lungs modify the postreceptor signal transduction steps, possibly G proteins.

471.3

AUTORADIOGRAPHIC LOCALIZATION OF ALPHA 1 ADRENOCEPTORS ALONG THE RAT SPINAL CORD AS REVEALED BY [^{3}H]PRAZOSIN : EFFECT OF NORADRENERGIC DENERVATION. C. Roudet, M. Savasta, and C. Feuerstein. INSERM-LAPSEN U.318, Pavillon de Neurologie, CHU de Grenoble, BP 217, 38043 GRENOBLE cedex 9, France.

The distribution of α_1 adrenoceptors along the different segments of spinal cord (cervical, thoracic, lumbar and sacral) of normal rats has been studied by quantitative autoradiography using the specific α_1-antagonist [^{3}H]Prazosin as a ligand. The same study was performed with rats bearing specific lesion of NA spinal cord system carried out by intracisternal (IC) injection of 6-hydroxy-dopamine (6-OHDA) and after transsection of spinal cord at level T8-T9. The binding of [^{3}H]Prazosin to spinal cord sections from the different segment of spinal cord was saturable, reversible and of high affinity (Kd ≈ 0.14nM). It occurred at a single population of sites and possessed the pharmacological features of the α_1-adrenoceptors. The results can be summarized as follows : 1) In control rats, the quantitative analysis of α_1 adrenoceptor densities revealed an homogeneous distribution of these receptors along all segments of the spinal cord with a similar pattern in the various subregions of the grey matter at all levels. However, the central area of the grey matter and the region where the motoneurons are localized presented the highest densities of α_1 adrenoceptors, while in the dorsal horn (proximal part) densities were the lowest. This distribution of α_1 adrenoceptors only partly corresponded to the distribution of NA nerve terminals revealed by immunohistochemistry. 2) After specific lesion of NA system by 6-OHDA IC an increase of α_1 adrenoceptor densities (13-43%) was observed at all levels of the spinal cord. 3) Transsection of spinal cord at T8-T9 level induced a similar increase of α_1 adrenoceptor densities (22 - 42%) in downstream segments (lumbar and sacral) as compared to that observed after 6-OHDA lesion. No significant effect has been observed in upstream segments.

These results showed that specific lesioning (6-OHDA) or non specific destruction (transsection) of NA spinal cord system caused a supersensitivity of α_1 adrenoceptors localized on target cells of this system.

471.4

IMPLANTED OSMOTIC MINI-PUMPS UP-REGULATE AND IMIPRAMINE DOWN-REGULATES BETA-ADRENOCEPTOR ACTIVITY IN RAT CA1 NEURONS; ADINAZOLAM INDUCES ONLY MARGINAL CHANGES. R.S. Neuman, Fac. of Medicine., Memorial University., St. John's, Nfld. Canada A1B 3V6

There are numerous reports that chronically administered antidepressants down-regulate beta-adrenoceptor function. We have now compared the triazolobenzodiazepine antidepressant, adinazolam (ADZ), with imipramine (IMI) in this regard. Rats were untreated or received ADZ (0.64 mg/kg/day; 2 or 15 days), IMI (10 mg/kg/day; 2 or 15 days) or saline (15 days). Drugs and saline were administered by osmotic mini-pumps implanted s.c. Hippocampal slices (500 um) were obtained on the appropriate treatment day for intracellular recording from CA1 neurons. Current injection (0.7-0.9 nA, 100 ms) through the microelectrode elicited 6 to 11 spikes followed by a slow afterhyperpolarization (AHP). In untreated rats, isoproterenol (ISO; 0.5 nM-100 uM) dose-dependently reduced the AHP by 56% with an EC50 of 80 nM. In contrast, the maximum depression was 70% with an EC50 of 20 nM in saline treated rats. Thus, the presence of a mini-pump, perhaps by increasing the level of stress, shifted the ISO dose response curve to the left. In comparison to the saline control, IMI shifted the curve to the right (2 and 15 days) and reduced the maximum inhibition (32%; 15 days). Dose response curves for ISO, in ADZ treated rats (2 and 15 days), were similar to the saline control and each other except for the maximum reduction of the AHP (70% and 58% respectively). In conclusion, implanted mini-pumps up-regulate and IMI down-regulates functional beta-adrenoceptor activity. In contrast, ADZ only marginally effects this activity.

Cytoskeletal Aspects of the Regulation of β-Adrenergic Receptor mRNA. Christopher Hough and De-Maw Chuang. Biological Psychiatry Branch,, NIMH, Bethesda, MD 20892.

The β_1- and β_2-adrenergic receptor mRNA levels in C_6 glioma cells are differentially regulated in response to isoproterenol. The nature of the changes in β-AR mRNA levels varied with different cell culture conditions. For example, at confluency, β_2-AR mRNA was down-regulated in response to isoproterenol treatment, but at low cell density β_2-AR mRNA could be transiently up-regulated. Because the cytoskeleton determines the morphology of cells in culture, we investigated the effect of microtubule-altering agents on β-AR mRNA regulation. The microtubule disrupter, colchicine, at 10 μM, induced a time dependent up-regulation of β_2-AR mRNA and down-regulation of β_1-AR mRNA. Simultaneously, the cells withdrew their processes, leaving large holes in otherwise confluent sheets of cells. Colchicine did not interfer with isoproterenol induced down-regulation of β_2-AR mRNA, but appeared to partially attenuate the down-regulation of the β_1-AR mRNA species. Taxol, a microtubule bundle promoter, produced effects opposite to those of colchicine: taxol at 10 μM induced the down-regulation of β_2-AR mRNA and early up-regulation of the β_1 mRNA species. Taxol had little or no effect on isoproterenol induced down-regulation of either receptor mRNA species. These results suggest that aspects of the cytoskeleton, play a role in the regulation of β-AR mRNA.

471.6

EFFECT OF CHRONIC TRICYCLIC ANTIDEPRESSANT TREATMENT ON β1-ADRENERGIC RECEPTOR (β1-AR) mRNA IN RAT FRONTAL CORTEX AND CULTURED GLIOMA C6 CELLS. K. Hosoda, P. H. Fishman and R. S. Duman. Lab. of Molecular Psychiatry, Depts of Pharmacology and Psychiatry, Yale Univ. School of Medicine, New Haven, CT 06508. Lab. of Molecular and Cellular Neurobiology, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD 20892.

One of the most consistent effects of nearly all classes of antidepressant treatment is down-regulation of β1-AR binding sites in rat cerebral cortex. Incubation of C6 glioma cells with a tricyclic antidepressant also decreases β1-AR binding, indicating an effect of the drug treatment directly on receptor coupled signal transduction pathways. The present study examines levels of β1-AR mRNA in rat brain and C6 cells to elucidate the molecular mechanisms mediating the regulation of β1-AR by antidpressant treatments. Absolute levels of β1-AR mRNA were determined by RNA-excess solution hybridization. Riboprobes corresponding to the sense and antisense DNA strand of β1-AR were synthesized with T7 & T3 RNA polymerase. Unlabelled cRNA was used to generate the standard curve. Chronic imipramine administration (21 d, 15 mg/kg, i. p.) significantly decreased levels of β1-AR mRNA in rat frontal cortex. This effect was not observed after only 3 or 7 d of treatment. Treatment of C6 glioma cells with desipramine (5 d, 10 μM) also significantly decreased levels of β1-AR mRNA. These results suggest that long-term changes in levels of β1-AR in response to antidpressant treatment may occur through regulation of levels of mRNA and gene expression.

471.7

THE INFLUENCE OF CHRONIC ANTIDEPRESSANT TREATMENTS ON THE EXPRESSION OF 5-HT2 RECEPTOR mRNA IN RAT FRONTAL CORTEX. M.O. Butler and R.S. Duman Laboratory of Molecular Psychiatry, Department of Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

Earlier studies have shown that chronic administration of most classes of antidepressant drugs decreases the level of 5-HT2 receptor binding in brain. Electroconvulsive shock (ECS), however, has been shown to increase levels of 5-HT2 receptor binding in rat brain. This raises some doubt concerning the role of the 5-HT2 receptor in antidepressant action since electroconvulsive therapy is considered to be extremely efficacious in the treatment of major depression.

The present study examines the influence of chronic antidepressant treatments on levels of 5-HT2 receptor mRNA in an attempt to address this discrepancy and to elucidate the molecular mechanisms underlying regulation of 5-HT2 receptors. RNA samples obtained from frontal cortex of control and treated rats were analyzed by Northern blot using a nick translated 5-HT2 receptor cDNA clone. Chronic ECS (10 daily treatments) increased levels of 5-HT2 receptor mRNA by about 60% ($p<.05$). Additionally, we have begun to study regulation of 5-HT2 mRNA by antidepressant drug treatments. Preliminary studies have indicated a similar increase of 5-HT2 receptor message in frontal cortex of chronic imipramine treated rats (18 days, 15 mg/kg i.p.) Therefore, although ECS and antidepressant drugs change 5-HT2 binding in opposite directions, these treatments appear to regulate levels of receptor mRNA and possibly gene expression in a similar up-regulated manner.

DEAFFERENTATION INDUCES A DIFFERENTIAL PATTERN OF EXPRESSION OF THE VARIOUS GUANINE NUCLEOTIDE BINDING PROTEIN mRNAs IN RAT STRIATUM M. Memo, A. Valerio *,M. Ribola *,M. Buonamici, P. Sarmientos * and P.F. Spano Section of Pharmacology, Dept. of Biomed. Sci. and Biotech., School of Medicine, University of Brescia, and Research and Development, Farmitalia-Carlo Erba, Erbamont Groups, Nerviano-Milano, Italy

This study was designed to assess the relative abundance of the mRNAs encoding various forms of Gs (long and short), Gi (1, 2, and 3) and Go α subunits in the striata of rats unilaterally injected with 6-hydroxy (6-OH) dopamine in the substantia nigra.A PCR-derived method was used to identify and quantitate the relative abundance of the different mRNAs (Memo et al.,Mol Pharmacol 1991 in press). Chemical deafferentation induced a differential pattern of expression of the mRNAs encoding the various α subunits of G proteins. In the striatum of rats lesioned with 6-OH dopamine in the substantia nigra, the mRNA levels of the Gαo and Gαi-1 subunit were increased by about 2-3 times, those of Gαi-3 decreased by 60 % and those of Gαi-2 and Gαs were unchanged. The changes in the pattern of expression of various G proteins are correlated with the development of functionally supersensitive striatal dopamine D-2 receptors.

EFFECTS OF REPEATED ADMINISTRATION OF DESIPRAMINE (DMI) OR ELECTROCONVULSIVE SHOCK (ECS) ON NOREPINEPHRINE (NE) UPTAKE SITES MEASURED BY 3H-NISOXETINE (3H-NIS) AUTORADIOGRAPHY. M.E. Bauer,* K.J. Kellar,+ and S.M. Tejani-Butt, Dept. Psych., Univ. of Pa Sch. of Med. & Dept. Vet. Affairs Med. Ctr., Phila., PA 19104 & +Dept. Pharmacol., Georgetown Univ. Sch. of Med. Wash., D.C. 20007.

The development of radioligands for monoamine "transporters" allows one to determine if these sites undergo regulation analogous to monoamine receptors. To determine if repeated administration of DMI or ECS regulate NE uptake sites in rat brain, the binding of 3H-NIS was measured using quantitative autoradiography. We have recently shown that 3H-NIS binds specifically and with high affinity to a single population of NE uptake sites (Eur. J. Pharmacol. 191:239, 1990) One group of rats received DMI (a NE uptake blocker) (10 mg/kg, daily) i.p. for 21 days and was killed 48 hr after the last injection. Another group of rats received ECS (increases release of NE) daily for 12 days (150 mA, 60Hz, 300 msec. duration) and was killed 24 hr after the last shock. DMI caused modest (15-30%) but statistically significant decreases in the binding of 3H-NIS in 5 of 17 areas measured. By contrast, except for the paraventricular nucleus of the thalamus where ECS caused a modest (20%) but statistically significant increase in binding, no other brain region was affected by ECS. In general, then, ECS does not seem to exert wide-spread effects on NE uptake sites in brain. It remains to be determined if the DMI-induced loss of binding of 3H-NIS in specific areas of brain represents a functional regulation of the NE uptake sites. (Research funds from the Dept. of Vet. Affairs and USPHS grants MH 45472 and MH 41819).

SEMICHRONIC ADMINISTRATION EFFECTS OF ADRENERGIC DRUGS ON ADRENOCEPTORS DENSITY IN DIFFERENT BRAIN AREAS. V. Alemán, M.E. Alvarez and *G.P. Jiménez*. Dept. Physiology, CINVES-TAV, IPN, Mexico, D. F., Mexico.

We wished to determine how both α_1 and α_2 adrenoceptors density is regulated by adrenergic drugs injected semichronically. Ninety six ninety-day-old rats were divided in three control and three drug treated groups. Rats were intradermically administered, 0.75 mg/kg of amphetamine every 12 hr during ten days, Prazosin (i.p.)1.0 mg/kg and Atipamezole (i.p.)3.5 mg/kg. Two hr after the last injection, cerebral areas were dissected and membrane fractions obtained. (^{3}H)-Prazosin and (^{3}H)-RX781094 were used as ligand for α_1 and α_2 receptors respectively. Amphetamine decreased α_1 receptors density in temporo-parietal cortex (T-PC) and in caudate (CN), but it increased in amygdala (Am). Amphetamine produced changes in α_2 receptors density, thus in frontal cortex (FC) and T-PC it was decreased significantly but it increased in hippocampus (Hp) and Am. Prazosin produced important decrements in FC, Hp and in CN α_1 receptors but it produced increments of α_2 in T-PC and Hp.Finally atipamezole increased α_1 receptors density in FC, T-PC, Am and CN. Receptors α_2 decrements were observed in FC, T-PC and Am. This type of regulation is in accord with either the administration of antagonists or agonists, with the presence of both hetero and autoreceptors and furthermore it depends on the brain area analyzed. But some unexplained changes were present too.

471.11

AGONIST INDUCED DOWN-REGULATION OF THE α_2-ADRENERGIC RECEPTOR SUBTYPES HAVE MARKEDLY DIFFERENT CHARACTERISTICS. P.E. Shreve, M.L. Toews and D.B. Bylund, Dept. of Pharmacology, Univ. of Nebraska Med. Ctr., Omaha, NE 68198-6260.

The purpose of the present study was to determine the effect of agonist pretreatment on α_2 adrenergic receptor (A2AR) number in cell lines expressing different A2AR subtypes. The cell lines used were Chinese hamster ovary (CHO) cells which have been stably transfected with the gene coding for the A2AR, human colonic adenocarcinoma (HT29) cells, and opossum kidney (OK) cells which have been pharmacologically characterized to express α_{2A}, α_{2A}, and α_{2C} subtypes of the A2AR, respectively. Cells were pretreated t norepinephrine (NE) at increasing concentrations for 24 h before harvesting. Binding studies with [^{3}H] rauwolscine showed that NE produced a concentration dependent down-regulation of the A2AR in all 3 cell lines (figure). The EC50 of NE was 0.073, 4, and 2 μM in OK, CHO, and HT29 cells, respectively. Thus NE was 27- to 55-fold more potent at down-regulating the A2AR in OK cells as compared to CHO and HT29 cells, respectively. These data suggest that differences in agonist induced down-regulation of the A2AR appear to be receptor subtype selective. This research was supported by NIH grant GM37664.

EFFECTS OF ANTIMYCIN A ON AGONIST BINDING TO ADRENERGIC RECEPTORS OF INTACT CELLS. S.J. Zhu*, P.E. Shreve and M.L. Toews. Dept. Pharmacology, Univ. Nebraska Med. Ctr., Omaha, NE 68198-6260.

For beta adrenergic, alpha-1 adrenergic, and alpha-2 adrenergic receptors and for muscarinic acetylcholine receptors, agonists have been shown to exhibit markedly lower apparent affinities in competition binding assays performed on intact cells than in assays with isolated membrane preparations. We have postulated that agonists induce receptor internalization during the course of the assay and that the apparent low affinity results from inaccessibility of hydrophilic agonists to internalized receptors. Since depletion of intracellular ATP with antimycin A has been shown to prevent both internalization and low affinity binding in the case of muscarinic receptors, the effects of antimycin A on low affinity binding to beta, alpha-1 and alpha-2 adrenergic receptors were studied. In DDT$_1$ MF-2 smooth muscle cells, antimycin A pretreatment increased affinity of the agonist epinephrine for beta receptors whereas binding of the antagonist metoprolol was not changed. However antimycin A did not increase epinephrine affinity for alpha-1 receptors in these cells. In Chinese hamster ovary cells expressing beta receptors, antimycin A increased affinity of the agonist isoproterenol but not the antagonist metoprolol. Similarly, in Chinese hamster ovary cells expressing alpha-2 receptors, antimycin A increased affinity of the agonist norepinephrine but not the antagonist prazosin. These results are consistent with involvement of receptor internalization (or another ATP-dependent mechanism) in low affinity binding of agonists to intact cell beta and alpha-2 receptors. They extend previous results suggesting that different mechanisms are involved in the case of alpha-1 receptors. (Supported by GM34500).

UPREGULATION OF β ADRENERGIC RECEPTORS AND β_2 m RNA BY CARBAMAZEPINE IN VITRO. G.Chen*, C.Hough, H.Manji, D.M.Chuang,I.N.Mefford and W.Z.Potter*, Exp Ther Branch and Biol.Psych. Branch, NIMH,Bethesda, MD 20982

Despite the widespread clinical use of carbamazepine (CARB), the molecular mechanisms underlying both its anticonvulsant and mood-stabilizing effects remain unknown. We have recently demonstrated that chronic in vitro exposure of C6 glioma cells to desipramine (DMI) results in a significant downregulation of β adrenergic receptors (βARs). Given the close structural similarity between DMI and CARB, and their opposite effects on seizure threshold, we examined CARB's effects on βARs. In contrast to DMI, incubation of C6 glioma cells with 40 uM CARB in vitro resulted in a significant increase in βARs. The upregulation of βARs was evident within 3 days of incubation, and exhibited a dose-response profile (10-100 uM). Moreover, the upregulation of beta receptors was accompanied by a marked increase in β_2 mRNA. CARB's effects on β_2 mRNA were also time and dose-dependent (and occured within the drugs therapeutic range). The mechanism(s) by which CARB and DMI produce opposite effects on βARs is currently under investigation.

NEUROENDOCRINE REGULATION II

EFFECT OF AGING ON INDUCTION OF FOS IN THE SUPRAOPTIC AND PARAVENTRICULAR NUCLEI IN RESPONSE TO CHRONIC DEHYDRATION. L. Trojanczyk, J.A. Olschowka and C. D. Sladek, Univ. of Rochester Sch. of Med., Rochester, N.Y. 14642.

In previous studies, this laboratory demonstrated that the vasopressin (VP) response to 72 hours of water deprivation is attenuated in aged rats (Neurobiol. Aging 1:293, 1981). Aged rats have a decreased concentration of VP in the neural lobe, and VP synthesis is decreased (Exp Gerontol. 22:113-125, 1987). These observations led to the hypothesis that defects in the mechanisms that regulate VP synthesis and release in response to stimuli may precipitate the observed aging associated deficits in VP release. Fos is a candidate for a signal involved in stimulus-transcription coupling in VP neurons, because it was recently demonstrated that the *c-fos* gene is induced in supraoptic and paraventricular neurons following dehydration. In this study we evaluated the effect of 72 hours of water deprivation on fos induction in the SON and PVN nuclei in 4, 14, and 30 month old Fischer 344 rats. Animals were processed for c-fos immunocytochemistry using an antisera against the M-peptide region of the c-fos protein. This antisera cross reacts with fos-B and fos-related-antigen 1, and therefore provides an index of activation of the Fos family of antigens. Densitometric analysis of the SON and PVN demonstrated c-fos induction in all water deprived rats regardless of age. The density of staining (analyzed from the integrated optical density) was increased in both nuclei following dehydration (SON: F=12.05, p=0.002; PVN: F=21.68, p=0.0001). There was also a significant increase in the number of cells expressing fos in both nuclei in the dehydrated animals (SON: F=11.64; p=0.002; PVN: F=9.11, p=.0056). There was no significant effect of age on the density of fos staining nor any significant interaction effect in either nuclei. These results suggest that a deficit in the induction of the fos or fos related proteins in response to dehydration is not responsible for the attenuation of VP release observed in aged rats, however further studies are warranted to evaluate the effect on c-fos specifically. Supported by R35-AG09016.

472.2

C-FOS PROTO-ONCOGENE EXPRESSION IN HYPOTHALAMUS AND VASOPRESSIN REGULATION AFTER DEHYDRATION. J. M. Ding and J. Buggy, Dept. of Physiology, University of South Carolina School of Medicine, Columbia, S.C. 29208

The proto-oncogene *c-fos* codes for the nuclear protein Fos which acts as a transcriptional regulator linking short-term stimuli to long-term responses by altering secondary target gene expression. This study in rats examined *c-fos* and vasopressin gene expression in brain areas associated with body fluid regulation in response to various dehydration stimuli. *Fos* is induced by acute intracellular dehydration or cerebroventricular injection (ICVT) of carbachol (but not by hypovolemia or ICVT angiotensin) in the hypothalamic magnocellular nuclei of paraventricular (PVN), supraoptic (SON), and nucleus circularis as well as in the dehydration-transducing structures of lamina terminalis: AV3V nucleus medianus, OVLT, and SFO. The induction of *fos* in magnocellular nuclei requires stimulus transduction since AV3V lesion attenuated *fos* induction by intracellular dehydration or carbachol in the PVN and SON. Dual-label immunocytochemical co-localization of *fos* and vasopressin in the magnocellular neurons of PVN and SON suggests that *fos* may regulate vasopressin. *In situ* hybridization analysis after acute dehydration revealed a rapid and transient *fos* induction followed by a slower-onset increase in vasopressin mRNA. The increase in vasopressin mRNA persisted for up to 2 days even after rehydration. Furthermore, prevention of fos translation by cycloheximide attenuated the dehydration-induced increase in vasopressin mRNA. These results support a role for *fos* in vasopressin regulation following intracellular dehydration.

472.3

DIFFERENTIAL RESPONSE OF ARGININE VASOPRESSIN (AVP) mRNA IN THE HYPOTHALAMIC PARAVENTRICULAR AND SUPRAOPTIC NUCLEI TO ANTIGLUCOCORTICOID TREATMENT IN LEAN AND OBESE ZUCKER RATS. U. Pesonen, M. Koulu and R. Huupponen', Dept. of Pharmacology, Univ. of Turku, SF-20520 Turku, Finland.

Arginine vasopressin (AVP) is a physiological regulator of ACTH secretion. It acts synergistically with corticotropin releasing factor (CRF) potentiating its action on pituitary corticotrophes. In the present study we have investigated the effects of antiglucocorticoid treatment on AVP mRNA expression in the hypothalamus of genetically obese Zucker rats. These rats are hyperphagic, hyperinsulinemic and there is also evidence of abnormal regulation of the hypothalamus-pituitary-adrenal -axis in obese Zucker rats.

Six obese and six lean controls were administered with mifepristone (RU486), a glucocorticoid receptor antagonist, 10 mg/kg p.o. twice daily for four days. Control animals were treated similarly with vehicle. The expression of AVP mRNA in the hypothalamic paraventricular (PVN) and supraoptic (SON) nuclei was quantitated using *in situ* hybridization assay with ^{35}S-labelled oligonucleotide probe.

Our results show that obese Zucker rats have significantly ($p<0.05$) lower basal expression of AVP mRNA in the PVN, but not in the SON compared to lean controls. Mifepristone treatment significantly ($p<0.01$) increased AVP mRNA levels in the PVN of obese animals, but did not modify AVP mRNA levels in the PVN in lean animals. In contrast, mifepristone lowered ($p<0.05$) AVP mRNA content in the SON in lean animals.

The results suggest that the regulation of AVP neurons in the PVN is altered under basal conditions in obese Zucker rats. Opposite responses to mifepristone treatment propose that glucocorticoids elicit different feedback control on AVP mRNA in the hypothalamus of lean and obese Zucker rats.

472.4.

MODULATION OF SUPRAOPTIC AND PARAVENTRICULAR PEPTIDE mRNA LEVELS BY THE POSTERIOR ARCUATE / PREMAMMILLARY REGION. S.E. Bachus, M. Palkovits*, and W.S. Young,III, Lab. Cell Biology, NIMH, Bethesda, MD 20892.

We previously demonstrated that hemisections anterior to the mammillary bodies dramatically elevated expression of galanin in the supraoptic (SON) and paraventricular (PVN) nuclei of the hypothalamus (Neurosci. 1:115). In order to determine the origin of fibers mediating this effect, we made electrolytic lesions (Physiol Behav. 23:421) of various posterior hypothalamic sites. We used hybridization histochemistry with ^{35}S-oligonucleotide probes against galanin, as well as cholecystokinin, and angiotensin mRNAs. Other rats' SONs were implanted with micropipettes (Brain Res. 235:174) containing the retrograde fluorescent tracer, Fluorogold. These rats were examined 5 days later for the presence of retrogradely labeled cells in the posterior hypothalamus.

Electrolytic lesions in the region of the premammillary nuclei and mammillary and premammillary portions of the arcuate nucleus elevated levels of galanin transcripts in the PVN and SON. Lesions of the mammillary and supramammillary nuclei were ineffective. The effective lesions also elevated levels of cholecystokinin mRNAs in the PVN and SON, whereas those for angiotensin were reduced in SON. Fluorogold-retrogradely labelled cells were present in the arcuate and premammillary nuclei after injections that included the SON, although potential contributions from extra-SON uptake are still being analyzed. We are also attempting more specific lesions with ibotenic acid and neonatal monosodium glutamate, but our results presented here suggest that projections from the posterior arcuate/premammillary region modulate SON and PVN gene expression.

472.5

THE GABA AGONIST MUSCIMOL REDUCES VASOPRESSIN SYNTHESIS AND RELEASE. Michelle M. Roberts and Alan G. Robinson, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

GABA is a major inhibitory transmitter of the neurohypophysis and GABAergic mechanisms are believed to modify both basal and stimulated vasopressin (AVP) release. We studied the effects of the GABA agonist muscimol on the synthesis and release of AVP and oxytocin (OT) in the rat. Acute intracerebroventricular (ICV) injection of muscimol (160 ng in 1 μL artificial CSF [aCSF]) inhibited the AVP and OT response to hemorrhage and hypertonic saline infusion. Following a 5 ml hemorrhage, plasma AVP levels were reduced to 26%, 46%, 27% and 59% at 5, 10, 15 and 25 min in muscimol treated rats relative to aCSF. Plasma OT levels were reduced to 18%, 15%, 14% and 27% of controls. Following infusion of 2 M saline (10 ml/kg over 60 min), plasma AVP was suppressed to 35%, 37% and 16% at 30, 60 and 90 min in muscimol-treated rats relative to aCSF. OT was dramatically suppressed to levels 5%, 16% and 33% of control responses. We next demonstrated that chronic infusion of muscimol into the lateral ventricle reduced basal synthesis rates of both AVP and OT. Following a 3 day infusion of 50 ng muscimol per hour, AVP synthesis rates were reduced from a baseline value of 1.5 ng/h to undetectable levels. OT synthesis decreased from a basal rate of 4.1 ng/h to 0.5 ng/h. AVP mRNA levels in muscimol treated rats were reduced to 53% of control. Plasma sodium and hydration were normal in all groups of rats. We conclude that acute ICV injection of muscimol inhibits AVP and OT release in response to both hemorrhagic and osmotic stimuli. Chronic infusion of muscimol inhibits basal AVP and OT synthesis and reduces AVP mRNA levels. These studies indicate that GABA is a major inhibitor of physiologic release and synthesis of AVP.

472.6

STIMULATION OF NEUROPHYSIN EXPRESSION IN CULTURED NEURONS BY CYCLIC AMP IS REVERSIBLE. C.D. Sladek and M.J. Gallagher.* Univ. Rochester Sch. Med., Rochester, N.Y. 14642

Previous studies have demonstrated that the number of vasopressin (VP) neurons present in primary diencephalic cultures can be markedly augmented by treatment with drugs that elevate intracellular cyclic AMP (cAMP; Oeding,et al, J. Neuroendo., 1990). In order to evaluate the effect of this drug treatment on VP secretion by hypothalamic cultures, we have exposed primary dispersed hypothalamic cultures derived from 14 day old fetal Sprague-Dawley rats to forskolin (25μM) and the phosphodiesterase inhibitor, IBMX (500μM) either continually or intermittently for up to 32 days. Culture medium was collected throughout the culture period for VP radioimmunoassay. At the end of the experiment, cultures were stained immunocytochemically for neurophysin (NP). As reported by previous investigators, exposure to the drugs for 11 days resulted in a 10X increase in the number of NP positive neurons. This increase in the cell number was sustained during longer periods of exposure. During this period the cells continued to increase in size and develop extensive neuritic processes. This increase in cell size and complexity was reflected in an increase in the concentration of VP in the culture medium from 1.4±0.15 pg/ml at 11 days to 8.4±0.6pg/ml after 32 days of drug treatment. The VP concentration remained undetectable (<1.25pg/ml) in non-treated cultures throughout this period. The effect on NP expression required the continuous presence of the drugs. Removal of the drugs from day 11-18 of culture resulted in an almost complete loss of NP positive cells, however re-exposure to the drugs reinstated the NP expression in a time dependent fashion. These results demonstrate that VP secretion and maturation of NP neurons in dispersed hypothalamic cultures can be markedly stimulated by chronic treatment with cAMP elevating drugs, but continuous exposure to the drugs is necessary to sustain the effect. Supported by RO1-DK19761 and PHS S7RRO5403-29.

472.7

ALTERED CNS EXPRESSION OF CYTOPLASMIC AND HETERONUCLEAR VP RNA IN THE BRATTLEBORO RAT. P. Szot, M.D. Brot and D.M. Dorsa. GRECC, Seattle VAMC, WA 98108 and Dept. of Pharmacology, Univ. Washington, Seattle,WA 98195.

The HOM-BB rat lacks the ability to synthesize VP and its neurophysin due to a single base pair deletion in the VP gene. This mutation in the gene results in a reading frame shift and inefficient translation of the mRNA encoding the peptide. The level of cytoplasmic VP mRNA was quantified autoradiographically by in situ hybridization in the paraventricular (PVN), supraoptic (SON) and suprachiasmatic (SCN) nuclei, as well as the extrahypothalamic nuclei of the bed nucleus of the stria terminalis (BNST) and medial amygdala (MA). The HOM-BB rat showed a significant reduction in the amount of VP mRNA expressed per cell compared to LE or HET-BB rats, while the number of hybridization positive cells was equivalent. In contrast, the SCN, BNST and MA of the HOM-BB rat showed a significant reduction in the number of VP mRNA positive cells and amount of VP mRNA being expressed than the LE or HET-BB rat. The number of VP mRNA expressing cells in the BNST and MA of the HOM-BB rat was not enhanced by elevating testosterone levels as in the normal LE rat. An oligonucleotide to intron 2 of the VP gene was used to detect heteronuclear VP RNA. Significant increases in the number of cells expressing the nuclear VP RNA were observed in the PVN (58%) and SON (62%), but not in the SCN of the HOM-BB rat when compared to the LE or HET-BB rat. These data suggest that the trans-cription rate of the VP gene in the magnocelluar nuclei of the HOM-BB rat may be elevated, though this increase does not appear to result in higher levels of mutant cytoplasmic VP mRNA.

472.8

COLD EXERTS OPPOSITE EFFECTS ON TRH mRNA LEVELS IN NEURONS OF THE PARAVENTRICULAR NUCLEUS (PVN) AND PREOPTIC AREA (POA), INDEPENDENT OF CHANGES IN BARORECEPTOR ACTIVITY. R.T. Zoeller, D. Dolan*, M.F. Nichols* and J. C. Schadt. Dept. Anat/Neurobiol. and Dalton Research Center, Univ. Missouri Sch. Med., Columbia, MO 65212.

TRH neurons of the POA have been implicated in the control of body temperature (T_b); their activity is believed to contribute to maintenance of T_b during cold exposure. Because TRH mRNA levels in other hypothalamic nuclei are linked to TRH release (Zoeller et al., *Endocrinology* 127:2955, 1991), we hypothesized that TRH mRNA levels in POA neurons would be elevated by cold exposure. Using *in situ* hybridization and single-cell analysis, we found that TRH mRNA levels in neurons of the POA were significantly lower ($p<0.01$) in animals exposed to 6h 5°C (n=8) compared to 25°C (n=11). Cold exposure produces changes in cardiovascular function which may account for some effects of cold. We manipulated blood pressure with 60 min infusions of Na nitroprusside (SNP, n=8), phenylephrine (PE, n=11), or saline (n=14) to initially investigate possible involvement of these TRH neurons in regulating cardiovascular function. Neither drug significantly affected TRH mRNA levels in PVN; nor did SNP affect TRH mRNA levels in POA. However, we did find that SNP significantly elevated TRH mRNA levels in specific raphe nuclei ($p<0.01$). These data suggest that separate populations of TRH neurons may be involved in different aspects of T_b regulation and cardiovascular function. [Supported by: AHA, MO Affiliate (RTZ) and HL31218 (JCS).

ENDOCRINE REGULATION II

473.1

INTERACTION OF F8Fa WITH DYNORPHIN IN MODULATING NEUROPEPTIDE SECRETION FROM ISOLATED NERVE ENDINGS OF THE RAT NEURAL LOBE. K. PAYZA. Laboratory of Biochemical Genetics, NIMH Neuroscience Center, WAW-113, St. Elizabeth's Hospital, Washington, D.C. 20032.

The neuropeptide FLFQPQRFamide (F8Fa) was tested for modulatory effect on secretion of the hormones oxytocin (OT) and vasopressin (VP) in isolated nerve endings of rat neural lobe, where F8Fa has been localized. The endings were loaded onto 0.45 μm filters, perfused with Ringer containing physiological salts and protease inhibitors, and stimulated by perfusion with 35 mM $[K^+]_o$. The OT and VP secreted into the eluate were measured by RIA. Dynorphin A 1-8 (1 μM) inhibited secretion of both OT and VP. F8Fa (2 μM) blocked the inhibition of OT and VP secretion induced by dynorphin A 1-8. These effects of F8Fa were similar to naloxone (10 μM), which also blocked or attenuated the effect of dynorphin on OT and VP secretion. These results suggest a local modulatory role for F8Fa in the rat neural lobe.

473.2

OPIOIDS INHIBIT SYNAPTIC INPUTS FROM THE REGION OF THE ORGANUM VASCULOSUM OF THE LAMINA TERMINALIS (OVLT) TO THE SUPRAOPTIC NUCLEUS (SON) IN VITRO. S.J.A. MacMillan, *Centre for research in Neuroscience, Montreal General Hospital and McGill Univ., Montreal, H3G 1A4.*

The activity of SON neurones is thought to be regulated by inputs from the region anterior and ventral to the third ventricle (AV3V). This input which is thought to be important, in part, in osmotic control of neurohypophysial hormone release is believed to be opioid sensitive. Using a superfused hypothalamic explant preparation and intracellular recording techniques we have examined the effects of opioids on this input to the SON. Morphine applied by addition to the superfussion line (1-10μM) inhibited the spontaneous firing of MNCs (n=21) but this was associated with only small membrane hyperpolarisations. However morphine (1μM) profoundly inhibited (n=5) spontaneous presynaptic potentials (PSPs). Electrical stimulation of the OVLT region produced short latency short duration mixed excitatory and inhibitory PSPs followed by longer latency excitations in 17 MNCs. Morphine (1μM) inhibited both early and late components of this response (n=11). These inhibitions peaked within 2-5 minutes of morphine reaching the tissue and recovered within 10 minutes of return to control solution and were prevented (n=4) by the opioid antagonist naloxone (1μM). We conclude that opioids exert a presynaptic inhibitory action on inputs from the OVLT region to the SON. *(Supported by the MRC)*

OSMOTIC STIMULATION OF THE ORGANUM VASCULOSUM OF THE LAMINA TERMINALIS (OVLT) ACTIVATES RAT MAGNOCELLULAR NEUROSECRETORY CELLS (MNCs) IN VITRO. D. Richard and C.W. Bourque. Centre for Research in Neuroscience, McGill University, Montreal, Canada.

The OVLT has been implicated as a central osmoreceptor involved in the regulation of neurohypophysial hormone release. Possible functional interactions were examined during intracellular recordings obtained in superfused explants of rat hypothalamus. Brief (5-10 sec) hypertonic stimulation (20-50 mOsm) of the OVLT area induced depolarization and increased firing in each of five local neurons tested. Selective osmotic stimulation of the OVLT also caused increases in the frequency of spontaneous postsynaptic potentials and accelerated the firing rate in each of 14 MNCs tested. These effects were dose-dependent and persisted for 1-3 minutes before reversing to control rates. In contrast to the pronounced depolarizations (3-10 mV) and decreases in input resistance (10-25%) observed during direct osmotic stimulation of MNCs (n=8), increases in firing rate recorded from MNCs during OVLT stimulation were not accompanied by changes in impedance or membrane potential. These results suggest that neurons located in or near the OVLT convey information concerning fluid osmolarity to MNCs via synaptic input to the supraoptic nucleus. Supported by FCAR and the MRC.

EFFECTS OF NEUROTENSIN ON RAT MAGNOCELLULAR NEUROSECRETORY CELLS (MNCs) IN VITRO. K. Kirkpatrick and C.W. Bourque. Montreal General Hospital and McGill University, Montreal, Canada H3G 1A4

The tridecapeptide neurotensin (NT) has been shown to induce antidiuresis in dogs. In this study we have examined the actions of this peptide on hypothalamic MNCs. Intracellular recordings were obtained from supraoptic nucleus MNCs in superfused rat hypothalamic explants. Application of NT (.1-5 μM) depolarized and enhanced spike discharge in each of 23 cells tested. Eight of these cells were classified as being vasopressinergic on the basis of their ability to display phasic firing. These effects were mimicked by the NT 8-13 fragment (n=7) and persisted in Ca^{++}-free solutions containing Mn^{++} (2mM, n=3). In addition to these effects NT decreased the magnitude of the Ca^{++}-dependent afterhyperpolarization (AHP) that follows spike trains in MNCs (n=4), as well as the corresponding outward current measured under hybrid clamp (n=2). Intracellular injections of Cs^{+} sufficient to abolish the AHP (n=4) did not prevent NT-induced depolarizations. These results suggest that activation of postsynaptic NT receptors can contribute to the regulation of vasopressin release by exciting MNCs in two distinct manners. *Supported by FCAR and MRC.*

473.5

VASOPRESSIN RELEASE BY CENTRAL ANGIOTENSIN II IS MEDIATED THROUGH AN ANGIOTENSIN TYPE-1 RECEPTOR AND THE DRINKING RESPONSE IS MEDIATED BY BOTH AT-1 AND AT-2 RECEPTORS. David C. Hogarty* and M. Ian Phillips. Dept. of Physiology, College of Medicine, University of Florida, Gainesville, FL 32610.

Angiotensin II, given centrally, releases vasopressin, increases blood pressure and stimulates drinking. With the advent of new receptor subtype antagonists, we are able to investigate whether the effects are mediated by AT-1 receptors or AT-2 receptors in the brain. Adult male Sprague Dawley rats were cannulated and 5 days later catheterized in the common carotid artery for blood pressure measurements. All experiments were carried out in chronic rats. Three treatments were given i.v.t. in 2 ul ACSF at 30 min intervals. 1) 50 ng Ang II, 2) AT-1 antagonist 0.7 μg DuP or AT-2 antagonist 7.0 μg EXP, + 50 ng Ang II, 3) 50 ng Ang II to test for recovery. Controls to test repeated doses were also used. Blood pressure and drinking responses were recorded and an arterial blood sample drawn for radioimmunoassay of arginine vasopressin. The results showed that plasma AVP release in response to Ang II, is reduced 70% by AT-1 antagonism but not altered by AT-2 antagonist. EXP had no significant effect on the pressor response, but DuP significantly blocked the pressor response ($p<0.01$). Drinking was also antagonized by DuP (64%), and partially by EXP (50%). The results show that the central vasopressin and blood pressure responses to Ang II i.v.t. are mediated by AT-1 receptors and the drinking response is mediated by AT-1 and partly by AT-2 receptors.

A D1-DOPAMINE RECEPTOR AGONIST AND ANGIOTENSIN II STIMULATE OXYTOCIN RELEASE IN THE LACTATING RAT VIA ACTIONS IN MAGNOCELLULAR HYPOTHALAMIC REGIONS. S.L. Parker and W.R. Crowley. Dept. of Pharmacology, University of Tennessee-Memphis, Memphis, TN 38163.

Dopamine activates OT release in the lactating rat, and our recent results suggest that the D1 receptor is preferentially involved (Neuroendocrinology 53: 493, 1991). The objective of the present studies was to test whether D1 stimulation of OT release occurs via an action in the hypothalamic magnocellular nuclei. Lactating Holtzman rats received cannula implants in the third ventricle (3v) or unilaterally above the paraventricular nucleus (PVN) or supraoptic nucleus (SON) at 4-7 days postpartum. Seven days later the D1-specific dopamine agonist SKF 38393 (SKF) was injected into the 3v at 12.5 or 50 μg/5 μl or into the PVN or SON regions at 8 μg/1 μl. Controls received an equal volume of vehicle. All sites were subsequently treated with angiotensin II (AII; 95 pmoles) as positive control. SKF dose-dependenly elevated plasma OT at 5-60 min following injections into the 3v. Highly significant stimulation was also seen following injection into the SON, and a lesser, but significant, stimulation was apparent after treatment of the PVN. The increase in plasma OT after 50 μg SKF in the 3v was attenuated by prior iv injection of the D1 antagonist SCH 23390 (750 μg/kg). AII significantly stimulated OT release from all three injection sites, but the same dose was ineffective after iv administration. Plasma OT levels were unaffected by vehicle injection at any site. SKF in the 3v also dose-dependently increased plasma concentrations of prolactin (PRL) and produced a strong priming of PRL release to subsequent 3v injection of AII.

473.7

OSMOSENSITIVITY OF MAGNOCELLULAR NEUROSECRETORY CELLS (MNCs) ISOLATED FROM THE SUPRAOPTIC NUCLEUS OF THE ADULT RAT. Stephane H.R. Oliet and Charles W. Bourque. *Centre for Research in Neuroscience. Montreal General Hospital and Mc Gill University, Montreal, PQ.*

Small (1-5%) increases in plasma osmolarity induce the release of oxytocin and vasopressin from the axon terminals of MNCs in the neurohypophysis. While a number of other osmoresponsive inputs may be involved, an endogenous osmosensitivity of MNCs is thought to be important for the in vivo response. We have examined the effects of small hyperosmotic stimuli on MNCs and non-MNCs acutely dissociated from the adult rat. Immunostaining revealed that 96% of the neurons with a cross-sectional area (CSA) > 160 μm^2 are oxytocin or vasopressin-positive. In response to a 3-10% increase in osmolarity (+ Mannitol), all cells (MNCs and non-MNCs) showed small reductions in CSA (< 5%). Whole-cell current clamp recordings from MNCs revealed reproductible and reversible depolarization and increase in firing rate (n=10). Non-MNCs (CSA < 50 μm^2) failed to show either response (n=6). Under voltage-clamp the response of MNCs was associated with the appearance of an ionic current reversing around -20 mV (n=3). These results confirm the intrinsic osmosensitivity of MNCs . The persistence of this response in isolated MNCs in the whole-cell configuration opens the way to an analysis of signal transduction in a physiological osmoreceptor. Supported by FCAR, FRSQ and MRC.

473.8

DISTRIBUTION AND ORIGINS OF GABAergic PROJECTIONS TO THE PARAVENTRICULAR NUCLEUS. B.L. Roland, M.R. Brown and P.E. Sawchenko, The Salk Institute, La Jolla, CA 92037 and UCSD Medical Center, San Diego, CA 92103.

Axonal transport and immunohistochemical methods were used to characterize the organization of glutamic acid decarboxylase-immunoreactive (GAD-IR) projections to the paraventricular nucleus of the hypothalamus (PVH) in the rat. In line with prior reports, GAD-IR varicosities were found to be densely and quite uniformly distributed throughout the hypothalamus, including the PVH and the supraoptic nucleus (SO). Small crystalline implants of the retrograde tracer, true blue, into the PVH labeled GAD-IR cells in the anterior periformical region, portions of the anterior hypothalamic area immediately ventral to the PVH and just doral to the optic tract at the level of the SO, and within the PVH, itself. Because possible uptake of retrograde tracer by local dendritic processes might have yielded false positive results, a combined anterograde transport (PHA-L)-immunohistochemical approach was used in an attempt to confirm some putative local sources of GAD-IR inputs. Tracer injections in the region immediately ventral to the PVH, or within the anterior third of the nucleus, labeled moderate axonal projections to the PVH; a variable, and generally small, proportion of anterogradely labeled axons and terminals in the PVH also displayed GAD-IR. Some PHA-L injections also labeled GAD-IR projections to the SO. These results suggest that GABAergic projections to the various visceromotor cell types in the PVH and SO arise at least principally from several diffusely distributed local sources. Peri- and intra-nuclear GABAergic neurons could provide an intermediary by which documented (and generally inhibitory) limbic system influences on neuroendocrine function are exerted.

ELECTROPHYSIOLOGICAL DIFFERENCES BETWEEN IDENTIFIED OXYTOCIN AND VASOPRESSIN NEURONS RECORDED INTRACELLULARLY FROM RAT SUPRAOPTIC NUCLEUS *IN VITRO*.

W.E. Armstrong, B.N. Smith & M. Tian. Dept. of Anat. Neurobiol., Univ. Tenn., Memphis, Memphis, TN 38163.

Oxytocin (OT)- and vasopressin (VP) -secreting neurons exhibit different patterns of spontaneous and evoked activity *in vivo*. To determine whether differences exist in the membrane properties of these two cell types, supraoptic neurons were recorded intracellularly *in vitro*, injected with biocytin or Neurobiotin, and immunocytochemically identified as either OT or VP-containing.

OT and VP neurons exhibited similar I/V relationships, input resistances, and membrane time constants. In response to positive pulses eliciting brief spike trains, both types exhibited spike frequency adaptation, although the amount was variable across neurons. Both types exhibited a similar long lasting afterhyperpolarization following a spike train which was reduced by apamin (up to 100 nM), known to block a Ca^{++}- dependent K^+ current in these neurons. The great majority of VP neurons exhibited a depolarizing afterpotential (DAP) following brief spike trains. While most OT neurons did not exhibit a DAP, a minority did. Continuous current injection which altered the membrane potential failed to force OT neurons to exhibit phasic bursting activity, including those few with a DAP. Many VP neurons adopted or spontaneously exhibited the phasic pattern, but several did not, and instead fired continuously, not unlike OT neurons.

The results on phasic bursting are consistent with those from several other labs, i.e., neurons exhibiting this pattern contain VP. However, the lack of this activity, or the expression of continuous firing, is clearly not a unique signature for OT neurons. Similarly, while the voltage-sensitive DAP is undoubtedly related to the phasic, bursting pattern, its presence, while characteristic of, is not unique to VP neurons. Supported by NIH #NS23941(WEA) and NIMH #MHO9933 (BNS).

THE EFFECTS OF HISTAMINE ON IMMUNOCYTOCHEMICALLY IDENTIFIED VASOPRESSIN NEURONS IN RAT SUPRAOPTIC NEURONS RECORDED INTRACELLULARLY *IN VITRO*.

B.N. Smith and W.E. Armstrong Dept. of Anat. Neurobiol., Univ. Tenn., Memphis, Memphis, TN 38163.

The effects of histamine on immunocytochemically identified vasopressin neurons in the rat supraoptic nucleus were investigated using intracellular recording techniques from the hypothalamo-neurohypophysial explant. Exogenous application of histamine (100 nM-100 μM) to vasopressinergic neurons results in a 3-10 mV membrane depolarization, accompanied by an increase in the amplitude of the depolarizing afterpotential and a coincident decrease in the afterhyperpolarizing potential following current-evoked trains of action potentials. The amplitude of the depolarizing afterpotential is also enhanced by histamine when the afterhyperpolarizing potential is blocked by 100-200 μM d-tubocurarine, as well as in the presence of 3 μM tetrodotoxin and 200 μM d-tubocurarine, indicating a post-synaptic action of histamine on the depolarizing afterpotential that is not simply a reflection of a decrease in the afterhyperpolarizing potential. In addition, the depolarizing afterpotential is enhanced by histamine in the presence of the histamine H_2-receptor antagonist, cimetidine (1 μM), or by the histamine H_1-receptor agonist 2-thiazolylethylamine (0.1-1 mM). Although preliminary, this result suggests that the effects of histamine on vasopressin neurons in the SON are mediated by the H_1-receptor.

The present findings indicate that histamine directly enhances the depolarizing afterpotential following current-evoked trains of action potentials observed in vasopressin neurons, possibly via histamine H_1-receptors.

473.11

IBOTENIC ACID LESIONS OF MEDIAN PREOPTIC NUCLEUS DO NOT INFLUENCE BARORECEPTOR INDUCED INHIBITION OF SUPRAOPTIC VASOPRESSIN-SECRETING NEURONS IN THE RAT.

R. Nissen, J.T. Cunningham, A.M. Allen & L.P. Renaud, Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Ontario, Canada. K1Y 4E9.

Electrical stimulation of two forebrain structures, the diagonal band of Broca (DBB) and the median preoptic nucleus (MnPO), induces $GABA_A$ receptor mediated synaptic inhibition of hypothalamic supraoptic vasopressin (VP) secreting neurons. The DBB relays inhibitory baroreceptor information associated with increases in blood pressure to VP-secreting neurons. The purpose of this study was to determine whether MnPO neurons are similarly involved in baroreceptor induced suppression of supraoptic VP neurons. Male Long-Evans rats were anesthetized with pentobarbital and stereotaxically injected with 0.25μl of ibotenic acid (5μg/μl) into the DBB or MnPO. Following a minimum of 3 days recovery, animals were reanesthetized with pentobarbital and prepared for extracellular recording from identified SON neurons using a transpharyngeal approach. The spontaneous activity of the VP neurons tested in control, DBB lesioned or MnPO lesioned rats were not different (8.5±0.7, 7.0±0.6, 9.9±0.8 spikes/sec respectively). While acute increases in blood pressure, achieved by intravenous administration of metaraminol (10μg/10μl), reliably arrested the activity of 18/18 neurons in the control group, ibotenate lesions in DBB significantly reduced the number of VP neurons responding to similar blood pressure elevations (8/21). In contrast, MnPO lesions had no effect on the sensitivity of vasopressin neurons to baroreceptor induced cessation in activity (24/29). Thus, MnPO neurons, which are involved in body fluid homeostasis, are not necessary for the transmission of inhibitory baroreceptor information to the supraoptic VP-secreting neurons. (Supported by FRSQ, Ontario Heart & Stroke, MRC & NHMRC of Australia)

473.12

INJECTIONS OF NOREPINEPHRINE (NE) IN THE DIAGONAL BAND OF BROCA (DBB) ATTENUATE THE ACTIVITY OF RAT SUPRAOPTIC (SON) VASOPRESSIN NEURONS.

J.T. Cunningham, R. Nissen, & L.P. Renaud, Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Ontario Canada K1Y 4E9.

In the rat, electrophysiological studies have demonstrated that transient drug-induced elevations in arterial blood pressure, which are sufficient to activate peripheral baroreceptors, produce a brief cessation in the spontaneous activity of SON magnocellular neurosecretory cells. This response is selective for vasopressin-secreting neurons and appears to be mediated by the noradrenergic innervation of the DBB. The present study evaluated whether or not direct NE injections into the DBB could similarly arrest the spontaneous activity of SON vasopressin secreting neurons. Extracellular recordings were obtained from antidromically identified SON neurons in pentobarbital anesthetized male, Long-Evans rats using a transpharyngeal approach. A triple barrel injection pipette containing NE (10 uM), pontamine sky blue, and the artificial CSF vehicle (with 0.1 % ascorbic acid) was placed in the DBB. Neurosecretory neurons were characterized as either vasopressin- or oxytocin-secreting based on their responses to increases in blood pressure produced by intravenous injections of metaraminol (10 ug/10 ul). Injections of 200 nl NE into the DBB region arrested the spontaneous activity of 78% of the SON vasopressin-secreting neurons. In contrast, only 11% of the oxytocin secreting-neurons showed a comparable decrease in excitability to the same NE injections. Vehicle injections did not influence the activity of any of the neurons tested. No changes in blood pressure were associated with the NE injections in the DBB. These results are consistent with the hypothesis that the baroreceptor-sensitivity of vasopressin neurons is mediated by a NE mechanism in the DBB. 473.13

SODIUM DEPRIVATION BLUNTS HYPOVOLEMIA-INDUCED NEUROHYPOPHYSEAL SECRETION OF OXYTOCIN (OT) AND VASOPRESSIN (AVP) IN RATS.

E.M. Stricker, J.G. Verbalis. Departments of Behavioral Neuroscience and Medicine, University of Pittsburgh, Pittsburgh, PA 15260.

The present studies determined the effects of dietary sodium intake on neurohypophyseal secretion of OT and AVP in response to plasma volume deficits in rats. Adult male rats were fed either standard sodium-rich diet or pelleted sodium-deficient (NaD) diet for 8 days, and then were injected sc with 5-10 ml of 30% polyethylene glycol (PEG) solution to induce hypovolemia. In rats maintained on either diet, secretion of OT did not begin until plasma volume deficits reached 25-30%, while AVP secretion increased gradually over this range. However, when hypovolemia was more pronounced, secretion of both hormones was significantly blunted in rats given NaD diet. These effects did not reflect a reduced responsiveness of the neurohypophyseal system because normal secretion of AVP and OT was observed after iv infusion of 2 M NaCl. Nor did they reflect insensitivity to hypovolemia because rats allowed access to water drank normally after 30% PEG treatment (13.9 ± 0.7 ml in 7 hr). Instead, the results likely represent a specific reduction of the stimulatory baroreceptor inputs into OT and AVP neurons during dietary sodium deprivation. In light of the pronounced salt appetite of rats maintained on NaD diet for 8 days, and the known co-activation of magnocellular and parvocellular OT neurons under some circumstances, the present observations are consistent with recent findings relating activity in central OT neurons with inhibition of salt appetite in rats.

473.14

CENTRAL SOMATOSTATIN INHIBITS CHOLECYSTOKININ-STIMULATED RELEASE OF MAGNOCELLULAR OXYTOCIN IN CONSCIOUS RATS.

R.E. Blackburn, E.M. Stricker, and J.G.Verbalis. Departments of Behavioral Neuroscience and Medicine, University of Pittsburgh, Pittsburgh, PA 15261.

Recent evidence has demonstrated a direct projection from the nucleus tractus solitarius (NTS) to oxytocin (OT) cells in the hypothalamic supraoptic nucleus (SON) that contains neurons immunoreactive for somatostatin (SS-28). Since NTS afferents are known to influence release of OT in response to peripheral cholecystokinin (CCK) and since SS-28 has been shown to suppress activity of SON cells in vitro, we studied the effect of central SS-28 administration on CCK-stimulated OT release. Conscious male rats were given either SS-28 (300 ng/rat in 5 μl) or vehicle (aCSF, 5 μl) icv. Blood samples for basal plasma OT levels were obtained 30 min later, or rats were injected with CCK (10 μg/kg or 100 μg/kg, ip) and then sampled 5 min later. In another group, plasma OT levels were measured 30 min after administration of hypertonic saline (2M NaCl, 2 ml, ip). Plasma OT levels (pg/ml) in each group are summarized below (** $p < 0.01$ compared to aCSF-treated control rats):

	aCSF (n)	SS-28 (n)
basal	4.2 ± 1.1 (5)	5.6 ± 1.5 (7)
CCK: 10 μg/kg	35.2 ± 2.4 (10)	7.8 ± 1.1 (12)**
100 μg/kg	42.2 ± 17.8 (7)	8.6 ± 2.4 (5)**
2M NaCl	28.1 ± 9.6 (7)	19.6 ± 4.9 (5)

These data indicate that central injection of SS-28 selectively inhibits CCK-induced OT release, while leaving osmotically-stimulated OT release intact. Our results therefore provide one of the first demonstrations of the importance of specific OT cell-innervating NTS pathways on neurohypophyseal secretion in conscious rats.

473.15

NALOXONE INHIBITS SODIUM APPETITE IN THE HYPOVOLEMIC RAT BY A MECHANISM INVOLVING CENTRAL OXYTOCIN. J.G. Verbalis, R.E. Blackburn and E.M. Stricker. Departments of Medicine and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

Sodium appetite in the rat is commonly associated with suppressed plasma oxytocin (OT) levels and can be inhibited by a variety of treatments that lead to increased pituitary OT secretion. Systemic administration of OT does not, however, abolish saline ingestion, and this has led us to postulate that it is central rather than peripheral OT which mediates the sodium appetite. To test our hypothesis, we investigated the effect of peripheral administration of naloxone, a treatment known to stimulate both peripheral and central OT secretion, on saline ingestion in the polyethylene glycol (PEG)-induced hypovolemia model of sodium appetite. Male rats were treated with PEG (30% w/w, 5 ml, sc) and deprived of food and water for 24 h, after which they were injected with either naloxone (2.5 mg/kg in 2 ml, ip) or isotonic saline (2 ml, ip) 30 min prior to a 5-h drinking test period. Naloxone administration was associated with a marked increase in plasma OT levels (252.0 ± 45.4 pg/ml, n=9 compared to 56.9 ± 6.0 pg/ml in saline-treated PEG rats, n=6, $p<0.001$). In one-bottle (0.5 M NaCl) drinking tests naloxone completely abolished the sodium ingestion observed in control rats (5-h intake = 8.3 ± 0.9 ml). This inhibition of 0.5 M NaCl ingestion by naloxone could be reversed by prior icv administration of the OT-receptor antagonist [d(CH_2)$_5$,Tyr(Me)^2,Orn^8]vasotocin at doses of either 10 μg (5-h intake = 5.9 ± 1.4 ml) or 1 μg (5-h intake = 4.1 ± 0.6 ml). These data demonstrate that naloxone, like other stimuli for OT release, completely inhibits sodium appetite in the hypovolemic rat. Since this inhibition could be reversed by icv pretreatment with an OT-receptor antagonist, the results also provide evidence that brain OT participates in naloxone-mediated inhibition of hypovolemia-induced sodium appetite in rats.

473.16

CENTRAL ADMINISTRATION OF SEROTONIN INCREASES PLASMA VASOPRESSIN LEVELS BY ACTIVATION OF 5-HT$_{2/1C}$ RECEPTORS. R.H. Alper, P.E. Pérgola, A.F. Sved and J.L. Voogt. University of Kansas Medical Center, Kansas City, KS 66103 and University of Pittsburgh, Pittsburgh, PA 15260.

We have demonstrated that intraventricular (icv) serotonin (5-HT) increases blood pressure and decreases heart rate by activation of 5-HT$_{2/1C}$ receptors in conscious rats (Pérgola and Alper, *Am J Physiol*, in press, 1991). The bradycardia, but not the hypertension, is eliminated by iv pretreatment with a V_1-vasopressin antagonist. To determine if 5-HT acts at the 5-HT$_{2/1C}$ receptor to increase plasma vasopressin (AVP) levels, 5-HT (2.5 μg in 5 μl saline containing 0.1% ascorbic acid) was administered icv to conscious male Sprague-Dawley rats instrumented with venous and arterial catheters. Arterial blood samples (0.5 ml, replaced with sterile saline) were obtained prior to and 5, 15 and 30 minutes after the injection of 5-HT. In rats pretreated with saline iv, 5-HT increased plasma AVP at 5, but not 15 or 30 minutes; the icv injection of vehicle did not alter AVP. In rats pretreated with the selective 5-HT$_{2/1C}$ receptor antagonist LY 53857 (100 μg/kg, iv), 5-HT was no longer capable of increasing AVP. LY 53857 alone did not alter plasma AVP. In addition, prolactin and corticosterone were measured in these same rats. As anticipated, 5-HT increased plasma levels of both hormones. In contrast, plasma renin activity was not affected by 5-HT. The 5-HT-induced increase in prolactin and corticosterone was not altered by the 5-HT$_{2/1C}$ antagonist. These data suggest: 1) 5-HT increases AVP secretion by activation of 5-HT$_{2/1C}$ receptors following a time-course similar to that observed previously in our hemodynamic studies, and 2) although 5-HT was also capable of increasing the secretion of prolactin and corticosterone, these effects are not mediated exclusively by activation the same 5-HT receptor subtype.

CENTRAL CATECHOLAMINERGIC PATHWAYS ARE REQUIRED FOR VASOPRESSIN RELEASE FOLLOWING SPLANCHNIC OSMORECEPTOR ACTIVATION. M.S. King and A.J. Baertschi, Neuroscience Program, University of Virginia, Charlottesville, VA 22908.

Previous studies in conscious rats demonstrated that peripheral osmoreceptors located at post-absorptive sites within the splanchnic mesentery are activated following hypertonic gastric infusions and project to the CNS through a spinal, and not a vagal, afferent pathway (Choi-Kwon and Baertschi, AJP, '90,'91). Electrolytic lesions indicated that, within the CNS, the osmotic pathway traverses the pontine reticular formation about 1mm below the locus coeruleus (LC; King and Baertschi, Br. Res., '91). In the current set of experiments, to determine the role of cell bodies and fibers of passage in this area, chemical lesions were induced one week prior to gastric infusions of 598 mOsm/kg (2ml/4min). Microinjection of 6-hydroxydopamine (6-OH-DA; 4ug/400nl; n=6) reduced the AVP response to hypertonic gastric infusions by 66.0% ($p<.05$; mean increase over baseline was 2.83 ± .49 pg/ml), indicating that a catecholaminergic component in this region is required for the AVP response. The effect of 6-OH-DA was reversed by desipramine pretreatment (25mg/kg; n=6; 5.78 ± .88 pg/ml). Ibotenic acid injections did not alter the AVP response (n=6; 4.83 ± 1.02 pg/ml), indicating that fibers of passage, and not cell bodies, in this area are part of the central osmotic pathway. Finally, microinjections of 5,7-dihydroxytryptamine (n=6; 5.36 ± 1.54 pg/ml) and vehicle (n=7; 7.58 ± 2.29 pg/ml) also did not alter the AVP response. These results demonstrate that a catecholaminergic pathway, which traverses the pons about 1mm below the LC, is a vital part of the central neural pathway which carries peripheral osmotic information to the hypothalamus. The origin of this pathway (i.e. NTS or VLM) and possible forebrain relays (i.e. preoptic area) are currently being investigated. [Supported by NSF BNS-8819877 and NIH RO1 NS27644].

DRINKING AND GLUCOSE UTILIZATION IN THE MAGNOCELLULAR SYSTEM (MCS) AFTER OSMOTIC AND Na STIMULATION. M. Kadekaro, M.L. Terrell, J.S. Harris*, S. Freeman*, J.Y. Summy-Long§, E.M. Koehler*§. Div. of Neurosurgery, UTMB, Galveston, TX; §Dept. of Pharmacology, Hershey Med. Ctr., Penn. State Univ., Hershey, PA.

We compared in male albino rats (n=71) the effect of jugular infusion (200 μl/min for 10 min) of 0.15 M NaCl, 0.85 M NaCl, 1.7 M mannitol or 1.7 M mannitol + 0.85 M NaCl on water intake and on the activity of the MCS, measured with the [^{14}C]deoxyglucose method. Plasma osmolality (mOsm/kg H_2O) increased after 0.85 M NaCl (Δ=14), 1.7 M mannitol (Δ=13) and mannitol + NaCl (Δ=26). Plasma [Na^+](mEq/l) either increased with NaCl (+8.8), decreased with mannitol (-7.7) or was unchanged after the combination of both. Drinking was similar in all groups but the activity of the MCS was stimulated to different degrees. Increases in glucose utilization in the supraoptic n. (SON, +18%) and neural lobe (NL, +52%) were observed with 0.85 M NaCl but only in the NL (+34%) with mannitol. With mannitol + NaCl glucose utilization increased in the SON (+58%), paraventricular n. (+28%) and NL (+152%). These increases were larger than the sum of changes induced by infusion of individual solutions.

Combined osmotic and hypertonic NaCl treatments, therefore, potentiate the activity of the MCS but not the drinking response. [Supported by NIH grants NIDS 2RO1 NS23055 (M.K.) and HD25498 (J.S-L.)].

FLUOXETINE INDUCES VASOPRESSIN ABNORMALITIES IN ACTIVITY-BASED ANOREXIA. P.F. Aravich, T.S. Rieg, I. Ahmed, S. Downing & T.J. Lauterio. Depts. Anatomy/Neurobiology & Internal Medicine, Eastern Virginia Medical School, Norfolk, VA 23501; V.A. Med. Ctr., Hampton, VA 23667.

Vasopressin (VP) and serotonin (5HT) abnormalities occur in anorexia nervosa (AN). It has been proposed that fluoxetine (FLX), an indirect acting 5HT agonist, may be useful in the treatment of AN. Because of the relationship between exercise and AN, we have been exploring activity-based anorexia (ABA) in the rat (restricted feeding 1.5 hrs/day; free running wheel access 22.5 hrs/day). This experiment determined the effects of FLX on VP in ABA. Suprachiasmatic (SCN), circulating and dorsal vagal complex (DVC) VP systems were evaluated. Adolescent male rats (N=83) were divided into ABA (following a 25% weight loss) and control groups, which included weight-matched (BWM), exercised (EXR) and non-exercised freely fed (AD LIB) rats. Subgroups were injected with FLX HCl (15 mg/kg, ip) or vehicle under resting, food-deprived conditions. The animals were killed by decapitation 0.5 hrs after injection. Fluoxetine induced ABA-specific VP abnormalities in the SCN but not the circulating or DVC VP systems. Specifically, FLX elevated SCN VP content in ABA rats but not controls. As a result, while basal SCN VP levels in ABA were not different from BWM and AD LIB controls, stimulated levels were reliably elevated compared to these groups. Fluoxetine caused an overall increase in plasma VP across groups. The BWM controls---but not the ABA and EXR rats---had elevated plasma VP levels under basal conditions. Finally, there was no effect of FLX (or behavioral treatment) on DVC VP content. Consequently, ABA is associated with specific 5HT abnormalities in the SCN VP system. Since disrupted circadian rhythms increase susceptibility to ABA (see ES Stanley et al., this meeting), these data raise concerns regarding the potential negative impact of FLX on circadian rhythms in anorexia nervosa. Support: V.A. Merit Award (PFA).

ORIGIN OF NEUROHYPOPHYSIAL MAMMALIAN FMRF-NH$_2$-LIKE PEPTIDE. E.A. Majane and H.-Y.T. Yang. Lab. of Biochem.Genetics, NIMH Neuroscience Ctr.@ St. Elizabeths, Washington, DC 20032.

The mammalian FMRF-NH2-like peptide, F-8-F-NH$_2$ (NPFF), is concentrated in nerve fibers and terminals of the neural lobe (NL)of rat pituitary where it can be regulated by osmotic stimuli. In this study, the source of pituitary NPFF was investigated by various lesions. Seven days following surgery, the content of NPFF in the NL was depleted by pituitary stalk transection implicating the hypothalamus as the source of pituitary NPFF. A group of NPFF positive cell bodies in a periventricular region of hypothalamus was revealed immunohistochemically however a lesion of this region failed to affect pituitary NPFF. Since the regulation of NL NPFF and AVP correlates very closely, we chose to lesion the AVP-containing magnocellular neurons of the supraoptic nuclei. Seven days following a bilateral lesion of the SON, the pituitary levels of both AVP and NPFF were reduced to 50% of control. These results strongly suggest that at least part of the NPFF in the NL arises from SON where it may be co-localized with AVP.

THE EFFECT OF SALT LOADING ON SEROTONERGIC ACTIVITY IN SPECIFIC BRAIN REGIONS OF THE RAT: J.A. Saydoff and M.S. Brownfield. Neurosci. Training Prog., Sch. Vet. Med., Univ. Wisconsin, Madison, WI 53706.

The aim of this study was to establish potential brain sites where serotonin (5-HT) influences osmoregulation of vasopressin. We previously demonstrated that depletion of brain 5-HT with 5,7-dihydroxytryptamine blocks the increase in plasma vasopressin due to i.p. hypertonic saline administration.

Groups of 10 male rats were given water (W) or 2% NaCl (SL) to drink for for 2 days and killed by decapitation. The midbrain (MB), hippocampus (HI), basal hypothalamus (BHT), dorsal hypothalamus (DHT), ventral forebrain (VF), septum (SE), and caudate nucleus (CN) were dissected. High pressure liquid chromotograhy with electrochemical detection was used to measure 5-HT, 5-hydroxyindoleacetic acid (5-HIAA), and dihydrophenylacetic acid (DOPAC). 5-HIAA and DOPAC are the major metabolites of 5-HT and dopamine respectively. The 5-HIAA/5-HT ratio was used as one of the indexes of serotonergic activity.

Analysis of covariance by brain region plotting 5-HIAA vs 5-HT revealed a similar pattern for the MB, BHT, and VF regions. This striking pattern in the MB, BHT, and VF indicated that salt loading increased both 5-HT and 5-HIAA. The SL group 5-HIAA/5-HT ratio was increased compared to the W group in the MB ($p < .01$) and CN ($p < .05$). The SL group 5-HIAA was increased compared to the W group in the BHT ($p < .01$) and HI ($p < .05$). Salt loading decreased 5-HT in the CN ($p < .05$). There were no significant changes in DOPAC concentration due to salt loading suggesting dopamine is not involved in the osmoregulatory response to salt loading.

These results demonstrate salt loading increases serotonergic activity in the brain regions that previous lesion studies have proven to be essential for osmoregulation of vasopressin. This study suggests a serotonergic pathway linking the MB to the BHT and VF is the circuit for osmoregulation of vasopressin by 5-HT. Supported by Univ. Wisc. Grad. Sch.

GLUTAMATE-INDUCED RELEASE OF VASOPRESSIN FROM THE ACUTE HYPOTHALAMO-NEUROHYPOPHYSIAL EXPLANT.

R.S. Greenwood, R.B. Meeker and J.N. Hayward. Dept. of Neurology and Pediatrics and Medicine and Neurobiology Curriculum, University of North Carolina, Chapel Hill, NC 27599

Recent studies (Meeker et al, 1989, 1991; Swanson et al, 1991; Van den Pol et al 1990) suggest that glutamate plays an important role in the excitatory control of vasopressinergic magnocellular neuroendocrine cells. To assess the influence of glutamate on vasopressin secretion we stimulated acute hypothalamo-neurohypophysial explants from male Sprague-Dawley rats in vitro with 10^{-5} M glutamate by perfusion or by direct microinjection into the supraoptic nucleus. Glutamate administered by microinjection or by perfusion induced a significant and rapid release of vasopressin not observed in hypothalamo-neurohypophysial explants from controls or in hypothalamo-neurohypophysial explants perfused or microinjected with other putative neurotransmitters. These results indicate that glutamate is a potent stimulus for vasopressin release even when locally applied to the supraoptic nucleus. The ablility of glutamate to induce vasopressin release from the hypothalamo-neurohypophysial explant is consistent with its proposed role as an important excitatory neurotransmitter in the vasopressinergic magnocellular neuroendocrine system.

QUANTITATIVE MAPPING OF GLUTAMATE IMMUNOREACTIVE PRESYNAPTIC TERMINALS IN THE REGION OF THE SUPRAOPTIC NUCLEUS.

D.J. Swanson*, R.B. Meeker, R.S. Greenwood and J.N. Hayward, Department of Neurology and Neurobiology Curriculum, University of North Carolina, Chapel Hill, NC 27599.

To evaluate the relative contribution of putative glutamatergic synapses to the innervation of magnocellular neuroendocrine cells in the rat, thin sections were stained with colloidal gold using an anti-glutamate antibody. Electron micrographs taken from the main body of the supraoptic nucleus (SON), the ventral dendritic neuropil (VDN) of the SON and the perinuclear zone (PNZ) dorsal to the SON were evaluated for the presence of glutamate immunoreactivity in presynaptic endings. At least two populations of presynaptic endings were apparent based on relative densities of colloidal gold postembedding staining: 1) putative glutamate terminals with a broad distribution of colloidal gold densities (26 to 100 particles/um^2) and 2) non-glutamate terminals with low densities of colloidal gold (0-25 particles/um^2. As many as 45% of the total terminals were glutamate-immunoreactive in the SON and VDN although the absolute number of terminals in the VDN was more than 50% greater than in the SON. The PNZ received the greatest density of total presynaptic terminals of the three regions sampled. However, a lower percentage (33%) of the terminals in the PNZ were glutamate immunoreactive. These results indicate that a large portion of the synaptic input in the basolateral hypothalamus represents glutamate-containing terminals. We consider it likely that glutamate or a glutamate-like transmitter is used extensively at excitatory amino acid receptors in the neuroendocrine hypothalamus.

ENDOCRINE REGULATION III

474.1

CONVERGENCE OF INNERVATION IN THE PITUITARY INTERMEDIATE LOBE.

S. Soinila, N. Bäck and G.J. Mpitsos. Dept. Anat., Univ. Helsinki, Finland and Oregon State Univ., Marine Sci. Ctr, Newport, OR 97365.

The intermediate lobe of the rat pituitary consists of a homogenous population of endocrine cells synthesizing α-MSH and β-endorphin. The intermediate lobe cells secrete these hormones under neural regulation from several loci. Several neurotransmitter-specific systems are involved in this regulation. However, it is not known whether each system affects a particular subpopulation of cells or whether all cells receive multiple innervation. We have used immunohistochemical techniques to visualize serotonin-, dopamine-, GABA-, enkephalin- and acetylcholine-containing systems, and computerized image analysis to study the distribution of these innervation systems within the lobe. Colocalization of these substances was also examined. Our results favor the notion that most if not all intermediate lobe cells receive innervation from several brain nuclei. This makes the intermediate lobe a useful model to study the mechanisms of multitransmitter regulation by converging innervation.

RELEASE OF cLHRH-I IN VITRO: EFFECTS OF CATECHOLAMINES AND AGING.

Q. Li, M.A. Ottinger, Tamarkin+, and J.A. Proudman*. Dept. of Poultry Science, Univ. of Maryland, College Park, MD 20742, +Assay Research Inc., College Park, MD 20742, and *Avian Physiology Lab., USDA, Beltsville, MD 20705.

The release of cLHRH-I was monitored in perfusion of microdissected slices of medial basal hypothalamus (MBH) in response to norepinephrine (NE), epinephrine (E) and isoproterenol. Tissue slices from an animal were equilibrated in a perfusion chamber for 2 hrs in media 199. Using separate tissue samples for each chemical, dose response curves were conducted (6 replicates/curve). Significant increases of LHRH were observed with 10^{-7}M NE and 10^{-8}M E. LHRH release was also slightly increased by isoproterenol (10^{-7}M).

Two experiments were conducted to determine if reproductive aging affects response of hypothalamic tissue to catecholamine challenge in vitro. In Experiment 1, hypothalamic slices from young hens (8 months old) and aged hens (2 yr) were challenged with NE(10^{-7}M). Slices from aged hens responded with a lower release of cLHRH-I than young hens. In Experiment 2, tissues from young (2 months) and aged (3 yrs) male Japanese quail were compared for cLHRH-I response to NE (10^{-6}M). Again, tissue from aged animals showed a lower response. Supported in part by Univ. of MD AES grant (MAO) and USDA 88-37242 (MAO).

CHARACTERIZATION OF GLUTAMATE RECEPTORS IN THE NEUROENDOCRINE HYPOTHALAMUS R.B. Meeker, R.S. Greenwood and J.N. Hayward, Department of Neurology and Neurobiology Curriculum, University of North Carolina, Chapel Hill, NC 27599.

NMDA and non-NMDA glutamate receptors were identified in the rostral hypothalamus-preoptic area (neuroendocrine hypothalamus) of the rat using [^{3}H]glutamate binding to washed membranes. Glutamate (1 mM) and 2-amino-5-phosphonovaleric acid (APV; 0.2 mM) were used to define specific total binding and specific non-NMDA binding, respectively. Non-NMDA type receptors greatly exceeded the number of NMDA receptors in the hypothalamus by a factor of approximately 10-fold. Saturation binding data revealed the presence of a single class of non-NMDA binding with a K_D of 0.2-0.4 x 10^{-6} M and a B_{max} of 130-150 pmoles/mg tissue. NMDA binding sites were barely detectable with an approximate K_D of 0.2 x 10^{-6} M and a B_{max} of 16-28 pmoles/mg tissue. This distribution of receptor subtypes contrasted with the hippocampus from the same brain where similar levels of of both NMDA and non-NMDA glutamate receptors were observed. Water deprivation for 48 hrs resulted in an increase in the number of non-NMDA receptors in the hypothalamus with no change in the K_D. Thus, the rostral hypothalamus appears to contain mostly non-NMDA receptors. A functional link between these receptors and the vasopressin neuroendocrine system which regulates water balance is suggested by the increase in receptors in response to water deprivation.

METABOTROPIC GLUTAMATE RECEPTORS ARE EXPRESSED IN PRIMARY CULTURES OF HYPOTHALAMIC NEURONS. M.A. Sortino, G. Aleppo*, F. Nicoletti and P.L. Canonico°. Institute of Pharmacology, University of Catania, School of Medicine, Catania, and ° Chair of Pharmacology, University of Pavia, School of Dentistry, Pavia, Italy.

Glutamate has been found to play an important role in neuroendocrine regulation in the hypothalamus. The control of neuroendocrine secretion by glutamate has been related mainly to activation of ionotropic glutamate receptors that are linked to the opening of ion channels. Thus, quisqualate, kainate and N-methyl-D-aspartate (NMDA) have been found to stimulate luteinizing hormone-releasing hormone (LHRH) and somatostatin release from the hypothalamus *in vitro*. We have previously shown that metabotropic glutamate receptors, whose activation results in the stimulation of phosphoinositide (PPI) hydrolysis, are present at the hypothalamus, and exhibit a typical developmental profile that may suggest a role for these receptors in the maturation of hypothalamic neurons. In the present study we have measured PPI hydrolysis induced by glutamate in primary cultures of hypothalamic neurons. Glutamate, as well as quisqualate, a metabotropic receptor agonist, produced a concentration-dependent stimulation of PPI turnover (as assessed by measuring [^{3}H]inositol monophosphate production) that appeared after 7 days of maturation in culture and was still present at 14 DIV. Ionotropic receptor agonists such as kainate, NMDA and α-amino-3-hydroxy-5-methyl-5-isoxazolpropionate (AMPA) were inactive. At 14 DIV, 100 μM glutamate induced a stimulation of 168 ± 18% of control whereas 100 μM norepinephrine activated PPI turnover by 233 ± 22%. Simultaneous addition of glutamate and norepinephrine resulted in an additive effect. The presence of glutamate metabotropic receptors in primary cultures of hypothalamic neurons, together with the lack of data regarding an involvement of this receptor in the control of neuroendocrine secretion, suggest a role for the metabotropic glutamate receptor in the maturation of hypothalamic neurons as already shown in other brain areas.

EFFECT OF SUSTAINED COLD EXPOSURE ON SOME PARAMETERS OF HYPOTHALAMIC-PITUITARY FUNCTION: *IN VIVO* AND *IN VITRO* STUDIES G. Cizza [1*], K. Fukuhara [2*], P.W. Gold [1] G.I. Perini [1], M.A. Kling [1] NIMH[1], NINDS[2], National Institute of Health (NIH) Bethesda 20892, USA,

The hypothalamic-pituitary-thyroid axis plays a major role in the metabolic response to cold exposure. We have previously demonstrated that the incubation temperature can modify the *in vitro* hypothalamic secretion of TRH, a peptide involved in the thermoregulation processes (Neuroscience 20th Meeting 1990;16 (1) 397 abstract # 168.7). In the present study we assessed how cold exposure affects hypothalamic-pituitary function. To perform this task, we exposed S-D male rats 4 months old to 4° C for 24 hours. At the end of the cold exposure the cold exposed animals and an adequate number of controls were rapidly decapitated, their blood collected and plasma kept at minus 20° C for subsequent hormonal determinations. Hypothalami from both cold-exposed and control animals were rapidly excised and incubated one per well in a 48 well-plate. After 2 h of preincubation, the hypothalami were exposed to plain media (M 199) in the first three wells, than to KCl 60 mM to assess the maximal secretory capacity, as well as the tissues' viability. The cold-exposed animals showed a significant increase in plasma TT_4 (8.49±0.50 vs 11.66±0.24 μg/dl; $p \leq .0001$ t test), whereas plasma TSH was unchanged (4.07±0.24 vs 4.51±0.26 ng/ml). Consistently with the plasma TSH, the *in vitro* TRH secretion both in basal conditions and under KCl-challenge was virtually the same (basal 34.75±1.80 vs 36.65±1.19 pg/well/20'; KCl 56.03±3.80 vs 55.85±4.35 pg/well/20'). All the explants responded to KCl stimulation, indirectly confirming tissues viability. Also plasma corticosterone (B) was increased in cold exposed animals (40.94±25.11 vs 134.14±17.95 ng/ml; $p \leq .009$ t test) whereas ACTH was unchanged (54.48±19.60 vs 66.29±24.85 pg/ml). We hypothesize that the TT_4 and B plasma increase observed in the animals exposed to cold is a residual effect of a concomitant activation of thyroid and glucocorticoid system, probably by noradrenergic system. The absence of modifications in plasma TSH and ACTH, as well as TRH *in vitro* secretion suggest that the activation of both axes takes place after less than 24 h of cold exposure.

We wish to thank the National Pituitary Agency for providing the materials used in the TSH assay.

ALPHA-2 ADRENERGIC INPUT IN LOCUS COERULEUS MODULATES THE RELEASE OF ADRENOCORTICOTROPIN IN CATS. D. E. Carlson and D. S. Gann. Depts. of Surgery and Physiology, Univ. of Maryland Sch. Med., Baltimore, MD 21201.

Previous evidence suggested that noradrenergic turnover in the vicinity of the ventrorostral locus coeruleus (vLC) increased in response to hemorrhage. To investigate the possible role of this response in the control of ACTH release, microinjections (100 nl/min for 2 min) of several agents were made at 42 sites in 21 cats anesthetized with chloralose. All sites were tested with L-glutamate (150 mM, GLU) and vehicle (VEH), 38 were tested with the α1 agonist, phenylephrine (1 mM, PE), and 18 were tested with the α2 agonist, clonidine (1mM, CLON). Plasma ACTH was measured by radioimmunoassay. Responses were tested statistically by repeated measures ANOVA. GLU at 9 sites in the region of the vLC elicited a significant increase in ACTH at 4 and 6 min ($P<0.01$) from the onset of injection. Injection of VEH at these sites and of PE at 8 of these 9 sites elicited no change in ACTH. Both of these latter responses differed from that to GLU ($P<0.01$). Injection of CLON at 6 sites that included all 4 of the sites in vLC that were tested with CLON and 2 additional sites immediately dorsal to vLC elicited a significant decrease in ACTH at 4 and 6 min ($P<0.05$) from the onset of injection that differed from the responses to VEH and GLU ($P<0.05$). Injections of all agents at sites remote from the region of the vLC elicited no change in ACTH. An increase in noradrenergic turnover in the vLC may provide inhibitory α2 modulation to neurons in the vLC that were shown previously to be activated by hemorrhage. This input may serve to modulate the influence of the vLC on ACTH release. Supported in part by NIH grant DK-26831.

CORTICOSTERONE MODULATES HIPPOCAMPAL PYRAMIDAL CELL ACTIVITY. S.G. Beck and K. Choi*, Department of Pharmacology, Loyola University Chicago Stritch School of Medicine, Maywood, Il 60153.

Adrenalcorticoid steroid receptors are present in hippocampal pyramidal cells. Intracellular recording techniques in hippocampal slices were used to measure chronic and short term effects of corticosterone on membrane properties of CA1 pyramidal cells and on $5HT_{1A}$-mediated hyperpolarization. Rats were adrenalectomized (ADX) for two weeks or ADX and implanted with a CT pellet (ADX+CT) to mimick basal CT levels. Blood samples were taken at the time of sacrifice to measure plasma CT and ACTH levels. During the experiment CT was present or not present in the stock buffer. Cell measurements included resting membrane potential, resistance, tau, spike characteristics, fast afterhyperpolarization (AHP) amplitude, and slow AHP amplitude and duration. Cells from ADX rats with undetectable CT levels had a lower membrane resistance than cells from ADX rats with CT levels less than 1 μg/dl, ADX+CT rats or ADX rats with CT in the buffer. The presence of CT in the buffer decreased the amplitude of the slow AHP in cells from ADX rats.

The Emax of the $5HT_{1A}$ hyperpolarization was larger with CT in the buffer for cells from ADX or ADX+CT treated rats. The EC_{50} and slope were not affected by CT. These results indicate that short term CT, not chronic CT, modulates cell characteristics and 5HT mediated responses. USPHS grants MH41917, NS28512, KO2-MH00880 to SGB.

474.8

CORTICOSTERONE REDUCES HIPPOCAMPAL GLYCOGEN CONTENT IN VIVO AND IN CULTURED ASTROCYTES. G.C. Tombaugh, R.A. Swanson, and R.M. Sapolsky, Dept. of Biol. Sci., Stanford Univ., Stanford, CA 94305, and V.A. Med. Ctr., Dept. of Neurology, UCSF, San Francisco, CA 94121.

Glucocorticoids (GCs) can exacerbate hippocampal neuronal injury following a variety of metabolic insults. The mechanism underlying this endangerment is unknown, but is thought to involve an impairment of metabolic energy potential. Given that these steroids can depress glucose uptake and enhance hypoxic vulnerability in hippocampal astrocytes, and that these cells represent the principal storage site for glycogen in the brain, we asked whether GC exposure could influence hippocampal glycogen content in vivo and the intracellular levels of glucose and glycogen in astrocyte cultures in vitro. Rats were adrenalectomized (ADX) for 3 days and received a single s.c. injection of corticosterone (CORT; 10mg/1ml). Brain tissue was fixed in situ by focused microwave radiation 1h, 6h, or 24h later. Hippocampal astrocyte cultures, derived from E18 rat fetuses, were grown for 10-11 days in DMEM with 10% FCS and 25mM glucose. Cells were refed for 24h with Krebs Ringer phosphate (5mM glucose) with or with 100nM corticosterone and then harvested for glycogen assay. Hippocampal glycogen content fell to 83% of the ADX control ($p<.01$) 6h post-injection and returned to control level by 24h. In contrast, cortical glycogen content remained unchanged at 6h but was significantly elevated at 24h. In hippocampal astrocytes, CORT reduced glycogen content to 62% of control ($p<.001$) without affecting intracellular glucose. These data suggest that GC secretion may enhance neuronal vulnerability in the hippocampus by causing a reduction in glial energy stores.

474.9

SECRETION OF MELANIN CONCENTRATING HORMONE FROM CULTURED RAT HYPOTHALAMIC CELLS. D.G.Parkes*, J.L.Nahon* K.A.Klivington and W.W.Vale. The Salk Institute, La Jolla, CA 92037 and IPMC, Sophia Antipolis, France.

Melanin concentrating hormone (MCH) is a cyclic nonadecapeptide present within the lateral hypothalamic region of the rat, man and guinea pig brain, defining a group of cell bodies with extensive projections throughout the brain. This suggests that MCH may play an important role in certain brain functions. In order to establish that the peptide is secreted by mammalian cells, we have examined the regulation of MCH secretion from primary hypothalamic cultures of 7 day old rats, employing a sensitive radioimmunoassay for MCH. Secretion was measured over a 6 hour time period. Basal secretion of MCH after 5 days of culture was 54±8 pg/dish/6h, 98±16 pg/dish/6h after 8 days, and increased to 190±11 pg/dish/6h after 10 days in culture and remained at this level for up to 2-3 weeks. On day 8 of culture, the cyclic AMP stimulant, forskolin (10μM), increased secretion to 146%. The cAMP analogue, 8-Br-cAMP (10mM) increased secretion to 573% of control, and 8-Br-cyclic GMP increased secretion to 261%. The phorbol ester, TPA (10nM), increased secretion to 133%. Cell content of MCH on days 5, 8, 10 and 12 of culture was 21±2, 89±14, 47±12 and 48±6 pg/dish respectively, and this was not significantly changed by any treatment. These results suggest that hypothalamic cells in culture do indeed produce MCH, and that this secretion may be regulated by multiple second messenger systems.

474.10

FUNCTIONAL CHANGES OF HYPOTHALAMIC CRF AND OPIOID NEURONS AFTER ADRENALECTOMY AND/OR CASTRATION. O.F.X.Almeida*,M.S.Harbuz*,C.Stein, E.A.Linton* & S.L.Lightman*. Max Planck Inst.for Psychiatry,Munich,FRG; Westminster Hospital, London,UK; University of Reading,UK.

The influences of short- and long-term adrenalectomy and castration (or both) upon CRF mRNA levels, CRF peptide levels, and endogenous opioid peptide (EOP) content in the hypothalamus, and basal and CRF-stimulated EOP release in vitro, were examined in male rats. Gonadal and adrenal steroids regulated the activity of these peptidergic systems in terms of peptide synthesis, storage pools and secretion. The steroids were also found to alter the sensitivity of EOPergic neurons to CRH. In some cases, evidence was obtained for an interaction between gonadal and adrenal steroids in determining these events (seen as additive or counteractive effects). A finding of major interest was that the response of these peptidergic systems was markedly influenced by the duration of steroid deprivation,the results of chronic treatment often being opposite to those of acute treatment. There was no simple relationship between peptide synthesis, storage and release, even within a single type of neuron.

Supported by the DFG (SFB 220/C8).

CENTRAL ADMINISTRATION OF NEUROTENSIN STIMULATES THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS AND IS BLOCKED BY THE CRF ANTAGONIST CRF 9-41. W. Rowe, Y.Viau, M.J. Meaney, R. Quirion. Douglas Hospital Research Ctr., Dept. of Psychiatry, McGill University, Montreal H4H 1R3, Canada.

The role of neurotensin (NT) as a neuromodulator in the CNS has focused mainly on the mesocorticolimbic dopaminergic system where NT receptors are localized on the majority of DA neurons. However, NT may also serve a neuroendocrine role as a modulator of HPA activity. Intraventricular (icv) administration of NT has been previously reported to increase circulating ACTH and corticosterone (B) levels (Gudelsky et al., Neuroendocrinology, 1989). We investigated the temporal profile of NT's effects as well as its possible mechanism of action. NT injected icv in freely moving adult male rats caused significant increases in plasma ACTH and B compared to saline treated controls: peak ACTH; 420 ± 64.7 vs 256 ± 30.6 pg/ml, respectively, peak B; 56.5 ± 8.5 vs 27.6 ± 2.75 μg/ dl, respectively. NT treated animals showed higher ACTH and B levels, 66% and 100 %, respectively, up to 4 h following injection: ACTH; 273.9 ± 18.4 vs 168.4 ± 9.7 pg/ml/min, respectively, B; 38.7 ± 6.4 vs 19.7 ± 1.1 μg/dl/min, respectively. Pretreatment with α-helical CRF (1 μmol/kg bw) attenuated the ACTH response to NT administration: 137.7 ± 47.4 pg/ml/min. These findings suggest that NT's actions occur, in part, at the level of the PVN to regulate the release of CRF. In support of this, it has recently been shown that immunoreactive (ir) NT is co-localized with parvocellular irCRF neurons of the paraventricular nucleus (PVN) projecting to the median eminence (Ceccatelli et al., Neuroendocrinology ,1989).

SEASONAL ALTERATIONS IN HYPOTHALAMIC NEUROTENSIN CONCENTRATIONS. G. Bissette, B. Levant, B. Banks and C.B. Nemeroff. Depts. Psychiat. and Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710

Neurotensin (NT) is a tridecapeptide neurotransmitter found in mammalian brain and gut. In the brain, NT is widely distributed within and outside of the hypothalamus, and is often found in close anatomic proximity to and colocalized with dopaminergic systems. The concentration of NT in the nucleus accumbens and striatum is increased by administration of antipsychotic drugs and certain "sigma" receptor antagonists. Previous work in this laboratory indicated that endogenous concentrations of NT were not constant throughout the year. To test this hypothesis, ten male Sprague-Dawley rats were killed at the middle of each month from July 1989 through July 1990. Brains were removed, frozen and subsequently dissected at one time. After dissection, hypothalami were extracted in HCL and NT was measured in duplicate aliquots by a single sensitive and specific radioimmunoassay. Values are reported as pg NT/mg protein. The seasonal concentrations of NT in the hypothalamus varied across the year with the nadir occurring in August through October and the apex in December through April (one-way ANOVA). The concentration of NT in December, March and April was significantly different from the concentration in August, September and October. Hypothalamic neurotensin concentrations exhibit seasonal concentration differences that must be taken into account in planning and interpreting the results of these types of radioimmunoassay experiments. (Supported by NIMH grant MH-39415).

CHANGES IN CALMODULIN COMPARTMENTALIZATION IN MDCK CELLS INDUCED BY MELATONIN. G. Benítez-King,* L. Huerto-Delgadillo,* and (1)F. Antón-Tay. Depto. Neurofarmacología, DIC, Instituto Mexicano de Psiquiatría. (1) Depto. Biología de la Reproducción,CBS, Universidad Autónoma Metropolitana-Iztapalapa. México, D.F. MEXICO.

It has been shown that incubation of MDCK cells with 10^{-9} M of melatonin (MEL) is followed by cytoskeletal rearrangements related to changes in total cell calmodulin (CAM) levels. In the present work, we studied CAM subcellular distribution in control or 10^{-9} M MEL treated MDCK cells. Double staining immunofluorescence method showed that CAM in control MDCK cells appeared as fluorescent spots at cell periphery. In contrast, MDCK cells cultured during 6, 12, 24 hrs. or 4 days with MEL, showed in addition CAM fluorescent spots distributed both all over the cytoplasm and the nucleus. These CAM rearrangements, were reverted 6 hrs. after MEL withdrawal. Moreover, RIA CAM measurements showed that in 10^{-9} M MEL treated cells, membrane bound CAM content was increased by 40 %, while cytosolic CAM decreased by 40% with respect to control cells. These results support that MEL interacts with CAM and suggest that rhythmic CAM compartmentalization could occur in phase with the MEL rhythmic secretion.

THE EFFECT OF STEROID REPLACEMENT ON ATRIAL NATRIURETIC POLYPEPTIDE (ANP) CONTENT OF THE HYPOTHALAMUS IN ADRENALECTOMIZED RATS. L.Y. Ma*, X.D. Yang*, M.L. Zhang*, S.Q. Xi*, Z.M. Qi*, G.L. Sun*, L. Liu*, with the advice of A.N. Epstein, E. Stellar. Tianjin Medical College, P.R. China and University of Pennsylvania.

We have recently demonstrated that ANP is present in the brain (hypothalamus) and plays a role in the release of the anterior pituitary hormones. Nothing is known concerning the role of the adrenal steroids on ANP synthesis or release in the hypothalamus. In this study Sprague-Dawley rats were divided into 5 groups: 1, Sham-operated (Sham); 2, adrenalectomized (ADRX); 3, ADRX and receiving Dexamethasone (Dex), (10 or 20 μg/100 g b.w./24 hr, s.c.); 4, ADRX and receiving deoxycorticosterone acetate (DOCA), (1 or 2 mg/24 hr, s.c.); 5, ADRX and receiving both Dex and DOCA as described above. Twelve days after surgery, the rats were decapitated and blood was collected for Na^+, K^+, Cl^- and AVP measurement, and the hypothalamus were removed for ANP content. The results showed no differences in plasma Na^+, K^+, Cl^- or AVP due to the adrenalectomy. The ANP content of the hypothalamus were lower in ADRX than in Sham, but the ADRX that received either DOCA, Dex, or DOCA and Dex were higher than Sham. Our results suggest that the adrenal steroids may directly increase ANP synthesis in the hypothalamus.

GLUTAMATE AGONISTS DO NOT INHIBIT MELATONIN PRODUCTION IN THE RAT PINEAL GLAND *IN VITRO*. L. Kus, R.J. Handa, J.A. McNulty. Department of Cell Biology, Neurobiology, and Anatomy, Loyola University, Maywood, IL 60153

We have previously described a saturable, stereospecific, pH, time, and temperature dependent binding site for [^{3}H]glutamate in the rat pineal gland. The function of this binding site is unknown. In the present study we examined the effect of glutamate agonists on the adrenergic stimulated secretion of melatonin using an *in vitro* perifusion system (Acusyst-S-APS 10, Endotronics). Pineal glands were perifused with an artificial CSF at a rate of 200 µl/min., and subsequent melatonin release measured by RIA (Guilday). Before drug treatment pineal glands were preincubating for a period of 4 hours by which time melatonin output reached basal levels. The addition of L-glutamate (10^{-3}M) to the media prior to stimulation with (-)isoproterenol ((-)Iso) and L-phenylephrine (L-PE) inhibited melatonin production. L-glutamate did not affect melatonin production when pineal glands were stimulated with (-)Iso alone. The addition of the glutamate agonists NMDA, quisqualate, kainate, and trans-ACPD (10^{-4}M) before (-)Iso and L-PE administration did not inhibit melatonin production. This suggests that glutamate's effects are not mediated by any of the known glutamate receptor subtypes. Simultaneous administration of L-glutamate with (-)Iso and L-PE did not inhibit melatonin production suggesting that glutamate's effects may be mediated via a conversion product (GABA?) of glutamate. Supported in part by Sigma Xi, Grants-in-Aid of Research and NSF #BNS-88-01726.

474.16

EFFECT OF MULTIPLE INJECTIONS OF ISOPROTERENOL ON PINEAL MELATONIN PRODUCTION IN TURKISH HAMSTERS. S.M. Hong, R.D. Rollag*, and M.H. Stetson*. Univ. of Delaware, Newark, DE 19716 and Uniformed Services Univ. for Health Sciences, Bethesda, MD 20816.

In previous studies we found that pineals of the Turkish hamster (Mesocricetus brandti) are responsive to single injection of adrenergic agonists only in the later dark phase. In order to further examine the factors involved in pineal melatonin production, two or three isoproterenol (ISO, 1 mg/kg) injections were given at 2 h intervals either in late afternoon or at midday, respectively. Animals given ISO injections at 1600 and 1800 h showed higher melatonin level (p=0.056, t-test) at 2200 h and lower level (p=0.008, t-test) at 2400 h than in saline injected animals. Pineal melatonin levels of animals that received three ISO injections at 1200, 1400 and 1600 h were no different than in saline groups. In comparison, pineals of the golden hamster (Mesocricetus auratus) responded to three ISO injections around noon or two ISO injections right before the dark onset with a significant elevation of melatonin production. These results showed that neither long term exposure (6 h) to ISO around noon, nor extended (4 h) exposure to the beta-adrenergic agonist prior to dark onset was sufficient stimulus to mimic the endogenous melatonin peak in the Turkish hamster. Whether other neurotransmitters are involved in pineal melatonin production in this species needs to be investigated. (supported by NSF Research Grant DCB87-14638)

474.17

MELATONIN MODULATION OF HYPOTHALAMIC FUNCTION AND ESTROGEN RECEPTOR EXPRESSION (ER) IN LSH/SsLak HAMSTERS. N.Lawson, B.Wee, C.Castles*, D.Blask$_1$, B.Benson$_1$, and S.Hill* Tulane Univ. Sch. of Medicine, New Orleans, LA 70112, and 1 Univ. of Arizona College of Medicine, Tucson, AZ 85745.

Short photoperiod or exogenous melatonin administration induces a state of anestrous in LSH/SsLaK female hamsters, which is associated with diminished gonadotropin levels. The neuroendocrine control of reproductive physiology is affected by gonadal steroids, particularly estrogen, which controls gonadotropin release through feedback mechanisms mediated by hypothalamic neurons containing ER. We therefore tested the hypothesis that the pineal hormone, melatonin, may alter hypothalamic sensitivity to estrogen by modulating ER expression. Regularly cycling females in long photoperiod (14L:10D) were bilaterally ovariectomized and then given late afternoon injections of melatonin (25 ug/day) or saline for 10 weeks, after which they were sacrificed. Melatonin treatment significantly suppressed FSH, LH, and prolactin serum levels, as determined by RIA. Brains from both groups of animals were analyzed by immunocytochemistry using the human ER monoclonal antibody H222 (Abbott) and DAB. A 50% decrease in the density of ER immunoreactive cells was noted in the medial preoptic area of melatonin treated animals. These data suggest that melatonin in female hamsters suppresses gonadotropin and prolactin levels, inducing anestrous possibly via its suppression of hypothalamic ER expression.

474.18

EFFECT OF ATP-SENSITIVE K+ CHANNELS ON DOPAMINE INHIBITION OF PRL SECRETION AND SECOND MESSENGER SYSTEMS IN MMQ CELLS, A PITUITARY CLONE NATURALLY EXPRESSING D2 RECEPTORS. G. Schettini, O.Meucci,C.Ventra,A.Scorziello*,M.Grimaldi*,E. Landolfi*,Dept.of Pharmacology, II School of Medicine, University of Naples ITALY .

In this study we used glibenclamide (Glib) to evaluate the role of ATP-sensitive K+-channels in dopamine (DA) inhibition of PRL secretion measured either in mixed pituitary cultures or at single lactotroph cell level, by means of reverse hemolytic plaque assay. The effect of Glib on free cytosolic calcium ([Ca++]i) and adenylate cyclase (AC) activity was also tested. The percentage of PRL-secreting cells was significanlty increased by Glib in a dose dependent manner (1nM-10uM). This effect was completely abolished by DA (1uM). The increase of PRL-secreting cells induced by forskolin was not modified by Glib pretreatment, while the dopaminergic inhibition of PRL was reduced by the blockade of K+(ATP)-channels. Glib neither affected basal AC activity nor modified DA inhibition of the AC enzyme. Finally, Glib induced a dose- and time-dependent membrane depolarization and increased [Ca++]i levels but did not prevent DA-induced membrane hyperpolarization and [Ca++]i reduction.

INTRACEREBROVENTRICULAR ADMINISTRATION OF BOMBESIN BLOCKS THE ESTROGEN-INDUCED AFTERNOON PROLACTIN SURGE. J.T. Pan and L.M. Mai* Inst. of Physiology, Natl. Yang-Ming Med. Coll., Taipei, Taiwan, R.O.C.

Bombesin, a putative peptide neurotransmitter, has been shown to inhibit both basal and stress-induced secretion of prolactin. It's mechanism of action may be via activating the hypothalamic tuberoinfundibular dopaminergic (TIDA) neurons. Two doses of bombesin, 0.15 and 0.75 µg, were administered i.c.v. at 1200 h in long-term ovariectomized, estrogen-treated rats. Hourly plasma samples were taken from 1100 to 1900 h through indwelling intraatrial catheters. The large dose of bombesin completely blocked the estrogen-induced afternoon prolactin surge, while the small dose just delayed the surge for an hour. Co-administration with [Leu^{13}-ψ(CH$_2$NH)Leu^{14}]-bombesin, a bombesin receptor antagonist, bombesin was no longer effective in blocking the prolactin surge. On the other hand, in bombesin-treated rats, a single injection of sulpiride (1 µg/rat, i.v.) at 1400 h also restored the prolactin surge. We conclude from the results that bombesin acts through specific receptor to activate the TIDA neurons and in turn inhibits prolactin secretion. (Supported in part by NSC80-0412-B010-55).

EFFECTS OF PASSIVE IMMUNONEUTRALIZATION OF PROLACTIN ON THE ACTIVITY OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS. A.E. Fleckenstein, T.W. Toney, C. Gopalan, K.J. Lookingland and K.E. Moore. Department of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824

This study examines the effects of prolactin (PRL) antisera (raised in rabbits) on tuberoinfundibular dopaminergic (TIDA) neuronal activity as estimated by measuring in the median eminence the concentrations of 3,4-dihydroxyphenylacetic acid (DOPAC), or the accumulation of 3,4-dihydroxyphenylalanine (DOPA) 30 min after administration of a decarboxylase inhibitor. One to 20 hrs after i.v. administration of PRL antisera TIDA neuronal activity was decreased in gonadally intact female, but not male rats. PRL antisera had no effect on TIDA neuronal activity in ovariectomized female rats, but blocked the stimulatory effect of estrogen (Silastic capsules containing 37.5 ug/ml; s.c.; 3 days) on these neurons. These results suggest that sexual differences in TIDA neuronal activity are due, in part, to the stimulatory effects of estrogen on PRL secretion, which in turn tonically activates TIDA neurons in female rats. In male rats, haloperidol (1 mg/kg; s.c.) increased the activity of TIDA neurons 12 hr later, and this effect was blocked by PRL antisera. These results confirm that the stimulatory effect of this dopaminergic receptor antagonist on TIDA neurons is mediated by PRL. Taken together, these results reveal that immunoneutralization with PRL antisera is a useful alternative to hypophysectomy in studies designed to identify PRL-mediated regulation of TIDA neurons (supported by ADAMHA grant MH 42802).

474.21

BOTH FOOTSHOCK STRESS AND DEFEAT DECREASE PLASMA PROLACTIN IN MALE HAMSTERS. K.L. HUHMAN[1], E.H. MOUGEY, & J.L. MEYERHOFF. [1]PO Box 4010, Dept. of Biology, Georgia State Univ., Atlanta, GA 30302-4010; Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

Although stress increases plasma prolactin (PRL) levels in male rats, it was reported that neither handling nor ether exposure affected plasma PRL in male hamsters. We have found increases in the stress-respondent hormones beta-endorphin, adrenocorticotropin and cortisol following exposure to acute and repeated social conflict, but only in hamsters that become submissive. We have now examined PRL responses following social conflict (resident-intruder paradigm). For comparison, we have also examined the effect of exposure to a footshock stressor. Plasma concentration of PRL was measured by RIA using antisera raised against hamster PRL. We found that footshock markedly decreased plasma PRL. Moreover, following both acute and repeated agonistic encounters, plasma PRL was significantly decreased in submissive hamsters. Thus, it appears that the PRL response to some stressful stimuli in golden hamsters may be anomalous.

474.22

ESTROGEN AND AN ESTROGEN-BSA CONJUGATE MEDIATE RAPID PROLACTIN RELEASE IN GH_3/B6 CELLS. T.C. Pappas, T. J. Collins*, C. S. Watson*. Dept. of Human Biol. Chem and Genetics, Univ. of Texas, Med. Br., Galveston, TX 77550.

Rapid release of prolactin (PRL) in GH_3/B6 cells in response to 17 ß-estradiol (E_2) or estradiol conjugated to bovine serum albumin (E_2-BSA) was investigated by radioimmunoassay. Attached cells cultured in defined or serum supplemented media were treated with steroid or vehicle, and PRL release into the media was assayed. PRL release in cells treated with 10 nM E_2 was increased over vehicle controls as rapidly as 1 min. At 5 min, however, there was no significant difference. At 1 min, the PRL release response was saturated at 10 nM E_2. E_2-BSA was effective in eliciting both 1 and 5 min PRL release over BSA controls at a concentration as low as 1 ng/ml (estimated maximum E_2 concentration 0.3 nM), with response saturation at 10 ng/ml; thus, immobilization of the steroid bound at the cell membrane increases the sensitivity of the response. The rapid time course of this PRL release enhancement as well as the ability of the BSA-linked ligand to elicit this response suggests a membrane site of action for estrogen.

BRAINSTEM ESTROGEN RECEPTOR- AND DOPAMINE-β-HYDROXYLASE-IMMUNOREACTIVITY IN MALE AND FEMALE RATS. D.H. Olster, J.D. Blaustein and A.P. Jones. Harbor/UCLA Medical Center, Torrance, CA 90502, University of Massachusetts, Amherst, MA 01003, and Pitzer College, Claremont, CA 91711.

Sexually differentiated, steroid-induced estrous behavior and gonadotropin secretion may include a noradrenergic component. Uptake of radiolabelled estradiol by brainstem noradrenergic neurons has been reported (Heritage et al., 1980). We compared brainstem localization of estrogen receptor- (ER-) and dopamine-β-hydroxylase-immunoreactivity (DBH-IR) in gonadectomized male and female rats. ER-IR cells were found in close proximity to DBH-IR cells, primarily in the rostral-most portion of the locus coeruleus. Cellular colocalization of DBH- and ER-IR was observed, but very rarely. Furthermore, no obvious sex differences in DBH- or ER-IR were found in the brainstem. These data suggest that effects of estradiol on noradrenergic activity may not be mediated directly by ERs in brainstem noradrenergic neurons in male or female rats. (Supported by NIH HD 23483, NS 19327 and RSDA MH 00885.)

A PLACENTAL FACTOR INCREASES TYROSINE HYDROXYLASE (TH) ACTIVITY IN TUBEROINFUNDIBULAR DOPAMINERGIC (TIDA) NEURONS. L. A. Arbogast, M. J. Soares* and J. L. Voogt. Dept. of Physiology, Univ. of Kansas Med. Ctr., Kansas City, KS 66103.

Rat choriocarcinoma (Rcho) cells, which have morphological features similar to trophoblast giant cells and produce placental lactogen I, were used to investigate placental effects on TIDA neuronal activity and prolactin (PRL) release. Rcho cells (100,000 cells/15µl/rat) or media, were injected i.c.v. to ovariectomized rats 65 h before sacrifice. Subsequently, bromocriptine (BROMO;3 mg/kg; s.c.) or vehicle was injected 50, 38, 26, 14 and 2 h before sacrifice. Four groups were used: 1) media + vehicle (control), 2) media + BROMO, 3) Rcho cells + vehicle and 4) Rcho cells +BROMO. *In vitro* TH activity was assessed by incubating hypothalamic explants with brocresine, a dihydroxyphenylalanine (DOPA) decarboxylase inhibitor. The accumulation of DOPA in the median eminence, which contains nerve terminals for the TIDA neurons, was determined by HPLC. DOPA accumulation was suppressed to 60% of control (7.7±0.6 ng/mg protein/30min) in BROMO-treated rats and was increased 2-fold above control in Rcho- and Rcho+BROMO-treated rats. In a second group, TH mRNA signal levels in the arcuate nuclei, which contain the perikarya of the TIDA neurons, were determined by *in situ* hybridization with a 35S-labeled cRNA probe for TH. TH mRNA signal levels were markedly reduced in BROMO-treated rats, but this effect was partially reversed in the Rcho+BROMO-treated rats. Serum PRL (ng/ml) was 16.6±2.5 in control rats, and was reduced to 1.0±0.1 or 1.6±0.4 in BROMO- and Rcho-treated rats, respectively. CONCLUSIONS: 1) Rcho cells produce a factor(s) which increases TH catalytic activity and is capable of reversing the BROMO-induced suppression of TH activity, in part, by a stimulatory effect on reduced TH mRNA levels and 2) factor(s) produced by Rcho cells may suppress PRL release, in part, by a dopaminergic mechanism. Supported by HD24190 and HD07368.

INTRAVENOUS m-CHLOROPHENYLPIPERAZINE INCREASES PLASMA PROLACTIN AND HYPOTHALAMIC SEROTONIN IN CONSCIOUS RATS. M. Baumann and J. Rutter. Dept. of Biological Sciences, Rutgers University, Piscataway, NJ 08855.

While it is generally accepted that m-chlorophenylpiperazine (mCPP) is a direct serotonin (5-HT) receptor agonist, this drug also releases 5-HT from brain slices *in vitro* (Pettibone and Williams, 1984). We employed the techniques of intracranial microdialysis and intravenous blood sampling to investigate the mechanism of mCPP-induced prolactin (PRL) release *in vivo*. Rats were fitted with indwelling jugular catheters, and microdialysis probes were inserted through guide cannulae aimed at the ventromedial hypothalamus. After overnight perfusion of the probe *in situ*, dialysate samples were collected at 30 min intervals and immediately assayed for 5-HT by HPLC-EC. Serial blood samples were withdrawn just prior to and at 30, 60 and 90 min after drug (or vehicle) injection. Plasma was assayed for PRL by RIA.

Intravenous mCPP (2.0 mg/kg) evoked a dramatic 8-fold increase in dialysate 5-HT that was maximal at 30 min, and was maintained for at least 120 min. In the same rats, plasma PRL was significantly elevated 30 min after mCPP. Dialysate 5-HT and plasma PRL were not altered by iv saline (1.0 ml/kg). Pretreatment with the 5-HT reuptake inhibitor fluoxetine (10.0 mg/kg, ip) blocked the mCPP-induced rise in dialysate 5-HT, but did not reverse the stimulatory effect of mCPP on plasma PRL. Fluoxetine alone elicited a modest 2-fold increase in dialysate 5-HT without affecting plasma PRL. Our results suggest that mCPP enhances extracellular levels of 5-HT by a presynaptic mechanism involving the 5-HT uptake carrier. The PRL-releasing action of mCPP appears to be independent of the presynaptic drug effects (Supported by the Bureau of Biological Research., Rutgers Univ.)

PROLACTIN RELEASE IN GOLDEN HAMSTERS IS UNDER DOPAMINERGIC INHIBITION. T.O. Moore, K.L. Huhman[1], E.H. Mougey and J.L. Meyerhoff. Neuroendocrinology Branch, Dept. of Medical Neuroscience, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100. [1]P.O. Box 4010. Georgia State University, Atlanta, GA 30302-4010.

Exposure to stressors produces either no effect or decreases plasma levels of prolactin (PRL) in male hamsters. This is in marked contrast to the response in the rat, in which stress increases plasma PRL. As a first step in exploring the neuroendocrine regulation of PRL secretion in hamsters in vivo, we sought to establish whether PRL secretion was under dopaminergic inhibition. Accordingly, we treated hamsters with Domperidone, a peripherally-active dopamine receptor blocker which reaches the anterior pituitary gland and has been used successfully to block dopaminergic inhibition of PRL release. Injections of vehicle, or 0.01, 0.1 or 1.0 mg/kg of Domperidone were given intra-peritoneally to male golden hamsters. One hour after the injections, trunk blood was collected in heparin, centrifuged and plasma frozen. Plasma PRL was measured by RIA, using antisera raised against hamster PRL. Domperidone elicited dose-related increases in plasma PRL, reaching 130 ng/ml at the highest dose. Thus, although the PRL response to stress in male hamsters is anomalous compared to the rat, its release does increase rapidly after blockade of dopaminergic inhibition.

CLONING OF THE HISTIDINE DECARBOXYLASE (HDC) GENE AND REGULATION BY ESTRADIOL IN RAT BRAIN. C.A.Zahnow, D.E.Millhorn, and D.R.Joseph. Depts. of Physiology and Pediatrics, University of North Carolina, Chapel Hill, NC 27599.

HDC catalyzes the single step synthesis of histamine from L-histidine. To study the effects of HDC regulation on the neuroendocrine system we have cloned 9kb of the rat histidine decarboxylase gene with HDC cDNA (PNAS 87:733, 1990) as probe and have identified the transcription start site by primer extension. Sequence data have revealed a putative promoter region which includes a TATA-like element,and sequences resembling hormone response elements. Experiments were conducted to determine whether the HDC gene is regulated by estrogen. Sprague-Dawley rats were ovariectomized and after 14 days were treated with 10ug of estradiol in 100ul sesame oil. Whole brains were removed and processed for in situ hybridization, Northern blot analysis and enzyme assay. After estradiol treatment, both the mRNA and HDC activity were elevated as compared to vehicle only controls. Experiments are in progress to define the level at which regulation occurs. (Supported by grants from the North Carolina Biotechnology Center and Glaxo Pharmaceuticals.)

RELAXIN IN THE CEREBROSPINAL FLUID OF FEMALE RATS. LJ Parry, RS Poterski*, C Wasnidge*, AJS Summerlee. Biomedical Sciences, Ontario Veterinary College, Guelph, Ontario, N1G 2W1, Canada.

Experiments were done to investigate whether the 6kD peptide hormone relaxin (**RXN**) injected into the peripheral circulation, enters the CSF in urethane-anaesthetized female rats. Rats were injected with either 5µg porcine **RXN** (in 0.1ml saline: n=64) or saline (0.1ml: n=61) into the carotid artery. A single 100µl sample of CSF per rat was withdrawn from the cisterna magna at either 0,1,5,10 or 20 mins following treatment; samples were pooled from each group. Porcine **RXN** concentrations were measured in the pooled CSF samples (n=8/group) by specific RIA (O'Byrne & Steinetz, 1976). **RXN** was not detected in the CSF either before treatment or in CSF samples from saline-treated animals. In contrast, significant ($P<0.05$:ANOVA) elevations in CSF **RXN** concentrations were observed in all **RXN**-treated animals. The presence of **RXN** in CSF samples was confirmed by SDS-PAGE separation of the CSF samples. Porcine **RXN** was identified only in CSF samples of **RXN**-treated animals by Western Blot analysis using a porcine **RXN** antibody (supplied by DG Porter). These data are the first demonstration that peripherally circulating **RXN** enters the CSF despite its 6kD molecular weight. Supported by NSERC (Canada) and OMAF.

FUNCTIONAL SUBPOPULATIONS OF INDIVIDUAL PANCREATIC B-CELLS SHOW DIFFERENTIAL RESPONSIVENESS TO CARBACHOL. M. Hiriart, M.C. Ramirez-Medeles‡,M.C. Fernandez* and G. Rosas*. Dept. Bioenergetica, I.F.C., UNAM;°Dept. Sist.Biol.UAM-X, Mexico

It is well known that acetylcholine modulates insulin secretion. We have used a reverse hemolytic plaque assay to study the effect of carbachol (CCh) in cultured rat B- cells, in different glucose concentrations.

CCh (100 nM) increased the percentage of plaque-forming cells in 5 and 10 mM glucose by 85 and 8%, respectively. However, in 15 mM glucose it was decreased in 18% (n=4).

Recently, we described functional subpopulations of B-cells, based on the amount of insulin secreted by single cells (Hiriart and Ramirez-Medeles, Endocrinology, in press). We classified them as: small (SP), medium (MP) and large (LP) plaque-forming cells.

In 5 mM glucose, mainly SP and MP cells were detected. CCh increased the percentage of MP cells and recruited LP cells. In 10 mM glucose, the three subpopulations were observed, CCh also augmented the percentage of MP and LP cells. In contrast, CCh in 15 mM glucose decreased the percentage of MP and LP cells.

The results suggest that the effect of CCh in low glucose is greater, because more cells are recruited to secreting activity. Moreover, B-cells subpopulations with higher secretion rates may be preferentially stimulated by carbachol.

PERIPHERAL-TYPE BENZODIAZEPINE RECEPTORS AND REGULATION OF STEROIDOGENESIS IN RAT BRAIN MITOCHONDRIA. L.D. McCauley*, N.C. Lan, J.M. Tomich[1], J.E. Shively[2], K.W. Gee. Department of Molecular Pharmacology and Toxicology, [1]Children's Hospital, University of Southern California, Los Angeles, CA 90033. [2]Beckman Research Institute of the City of Hope, Duarte, CA 91010.

Recent evidence has suggested that steroid biosynthesis may occur in central nervous system tissue. Increased pregnenolone synthesis can be induced via a benzodiazepine (BZ) receptor located on the outer mitochondrial membrane. To evaluate the synthetic capabilities of brain mitochondria isolated from male Sprague-Dawley rat brains, ligands with varying affinities for the peripheral-type BZ receptor on the mitochondrial membrane were examined for their ability to stimulate pregnenolone production from cholesterol. Diazepam, Ro5 4864 and PK 11195 increased steroidogenesis by at least two-fold whereas clonazepam had no significant effect. In addition, the ability of steroidogenesis activator peptide (SAP) and three partial fragments of diazepam binding inhibitor were evaluated for activity. All peptides significantly stimulated cholesterol conversion to pregnenolone in brain mitochondrial preparations. Furthermore, SAP displayed competitive kinetics against Ro5 4864 as determined by Scatchard analysis. The K_d for [^{3}H]Ro5 4864 binding in the presence of SAP was calculated to be 5.69 nM, about twice that of control [^{3}H]Ro5 4864 binding. These results suggest that the brain may be capable of *de novo* synthesis of steroids and that peptides and small molecules such as Ro5 4864 may share a common site of action. (Supported by NIH grants NS25986 and NS24645)

NEURAL-IMMUNE INTERACTIONS: INTERLEUKINS AND NEURAL FUNCTIONS

475.1

INTERLEUKIN-1 RECEPTOR ANTAGONIST PROTEIN (IRAP) EQUALLY INHIBITS IL1α- AND IL1β-INDUCED ACTH SECRETION AND THYMOCYTE PROLIFERATION. S.G.Matta, K.M.Linner* and B.M.Sharp*. Endocrine-Neurosci Res Lab, Dept of Medicine, Hennepin Cnty Med Ctr and U of MN, Mpls, MN

Interleukin-1 (IL1) stimulates the release of ACTH via a central mechanism. Whether apparent differences in efficacy of IL1α vs IL1β are due to two different receptors has not been clarified. We sought to address this from a functional perspective, by examining the inhibition by IRAP of ACTH secretion and thymocyte proliferation in response to rhIL1α vs rhIL1β. To determine an equieffective dose for ACTH release in rats, IL1α was given i.v. (25-200 ng/200 g b.w.) or proximate to the median eminence (intra-ME; 1-75 ng/0.5 µl) and compared to IL1β (i.v. 25 ng/200 ng and intra-ME 10 ng). I.V. IL1α 200 ng was equieffective to IL1β 25 ng: peak ACTH responses (pg/ml; mean ± sem) were 520±78 and 489±69, respectively. Intra-ME IL1α 75 ng (276±58 pg/ml) was equieffective to IL1β 10 ng (273±35 pg/ml). To examine the interaction between IRAP and IL1, studies determined that the IC_{50} for IRAP delivered i.v.prior to i.v. IL1α 200 ng or IL1β 25 ng were 2.5 µg or 5.5 µg, respectively. Intra-ME IRAP 1 µg prior to ME IL1α or IL1β also reduced the ACTH response (pg x min/ml):

Dose (ng/0.5 µl)		(-) IRAP	(+) IRAP	% reduction
Buffer		3132±365	3940±301	-
IL1α	200	6777±842	2316±368	100
	75	4890±660	3170±568	100
IL1β	25	13125±918	1079±989	31
	10	11780±1068	6785±669	67

In the rat thymocyte co-mitogenesis assay, the proliferative response to 5 ng/ml IL1α or β was reduced by IRAP (IC_{50} of 12.5 and 25 µg/ml, respectively). In summary, IL1α was less potent than β regarding ACTH secretion, but equipotent in thymocyte proliferation; however, at equieffective IL1 doses, IRAP was similarly effective in both assays. Therefore, it appears that one CNS receptor for IL1α and β, which is similar to the thymocyte receptor, mediates ACTH secretion.

SYSTEMIC INTERLEUKIN-6 INDUCTION BY CENTRAL INTERLEUKIN-1: NEURAL-IMMUNE MODULATION A. Manfridi*, C. Gemma* M. Sironi*, A. De Luigi*, P. Ghezzi* and M. G. De Simoni. Istituto di Ricerche Farmacologiche "Mario Negri", via Eritrea 62, 20157 Milan, ITALY.

Some of the activities of IL-1 are known to be mediated by IL-6. Intracerebroventricular (i.c.v.) administration to rats of 200 ng of human recombinant ß IL-1 results in a more marked induction of IL-6 compared to systemic injection. This effect is antagonized by the i.c.v. administration of the IL-1 receptor antagonist (IL-1ra, 20 µg). Induction of serum IL-6 by central IL-1 is greatly attenuated by naloxone (10 mg i.p.) pretreatment and by 6-OHDA or 5,7-DHT lesions, suggesting the involvement of opioid peptides and brain monoamines in the induction of circulating IL-6 by central IL-1. Induction of IL-6 was potentiated in adrenalectomized and in hypophysectomized rats indicating that the hypothalamus-pituitary-adrenal axis provides inhibitory signals for this IL-1 central effect. Neither MSH (30 µg icv), nor anti-CRF antibody, compounds known to inhibit several IL-1 activities, could antagonize IL-6 induction, but rather enhanced it. Intracerebroventricular administration of endotoxin (2.5 µg) also induced a preferential induction of circulating IL-6.

Centrally mediated induction of IL-6 indicates the existence of a pathway that could explain how infections or lesions confined to the CNS result in systemic alterations.

INTERLEUKIN (IL)-1ß DEPOLARIZES MEMBRANE POTENTIALS OF HYPOTHALAMIC SUPRAOPTIC (SON) NEURONS IN RAT SLICE PREPARATION. H. Yamashita, Z. Li* and K. Inenaga*, *Dept. Physiol., Univ. Occupational and Environmental Health, Sch. of Med., Kitakyushu 807, Japan.*

Recent studies have shown existence of IL-1ß immunoreactive neurons in the hypothalamus and elevation of plasma AVP and OXT levels induced by IL-1ß injected intravenously. To provide the direct electrophysiological evidence that IL-1ß affects the activities of hypothalamic neuroendocrinological cells, intracellular recordings were made from SON neurons in brain slices (400µm) of adult male Wistar rats. Total 42 (consisting of 29 phasic and 13 non-phasic) neurons were tested. Their resting potential, membrane resistance and action potential are, respectively, 58.6±1.1 mV, 160.8±9.0 MΩ and 68.2±1.3 mV (Mean±SE). Application of human recombinant IL-1ß at 1.2×10^{-8} M to bath medium for 2 min depolarized membrane potentials (3.39±0.46 mV) with obvious increase of discharges in 25 (59.5%) SON neurons. In other 11 (26.2%) neurons, biphasic responses, depolarization followed by hyperpolarization were observed. The depolarizing effect of IL-1ß usually started 30 s after drug application and ended within 10 min. Such effect could not be blocked by TTX (9/9) but was completely abolished by salicylic acid (4/4). Only 4 neurons were hyperpolarized (2.50±0.96 mV) and the remaining (2 neurons) were not affected by IL-1ß. These results show that IL-1ß directly excites SON neurons through some process involved in prostaglandin metabolism and suggest that IL-1ß may modulate hypothalamic AVP and OXT secretion. (This work was entrusted to UOEH by Sciences and Technology Agency of Japan. Dr. Li was supported by Sasakawa Foundation.)

INTERLEUKIN 1-BETA INCREASES INTRACELLULAR CALCIUM AND ALTERS THE ELECTROPHYSIOLOGY OF CULTURED CEREBELLAR PURKINJE NEURONS. N. Di Julio*, A. Urrutia* and D. L. Gruol. Dept. of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

Interleukin-1-beta (IL-1β) mediates signaling between cells of the immune system. IL receptors are located in the cerebellum (Farrar et al, J. Immunol. 139:459-463). To examine whether IL-1β mediates immune system communication with the nervous system, the effects of IL-1β on intracellular calcium levels and the electrophysiological properties of cultured cerebellar Purkinje neurons (PNs) were studied.

Changes in intracellular calcium ($[Ca^{2+}]_i$) of PNs (14-24 days in vitro) after exposure to IL-1β were measured with Fura-2 Ca^{2+} imaging. Pressure ejection from a pipette or bath application of IL-1β (10 or 100 units/mL) significantly increased $[Ca^{2+}]_i$ in the PN somas (n=36) and PN dendrites (n=15) an average of 76% and 42% above resting, respectively ($P < 0.05$, paired t-test). The mean latency was 4.5 minutes and the average time to peak $[Ca^{2+}]_i$ was 13 minutes (n=32). Partial recovery (25%) was observed in an average of 16 minutes after the peak response (n= 32). Application of antibody-neutralized IL-1β produced a 9% increase in $[Ca^{2+}]_i$ above resting compared to a 100% increase above resting with active IL-1β.

In electrophysiological studies, IL-1β depressed current evoked spiking, the afterhyperpolarization evoked at the termination of a depolarizing pulse and input resistance measured in the hyperpolarizing range of membrane potentials. These data demonstrate that factors secreted by immune cells can alter the physiological function of this CNS neuronal type. (*Supported by MH47680*)

INTERLEUKIN-1 BETA INHIBITS FIRING OF RAT CEREBELLAR PURKINJE CELLS IN SITU. S.R. White, D.D. Crossley* and J. Smith. Dept. of VCAPP, Washington State Univ., Pullman, WA 99164.

The cytokine interleukin-1 beta (IL1b) has been proposed as a messenger between the immune system and the central nervous system (CNS). It is released by macrophages during the immune response and by activated astrocytes and ameboid microglia during CNS injury. IL1b binding sites are distributed heterogeneously in the CNS and are particularly densely concentrated in the cerebellar cortex (Farrar et al., *J. Immunol.*, 1987, 139:459). This study examined the effects of local application of IL1b on the firing rate of cerebellar cortex Purkinje cells (PC) in chloral hydrate- or urethane-anesthetized rats. IL1b (1.5 nM, 0.4 - 4.8 pg) applied by micropressure ejection produced a dose-dependent inhibition of PC firing that recovered over time. This inhibition was observed in 77% of the PC that were tested and resembled the inhibition that was produced by micropressure ejection of norepinephrine. Equivalent ejections of the vehicle control solution had no effect on PC firing. These results indicate that IL1b can alter neuronal excitability in a region of the CNS that contains dense IL1b binding sites, and support the hypothesis that IL1b may have a neuromodulatory effect in the CNS.

475.6

DIFFERENTIAL EFFECTS OF CENTRAL AND PERIPHERAL INJECTION OF INTERLEUKIN-1ß ON BRAIN *C-FOS* EXPRESSION AND HYPOTHALAMO-PITUITARY-ADRENAL AXIS ACTIVITY. Serge Rivest*, German Torres and Catherine Rivier. The Salk Institute, The Clayton Foundation Laboratories for Peptide Biology, San Diego, CA 92186.

The present study investigated the neuroanatomical sites involved in the stimulatory effects of interleukin (IL) on the activity of hypothalamo-pituitary adrenal (HPA) axis. *C-fos* expression was used to identify the neurological activity of various brain areas following iv or intracerebroventricular (icv) injection of IL-1ß. Intracerebroventricular injections were done by means of a permanent cannula implanted in the right lateral ventricle, while peripheral administrations were carried out through a jugular catheter. Blood samples were taken before, as well as 30 and 120 min after icv or iv IL infusion. Immediately therafter the rats were anesthetized with pentobarbital, then perfused transcardially with 150 mL of heparinized saline followed by 4 % parafolmaldehyde in 0.1 M sodium phosphate buffer. Brains were removed, postfixed for 1 hr, then placed in 30 % sucrose in 0.01 M sodium phosphate buffer until the brains sank. Thirty micron frozen sections were cut on a sliding microtome and cryoprotected at -70 °C until processed. Approximately every fourth tissue section was processed for *c-fos* expression by an Avidin-Biotin-peroxidase method. Both iv (1 µg) or icv (100 ng) injections of IL-1ß increased plasma ACTH levels. Intracerebroventricular infusion of IL markedly increased *c-fos* expression in the paraventricular nucleus (PVN) and in the arcuate nucleus (ARC) of the hypothalamus. In contrast, iv injection of IL-1ß did not measurably alter *c-fos* expression in the PVN or in ARC, while significantly augmenting the *c-fos* expression in the external zone of the median eminence. These results suggest that iv injected IL-1ß acts at the level of external zone of the median eminence to stimulate the HPA axis activity, while icv administered IL-1ß activates neurons within the PVN.

INVOLVEMENT OF THE EPOXYGENASE PATHWAY IN INTERLEUKIN-6 (IL-6) STIMULATED CORTICOTROPIN-RELEASING FACTOR (CRF) SECRETION IN VITRO. K.Lyson and S.M.McCann. Department of Physiology, Neuropeptide Division, U.T. Southwestern Medical Center, Dallas, Tx 75235-9040.

Since we suggested that the epoxygenase (EPO) pathway of arachidonic acid metabolism system may mediate IL-6-stimulated CRF release in vitro, we decided to examine the influence of clotrimazole (CLO), a specific EPO inhibitor, on IL-6-stimulated CRF release from the rat medial basal hypothalamus (MBH). After 30 min preincubation in Krebs-Ringer bicarbonate buffer (KRB) or KRB containing CLO (10^{-9}-10^{-5}M), MBHs were incubated for 30 min with KRB or KRB containing IL-6 (10^{-13}M) and/or CLO. CRF release into the incubation medium was measured by RIA. None of the CLO concentrations used changed basal CRF release significantly. As reported previously, 10^{-13}M IL-6 evoked increased CRF release which was significantly suppressed by CLO in a dose-dependent manner at concentrations ranging from 10^{-9} to 10^{-5}M. The maximal inhibitory effect was observed with 10^{-5}M CLO: KRB=3.14±0.18 (mean±sem pg/mg MBH); 10^{-13}M IL-6=5.52±0.27, $p<0.001$ vs. KRB; 10^{-13}M IL-6 + 10^{-5}M CLO=2.93±0.29, $p<0.001$ vs. IL-6. The results suggest that IL-6 stimulates CRF release from the MBH in vitro by the activation of the EPO pathway.

INTERLEUKIN-1 EFFECTS ON LH RELEASE: MODE OF ACTION. J.J. Bonavera*, S.P. Kalra, and P.S. Kalra, Dept. OB-Gyn, Univ. Fla. Col. Med., Gainesville, FL 32610

We have reported that central administration of the cytokine, IL-1β, blocked the steroid-induced LH surge in ovariectomized rats apparently due to decreased hypothalamic LHRH secretion via an increase in endogenous opioid activity. To determine the component of LH episodes responsible for the diminution in LH release, we examined the effects of IL-1β on pulsatile LH secretion in castrated male rats. Two weeks after castration, rats received either IL-1β (Eli Lilly, Co., 100 ng/3μl, n=8), or saline (3 μl, n=8) via a chronic IIIrd ventricle cannula (icv). Blood was continuously withdrawn (100 μl/5 min) from indwelling intra-atrial cannulae for 1 h before and 2 h after injection. Plasma LH levels declined gradually after IL-1β administration. Analysis of LH pulsatility (CLUSTER method) revealed no change in LH pulse frequency, however, the decrease in LH levels could be attributed to significantly lower peak heights, amplitude and nadir in IL-1β-treated rats vs controls.

Since IL-1 stimulates release of CRF which, in turn, inhibits LHRH-LH we have tested whether CRF mediates the IL-1β-induced LH suppression. Castrated rats were passively immunized with CRF antibody (courtesy Dr. W. Vale; dil 1:5) injected icv (3 μl) at either 15 mins or at 75 and 15 mins before IL-1β (100 ng/3 μl); control rats received 3 μl normal rabbit serum (n=5-7/group). Neither treatment with CRF antibody blocked the inhibitory effects of IL-1β on LH release. Similarly, the CRF antagonist, α-helical oCRF (Bachem, 100 μg/5 μl, icv) injected 15 mins before IL-1β failed to block the decrease in LH release. These results suggest that (a) IL-1β decreases LH secretion apparently by diminishing hypothalamic LHRH output without affecting the frequency of LHRH discharge, and (b) CRF may not mediate the IL-1β-induced decrease in LHRH-LH release. (Supported by NIH HD 11362).

INTERLEUKIN-1 (IL-1)ß-INDUCED INTERCELLULAR ADHESION MOLECULE-1 (ICAM-1) EXPRESSION IS BLOCKED BY IL-1ß RECEPTOR ANTAGONIST (IL-1ra).
L. Hong*, M.R. Opp, and J.M. Krueger. University of Tennessee, Memphis, TN 38163

ICAM-1 is a cellular ligand that binds lymphocyte function-associated antigen-1 and mediates lymphocyte-tissue cell contact (1). ICAM-1 expression is important in inflammatory responses and is regulated by cytokines such as IL-1, interferon (IFN) gamma, and tumor necrosis factor-α (TNFα) (1). To study ICAM-1 expression in brain cells, we examined ICAM-1 expression in a human glioblastoma cell line (HTB16) and a neuroblastoma cell line (HTB11) using an ELISA to quantitate ICAM-1. Cells were incubated for 4 to 6 days with various concentrations of recombinant human IL-1ß (rhIL-1ß), rhIFN gamma, and rhTNFα in the absence or presence of IL-1ra (1 or 10 μg/ml). rhIL-1ß, rhIFN gamma, and rhTNFα potentiated ICAM-1 expression in both cell lines in a dose-related manner. The effect of rhIL-1ß on ICAM-1 expression was more potent in HTB16 cells, while that of rhIFN gamma was more potent in HTB11 cells. rhIL-1ß-induced ICAM-1 expression, but not rhTNFα-induced ICAM-1, was completely blocked by 10 μg/ml of IL-1ra. Our findings also indicate that expression of ICAM-1 by neuronal cells is regulated by cytokines, thus suggesting neuronal cells are also a target of binding to lymphocytes and could be involved in inflammatory responses.

CENTRAL IL-1ß INDUCES A RISE IN BLOOD PRESSURE IN ANAESTHETIZED MICE.
RS Poterski*, AJS Summerlee. Department of Biomedical Sciences, Ontario Veterinary College, University of Guelph, Guelph, Ontario Canada N1G 2W1.

We previously reported that central administration of rhIL-1ß induces postimplantation pregnancy loss in mice (Croy et al., PNEI 1990; 3: 242-250). Preliminary data indicates that i.c.v. IL-1ß causes a rise in systemic blood pressure leading to disruption of blood supply to the developing fetus. We tested whether injection of rhIL-1ß (Genzyme, Boston, MA) into the cerebral ventricles of CD-1 non-pregnant mice (7-8 weeks old) would have a pressor effect. Mice were anaesthetized with tribromoethanol i.p. and the left common carotid artery cannulated for direct recording of blood pressure. Each animal was then placed into a steriotaxic frame and a small hole drilled above the left lateral cerebral ventricle. A 10 μl microsyringe was placed with its tip in the ventricle. The effects of IL-1ß (1 ng in 1 μl) i.c.v. were compared with control injections of 1 μl PBS-BSA (vehicle) i.c.v. One minute after injection of IL-1ß, there was a significant ($P<0.05$) rise in systolic and diastolic blood pressure (mode 16-20 mm Hg: range 5-26 mm Hg) in all animals (9/9). In contrast, no change in blood pressure was seen after PBS-BSA i.c.v. The data indicate that rhIL-1ß i.c.v. causes a consistent pressor effect in mice.

CONVULSANTS INDUCE INTERLEUKIN-1β mRNA IN RAT BRAIN.
M. Minami*, Y. Kuraishi, K. Yabuuchi* and M. Satoh. Dept. of Pharmacol., Fac. of Pharm. Sci., Kyoto Univ., Kyoto 606, Japan.

To estimate whether changes of neuronal activity could alter the synthesis of interleukin-1β (IL-1β) in the brain, the influences of convulsion evoked by drugs on the mRNA level of IL-1β were studied in the rat. Male Sprague-Dawley rats were injected with kainic acid (KA: 10 mg/kg i.p.) or pentylenetetrazol (50 mg/kg i.p.). The expression of IL-1β mRNA in the eight brain regions, that is, the cerebral cortex (CC), hippocampus (HPP), striatum (STR), thalamus (THL), hypothalamus (HT), midbrain (MB), pons-medulla (PM) and cerebellum (CRB), was examined by northern blot analysis. IL-1β mRNA was induced by KA intensely in the CC, THL and HT, moderately in the HPP and weakly in the STR 2.5 h after the injection, but was not detected in the MB, PM and CRB. Pentylenetetrazol induced IL-1β mRNA intensely in the CC, weakly in the HPP, THL and HT 30 min after the injection. Diazepam (10 mg/kg i.p.) suppressed both the convulsion and the induction of IL-1β mRNA produced by KA. Dexamethasone (1 mg/kg i.p.) suppressed the induction of IL-1β mRNA by KA in the brain, but did neither the convulsion nor the induction of c-fos mRNA following the injection of KA. *In situ* hybridization study confirmed the regional difference in the induction of IL-1β mRNA by KA. These results provide the evidence that intensive neuronal excitation induces IL-1β mRNA in particular regions of the brain.

475.12

INCREASES IN RENAL SYMPATHETIC NERVE ACTIVITY, ARTERIAL BLOOD PRESSURE AND HEART RATE INDUCED BY INTERLEUKIN 1-β IN CONSCIOUS RATS.
KANNAN,H.[1], NAKAMURA,T.[2*], HAYASHIDA,Y.[2*] AND YAMASHITA,H.[1] Dept.Physiol.[1] and Dept.Systems Physiol.[2], Univ. of Occup. and Environ. Health, Kitakyushu 807, Japan

The present study was undertaken to determine the effects of interleukin 1β (IL-1β) on renal sympathetic nerve activity (RSNA), arterial blood pressure (AP) and heart rate (HR) as well as body temperature in conscious rats. Either intravenous (i.v.) or intracerebroventricular (i.c.v.) administration of IL-1β elicited increases in AP, HR and RSNA accompanied by a rise in body temperature. The maximum changes in AP, HR and RSNA occurred 10-15min after i.v. injection of IL-1β (100ng), and 20-25 min after i.c.v. injection (5ng). The responses induced by the i.v.and i.c.v.injections lasted for about 15-30 min and were completely abolished when the animals were pre-treated with a cyclo-oxygenase inhibitor, indomethacin (i.v.,10mg/kg). Moreover, i.c.v. injection of prostaglandin E_2(1μg)produced responses similar to those induced by IL-1β but with a rather short latency. The results suggest that IL-1β auguments cardiovascular and sympathetic outflow through the central action of prostaglandin E_2 in conscious rats. (This work was entrusted to University of Occupational and Environmental Health, using the Special Coordination Funds for Promoting Science and Technology.)

475.13

INTERLEUKIN-1 (IL-1) RECEPTORS IN THE BRAIN-ENDOCRINE AXIS CORRESPOND TO TYPE I BUT NOT TYPE II RECEPTORS : EVIDENCE FROM AFFINITY CROSS-LINKING STUDIES.
D.E. Grigoriadis, T. Takao, E.L. Webster, D.E. Tracey* and E.B. De Souza. The Du Pont Merck Pharmaceutical Co., Wilmington, DE 19880, NIDA/ARC, Baltimore, MD 21224, and The UpJohn Co., Kalamazoo, MI 49001.

IL-1 is a key mediator of the immune response to stress, infection and antigenic challenge. IL-1 also alters neuroendocrine activity through indirect effects in brain and direct actions in endocrine tissues. IL-1 receptors have been identified in brain and in endocrine organs with kinetic and pharmacological characteristics similar to IL-1 receptors in the T-lymphoid cell line EL-4 6.1. Recently, multiple IL-1 receptors, referred to as type I (M.W. = 80 kDa) and type II (65 kDa), have been identified in T- and B/macrophage-cell lines, respectively. In the present study, we have used chemical affinity cross-linking of ^{125}I-recombinant human IL-1α (^{125}I-IL-1α) followed by SDS-PAGE and autoradiography to compare the apparent M.W. of IL-1 receptors in the brain-endocrine-immune axis to that in T- and B-lymphoid cell lines. ^{125}I-IL-1α was incorporated in mouse spleen homogenates into two specific and distinct proteins corresponding to the respective M.W. of type I and type II receptors. On the other hand, ^{125}I-IL-1α was incorporated into hippocampus, anterior pituitary, testis and in AtT-20 pituitary tumor cells exclusively into a single protein corresponding to the higher M.W. type I receptor. IL-1α, IL-1β, and an analog IL-1β^+ inhibited the incorporation of ^{125}I-IL-1α in the brain and endocrine tissues in parallel with their relative bioactivities in the T-cell comitogenesis assay while tumor necrosis factor had no effect. These data demonstrate a similarity between IL-1 receptors in the brain-endocrine axis and type I IL-1 receptors in T-lymphocytes and suggest the importance of the cytokine in coordinating brain-endocrine-immune function.

475.14

TYPE I INTERLEUKIN-1 (IL-1) RECEPTORS IN THE MOUSE BRAIN-ENDOCRINE-IMMUNE AXIS LABELLED WITH ^{125}I-RECOMBINANT HUMAN IL-1 RECEPTOR ANTAGONIST.
T. Takao, R.C. Newton* and E.B. De Souza. The Du Pont Merck Pharmaceutical Company, Wilmington, DE 19880 and NIDA Addiction Research Center, Baltimore, MD 21224.

The cytokine IL-1 has a variety of effects in brain including induction of fever, alteration of slow-wave sleep and alteration of neuroendocrine activity. Previous studies utilizing ^{125}I-recombinant human IL-1α (^{125}I-IL-1α) have identified high-affininty binding sites for IL-1 in brain and endocrine tissues with characteristics of Type I receptors in T lymphocytes. Recently, a recombinant human IL-1 receptor antagonist (IL-1ra) with selective actions at Type I receptors both in vitro and in vivo has been identified. In the present study, we utilized ^{125}I-IL-1ra to further determine the characteristics of IL-1 receptors in the brain-endocrine-immune axis. Specific high affinity ^{125}I-IL-1ra binding (displaceable by 100 nM recombinant human IL-1β) was present in homogenates of mouse (C57BL/6) spleen, testis and hippocampus, with low to negligible binding seen in other brain areas such as the frontal cerebral cortex and hypothalamus. Of note, there was a dramatic species difference in the level of ^{125}I-IL-1ra binding in mouse and rat tissues with barely detectable binding present in the rat; a similar species difference was previously noted for ^{125}I-IL-1α binding. In competition studies in hippocampus, Il-1β and a weak analog Il-1β^+ inhibited ^{125}I-IL-1ra binding in parallel with their relative bioactivities in Type I IL-1 receptor dependent assays; tumor necrosis factor did not inhibit ^{125}I-IL-1ra binding. These data demonstrate comparable binding characteristics of ^{125}I-IL-1α and ^{125}I-IL-1ra to Type I IL-1 receptors in the tissues examined and provide further support for role for IL-1 in coordianting brain-endocrine-immune responses to physiological and pharmacological stimuli.

475.15

OCCURRENCE OF INTERLEUKIN-1 RECEPTOR IN THE RAT AND MOUSE PITUITARY. M. Schultzberg, C. Andersson*, J. Bristulf*, S. Nobel*. Karolinska Institute, Clinical Res. Center., Div. of Med. Cell and Neurobiology, Huddinge Hospital, and Dept. of Biochem., Stockholm Univ., Stockholm, Sweden.

Interleukin-1 (IL-1), a cytokine of multiple actions, has been shown to affect hypothalamic and pituitary hormones, notably with resulting increase in corticosterone production. Studies were carried out in order to investigate the occurrence of IL-1 receptor (IL-1R) in the rat pituitary. Antisera raised in rabbits against synthetic peptides of the murine lymphocyte IL-1R were used in immunohistochemical studies and the polymerase chain reaction (PCR) technique was employed to detect IL-1R mRNA. Antisera to the second loop of the extracellular domain of the protein gave an intense immunoreaction in the cells of the intermediate lobe of both mouse and rat pituitary. In addition, a population of the cells in the anterior lobe were mIL-1R immunoreactive. PCR analysis using primers for human and mouse lymphocyte IL-1R confirmed the synthesis of this protein in the pituitary. Experiments using *in situ* hybridization histochemistry to determine the cellular localization of IL-1R mRNA in the pituitary and to investigate its regulation are in progress.

These findings add morphological and biochemical support to the functional evidence of IL-1 receptors in the pituitary, although the source of IL-1 acting on these receptors remains unclear.

INTERLEUKIN-1 COMPROMISES CHOLINERGIC FUNCTION IN FOREBRAIN STRUCTURES *IN VIVO*. L. Ni, R.P. Hart, G. Buzsáki, and G.M. Jonakait, Dept. Biol. Sci. and Center for Mol. & Behav. Neurosci., Rutgers Univ., Newark, NJ 07102

The possible role of immune cytokines in the etiology of Alzheimer's disease (AD) has received increasing attention since the discovery that brain levels of interleukin-1 (IL-1) are elevated in the disease, that IL-1 is localized to plaques, and that IL-1 rapidly increases mRNA coding for the amyloid β-protein precursor. Moreover, we have found that IL-1 significantly lowers cholinergic biosynthesis in cultures of embryonic rat basal forebrain and striatum.

In order to determine whether IL-1 compromises cholinergic neurons in adult rats *in vivo* as well, we infused IL-1β (50 U/day) into the lateral ventricles using a subcutaneously implanted Alzet minipump. Choline acetyltransferase (ChAT) activity was measured as an index of cholinergic function. After 10 days, ChAT activity was dramatically lowered in n. basalis (66±5.4% of saline-cannulated controls) and septal region (78±3.6%). After 14 days, ChAT activity in n. basalis was further depressed (50±2.4%). Modest but significant decreases occurred in the frontal cortex (86±3.0%) and striatum (91±1.3%) and after 14 days in amygdala (85±1.5%) and hippocampus (89±3.1%). ChAT activity remained unchanged in the anterior hypothalamus and spinal cord. Neither substance P in striatum nor tryptophan hydroxylase activity in the midbrain raphe were changed by the treatment, suggesting that IL-1 was somewhat specific in its action on cholinergic neurons.

These data suggest that subchronic exposure to IL-1 challenges cholinergic function differently in different cholinergic populations.

IMMUNOACTIVE AGENTS STIMULATE SUBSTANCE P IN CULTURED SYMPATHETIC GANGLIA. A. M. Shadiack*, D. Ganea*, R. P. Hart, and G. M. Jonakait, Dept. of Biological Sciences, Rutgers University, Newark, NJ 07102.

Immune cytokines are now known to regulate neurotransmitter gene expression. Our laboratory has recently shown that in explant cultures of superior cervical (sympathetic) ganglia (SCG), the macrophage product interleukin-1 (IL-1) dramatically increases both the levels of substance P (SP) and the mRNA coding for its prohormone precursor, preprotachykinin (PPT). We have now tested other products of activated macrophages, including tumor necrosis factor-α (TNF-α) and IL-6. While human recombinant (hr) TNF-α (20 U/ml) produced a modest doubling of SP, hrIL-6 had no effect on SP expression at any dose tested.

Lipopolysaccharide (LPS, 5μg/ml) from *E. coli*, a strong activator of the immune system, caused a two- to five-fold increase in SP that was inhibited by an IL-1 receptor antagonist (Synergen). These data suggest that SP induction by LPS may be mediated through the production of IL-1 in the culture.

In testing the effects of T-cell products on SP expression, we found that doses as high as 50 U/ml of hrIL-2 (Collaborative Research) or 800 U/ml of murine recombinant IL-4 (Genzyme) failed to alter SP levels. However, in the presence of LPS, a common co-stimulant with other immune cytokines, IL-4 increased SP levels above those induced by LPS alone.

These data taken together provide further evidence for a regulatory interaction between the immune and nervous systems.

(Supported by a grant from the ONR.)

INTERLEUKIN-2 (IL-2) INCREASES [^{3}H]DOPAMINE RELEASE FROM RAT STRIATAL SLICES: CORRELATION WITH THE PRESENCE OF ENDOGENOUS IL-2, IL-2 RECEPTORS AND IL-2 mRNA IN THE RAT STRIATUM. Paul A. Lapchak, Andrus Gerontology Ctr., USC, Los Angeles, CA, 90089-0191, USA.

Intrastriatal application of IL-2 elicits an asymmetric body posture with long-lasting ipsilateral turning and ipsilateral circling behavior suggesting that IL-2 may be interacting with IL-2 receptors that may be present on dopaminergic neurons of the nigro-striatal pathway. The present study determined whether IL-2 receptors are present in the striatum and whether the striatum contains endogenous IL-2 and IL-2 mRNA. In addition, the effects of IL-2 on dopaminergic neurotransmission in the striatum were determined by assessing the effect of IL-2 on [^{3}H]dopamine (DA) release from prelabeled transmitter stores. Immunoautoradiographic analysis and in situ hybridization indicated the presence of low levels of IL-2, IL-2 receptors and IL-2 mRNA in the striatum. Exogenous IL-2 (10^{-11} to 10^{-9} M) was effective in increasing [^{3}H]DA release (37-52%) from striatal slices. In addition, IL-2 (10^{-11} and 10^{-10} M) increased potassium (25 mM)-evoked [^{3}H]DA release from striatal slices (by 25 and 81 %, respectively). The IL 2-induced enhancement of basal and evoked [^{3}H]DA release from striatal slices was not observed when slices were incubated in the presence of the sodium channel blocker tetrodotoxin (0.1 μM) or when striatal slices were incubated with reduced concentrations of external calcium. In summary, it appears that IL-2 and IL-2 receptors are present in the striatum. Furthermore, this study shows that activation of IL-2 receptors is involved in the regulation of striatal dopaminergic neurotransmission. (Supported by HFSP).

EFFECTS OF LYMPHOKINES ON GLIAL AND NEURONAL CELLS *IN VITRO*: A ROLE FOR LYMPHOKINES AS MODULATORS OF NEURAL-GLIAL INTERACTIONS. D. M. Araujo and C. W. Cotman, Dept. Psychobiol., Univ. California, Irvine, CA, USA.

Lymphokines, in particular the interleukins (ILs), can be released from microglia and astrocytes in culture. However, the effects of ILs on the function of neuronal and glial cells *in vivo* is not completely understood. The present study characterized the effects of various lymphokines on microglial and astrocyte function in culture, by measuring the uptake of ^{3}H-thymidine and the release of IL-1 and -2 from these cells. Furthermore, effects of these lymphokines on the survival of hippocampal neurons *in vitro* was also assessed. Our results show that IL-3, -6, and other lymphokines enhanced the uptake of ^{3}H-thymidine (by 47-86%), as well as the release of IL-1 and -2 (by 25-120%) in microglial cell cultures. In addition, several "classical" growth factors (GFs) such as NGF, FGF and EGF also increased both measures. Similar results were obtained for astroglial cultures. In hippocampal neurons *in vitro*, the effects of lymphokines were complex: both neurotrophic and neurotoxic effects that were clearly time- and concentration-dependent were evident with various ILs, GCSFs, IFNs and TGFs. With IL-2, significant neurotoxic effects were apparent by 24h in culture. Thus, changes in lymphokine release resulting in altered glial cell function may disrupt central neuronal function. This in turn may be further exacerbated by neuronal factors that affect glial cell function.

LOCALIZATION OF mRNA FOR INTERLEUKIN-2 (IL-2) IN MOUSE BRAIN BY IN SITU HYBRIDIZATION. F. Villemain, T. Owens*, T. Renno* and A. Beaudet. Neuroanatomy Lab., Montreal Neurological Institute, Montreal, Quebec, H3A 2B4, Canada.

Immunohistochemical studies from our laboratory have previously documented the distribution of interleukin-2 (IL-2) in rodent and human brain (Neurosci. Abstr., 1990, 499.13). In normal CD-1 mice, IL-2 immunoreactivity was found to be concentrated within the arcuate nucleus of the hypothalamus where it is selectively associated with a subpopulation of neurons (Neurosci. Abst., 1990, 499.14). In the present study, we sought to determine whether IL-2 was expressed by these cells, or merely taken up from the bloodstream, by localizing IL-2 mRNA using *in situ* hybridization. We used as a probe the 337 base pair PstI-HindIII fragment from the coding sequence of the mouse IL-2 cDNA. A 330 base pair from a cDNA random sequence was used for negative controls. Hybridization was performed on 20 μm-thick paraformaldehyde-fixed serial sections through the forebrain of CD-1 mice. Transformed murine plasmocytomas producing IL-2 or IL-4 served as positive and negative tissue controls, respectively (Eur. J. Immunol., 1988, 18: 97). IL-2 mRNA was detected in a subpopulation of arcuate neurons, confirming that the IL-2 previously detected in this region by immunohistochemistry was synthetized by those cells. Moreover, IL-2 mRNA was also detected within the hippocampal formation, the medial habenula and the cerebral cortex, in conformity with our earlier immunohistochemical findings in the rat. Taken together, these results provide the first evidence for the expression of IL-2 by neurons in mammalian brain. Supported by the Fondation IPSEN and the MRC.

IMMUNOCYTOCHEMICAL LOCALIZATION OF INTERLEUKIN-4 (IL-4) IN BRAINS OF BALB/c, NUDE AND SCID MICE. I. Šterzl, N. Sadatyar* and G.P. Kozlowski. Dept. of Physiology, Univ. of Tex. Southwestern Medical Center, Dallas, TX 75235-9040.

Monoclonal antibody 11B11 rat anti-mouse rIl-4 (Ohara & Paul, Nature, 325:537, 1987) was used with biotinylated protein-G (BPG-Zymed Labs) and the ABC Elite kit (Vector Labs). In order to enhance the final reaction product, the sections were sequentially reincubated in BPG and ABC prior to color development. Staining for Il-4 disappeared when sections were incubated in a mixture of purified 11B11 added to rIl-4 produced by Sf 9 cells . Similarly, staining in lymph nodes from control and anti-IgD (induces IL-4) injected animals also disappeared. Although individual patterns varied, wide areas of the forebrain were immunopositive. Intense punctate staining was associated with neuronal perikarya and proximal segments of their fibers in field CA3 of the hippocampus, supracallosal and endopiriform layers of the cortex, olfactory stria and nuc triangularis septi (NTS). Non-neuronal staining occurred in astrocytes, microglia and blood vessels. In the athymic nude mouse, the frequency and intensity of staining in most brain regions were greatly reduced. In contrast to BALB/c mice- CA1 stained more than CA3 and more microglia were positive in the NTS. In the severe combined immunodeficient (SCID) mouse there was no staining of brain structures. Therefore, the degree of immunodeficiency in both of these mutant models determines the presence of Il-4 in brain. Supported by AA-06014.

475.22

DISTRIBUTION OF CD4 IN THE FOREBRAIN OF NORMAL (BALB/c), MODERATELY (NUDE), AND SEVERELY (SCID) IMMUNODEFICIENT MICE G.P. Kozlowski and I. Šterzl. Dept. of Physiol., Univ. Tex. Southwest. Med. Ctr., Dallas, TX 75235-9040.

The human immunodeficiency virus (HIV) binds to the cell surface molecule-CD4, an Ig superfamily molecule. Our aim was to determine the regional presence of CD4 in brain. 40 um thick sections were pretreated with 0.1% triton. Monoclonal antibody GK1.5 rat anti-mouse (αL3T4) rCD4 from E.S. Vitetta (Science 242:1166,1988) was used with biotinylated protein-G (BPG-Zymed Labs Inc) and the ABC Elite kit (Vector Labs). Sections were reincubated in BPG and ABC prior to color development. For negative controls, some sections were preincubated with GP120 (5 μg/ml). Punctate final reaction product marked cell surfaces of neuronal perikarya and fibers in wide regions of the brain. Although there was individual variation among BALB/c animals, strongest stain was in the: nu lat olfactory tract, septohypothalamic nu, bed nu stria terminalis, indusium griseum, hippocampus, supraoptic nu, median eminence and the supracallosal, piriform and endopiriform layers of the ctx. Staining was also associated with astrocytes, microglia and blood vessels. In contrast to BALB/c mice, the frequency and intensity of staining were greatly reduced in brains of athymic nude mice; although, glial staining remained intense. In the severe combined immunodeficient (SCID) mouse there was no staining of brain structures. Thus, the degree of immunodeficiency in these mutant animals parallels the relative presence of brain CD4. Supported by AA-06014.

NEURAL-IMMUNE INTERACTIONS: STRESS AND BEHAVIOR

476.1

cAMP AND INTRACELLULAR CALCIUM LEVELS IN SPLENIC MONONUCLEAR CELLS FROM STRESSED RATS. **E.M. Sonnenfeld and B.S. Rabin, Brain Behavior and Immunity Center, University of Pittsburgh Sch. of Med., Pittsburgh, PA. 15261**

Previous findings have implicated norepinephrine as the neurotransmitter involved in stress-induced splenic lymphocyte immunosuppression. Although work by others indicates that sustained elevations of cAMP tend to suppress DNA synthesis, our findings indicate that this mechanism is not a likely explanation for the splenic lymphocyte immunosuppression induced by stress. The cAMP levels from cells taken from stressed rats were not elevated over levels from control cells. Additionally, when cells were stimulated with Con-A for various times, essentially no differences were seen in cAMP levels between stressed and control lymphocytes. However, initial calcium levels in cells taken from stressed animals were found to be significantly higher than levels in cells from control animals. In addition, the response by fura-2 loaded cells to stimulation with Con-A tended to be different for cells from shocked verses cells from control animals. Further studies are in progress to define the mechanism of stress-induced mitogenic suppression.

476.2

IL-1 EFFECTS ON STRESS-RESPONSIVE AND -NON-RESPONSIVE CRH NEUROSECRETORY AXONS IN RATS. M.H. Whitnall, R.S. Perlstein*, E.H. Mougey[1] and R. Neta*. Armed Forces Radiobiology Research Institute, Bethesda, MD 20889-5145, and [1]Walter Reed Army Institute of Research, Washington, D.C. 20307-5100, USA

VP-containing, stress-responsive and VP-deficient, stress-nonresponsive CRH axon subtypes were identified by EM immunocytochemistry, which was also used to monitor axon activation (vesicle depletion). Five h after ip injection of 3 or 10 μg IL-1α, or 1, 3 or 10 μg IL-1β, into 450g Sprague Dawley rats, there were similar increases in plasma ACTH (to 3 times control) and decreases in prolactin (to 30% of control). Endotoxin (LPS, 0.1 or 1 mg) produced comparable effects. One μg IL-1α did not affect ACTH levels. Five h after 10 μg IL-1β, both VP-containing and VP-deficient CRH axons displayed depletion of secretory vesicles (to 22% and 36% of control, $p<0.01$ for both subtypes). Significant depletion was also seen after 1 mg LPS. Vesicle depletion after 10 μg IL-1α was less consistent, perhaps due to a lower affinity of IL-1α to IL-1 receptors mediating the response. The results demonstrate for the first time that, unlike stress, IL-1 can activate both the VP-containing and the VP-deficient subtypes of CRH axons. In contrast to recent suggestions in the literature, we conclude that the ACTH response to IL-1 involves stimulation of pituitary corticotropes by both CRH *and* VP.

476.3

EFFECTS OF SIGNALLED AND UNSIGNALLED STRESS ON NATURAL KILLER CELL ACTIVITY. J. Irwin and C. Neitzert*, Psychology Dept., Queen's University, Kingston, Ont., K7L 2Y1.

A variety of stressors have been shown to reduce cell-mediated immune functions in humans and in animals. It has been argued that the extent of this immune suppression may be limited by the controllability or predictability of the stressor. In the present study we assessed whether the presentation of a warning signal prior to stress exposure would attenuate or exaggerate the suppression of natural killer (NK) cell activity associated with stress.

NK activity was assessed in male CD-1 mice following exposure to one of two stress conditions. For mice in the Signalled Stress group, 6 sec footshock trials (150 μAmp, 60 sec intertrial interval) were preceded by a 10 sec light and tone CS. Those in the Unsignalled Stress condition also received 6 sec trials of footshock, but the light-tone CS presentations were presented on a random schedule. Two additional groups were included to control for any effects of the light-tone CS itself. To establish the association between the signal and the aversive stimulus, the Signalled Stress group was provided with 10 CS-footshock pairings a day for 5 successive days. The Unsignalled Stress group also received 10 footshock trials over 5 days. On the sixth day both groups received 60 trials of stressor exposure and controls received an equivalent amount of handling. Twenty-four hours later splenic NK activity was assessed with a chromium release assay.

Mice exposed to the CS alone or to Unsignalled shock exhibited a modest reduction in NK activity, suggesting that both conditions were mildly stressful. However, mice in the Signalled Stress condition showed a marked suppression of NK activity. Contrary to the view that a warning signal allows animals to adopt preparatory responses to buffer the impact of the stressor, these data indicate that the signal increases the aversiveness of the situation.

476.4

STRESSOR-INDUCED C-FOS EXPRESSION IN BRAIN STEM LOCI OF THE RAT: A CORRELATION OF NEURONAL ACTIVATION WITH IMMUNE ALTERATION. M.A. Pezzone, W.-S. Lee, G.E. Hoffman, K.M. Pezzone,* and B.S. Rabin, Depts. of Pathology and Physiology, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261.

Physically aversive stressors such as mild electric footshock suppress the mitogenic responsiveness of peripheral blood and splenic lymphocytes and depress splenic natural killer cell activity. In addition, these same immune alterations are elicited with non-aversive, conditioned stimuli when paired with aversive stimuli. In an attempt to define areas of the brain that influence immune function and respond to stressors, we have previously identified stress-induced c-Fos activated areas of the diencephalon. In accordance with our model, we found that c-Fos was strongly expressed in cells of the periventricular nuclei (some of which contain CRH) and other hypothalamic areas directly associated with autonomic function. In this study, c-Fos induction in the brain stem of the rat was examined in control, shocked, and conditioned animals. C-Fos was strongly expressed in the locus ceruleus (A6), the nucleus of the solitary tract (A2/C2), the ventral lateral medulla (A1/C1), and the periaqueductal gray matter in response to the unconditioned stimulus (US, electric footshock). Conditioned animals showed c-Fos induction in these same areas but to a lesser degree. Control animals exposed to a conditioning stimulus (CS, electronic tone) in the absence of the US, expressed very little, if any, c-Fos activity in the above loci, except for a small degree of expression in the periaqueductal gray matter. These results further confirm the role of autonomic and endocrine pathways as mediators of the stress response and will help to more fully characterize the pathways of stress-induced immune alteration.

476.5

STRESS-INDUCED ALTERATIONS IN INTERFERON PRODUCTION AND IA ANTIGEN EXPRESSION: ATTENUATION BY A B-ADRENERGIC RECEPTOR ANTAGONIST. J. E. Cunnick, G. Sonnenfeld[x], A. V. Armfield[x], P. G. Wood[x], and B. S. Rabin. Brain, Behavior and Immunity Center, Dept. of Pathology, University of Pittsburgh, Pittsburgh, PA 15261.

Previous work in this lab has demonstrated that the physical stress of electric foot-shock can alter splenic mitogen response to Con A and splenic NK activity. However, this stressor does not alter splenic IL-2 production. The present study examined the effects of foot shock on the production of another T-cell produced lymphokine, IFN-gamma. IFN-gamma was induced by Con A stimulation of splenocytes for 48 hr. The splenocytes from shocked rats produced 50% less IFN-gamma as measured by ELISA. The reduction in IFN-gamma could be attenuated in a dose dependent manner by administration of nadolol (a gift from E.R. Squibb) prior to shock. Cell surface expression of class II antigen was also found to be reduced in splenocytes from shocked rats. Expression of class II antigen on macrophages is mediated by IFN-gamma and is important in cell-cell interactions.

A COMPARISON BETWEEN SPRAGUE-DAWLEY, FISCHER 334, AND LEWIS RATS: CORTICOSTERONE RESPONSE TO ACUTE RESTRAINT STRESS; AND ADRENAL STEROID RECEPTOR LEVELS IN BRAIN AND IMMUNE TISSUE. F.S. Dhabhar, R.L. Spencer, and B.S. McEwen. Laboratory of Neuroendocrinology, The Rockefeller University, New York, NY 10021.

We are examining the hypothalamic-pituitary-adrenal (HPA) axis and its interaction with the immune system of 3 strains of rats [Sprague-Dawley (SD), Fischer 344 (F), and Lewis (L)] known to vary in their reactivity to acute stress. Animals were subjected to 1 h restraint stress, (one AM session & one PM session) to examine diurnal differences in the stress response. At each session, three tail blood samples ("basal," "acute stress," and "recovery") were collected for RIA determination of plasma corticosterone (CORT). There was a significant difference in the CORT response between strains. In AM and PM, the CORT response of F rats was the highest [59.8 μg/100ml (AM); 61.2 μg/100ml (PM)]; that of SD rats was intermediate [21.3 μg/100ml (AM); 26.2 μg/100ml (PM)]; and that of L rats was the lowest [11.4 μg/100ml (AM); 25.6 μg/100ml (PM)]. Also, the L rats did not show a diurnal rise in basal CORT levels. The concentration of Type I (mineralocorticoid) and Type II (glucocorticoid) receptors was measured in the hippocampus, hypothalamus, pituitary, spleen, thymus and peripheral blood mononuclear cells. Type II receptor levels were significantly higher in the hippocampus and spleen of SD, and in the thymus of L. Relative to SD rats, Fischer rats are hyper-responsive, and Lewis rats are hypo-responsive, to acute stress. The consequences of HPA axis differences between strains on habituation to chronic stress and on immune parameters are presently being investigated. (Supported by MH 41298.)

476.7

IMMUNOSUPPRESSION IN MICE INDUCED BY ISOLATED HOUSING: ANTAGONISM BY DIAZEPAM. N. Shanks, C. Renton, S. Zalcman & H. Anisman. Dept. Of Psychology, Carleton University, Ottawa, Canada K1S 5B6.

Noninbred CD-1 mice transferred from grouped to isolated housing exhibited a decrease of the peak plaque forming cell (PFC) response and antibody titers observed 4 days after inoculation with sheep red blood cells (SRBC: 10^6). This effect was not due to the transfer of housing condition, but instead was a consequence of the isolation. Moreover, the reduced immune response was dependent on the duration that mice were isolated prior to inoculation. The maximal decline of the immune response appeared in mice that received 5 to 10 days of isolation, after which the PFC response and antibody titers began to increase, approaching the values of group housed mice. Treatment with diazepam (1.0 mg/kg) for 5 days prior to inoculation and throughout the 4 day period following antigen treatment, antagonized the effects of the isolation treatment. These data suggest that the immunosuppression may have resulted from the anxiety or arousal stemming from the isolation.

476.8

DEPRESSION, STRESS, AND IMMUNE FUNCTIONING IN PREPUBESCENT CHILDREN: EFFECTS ON PHAGOCYTOSIS.
M.K. Demetrikopoulos, J.A. Bartlett*, H.L. Niu*, S.J.Schleifer* and S.E. Keller* Departments of Neurosciences and Psychiatry, University of Medicine and Dentistry of New Jersey, Newark, NJ, 07103.

Previous work has shown there to be an age related effect of depression on the immune system such that in older adults depression was associated with a decrease in immune functioning and in younger adults with an enhancement of immune function as measured by mitogen stimulation of peripheral lymphocytes. To further examine the effects of depression on immune functioning across the life span, subjects and controls between 8 and 12 years of age who were Tanner 1 stage of development were studied. The depressed subjects met criteria for major depressive disorder based on the Diagnostic Interview Schedule for Children (DISC-R). Subjects were studied the same day and time as healthy age, sex, SES, and race matched controls. The depressed subjects were significantly more likely to come from non-intact families. We previously reported a decrease in natural killer cell activity in the depressed children, but higher numbers of lymphocytes and B cells. The present experiment examined granulocyte functioning assessing phagocytosis and killing of Staph a. While there were no overall effects of depression, there were striking age related effects such that the older children demonstrated increased phagocytosis ($T=2.3, p<0.04$) and killing ($T=2.2, p<0.04$). Family composition was shown to be significantly related to granulocytic killing, with those from non-intact families showing decreased activity($T=2.4, p<0.03$). These data suggest that the stress of living in a non-intact family may be associated with altered granulocyte function.

476.9

INTERACTIONS BETWEEN SEX AND HANDLING: THYMIC AND SPLENIC GLUCOCORTICOID RECEPTORS (GCCR), MITOGEN RESPONSES, AND PLASMA HORMONE LEVELS IN ADULT RATS. R.E. Landsman, M. Umali*, B.J. Branch*, J.E. Shyrne*, R.A. Gorski and A.N. Taylor. Lab. of Neuroendocrinology, Brain Res. Inst. and Dept. Anatomy & Cell Biology, UCLA; West L.A. VAMC, Brentwood Div., Los Angeles, CA 90024.

GCCR in immune glands may be involved in hormone-modulated effects of stress on immune responsiveness. The effects of daily handling on thymocyte (TC) and splenocyte (SC) proliferative responses to in vitro mitogen challenge and GCCRs were studied in relation to endogenous plasma hormone levels. Male (M) and estrus female (F) Sprague-Dawley rats were either handled (H) 10-min daily for 20 days (n=3) or unhandled (UH) (n=3) prior to sacrifice on day 80. Significant SEX x HANDLING interactions were found for TC but not SC responses to concanavalin A (CON A), TC- and SC-GCCR, and testosterone (T) levels [TC-GCCR & TC-CON A: UHM > HM or UHF; TC-GCCR: HF > UHF or HM; SC-GCCR: UHF < HF or UHM; T: HM > UHM & UHF > HF]. Handling decreased plasma corticosterone (C) and progesterone (P) levels [C: HF < UHF; P: HM&F < UHM&F]. UH M and F exhibited significant negative relationships between C or P and TC-CON A, TC-GCCR and SC-GCCR, while T correlations were positive. Handling abolished these relationships and reversed T vs TC-GCCR. TC-CON A was positively related to TC-GCCR in UH, but not H, M and F. These results implicate hormone changes in handling effects on GCCR and immunoreactivity. (Supported by NIH HD07228 & HD01182 & VA Medical Res.)

476.10

CORTICOSTERONE RESPONSES TO INTERLEUKIN-1 AND RESTRAINT IN RATS LESIONED WITH 6-HYDROXYDOPAMINE
H. Eduardo Chuluyan*, Adrian J. Dunn and David Saphier.
Dept. of Pharmacology and Therapeutics, Louisiana State University Medical Center, Shreveport, Louisiana 71130-3932.

Stress and immune activation are associated with increases in plasma concentrations of corticosterone (CS). To determine whether this phenomenon is affected by catecholaminergic innervation of neurons in the hypothalamic paraventricular nucleus (PVN), selective lesions were made, using 6-hydroxydopamine (6-OHDA). Injection of 6-OHDA into the PVN depleted norepinephrine (NE) by 75% and significantly inhibited the increase in CS after human interleukin-1α (hIL-1α 0.5 μg/rat i.p.). The lesions did not affect the adrenocortical response to 20 min restraint. Injection of 6-OHDA into the ventral noradrenergic ascending bundle depleted the hypothalamus of NE to a similar extent. This lesion also attenuated the CS response to hIL-1α, but did not alter that to restraint. These results indicate that the IL-1-induced increases in plasma CS concentrations depend at least partly on catecholaminergic innervation of the PVN, whereas non-catecholaminergic pathways participate in activation of the hypothalamo-pituitary-adrenal axis associated with restraint.

ALTERATIONS OF CENTRAL CATECHOLAMINES ASSOCIATED WITH PRIMARY AND SECONDARY IMMUNOLOGICAL CHALLENGE. S. Zalcman, N. Shanks, Z. Merali and H. Anisman. Departments of Psychology, Carleton Univ. and Univ. of Ottawa, Ottawa, Canada.

Central catecholamine variations in CD-1 mice were assessed after primary and secondary inoculation with sheep red blood cells (SRBC; 10^6 cells, ip). At the time of the peak primary and secondary immune responses (4 and 2 days post-immunization, respectively), increased dorsal bundle norepinephrine (NE) utilization was evident. Moreover, like stressors, antigenic challenge provoked variations of mesocorticolimbic but not nigrostriatal dopamine (DA). While the catecholamine changes associated with the primary response were only evident on the day of the peak response, the effects associated with the secondary response persisted for several days. Further studies using in vivo microdialysis in Sprague-Dawley rats confirmed the increased DA release in the nucleus accumbens associated with primary SRBC inoculation. However, this release occurred earlier than that detected in mice using HPLC determinations. These data are consistent with the proposition that the immune system acts as a sensory organ and that the immune response may be interpreted as a stressor leading to central catecholamine alterations.

476.12

TIME-DEPENDENT VARIATIONS OF SELF STIMULATION FROM THE NUCLEUS ACCUMBENS FOLLOWING ANTIGEN ADMINISTRATION. G. MacNeil, S. Zalcman, R. Zacharko and H. Anisman. Dept. of Psychol., Carleton Univ., Canada.

Central nervous system activity may influence immune functioning, and conversely immune activation may affect central neurotransmitter activity. Administration of sheep red blood cells (SRBC), for instance, provokes brain region-specific alterations of norepinephrine and dopamine activity at a time which coincides with the peak immune response. The antigen-induced neurochemical changes were reminiscent of those induced by stressors. The present investigation demonstrated that in CD-1 mice SRBC (10^6) inoculation, like stressor exposure, disrupted self-stimulation responding from the nucleus accumbens, coincident with the peak immune response. That is, self-stimulation was unaffected either immediately, 1 or 2 days after inoculation, but was markedly reduced 3 or 4 days after immunization. These data suggest a functional relationship between the immune system response and central neurotransmitter activity. Essentially, it is thought that immune responses are interpreted as stressors, ultimately leading to variations of central catecholamine activity, hence provoking an anhedonia.

476.13

δ– AND κ–, BUT NOT μ–, SELECTIVE OPIOID AGONISTS INHIBIT SYMPATHETIC POST-GANGLIONIC NEURON–DEPENDENT PLASMA EXTRAVASATION IN KNEE JOINT OF THE RAT.

Paul G. Green and Jon D. Levine* *Depts. of Medicine and Oral Surgery and Division of Neurosciences, UCSF, Box 0452A, San Francisco, CA94143.*

Plasma extravasation (PE) was induced in the knee joint of the rat by local infusion of either bradykinin (BK) (160 ng/ml), an inflammatory mediator produced at sites of tissue injury, or capsaicin (5 mg/ml). BK–induced PE is dependent on the sympathetic postganglionic neuron (SPGN), whereas capsaicin–induced PE is dependent on primary afferent neurons and the SPGN. When selective δ– (DPDPE) (10 μM), or κ– (U50,488H) (10 μM) opioid agonists were co-infused, BK–PE was significantly attenuated, and this attenuation was reversed by co-infusion of naloxone (1 μM). In contrast, co-infusion of a selective μ–opioid agonist (DAMGO) (10 μM) did not reduce the PE induced by bradykinin. In contrast, DAMGO, was able to block the PE produced by capsaicin. These results suggest that the inhibition of neurogenic PE by opioids is dependent on the specific opioid receptor subtype and the relative contribution of unmyelinated afferent and SPGN terminals: δ– and κ–selective opioid agonists inhibit SPGN-dependent PE and μ–selective opioid agonist inhibits primary afferent but not SPGN–dependent PE. *Supported by NIH grant AM32634*

HEART RATE LEVEL, HEART RATE VARIABILITY, AND SPECIFIC ANTIBODY RESPONSE IN FREE-RANGING RHESUS MACAQUES. M. L. Laudenslager, K.L. Rasmussen*, and S. Suomi. Univ. Co. Hlt. Sci. Ctr., Behavioral Immunology Laboratory and NIH/NICHD, Laboratory for Comparative Ethology.

The immune response may be influenced by a number of behavioral factors, mediated through two possible routes, circulating hormonal factors and direct autonomic innervation of lymphoid tissue. The present study related measures of autonomic reactivity to the appearance of tetanus toxoid (TT) specific IgM and IgG appearing in the plasma following TT immunization of juvenile Rhesus macaques free-ranging on the island of Cayo Santiago, P.R. Eleven subjects, 250-377 days old, were captured and briefly fitted with telemetry devices for unrestrained monitoring of EKG. A blood sample was obtained from each subject prior to immunization with TT on the day of release. After 10-15 days, subjects were recaptured and a second blood sample was obtained for the determination of plasma IgM and IgG specific to TT by an ELISA. A strong relationship between IgG levels and heart rate ($r=.86$, $p=.003$) and heart rate variability ($r=-.79$, $p=012$) was noted. Plasma cortisol levels measured 24 hr following the first capture prior to immunization were not related to TT antibodies. (Supported in part by NIH Research Grant MH37373)

GENETIC DIFFERENCES IN SOCIAL BEHAVIOR: RELATION TO CANCER SUSCEPTIBILITY AND NK CELL FUNCTION

J.M. Petitto*, D.T. Lysle, J.-L. Gariepy*, R.B. Cairns*, M.H. Lewis. Brain and Development Research Center, Depts. of Psychiatry and Psychology, University of North Carolina, Chapel Hill, N.C. 27599.

Much of the psychoneuroimmunology literature has focused on understanding how various social and non-social "states" can influence aspects of immune function. Despite considerable theorizing about the relationship of personality variables to disease susceptibility (e.g., cancer), few studies have related immune function to gentically-determined individual differences that are stable across development ("traits"). We studied the 23rd generation (S_{23}) of ICR mice selectively bred for high and low levels of aggression. The high aggressive line (NC900) shows rapid and repeated attack following social isolation, with little variability observed across generations. Conversely, low aggressive mice (NC100) have departed substantially from the foundational stock (S_0), exhibiting high levels of freezing ("timidity") in response to social contact. This robust and reliable line difference appears to be correlated with differences in midbrain dopamine function. We hypothesized that the genetic differences in social behavior observed in NC100 mice would correlate with increased vulnerability to cancer development and reduced natural killer (NK) cell function. To test these hypotheses we assessed 3-methylcholanthrene-induced tumor development and splenic NK cell activity in the NC900 and NC100 lines. Only 44% of the NC900 mice developed tumors, whereas all NC100 mice had palpable neoplasms. Additionally, baseline NK activity was significantly lower in socially inhibited (NC100) mice versus aggressive (NC900) mice. Conversely, no baseline differences in NK activity were found between NC900 and non-selected, socially isolated mice (NC 600). These latter data complement existing behavioral evidence supporting the unidirectional outcome of the selective breeding program. Our data support the hypothesis that genetic ("trait") differences in social behavior may predict differences in disease susceptibility and immune function. Integration of future neurobiological and immunological findings using this mouse model may provide important information concerning mechanisms of brain-immune interactions. (Supported by the Foundation of Hope and MH45371)

476.16

BEHAVIORAL DIFFERENCES IN LEW/N AND F344/N RATS.

J. R. Glowa. Clin. Neuroendo. Br., NIMH, Bethesda, MD 20892

Recently several differences in the neuroendocrine response to inflammatory mediators have been characterized between F344/N and LEW/N rats. These differences are important because they are related with the differential susceptibility to arthritis across these strains. Previous studies have indicated that this susceptibility appears to be mediated by a deficiency in central corticotropin releasing hormone (CRH) biosynthesis or secretion, and is reflected by a difference in hypothalamic-pituitary-adrenal response during stress in these strains. We have also shown that the LEW/N rat hyperresponds to acoustic startle stimuli whereas the F344/N rat hyporesponds, compared to Sprague-Dawley rats. Consistent with previous studies using various stressors, the F344/N rats exhibit an exaggerated corticosterone response to startle stimuli while the LEW/N rats do not. The current studies sought to further characterize potential behavioral differences in these strains. LEW/N rats consistently ambulate less than F344/N rats in an open field, with the ratio of time spent in inner, as opposed to outer, portions of the field being approximately 0.1 for the LEW/N and 0.4 for the F344/N rats. CRH decreased ambulation in both strains, but did not alter this ratio in either strain. In contrast, LEW/N rats entered the open arms of an elevated plus maze more often than F344/N rats, but the time spent per entry was the same for both strains. These results demonstrate that these strains differ in baseline response on several behavioral measures of response to noxious environmental influences, substantiating the useful ness of behavioral markers for neuroimmunological disease.

BEHAVIORAL EFFECTS OF REPEATED INJECTION OF INTERFERON-α A/D IN BALB/C MICE. L.S. Crnic and A.L. Dunn*. University of Colorado School of Medicine, Denver, CO 80262.

The hybrid recombinant interferon α-A/D (a gift of Hoffman-La Roche) has antiviral activity and produces liver P-450 depression in mice (Renton et al, 1984) but behavioral effects are unknown. Measures of activity (open field), depression (tail hang), muscle strength (forelimb grip strength) and motor ability (swim posture and endurance with 0%, 3%, and 6% added body weight) were examined in BALB/c mice exposed to 1600 U/g of IFN-α-A/D daily for 5 days (n = 9) or to the IFN vehicle (n = 11). Behavior was tested on each day, except for swimming which was tested on day five.

Open field activity was significantly depressed on all days of testing in the group exposed to IFN ($p < 0.02$). The number of times the head dipped under the water when swimming with 3% added body weight was higher in the IFN treated mice (24.1 vs 8.9, $p < 0.025$). Thus, this human hybrid IFN is behaviorally active in mice. Depression of motor activity is a general effect as seen both in this study and in our prior study with acute doses of non-recombinant mouse IFN-α (Lee BioMolecular, Segall and Crnic, 1990). The generality of the effect is seen across different activity measures in these two studies. Further, swim endurance is depressed by IFN. Supported by grants MH00621, HD04024, and MH15442.

SECOND-ORDER AND SENSORY PRECONDITIONING OF IMMUNOSUPPRESSION: EVIDENCE FOR COGNITIVE CONTROL. B.J. Kucinski, J.E. Cunnick, and H. Fowler*. Dept. of Psychology and Pathology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Two experiments evaluated the effects of higher-order conditioning on immune function. In the first, rats were given pairings of stimulus A and shock and then pairings of stimulus B and A but without shock. Control subjects received the same except that B and A were unpaired. After a recovery period, different groups received exposure to A, the paired B (B+), the unpaired B (B-), the training context (X), or no treatment (N) just before sacrifice. Mitogen-stimulation assays of lymphocytes from the spleen and blood and an NK cell assay of splenocytes showed comparably pronounced immune suppression for the A and B+ groups, relative to the B-, X , and N groups, attesting to a second-order effect for B+. These results suggest that immune function is affected by psychological forms of stress that derive from a cognitive processing of events; i.e., B+ implies A and A implies shock. To corroborate this, we conducted a second experiment on sensory preconditioning. That study duplicated the first except that pairings (or unpairings) of B and A occurred prior to pairings of A and shock, so as to preclude association of B+ and A's suppressive effect. In evidence of cognitive control, the results showed comparably pronounced immune suppression for the A and B+ groups, relative to the rest, establishing that "worrisome" thoughts about something, even remote, profoundly affect immune function.

CLINICAL AND IMMUNOLOGICAL CORRELATES OF ANTI-HIPPOCAMPAL IGG ANTIBODIES IN SCHIZOPHRENIA. K.N. Roy Chengappa, R. Ganguli, L. Wechsler and B.S. Rabin, Immunopsychiatry Program, Western Psychiatric Institute and Clinic, Pittsburgh PA 15213

Raised hippocampal autoantibody levels may occur in a subgroup of schizophrenics characterized by negative symptoms, low IL-2 production and the presence of non-CNS autoantibodies. Using an enzyme immunoassay (ELISA), we tested for IgG autoantibodies to human hippocampus in 99 RDC schizophrenic patients and 81 normal controls matched for age and the presence of autoantibodies to non-CNS antigens. Anti-hippocampal antibody levels were correlated with the severity of positive and negative symptoms, duration of illness and Interleukin-2 (IL-2) production. First episode subjects had lower hippocampal autoantibody concentrations than other patients ($p=0.01$). Acutely ill patients with non-CNS autoantibodies had higher anti-hippocampal antibody levels ($p=0.02$). Negative symptoms were significantly correlated with anti-hippocampal antibody levels in remitted patients ($r=0.44$, $p=0.016$). Patients with anti-hippocampal antibody levels above the 75th percentile had the lowest IL-2 production ($p=0.029$).

IMMUNE COMPETENCE INFLUENCES SLEEP AFTER MICROBIAL CHALLENGE. L.A. Toth and J.M. Krueger. Univ. Tennessee, Memphis, TN 38163.

To evaluate the role of the immune system in mediating the somnogenic effects of infectious disease (FASEB J 3:2062, 1989), we monitored sleep after Candida albicans (CA) infection in rabbits with altered immune competence. Immune function was enhanced by immunization with killed CA or injection of incomplete Freund's adjuvant (IFA; 0.25 ml/kg SQ), or was suppressed by injection of cortisone (40 mg/kg IM) or cyclosporin (25 mg/kg SQ). Cortisone markedly attenuated the fever, increased slow-wave sleep, increased delta-wave amplitude during sleep and acute phase responses that were induced by CA alone. Other regimens were ineffective. Theta-wave amplitude during wakefulness decreased slightly after CA alone and markedly after CA with IFA, but increased after CA with cortisone, cyclosporin or immunization. We conclude that the somnogenic effects of infectious challenge can be altered by manipulation of the immune system. Supported by NS-26429 and NS-25378.

ANOREXIC EFFECTS OF INTERLEUKIN-1 (IL-1) ARE MEDIATED PERIPHERALLY. S. KENT, K.W. KELLEY* and R. DANTZER*. INSERM U.176, rue Camille Saint-Saëns, 33077 Bordeaux Cédex, France (SK and RD); Dept. of Animal Sciences, Univ. of Illinois, Urbana, IL 61801 (KWK).

IL-1 is a cytokine that is released by activated macrophages and monocytes and mediates many of the local and systemic responses to inflammation. Although both peripheral and central injections of IL-1 produce anorexia, it isn't clear whether this effect is mediated peripherally, centrally, or both. Recently, a specific antagonist for the IL-1 type 1 receptor has been characterized and cloned (IL-1ra; Synergen, Boulder, CO). We have used this protein to determine the site of action for the effects of IL-1 on feeding. Male rats were food restricted and trained on an operant schedule (FR10) for food reinforcement. Rats were tested for 5 min before injection of recombinant human IL-1β (Glaxo, Geneva; 4 µg ip or 40 ng icv)) and then retested 1, 2, 4, 8, and 24 h later. Both ip and icv injections produced profound decreases in responding, with maximal effects 2-4 h post-injection. IL-1ra pretreatment (8 mg/kg ip or 80 µg/kg icv) completely blocked these effects when administered by the same route. In contrast, icv IL-1ra was unable to block the anorexic effects of ip IL-1. IL-1ra had no effects by itself. These results are in agreement with previous suggestions that the anorexic effects of IL-1 are mediated peripherally.

EFFERENT PROJECTIONS FROM THE LATERAL PARABRACHIAL NUCLEUS AS DEMONSTRATED BY PHA-L. RM Slugg and AR Light. Dept. of Physiology, UNC-Chapel Hill, Chapel Hill, NC 27599.

To determine the projection sites of nocireceptive and thermoreceptive neurons, discrete injections of PHAL were placed in PBL following the recording of unit activity from the injection micropipette. These injections indicated the presence of two major ascending pathways. 1) The medial pathway branched at the pontomesencephalic junction and coursed bilaterally along the ventrolateral edge of the central gray. This pathway projected heaviest bilaterally into the ventrolateral PAG immediately rostral to the injection site. The parent axon then ascended rostrally into the central gray matter and split into two pathways, one which continued rostrally and gave rise to numerous terminations in the midline thalamic nuclei. The other turned ventrally and terminated densely in the ventromedial hypothalamus, but was observed only from injections confined to the lateral half of PBL. 2) The lateral pathway was ipsilateral only and ran diffusely through the central tegmental tract with occasional terminations. These fibers then branched in the rostral half of the lateral hypothalamus, and both terminated heavily in this region and also crossed the ansa peduncularis to enter the amygdala where terminations were observed equally in the central and medial nuclei. Supported by grants PHS DA04420 and NS16433.

477.2

DISTRIBUTION OF NEUROTENSIN-LIKE IMMUNOREACTIVITY IN THE CAT'S BRAINSTEM AND THALAMUS.

D. Harder, C. Vahle-Hinz and K.-D. Kniffki. Physiologisches Institut, Universität Würzburg, D-8700 Würzburg, Germany.

To further characterize the diencephalic regions involved in nociception the neuropeptide content of the thalamus and its afferent systems were studied in the cat. Neurotensin (NT) has been associated in the rat with visceral sensory pathways, probably including systems involved in nociception.

Deeply anesthetized adult cats were perfused transcardially with 4% paraformaldehyde and 0.2% picric acid. Serial frontal sections were reacted with an antibody against NT (Incstar, 1:6000) using the peroxidase-antiperoxidase (PAP) method (2nd antibody: goat-anti-rabbit, Dakopatts; 3rd antibody: PAP complex, Dakopatts).

Several regions with different densities of NT-like immunoreactive (NT-LI) fibers were found in the brainstem and the thalamus. Dense staining was seen in all parts of the parabrachial n. (PB), the n. coeruleus and the periaqueductal gray of the brainstem as well as in the hypothalamus, whereas moderate staining was observed in the n. of the solitary tract (NTS), the marginal layer of the caudal n. of the spinal trigeminal complex and the principal trigeminal n. At the thalamic level moderate immunoreactivity was present in the habenula and in a region extending from the subparafascicular n. to the midline, apparently including parts of the principal ventromedial n. and the dorsal hypothalamus. In addition, scattered NT-LI fibers were found in the oral n. of the spinal trigeminal complex and in all tegmental fields of the brainstem and in the thalamus within the external medullary lamina ventral of the ventrobasal complex, the mediodorsal n. (MD), the fields of forel and the zona incerta.

The results indicate that NT might play a role in the transmission of visceral and possibly nociceptive information in the cat, since NT-LI fibers were observed in the NTS (medulla), the PB (pons) and the MD (thalamus).

RECIPROCAL CONNECTIONS BETWEEN THE MEDIAL PREOPTIC AREA (MPO) AND THE VENTRAL MEDULLA: A WGA-HRP AND PHA-L STUDY. Tilat A Rizvi, M Ennis, M T Shipley and M.M. Behbehani. Depts. Anatomy & Physiology. Univ. Cincinnati. Coll. Med., Cincinnati, OH 45267.

Anatomical studies suggest that the MPO and ventral medulla are interconnected. Here, we report on the organization of reciprocal connections linking these basal forebrain and brainstem structures.

WGA-HRP injections into MPO retrogradely labeled numerous neurons in the ventrolateral medulla (VLM) and the midline portion of nucleus raphe magnus (NRM). Both WGA-HRP and PHA-L injections in MPO resulted in dense anterograde labeling throughout NRM; less dense anterograde labeling was also present in VLM. Retrograde tracer injections in NRM produced intense retrograde labeling in median preoptic nucleus (MePO) and MPO. Rostrally, in MPO the majority of labeled cells were located medially; caudally retrograde labeling was concentrated in the more lateral cells. MPO also contained heavy anterograde labeling after WGA-HRP injections in NRM.

The present findings suggest that connections between MPO and ventral medulla are reciprocal but are organized in an asymmetrical fashion: NRM receives heavy inputs from MPO while there is a more moderate projection from MPO to VLM. On the other hand, VLM appears to project more heavily to MPO than does the NRM. These two asymmetrically organized circuits might function to coordinate antinociception and autonomic activity during stereotyped sexual behaviors. (PHS Grants NS20643, NS24698, HL08097).

ROLE OF NEUROTENSIN NEURONS FROM THE PAG TO THE NRM IN THE RESPONSE TO OPIATE ADMINISTRATION IN THE PAG. M.O.Urban* and D.J.Smith.Anesth. & Pharmacol., WVU-HSC, Morgantown, WV 26506

Some neuronal processes from the periaqueductal gray (PAG) to the nucleus raphe magnus (NRM) contain the tridecapeptide neurotensin (Beitz,J.Neurosci.2:892,1982). When the peptide is injected into the NRM, a dose dependent antinociceptive effect is observed as an increase in tail-flick latency (TFL). Since the NRM functions as a relay involved in opiate effects from the PAG, the role of neurotensin in this relay was studied.

Male Sprague-Dawley rats fitted with guide cannulas over both the PAG and NRM were used. Microinjection of neurotensin into the NRM produces a dose-dependent increase in TF latency with an EC 50 of about 6 nmol. The partial agonist [D-Trp-11]-neurotensin (Quirion et al.,EuropJ.Pharmacol.61:309,1980), at a dose of 3 pmol, antagonized the effect of neurotensin when injected sequentially.

β-endorphin (10 nmol) injected into the PAG produced an antinociceptive response that was inhibited by the injection of the antagonist into the NRM. In contrast, the response to morphine (6 nmol) was potentiated by the antagonist. These results suggest that there may be more than one functional type of neurotensin neuronal projection from the PAG to the NRM.

A HIGH THRESHOLD VENTROBASAL THALAMIC POTENTIAL ATTENUATED SPECIFICALLY BY ANALGESIC DOSES OF MORPHINE OR COCAINE. J.A. Kiritsy-Roy, T.J. Morrow and K.L. Casey, Depts. of Neurology and Physiology, Univ. of Michigan and Neurol. Res. Labs., VA Med. Center, Ann Arbor, MI 48105.

Previous studies have analyzed rostrally projecting pain pathways by recording from antidromically identified spinothalamic/spinoreticular tract cells in the spinal cord. We wish to study the neurophysiology and neuropharmacology of supraspinal mechanisms activated by these extralemniscal (EL) pathways. Accordingly, we are developing a model for the study of pain pathways using orthodromic activation of the EL system and its target cells in the thalamus. Studies were undertaken to identify and characterize thalamic field potentials evoked by noxious stimulation in the hindpaw region of the chloral hydrate anesthetized rat (n=15). Slow wave activity evoked by electrical stimulation of the hindlimb was recorded in the ventral posterior thalamus. An evoked potential averaged over 32 stimuli consisted of four components: a negative peak at 11.7±0.4 msec (N12), a positive peak at 23.2±1.2 msec (P23), a negative peak at 50.9±2.2 msec (N51) and a positive peak at 93±3.5 msec (P93). Lesions of the dorsal columns at approximately T6 reduced the amplitude of the N12-P23 complex whereas lesions of the ventral spinal cord (EL pathways) attenuated the amplitude of the N51-P93 components. The lemniscal potential was highly somatotopic, but the EL components were not. The threshold for activation of the EL potentials was 3 to 4 times higher than for the lemniscal potentials. Morphine (1.5-18 mg/kg i.v.) or cocaine (1-4 mg/kg i.v.) produced dose-related suppression of N51-P93 amplitude with little or no effect on the lemniscal components. The effect of morphine was antagonized by naloxone (0.8 mg/kg i.v.).

This ventrobasal thalamic EL potential has physiological and pharmacological characteristics suggesting its' use as a measure of activity in ascending nociceptive systems. (Supported by grants from the Dept. of Veterans Affairs and Bristol-Meyers Squibb)

ULTRASTRUCTURAL FEATURES OF SPINAL CORD AFFERENTS TO THE INTRALAMINAR AREA OF THE CAT THALAMUS. I.A. Ilinsky[1], R.G. Mackel[2], E. Miyashita[2] and K. Kultas-Ilinsky[1]. [1]Department of Anatomy, University of Iowa College of Medicine, Iowa City, IA, 52242, [2]Rockefeller University, New York, NY 10021.

Topographical distribution of spinothalamic fibers has been investigated in many light microscopic studies (see review by Craig and Burton, Exp. Brain Res. 58:227-254, 1985) which agree that the intralaminar, submedian, posterior complex, ventral posterior and ventral lateral nuclei represent the major domains of spinothalamic projections. Unlike medial lemniscal projections, spinothalamic afferents cluster around motor cortex-projecting neurons in the ventral lateral (VL) and intralaminar (CLn) nuclei (Hirai and Jones, Exp. Brain Res. 71:32-344, 1988). Significantly less is known in regard to fine structural features of their terminals, particularly in the VL and CLn. This study was aimed on identification of spinothalamic boutons in the intralaminar region of the cat thalamus. Multiple injections of a mixture of 10% HRP and 7% WGA-HRP in 2% DMSO were placed bilaterally at C_3-C_5 level of the spinal cord in two adult cats. Anterograde labeling was observed in thin fibers which formed varying density terminal plexuses in the posterior complex, CLn, and VL. However, the densest zone of labeling in both cases was in the postero-medial intralaminar region where CLn borders the parafascicular and mediodorsal nuclei. For ultrastructural analysis, this zone was sampled from serial vibratome sections processed for HRP histochemistry with TMB at pH 6.0 and stabilized with OsO_4. Spinothalamic boutons labeled with HRP were of LR type (large boutons filled with round vesicles) which formed multiple asymmetric synaptic contacts on distal dendrites of projection neurons and vesicle-containing dendrites of local circuit neurons. Occasionally labeled boutons were apposing somata of small cells, however, no synaptic contacts have yet been observed. The majority of the labeled boutons in this thalamic region were a part of glomeruli. Supported by RO1NS24188 and RO1NS26288.

ULTRASTRUCTURE OF LAMINA I TERMINALS IN NUCLEUS SUBMEDIUS OF THE CAT. A. Blomqvist, A.-C. Ericson*, J. Broman and A.D. Craig. Dept of Cell Biology, University of Linköping, S-581 85 Linköping, Sweden, and Division of Neurobiology, Barrow Neurological Institute, Phoenix, Arizona 85013, U.S.A.

Previous anatomical studies have demonstrated that the nucleus submedius (Sm) is a specific lamina I termination site in the medial thalamus. In the present study, the ultrastructure and synaptic organization of the lamina I terminals in Sm were examined. *Phaseolus vulgaris* leucoagglutinin (PHAL) was injected into lamina I at different spinal levels. PHAL-containing axon terminals in Sm were demonstrated with the peroxidase-antiperoxidase method and analyzed in the electron microscope. Labeled terminal boutons packed with round synaptic vesicles were seen in synaptic contact with dendritic profiles that presumably originate from thalamocortical relay cells. Synaptic contacts were also seen with presynaptic dendrites that in turn synapsed with relay cell dendrites. Examination of serial sections suggests that such serial synapses exist both independently and in the triadic arrangement typical of thalamic sensory relay nuclei. Complex synaptic aggregations in which a relay cell dendrite received inputs from several lamina I afferent terminals and presynaptic dendrites were found. These results suggest that processing of lamina I spinothalamic input to Sm involves afferent inhibition, probably via GABAergic interneurons.

Supported by grants from the NIH and the Swedish Medical Research Council.

RESPONSES OF RAT NUCLEUS SUBMEDIUS (Sm) NEURONS TO NOXIOUS THERMAL, CHEMICAL AND ELECTRICAL STIMULATION. J.S.Tang*, C.Y.Chiang and J.O.Dostrovsky, Dept. of Physiology, Univ. of Toronto, Toronto, Ontario M5S 1A8, Canada

Recent studies have suggested that Sm may be an important thalamic relay for nociceptive information. The present study investigated the effects of thermal, chemical and electrical stimulation on Sm neurons in urethane/chloralose anesthetized rats. Noxious but not innocuous mechanical stimulation induced responses in 67 of the 86 neurons studied that were histologically verified to be in Sm. Most of these neurons could also be activated by noxious heating (mean threshold 47.6 $\pm$0.4^{o}C), but in many cases the responses to increasing temperatures were not well graded. Many of these neurons were also excited or their response to cutaneous stimulation facilitated by subcutaneous, intramuscular or intraperitoneal injection of 2.5% formalin or hypertonic saline (0.1-0.2 ml). Thirty-eight of 49 Sm neurons tested could be activated by intense electrical stimulation (15-25ms 200 Hz trains, 3 ms pulse duration, 5-10 mA/ 3 s) of tail, paw and vibrissal pad. The latency of the responses ranged from 20 to 500 ms (mean 174$\pm$27 ms, S.E.M.). The conduction velocities of the primary afferents eliciting the responses were estimated for 8 cells by comparing the latencies of the Sm neuron responses to stimulation of the tail at distal and proximal sites and found to range from 0.8 to 33 m/s. The Sm neuron responses to electrical stimulation often appeared only after repetitive train stimulation, and then showed "wind-up", suggesting a polysynaptic pathway to Sm. The response characteristics of the Sm neurons revealed in this study support the hypothesis that Sm may be involved in mediating the affective-motivational aspects of pain. (Supported by NIH)

NOXIOUS HEAT AND INNOCUOUS COLD PERCEPTION IN MONKEY AFTER INJECTION OF LIDOCAINE INTO THE VPM THALAMIC NUCLEUS. M.C. Bushnell, J.L. Oliveras, N. Bastrash, N. Tremblay, and G.H. Duncan. Fac. Médecine dentaire, Univ. Montréal, Québec, Canada H3C 3J7.

In thalamus, information about pain and innocuous cold is transmitted to the ventroposterior nuclei (VPL and VPM) and to more medial nuclei, such as submedius. The present study evaluates the role of VPM in facial pain and temperature perception, by determining the effect of transient inactivation of VPM on a monkey's detection of changes in intensity of noxious heat and innocuous cold.

Two rhesus monkeys were trained to detect small differences in the intensity of a white light and of noxious heat (near 46°C) and innocuous cold (near 30°C) applied to the facial maxilla. Single cell recordings identified regions within VPM responding to noxious heat and/or cooling. Lidocaine hydrochloride 2% (1.0-5.0µl) was injected into VPM, and the monkey's ability to detect near-threshold changes in stimulus intensity was compared before and after each injection.

In three instances single injections of 1.0-4.0µl lidocaine into caudal VPM were confirmed to block the activity of neurons recorded 2mm from the injection site, but produced no decrement in the monkey's detection ability. Three similar injections, for which neuronal deactivation was not electrophysiologically confirmed, also did not alter thermal detection. However, when two injections were made simultaneously through cannulae separated by 1mm in the AP direction, there was a profound decrease in the monkey's ability to detect intensity changes in noxious heat and a lesser decrease for cold. Nevertheless, electrode recordings showed that these large injections did not deactivate neurons in more medial thalamic nuclei.

These data suggest that VPM plays an important role in thermal perception. However, it appears that deactivation must occur through a large AP extent of VPM to disrupt thermal discrimination, possibly because of overlapping receptive fields along the anteroposterior plane. [Supported by the Canadian MRC.]

SPINOTHALAMIC (STT) ACTIVATION OF PRIMATE THALAMIC NEURONS IS NOT MODULATED BY GABAERGIC LOCAL CIRCUIT NEURONS. H.J.Ralston, III, A.M. Milroy and D.D.Ralston, Department of Anatomy, University of California, San Francisco, California, 94143

We have examined several hundred labeled STT terminals in macaque monkeys and have contrasted their synaptic interactions with those made by labeled medial lemniscal (ML) terminals. Anesthetized monkeys received microinjections (0.02-0.04µl) of wheatgerm agglutinin horseradish peroxidase (WGA-HRP) into the dorsal horn of the cervical or lumbar enlargements or into the dorsal column nuclei. Following appropriate survival times, the animals were reanesthetized, perfused with aldehydes and thalamic nuclei (VPLc and SG/PO) processed for the light and electron microscopic demonstration of HRP reaction product and GABA immunoreactivity. STT and ML terminals share a similar morphology, being large (approximately 4 µm in diameter) with abundant, rounded synaptic vesicles and numerous mitochondria. ML terminals contact dendritic shafts of projection neurons and, in more than 95% of cases, the GABAergic appendages of local circuit neurons (LCN) which in turn contact the projection cell dendrite to form a triadic relationship and presumably mediate feed forward inhibition. In contrast, STT terminals form axodendritic synapses with projection neurons but rarely (<10% of cases) contact GABAergic LCN's. We conclude that the excitation of thalamic neurons by STT axons, many of which convey noxious information, is rarely subject to GABAergic modulation by thalamic LCN's. THE TRIGEMINO-PONTO-AMYGDALIAN PATHWAY DEMONSTRATED BY RETROGRADE TRANSNEURONAL TRANSPORT OF PSEUDORABIES VIRUS. L. Jasmin, J.P. Card† and A.I. Basbaum, Dept. Anatomy and Physiology, UCSF, San Francisco, CA 94143 and †Dupont-Merck, Wilmington, DE 19880

Although limbic structures must contribute to the affective component of the pain response, the circuitry through which nociceptive inputs access these forebrain sites is poorly understood. Recently, Bernard et al (1989) used a combined anterograde and retrograde tracing study that implicated a disynaptic spino/trigemino-ponto-amygdalian pathway (STPA) in the transmission of nociceptive messages. We have initiated a parallel series of studies using an alpha herpes virus (pseudorabies) as a retrograde transneuronal tracer to evaluate the spinal cord and brainstem cells which directly or indirectly access several forebrain sites implicated in pain processing. In the present study we describe results after restricted injections (0.2µl) of the virus into the central nucleus of the amygdala of rats. After different survival periods the rats were perfused with 4% paraformaldehyde and 50µm frozen sections through the brain and spinal cord were immunoreacted with an antiserum directed against the entire virion.

The pattern of retrograde labelling after one day was comparable to that reported in previous studies of the afferent connections of the amygdala, including the lateral parabrachial nucleus, locus coeruleus, periaqueductal gray and dorsal raphe nucleus. At two days we found a more extensive pattern of labelling, in many brainstem structures which are not known to project directly to the amygdala. Consistent with there being an STPA pathway, we found large numbers of cells in the superficial layers of the trigeminal nucleus caudalis and in the paratrigeminal nucleus. Many labelled neurons were also located in the subjacent reticular formation, a region that contain cells which express the c-fos proto-oncogene following noxious stimulation. Scattered cells were found in various laminae of the spinal cord (Later time points are being evaluated). Furthermore, by combining the retrograde transneuronal transport of this virus with noxious-stimulus evoked c-fos expression we believe that a better understanding of how nociceptive inputs access specific regions of forebrain can be obtained.

ELECTROPHYSIOLOGICAL EVIDENCE FOR AN INVOLVEMENT OF THE NUCLEUS CENTRALIS OF THE AMYGDALA IN NOCICEPTION. J.F. BERNARD, G.F. HUANG* and J.M. BESSON. Unité de Recherches de Physiopharmacologie du système Nerveux, INSERM U 161, 2 rue d'Alésia F-75014 PARIS, FRANCE.

On the basis of anatomical investigations, we have suggested (Bernard et al., Neurosci. lett., 1989, 100:83-88) that a spino-ponto(parabrachial area)-amygdaloid pathway, originating in lamina I of the dorsal horn, could play an important role in pain processes. This was confirmed by the demonstration that a high proportion of neurons located in the external parabrachial (PBe) area (i.e. external lateral (PBel) and external medial (PBem) subnuclei) and that projected to the nucleus centralis of the amygdala (Ce) was exclusively driven by noxious stimuli. The aim of the present study was to extend our investigation at the level of the Ce. Neurons were recorded in and around the Ce using extracellular micropipettes, in anesthetized rats. The units (n=177) were characterized by their responses to innocuous and noxious natural (mechanical and thermal) and transcutaneous electrical stimuli. A large proportion (80%) of Ce neurons responded exclusively or preferentially to noxious stimuli, either by an excitation (46%) or by an inhibition (34%). The receptive field of both groups of neurons was very large (in most cases all parts of the body). A majority (53%) of neurons responding to noxious stimuli were exclusively and stongly driven by noxious mechanical and thermal stimuli. Transcutaneous electrical stimulation revealed that these latter neurons were driven by Aδ and C fibers. The excited as well as the inhibited neurons exhibited a clear capacity to encode thermal stimuli in the noxious range with a mean threshold between 44 and 45°C. The response of nociceptive excited neurons were depressed by systemic morphine in a dose-related and naloxone-reversible fashion. Thus these results support the conclusion that Ce neurons are involved in nociceptive processes. According to previous study (Bernard and Besson, J. Neurophysiol., 1990, 63:473-490) the spino-parabrachial pathway seems likely to be the major source of nociceptive inputs to Ce.

IS THERE A NOCICEPTIVE AREA IN SII ? EVIDENCE FROM LASER EVOKED POTENTIALS IN HUMANS.

V.Kunde*, R.-D.Treede* (SPON:ENA) Institute of Physiology, University Hospital Eppendorf, D-2000 Hamburg 20, FRG.

In a previous study (EEG J 70, 1988, 429-441), we first found a mid-latency component of the laser evoked potential that projected to the somatosensory cortex. We now describe the scalp topography of this N1 in detail and distinguish it from the vertex potential (N2).

CO_2-laser heat stimuli (15 W, 20 ms, 5 mm beam diameter) where applied to the dorsum of the left hand in 15 subjects. The EEG was recorded from 15 leads, distributed over the whole scalp (bandpass 0.33-200 Hz, linked earlobes reference).

The laser evoked potential began at 140 ms after stimulus onset, with a negativity in contralateral posterior temporal leads (N1). At 170 ms it was significantly larger contra- than ipsilateral to the stimulus (T4 vs. T3). Simultaneously with this posterior temporal negativity, a significant positivity appeared in frontal midline leads. The vertex potential began at about 200 ms and reached its maximum scalp negativity (N2) at 240 ms in the lead FCz. There was no concurrent localized positivity.

The N1 may reflect activity of a tangential generator in or near SII. After electrical nerve stimulation (radial or median nerve) no potential with such a lateral localization could be identified. The N2 topography corresponds to that of other vertex potentials.

PRIMARY SOMATOSENSORY CORTICAL LESIONS REDUCE THE MONKEYS' ABILITY TO DISCRIMINATE AND DETECT NOXIOUS THERMAL STIMULATION. D.R. Kenshalo, Jr., D.A. Thomas, R. Dubner Neurobiology and Anesthesiology Branch, National Institute of Dental Research, NIH, Bethesda, MD 20892

SI was bilaterally ablated in two monkeys (*M. mulatta*) trained to discriminate and detect noxious thermal stimuli in a reaction time paradigm, where speed of detection (1/sec) was measured. The monkeys discriminated differences of 1.0°-4.0°C, and detected 0.2°, 0.4°, 0.6° and 1.0°C temperature increases. SI lesions significantly ($p < 0.05$) reduced discrimination speeds for both monkeys. Twenty-one weeks after the lesions, discrimination performance had not recovered. Deficits were observed on the heat detection tasks. Detection of these stimuli recovered within 21 weeks, with the exception of the 0.4°C detection task in one monkey. The monkeys also detected innocuous cooling (-0.5°C) and visual stimuli in the same paradigm. After the lesions, detection of visual stimuli remained intact and the detection of the cooling stimulus was unimpaired in one monkey and only slightly impaired for a limited time in the other. The lack of clear deficits in the detection of visual and cooling stimuli indicates that the lesions did not significantly affect motoric, attentional or motivational components of the monkeys' behavior. The findings implicate SI in the neural process underlying the discrimination of noxious thermal stimuli.

PAIN MODULATION: PEPTIDES AND EXCITATORY AMINO ACIDS

478.1

EXPERIMENTAL PERIPHERAL NEUROPATHY ENHANCES EXCITATORY AMINO ACID RELEASE IN THE SPINAL CORD FOLLOWING INTRATHECAL SUBSTANCE P, BUT NOT CHEMICAL NOCICEPTIVE STIMULATION. D. H. Harkness, S. R. Skilling and A. A. Larson. Department of Veterinary Biology, University of Minnesota, St. Paul, MN 55108.

Partial sciatic ligation in rats produces a peripheral neuropathy associated with hyperalgesia and allodynia similar to that seen in human neuropathy. The mechanism by which ligation produces these effects is unknown. Based on evidence that excitatory amino acids play a role in nociception at the spinal cord level and that their release is modulated by the nociceptive transmitter substance P (SP), we examined whether sciatic ligation affects amino acid release in the spinal cord in response to chemical nociceptive stimulation or SP.

Partial sciatic ligation or sham surgery of male rats was done using the method of Bennett and Xie. Seven days later, loop dialysis and infusion cannulae were implanted in the lumbar intrathecal space. The CSF of animals was dialyzed and 2 min samples collected before and after the intrathecal injection of 2.5 nmoles of SP or application of 50% mustard oil to the dorsal surface of the hindpaw.

Mustard oil produced a significant release of both Asp, Glu and Tau, however, there was no significant difference in the release between sciatic ligation and sham operated animals. Likewise, the magnitude of the SP-induced release of Glu or Tau was also not altered by ligation. In contrast, SP-induced release of Asp was significantly enhanced by ligation.

These results are consistent with the hypothesis that the neuropathy associated with sciatic ligation is mediated through SP-induced Asp release. This enhanced release of Asp may reflect an up-regulation of SP receptors secondary to a decreased release of SP from primary afferents. Chemogenic pain-induced release of excitatory amino acids is not significantly changed in peripheral neuropathies. Supported by USPHS Grants DA04090, DA00124, DA04190, DA07234 and CA01342)

478.2

NALOXONE AND NEONATAL CAPSAICIN BLOCK NOCICEPTIVE (MUSTARD OIL)-INDUCED RELEASE OF EXCITATORY AMINO ACIDS FROM THE ADULT RAT SPINAL CORD, BUT NOT THE BEHAVIORAL RESPONSE S. R. Skilling, D. H. Harkness and A. A. Larson. Department of Veterinary Biology, University of Minnesota, St. Paul, MN 55108.

Selective activation of the C-terminal substance P (SP) receptor (NK1) using the SP fragment SP(5-11) produces a naloxone-insensitive release of excitatory amino acids (EAAs) in the dorsal lumbar spinal cord. In contrast, the parent molecule SP(1-11) causes a naloxone-sensitive release of EAAs, possibly through activation of N-terminal SP receptors. To determine if either of these SP-induced changes in EAAs plays a role in nociception, we examined the effect of chemogenic pain stimulation (mustard oil) on the release of EAAs in the dorsal spinal cord before and after systemic naloxone or loss of C-fiber afferents produced by neonatal capsaicin.

Vehicle (50% DMSO) and capsaicin (50 mg/kg s.c.) treated male rats were implanted with a microdialysis cannula in the intrathecal space surrounding the lumbar spinal cord. Twelve hours later, animals were dialyzed and 2 min samples collected before and after application of mustard oil.

Mustard oil (50% mustard oil in ethanol applied to the dorsal surface of the hindpaw) produced a behavioral reaction in rats consisting of caudally-directed biting and shaking of the limb, digging of the bedding and attempts to climb out of the cage. Mustard oil also caused a significant release of Asp, Glu and Tau into the CSF. Release, but not behavior, was blocked by either naloxone pretreatment (10 mg/kg i.p. 15 min prior to mustard oil) or neonatal capsaicin. These results are consistent with the hypothesis that nociceptive stimulation produces an N-terminal SP receptor-mediated increase in EAA transmitter release in the spinal cord and that this release does not appear to be involved in the initial sensation of pain but may play a significant role in its later modulation. Supported by USPHS Grants DA04090, DA00124, DA04190 and CA01342)

478.3

MEDIATION OF KAINATE-INDUCED BEHAVIORAL SENSITIZATION BY SUBSTANCE P (SP) AND SP N-TERMINAL FRAGMENTS IN THE MOUSE.

X. Sun and A. A. Larson. Univ. of Minnesota, St. Paul, MN 55108

Sensitization to the behavioral effects of repeated intrathecal (i.t.) injections of kainic acid (KA) in mice is inhibited by pretreatment with 0.8 μg of capsaicin i.t. The present study was designed to characterize the interaction between SP and KA *in vivo*. Pretreatment of mice at two min intervals with three injections of 7.5 pmoles of SP(1-11) or SP(1-7) potentiated the behavioral response to subsequent injections of KA, while SP(5-11) did not alter the intensity of responses to KA. This suggests that the N-terminal rather than the C-terminal of SP enhances subsequent KA-activity. Sensitization to the behavioral effects of KA was slightly inhibited by pretreatment with either 1 μg of DPDT-SP, a neurokinin antagonist, or even more by 1 μg of d-SP(1-7), an inhibitor of [^{3}H]SP(1-7) binding in the CNS. Coadministration of SP(1-7), not only failed to potentiate KA-activity, but actually inhibited KA-, SP- and NMDA-induced behaviors, an effect that was both prevented and reversed by naloxone. While naloxone attenuated the inhibitory effects of SP(1-7), it prevented, but did not reverse the potentiative effects of SP(1-7) on KA-induced behavior. This suggests a possible link between SP(1-7) and motor activity observed in mice during opioid withdrawal. Supported by USPHS grants DA4090, DA04190 and DA00124.

EXAMINATION OF THE ROLE OF SPINAL SUBSTANCE P IN TONIC NOCICEPTIVE BEHAVIORS. L.N. Holland and B.D. Goldstein. Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA 30912-2300.

Substance P (SP) in the dorsal horn has been shown to mediate certain types of phasic nociception. Intrathecal administration of SP reduces tail-flick and paw pressure latency in the rat. However, these responses are attenuated following successive administration of SP. We have confirmed this observation and determined that behaviors remain attenuated for up to 150 minutes and that these behaviors correlate with a reduction in the number of SP binding sites and a decrease in SP binding affinity in the dorsal horn. In this study, we examined the role of spinal SP in tonic nociception using a method of SP receptor desensitization. Two models were employed: the formalin test and the monosodium urate (MSU) test.

Male Wistar rats (300-400g) were implanted with intrathecal catheters. SP (0.7mM, i.t.) was administered at 0, 30 and 60 minutes. Rats were then injected into the hindpaw with 5% formalin (100 μl) or into the ankle-joint with MSU (1 mg dissolved in 25 μl 10% Tween 80). Formalin and MSU-induced responses were assessed by measurement of automated stereotypic behaviors and hindpaw pressure ratio, respectively.

In the formalin test, the repeated administration of SP reduced the first phase of pain-related behaviors but had no effect on the second phase response. In the MSU model, the repeated administration of SP did not have any effect on MSU-induced pain-related behaviors.

These data show that alteration of SP receptor activity in the dorsal horn using a method of SP receptor desensitization does not affect tonic nociceptive behaviors. These data suggest that SP in the dorsal horn does not mediate tonic nociception. Supported by the MCG Research Institute.

INTRATHECAL COADMINISTRATION OF SUBSTANCE P AND NMDA INCREASES THE BEHAVIOURAL RESPONSES TO PAIN IN THE FORMALIN TEST. O.-G.Berge, N.Mjellem-Joly*, A.Lund* and K.Hole. Astra Pain Control, S-151 85 Södertälje, Sweden & Dept. of Physiology, Univ. of Bergen, N-5009 Bergen, Norway.

Excitatory amino acids and substance P are involved in primary afferent transmission of nociception and in spinal processing of nociceptive information. We have studied the spinal action of NMDA and substance P in the formalin test in mice. Formalin (1%) was injected in a volume of 20 µl. Biting or shaking of the injected paw was scored. The substances were administered intrathecally in a volume of 7 µl. A significant increase of the response in the late phase of the formalin test (20-40 min after injection of formalin) was observed after intrathecal coadministration of NMDA (0.125 nmol) and substance P (2 pmol). Single administration of either NMDA or substance P did not induce any change in the response. These findings indicate that combined activation of NMDA receptors and substance P receptors induces a sensitization of the nociceptive response in the formalin test.

478.6

INTRATHECAL COADMINISTRATION OF SUBSTANCE P AND EXCITATORY AMINO ACID AGONISTS IN MICE: POTENTIATION OF A BEHAVIORAL RESPONSE. N.Mjellem-Joly*, A.Lund*, O.-G.Berge and K.Hole. Dept. of Physiology, Univ. of Bergen, Bergen, N-5009 Norway.

The functional interaction between substance P and excitatory amino acid (EAA) agonists in the spinal cord was studied. All substances were injected intrathecally in a volume of 7 µl. A strong potentiation of the behavioral response (biting and scratching) was observed when substance P (2.5 ng) was coadministered with NMDA (0.025 nmol), AMPA (0.0125 nmol) or kainic acid (0.025 nmol). The effect of each drug as well as of the combinations was blocked by the corresponding antagonists injected 5 min prior to the agonists: the selective NMDA receptor antagonist CPP (1 nmol), the non-MNDA receptor antagonist CNQX (2 nmol) and the substance P analog Spantide I (5 µg).

These findings indicate a functional interaction between substance P and EAA neurotransmitters in the dorsal horn of the spinal cord, compatible with the hypothesis that corelease of these substances from primary afferent neurons may enhance nociception.

INTRATHECAL ANTI-SOMATOSTATIN INHIBITS THERMAL HYPERALGESIA OF THE INFLAMED RAT HINDPAW. R.J.Traub. Dept. of Pharmacology, University of Iowa, Iowa City, IA 52242

Inflammation of a rat's hindpaw results in hyperalgesia to noxious thermal and mechanical stimuli produced in part by central mechanisms. The role of somatostatin in producing this hyperalgesia was examined.

Intrathecal (i.t.) catheters were implanted in male Sprague-Dawley rats and 5 days later the latency for withdrawal of the hindpaw from a noxious thermal stimulus was tested. Hindpaws were tested alternately at 4 min intervals to establish baseline values. Following testing, rats were given 3 i.t. doses over 24 hrs (10 µl/dose) of a monoclonal antibody raised against somatostatin-14 (#Ab607; provided by Dr. John H. Walsh, CURE Antibody Core, NIH Grant DK 17294). Immediately following the last dose, the left hindpaw was inflamed by s.c. injection of 2 mg carrageenan in 0.1 ml saline. The rats were tested again 2 hrs later.

In control rats the withdrawal latency of the inflamed hindpaw was significantly faster than the non-inflamed side. In contrast, there was no significant difference between the mean withdrawal latency of the inflamed and non-inflamed hindpaws in antisera-treated rats. The difference in the size of the inflamed compared to the non-inflamed hindpaw was the same in both groups. The antisera had no effect upon the withdrawal latency of the non-inflamed side compared to baseline values or the non-inflamed control.

The data show that i.t. anti-somatostatin inhibits the hyperalgesia to thermal stimuli applied to the inflamed hindpaw but does not affect acute pain transmission in non-inflamed tissue, suggesting a role for neuropeptides in generating central sensitization and hyperalgesia.

PLASMA AND CEREBROSPINAL FLUID SP-LIKE IMMUNOREACTIVITY IN ARTHRITIC AND FREUND ADJUVANT PRETREATED RATS. B. CALVINO*, J.Y. COURAUD*, S. MAILLET*, P. PRADELLES* and J.M. BESSON*. INSERM U161 and CEA, 75014 Paris and Saclay, FRANCE (SPON: European Neuroscience Association).

Behavioral parameters and levels of plasma substance P-like immunoreactivity (SPLI-Pl) were studied in adjuvant induced arthritic rats (AIA), a chronic pain model.

Exp.I: 14, 21 and 42 post-inoculation (PI) days were studied and were compared with the day of inoculation. Levels of SP-like immunoreactivity were also determined in cerebrospinal fluid (CSF) on the same PI days. In arthritic rats SPLI-Pl was enhanced (x4) as early as 14 days PI and remained increased at all stages studied whereas SPLI-CSF was increased (x2) only at 21 days PI.

Exp.II: one group of rats was pretreated with diluted Freund adjuvant before inoculation with the stronger arthrogenic solution, while a control group was pretreated with saline. Rats in the control group developed all symptoms of AIA including chronic pain; SPLI-Pl was strongly increased (x4) and remained at this level as long as 9 weeks PI. In adjuvant pretreated rats, AIA symptoms were strongly reduced and animals developed no pain state. In this group SPLI-Pl was slightly increased (x2) and significantly different from levels of control group.

These data suggest that SP could be distributed in 2 different pools, a peripheral one of inflammatory origin, and a central one which could be more specific to the chronic pain situation.

EFFECTS OF DELTA-SLEEP INDUCING PEPTIDE ON STRESS-INDUCED ANALGESIA IN RATS. A.S. Wensel*, A.M. Vasquez*, G.A. Olson, and R.D. Olson. Department of Psychology, University of New Orleans, New Orleans, LA 70148.

This study was designed to explore the effects of delta-sleep inducing peptide (DSIP) on stress- and pain-inhibitory mechanisms that are activated in response to environmental stressors. In Experiment 1, DSIP (0 30, 60, or 120 nmol/kg) or naloxone (10 mg/kg) was peripherally (IP) administered to rats before intermittent (ICWS) and continuous (CCWS) cold-water swims. Tail-flick latencies and core body temperatures were taken immediately before and 0, 15, 30, 60, and 120 min after swims. Testing was conducted during the beginning and middle of the light and dark photo-periods. In Experiment 2, animals were retested under matching schedules but without exposure to CWS. In Experiment 1, 60 nmol/kg of DSIP attenuated absolute and relative measures of analgesia 30 min after ICWS without affecting body temperature. The 30 nmol/kg dose had similar but less consistent effects 15 min after CCWS. Naloxone did not reduce analgesia induced by ICWS or CCWS. Experiment 2 failed to demonstrate any direct effects of DSIP upon nocioception or thermoregulation. Although the mechanisms underlying DSIP's anti-stress actions remain unclear, the observed effects of DSIP on CWS-induced analgesia are more consistent with a non-opiate mediated system.

IONTOPHORETIC CGRP FACILITATES SP AND NOXIOUS STIMULI EVOKED EXCITATIONS OF RAT LUMBAR CORD NEURONS. G.Biella* and M.L.Sotgiu. Dept. Physiopathol.and Therapy of Pain, Fac.of Med.Univ.of Milan and I.F.C.N.-CNR, Milan, Italy.

In vitro preparations and in vivo superfusates have evidenced that coexistence of Calcitonin Gene-related Peptide (CGRP) and substance P (sP) could reflect a functional role in sensory processing of spinal cord networks. We examined in vivo the effects of CGRP and sP administration on both the spontaneous and the noxious and non-noxious evoked neuronal activities in anesthetized rats. Single unit recordings and concomitant iontophoresis/micropressure spotted drug applications (CGRP: 0.5-0.7 µM pH5; sP:10µM pH5) have been performed on wide-dynamic range neurons in lumbar cord. Results from 40 neurons showed that: i) application of sP alone provoked excitation and enhanced the responses to noxious thermal stimuli applied in the periphery ($p<0.001$), ii) CGRP alone was uneffective on the spontaneous activity while enhanced the excitatory responses to noxious stimuli ($p<0.001$), iii) CGRP potentiated the sP induced excitation both on the spontaneous and on the noxious evoked activities ($p<0.001$). This synergism was evident only when sP was applied on a previously running CGRP ejection. iiii) Non-noxious evoked activity remained unmodified by concurrent sP and/or CGRP ejections. It is suggested that when coreleased the CGRP could play the role of "enhancer" of the sP effects in the noxious information encoding.

MK 801, AN NMDA RECEPTOR ANTAGONIST, POTENTLY REDUCES NOCICEPTIVE BEHAVIORS IN RATS WITH PERIPHERAL MONONEUROPATHY R. L. Hayes[1], J. Mao[2], D. D. Price[3], J. Lu[2], and D. J. Mayer[2]. Dept. of [1]Neurosurgery, [2]Physiology, and [3]Anesthesiology, Medical College of Virginia, Richmond, Virginia 23298

Hyperalgesia in neuropathic pain syndromes could result from either abnormal peripheral nociceptive input or overactivity of endogenous excitatory amino acids at primary afferent synapses. In the present experiment, we examined the effect of MK 801, a non-competitive NMDA receptor antagonist, and a local anesthetic agent, bupivacaine, on thermal hyperalgesia associated with a rodent peripheral mononeuropathy produced by sciatic nerve ligation. Intrathecal injection of MK 801 or perinerve injection of bupivacaine was given on day 3 postsurgery, and thermal hyperalgesia was assessed 24 hrs after injection and on days 5, 6, and 7 postsurgery. Hyperalgesia to radiant heat was significantly reduced 24 hrs after injection in nerve ligated rats receiving either MK 801 (2.5, 5, 10 and 20 nmol) at the lumbar spinal cord, or perinerve injection of 0.5% bupivacaine (0.6 ml), but not in rats receiving saline or MK 801 (10 nmol) at spinal cord thoracic segments (ANOVA, $P < 0.001$). While nerve block or intrathecal MK 801 (2.5 nmol) injection alone on day 3 postsurgery reduced hyperalgesia only within the following 24 hrs, the combination of these two manipulations significantly reduced hyperalgesia for 3 days postinjection (ANOVA, $P < 0.01$). The effect of perinerve block and its potentiation by MK 801 treatment indicates that hyperalgesia after peripheral nerve injury may be induced and maintained by both peripheral and central mechanisms. Our data suggest that NMDA receptor-mediated central mechanisms may be critical to chronic neuropathic pain syndromes, and the pharmacological intervention by excitatory amino acid antagonists may be an important approach for clinical treatment of neuropathic pain.

N-METHYL-D-ASPARTATE ADMINISTERED INTRATHECALLY ENHANCES PERSISTENT HINDLIMB FLEXION IN RAT. R.D. Moore*, D.J. Mokler and B.J. Winterson. Departments of Physiology and Pharmacology, University of New England, College of Osteopathic Medicine, Biddeford, ME 04005.

Previously, we have shown that non-competitive NMDA antagonists interfere with the induction of peripherally-induced persistent hindlimb flexion (Anderson & Winterson, Neurosci. Abstr.,1988). The present experiments examined whether intrathecally applied N-methyl-D-aspartate (NMDA) would modulate the development of persistent hindlimb flexion.

Adult Long-Evans rats were anesthetized with Na+ pentobarbital. Saline or 1 mmol NMDA was injected intrathecally in 5 μl volumes via a 27 g needle between T12 and T13. Wound clips were attached to the medial and lateral skin of the thigh. Electrical current (2mA,7ms,100Hz) was applied across the wound clips for 1 hr. Flexion was measured by attaching weight to the hindlimbs until leg lengths were equal. Rats that had received NMDA showed a mean flexion of 20.5g (sem = 2.0g, n = 10), 147% above rats that had received saline (X = 8.3g, sem = 1.4g, n = 7). Rats were returned to individual cages for recovery. At 3 days, rats were reanesthetized, and flexion was again measured. Rats that had received NMDA showed a mean flexion of 15.3g (sem = 1.7g), 110% above rats that had received saline (X = 7.3g, sem = 1.0g). Rats were then spinalized and flexion was measured again. Rats that received NMDA showed a mean flexion of 16.2g (sem = 1.7g), 95% above rats that had received saline (X = 8.5g, sem = 1.5g).

These results provide further support to the hypothesis that the induction of persistent hindlimb flexion is dependent upon spinal NMDA receptors.

MK-801 BLOCKS THE INDUCTION OF PERSISTENT HINDLIMB FLEXION DUE TO MUSCLE STIMULATION IN INTACT AND SPINALIZED RATS. M.F. Anderson and B.J. Winterson. Department of Physiology, University of New England, College of Osteopathic Medicine, Biddeford, ME 04005.

We have shown that NMDA antagonists interfere with the induction of peripherally-induced persistent hindlimb flexion (Anderson & Winterson, Neurosci.Abstr.,1988) and that muscle stimulation alone is sufficient to produce persistent flexion comparable to that generated by percutaneous stimulation (Anderson & Winterson, Neurosci.Abstr.,1990). The present experiments examined whether NMDA receptor blockade during muscle stimulation attenuated persistent hindlimb flexion.

In pentobarbital anesthetized adult Long-Evans rats, skin was removed from the thorax and hindlimbs, exposed muscle was wrapped in saline moistened gauze. Rats were kept warm via a thermostatically controlled blanket. Wound clips were applied to the muscle through the gauze, current (2mA, 7ms, 100 Hz, 1 hr) was delivered across the wound clips. Twelve rats were stimulated intact (CONTROL) and 12 rats were spinalized prior to skin removal (SPINAL). From each group, half were treated with the non-competitive NMDA antagonist, MK-801(10 mg/kg,i.p.) 1 hr prior to stimulation (MK-801) and (SPINAL-MK-801). Following stimulation, lidocaine (12.5 mg/kg, i.m.) was injected at the wound clip sites. Flexion was measured for 30-90 min. Flexion of rats pretreated with MK-801 was significantly less whether intact (MK-801: X = 0.0g, sem = 0.0g vs. CONTROL: X = 8.5g,sem = 0.7g) or spinalized (SPINAL-MK-801: X = 0.8g, sem = 0.5g vs. SPINAL: X = 10.8g, sem = 1.9g). These data suggest that 1) persistent hindlimb flexion is mediated through the spinal cord and 2) induction is dependent on NMDA receptor activation driven by muscle afferents. EFFECTS OF MK-801 ON BEHAVIORAL HYPERALGESIA AND DORSAL HORN NEURONAL ACTIVITY IN RATS WITH ADJUVANT-INDUCED INFLAMMATION. K. Ren, J.L.K. Hylden, G.M. Williams, M.A. Ruda and R. Dubner, Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

The involvement of NMDA receptors in a rat model of inflammation and hyperalgesia was evaluated by systemic administration of the non-competitive NMDA receptor antagonist, MK-801. Inflammation was induced by intradermal injection of complete Freund's adjuvant (CFA) into the left hindpaw. Paw withdrawal latency (PWL) from a thermal stimulus was used as a measure of CFA-induced hyperalgesia in awake rats. MK-801 (1.6 mg/kg, i.p.) significantly increased PWLs in comparison to saline-injected rats ($p < 0.05$). Spinal dorsal horn nociceptive neuronal activity was recorded extracellularly in chloralose anesthetized rats. The expanded receptive field size of nociceptive-specific and wide-dynamic-range neurons in the superficial and deep dorsal horn recorded 24 h after CFA injection was significantly reduced to 73 ± 6% ($p < 0.05$) and 74 ± 4% ($p < 0.01$) of control values, respectively, by 2 mg/kg of MK-801 (i.v.). The same dose of MK-801 prevented the expansion of receptive fields 5 to 8 h after CFA injection as compared to saline-injected rats ($p < 0.05$). MK-801 had no significant effect on receptive field size of dorsal horn neurons in rats without CFA-induced inflammation, but blocked a transient expansion of the receptive fields induced by 1 Hz, C-fiber intensity stimulation of the sciatic nerve. Background activity and noxious heat-evoked responses of dorsal horn neurons in rats with CFA-induced inflammation were primarily inhibited while noxious pinch-evoked activity was both facilitated and inhibited by administration of MK-801. These results support the hypothesis that NMDA receptors are involved in the dorsal horn neuronal plasticity and behavioral hyperalgesia that follow peripheral tissue inflammation.

478.15

DELAYED APPLICATION OF MK-801 ATTENUATES DEVELOPMENT OF MORPHINE TOLERANCE IN THE RAT. P. Marek, S. Ben-Eliyahu, A. L. Vaccarino, W. Sternberg, J. Mogil and J. C. Liebeskind. Department of Psychology, University of California, Los Angeles, CA 90024.

The specific NMDA receptor antagonist MK-801 (0.15 mg/kg, i.p.) was administered two hours after morphine injection (20 mg /kg, .ip.), during a four-day period of tolerance induction. Animals receiving delayed injections of MK-801 diplayed significantly less tolerance to morphine than saline injected controls when tested on the fifth day (hot-plate test, 52°C). These results suggest that long-lasting or delayed changes in NMDA receptors may be involved in the mechanism of morphine tolerance. Additionally, MK-801 applied two hours after morphine injection could not serve as a cue for morphine administration, which indicates that the effect of MK-801 was not due to blocking state dependent learning. To examine further the possible effect of MK-801 on the learning component of morphine tolerance, rats were given a single injection of a slow-release suspension of 50 mg/kg of morphine and 0.15 mg/kg of MK-801 and tested for morphine tolerance (15 mg/kg) and naloxone precipitated withdrawal 24 hours later. MK-801 completely blocked the development of morphine tolerance and significantly attenuated withdrawal symptoms (diarrhea, teeth-chattering). These data indicate that the effect of MK-801 is not attributable to blocking the learning component of morphine tolerance. Supported by an Unresricted Pain Research Grant from the Bristol-Myers Squibb Company and NIH grant NS 07628.

SWIM STRESS PRODUCED ANALGESIA IN THE FORMALIN TEST IS MEDIATED VIA THE NMDA RECEPTOR. A.L. Vaccarino, P. Marek, W. Sternberg and J.C. Liebeskind Department of Psychology, University of California, Los Angeles, CA 90024.

Different forms of stress can produce potent analgesia. In the hot-plate test, a 3-minute swim stress of 32° C produces analgesia which is predominantly opioid in nature. In contrast, the analgesia produced by a 20° C swim stress has a strong non-opioid component which is effectively blocked by the *N*-methyl-D-aspartate (NMDA) antagonist, MK-801. To determine the effect of swim stress in a model of tonic inescapable pain, the analgesic effect of a 3-minute swim stress was assessed using the formalin test. Male Swiss mice (30-40 g) were injected subcutaneously with naloxone HCl (1 mg/kg), MK-801 (0.075 mg/kg) or saline 15 minutes prior to swimming for 3 minutes in water maintained at 20° C or 32° C. An additional group of mice received saline. Following a 2-minute drying off period, the mice were injected with 20 µl of 5% formalin in saline into the plantar surface of one hindpaw. The animal's pain-related behaviour (time spent licking the injected paw) was then continuously rated during the subsequent 10 minutes. Swim stress produced a significant suppression of formalin pain scores relative to non-stressed controls at both the 20° C and 32° C temperatures. No difference was found in the magnitude of analgesia produced at these two temperatures. The analgesia produced in both the 20° C and 32° C swim stress was completely abolished in mice pre-treated with MK-801. Naloxone had no effect. These results suggest that the analgesia produced by swim stress in the formalin test is non-opioid in nature and is mediated at the NMDA receptor. Supported by an Unrestricted Pain Research Grant from the Bristol-Myers Squibb Company and NIH grant NS 07628.

MK-801 ATTENUATES NON-OPIOID STRESS-INDUCED ANALGESIA IN SELECTIVELY BRED MICE: COMPARISON ACROSS THREE SWIM STRESS PARADIGMS . J.S. Mogil, P. Marek, W.F. Sternberg, I. Panocka and J.C. Liebeskind. Dept. of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Recent evidence has implicated excitatory amino acids in the mediation of endogenous mechanisms of pain inhibition. The specific, non-competitive NMDA receptor blocker MK-801 (dizocilpine) has been found to affect opioid-mediated systems of stress-induced analgesia (SIA). We now report that a lower dose of MK-801 selectively attenuates non-opioid forms of SIA. Mice selectively bred for high (HA) and low (LA) swim stress-induced analgesia were tested on the hot-plate (56°C) immediately prior to and 2 minutes after a 3 minute forced swim in 15°C, 20°C or 32°C water. Twenty minutes before testing, animals were administered naloxone (10 mg/kg, i.p.), MK-801 (0.075 mg/kg, i.p.), naloxone + MK-801, or saline. In a separate experiment, mice similarly pre-treated were all given a systemic injection of morphine (10 mg/kg, i.p.). The magnitude of analgesia observed in all experiments was similar. In the HA and C (control) lines, MK-801 attenuated non-opioid SIA selectively. Specifically, MK-801 attenuated SIA induced by 15°C swim, on which naloxone had no effect. Conversely, MK-801 was ineffective on 32°C SIA and morphine analgesia, both of which were reversed by naloxone. MK-801 and naloxone acted additively to reverse 20°C SIA in HA mice. Supported by NIH Grant NS07628 and an Unrestricted Pain Research Grant from the Bristol-Myers Squibb Company.

VISUAL PSYCHOPHYSICS AND BEHAVIOR: HIGHER FUNCTIONS AND MODELS

479.1

INFORMATION TRANSMISSION AND EQUIVOCATION BY SINGLE NEURONS P.H. Bedenbaugh, G.L. Gerstein, *Departments of Physiology and Bioengineering, University of Pennsylvania, Philadelphia, PA 19104*

Neurons both transmit information about their inputs and classify or equivocate them. Equivocation is the extent to which different inputs produce the same output, and can be viewed as a measure of the importance of nonlinear processing by the neuron. We were interested in the relative importance of information transmission and equivocation.

Using computer simulations we generated input data from pools of random Poisson spike trains. Some spike trains were common to all such input data sets, others were unique; the ratio was varied parametrically. Such input data was submitted to a simulated neuron and mutual information was calculated between outputs on separate trials arising from different ratio inputs. Mutual information is a measure of the extent to which one such output could be predicted knowing another. Our neurons were modeled as in MacGregor's SYSTM22 (*Neural and Brain Modeling*, Academic Press, 1988), a simple model with some physiological verisimilitude. We calculated mutual information both with a simple code based on whether the neuron was firing or not, and with a more complex code that took into account instantaneous firing rate, phase, medium term average firing rate, and medium term change in firing rate. The complicated code yielded slightly higher values of mutual information than the simple code. We found that different ratios of common to unique input produced distinct values of mutual information between corresponding outputs. Using trials where the inputs differed but little, the calculated mutual information was much less than one would expect from the similarity of inputs, i.e. a loss of information. We conclude that nonlinear effects and equivocation are important facets of neural function. In fact, for our simulated neuron, equivocation seems to be larger than information transmission. Supported by NIH MH46428. Thanks to D. Kepke and I. Nelken for helpful discussions.

SYNCHRONIZED OSCILLATIONS DURING COOPERATIVE FEATURE LINKING IN A MODEL OF VISUAL CORTEX. D. Somers and S. Grossberg, Department of Cognitive and Neural Systems, Boston University, Boston, MA 02215

A model of synchronized oscillations in visual cortex is presented to account for neurophysiological findings (Eckhorn, et al, Biol. Cyber., 60, 1988, Gray, et al, Nature, 338, 1989) that synchronization of neural activity may reflect the binding of local feature detectors into a globally coherent perceptual grouping. Grossberg (Biol. Cyber., 23, 1976;1978) had previously predicted that cortical codes would be expressed by resonant standing waves in which cooperatively linked cells oscillate in phase with one another. It was also noted that the standing waves could be replaced by an approach to an equilibrium point if no "slow" variables exist in the network.

Our model utilizes two neural network architectures previously used in modeling pre-attentive vision (Boundary Contour System[BCS]) and attentive visual object recognition (Adaptive Resonance Theory[ART]). The oscillations in our model are not merely assumed to exist as has been done by others, but rather emerge from a system of nonlinear feedback equations in which inhibition acts more slowly than excitation. Our model and computer simulations account for the rapidly synchronizing response of distant visual cortical cells to both single and double bar moving stimuli. The two network architectures make complementary predictions about the processing of disjoint patterns. The "Bipole Cell" architecture of the BCS predicts that, under appropriate stimulus conditions, activity will be induced and synchronized at sites between disjoint patterns, thus performing a pre-attentive boundary completion. Conversely, the "Adaptive Filter" architecture of ART synchronizes, but does not connect, disjoint patterns during attentive object recognition.

Even nearest neighbor and random coupling schemes can generate synchrony for the single bar input, which demonstrates the robustness of the synchrony effect in cooperative networks. These results suggest how research on this topic can be integrated into formal models of visual perception in cortex.

479.3

A NEURAL NETWORK MODEL FOR TEXTURE SEGMENTATION AND PERCEPTION J. Xing, G.L. Gerstein, M.R. Turner, *Department of Physiology, School of Medicine, University of Pennsylvania, Philadelphia, PA-19104*

A neural network is set up to investigate the possible mechanism of texture segmentation in visual cortex, based on M. Turner's algorithm (M.Turner, Biol. Cybern, 55,1986). In this model, there are sixteen neural pools, each receives the output from one kind of Gabor filter; they are tuned to four spatial frequencies and four orientations. Neurons in a pool are arranged into arrays according to their spatial locations. The activity of each neuron is simulated by MacGregor's program PTNRN10. There are both excitatory and inhibitory interconnections among neurons in the same and different pools. The outputs of all the sixteen pools are integrated in a higher layer.

With this model, we tested neural representations in the network for many textures, from regular patterns to complex natural images. "E" represents the sum of excitatory strengths of all connections to that neuron, "I" is the corresponding inhibitory sum. We found that: (1) With appropriate E/I values, all texture images we tested can be segmented; the optimal sets of E/I values fall in the same region for most images; (2) The representations of texture images in the neural network mainly depend on E/I, Boundaries or segmentations could be respectively obtained by varying E/I; however, the spatial distributions of excitatory and inhibitory strengths with distance have little effect on the resulting boundaries or segmentations; (3) The time required for a representation of texture segmentation in the network varies with texture structures; regular, high density textures need less time to be segmented. Generally, the boundary or segmentation can appear in 60 ~ 120ms, and becomes stable after ~ 150ms. We also investigated the mechanism of texture perception. We suggest that the perception of a texture image could involve several different neural representations, which are obtained by the clustering of neural pools with similar firing pattern. THE EFFECT OF 40 Hz FLICKER ON THE PERCEPTION OF GLOBAL STIMULUS PROPERTIES

Daniel C. Kiper, Karl R. Gegenfurtner and J. Anthony Movshon
Howard Hughes Medical Institute, Center for Neural Science, New York University, New York 10003.

Neurons in the cat visual cortex show oscillatory responses in the range 20-60 Hz. Under certain conditions, influenced by global stimulus properties, neurons in spatially separate functional columns synchronize their oscillatory responses. This has been interpreted as support for the hypothesis that synchronized oscillatory responses serve to establish relations between spatially separate features (Gray *et al.*, 1989). If these coherent oscillations influence perceptual judgements, we reasoned that neuronal oscillations induced by flickering visual targets might have an effect on visual segmentation.

We measured psychophysical performance of human subjects in a texture segregation task, where the texture elements flickered against a gray background at a temporal frequency between 20 and 50 Hz. The stimuli were fields containing line segments whose position was jittered from a regular array. A rectangular patch contained segments differing in orientation from the rest of the field. The subject's task was to indicate whether the rectangle itself was oriented horizontally or vertically. We varied the difference in orientation between the segments inside and outside the rectangle to find a value that just supported reliable performance. We tested four temporal phase conditions: no flicker, synchronized flicker of all texture elements, synchronized flicker of the elements within one region, and unsynchronized flicker of all texture elements.

Performance depends in the expected way on signal strength as determined by contrast. It is, however, entirely independent of the temporal pattern of the flicker. We conclude that either stimulus-induced oscillations do not interfere with other oscillatory responses, or that the physiologically observed oscillatory responses are not necessary for perceptual grouping.

CHANGES IN GAMMA-BAND ACTIVITY OF RHESUS MACAQUE NEOCORTEX DURING A VISUAL PATTERN DISCRIMINATION TASK.

S.L. Bressler, R.K. Nakamura. Center for Complex Systems, Florida Atlantic Univ., Boca Raton, FL 33431 and NIMH, Bethesda, MD 20892.

Recent findings of stimulus-dependent gamma-band (25-75 Hz) activity in visual cortex have led to questions concerning its functional role in cortical processing. Transcortical field potentials were simultaneously recorded from 16 chronically implanted bipolar electrodes in rhesus macaque monkeys as they performed a visual pattern discrimination task. The electrodes were distributed across the cortical convexity of the hemisphere contralateral to the preferred hand. The monkeys were trained to respond to one stimulus pattern type (4 squares arranged in a diagonal line) by lifting a lever within 500 msec (GO task), and to another type (the same squares arranged in a diamond) by holding the lever for 500 msec (NO-GO task). The gamma band was isolated by digital filtering, and the rms amplitude was computed for each of 141 100-msec-long windows spanning 700 msec post-stimulus. For each task type, the rms amplitude of each window was averaged over all correctly performed trials. The averaged gamma amplitude showed location-specific deviations from baseline. The magnitude and timing of these deviations differed according to task type, the strongest changes occurring before 500 msec in the GO task and after 500 msec in the NO-GO task. These findings suggest that activity in the gamma frequency band in many cortical regions may have a functional role in performance of visual pattern discrimination tasks. SPATIO-TEMPORAL DYNAMICS OF STIMULUS-INDUCED VISUAL ATTENTION.

S.Miyauchi(1)*, O.Hikosaka(1) and S.Shimojo(2)*,
(1) National Institute for Physiological Sciences, Okazaki, Japan,
(2) University of Tokyo, Tokyo, Japan

We have shown that the focus of visual attention is detected by motion sensation in an adjacent line (Hikosaka et al., ARVO '91). When a spot (cue) appears on a screen, followed by appearance of a line, the line is perceived to be drawn from the cued side. This is because the cue facilitates the perception of the nearby portion of the line (Miyauchi et al., ARVO '91).

We now report that the spatio-temporal dynamics of attention can be plotted using a short line (length: ≈0.2deg) as the probe. While the observer fixated on a spot, a cue spot and then a short line appeared. We found that the motion sensation was greater when the line was closer to the cue stimulus. We used a cancellation method to quantify the gradient of attention: the probe line was drawn in the direction toward the cue so as to cancel the attention-induced motion effect. If the attentional effect was large, we needed to draw the line more slowly. The speed of the line drawing was taken to be a measure of local attentional gradient. A two dimensional map of the magnitude of attention was thus obtained. We studied the effects of single and multiple cues. A single cue produced a single peak with quasi-exponential decay outward. The map changed its magnitude and shape after onset of the cue stimulus. Two cue stimuli produced two corresponding peaks, suggesting the presence of multiple foci of stimulus-induced attention. We also studied the spatial and temporal interactions of the two stimuli.

479.7

Lack of spontaneous "popout" in a patient with severe agnosia and achromatopsia

K. Nakayama[1] and G. Plant[2]. Dept. Psychology, Harvard Univ[1]. and Maida Vale Hospital, London[2]

A 51 year old patient suffered bilateral strokes involving the ventral occipito-temporal cortex. He presented with a bilateral superior altitudinal field defect, with normal funduscopy and ERG.

In addition to his achromatopsia (reported by Haegerstrom-Portnoy, et al, ARVO 1991, p.1215), he had severe agnosia, particularly with more complex visual forms such as faces, animals, cars, etc., yet he could read very difficult material, albeit haltingly. Surface representation seemed largely intact insofar as he could recognize Kanisza demonstrations of occluding and occluded contours. Visual acuity at high photopic light levels was normal. Brightness discrimination, 2-D structure from motion, as well as the recognizing of Johanson biological motion figures appeared to be largely intact. In a task where he was to find a backward letter R, he was surprisingly unable to find the letter when it was uniquely marked with an opposite brightness polarity in comparison to the normal distractor Rs. Yet, when explicitly asked to find an opposite polarity letter against others, his performance improved dramatically. Despite this lack of spontaneous "popout" with opposite polarity targets (which was repeatedly observed), the backwards letter R was quickly identified if it was marked by motion against a stationary background.

FRONTAL ACTIVATION DURING SHIFTS OF VISUAL SPATIAL ATTENTION: A PET STUDY.

S.E.Petersen, M.Corbetta, G.L.Shulman*, and F.M. Miezin Dept. Neurology & Neurol. Surg., McDonnell Ctr. for Studies of Higher Brain Function, Wash. Univ. Sch. of Med., St.Louis, MO 63110.

Theories of attention posit a mechanism that shifts attention in space and is organized in direction and/or field specific coordinates. To examine this idea, normal subjects were scanned with PET activation methodology during a task in which visual field (left, right) and direction of attention movements (left,right) were manipulated in a blocked design. Previously we have reported a superior parietal activation dependent on the field of attention shift. The task display was a horizontal row of small boxes extending into both hemifields. Subjects detected a star presented for 150 ms within one of the boxes. On 80% of trials the order of probed locations predictably followed a particular direction; on 20% random positions were probed (shifting task). A central detection task was run in which peripheral probes were presented but subjects detected the onset of a star in a central box. PET sessions also included a fixation point control with no stimulation as well as a passive control in which the peripheral stimuli were presented but no task performance was required. PET subtraction images were obtained using shifting -, central detection -, and passive - fixation conditions. These images indicated that: 1. A region of the prefrontal cortex was activated when subjects shifted attention in the contralateral visual field, but not during central detection, with minimal activation when the stimuli were passively presented; 2. There was no evidence of activation related to attention shifts in a particular direction. This is similar to the results found in the superior parietal lobe, except that parietal activation was seen in the passive condition. These results are consistent with an interpretation that both parietal and frontal mechanisms contribute to shifting attention in space, but serve different task demands.

ACTION-BASED SPATIAL ATTENTION IN NORMAL AND HIPPOCAMPAL LESIONED MONKEYS.

Michael Taffe*, Beth O. Moore, Steven P. Tipper* and Gordon C. Baylis. Dept. of Psychology, U. C. San Diego, CA 92093, and Dept. of Psychology, McMaster University (S.P.T.)

Human subjects display an action-based attentional system when tested on a task that requires them to reach for a target stimulus. Distractor objects on the action path towards the target cause very much more interference than those located beyond the target (Tipper et al., *Psychonomic Soc. Meeting*, 1990). In order to prevent inadvertant responses to distracting stimuli on the path to the target, it is hypothesized that subjects use a mechanism of distractor inhibition. We examine the extent to which spatial attention in macaque monkeys is organized in a similar way.

It was found that the pattern of results for both normal and hippocampal-lesioned monkeys was very similar to that seen in normal humans. It is suggested that inhibition of distractor items is a mechanism also utilized in infra-human primates. Hippocampal lesions were found not to affect performance of this task in any way. This suggests that while lesions to the hippocampal system may impair monkeys' ability to make spatially selective responses (Rupniak & Gaffan, *J. Neurosci, 7, 2331*, 1987), spatial attention remains largely intact.

479.10

VISUAL SPATIAL ATTENTION DEFICIT IN DYSLEXICS. EVIDENCE OBTAINED FOR COMPUTER PROGRAMS.

Zarco de Coronado I.,Gutiérrez L.A.* and Orozco C.* Dpto. de Fisiología.Fac de Medicina. C.P.70250 and Ito. Nal. de la Comunicación Humana. C.P. 01480, MEXICO.

Computer animated programs were prepared to be applied in normal and dyslexic children.The exercises started with a sample figure:faces, letters,numbers or special lines patterns with 1-4 discrimination details. They are followed by 10 fixed or 24 randomized complete or incom plete test figures moving on lines.The images run to velocities of 0.1 to several seconds. A sound and congratulations message is presen-ted if the child counts the correct number of complete figures. Another sounds accompany erroneus answers.

The adequate solution of the task showed age dependence. In this way, normal children were capable to count correctly until 0.1 sec. velocities the simplest figures. But subjets up to 12 years old need 0.5 sec. to answer co-rrectly the more complex exercises.For dysle-xic children it was very difficult to obtain correct answers, even tough the programs were runned very slowly. This results indicate vi-sual spatial attention deficits for disabled readers.

479.11

A HIERARCHICAL MODEL FOR 3D OBJECT RECOGNITION BASED ON 2D VISUAL REPRESENTATION. E.Sklar[1,2], N.Intrator[2*], J.I.Gold[2*], S.Y.Edelman[3*] & H.H.Bülthoff[1,4]. 1Dept. of Cognitive Science & 2Center for Neural Science, Brown University, Providence, RI 02912; 3Dept. of Applied Mathematics & Computer Science, Weizmann Institute of Science, Rehovot 76100, Israel; 4Center for Biological Information Processing, MIT E25-201, Cambridge, MA 02139.

A central question in visual recognition is whether internal representations of 3D objects are themselves 3D and object-centered or 2D and viewer-centered. Recent evidence suggests that recognition performance for some classes of 3D objects is constrained by the 2D properties of the stimulus image. Specifically, [1] the ability to generalize from a few 2D images of a 3D object to novel views is limited (Bülthoff & Edelman, *in press*), and [2] the influence of 3D transformations (affine and non-affine) on recognition is correlated with the induced image-plane distortion and not with the extent of the 3D transformation itself (Edelman & Bülthoff, *MIT-AI Memo* 1239).

These findings are consistent with a representation scheme based on multiple 2D views along with some means for view interpolation (*e.g.* Poggio & Edelman, *Nature*, 343). A computational network model of visual processing for view interpolation has been developed (Intrator & Gold, *in press*) using a biologically motivated learning and self-organization scheme (Bienenstock *&al., J. Neurosci.* 2). The model not only agrees with the psychophysical data, but can be shown to perform a sophisticated statistical analysis for dimensionality reduction (Intrator, *NIPS-90*) through feature extraction. We compare simulation results to human performance for several types of stimuli, and evaluate the predictiveness of the the model's feature analysis.

A possible physiological interpretation of these results is suggested by a 'hierarchical organization model' of visual cortex (*e.g.* VanEssen & Maunsell, *TINS* 6). Key aspects of this model are the increasing receptive field size and stimulus selectivity of cells in the 'higher' visual areas of extrastriate cortex, particularly on the 'form pathway' projecting to inferotemporal cortex. We suggest that a correspondence can be draw between the computational and physiological models at the level of feature extraction / stimulus specificity. Additionally, view generalization may be accounted for by changes in receptive field size and topography in a hierarchical cortical model.

479.12

ORIENTATION BUT NOT PATTERN DRIVES VISUALLY GUIDED PREHENSION IN A VISUAL FORM AGNOSIC. L. S. Jakobson and M. A. Goodale. Univ. Western Ontario, Canada.

We recently described a patient (DF) with visual form agnosia who showed strikingly accurate guidance of hand and finger movements directed at objects whose size, shape, and orientation she failed to perceive (Goodale et al. *Nature* 1991). MRI revealed damage in areas 18 and 19, with considerable sparing of primary visual cortex. The dissociation in visual performance suggests that visual mechanisms underlying "conscious" perceptual judgements normally operate separately from those underlying the "automatic" visuomotor guidance of skilled actions of the hand and limb. We have since shown that DF is unable to use visual pattern to guide her hand movements although she remains sensitive to the orientation of the elements that comprise the pattern. Thus, when presented with a slotted surface in which the slot was cut in the shape of the letter T, DF was able to guide a T-shaped form into the slot on only half the trials. Interestingly, her visually-driven errors were almost always perpendicular to the correct orientation. In other words, the mechanisms controlling her visuomotor behaviour appeared unable to 'discriminate' the stem from the top of the T, even though the hand-held form was rotated to the correct orientation of one element of the T or the other. This result combined with our earlier observations suggests that in normal brains there may be a contribution to visuomotor guidance from the systems underlying pattern recognition although more basic information about object dimensions and orientation can be processed independently from these pattern recognition systems. *Supported by MRC grant #MA-7269 to MAG and an MRC studentship to LSJ.*

479.13

THE EFFECT OF THE LOWER AND HIGHER ORDER VISUAL CORTICAL LESIONS ON ILLUSORY CONTOUR ORIENTATION DISCRIMINATION AND TEXTURE SEGREGATION IN THE CAT. DeWeerd P., Sprague J.M., Vandenbussche E. and Orban G.A., Lab Neuro-en Psychofysiologie, K.U. Leuven, B-3000 Leuven, Belgium and Dept. of Anatomy, Sch. of Med., Univ. of Pennsylvania, Phila., PA 19104-6058, U.S.A.

We have trained 5 cats in orientation discrimination with illusory contours (IC) in which the contour was induced by two sets of circle halves of which the endpoints were either separated by a gap or shifted in phase. Five cats were trained in texture (TEXT) segregation (square of line segments of one orientation surrounded by line segments of different orientation). In three IC- and three TEXT-cats we made bilateral ablations of areas 17 and 18 (type-1 lesion). Performance after lesion was close to chance, with little or no recovery despite intensive retraining for 0.5 to 1 year. In 4 cats (2 IC- and 2 TEXT-cats), we made combined bilateral lesions of areas 7,19,20a,21b,AMLS,PMLS, which receive direct projections from 17 and/or 18 (type-2 lesion). The initial effect (first two months) was as devastating as after type-1 lesions, for both IC- and TEXT-cats. However, retraining allowed 3 of the 4 cats to reattain close-to-normal performance. Our data suggest that the areas destroyed by type-1 and type-2 lesions intervene in the normal processing of illusory contours and textures, and that intactness of areas 17 and 18 is critical in the recovery observed after type-2 lesions.

479.14

THE ROLE OF INFERIOR TEMPORAL CORTEX AND DORSOLATERAL FRONTAL CORTEX IN VISUAL IMAGERY IN MONKEYS. M. Colombo, A. Eickhoff, and C. G. Gross, Department of Psychology, Princeton University, Princeton, NJ 08544.

Four monkeys were trained on a serial-order task (D'Amato and Colombo, J Exp Psychol [Anim Behav], 14, 131-139) to press five simultaneously presented visual stimuli in one specific order, symbolized as A→B→C→D→E. Two monkeys then received bilateral lesions of inferior temporal cortex and two received bilateral lesions of dorsolateral frontal cortex. The frontal lesions had no effect on performance of the serial-order task. In contrast, inferior temporal lesions severely disrupted performance.

After relearning the task postoperatively, the monkeys were given a test of visual imagery in which two of the five stimuli were presented at a time and the subject was required to respond to them in the order in which they appeared in the sequence (e.g. C→E; A→D; B→E). Neither inferior temporal nor dorsolateral frontal lesions impaired performance on this test.

The significance of these findings for understanding the neural mechanisms of visual imagery and their relation to the response properties of inferior temporal neurons is discussed.

479.15

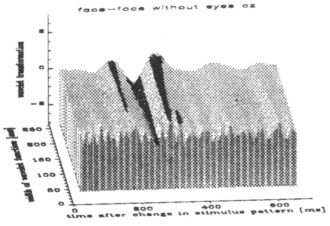
WAVELET METHOD AS THE NEW APPROACH TO ANALYSIS OF EVOKED POTENTIALS IN THE ELECTROENCEPHALOGRAM. A.W. Przybyszewski, Q.-J. Grüsser, Dept. of Physiology, Freie Universität Berlin, Arnimallee 22, 1 Berlin 33, Germany.

A new method in analyzing stimulus-category-related visual evoked potentials (EPs) is demonstrated.

(a) EPs related to face, hand, person and object perception were convoluted with the second derivative of the Gauss function (so-called wavelet function) to obtain wavelet transformation. The width of the wavelet function was varied from 44 to 264ms, resulting in 3D-pictures.

(b) The same procedure was applied for category-specific difference EPs.

(c) To obtain statistical evaluation criteria the individual EPs were randomly shuffled across stimulus categories, and from these "random groups" average EPs were computed. From these "average random EPs" difference curves were computed and treated with the wavelet method as described above.



(d) This "statistical error" basis was compared with wavelet transformation of category difference EPs and the range where this difference exceeded ± 3 s.e. – was determined (figure).

(e) This range was mapped on a 2D-diagram ("contour plot"). (see figure in Seidler et al. abstract this meeting). (Supported by DFG grant Gr. 161).

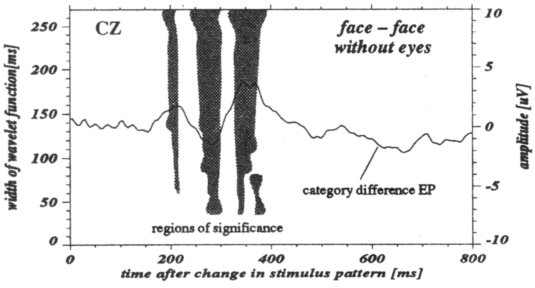
WAVELET FILTERING APPLIED TO FACE-RESPONSIVE COMPONENTS OF VISUAL EVOKED POTENTIALS. W.S. Seidler*, A.W. Przybyszewski, K.-H. Dittberner, Q.-J. Grüsser. (SPON: ENA). Dept. of Physiol., Freie Universität Berlin, Germany.

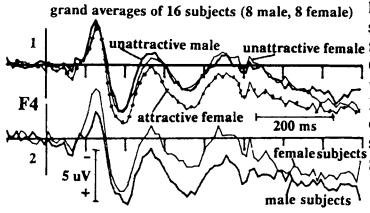
The visual evoked potentials (EPs) in adult volunteers to suddenly changed slides (4 x 6°) were convoluted with the second derivative of a Gauss function (wavelet), the width of which was varied from 44 to 264 ms. We analyzed EP-wavelet transformations of category difference-EPs (face/ face without eyes/ horizontal eyes/ vertical eyes) and found significant differences in time ranges around 160, 200, 270, 300, 360 and 450 ms after stimulus change. (Supported by a DFG-grant Gr.161).



479.17

INFLUENCE OF STIMULUS GENDER AND ATTRACTIVITY ON THE FACE-RELATED COMPONENTS IN VISUAL EVOKED POTENTIALS Margitta Seeck*, S. Bork*, O.-J. Grüsser, Dept. Physiol. Freie Univ. 1 Berlin 33, Germany

The influence of gender and face appearance on visual evoked potentials (EPs) was studied. In 16 subjects (8 male, 8 female, range: 23-31 years) EPs were recorded through the electrodes F3, F4, T5, T6, Cz, Oz, with reference to linked mastoids (intern. 10/20-system). 160 different slides were projected for 2.5-4.5 seconds (random variation). Black/white-photos of "attractive" and "unattractive" male and female faces, which had been previously rated by other independent subjects, served as stimuli. The face-responsive component appearing in the EP (Bötzel & Grüsser, 1989) was confirmed, consisting of a pronounced positive peak at about 200 ms with a consecutive very rapid negativity. Significant differences were found between the stimulus category "attractive females" and the other 3 categories. The presentation of attractive female faces led to larger positive amplitudes beyond 150 ms latency, which were significant at the right frontal electrode F4 and Cz (fig. 1). This result was more pronounced in EPs of male subjects compared to female subjects (fig. 2). DFG grants (Gr161 & Se520)

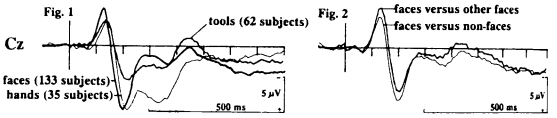


479.18

EVALUATION OF FACE-RELATED EVOKED POTENTIAL COMPONENTS ACROSS DIFFERENT PARADIGMS. Elke Heusser*, S. Bork, A. Brokate, W. Fischer, O.-J. Grüsser, Margitta Seeck, W. Seidler. Dept.Physiol. Freie Univ. 1 Berlin 33, FRG (SPON: EBBS)

Bötzel and Grüsser described components in EEG-evoked potentials (EP) related to the presentation of b/w-photos of faces but not to other meaningful stimuli. Within the last two years this finding could be confirmed in several studies. The largest amplitude of the EP related to faces and the most distinct category-related differences were found at electrodes F3, F4 and Cz. At Cz (reference: linked mastoids) an EEG-response of 3 prominent peaks (N135-P200-N290) was found.

We presented photos of faces in 11 different paradigms to 133 right-handed subjects (50% female, 50% male). In 4 paradigms ("class 1") we compared face- to non-face-stimuli (e.g. body-parts, tools), in 3 paradigms ("class 2"), to other face-stimuli (e.g. different views of the head). The early components related to body-parts were similar to those evoked by faces and revealed a large positive peak at about 200-210 ms. Beyond 210 ms the EPs deviated significantly from "face"-EPs. The EPs related to flowers and tools were very similar and had less prominent and later peaks (Fig.1). Comparing the results between the two classes of experiments, significant differences in "face"-EPs occurred only between 340-440 ms. In the earlier face-specific-components, no difference could be detected (Fig.2). Gender-differences appeared for face-stimuli beyond 340 ms. (DFG-grants Gr161, Se520)



COCHLEA: NERVE RESPONSES, TRANSMITTERS AND SECOND MESSENGERS

480.1

DII LABELING OF THE AUDITORY NERVE IN THE CHINCHILLA AND MONGOLIAN GERBIL. P. R. Schuyler*[1,2], A. Al-Ahmad*[3], S. C. Chamberlain[1,3], N. B. Slepecky*[1], R. L. Smith*[1,3], and R. T. Verrillo[1]. [1]Institute for Sensory Research, [2]Department of Electrical and Computer Engineering, and [3]Department of Bioengineering, Syracuse University, Syracuse, NY 13244

The auditory nerves of chinchillas and gerbils were labeled with minute crystals of DII. In chinchilla, the dye was placed either at the surface of the auditory nerve in the internal meatus or in Rosenthal's canal at various sites along the cochlear spiral. In gerbil, dye was placed only at sites in Rosenthal's canal. Diffusion of the dye occurred in darkness at room temperature for 4-11 months while the tissue was stored in 4% paraformaldehyde in 0.1M phosphate buffer at pH = 7.2. Tissue was then dissected and decalcified with buffered EDTA. Serial 20-µm frozen sections were mounted on gelatin-coated slides. Slides were stored uncovered and frozen for months without loss of fluorescence or resolution.

When DII was placed on the auditory nerve, the neurons of radial fibers to inner hair cells were continuously labeled along a region in the apical half turn of the basal turn; however, no labeled spiral fibers were observed in the organ of Corti. This suggests that the axons of type II ganglion cells are segregated from type I fibers in the internal meatus. In both species, punctate labeling in the spiral ganglion resulted in: a discrete dense band of labeled fibers in the modiolus; a mottled region in the peripheral internal meatus; and a discrete dense band as the nerve trunk enters the cochlear nuclei. The mottled region suggests that a zone of tonotopic scrambling may exist at the base of the modiolus. We examined carefully the labeling of stained fibers in the gerbil cochlear nucleus. No DII was observed surrounding the characteristic microcystic lesions confirming that these structures are postsynaptic and not part of the auditory nerve fibers. The ultimate objective of continuing studies is a detailed map of the tonotopic organization of the auditory nerve in the modiolus, internal meatus, and cochlear nuclei in both species. MECHANICAL AND NEURAL CONTRIBUTIONS TO PROLONGED RESPONSE LATENCIES IN IMMATURE KITTENS. E.J. Walsh and J. McGee*. Boys Town National Research Hospital, Omaha, NE 68131.

It is well known that neural responses to acoustic stimulation are significantly prolonged in neonatal kittens relative to those observed in adults (Walsh et al., 1986). The source of the prolongation is unknown and both cochlear and neural factors may contribute to the immaturity. Onset latency of the cochlear microphonic (CM) was measured to estimate cochlear delay associated with responses to acoustic stimulation, and auditory brainstem response (ABR) Wave I latency was measured simultaneously to determine overall response latency. The difference between the onset of CM and ABR Wave I latency was taken as an inferential estimate of synaptic and other neural delays. Far-field procedures were used to record CM and ABR so that measurements could be made from individuals longitudinally.

CM and ABR Wave I latencies declined along roughly exponential trajectories and CM acquired adultlike latencies relatively early compared to Wave I (i.e., CM latencies were adultlike by the end of the second postnatal week). At 4 kHz, CM latency accounted for approximately 70% of the overall response delay on the 7th postnatal day, 67% on day 11, and 60% on the 15th day. Similar findings were made for responses to 11 kHz, although CM accounted for approximately 60% of the total delay at both 11 and 15 postnatal days. Thus, preliminary results indicate that mechanical immaturities originating in the cochlea are the primary determinants of Wave I latency prolongation and that neural immaturities associated with synaptic delay and myelination account for the remainder.

FUNCTIONAL CHARACTERISTICS OF SPIRAL GANGLION NEURONS AFTER HAIR CELL REGENERATION. R.J. Salvi, S.S. Saunders*, and E. Hashino*, Hearing Research Lab., SUNY University at Buffalo, Buffalo, NY 14214

Recent studies have shown that sensory hair cells in the avian ear can regenerate after being destroyed by ototoxic drugs or acoustic trauma. One of the important questions that needs to be answered is whether spiral ganglion neurons which reinnervate the newly formed hair cells function normally. In the present study, extensive hair cell lesions were produced in adult chickens using kanamycin (KM) (400 mg/kg/d x 10 days). Immediately after KM treatment, the compound action potential (AP) threshold was significantly elevated and the amplitude greatly depressed. The only neurons that responded to sound immediately after KM treatement were those with low characteristic frequencies (CF); however, thresholds of the units were extremely high and their tuning curves were broader than normal. In addition, the spontaneous discharge rates of neurons that were responsive to sound were reduced significantly. Over the next few weeks, the AP threshold and amplitude recovered rapidly and neurons with a broader range of CFs were encountered. Similary, the neural thresholds improved, the tuning curves became more sharply tuned and the spontaneous discharge rates increased with recovery time; however, these measures had not fully recovered by 40 days post-treatment. (Supported by NSF BNS9007822).

CHARACTERISTICS OF THE RESPONSE RECOVERY FOLLOWING TWO-TONE SUPPRESSION IN AUDITORY-NERVE FIBERS. K.G. Hill*[1] and C.D. Geisler[2]; Research School of Biological Sciences, Australian National University, Canberra City, Australia[1]; Depts. of Neurophysiology and Electrical and Computer Engineering, University of Wisconsin, Madison, WI 53706[2].

During a period of tens of milliseconds following termination of an excitatory, conditioning tone, the neural rate response in an auditory nerve fiber to a second excitatory test tone is reduced, relative to the response to the test tone preserved in isolation. Normal response magnitude to the test tone characteristically recovers as the delay between termination of the conditioning tone and the test tone is increased (Harris and Dallos, J. Neurophys. 42, 1083, 1979). This effect, is also manifest as post-excitatory depression of spontaneous rate.

Immediately following termination of a suppressor tone imbedded in a continuous, excitatory tone at fiber "characteristic frequency (CF)", the CF-driven neural rate is re-established with a characteristic recovery that becomes slower as the level of the suppressor tone is increased above excitatory threshold (Hill and Palmer, Hearing Research, in press).

In a two-tone paradigm, if the suppressor tone is set to that level that elicits a neural rate equal to the steady-state, CF-driven rate, or, if the suppressor tone and the CF tone at corresponding levels are presented in sequence with the suppressor tone leading as conditioner, then a similar delayed recovery of the CF-driven rate is observed. This suggests that recovery of response to the CF tone following presentation of the suppressor, either in the two-tone paradigm or as a prior conditioning tone, shares a common mechanism.

DEVELOPMENT OF EVOKED MEASURES OF AUDITORY FUNCTION IN THE CANINE NEWBORN. G.M. Strain and B.L. Tedford*. Vet. Physiol., Pharmacol. & Toxicol., Louisiana State Univ. Sch. Vet. Med., Baton Rouge, LA 70803.

Congenital deafness resulting from perinatal degeneration of the stria vascularis occurs in species ranging from human to mouse. Many dog breeds are affected, especially Dalmatians, where the incidence reaches 30%. Prior to studying the perinatal process of hearing loss in Dalmatians we studied the normal pattern of development of auditory function in hearing dogs from birth until after opening of the ear canal using chronically implanted electrodes.

A silver ball electrode was implanted in the ear canal adjacent to the tympanum 24-48 hr after birth in beagle puppies; an L-shaped polyethylene tube was also implanted for presentation of auditory stimuli. Implants were also made in two Dalmatians known to carry the deafness gene(s). Click stimuli (100 μs, 11.4/s, 135 dB SPL; rarefaction [R], condensation [C] and alternating [A] polarity) were used to elicit brainstem auditory evoked potentials (BAEP) and other derived responses; recordings (n=1000 X 2, 10 ms, 150-3K Hz, vertex to tympanic electrode) were made daily until after opening of the ear canals.

Cochlear microphonics (CM) were present 3 days after birth, the earliest time at which recordings were taken. Recognizable BAEP peaks were first present on days 4-6 after birth in response to R and C stimuli, along with N1, the 8th nerve action potential, while responses to A stimuli were not present until 1-2 days later. A similar pattern was observed in one Dalmatian, although possibly delayed. The second Dalmatian showed a CM but no BAEP or N1 up through the age of 9 days when it died; it is assumed that this dog would have been deaf in the implanted ear. The observed sequence of development was earlier than previously reported for the dog (*Acta Otolaryng* 76;1, 1973).

MODULAR, EXPANDABLE MICROCOMPUTER WORKSTATION FOR SYNTHESIZING COMPLEX AUDITORY STIMULI, AND FOR RECORDING AND ANALYZING NEUROPHYSIOLOGICAL RESPONSES. J.D. Vrieslander*, J.F. Skovira*, and R.R. Capranica. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853. Current address for JFS: Engineering Accelerator Systems, IBM Corp., Endicott, NY 13760.

A microcomputer-based system has been developed for fast, digital synthesis of complex sound stimuli, recording of single-unit spike trains, and interactive graphic analysis of response properties. For synthesis and spike recording, the system uses an Apple Macintosh II, a GW Instruments data acquisition card, and a modest amount of interfacing and signal conditioning electronics. The software for analyzing acquired data files runs on any Macintosh.

Stimuli can be computed waveforms or digitized natural sounds; both types are outputted in 16-bit samples at rates up to 100 ksamples/s. The software design is very flexible; by adding new program modules virtually any computable waveform can be synthesized, and any stimulus parameter can be set to a constant or selected as a variable. Experimenters can quickly design a series of parametrically varying stimuli, and immediately generate them under manual or automatic control.

Neural responses are recorded using either of two interfaces. For simultaneous recording from multiple units, spike events can be separated by external threshold discriminators or spike sorters, with timestamps saved for eight independent channels. For single-unit experiments, the spike train waveform is digitized, and the spike times are extracted by seeking pattern matches to a single-spike template. The algorithm uses separately optimized "coarse" and "fine" scans to improve speed and accuracy, and template updating to adapt to slow changes in spike shape. With either interface, spike timing can be as precise as ±5 μs. The pattern-matching scheme outperforms threshold discriminators when there is substantial noise or baseline drift in the spike train waveform.

The workstation has been used successfully in several studies of sound encoding in the peripheral auditory systems of frogs and lizards. Supported by NIH grant NS 09244 and (for JFS) IBM Corp.

OLIVOCOCHLEAR NEURONS IN RHESUS MONKEY AND CHIMPANZEE. R.N. Strominger, N.L. Strominger, S.M. Silver* and S.M. Parnes*. Department of Anatomy, Cell Biology and Neurobiology and Division of Otolaryngology, Albany Medical College, Albany, NY 12208.

A study was performed of the distribution and morphology of olivocochlear neurons (OCN) in rhesus monkey and chimpanzee after unilateral cochlear injections of HRP.

Two distinct cell clusters were labeled bilaterally in monkey. The predominant cluster, composed of small fusiform neurons, was ipsilateral to the injection just dorsomedial to the lateral superior olive (LSO). Similar neurons were labeled in this area contralaterally, but were less numerous. The second group was a diffuse collection of large multipolar neurons in the region of the ventral nucleus of the trapezoid body (VTB). In one animal the ipsilateral group was larger but in the other the contralateral group had more labeled neurons.

In chimpanzee three distinct cell groups were labeled ipsilaterally. The predominant group was composed of large multipolar neurons in the region of the lateral nucleus of the trapezoid body. A slightly smaller group, composed of intermediate sized neurons, was dorsomedial to the LSO. The smallest group composed of large multipolar neurons was in the VTB. Only 4-5% of some 340 OCN were contralateral; all were in the VTB. The number of OCN in chimpanzee was about a third that of monkey.

TRANSIENT INTRACRANIAL PRESSURE EVOKES EIGHTH NERVE POTENTIALS IN FROG. R.L. Seaman and J.A. Rasbury*. Dept. of Biomedical Engineering, Louisiana Tech Univ., Ruston, LA 71272.

To evaluate the potential of intracranial pressure to stimulate the inner ear, experiments were performed on Rana catesbeiana (140-250 g, M/F) under ketamine anesthesia at room temperature. After removal of midline skin, muscle, and partial frontoparietal bone, dura was contacted with a vertical probe. An Etymotic ER-3A earphone and an ER-10 microphone were coupled to the left tympanum. Potentials were recorded between electrodes in midline frontoparietal bone and posterior to the left otic capsule.

Transient displacements of the probe evoked tympanum pressures and eighth nerve potentials (EPs). The pressures consisted primarily of damped sinusoids with a frequency of 100-200 Hz. Individual EPs were similar in shape to EPs to acoustic clicks but occurred 1-1.5 ms later. Pressure and EP responses were absent when the driven probe was not touching the flexible floor and were different from responses evoked when the probe contacted bone.

Results demonstrate the ability of time-varying intracranial pressures to stimulate the vertebrate inner ear, most likely through ducts connecting brain and inner ear chambers.

P_2 PURINOCEPTORS STIMULATE INOSITOL PHOSPHATE RELEASE IN THE GUINEA PIG ORGAN OF CORTI. A.S. Niedzielski and J. Schacht. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI, 48109-0506.

Extracellular ATP is known to bind to P_2 purinoceptors and elicit responses in a variety of cell types, including neurons. Cellular responses to ATP have also been found to be mediated by the phosphoinositide second messenger cascade. In some cases, ATP may act as a cotransmitter in conjunction with acetylcholine. In the mammalian auditory periphery, acetylcholine is believed to be the primary efferent neurotransmitter. Recent studies by Ashmore and Ohmori (J. Physiol. 428:109-131, 1990) have demonstrated that ATP stimulates an increase of intracellular calcium in isolated outer hair cells from the guinea pig cochlea, whereas acetylcholine had a much smaller effect. This raises the possibility that ATP acts as a neuromodulator or neurotransmitter in the cochlea.

Previously, we reported that phosphoinositide hydrolysis is stimulated by muscarinic agonists in the guinea pig organ of Corti, possibly at the level of the outer hair cell. We have now determined that the P_2 receptor agonist ATP-γ-S (200 μM) elicits a 5-fold increase in inositol phosphates in the organ of Corti. Another P_2 agonist, α,β-methylene ATP (200 μM), elicited a 1.8-fold increase. By comparison, 1 mM carbachol increased inositol phosphates 2-fold.

These results suggest new functional roles for the phosphoinositide second messenger system in the cochlea, in addition to its activation via muscarinic receptors. Physiological responses to ATP via phosphoinositide-coupled receptors may include modulation of afferent and efferent neurotransmission.

CALMODULIN-DEPENDENT INHIBITION OF PHOSPHORYLATION OF TWO SPIRAL GANGLION PROTEINS.
R. Naik*, D. Coling and J. Schacht. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109-0506.

Phosphorylation of spiral ganglion proteins by endogenous protein kinase activity was assayed in homogenates from guinea pig inner ear with [γ-^{32}P] ATP. Regulation of protein phosphorylation by second messenger systems was assessed by additions of calcium, calmodulin, cyclic nucleotides and lipids. Phosphorylation of two prominent spiral ganglion proteins, 12 and 81 kD, was significantly reduced in the presence of calcium and calmodulin. This effect was partially blocked by the calmodulin antagonist trifluoperazine. Three models for this regulation are considered involving the stimulation of either protein phosphatase or proteolytic activity or the inhibition of protein kinase activity. In chase experiments designed to test the involvement of phosphatase and protease activity, the time-dependent decrease in ^{32}P label in both the 12 and 81 kD proteins was independent of calcium, calmodulin and trifluoperazine. These data favor regulation by a calcium/calmodulin-dependent inhibition of kinase activity. This type of regulation has been proposed for another 80-87 kD protein, MARCKS (Alberts et al., 1984). The 12 kD spiral ganglion protein appears to be a novel substrate for this unusual mode of regulation.

MOLECULAR CLONING OF cDNAs FOR G PROTEINS FROM COCHLEAR TISSUES. M.Tachibana*, E.Wilcox*, N.Yokotani*, M.Schneider*, D.Drescher and J.Fex*. Lab. of Molecular Biology, National Institute on Deafness and Other Communication Disorders, Bethesda, MD 20892

G proteins play crucial roles in sensory organs such as retina and olfactory epithelium. Little is known, however, about G proteins in the hearing organ. The purpose of this study was to obtain the primary structure of G proteins in the cochlea by molecular cloning techniques.

Total RNA was extracted from the whole cochlea of the mouse and from the organ of Corti or stria vascularis/spiral ligament of the guinea pig. RNA was reverse transcribed and cDNAs with nucleotide sequences resembling those coding for G proteins were selectively amplified by polymerase chain reaction (PCR), using degenerate primers. Agarose gel electrophoresis revealed two bands of PCR products of approximately 300 and 350 base pairs. Individual PCR products were cloned into pGEM-7Zf(+).

Three G_S-like cDNAs were obtained from the whole mouse cochlea and from the guinea pig organ of Corti. The molecules showed high (>94%) nucleotide similarity to known G_S cDNAs from other tissues. Four G_i-like cDNAs were obtained from the guinea pig stria vascularis/ spiral ligament. Three of these had moderate (74-81%) nucleotide similarity to the known G_i cDNAs from other tissues. One of them showed high (97%) similarity to the G_i cDNA from the macrophage cell line. Using these G protein-like cDNAs as probes, we are now trying to determine full-length sequences of G protein cDNAs from a cDNA library, which we are making from the mouse cochlea.

MORPHOLOGY AND DISTRIBUTION OF TERMINAL FIBERS IN THE AMPHIBIAN AND BASILAR PAPILLAE. C.Bertolotto*, D.D.Simmons, and P.M.Narins. Dept. of Biology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

There are two distinct auditory organs in the frog: the amphibian papilla (AP) and the basilar papilla (BP). Biocytin injections were made into the posterior branch of the VIII nerve of *Rana pipiens*. Fibers were labeled retrogradely to both auditory organs. Both the AP and BP were sectioned systematically and reconstructed in the light microscope. Additionally, the gross innervation patterns as well as the fiber caliber and myelination in thin sections were also observed. Although labeled fibers in the AP exhibited more morphological heterogeneity than fibers in the BP, the two organs were surprisingly very similar. In caudal regions of the AP, labeled fibers had an average diameter that ranged from 0.65-3.75 μm, and contacted as many as 5 hair cells (HCs). The average number of terminal branches was 8.2 with a branching asymmetry of 0.5. In the rostral regions, the fibers had an average diameter that ranged from 0.75-4.5 μm, and contacted as many as 9 HCs. The average number of terminal branches was 7.5 with a branching asymmetry of 0.6. Labeled fibers in the BP had a more homogeneous morphology. The average diameter of labeled fibers was roughly 4 μm, and they contacted as many as 9 HCs. The average number of terminal branches was 11 with a branching asymmetry of 0.6. The morphological heterogeneity of fibers in the AP may be a function of the systematic place differences in frequency response of the papilla.

FIBRONECTIN STAINING OF THE BASILAR MEMBRANE OF YOUNG AND AGED RATS. E.M. Keithley, L. Kitabayashi and N.K. Woolf. Division of Otolaryngology, University of California, San Diego, La Jolla, CA 92093.

Mechanical presbycusis was hypothesized by Schuknecht (Arch Otolaryngol 80:369 '64) to account for age-related hearing loss in excess of that attributable to the loss of hair cells and neurons in the human cochlea. Aged animals also show hearing losses that seem large relative to the loss of sensory-neural elements. It has now been demonstrated that fibronectin is a major component of the basilar membrane (BM) and it is possible that this large (220kD) matrix protein contributes to BM stiffness (Santi et al Hear Res 39:91 '89). Young (2 months) and aged (25 months) Sprague-Dawley rats were perfused with mixed aldehydes and cochlear sections were incubated with biotinylated goat anti-rabbit fibronectin. The BM in the young animals had strong reactivity throughout its length. The old animals showed comparable staining of the BM in the basal turn, but weak or no staining in the apical cochlear turn. It is possible that the decrease in BM fibronectin affects cochlear mechanics and contributes to the observed threshold shifts in aged cochleas.

TRANSIENT EXPRESSION OF FIBRONECTIN-LIKE PROTEIN IN THE ORGAN OF CORTI FOLLOWING NOISE EXPOSURE. N.K. Woolf, F.J. Koehrn*, H. Gompers-Foster* and A.F. Ryan. Div. of Otolaryngology, UCSD Medical Center and Veterans Administration Medical Center, La Jolla, CA 92093-9112.

Noise trauma is a significant source of hearing loss and cochlear pathology. While the anatomical and functional correlates of noise exposure are well established, the molecular bases for temporary (TTS) and permanent (PTS) threshold shift are poorly understood.

Mongolian gerbils were exposed to a two-octave (1414-5656 Hz) band of noise for one hour at 110 dB SPL. Auditory brain stem evoked potential thresholds were determined prior to noise exposure, and at either 6 hours, 24 hours or 7 days postexposure. Animals were sacrificed following their postexposure hearing test and processed for immunocytochemical examination. Fibronectin-like protein was detected in Deiters' cells beneath the outer hair cells during periods of TTS at 6 and 24 hours postexposure, but not following recovery from TTS at 7 days. Fibronectin expression reflects either synthesis or uptake of this glycoprotein by Deiters' cells during recovery from TTS.

DUAL MECHANISMS FOR PRODUCTION OF NEW HAIR CELLS IN REGENERATING AVIAN COCHLEA. Y Raphael* and J.M. Miller. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109

Acoustic overstimulation of chick auditory epithelium results in hair cell loss and subsequent replacement by new hair cells (Corwin and Cotanche, 1988; Ryals and Rubel, 1988). Although the complete mechanism by which avian hair cells regenerate is not known, it has been shown that repair is based, at least in part, on production of new hair cells which eventually replace lost cells. The source of new hair cells, however, has not yet been unequivocally established. In the present study we examined the auditory epithelium immediately following pure tone (1.5 kHz, 124 dB, for 10 h) overstimulation. We observed the presence of mitotic figures in the luminal surface, among the cells which constitute the auditory mosaic in the region of short hair cells. Transmission electron microscopic analysis also showed cells which appeared like differentiating hair cells. These cells had a luminal surface, a microvilli cover, dense cytoplasm, basal bodies and a kinocilium. Our preliminary interpretation for this early appearance of cells with this "immature hair cell-like" combination of morphological features is that supporting cells may transdifferentiate to become hair cells without divisions. This suggests there may be at least two different mechanisms for hair cell regeneration in chicks: 1. Supporting cells of the epithelial mosaic divide during or early after the insult and some of them become new hair cells. 2. Supporting cells transdifferentiate to new hair cells.

IMMUNOCYTOCHEMICAL LOCALIZATION OF AMPA RECEPTOR SUBUNITS IN THE RAT COCHLEA. R.A. Altschuler, C. Hunter, Y. Raphael* and R.J. Wenthold. Kresge Hearing Research Institute & Dept. Anat & Cell Biology, University of Michigan, Ann Arbor, MI 48109 and Lab. Molecular Otology, NIDCD, NIH, Bethesda, MD 20892.

While the endogenous transmitter of hair cells has yet to be identified, there is considerable evidence that it acts on an excitatory amino acid (EAA) receptor. Recently, a family of EAA receptors (GluR) was cloned (Hollmann et al,1989; Keinanen et al,1990; Boulter et al,1990) . The GluR family is composed of at least four similar members (A-D) which, when expressed in oocytes or cultured cells, can combine to form heteromeric complexes with physiological properties that appear to be related to subunit composition. It is therefore important to know which subunits are expressed in the cochlea and their localization.

Antibodies were made to synthetic peptides corresponding to carboxy terminal sequences for GluR-A, GluR-B/C and GluR-D. The antibodies were applied either to cryostat sections or surface preparations of paraformaldehyde fixed rat cochlea and visualized with immunofluorescence and immunoperoxidase techniques respectively. 0.3% triton-X was used to increase permeability in surface preparations. In cryostat sections immunolabeling of spiral ganglion cells was observed using antibodies to GluR B/C and GluR-D but not with antibodies to GluR-A. Antibodies to GluR-B/C and GluR-D also immunolabeled afferent dendrites at the bases of inner and outer hair cells, visible in both cryostat sections and surface preparations. No labeling in the organ of Corti was observed using antibodies to GluR-A. These results suggest that a similar excitatory amino acid receptor is present at synapses of inner and outer hair cells and that the receptor complex contains GluR-D, and GluR-B/C but not GluR-A.

FUROSEMIDE OTOTOXICITY IS ENHANCED IN ALBUMIN-DEFICIENT RATS. L.P. Rybak, C. Whitworth,* V. Scott,* A. Weberg*. Dept. of Surgery, SIU School of Med.,Springfield,IL 62794

The analbuminemic rat was developed from Sprague-Dawley rats (Nagase et al., Science 205:590, 1979). The Nagese analbuminemic rat (NAR) has only barely detectable amounts of albumin in its serum. These mutants have no grossly discernible signs of pathology, and the total serum protein concentration is similar to that of normal Sprague-Dawley rats because of an increased globulin fraction. Furosemide is a loop diuretic which is highly protein-bound. Ototoxicity is one of its potential side effects. The purpose of the present studies was to investigate the effect of furosemide on the endocochlear potential (EP) of the Sprague-Dawley and NAR rats. Young adults of either type were anesthetized with Rompun (1 mg/kg). Tracheotomy was performed and the EP was measured with a microelectrode inserted through the round window membrane. After a stable EP was recorded, furosemide 35 mg/kg was injected through a cannula in the jugular vein. Sprague-Dawley rats were found to have very small reduction of the EP (9.46 ± 2.9 mv). In sharp contrast, the NAR's exhibited an extremely large reduction of the EP (88.0 ± 10.0 mv) ($p<0.001$). These findings support the hypothesis that the access of furosemide to its site of ototoxic action in the cochlea depends on the quantity of unbound furosemide in the serum. CHEMICAL SENSES: PERIPHERAL MECHANISMS IV

481.1

RAT TASTE EPITHELIAL cDNA LIBRARY: MOLECULAR GENETIC APPROACH TO TASTE TRANSDUCTION. P.M. Hwang, C.E. Glatt, D.S. Bredt, G. Yellen, R.R. Reed and S.H. Snyder. Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The mammalian taste receptor cells utilize diverse signal transductory mechanisms for different taste modalities. These are thought to range from direct interactions with apical membrane channels by certain ionic tastants to the generation of intracellular second messenger molecules by other types of tastants. Data from our laboratory as well as from others suggest a role for second messengers in taste signal transduction. However, the scarcity of taste receptor cells has limited biochemical investigations into the mechanisms of taste transduction. In order to circumvent this difficulty we have recently constructed a cDNA library from rat tongue epithelial tissue highly enriched in taste receptor cells, and we have initiated a search for the various genes involved in the cyclic nucleotide and phophoinositide signal transduction pathways in our cDNA library.

We describe the construction and the characterization of the rat taste epithelial library as well as the identification of various signal transductory genes found in it. Also we report the cloning and characterization of a unique potassium channel gene that has high homology to a delayed rectifier potassium channel.

481.2

PARTIAL PURIFICATION AND CHARACTERIZATION OF AN L-ARGININE RECEPTOR/CHANNEL FROM CATFISH TASTE EPITHELIUM. J.G. Brand[1,2,3*], J.H. Teeter[1,2], and D.L. Kalinoski[1], [1]Monell Chemical Senses Center, [2]Univ. of Penn., and [3]Veterans Affairs Administration, Phila. PA 19104.

Behavioral, neurophysiological and biochemical studies suggest that there are independent high affinity receptor sites for the stimuli L-alanine (L-ALA) and L-arginine (L-ARG) in the catfish taste system. Biochemical studies have characterized binding of L-ALA and L-ARG to a sedimentable membrane fraction (P2) from taste epithelium and have begun to characterize L-ALA-stimulated second messenger accumulation in taste tissue. Electrophysiological studies have identified L-ARG-gated cation channels in purified taste membranes. More recent studies have shown that taste stimulus binding to fraction P2 could be selectively inhibited by the lectins DBA, Jacalin, PHA E&L and RCA I. Furthermore, the biotinylated lectins selectively labeled only a few glycoproteins by Western blotting to SDS-PAGE separated taste membranes. We have taken advantage of this selective labeling by lectins to partially purify and reconstitute an L-ARG receptor/channel. Fraction P2 from taste epithelium was extracted using 4% CHAPS. Extracted material was incubated with either PHA E or RCA I coupled to agarose for 90 min at 10°C. The lectin-agarose was poured into a column, washed, and specifically bound material eluted with either the specific hapten sugar or 1 M NaCl. Eluted material was either separated by SDS-PAGE or reconstituted into phospholipid vesicles by extensive dialysis. Phospholipid bilayers into which PHA- and RCA- purified membrane vesicles had been incorporated frequently displayed reversible increases in cation conductance in the presence of micromolar concentrations of L-ARG. The conductance, ion selectivity and concentration dependence of the partially purified L-ARG-activated channels were similar to those observed with native membrane vesicles.

481.3

ANTAGONISM OF THE GERBIL'S SUCROSE TASTE RESPONSE BY 6-CHLORO-N-ACETYL-D-TRYPTOPHAN. William Jakinovich, Jr. Dept. of Biological Sciences, Lehman College and the Graduate School, CUNY, Bronx, NY 10468.

We have discovered a fourth sucrose taste antagonist, 6-Chloro-N-Acetyl-D-Tryptophan (6-CNAT), an amino acid rather than a sugar derivative, which has been partially characterized as follows:

a) In solution, by itself, it does not stimulate the gerbil's chorda tympani nerve.

b) The taste response produced by sodium chloride was unaffected by 6-CNAT.

c) Sucrose responses were inhibited when mixed with 6-CNAT.

Supported by NIH NINCDS grant #DC00434.

481.4

DYNAMIC FILTER PROPERTIES OF CHEMORECEPTOR CELLS IN SIMULATED ODOR PLUMES. J. Atema, R. Voigt* and G. Gomez*. Boston University Marine Program, Marine Biological Laboratory, Woods Hole, MA, 02543

Intensity fluctuations in turbulent odor plumes are typically chaotic in time and space dimensions. These stimulus intensity patterns are filtered by a fluid boundary layer before they reach the receptor surfaces. Microvoltammetry allows us to measure a more precise temporal correlation between stimulus arrival and cell response than previously possible. A carbon-tip microelectrode approximately the size of a lobster olfactory sensillum (30 um diameter) was placed into the tuft of sensilla in a recording chamber allowing simultaneous measurements of the chemical signal and the neural response to the stimulus. We used both well-defined pulses and with semi-natural odor plume patterns. The instantaneous firing rate of spikes in relation to the instantaneous stimulus intensity profile allowed us to determine how chemoreceptor cells in situ translate the chaotic chemical intensity signal characteristic of odor plumes into a temporal neural signal pattern (transfer function). The data confirm results from earlier studies on adaptation and disadaptation properties of receptor cells and predictive computer models based on information contained in odor plumes (Moore & Atema, 1988 *Biol. Bull.*). The rate of stimulus onset and its relation to the immediately preceding stimulus history appear to be critical features for these chemoreceptor filters.

IN SITU RECORDING FROM HAMSTER FUNGIFORM TASTE CELLS: RESPONSE TO SOUR STIMULI. T.A. Gilbertson, P. Avenet, S.C. Kinnamon and S.D. Roper. Dept. of Anat and Neurobiol, Colo St Univ, Ft. Collins CO 80523, and Rocky Mt. Taste and Smell Center, Univ Colo Health Science Center, Denver, CO 80262.

Current transients reflecting taste cell action potentials were recorded in response to sour stimulation using a non-invasive technique (Avenet and Lindemann, Biophysical Abstracts 59:594, 1991). A recording pipette of 100 μm tip diameter which could be internally perfused with sour (acid) stimuli was pressed onto fungiform papillae of whole tongues excised from hamsters. Stimulus solutions contained 30 mM NMDG-Cl, 5 mM HEPES, pH 7.0 or 30 mM NMDG-Cl and various combinations of either citric acid (CA) or HCl. Action currents were 5 to 20 pA in amplitude and their frequency varied in a dose-dependent manner with pH. Shapes of action currents were generally biphasic, but monophasic currents were also recorded. In a single taste bud, CA always gave a stronger response than HCl at an equivalent pH, but NMDG-citrate buffered to pH 7.0 gave no response. Taste buds previously adapted to NaCl (10 mM) still showed responses to CA indicating that different cells are involved in salt and sour responses. Unlike the mudpuppy (Kinnamon and Roper, J. Gen. Physiol. 91:351, 1988), the citric acid response was not affected by KCl or TEA. The response to CA was also unaffected by vanadate, 9-AC, cadmium, DIDS, nor was it affected by exposing the apical membrane to NH_4Cl to modify internal pH. Amiloride (30 μM), however, completely and reversibly suppressed the action currents elicited by CA. An amiloride-sensitive steady state current could also be measured in the presence of CA. These data suggest that sour (acidic) stimulation involves an amiloride-sensitive process and that in mammalian fungiform papillae the transduction mechanism for sour taste does not involve a blockage of apical K-channels. MEMBRANE CAPACITANCE MEASURES ELECTRICAL COUPLING BETWEEN TASTE CELLS. A. R. Bigiani and S. D. Roper. Dept. of Anatomy and Neurobiology, Colorado State University, Ft. Collins, CO 80523, and the Rocky Mt Taste & Smell Center, Denver, CO 80262.

In vertebrate taste buds, intracellular dye injections with Lucifer Yellow have revealed coupling between receptor cells (Yang & Roper, 1987). To study functional intercellular coupling in taste buds, we have developed a new experimental approach consisting of applying patch pipettes onto taste cells in thin (100-200 μm) slices of lingual epithelium from *Necturus maculosus*. In this preparation, interrelationships among cells within the taste bud are preserved. The whole-cell voltage-clamp configuration of the patch recording technique readily allows one to measure the membrane capacitance of taste cells. Membrane capacitance gives an estimation of the cell membrane available to be charged during a voltage step command, including any additional membrane contributed by electrically-coupled cells. We tested whether capacitance measurements monitored functional electrical coupling by perfusing the slice preparation with 1-octanol, a blocker of gap junctions. If taste cells are electrically-coupled via gap junctions, we should initially record high values of cell capacitance which would be reduced by 1-octanol. Indeed, in some experiments, cell capacitance was initially high and decreased when 500 μM 1-octanol was added to the bath. Lucifer Yellow in the patch pipette confirmed that these cells were coupled to adjacent cells. In other experiments, 1-octanol had no effect and these cells were not dye-coupled. These data indicate that functional electrical coupling between taste cells can be monitored by measuring membrane capacitance during patch clamp recordings. This now provides a means to test whether electrical coupling in the taste bud is affected by chemosensory stimulation or by neuromodulators.

UNILATERAL NARIS CLOSURE IN ADULT MICE PRODUCES A DOWN-REGULATION OF THE OLFACTORY BULB DOPAMINE PHENOTYPE H. Baker[1], D. Stone[1] and J. Maruniak[2]. [1]Cornell U. Med. Coll., White Plains, NY 10605 and Univ. Missouri-Col., Columbia, MO 65211.

Recent studies have shown that unilateral neonatal naris closure, assessed in adult rodents, produces a decrease in the expression of the dopamine phenotype in periglomerular neurons of the ipsilateral olfactory bulb. To distinguish afferent regulation of development from maintenance of phenotype, the current studies investigated the effects of unilateral naris closure produced in adult (4- to 6-month old) CF-1 mice. The changes in the dopamine phenotype, i.e., activity, immunoreactivity and mRNA for tyrosine hydroxylase (TH), the first enzyme in catecholamine biosynthesis, were measured 6-8 months post-closure. TH activity ipsilateral to the closure was reduced to 25% of that in the contralateral side and to 20% of that in sham operated animals. TH immunoreactivity (evaluated with a specific TH-antiserum) and mRNA [demonstrated by in situ hybridization (ISH)] exhibited a similar down-regulation. In contrast, immunoreactivity and mRNA (by ISH) for the GABA synthesizing enzyme, glutamic acid decarboxylase, were unchanged both ipsilateral and contralateral to the closure. These data suggest that maintenance as well as development of the dopamine phenotype are dependent on odor stimulation.

STRESS PROTEINS IN BULBECTOMIZED AND CONTROL RAT OLFACTORY EPITHELIUM (OE). V.McM.Carr and A.I.Farbman. Dept. of Neurobiology & Physiology, Northwestern Univ., Evanston, IL 60208.

We have examined the immunohistochemical reactivity of monoclonal antibodies directed against a 70 kDa heat shock protein (HSP70) and ubiquitin in the OE of control and unilaterally bulbectomized (OB-X) rats. These proteins are expressed rapidly and transiently in response to a variety of stresses. OE from Bouin's-perfused unoperated rats showed widely scattered HSP70-positive olfactory sensory neurons in the apical half of the OE. This localization and their absence from OB-X OE at 10 d. postop. indicates they are very mature neurons. Following OB-X, reactivity to ubiquitin and HSP70 appears in the supporting cells at 2 and 6 hrs postop, respectively. These initial responses were bilateral and also occurred in sham operated controls. However, by 24 hr supporting cell reactivity occurred on the OB-X side only. By 48 hr postop this supporting cell reactivity had disappeared. The results support other data showing rapid, transient stress protein responses in other systems (Brown, Neurosci.Res.,27:247,1990).

FLUORESCENT DYE (DII) REVEALS THE TASTE BUD CELLS AND AFFERENT INNERVATION IN THE LINGUAL EPITHELIUM OF THE MEXICAN SALAMANDER, AXOLOTL: A CONFOCAL LASER SCANNING MICROSCOPIC STUDY. T. Nagai. Dept. of Physiology, Teikyo Univ. Sch. of Med., Tokyo 173, Japan

Use of salamanders with large taste buds of a simpler structure has promoted cellular studies of taste receptor cells. However, little is known about afferent innervation to the cells. In a whole mount preparation of the anterior of the lingual epithelium, the overall innervation pattern of the glossopharyngeal nerve (IX) was clearly shown by the fluorescent carbocyanine dye, dioctadecyl-tetramethylindo-carbocyanine perchlorate (DiI) applied to the IX nerve stump. Beneath the epithelium, the labeled nerve fibers expanded horizontally to form a mesh-like structure, from which fascicles of the fibers extended outward toward the epithelium to innervate taste buds. Numerous taste buds (10/square mm at the tip) were labeled possibly transneuronally. In sectioned preparations, a single or several labeled cells with apical elongation toward a taste pore, showing a typical taste cell, was seen. In-between the distributed taste buds, fine fibers apparently formed free nerve endings within the epithelium.

Responses of subthalamic nucleus cell to pallidal stimulation and dopamine receptor blockade *J.R. Hollerman and A.A. Grace,* Departments of Behavioral Neuroscience & Psychiatry, Center for Neuroscience,University of Pittsburgh, Pittsburgh, PA 15260.

The subthalamic nucleus (STN) provides excitatory drive to the output nuclei of the basal ganglia, and to dopamine neurons in the midbrain. In this study, we recorded the response of subthalamic cells to stimulation of the globus pallidus in anesthetized rats in order to identify and characterize STN neurons. In addition, the influence of dopaminergic transmission on STN cell activity was assessed by recording the responses of individual STN neurons to acute administration of the dopamine receptor blocker haloperidol (HAL). In peristimulus time histograms, three types of response to pallidal stimulation could be identified: 1) excitation (lasting from 2-10 msec post-stimulus) followed by inhibition (from 10-40 msec, N=6), 2) inhibition (from 2-20 msec) followed by excitation (from 20-40 msec, N=5) and 3) inhibition only (from 2-40 msec, N=3). These responses most likely reflect and interaction between an inhibition mediated by pallidosubthalamic fibers (Rouzaire-Dubois, 1980) and a short latency excitation resulting from stimulation of excitatory corticosubthalamic fibers passing through or near the globus pallidus (Kitai and Deniau, 1981). In contrast, the longer latency activation observed may be a "rebound" excitation. Administration of HAL (cumulative dose of 0.8 mg/kg, i.v.) caused an increase in the firing rate of 2 cells, a decrease in the firing rate of 4 cells and no change in the firing rate of 3 cells. In 4 cells tested following HAL administration, i.v. apomorphine (0.8 mg/kg) reversed the change in firing rate caused by HAL.

NEOSTRIATAL UNIT ACTIVITY RELATED TO MOVEMENT PREPARATION IN A GO/NO-GO TASK IN THE CAT. J.W. Aldridge, J.F. Thompson*, E.A. Walters*, J.M. Groh and S. Gilman. Dept. of Neurology, Univ. of Michigan, 1103 E. Huron, Ann Arbor, MI 48104.

The functional role of single units in the putamen (PUT) and caudate nucleus (CN) in relation to the preparation of visually cued reaching movements was studied. Two cats were trained in a GO/NO-GO visual discrimination task. The animals sat on a force platform that had sensors for each limb, head movements and contact with the food delivery apparatus and target display. Visual cues were presented after a control period in which all limbs had to remain in contact with the force platform. Correct actions were: 1) GO cue - touch display with right forepaw; 2) NO-GO cue - maintain steady contact with force platform. Single units were recorded with microelectrodes inserted through a recording chamber. Changes in discharge rate were identified by a statistical comparison of epochs in the control and cue-to-movement periods. Significant rate changes in the GO task were detected in 31.9% of PUT (30/94) and 24.2% of CN (98/405) units. Lateral CN regions had more responsive units (32.1% vs 17.4%) than medial regions. Discharge changes prior to movement were usually (60.0% PUT, 56.1% CN) more tightly coupled to the stimulus than to the up-coming movement. Units with vigorous GO cue-related activity were usually (72.2% PUT, 54.5% CN) activated in the NO-GO task. Units with a weak link to the GO cue were rarely activated in the NO-GO task and units responsive to the NO-GO cue alone were uncommon. These findings suggest that, in the behavioral setting of a GO/NO-GO motor task, neostriatal activity is strongly related to preparation for executing or withholding movement. Furthermore, unit discharge related to the sensory cues is strongly linked to the context of movement requirements in the task. Support: NIH grant NS19613 and United Cerebral Palsy Foundation.

SYNAPTIC COOPERATIVITY MAY ARISE FROM THE FAST INWARD RECTIFICATION IN NEOSTRIATAL SPINY CELLS. C.J. Wilson, Dept. of Anatomy and Neurobiology, University of Tennessee, Memphis. TN, U.S.A.

Each neostriatal spiny neuron receives thousands of excitatory synaptic inputs from afferent fibers, which somehow act together to determine the timing and duration of the episodes of firing that are characteristic of these cells. Computer simulations of spiny neurons including large numbers of afferent synapses were employed to examine the degree to which the known morphological and biophysical properties of the cell may contribute to interactions among concurrently-active excitatory synaptic inputs.

Despite the location of excitatory synapses on dendritic spines, local dendritic EPSPs were extremely large when more than a few percent of synapses were activated in a clustered fashion on a portion of the dendritic field. Clustered activation of the dendrites was very ineffective in firing action potentials due to current attenuation by the classical synaptic nonlinearity. Synaptic activation distributed over the dendritic field produced much smaller local PSPs which summated more linearly and so were much more effective in exciting the cell. Simulation of the fast inwardly rectifying conductance known to be present on neostriatal neurons had little effect on clustered synaptic input. With distributed synapses inward rectification produced a cooperativity in which an excitatory input was more effective if it occurred concurrently with a limited number of others. There was an optimal number of inputs, beyond which additional synapses again had diminishing effects. The optimal number of inputs depended upon the size of the synaptic conductance change, the membrane potential and the activation curve for the inward rectifier, but invariably resulted in an EPSP amplitude that approximated spike threshold at the soma. ENHANCEMENT OF MOTOR CORTEX EVOKED NEURONAL RESPONSES IN THE SUBTHALAMIC NUCLEUS FOLLOWING GLOBUS PALLIDUS LESION IN RATS. Lawrence J. Ryan and Kevin B. Clark*. Department of Psychology, Oregon State University, Corvallis, OR 97331-5303.

The reciprocal connections of the globus pallidus and the subthalamic nucleus provide an important basal ganglia site for interaction of information arising from the cortex. Motor cortex information arrives via projections to the neostriatum or the subthalamic nucleus, whereas limbic cortex information arrives only via the neostriatum. The effect of globus pallidus lesion on the response of subthalamic nucleus neurons to motor or prelimbic cortex stimulation was examined.

Large kainic acid lesions of the globus pallidus, much of the neostriatum and the lateral portions of the thalamus were made in 5 rats. Smaller lesions, which partially damaged the globus pallidus and involved either the neostriatum or the lateral thalamus were made in 8 rats. Two groups of naive rats (n= 9 and 6) were examined. Extracellular recordings of antidromically activated (from globus pallidus or substantia nigra) subthalamic neurons were made. Primary motor and prelimbic cortex were stimulated with 0.3 and 0.7 mA (0.2ms) single pulses.

GP lesions increased 1) the high frequency bursting of subthalamic neurons, 2) the duration of excitation elicited from motor cortex [0.7 mA: Large lesions - X(SEM,n cells)=58.5(3.46,42) ms; Small lesions - 62.9(7.18,36); Cont.1 - 24.5(3.25,29); Cont.2 - 42.47(1.63,33)], 3) response amplitude (# action potentials evoked per stimulus) [0.7mA: Large lesions - 1st Excitation - 1.17(0.08,29), 2nd excitation - 9.59(0.92,42); Small lesions - 1st - 1.43(0.26,19), 2nd - 5.87(1.36,36); Cont.1 - 1st - 1.0(0.15,15), 2nd - 2.02(0.28,36); Cont.2 - 1st - 0.54(0.09,24), 2nd - 1.48(0.28,23) and 4) the percentage of subthalamic cells that responded to motor cortex stimulation (Large lesions - 98%; Small Lesions - 61%; Cont.1 - 59%; Cont.2 - 58%). Large lesions eliminated responses to prelimbic cortex.

Thus globus pallidus modulates subthalamic neuronal responsiveness to afferent input arriving from the motor cortex and acts as a conduit for information from limbic areas to reach the subthalamic nucleus.

MOTOR AND OCULOMOTOR SEQUENCING AND NEURAL ACTIVITY IN THE CAUDATE NUCLEUS OF MONKEYS. Y. Jurquet* and J.P. Joseph. Vision et Motricité, INSERM U94, F-69500 Bron, FRANCE

Neural activity in the head of the Caudate Nucleus of a behaving monkey was investigated during performance of a sequencing task derived from a paradigm used by Barone and Joseph in Prefrontal Cortex (EBR, 1989, 312-333). Basically, during a central fixation task, the animal had to remember the order of illumination of three fixed peripheral targets which were briefly illuminated in a random order. After a delay, using the same order, the animal had to orient successively towards each target and press it with an arm movement.

A) Visual responses to target onset usually consisted in a brief activity which depended on 1) the location of the target, 2) its rank (first or second) in the sequence, and 3) if the rank was second, on the location of the first target. In many cells, if the animal correctly encoded onset of a target but was prevented to use this information in the orienting and key-pressing task (by the experimenter who aborted the trial), then onset of the target was not re-encoded in the course of an identical trial executed 10 sec later. However, if identical trials separated by 10 sec. were successively presented to the animal and were all executed, then the information regarding location and rank of the targets was encoded each time. B) Many neurons were activated in relation to target acquisition by the gaze and/or by the arm. The main finding is that the activation depended not only on the parameters of the movements but also on the temporo-spatial characteristics of the whole sequence and on their rank in the sequence.

482.6

EFFECTS OF UNILATERAL NEOSTRIATAL LESIONS ON CUE- AND MOVEMENT-RELATED RESPONSES OF PALLIDAL NEURONS DURING A TRIGGERED HEAD MOVEMENT IN THE RAT. S. Usui, T.W. Gardiner, & S.T. Kitai Dept. Anatomy & Neurobiology, College of Medicine, University of Tennessee, Memphis, Memphis, TN 38163.

In previous work, we have demonstrated that neurons in the globus pallidus (GP) and neostriatum (Str) of the rat exhibit both cue- and movement-related changes in firing rate during performance of a trained head movement. GP appears to receive primarily inhibitory input from Str and excitatory input from the subthalamus, and in turn sends efferents to the entopeduncular nucleus, substantia nigra reticulata, and subthalamus. These circuits may participate in the control of sensory-triggered head movements. We examined the effects of unilateral Str lesions on behavioral performance and neuronal activity in GP during the head movement task. Rats were trained to hold their heads centered and then move to a left or right target in response to an auditory cue. Subsequently, unilateral lesions were made by injecting quinolinic acid (QA, 30-50 nmol) into lateral Str. Reaction and movement times were measured both before and several days after the lesion. To date, single-unit recordings have been obtained from 96 GP neurons. Thirty-four units have exhibited task-related changes. Seventeen units (50% of task-related neurons) altered their firing rates in association with cue presentation, whereas only movement-related changes in activity were observed for the remaining 17 units. The data obtained thus far contrasts with our previous data from intact rats in which nearly 80% of task-related units in GP exhibited changes in firing rate with cue presentation. Supported by NS-26473 and NS-20702.

482.7

THE RELATION OF PALLIDAL ARM NEURON DISCHARGE TO THE AMPLITUDE AND VELOCITY OF MOVEMENT. R.S. Turner and M.E. Anderson Depts of Psychology, Physiol. and Biophysics, Rehab. Medicine, and Regional Primate Research Center, University of Washington SJ-40, Seattle, WA 98195

Pallidal arm neuron discharge is often related to movement amplitude or velocity (Georgopoulos et al., 1983). We addressed two questions: (1) is pallidal activity better related to movement amplitude or velocity, (2) do movement amplitude effects interact with other characteristics of movement related changes in discharge?

Pallidal neurons were recorded from the external and internal segments (GPe and GPi) of two monkeys while they performed a two dimension reaching task. This required hand movements across a surface to targets in 8 directions and 3 distances from a central start position. Arm neurons were identified by: (1) task related changes in firing, and (2) responses to passive manipulation of the arm.

A high proportion of the neurons had task related changes in firing that were scaled with movement amplitude. Fewer were related to movement velocity. Of the 30 GPe and 12 GPi arm neuron studied during movements to three target distances, 67% had a linear relation between the average firing rate during the movement time and movement amplitude. All neurons in which more than 4 movement directions were tested (8 neurons) had a significant movement amplitude effect. The amplitude effects were independent of the magnitude, sign, and directionality of a neuron's task related discharge. Firing rate was better related to movement amplitude than peak velocity in 71% of the cases studied. Partial correlation coefficients confirmed this last finding.

Thus, pallidal activity is preferentially and independently related to movement amplitude. Supported by NS15017, RR00016 and H133B00081.

CHRONIC MULTI-CHANNEL SINGLE-UNIT RECORDINGS FROM 6-OHDA-TREATED RATS DURING L-DOPA-INDUCED CIRCLING. S.F. Sawyer, C.D. Myre and D.J. Woodward. *Department of Cell Biology and Neuroscience, University of Texas Southwestern Medical Center, Dallas, TX 75235*

Damage to the dopaminergic nigrostriatal projection in rats following intracerebral injection of 6-hydroxydopamine (6-OHDA) constitutes a useful animal model of Parkinson's disease. We have previously reported altered rates and patterns of neuronal activity in the neostriatum of 6-OHDA-treated rats. In this study, neostriatal unit activity was monitored following administration of L-dopa in unilaterally dopamine-depleted rats. Male Sprague-Dawley rats received an injection of 6-OHDA (8 µg in 4 µl) into the left medial forebrain bundle. Two arrays of 16 microwires were implanted in the basal ganglia, with at least one array positioned in the left neostriatum. Damage to the dopaminergic nigrostriatal projection was assessed by behavioral testing and contralateral circling to apomorphine (0.25 mg/kg, i.p.) or L-dopa (50 mg/kg, i.p.). Microwire localization was determined from X-rays and histological reconstruction. Spike activity of up to 8 neurons was recorded concurrently for weeks following 6-OHDA administration. Neurons in dopamine-depleted neostriatum tended to have higher rates and more bursty patterns of spike activity compared to neostriatal neurons in intact animals. L-dopa administration (50 mg/kg, i.p.) had heterogeneous effects on neuronal activity in the neostriatum: some neurons exhibited lower firing rates and less bursty patterns that resembled those found in neurologically-intact animals, whereas other units displayed an increase in spike activity that was correlated with circling behaviors. Preliminary studies indicate that neither SCH 23390 (0.3 mg/kg, i.p.; D1 antagonist) nor sulpiride (30 mg/kg, i.p.; D2 antagonist) blocked circling induced by L-dopa, and did not profoundly modify L-dopa-induced alterations of neostriatal spike activity. Administered together, the antagonists blocked both rotation and alterations in unit activity. Further studies are underway to investigate the basis of heterogenous responses to L-dopa. *Supported by DA-05352, MH-44337, AFOSR 90-0416 and Biological Humanics Foundation.*

ACTIVITY OF DOPAMINE NEURONS IN MONKEYS LEARNING AND PERFORMING COGNITIVE TASKS. W. Schultz*, T. Ljungberg* and P. Apicella* (SPON: European Neuroscience Association). Institut de Physiologie, Univ. Fribourg, CH-1700 Fribourg, Switzerland

Cognitive deficits are major symptoms of Parkinson's disease. Previously we showed that dopamine (DA) neurons in behaving monkey respond to attention-generating and motivating stimuli. We now tested DA neurons in cognitive tasks.

In spatial delayed responding, one of two horizontally arranged lights was illuminated for 1 s as instruction. A central light appearing 2 s after instruction offset triggered a reaching movement toward a lever indicated by the instruction light. Correct responses were rewarded with a drop of juice. Typical DA neuron impulses were recorded during and after task conditioning from areas A8, A9 and A10 in 2 Macaca fascicularis monkeys. During conditioning, 29%, 21% and 21% of 28 neurons responded phasically to instruction stimuli, trigger stimulus and delivery of reward, respectively. Responding neurons were located throughout areas A8, A9 and A10, although reward responses predominanted in A10. After task acquisition, the fraction of neurons responding to instruction and trigger stimuli increased (38% and 49% of 73 neurons, respectively), whereas reward responses diminished (11%).

In delayed alternation, the rewarded lever was alternated after each successful movement, and instructions were absent. Of 88 DA neurons, 65% and 52% responded to the trigger and reward, respectively. Trigger responses were lower before task acquisition and after overtraining, and reward responses diminished after overtraining. None of the DA neurons in either task showed delay-related sustained activity typical for striatum and frontal cortex.

These data demonstrate that DA neurons respond to the most significant attentional and motivating stimuli during performance of a cognitive task. Their activity does not reflect the specific cognitive components of the tasks, such as preparation of movement, expectation of external stimuli, expectation of reward, or working memory. Rather, DA neurons appear to participate in underlying attentional and motivational processes necessary for cognitive performance.

482.10

LEARNING-RELATED PLASTICITY OF STRIATAL FORELIMB NEURONS IN THE AWAKE, UNRESTRAINED RAT. R.M. CARELLI and M.O. WEST. Dept. Psychology, Rutgers Univ., New Brunswick, NJ 08903.

Long-Evans male rats (n=5) were chronically implanted with a detachable microdrive to record forelimb neurons in the dorsolateral striatum during a tone-discrimination task involving lever-pressing with the contralateral (right) forelimb for water reinforcement. To reduce trial-to-trial variability in reaching toward the lever, rats were trained to stand facing the lever, with the right forepaw on the floor in order to initiate tone onset at the start of each trial. Prior to each session, neurons related to forelimb movement were identified by sensorimotor exam. Increased discharge time-locked to the lever-press (relative to baseline firing when the forepaw was motionless on the floor) was termed "Signal:Baseline" (S:B). We have previously reported that forelimb neurons discharged in relation to the lever-press during early sessions (S:B range 2-10) but in no instance did a forelimb neuron discharge during the same skilled movement during repeated sessions (S:B=1) despite the fact that EMG activity showed consistent relationships to the lever-press across all sessions (Neurosci.Abs. 16: 233, 1990). Within-subject analysis revealed significant correlations between S:B and behavioral measures indicative of learning the task. However, S:B was not consistently correlated with the same aspects of learning between subjects. Thus, the change in forelimb neuronal firing is interpreted as a learning-related plasticity, reflective of learning about static conditions relevant for movement. As the subject learns that the context and contingencies governing a particular movement remain constant from trial-to-trial and session-to-session, the striatal representation of that movement gradually declines to a level indistinguishable from baseline. A similar decline would not be expected in sensorimotor cortical representations of the movement, which are projected to frontal cortical areas which receive convergent input from the striatum (via the pallidum and thalamus). This implies that a unique quality of the striatal contribution to motor programming regards the degree of constancy in sensorimotor contingencies relevant for movement. Supported by NSF BNS-8708523, DA 04551 and PHS RR 07058-21.

A COMPARISON OF PREMOVEMENT NEURONAL ACTIVITY IN MONKEY NEOSTRIATUM AND SENSORIMOTOR CORTEX. R. J. Nelson and T. W. Gardiner. Dept. of Anatomy and Neurobiology, College of Medicine, University of Tennessee, Memphis, 875 Monroe Avenue, Memphis, TN 38163.

Premovement activity (PMA) of primary somatosensory (SI) and primary motor (MI) cortical neurons often begins prior to EMG activity when monkeys perform sensory triggered movements. Recent studies suggest that some neostriatal neurons also discharge early in similar tasks. PMA was compared for cortical or neostriatal neurons recorded from five adult rhesus monkeys (*Macaca mulatta*) trained to make wrist flexion and extension movements in response to vibratory stimuli to the palm or to visual cues. They were also trained to maintain their wrist position following the same vibratory cues used in the movement task. Accordance with the *NIH Guide for Care and Use of Laboratory Animals, revised 1985* was maintained. To date, 27 area 3b, 63 area 1, 84 putamen and 29 caudate neurons have been analyzed. In general PMA for both putamen and caudate neurons occurred significantly earlier (means 110-170ms) before movement than PMA for area 3b and 1 neurons (means 70-110ms), depending upon movement direction and cue stimulus type ($p<.05$; single factor ANOVA; Scheffé comparison test). Neostriatal PMA occurred significantly earlier than that for MI neurons during extension but not flexion movements. One third of the neostriatal PMA neurons showed qualitatively different activity patterns immediately after, as compared with before movement onset. Over 85% of cortical PMA neurons showed early activity that was sustained for ≈100ms after movement onset. The magnitude of PMA from background for area 1 neurons was significantly smaller during vibratory as compared with visually cued trials. This was not the case for MI, area 3b or neostriatal neurons. Like the SI neurons, neostriatal PMA neurons rarely showed vibratory stimulus related responses in the no-go task if these responses were not present in the movement task.

These results suggest that: 1) PMA in neostriatal neurons can occur prior to that in MI and SI, 2) unlike area 1 neuronal PMA, decreased PMA magnitude in vibratory-cued trials is not commonly seen for neostriatal PMA neurons and 3) neostriatal PMA neurons could influence cortical neuronal PMA via demonstrated pallidothalamocortical circuitry projecting ultimately to MI and SI. Support by **NIH Grant NS26473.**

SYSTEMIC AMPHETAMINE INCREASES MOTOR-RELATED FIRING OF NEURONS IN THE DORSOLATERAL STRIATUM OF THE FREELY-MOVING RAT: L.L. Peoples*, D.J. Woodward#, C.F. Flaherty, M.O. West. Rutgers U., New Brunswick, NJ; #Anat., U. of Texas Southwestern Medical School, Dallas TX.

The present study characterized the effects of intraperitoneally administered d-amphetamine (amph) on the activity of single cells in the dorsolateral striatum of freely-moving rats. Male Long-Evans rats were chronically implanted with detachable microdrives positioned for recording in the dorsolateral striatum (+2.0 to 0.0 mm A-P from Bregma, 3.5 to 4.5 mm from midline, and 3.0 to 6.0 mm from skull, Paxinos and Watson, 1986). In each of 12 experiments, a given cell was first recorded after a saline injection and then subsequently recorded after an amph injection (0.5 or 1.0 mg/kg). To control for the potential effects of amph-induced motor behaviors on the activity of striatal cells, pre- vs post-amph comparisons of firing rates were made during behaviors that remained stable across the pre- and post-drug periods. Specifically, comparisons were made across pre- and post-drug periods in which the rat either: 1) locomoted, at a constant rate on a treadmill which rotated on a 30 sec on/30 sec off schedule or 2) engaged in specific body part movements with amplitudes and velocities unaffected by amph. The activity of 10/12 cells was positively correlated with locomotion (i.e., firing rates were greater during TM locomotion than they were during rest). Moreover, 3 cells exhibited firing patterns positively correlated with a specific movement of a particular part of the body (i.e., firing rates were greater during the specific movements than they were during any other movement). As compared to saline, amph consistently increased the mean firing rates exhibited during locomotion, as well as that exhibited during specific body part movements. Moreover, for the three cells that exhibited a specific movement correlate, amph-induced increases in firing rates were greater during the correlated movement than during any other movement. Previous experiments indicate that the striatum is involved in the transduction of amphetamine's pharmacological actions into stereotyped motor output. The present data strongly suggest that the cellular correlate of this transduction process, in the dorsolateral striatum, is enhanced excitation. COCAINE EFFECTS ON SINGLE NEURONS IN THE DORSOLATERAL STRIATUM OF FREELY-MOVING RATS: T. Mittler*, L.L. Peoples* and M.O. West. Dept. Psychol,Rutgers U.,New Brunswick, NJ.

The present study was designed to characterize the effects of the psychomotor stimulant cocaine on neuronal processing related to motor activity. Adult male Long-Evans rats were chronically implanted in the dorsolateral striatum (at Bregma A-P, 4.0 mm from midline, 4.5 mm from skull, verified histologically) with bundles of 6-10 microwires (62μ diam., stainless steel, teflon coated). To differentiate cocaine's effects on neuronal firing from drug induced motor effects on neuronal firing, pre- vs. post-drug comparisons were made with behavior constant across conditions. This was achieved by forcing locomotion on a treadmill which was activated periodically (20 sec. on/40 sec. off), and by video analysis. A computerized system that time-stamped each neural discharge and each video frame allowed comparison of neuronal activity pre- vs. post-drug both within and between different motor behaviors. After a saline injection (IP) a firing rate baseline was recorded for 1 hr., followed by an IP cocaine injection (10 mg/kg) and a 3 hr. recording. Preliminary results (from 8 units in 4 rats) show that most neurons increased firing during locomotion, while either increasing or decreasing firing in response to cocaine. BIPHASIC EFFECT OF SUBTHALAMIC NUCLEUS ACTIVITY ON SUBSTANTIA NIGRA DOPAMINE NEURON FIRING. I.D. Smith and A.A. Grace, Deptartments of Behavioral Neuroscience and Psychiatry, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

The subthalamic nucleus (STN) is known to play a major role in the regulation of movement by the basal ganglia. Both anatomical and electrophysiological studies show that the rat STN directly modulates basal ganglia output via an excitatory projection to the entopeduncular nucleus and the substantia nigra zona reticulata (SNzr). Furthermore, several studies suggest that the STN also projects to dopamine (DA) neurons of the substantia nigra zona compacta (SNzc), although the net influence of the STN on DA neuron activity remains unclear. Our prior investigations have shown that the STN is involved in the induction and maintenance of burst firing in SNzc DA cells. However, chemical (Robledo and Feger; *Brain Res. 518*, 1990) or electrical activation of the STN rarely elicits a clear effect on DA cell activity. In this study, we examined the effects of $GABA_A$ antagonist and agonist infusion into the STN on SNzc DA neuron firing rate and pattern.

Microinjections of the GABAA antagonist bicuculline methiodide (200 μM, 200 μl) into the STN resulted in an immediate 70.5±24.5% decrease in DA cell firing frequency (N=6). Although these neurons recovered their baseline firing rates within 7 to 16 minutes following the injection, there was an 81.8±26.8% increase in the prportion of spikes fired in bursts. This is consistent with our finding that electrical stimulation of the STN results in a population increase in burst firing. In contrast, injection of the GABAA agonist muscimol into the STN (200 μM, 200 μl) caused a rapid and reversable 15 to 150% increase in DA neuron firing rate (N=7).

Thus the STN appears to exert a dual action on SNzc DA cells: 1) an inhibition possibly mediated through STN excitation of the inhibitory SNzr or globus pallidus projections to the SNzc, and 2) a facilitation of burst firing which may be a direct effect of excitatory STN afferents. The activation of the STN in DA depleted animals shown by metabolic mapping studies could contribute to the elevated level of DA neuron burst firing reported in 6-OHDA treated rats (Hollerman and Grace, 1990).

ELECTROPHYSIOLOGICAL RECORDINGS OF PALLIDAL NEURONS IN RATS RUNNING IN PLACE ON A TURNTABLE TREADMILL. P. Patino, E. Kriek, and C.R. Freed. Div. Clinical Pharmacol., Univ. of Colo, Hlth. Sci. Ctr., Denver, CO 80262.

Previous studies in our laboratory have shown that neurons in ventromedial striatum of the rat increase their firing when animals run in place on a turntable treadmill for a water reward. Globus pallidus (GP) is an important part of the output pathway of the striatum. With the circular treadmill, we have now recorded pallidal neurons in moving animals. Both intact animals and animals with unilateral dopamine depletion of striatum were studied using chronically implanted 18 micron stainless steel electrodes insulated with Parylene C. In intact animals, basal firing rates ranged from 23 to 62 hz and responded to changes in motor activity in 83% of cases. 28% of cells increased firing rate more than 100% during running while 55% of cells reduced firing rate at least 50% during locomotion. In dopamine depleted animals, GP neurons were slower under resting conditions - 5 to 30 hz - and fired mainly in bursts. Only 33% of cells showed a change in firing during movement. In summary, GP neurons fire rapidly in intact animals at rest and show complex changes in firing with movement. In animals with unilateral dopamine depletion, there is a marked reduction in firing rate and a loss of movement related change in cell firing.

OCULOMOTOR ACTIVITIES IN THE MONKEY SUBTHALAMIC NUCLEUS M. Matsumura,J. Kojima,T.W.Gardiner AND O. Hikosaka Lab. of Neural Control, National Institute for Physilogical Sciences,Okazaki, 444,Japan.

The subthalamic nucleus sends excitatory signals to the substantia nigra pars reticulata, which exerts tonic inhibition on saccade burst cells in the superior colliculus. To investigate the nature of the subthalamic signals we recorded single cell activities in monkey subthalamic nucleus in relation to visuo-oculomotor tasks. Of 265 neurons tested, 95 were related to the tasks, while 66 neurons responded to active or passive body movements. The task-related activities were classified into: eye fixation(n=22), saccade(n=22), visual(n=14), target-reward(n=29), and lever-release(n=49). Eye fixation activity was sustained spike activity occurring while the monkey was fixating on a light target during the task; it ceased when the target went off and the monkey made a saccade. Saccade activity was a phasic increase of spike frequency time-locked with a saccade made in the task. It usually peaked after saccade onset. The activity had optimal directions, mostly toward the contralateral side. Visual response had receptive fields, most frequently centered on the contralateral parafoveal region. Its latencies were 70-120 ms. Target-reward activity was sustained spike activity preceding and dependent on expectation of reward. These visuo-occulomotor neurons were located mostly in the ventral part of the subthalamic nucleus, whereas skeletomotor-related neurons were in the dorsal part. These resuslts suggest that the subthalamic nucleus acts to maintain eye position on an object of interest or recover eye fixation once a saccade is executed.

BASAL GANGLIA AND THALAMUS IV

DISSOCIATION OF OPPOSITE EFFECTS OF D1 AND D2 DOPAMINE AGONISTS FOLLOWING LESION OF THE EXTERNAL PALLIDAL SEGMENT IN THE MONKEY. M. Filion, L. Tremblay, B. Gomez-Mancilla, M. Matsumura and P.J. Bédard. Neurobiology Res. Ctr, Laval Univ., Québec, Qué., Canada.

Kainic acid was used to destroy exclusively neurons in nearly two thirds of the external segment of the globus pallidus (GPe) unilaterally in a cynomolgus monkey. Ventral and rostral parts of the structure were spared. Neurons of the caudate nucleus and putamen were also destroyed but only in a small area above the GPe. The internal pallidal segment (GPi) was totally intact. Within the first 24 hours, generalized hypokinesia, bradykinesia, and flexed posture appeared. The signs gradually decreased in severity, became localized to the side contralateral to the lesion, but persisted until the animal was sacrificed, 19 days after the lesion. In particular, the upper limb remained flexed. Spontaneous circling toward the lesion occurred from day 5 to 11. From day 9 to 15, drugs thought to act specifically on either D1 (CY-208243) or D2 (LY-171555) dopamine receptors were tested. The D1 agonist decreased whereas the D2 increased the hypokinesia. Only weak doses of the D1 agonist (0.1 mg/kg) decreased the hypokinesia. At stronger doses (0.5 mg/kg), the drug acted like the D2 agonist, which induced the same effect at both weak and strong doses (0.01 and 0.1 mg/kg). The present results suggest that effects of D2 receptors activation are weakened by selective GPe lesion, unmasking opposite effects induced by D1 receptors activation and mediated mainly through the GPi (Gerfen et al., Science (1990) 250: 1429-32). Electrophysiological correlates of these results are currently under study.

DIFFERENTIAL EFFECT OF D1 AND D2 DOPAMINE RECEPTOR STIMULATION ON SOMATOSTATIN AND NEUROPEPTIDE Y LEVELS IN RAT STRIATUM. T.M. Engber, R.C. Boldry, S. Kuo* and T.N. Chase. ETB, NINDS, NIH, Bethesda, MD 20892.

Little is known about the influence of dopamine on striatal medium aspiny neurons, a type of interneuron which expresses both somatostatin and neuropeptide Y (NPY). We have examined the effects of dopamine denervation and D1 or D2 dopamine receptor stimulation on the levels of somatostatin and NPY in the striatum. Rats with a unilateral 6-hydroxydopamine lesion of the median forebrain bundle were treated for 7 days with either the D1 agonist SKF 38393 (12.5 mg/kg/day) or the D2 agonist quinpirole (1 mg/kg/day) on either an intermittent (once daily i.p. injection) or continuous (via osmotic pump implanted i.p.) regimen; lesioned control animals were given vehicle solution by both injection and infusion. Rats were sacrificed 3 hours after the last injection, and both striata were dissected using the nuclei punch method; somatostatin and NPY levels were measured by radioimmunoassay. Striatal dopamine denervation had little effect on the levels of either somatostatin or NPY. In comparison with controls, intermittent SKF 38393 treatment caused a substantial reduction in the content of both somatostatin (61%) and NPY (57%) in the denervated striatum; continuous SKF 38393 decreased NPY to a lesser extent (39%) but had no effect on somatostatin. Intermittent quinpirole decreased both somatostatin (35%) and NPY (27%) content relative to control values. Continuous quinpirole, on the other hand, increased the levels of both somatostatin (43%) and NPY (39%) These results suggest that striatal medium aspiny neurons are influenced by both D1 and D2 receptor stimulation and that they respond differentially to continuous and intermittent D2 stimulation.

483.3

DIFFERENTIAL EFFECT OF SUBTHALAMIC NUCLEUS LESION ON D1 AND D2 AGONIST-INDUCED ROTATION IN 6-HYDROXYDOPAMINE LESIONED RATS. J.J. Anderson, T.M. Engber, and T.N. Chase. ETB, NINDS, NIH, Bethesda, MD 20892.

Evidence suggests that activity of the pathway from the striatum to the lateral globus pallidus (LGP) may be modulated by dopamine primarily via D2 receptors. The subthalamic nucleus (STN) receives a large inhibitory input from the LGP. Increased excitatory drive of the STN to the substantia nigra pars reticulata and medial globus pallidus, as an indirect result of nigrostriatal dopamine cell loss, may contribute to motor impairments observed in Parkinson's disease. The effect of STN lesion on D1 agonist SKF 38393 and D2 agonist quinpirole-induced rotation was examined in rats with unilateral 6-hydroxydopamine lesion of the medial forebrain bundle. Ten days following infusion with 6-hydroxydopamine, the nigrostriatal lesion was verified by examining the rotational response to apomorphine (0.05 mg/kg sc). A homogeneous group of responders was selected and half of these animals were microinjected with the neurotoxic agent quinolinic acid (60 nmoles/0.2 ul phosphate buffered saline vehicle; pH 7.4) in the STN. The other half were microinjected with 0.2 ul vehicle in the STN and served as controls. After 7 days, the rotational response to SKF 38393 (1.5 and 5.0 mg/kg sc) and quinpirole (0.1 and 0.5 mg/kg sc) was examined. In STN-lesioned rats, both SKF 38393 and quinpirole-induced rotations were markedly reduced relative to controls in a dose-dependent manner with a significantly greater reduction seen in quinpirole turning (93% reduction) compared to SKF 38393 turning (69% reduction). These results indicate that lesion of the STN differentially affects D1 and D2 agonist-induced rotational behavior in 6-hydroxydopamine lesioned rats.

483.4

EFFECTS OF KAPPA OPIOID AGONISTS ON ROTATIONAL BEHAVIOR IN 6-HYDROXYDOPAMINE-LESIONED RATS R.C. Boldry, T.M. Engber, and T.N.Chase. Experimental Therapeutics Branch, NINDS, NIH, Bethesda, MD 20892.

The effects of dopamine receptor activation in the striatum are mediated by projections to the globus pallidus and the substantia nigra pars reticulata. Recent studies have suggested that D2 receptors are predominantly expressed on neurons which project to the globus pallidus while D1 receptors are primarily located on the striatonigral projections. The opioid peptide dynorphin is thought to act as a neurotransmitter in the striatonigral projection and to produce its effects by activating kappa opioid receptors. To evaluate the role of dynorphin receptor activation in motor function, we have examined the effects of the kappa agonists U50,488 (2.5, 10 and 25 mg/kg, s.c.) and spiradoline (0.5, 1 and 5 mg/kg, s.c.) on the rotational behavior elicited by D1 and D2 dopamine agonists in rats which were unilaterally lesioned with 6-hydroxydopamine. Both U50,488 and spiradoline dose-dependently decreased the rotational response to the D1 agonist SKF 38393 (1.5 mg/kg, s.c.). Conversely, neither drug affected the total number of turns produced by the D2 agonist quinpirole (0.1 mg/kg s.c.). However, changes were observed in the time-course of quinpirole-stimulated rotation following kappa agonist treatment at the highest doses tested. U50488 and spiradoline appeared to decrease the initial response to quinpirole, followed by an increase in turning in the later time periods. Taken together, these data indicate that kappa agonists produce differing effects on D1 versus D2 agonist-induced behaviors; the data also suggest that endogenous dynorphin may act to dampen striatal output through the D1 receptor-regulated striatonigral pathway.

483.5

THE ROLE OF DOPAMINE IN THE MAINTENANCE AND BREAKDOWN OF D1/D2 SYNERGISM. G.J. LaHoste, M. Andreini* and J.F. Marshall. Depts. of Psychobiology and Physical Medicine & Rehabilitation, Univ. of California, Irvine, CA 92717.

Concomitant stimulation of both D1 and D2 subtypes of dopamine (DA) receptor is normally required for the expression of behavior, a phenomenon referred to as D1/D2 synergism. Certain treatments, however, such as destruction of DAergic neurons and repeated treatment with reserpine induce a breakdown in synergism such that independent stimulation of either receptor subtype elicits behavior. To identify the factors involved in the breakdown of synergism, we injected rats with vehicle or reserpine (1 mg/kg) at 0, 24 and 48 hours. Two hours after the last injection, reserpine- but not vehicle-treated rats showed stereotyped motor behavior in response to quinpirole (3 mg/kg) while D1 receptors were antagonized (SCH 23390, 0.1 mg/kg), indicative of a breakdown in synergism. Rats treated with the same reserpine regimen and given L-DOPA/carbidopa (100/25 mg/kg) every 6 hours from 0 to 48 hours also showed a breakdown in synergism. Rats treated with SCH 23390 and eticlopride (0.5 mg/kg each) every 6 hours from 0 to 48 hours also showed a breakdown in synergism when tested 24 hours after the last neuroleptic injection. The results suggest that treatments that profoundly interfere with the ability of DA to interact with its receptors over the course of 48 hours result in a breakdown in synergism. The inability of L-DOPA/carbidopa to reverse this effect may be due to the failure of the intermittent injection schedule to normalize synaptic DA content.

483.6

SYSTEMIC HALOPERIDOL DECREASES THE HYPERKINETIC PAW TREADING INDUCED BY VENTROMEDIAL STRIATOPALLIDAL LESIONS IN THE RAT. H.C. CROMWELL AND K.C. BERRIDGE. THE DEPARTMENT OF PSYCHOLOGY, THE UNIVERSITY OF MICHIGAN. ANN ARBOR MI. 48109.

Haloperidol is used to decrease the severity of several different hyperkinetic syndromes in humans with damage in the basal ganglia. Previous work has discovered a hyperkinetic syndrome in the rat which is induced by ventromedial striatopallidal lesions and triggered by oral sensory stimulation (Berridge et al.,1988). The hyperkinesia appears as exaggerated and perseverative forepaw treading and is never seen in intact rats.

To better characterize the neuropharmacological nature of the syndrome, systemic injections of haloperidol were given to rats expressing the paw treading syndrome. Quinolinic (QUIN) acid (60NM in .5ul) was injected bilaterally into the ventromedial striatopallidal complex. Behavioral testing began 48 hrs. post surgery. Rats were given injections (ip.) of either haloperidol (1mg\kg) or diazepam (5mg\kg) 30 minutes prior to the taste infusion. Most rats were tested with both haloperidol and with valium on separate days. Tests of motor abilities (wire mesh hangtime, righting reflex latency) were completed to record general motor effects of the drug injections.

Results showed that haloperidol was effective in ameliorating the hyperkinesia only in the rats that showed mild to moderate treading post-lesion and not in rats expressing severe treading post-lesion. Diazepam did not decrease the hyperkinesia and in fact, increased it in most cases. Diazepam but not haloperidol impaired performance on motor ability tests. These results implicate a role for dopamine in the expression of the hyperkinetic treading syndrome in the rat.

483.7

SIMPLE AND CHOICE REACTION TIME PERFORMANCE FOLLOWING UNILATERAL IBOTENIC ACID LESIONS OF MEDIAL OR LATERAL STRIATUM IN THE RAT.

D. O. Pretsell and T. W. Robbins, (SPON:Brain Research Association), Dept. Exptl. Psychology, University of Cambridge, Cambridge, U.K.,

Rats were trained to perform a visual spatial discrimination, where stimulus luminance provided information regarding the required direction of response. The visual stimuli were presented either in advance of a temporally unpredictable auditory imperative stimulus (simple reaction time condition) or simultaneously with the imperative stimulus (choice reaction time condition). Rats were given unilateral lesions of either the lateral or medial striatum using 1 microlitre of 0.06M ibotenic acid. Following the lateral lesion an ipsilateral response bias and lengthened contralateral reaction times were seen in both conditions. In the group with the medial lesions no response bias was observed. No consistent effect on reaction time was seen following the medial lesion although there was an indication of contralateral reaction time lengthening in the choice condition only.

These results suggest a functional dissociation of the medial and lateral striatum in attentional processes involved in the control of action and are relevant to studies of the effects of basal ganglia disorders on reaction time performance.

483.8

INITIATION IMPAIRMENT AFTER GLOBUS PALLIDUS LESION DEPEND ON THE REACTION TIME TASK. E. Trouche*, M. Alamy*, E. Legallet* and F. Viallet. Lab. Functional Neurosciences, LNF 3, CNRS, 13402 MARSEILLE CEDEX 9, France.

The authors of previous studies using reaction time (RT) procedure have described the effects of globus pallidus (GP) lesion on the performance of an arm movement in response to a visual stimulus. No change in the RT was reported in any of these studies as the result of GP lesion. These results suggested that the GP was not involved in motor initiation. This conclusion was not in agreement however with some electrophysiological data showing the existence of GP cells which discharge before the onset of the movement. In our study, we investigated the effects of GP lesion on both the simple reaction time (RTs) and the choice reaction time (RTc) in a pointing task with variable movement amplitude. Two monkeys were trained to perform the two RT paradigms. After unilateral neurochemical GP lesion, no change in the RTs was observed, whereas a significant increase in the RTc occurred in the contralateral limb. These results indicate that the GP may involved in motor initiation in RTc task particularly when there is uncertainty as to the amplitude of the forthcoming movement.

483.9

TREMULOUS ORAL MOVEMENTS AND FEEDING DEFICITS IN RATS WITH VENTROLATERAL STRIATAL DOPAMINE DEPLETIONS: POSSIBLE RELATION TO PARKINSONIAN SYMPTOMS. J. D. Salamone, G. Jicha, and S. Rogers. Dept. of Psychology, Univ. of Connecticut, Storrs, CT 06269-1020.

Local depletion of dopamine (DA) produced by injections of 6-hydroxydopamine in the ventrolateral striatum (VLS) caused a substantial decrease in food intake, from which the animals recovered. In behavioral observation sessions, rats with VLS DA depletions showed no reduction in time spent feeding, but did have substantial impairments in the rate of feeding and forepaw use during feeding. DA depletions in nucleus accumbens, anteroventromedial (AVMS) or dorsolateral striatum (DLS) did not produce signifcant feeding deficits. Rats with VLS DA depletions showed no deficits in locomotor activity or rearing. Tremulous chewing movements were produced by VLS DA depletion, but not AVMS or DLS depletions. Systemic administration of haloperidol (0.4 mg/kg) increased tremulous chewing responses in DA-depleted and control rats. Thus tremulous chewing responses can result from reduced functional activity of VLS DA, and these responses share some characteristics with human Parkinsonian symptoms. These data support the notion that the neostriatum is functionally heterogeneous and that the VLS is particularly important for oral and forelimb motor control.

483.10

BEHAVIOURAL AND ANATOMICAL ANALYSIS OF RATS WITH QUINOLINIC ACID-INDUCED STRIATAL LESIONS

JCS Furtado and MF Mazurek, McMaster University Medical Centre, Hamilton, Ontario, CANADA.

It is not understood how the cognitive impairment in patients with Huntington's Disease (HD) is related to the striatal degeneration that is the neuropathological hallmark of the disease. In order to explore this issue, we have examined the behavioural consequences of quinolinate-(QUIN) induced striatal lesions in rats. Animals with bilateral striatal QUIN lesions were impaired performance in the place task version of the Morris Water Maze and the delayed alternation task when compared to controls. However, the QUIN group was no different from the control group on some unlearned tests (eg, food manipulation, swimming posture, tongue extension, general motor ability). Post-mortem analysis using the Bioquant IV programme showed significant striatal atrophy but no differences in five cortical areas, in relation to controls.These findings demonstrate that rats with striatal lesions induced by quinolinic acid are impaired in the performance of tasks requiring visuospatial skills, long-term memory and cognitive flexibility. These results are consistent with the notion that cognitive impairment in HD may represent disordered function in the striatal-pallidal-thalamic-cortical feedback loop.

483.11

THE EFFECTS ON TRAINED ARM MOVEMENTS PRODUCED BY INJECTIONS OF MUSCIMOL OR BICUCULLINE INTO THE GLOBUS PALLIDUS. M. Inase* and M.E. Anderson. Depts of Physiol. and Biophys. and Rehab. Med. and Reg. Primate Res. Center, Univ. of Wash., Seattle WA 98195.

Disruption of nigrocollicular inhibition results in saccadic jerks during fixation and saccades with shorter reaction time (RT), higher peak velocity (PKV) but smaller amplitude (MAMP), especially to precued target locations (Hikosaka and Wurtz, 1985). We examined the effect on arm movements produced by changing the output of the globus pallidus (GPi). Monkeys were trained to make arm movements to targets that were illuminated coincident with a GO tone or were lit briefly as a precue.

Injection of muscimol into GPi produced a flexor drift of the contralateral arm from the start position. When the initial position was maintained until the GO tone, the RT was normal, but the MAMP and PKV to some targets were decreased and the amplitude/peak velocity scaling relation was disrupted. Injection of bicuculline into GPi did not cause a flexor drift, but it produced involuntary movements, primarily proximally. RT's were not changed, but the MAMP and PKV also were reduced to targets in some directions.

Positional instability of the eye or arm follows injections of muscimol into appropriate basal ganglia nuclei. However, changes in arm movements produced by changes in GPi output were more complex than predicted from oculomotor studies.

D1 AND D2 DOPAMINE RECEPTOR SUBTYPES: MODULATION OF THE SPEED AND SUCCESS OF REACTION TIME PERFORMANCE IN THE RAT. R.E. Wilcox, P.K. Randall and R.D. Mayfield*. Dept. of Pharmacol., Univ. of Texas at Austin, Austin, TX 78712.

The purpose of this investigation was to determine whether D1 and D2 dopamine receptor subtypes have different roles in modulating the speed and success of rodent reaction time performance. Animals were shaped to release a lever in response to an auditory/visual stimulus in order to avoid mild footshock. Shaping was continued until the animals were responding reliably with response latencies of 180-220 msec. The effects of apomorphine (0.15, .30, .60, 1.2, 2.4 and 4.8 mg/kg) on reaction time were determined in animals pretreated with the selective D1 antagonist, SCH 23390 (0, 50 and 100 µg/kg), or the selective D2 antagonist, spiperone (0, 1 and 10 µg/kg). Apomorphine alone resulted in a dose dependent decrease in successful avoidance with an ED_{50} of 3.9 mg/kg. Response latencies were unaffected by apomorphine treatment. SCH 23390 pretreatment resulted in a significant impairment of both successful avoidance and response latency. Increasing doses of apomorphine effectively attenuated SCH 23390's effects on successful avoidance, and to a lesser extent blocked the SCH 23390-induced increase in response latency. Spiperone pretreatment attenuated the effects of apomorphine on successful avoidance, resulting in a 6-fold shift to the right in the apomorphine dose-response curve. These results suggest that D1 receptors play an important role in modulating the speed of reaction time responses and that D2 receptors predominantly modulate successful response initiation.

483.13

ORIENTATION TO EDGES AND ITS MODULATION BY STRIATAL DOPAMINE IN RATS. R. Sullivan', A. Fraser', C. Coulter' and H. Szechtman. Dept. Biomedical Sciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

Male Sprague-Dawley rats received either control operations (N=14) or unilateral 6-hydroxydopamine lesions of the left or right substantia nigra (N=22 per group). At eight weeks post-lesion, all rats were tested (undrugged) in a large open field (160 cm square and elevated 100 cm) for ten minutes. From videotapes, a measure of net orientation was obtained for time spent at the edge (locomoting or not). Following testing, brain regions were assayed for levels of DA and metabolites by HPLC. Left and right lesioned rats differed significantly in their orientation to edges ($p<0.001$), such that for each, the intact striatum was contralateral to the edge. When controls were subdivided according to their left/right asymmetry in striatal DA turnover, they too oriented differently ($p<0.015$), with the striatum of greater DA activity being contralateral to the edge. DA activity in other regions was unrelated to edge behavior, emphasizing the importance of striatal DA in directing behavior. Because attraction to, or exploration of edges appear to be regulated at behavioral and neurochemical levels, this suggests that edges are significant stimuli in the organization of behavior. Supported by NSERC.

483.14

INVOLVEMENT OF GLUTAMATE RECEPTORS IN THE ZONA INCERTA IN AMPHETAMINE-INDUCED STEREOTYPY BUT NOT LOCOMOTOR ACTIVITY. D.E. Supko*, N.J. Uretsky, L.J. Wallace. College of Pharmacy, The Ohio State University, Columbus, OH 43210

A pathway projecting from the nucleus accumbens (NA) to the subpallidum and on to the pedunculopontine nucleus (PPN) has a role in locomotor activity (LMA), including amphetamine (AMPH)-induced hypermotility. It is reported that the descending neurons projecting from the subpallidum to the PPN synapse first at the level of the zona incerta (ZI) and glutamate neurotransmission in the ZI may be involved in motor activity. We have found that activation of non-NMDA receptors by direct injection of AMPA or kainic acid into the ZI stimulates locomotion, which is attenuated by the specific antagonist DNQX. Considering this, we investigated the role of non-NMDA receptors in the ZI in AMPH-induced LMA. Injection of DNQX (4 nmol) into the ZI had no effect on the locomotor response to low dose AMPH (0.5 & 1.0 mg/kg, SC). DNQX, however, increased by 3 fold the locomotor response to high dose AMPH (10 mg/kg, SC) and attenuated stereotypy induced by both AMPH and apomorphine. The augmented locomotor response was likely due to an inhibition of AMPH-induced stereotypy which competes with LMA. Ibotenic acid lesions of the ZI produced effects similar to DNQX administration. Thus, non-NMDA glutamate receptors in the ZI appear to be involved in mediating the effects of AMPH resulting from striatal activation but not NA activation.

483.15

DOPAMINERGIC INPUT TO THE SUBTHALAMIC NUCLEUS REGULATES LOCOMOTOR ACTIVITY IN THE PARKINSONIAN RAT. G. Flores*, D. Martínez-Fong and J. Aceves. Dept. of Physiology. CINVESTAV-IPN. Mexico.

Here we studied the role of the DA innervation of the subthalamic nucleus on locomotor activity (loc act.) 6-OHDA was injected bilaterally into the pars compacta. Shams: saline. Injected site was assessed hitologically. DA content was measured in striatum (str), accumbens (acc) and subthalamic nucleus (STN). Two groups of rats could be distinguished, one with decreased (from 21 ± 2 to 7 ± 2 counts/10 min), and another with increased (from 23 ± 2 to 69 ± 6) loc act. No change (before: 23 ± 2; after: 24 ± 2) in loc act was seen in shams. Injected sites in hypokinetic rats were rostrally, and in hyperkinetics ones they were caudally located in pars compacta. DA (ng/mg prot.) contents were (mean ± SEM; n = 6):

nucleus	hypokin.	hyperkin.	sham
Str	3.7±1.0	4.6±0.8	100±4.8
acc	27±15	16±5	82±3.0
STN	0.6±0.1	3.7±0.1	3.7±0.2

Hypokinesia was associated with loss of DA input to subthalamus. Data suggest that STN is normally under a tonic inhibitory DA action via a nigrosubthalamic pathway. Loss of this action, disinhibits the STN, producing hypokinesia (or akinesia).

THE MOTOR EFFECTS OF UNILATERAL AND BILATERAL STIMULATION OF THE DEEP MESENCEPHALIC NUCLEUS AND SUBSTANTIA NIGRA IN THE RAT. D. ASDOURIAN. DEPT. OF PSYCH., WAYNE STATE UNIV., DETROIT, MI 48202.

Unilateral stimulation of either the deep mesencephalic nucleus (DpMe) or substantia nigra reticulata (SNr) in anesthetized animals (60 mg/kg pentobarbital) drives activity in the trapezius pars cervicalis and rectus capitis dorsalis major. Both muscles typically respond bilaterally to unilateral stimulation of DpMe or Snr. Each experimental session consisted of two phases. During the first phase stimulation was delivered unilaterally to DpMe or SNr as single square waves having a duration of 1.0 msec and intensities ranging between 0.5 and 2.0 mA. Muscle response amplitudes (measured electrophysiologically) were maximal at a stimulation frequency of 1/4 sec and declined steadily as the frequency was increased to 1/3 sec, 1/2 sec, 1/sec, and 15/sec. At frequencies 1/sec and 15/sec response amplitudes sometimes dropped to zero. During the second phase of the experiment, stimulation frequency was kept constant at 1/3 sec with stimulation duration and intensity as described above, however, stimulation was delivered bilaterally to DpMe or SNr with delays between stimulation of one side of the brain and the other. So, for example, stimulation of the left DpMe was followed, with a delay of 5.0 msec, by stimulation of the right DpMe. The delays used were 5.0, 10.0, 15.0, and 20.0 msec. Muscle activity was recorded bilaterally in response to both the first and the second stimulus. The major effect of this procedure was that the bilateral responses elicited by the second (delayed) stimulus were augmented at a delay of 5 msec, but were inhibited at delays of 10, 15, and 20 msec. The inhibition became deeper as the delay was increased. Future work should investigate the pathways and nuclei over which the two types of inhibition seen in the two phases of this experiment are mediated.

IN VIVO SUBREGIONAL EFFECTS OF AMPHETAMINE AND CORTICAL STIMULATION IN THE RAT CAUDATE PUTAMEN. G.E. GLYNN and B.K. YAMAMOTO. Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44263.

A topographic projection from the cortex to the striatum exists in the rat. The effects of dopamine on the electrophysiology of this corticostriatal projection are controversial. The purpose of this study was therefore to determine the relative electro-physiological importance of these projections and the regional role that dopamine plays in modulating this striatal input.

An 8 electrode array of graph-epoxy voltammetric electrodes, each simultaneously measuring multiple unit activity (MUA) and dopamine, was placed at two depths in the striatum. 8 cortical sites were repeatedly stimulated. Amphetamine was administered and its effects on dopamine and MUA monitored. Overall there was a 103% greater dopamine concentration increase in dorsolateral as compared to dorsomedial regions, a 52% greater increase in ventrolateral as compared to ventromedial and a 56% greater increase in dorsal as compared to ventral regions. A rostrocaudal gradient was also evident. A distinct regional pattern in the striatal electrophysiological response to each cortical stimulation site was evident. Data will be presented on the effects of dopamine concentration changes on this electrophysiology response within 14 subregions of the striatum.

CONTROL OF POSTURE AND MOVEMENT III

EVIDENCE FOR CHANGES IN LENGTH-TENSION CHARACTERISTICS IN SPASTIC MUSCLE. J.P.A. Dewald, A.C. Shen*, S.L. Delp*, D.C. Lin, and W.Z. Rymer. Sensory Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, IL 60611.

In an effort to characterize length-tension relations in spastic muscle, torques produced over a range of elbow angles in the impaired versus unimpaired upper extremity were compared in hemiparetic stroke subjects. In the first part of this study, a biceps RMS EMG matching routine was used to ensure a constant biceps activation level at each elbow angle. EMGs from the remaining elbow flexors were recorded to check for variations in their activation, which could affect torque. The upper limb was placed in 90° abduction at the shoulder, and the elbow angle was varied from 120° to 15° flexion, lengthening the biceps approximately 7 cm. Torques were measured using a 3 d.o.f. loadcell. Four of five subjects showed marked changes in elbow torque-angle curves. The joint angle at which torque peaked shifted 20-30° to more extended elbow positions in the hemiparetic arm. In addition, the torque-angle curves were less steep for extended elbow positions in the impaired limb. Since moment arms in both arms are presumed identical in each subject, changes in the length-tension relation in spastic muscle are implied.

To further substanciate the above findings, electrical stimulation of the biceps muscle was used in the second part of this study. This allows for a more controlled activation of elbow flexors provided one stimulates both arms using the same current intensity. Surface stimulation of the biceps was performed using 3 ms pulses delivered at a frequency of 20 Hz for 500 ms during which torque was measured, followed by a 2 min. rest period. Four of four subjects showed shifts in the angle of peak torque to more extended elbow angles and thus concur with the findings observed during voluntary activation. In both parts of the study normal subjects did not show a shift in the angle of peak torque or a change in shape of the torque-angle curves when comparing their upper limbs.

The fact that torque-angle changes were observed in both voluntary and electrical stimulation paradigms points to possible changes in the length-tension property in the impaired limb. This may be caused by increased compliance of the series elastic element, increased tendon length, changes in fiber length, or other adaptations of the muscle-tendon complex. This work is supported by NIH grant NS-19331.

INTERSPIKE INTERVALS OF MASSETER SINGLE MOTOR UNITS DURING INCREMENTED BITE FORCES ON MOLARS, CUSPIDS AND INCISORS. B. Bishop, T-K. Mao, W. D. McCall, Jr. Depts. of Physiology & Oral Med. SUNY at Buffalo, NY 14214.

Is more masseter (MA) activity required to generate a given force when biting on incisors than when biting on molars? To answer this question we built splints for each of 4 subjects (Ss) to keep jaw separation at 10 mm and MA length constant whether the bite-transducer was between molars, cuspids or incisors. Fine wires in the right MA detected unit activity. Ss generated clenches of 15, 30 or 60 N while viewing the transducer output. From continuous recordings, relationships between firing rates and forces were determined for each bite location and clench strength. Interspike intervals (ISIs) were shorter for any given force when clenching on incisors than on molars. During a clench at each bite position, changes in ISIs and small, concomitant force fluctuations were seen. Rate coding was more pronounced when biting on incisors than on molars. Increasing bite force lead to recruitment of new units and a decreased mean ISI in every unit. We conclude that to maintain the same force at the incisors as at the molars more MA activity is required.

EFFECTS OF DORSAL COLUMN LESIONS ON MOTOR CONTROL AND LONG-LATENCY RESPONSES IN THE INDEX FINGER OF MACAQUES D.S. Glendinning and C.J. Vierck, Dept. of Neuroscience, Univ. of Florida, Gainesville, FL. 32610

These experiments were designed to test the hypotheses that afferents carried in the dorsal columns (DCs) 1) are needed to regulate the forces of finger movements, and 2) form the afferent limb of long-latency stretch reflexes. Three stumptailed-macaques were trained to hold the index finger stationary (within a ± 5° range) for 3 seconds. In one condition ("move and hold"), they flexed or extended the finger 20°, at the metacarpophalangeal joint, to reach the target zone. In a second condition ("hold"), the finger was positioned in the target zone at the start of the trial. Resistive loads were applied to the finger through a torque motor. The loads were either constant or varied from 0.3 - 1.0 Nm. The monkeys had to resist these torques to maintain the finger position. To elicit stretch reflexes, 500 ms. torque pulses were generated by the torque motor while the finger was holding against a small force. Electromyographic (EMG) activity was measured with surface electrodes placed over the forearm flexors and extensors, and over the first dorsal interosseous muscle. EMG records were rectified, integrated and averaged . The patterns of muscular activity were compared for each condition. Following the lesions, the monkeys were able to hold the finger against many of the resistive loads in the "hold" conditions, but performance deteriorated in the "move and hold" condition. Long-latency responses varied and were related to the severity of the behavioral deficit. These results suggest that afferents in the DCs are not necessary for force regulation of the fingers during postural holding, but are required to regulate muscular activity during active movements. Supported by MH09734 and NSS17474.

EFFECTS OF ALTERING VISUAL AND PROPRIOCEPTIVE INFORMATION DURING VISUOMOTOR TRACKING. S.H.Brown, J.D.Cooke, T.Ohtsuki*, Depts. of Physical Therapy and Physiology, University of Western Ontario, London, Ontario, Canada N6A 5C1

Gauthier et al (1988) have suggested that co-ordination of eye and arm movements relies heavily on limb proprioceptive information. We have studied the linkage between visual and limb afferent signals by disrupting their normal temporal and spatial relations during visuomotor tracking tasks.

Subjects performed sinusoidal movements about the elbow (frequency 0.1 - 1.5 Hz) in a pursuit tracking task or in time with an auditory cue. Visual feedback was altered by introducing a delay (0 - 400 ms) between actual and displayed arm positions. Proprioceptive information was altered by vibrating the biceps and/or triceps tendon. Horizontal eye movements were monitored by EOGs or an infrared detection system.

Under all conditions, saccadic and smooth pursuit eye movements remained time linked to the displayed arm position. Visual delay and/or vibration had no apparent effect on the time course of either type of eye movement. In contrast, both visual delay and vibration caused disruption in the arm movements with low frequency oscillations (0.4 - 1.0 Hz) superimposed on the tracking frequency. The severity of this disruption varied inversely with the tracking frequency and was greater during pursuit tracking than when movements were made in time with the auditory cue. The combination of visual delay and tendon vibration produced the most severe movement disruption.

Eye and arm movements can thus be temporally dissociated during visuomotor tracking. Eye movements do not rely on limb proprioception whereas limb movements are dependent on both visual and proprioceptive information. Supported by NSERC (Canada) and the Ontario Ministry of Health.

USING THE c-fos IMMUNOHISTOCHEMICAL METHOD TO LOCALIZE BRAINSTEM CELLS ACTIVATED DURING LOCOMOTION X.Dai, J.R.Douglas, B.R.Noga, J.I.Nagy and L.M.Jordan, Dept.of Physiology, University of Manitoba, Winnipeg, M.B., Canada R3E 0W3

Locomotion can be induced by electrical stimulation of the mesencephalic locomotor region (MLR) in the decerebrate cat. The MLR has been shown to project to the medial aspect of the pons and medulla (Steeves & Jordan, Brain Res., 307:263-276, 1984) where it is thought to produce locomotion by activation of cells located within the medial reticular formation (Noga et al., J. Neurosci., in press). Using the c-fos immunohistochemical method to label the nuclei of activated cells, we have previously investigated the distribution of labelled interneurons in the spinal cord following stimulation of the MLR (Dai et al., Soc. Neurosci. Abstr., 16:368.4). Here, we report on the distribution of labelled cells found within the brainstem of cats induced to walk by stimulation of the MLR.

Experiments were performed on cats decerebrated at the precollicular-postmamillary level. Data was obtained from cats induced to walk on a treadmill (n=2), from cats exhibiting fictive locomotion with stimulation of the MLR (n=2) or without stimulation of the MLR (n=2). Prominent labelling was found in the: a) magnocellular tegmental field; b) locus caeruleus; c) marginal nucleus of the brachium conjunctivum; d) cuneiform nucleus; e) ventrolateral reticular formation; and, f) the vestibular nuclei. Non-paralysed animals which were not subjected to the locomotor task (n=2) showed labelling of cells in the same areas but fewer cells were labelled compared to animals subjected to the MLR-evoked treadmill locomotion. In fictive locomotion preparations, larger numbers of labelled cells were found in cats that were induced to walk with stimulation of the MLR compared to animals which showed either spontaneous locomotion (n=1), locomotion produced by forelimb swinging (n=1) or in animals which served as non-locomoting controls (n=3). SPINAL INTERNEURONS SYNAPTICALLY ACTIVATED BY STIMULI APPLIED TO THE MESENCEPHALIC LOCOMOTOR REGION. L.M. Jordan and B.R. Noga, Department of Physiology, University of Manitoba, Winnipeg, Manitoba, Canada, R3E 0W3

Few lumbar spinal interneurons have been described which show activation by stimuli applied to the mesencephalic locomotor region (MLR). To date, this category includes only mid-lumbar group II muscle spindle afferent-activated interneurons (Shefchyk et al., Exp. Brain Res. 80:290, 1990) and contralaterally-projecting laminae VIII interneurons (Jankowska and Noga, Brain Res. 535:327, 1990). Regions of the spinal gray matter showing activity-dependent labelling by c-fos and transneuronal WGA-HRP due to MLR-evoked locomotion (Dai et al. Soc. Neurosci. Abstr., 16:889, 1990; Noga et al., SN Abstr., 13:826, 1987) or negative field potentials evoked by stimulation of the MLR (Fortier et al., SN Abstr.14:264, 1988) have now been identified and these areas have been searched in order to identify rhythmically active interneurons which receive short-latency input from the MLR.

Experiments were conducted on paralysed precollicular-postmammillary decerebrate cats with stimulation of the MLR (30-220 μA, 1.0 ms, 10-20 Hz) used to elicit fictive locomotion. Stimulating electrodes were placed at low thoracic levels to exclude ascending tract and propriospinal neurons from the sampled population. In mid-lumbar (L4-5) spinal segments, rhythmically active and MLR-activated spinal interneurons were found in laminae VIII and medial laminae VII. In caudal segments (L6-7), rhythmically active and MLR-activated neurons were localized throughout laminae VII and IX (laminae VIII not examined). The average latencies for activation ranged from 4.4-8.1 ms. In general, latencies of activation were shorter for neurons in mid-lumbar than caudal lumbar segments and for ipsilateral as opposed to contralateral MLR stimulation sites. Most cells tested showed polysynaptic activation by afferents of ipsilateral sural, superficial peroneal or saphenous nerves and occasionally produced late, long-lasting discharges in response to cutaneous nerve or MLR stimulation. Responses from various muscle nerve afferents were also observed. These results show synaptic activation of spinal neurons with latencies required to mediate short-latency MLR-evoked postsynaptic potentials in lumbar motoneurons (Shefchyk et al. J. Neurophysiol., 53:1345, 1985). Supported by Medical Research Council of Canada.

TRANSPORT KINEMATICS TO DOWELS OF DIFFERENT SHAPES. P.L. Weir[1] and C.L. MacKenzie[2], Dept. of Kinesiology, [1]University of Windsor, Canada, N9B 3P4 and [2]University of Waterloo, Canada, N2L 3G1.

Weir and MacKenzie (1990) examined the effects of task intent on the kinematics of prehension when reaching for a dowel that had been instrumented for quantifying grasping forces. While the grasping forces were found to be appropriately scaled for different tasks (lifting versus placing), no effect of task intent was found on the relative timing characteristics of the free motion phase. Marteniuk et al. (1987) had earlier reported that such a manipulation of task intent did influence the kinematics of the free motion phase. It was hypothesized that the lack of effect in Weir and MacKenzie (1990) could have been the result of using a dowel with square gripping plates, since Marteniuk et al. (1987) had used cylindrical dowels.

The purpose of the present study was to compare the effects of task intent on the kinematics of the free motion phase when grasping for different shaped dowels. The two dowels had identical cylindrical bases, but one dowel (the 'force' dowel) had flat, square gripping plates, while the other dowel (the 'cylindrical' dowel) had a curved gripping surface. Trials were blocked for the two dowels (weighing 155 grams), and the orders of presentation of the dowels and tasks (lift versus place) were counterbalanced across subjects.

Spatio-temporal analyses of a marker placed on the wrist (transport component) revealed that the decelerative portion of the free motion phase was longer when reaching to grasp the cylindrical dowel than the force dowel. In addition reaching for the cylindrical dowel was significantly influenced by task intent as evidenced by a differential lengthening of the deceleration portion for the lift task. No such effect was found for the force dowel. Once the subjects had acquired a stable grasp, dowel shape did not influence the transporting of the dowel to the target location. These findings suggest that dowel shape does influence the free motion phase of prehension, and may obscure task effects if the dowel has a large contacting surface. (Supported by NSERC)

MOVEMENT VARIABILITY ASSOCIATED WITH DIFFERENT SHAPED DOWELS. C.L. MacKenzie[1] and P.L. Weir[2]. Dept. of Kinesiology, [1]University of Waterloo, Canada, N2L 3G1 and [2]University of Windsor, Canada, N9B 3P4.

When reaching to grasp a dowel, the transporting of the arm is influenced by the shape of the grasping surface (Weir and MacKenzie, 1991). A longer percentage of time is spent in deceleration during the free motion phase when reaching to a dowel with a flat, square gripping surface as compared to a dowel with a curved gripping surface. The purpose of the present study was to examine the reasons for this difference. The two dowels were equated for weight (155 grams) and had cylindrical bases. The one dowel had square, flat gripping plates and was instrumented to quantify grasping forces, while the second dowel had a cylindrical top and a curved grasping surface. The amount of surface area available for grasping was equated between the two dowels.

Ink was applied to the pads of the thumb and index finger so that the amount of surface area used when contacting each dowel could be assessed. The area used was substantially smaller for the curved gripping surface than the flat. Given that a difference in contacting area was found, we hypothesized that this might reflect the terminal accuracy of the transport and grasp components. A difference in terminal accuracy may account for the lengthening of the deceleration phase observed by Weir and MacKenzie (1991), as it corresponds to the 'precision effect' reported by MacKenzie et al. (1987) and Marteniuk et al. (1987, 1990). Indeed, the variability of the wrist and index finger markers at dowel contact was greater for the flat gripping surface. In addition the variability in the wrist marker measured over the free motion phase was greater when moving to grasp the flat gripping plates. This increased variability occurred later in the free motion phase when the arm and hand were quite close to the dowel. These data suggest an influence of dowel shape on variability measures associated with both the arm and hand, reflecting the tight coupling between the two components. (Supported by NSERC)

Do Common Postural Synergies Regulate Upright Stance During External and Voluntary Perturbations? II. Biomechanical Patterns. E.M. Earl and J.S. Frank. Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

Electromyographic (emg) analyses have been used to demonstrate that a common muscle synergy may serve to regulate stance posture in the presence of either voluntary or external perturbations (Frank and Earl, 1991). Emg analyses reflect the CNS drive which effects a compensatory adjustment, but kinematic and kinetic analyses are required to predict the body movements which stabilize stance. The purpose of this study was to conduct a biomechanical comparison of the compensatory strategies used to cope with external and voluntary perturbations. Subjects were instructed to maintain handle position against a 20 N background load, acting in the anterior direction. Voluntary perturbations were created when subjects pulled the handle against the load. External perturbations were generated by imposing a step increase in the handle force (100 N/300 ms). Ground reaction force data and kinematic data were combined in an inverse dynamic solution to calculate net moment and power profiles for the ankle, knee and hip joints. Net joint moments reflect the sum of the muscle forces acting about a joint; joint power indicates the energy absorption and generation which occurs at a joint.

Invariant compensatory actions, as illustrated by the net joint moments, were used to cope with both types of perturbations: predominant ankle plantarflexor moments were accompanied by smaller knee flexor and hip extensor moments. Joint power profiles revealed energy absorption at the ankle; between and within subject differences in energy absorption and generation were observed at the knee and hip joints. Anterior displacements of the center of pressure observed for the external perturbations exceeded the magnitude of those observed during the voluntary disturbances. Center of mass excursions differed depending on the source of the perturbation. (This research supported by NSERC Grant #OGP0022785).

Do Common Postural Synergies Regulate Upright Stance During External and Voluntary Perturbations? I. EMG Patterns. J.S. Frank and E.M. Earl. Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

Upright stance is perturbed by external forces, as well as reactive forces arising from our own voluntary movement. We examined whether common postural synergies might subserve the regulation of upright stance under these two conditions when the direction of destabilization was the same. Subjects were instructed to grasp and maintain the position of a handle against a 20 N background load. Voluntary perturbations were created when subjects pulled or pushed the handle against the resisting background load. External perturbations were generated by imposing a step increase in the handle force (100 N, 300 ms) either forward or backward. The latency and magnitude (first 75 ms) of activation of 6 postural and 2 focal muscles were recorded: medial gastrocnemius, tibialis anterior, biceps femoris, rectus femoris, erector spinae, rectus abdominus, triceps brachii, and biceps brachii.

Voluntary displacements of the handle were preceded by activation of a sequence of postural muscles with a mean onset latency of -83 ms (focal muscle onset = 0 ms). External displacements of the handle triggered a stabilizing postural reaction with a mean onset latency of 85 ms. During forward destabilization, both postural adjustments accompanying voluntary movement and triggered postural reactions were characterized by predominant activation of posterior muscles. The first muscle activated consistently was the medial gastrocnemius; the order of activation of biceps femoris and erector spinae varied both between and within subjects. The pattern of muscle activation accompanying backward destabilization revealed greater variability. These findings provide some evidence for the use of common muscle synergies for the regulation of upright stance during forward destabilization imposed by external and voluntary perturbations. (This research supported by NSERC #OGP0022785)

CHARACTERISTICS OF FOOT TRAJECTORY WHILE GOING OVER OBSTACLES DURING LOCOMOTION. A.E. Patla and S. Rietdyk*. Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

Foot trajectory during the swing phase of normal unobstructed locomotion is primarily dictated by passive pendular dynamics of the limb and is characterised by minimal ground clearance (~1 cm) at very high velocity (~ 4 m/s). The focus of this study is to characterise the changes in foot trajectory when obstacles of different heights and widths are encountered at the normal minimal clearance position in the step cycle. Kinematics, ground reaction force data, and EMG signals from four ipsilateral limb muscles were collected and analysed while subjects (N=7) avoided obstacles placed in their path and maintain their step length.

The results revealed that the trajectory is modulated for height changes but not the width, provided the width of the obstacle does not force subjects to alter their step length. The average clearance of the toe over the obstacle was ~10 cm, with four subjects increasing the clearance for higher obstacles. The horizontal toe velocity while going over obstacles was reduced more than the hip velocity as a function of obstacle height, while the hip position was further back and closer to the contralateral limb. Subjects landed with an increase in vertical velocity, while reducing the horizontal velocity. These modifications serve to ensure stability and safety of the subject. The scaling of the trajectory for different heights was not achieved through simple scaling of muscle activity or ground reaction forces. This study provides insight into the critical information required for obstacle avoidance during navigation in a cluttered environment. (Supported by a grant from NSERC, Canada)

EFFECTS OF COMPLEXITY AND PRACTICE ON MOTOR PROGRAMMING. Hanneke van Mier (1,2), Wouter Hulstijn (2) 1= Dep. of Neuropsychology, School of Medicine, Washington Univ., St. Louis, MO 63110, 2= Nijmegen Institute for Cognition Research and Information Technology (NICI), Univ. of Nijmegen, The Netherlands.

A large number of reaction-time studies have shown that the initiation of more complex movements requires more advance programming than simpler movements, thereby increasing initiation time. In handwriting experiments, however, increases in initiation time as a function of the number of strokes tend to be very small or nonexistent. This may be caused by the well-practised nature of letter writing and the level of advance programming.

To investigate this, an experiment was done in which subjects had to copy, as quickly as possible, stimuli consisting of three categories. Not only letters but also figures and patterns were used, consisting of familiar figures and novel nonsense (unfamiliar) patterns both of which were rarely or never drawn before. These stimuli were presented on a computer screen; writing and drawing movements were recorded by means of an XY-tablet.

Initiation time was found to increase linearly with the number of strokes -- which was varied from four to ten -- but the effect was much larger for figures and patterns than for letters and rapidly decreased with practice (successive presentations). In order to try to eliminate a difference in initiation time on account of perceptual processing, the same stimuli were presented, but had to be written and drawn in another style, which differed only in motor complexity (the number of strokes had to be doubled by requiring the subject to draw each line twice).

Drawing double lines increased initiation time with increasing number of strokes significantly for the figures and patterns. For letters, the increase was irrespective of the number of strokes. These results suggest that the planning of a movement sequence occurs at several levels and that the level is highly influenced by the amount of motor practice.

MODULATION OF STRETCH REFLEXES BY SURFACE ELECTRICAL STIMULATION IN SPINAL CORD INJURED AND NEUROLOGICALLY INTACT SUBJECTS. B. Flaherty[1,2], C.J. Robinson[1,3], G.C. Agarwal[2] [1]VA Rehabilitation R&D Center, Hines, IL; [2]Bioengr. & EECS Depts., Univ. of Illinois at Chicago, Chicago, IL; [3]Neurology Dept., Loyola Univ., Maywood, IL

The effect of sub-maximal surface electrical stimulation on the stretch reflexes of spinal cord injured (SCI) (n=2) and neurologically intact (NI) (n=2) was studied by simultaneously stimulating the soleus muscle and applying rapid 20° dorsiflexion perturbations to the ankle. The stimulator was turned off for 100 msec at the onset of the perturbation so the M-waves would not interfere with evoked response. Stimulation was monophasic with a frequency of 20 Hz and a pulse width of 400 μsec, with current adjusted so that about 2 Nm of plantarflexion torque was developed in three of the four subjects. The rectified and averaged surface soleus EMG was used to measure the evoked reflex responses. Seven stimulated and seven relaxed trials were presented in random order interspersed with six non-perturbed trials. The perturbation was provided by position controlled torque motor driven footplate so that all the perturbations would be nearly identical (see Flaherty et al, Soc. Neurosci. Abstr. '90).

The EMG response consisted of a short latency (40 - 70 ms after start of perturbation) burst and longer latency (70 - 100 ms) burst of activity. In two subjects (one SCI, one NI) the short latency response was markedly decreased with stimulation, in the other NI subject it was unchanged. One SCI subject, who could not generate any torque with stimulation, showed no change in EMG response. Two subjects (one SCI, one NI) showed an increase in long latency response with stimulation while in the other NI subject it was unchanged.

NONLINEAR DYNAMIC (CHAOTIC) DIMENSIONS OF MESENCEPHALIC LOCOMOTOR REGION (MLR) NEURONS DURING LOCOMOTION. K.L.Turner*, R.D.Skinner and E. Garcia-Rill. Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Locomotion is a rhythmic biological process which has parameter dependent transition points (gait changes). The locomotion generating system, then, should have characteristics of a nonlinear (chaotic) system which include an attractor with fractal dimension. The attractor is a phase space construct of the dynamics of a system as derived from a time series of data. The dimension of a system, then, is the number of parameters necessary to describe its attractor. An estimate of this dimension for MLR neurons was obtained using the Grassberger-Procaccia method. Interspike intervals were obtained from locomotor related (burster-each step and tonic-locomotor episode) neurons in the cat pedunculopontine nucleus, a part of the MLR, during spontaneous fictive locomotion using methods previously reported (Neurosci. 27:639, 1988). Two burster and two tonic neurons have been analyzed to date. The fractal dimensions were 3.6 and 3.7 for the burster cells and 5.1 and 5.5 for the tonic cells. The difference in the dimensions of the attractors of these two types of neurons suggests that during locomotion the firing pattern of the burster neurons is more coherent than that of the tonic. This is indicated by the lower fractal number of estimated parameters needed for a description of their behavior. Thus, tonic neurons display greater variability and may have a greater influence on the transition points of the locomotor pattern, which may be related to a greater variety of synaptic inputs and/or to intrinsic membrane properties.

Supported by NIH Grants NS21981 and NS20246.

QUADRUPEDAL GALLOP: THE UNSTUDIED GAIT. J.L. Smith, S.H. Chung, J.A. Buford, and R.F. Zernicke, UCLA Kinesiology, Los Angeles, CA 90024-1568.

Galloping at moderately high treadmill speeds (3-4 m/s) is difficult to elicit in the cat and has not been well assessed. We trained cats to gallop at these speeds and quantified hindlimb dynamics (for methods see Smith and Zernicke, *TINS* 10: 123-128, 1987) and EMG of selected muscles (see Buford and Smith, *J. Neurophysiol.* 64: 756-766, 1990). We focus here on limb dynamics during the swing phase (69%) of the step cycle and action requirements for bifunctional posterior thigh muscles, such as semitendinosus (ST), that extend the hip and flex the knee as well as anterior thigh muscles, such as rectus femoris (RF) and anterior sartorius (AS), that flex the hip and extend the knee.

At the knee joint in early swing, an extensor muscle torque is needed to counterbalance a large flexor torque created by leg angular acceleration (LAA). But, during the walk and trot, active muscles provide a flexor torque and there is no need for an extensor muscle torque because LAA is relatively small. At the hip joint in early swing, LAA creates an extensor torque. In early swing, therefore, muscles that flex the hip and extend the knee must counter LAA; both requirements can be satisfied by activation of the RF or AS.

Later in swing, passive muscle forces appear responsible for decelerating forward motion of the limb associated with LAA, because muscles with hip extensor and/or knee flexor functions are not active before hip extension and knee flexion begin. During the walk and trot, active muscle torque from posterior thigh muscles (*e.g.*, ST) decelerates forward limb motion prior to paw contact, but during the gallop, ST activity occurs just at or after knee flexion begins and is associated with rapid knee flexion and hip extension prior to paw contact. Our results suggest that swing phase limb dynamics during the gallop, in contrast to the walk and trot, require different demands of active bifunctional muscles. These changes have not been considered by those who emphasize only the need to change interlimb coordination to control the gallop. Research supported by NIH NS 19864.

CONTEXT, PHASE, AND LOCATION DEPENDENT RESPONSES TO HIND PAW STIMULATION DURING THE STEP CYCLE. J.A. Buford and J.L. Smith. Neuromotor Control Lab, Dept. Kinesiology, UCLA, L.A., CA 90024-1568.

Our previous studies comparing backward (BWD) and forward (FWD) walking revealed differences in hindlimb kinematics, especially at the hip and knee joints (Buford et al. 1990). Yet underlying muscle synergies were similar, with flexors active in swing and extensors in stance (Buford and Smith 1990). Is sensory input modulated differently for BWD walking even though motor output is grossly similar?

Others have demonstrated phase- and location-dependent modulation in cutaneous reflexes (Forssberg 1979, Drew and Rossignol 1986), especially for stumbling corrective reactions. What about context-dependent modulation? A ventral stimulus in early swing would be an obstacle for BWD walking but not for FWD. Do responses to such stimuli differ for BWD and FWD walking? We recorded EMG from hindlimb muscles of cats trained to walk BWD and FWD on a motorized treadmill (0.4-0.6 m/s). Stimuli (1 ms pulse; ~1 mA) were applied at various phases of the step cycle through subcutaneous electrodes implanted at the dorsal and ventral aspects of the paw. EMG, stimulus records, and ciné data were recorded.

We focus here on semitendinosus (ST), a muscle that bursts at the start and end of FWD swing but is active throughout swing for BWD. For dorsal stimuli, responses for BWD and FWD walking were similar. ST did not respond to stimuli delivered in the extensor period. For stimuli delivered in the flexor period (Flx), ST displayed two waves of facilitation, one from ~10-25 ms and a second from ~30-50 ms post-stimulus. Perhaps ST responses programmed to avoid dorsal obstacles for FWD swing are retained for non-obstructing dorsal stimuli in BWD swing.

For ventral stimulation, responses were context-dependent: for stimuli delivered in early Flx, the first wave was inhibitory for BWD walking but excitatory for FWD. ST inhibition in early BWD swing may help avoid a ventral obstacle. Thus, responses to hind paw stimulation were influenced by the direction of walking. We attribute this context dependency to different modulation of sensory input despite similar motor ouput. NIH NS19864 & the Foundation for Physical Therapy.

HINDLIMB STANCE KINETICS DURING BACKWARD WALKING: UNEXPECTED FINDINGS. K.L. Perell*, R.J. Gregor, M.M. Ryan*, J.A. Buford, and J.L. Smith, Dept. of Kinesiology, UCLA, Los Angeles, CA 90024-1586.

Based on results from hindlimb kinematics and EMG (see Buford *et al., J. Neurophysiol.* 64: 745-755, 1990; Buford and Smith, *J. Neurophysiol.* 64: 756-766, 1990) extensor moments were predicted for the hip and knee during backward (BWD) stance. Combined with hip flexion and knee extension, extensor moments would lead to power (P = Moment x angular velocity) generation at the knee and absorption at the hip. Movement kinematics and EMG, however, are insufficient to test such predictions, and forces and torques that cause such motion must be determined (see Smith and Zernicke, *TINS* 10: 123-128, 1987). As a result, kinetic analyses were done on 2 cats trained to walk BWD through a plexiglass enclosed walking containing 2 concealed force platforms capable of measuring center of pressure (COP) and ground reaction force (GRF). For apparatus decription see Fowler *et al.* (*Neurosci. Abst.*, 1987). We focus here on the response of the muscle synergies to the external demands created by the GRF and posture during BWD stance.

During the BWD stance phase, the GRF is directed vertically upward and anterior to the knee joint. This creates a need for ankle plantarflexor, knee flexor, and hip extensor muscle moments. Power analyses show generation at the ankle and absorption at the knee and hip. The knee flexor moment was unexpected because the vastus lateralis (VL) is active as the knee extends during stance. The lateral gastrocnemius (LG) activity, however, increases as VL activity declines during stance. With the VL shortening and decreasing in activation, the LG and its bifunctional synergists may have the mechanical advantage necessary to produce the knee flexor muscle moment. Our results suggest that the bifunctional capability of the LG is exploited by the nervous system to control the unique demands of BWD walking. Research supported by NIH NS 19864.

A COMPARISON OF IPSILATERAL AND CONTRALATERAL CUTANEOUS REFLEX RESPONSES DURING HUMAN RUNNING. A.A.M. Tax*, J. Duysens, C.C.A.M. Gielen, M. Trippel* and V. Dietz* Dept of Medical Physics & Biophysics, Univ of Nijmegen, 6500 HB Nijmegen, The Netherlands and Dept of Clin. Neurology & Neurophysiology, Univ of Freiburg, D-7800 Freiburg i. Br., Germany.

By electrically stimulating the human sural nerve at the ankle one can obtain both ipsilateral and contralateral low threshold reflex responses with a latency of about 80 ms in the Biceps Femoris (BF) and the Tibialis Anterior (TA). The modulation of these reflexes during the step cycle is studied in volunteers running on a treadmill at a speed of 8 km/h.

Both ipsi- and contralaterally, BF shows large responses during stance, while near the end of swing the responses of both BF and TA are reduced on either side. Because the size of these reflex responses does not tightly covary with the background activity during the step cycle a premotoneuronal gating mechanism is proposed. In addition, the similarity of the modulation of the ipsi- and contralateral reflex responses shows that the gating of cutaneous reflexes in these muscles depends on the phase of the corresponding leg in the step cycle and not on the phase of the stimulated leg.

PERIPHERAL CONTROL OF ELEVATOR MUSCLE ACTIVITY DURING SIMULATED CHEWING IN MAN.
F.A.M. Ottenhoff*, A. van der Bilt*, H.W. van der Glas and F. Bosman. Dept. of Oral Pathophysiology, University of Utrecht, Padualaan 14, 3584 CH, Utrecht, The Netherlands.

The Additional Muscle Activity (AMA), which is required to overcome the resistance of the food during chewing, was investigated. Subjects made rhythmic open-close movements at their natural chewing frequency, while food resistance was simulated by a computer controlled external force. Sequences of cycles with a force were randomly alternated with sequences with a larger, a smaller or without force. Jaw gape, the applied force and the surface EMG of the masseter and temporal muscles were recorded. The AMA adapted to a larger, a smaller or no force within 30 ms after the force started to differ from the force in the previous cycles. However, when the force was applied for the first time after a sequence without force, the AMA started 130 ms after the onset of the force. Thus, the central nervous system is able to generate jaw elevator muscle activity within 30 ms when a force is expected, irrespective of the amplitude of the force actually applied. A mandibular load (food resistance) during a chewing cycle may enable the use of short, fast pathways in the following chewing cycle.

484.20

SELECTIVE ACTIVATION OF HUMAN SOLEUS OR GASTROCNEMIUS IN REFLEX RESPONSES DURING WALKING AND RUNNING. J.Duysens, A.A.M.Tax*, M.Trippel* and V.Dietz.*
Dept. of Med. Physics & Biophysics, K.U.N., Nijmegen, The Netherlands and Dept. of Clin. Neurology & Neurophysiology, Univ. of Freiburg, F.R.G.

During the stance phase of running of the cat, stimulation of skin, innervated by the sural nerve, elicits responses in gastrocnemius (MG) with a latency of 25 ms, while such responses are absent in soleus (SOL, Duysens and Loeb,1980). In man, some evidence for a differential recruitment of these muscles was obtained in stretch responses, but not for sural stimuli and not during locomotion (Nardone et al.,1990).

Therefore, the phase-dependent modulation of MG and SOL responses to sural nerve stimulation was studied using a 20 ms train of 5 electrical pulses, applied to the sural (or tibial) nerve at the ankle, in 14 volunteers walking or running on a treadmill. Although both the spontaneous activity and the reflex responses were usually similar for both muscles, instances were identified in which separate control was evident. During walking (4 km/h), activity in SOL started earlier in the stance phase than GM activity. Correspondingly, the amplitude of the reflex responses was larger in SOL than in GM in early stance, both ipsi- and contralateral to the side of stimulation. In some cases, the same stimulus could elicit contralaterally a suppression of GM in synchrony with a facilitation of SOL (latency between 72 to 105 ms). During running (8 km/h or more), responses were seen selectively in GM instead (82 to 158 ms latency), without concomitant responses in SOL, during the first extension phase at the end of swing. The independence from the level of background activity suggests premotoneuronal gating.

ARE THERE COMMON PROCESSING CONSTRAINTS FOR VISUOMOTOR AND PERCEPTUAL MENTAL ROTATIONS? G. Pellizzer*, J.T. Massey, H. Bains*, and A.P. Georgopoulos. Bard Laboratories of Neurophysiology, Department of Neuroscience, The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

The hypothesis of a mental rotation of a movement vector when a movement has to be made at an angle from a stimulus direction is supported by the results of behavioral (Georgopoulos & Massey, Exp. Brain Res. 65: 361, 1987) and neural studies (Georgopoulos et al., Science 243: 234, 1989). Does this process share common constraints with the mental rotation of visual images (Shepard & Cooper, Mental Images and their Transformations, 1982)? To answer this question, we took advantage of the fact that mental rotation rates (reaction time vs. angle) may vary considerably among subjects: If common constraints underlie the spatial transformations involved in these tasks, then a correlation should be observed between the rates of mentally rotating visual images and those of mentally rotating a movement vector. We found that, indeed, these rates were significantly correlated ($p < 0.001$, N = 39 naive human subjects); in contrast, mental motor rotation rates did not correlate with rates (reaction time vs. number of movements in a memorized list) observed in a context-recall visuomotor memory scanning task (Georgopoulos & Lurito, Exp. Brain Res. 83: 453, 1991) which does not involve mental rotation. These results suggest that perceptual and visuomotor mental rotation tasks possess common processing constraints. (Supported by NIH, ONR and HSFP.)

PLANAR SEGMENTATION OF FORCE TRAJECTORY IN 3-D ISOMETRIC CONDITIONS. J.T. Lurito, G. Pellizzer*, J.T. Massey, and A.P. Georgopoulos. Bard Labs., Dept. of Neuroscience, The Johns Hopkins Univ., Sch. of Med., Baltimore, MD 21205.

Soechting & Terzuolo have shown (Neuroscience 23: 39, 1987) that the plane of motion of the wrist in free space may change abruptly between segments of the trajectory and be almost constant within each segment; this change of plane occurs usually at the points of inflection of the trajectory and may be a consequence of a segmentation at the level of motor programming. It was also shown that, for a given plane, the phase relations among upper- and fore-arm angular elevation are kept constant, which suggests that they may be part of an internal coordinate system for planning of movement trajectory. It can then be worth to analyze the plane of force trajectory in the absence of overt joint motion. In our experiment, subjects exerted forces with an unrestrained arm and the hand pronated on a 3-D isometric handle which controled the position of a visual cursor in a stereographic display (Massey et al., J. Neurosci. Methods 26: 123, 1988). They were asked to trace lemniscates (figures "8") in frontal or sagittal planes. We found that the planar orientation of the force trajectory often changed by more than 20 degrees between the two loops of the lemniscate, which by definition are divided by a point of inflection. These results are similar to those of Soechting and Terzuolo above and suggest that a common constraint might underlie planning of motor trajectory in space, whether or not it involves motion about joints. (Supported by NSF and ONR.)

MODELING OF POSTURAL ADJUSTMENTS DURING MULTI-ARTICULAR PULLS MADE BY STANDING HUMANS. W.A. Lee and C.F. Michaels*, Physical Therapy and Northwestern University Institute for Neuroscience, Northwestern University, Chicago IL 60611 and Psychology, Lake Forest College, IL 60045.

The control mechanisms by which standing subjects organize postural adjustments when they exert abrupt, bilaterally symmetrical near-maximal pulls on a handle in the sagittal plane are not well understood. We will present a kinematic and kinetic analysis of the kinematic and kinetic degrees of freedom of the task which helps explain empirically observed invariances and variations in body motion (postural adjustments). The analysis shows that the task has two kinematic degrees of freedom which can be expressed as the anterior-posterior (ap) and vertical (v) coordinates of the center of mass (CMap and CMv). The task also has three kinetic degrees of freedom (two Static; one Inertial); two of these are related to CMAP parameters. Six well-practiced subjects used qualitatively invariant proportions of Static and Inertial Components of pulling force (computed from force platform, load cell and kinematic data) and demonstrated invariant CMap phase planes during near-maximal pulls (~95% maximum). In contrast, CMV and joint angle motion varied substantially. The invariance in CMap motion appears to reflect the strong kinetic constraints on CMap revealed by the biomechanical analysis; variability in body motion is associated with the less constrained movement of CMv. We will present a preliminary dynamic model of how CMAP motion and horizontal pulling force are related. The model consists of an inverted pendulum acted upon by the force of gravity, a force due to a torque about the axis of rotation generated by a virtual spring between the pendulum and the support surface and a force due to an elastic cord connected to the pendulum mass. Simulated CMap phase planes compare well with the empirical data for near-maximal pulls. The model suggests that subjects may generate pulling movements by controlling dynamic parameters (e.g., stiffness; resting length) rather than torque parameters (timing, height and durations of impulses). We will present data from well-practiced subjects to determine if the model also predicts body motions during sub-maximal pulls. We predict that scaling the "resting length" of the elastic cord to peak pulling force will generate changes in CMap trajectories which match those which subjects actually produce.

PLANNING AND EXECUTION OF LIMB MOVEMENT IN CAT LOCOMOTION. L. Shen and R.E. Poppele. Dept. of Physiology, Univ. of Minnesota, Minneapolis, MN 55455

The cat hindlimb is a redundant mechanical system for producing planar limb movement in locomotion. The object of this study was to understand issues related to the control of this system. Assuming controls are realized at joint level, the problem then is to relate movements as specified in limb coordinates (limb length and orientation) and ground coordinates (foot position relative to ground) to movements in joint coordinates (limb segment orientation).

Cat hindlimb movements were recorded in unrestrained over ground locomotion for a variety of surface conditions and speeds (0.5-2.0 m/s). An analysis of movement kinematics revealed that: 1) the orientation of limb segments at touchdown relates linearly to whole limb orientation; and 2) trajectory of hind paw can be regulated by adjusting the timing of movements of limb segments. We propose therefore that different variables are used to control the trajectory of hind paw in the step cycle and the orientation of limb at touchdown, namely the timing across movement of segments and the segment orientation. For limb movements in locomotion, this control scheme provides a simple and adequate solution to the two most difficult problems in control of such redundant systems, namely trajectory planning and inverse kinematics. An interesting consequence of this control scheme is that regulation of the main features of hind paw trajectory is realized without planning the details of trajectory.

SEQUENTIAL MOVEMENTS IN TYPING. J.F.Soechting and M.Flanders. Dept. of Physiology, University of Minnesota, Minneapolis, MN 55455.

Last year we described the hand and finger movements of subjects who typed a single letter with one hand, while typing words in which the rest of the letters were typed with the other hand. For each letter (and subject) we found a characteristic pattern of movement (flexion-extension and rotation in the horizontal plane) that was independent of the movement of the other hand. Typically, this pattern comprised coordinated movements of all four fingers, beginning as much as 250 ms before the keystroke and lasting at least 500 ms. We have now extended this study to a description of the hand motion while subjects typed pairs of letters with one hand, embedded in words in which the rest of the letters were typed with the other hand. Up to the keystroke of the first letter, the kinematics of the movement do not depend on any subsequent movements; however, immediately after the first keystroke, the trajectory of hand motion for pairs of letters begins to diverge from the reference trajectory for a single letter. We have also found evidence that the planning of movement sequences in typing involves "look-ahead" processing, in the sense that the trajectory immediately after the first keystroke is altered even when there are as many as three letters typed with the opposite hand before the second keystroke of the pair. Therefore, the execution of skilled movements in typing exhibits serial aspects (the second movement of one hand does not begin until the first keystroke has been executed) as well as parallel aspects ("look-ahead" processing).

ARM POSITIONS WHEN POINTING IN A LARGE WORKSPACE. J. Hore, S. Watts* and T. Vilis. Dept. of Physiology, University of Western Ontario, London, Ont. Canada.

We and others have previously reported that when subjects point or grasp in a restricted workspace (e.g. 50 deg) the positions the arm adopts appear to follow an analog of Listing's law. This law states that with the head stationary the eye when fixating only assumes those positions that can be achieved by a single rotation about an axis that lies in a plane with zero torsion. Thus when positions of the arm were described in terms of a rotation from a reference position, the axes of these rotations lay in a plane-like surface. However further study of pointing movements over a larger (90 deg) range makes it clear that the axes surface is not flat but is consistently twisted like that associated with rotations around 2 axes of a Fick gimbal. The axes surface had a similar twisted shape whether subjects were pointing at targets or moving between them and whether subjects were pointing with or without vision.

Thus, although as previously reported, the arm shows major constraints in position when pointing, it does not accurately follow Listing's law. Instead the positions it adopts are similar to those of the eye in space in combined head-eye movements (Vilis, Glenn, Tweed this meeting).

THE MUSCLE SYNCYTIUM OF ASCARIS AND CONTRACTILE WAVE PROPAGATION. S. Solórzano*, J. Serrato*, C. Argüello* and A. Rivera. Dept. of Physiology, CINVESTAV-IPN, México City, DF, México.

The neuromuscular system of Ascaris suum consists of longitudinally oriented muscle cells that give off processes to contact the nerve cords. The prolongations from many cells intertwine at the surface of the cords to form the muscle syncytium or sarcopile. At this level the muscle cells exhibit myogenic activity, form neuromuscular junctions and are coupled by gap junctions. The possible role of gap junctions in contractile wave propagation is not yet known. Our data from scanning microscopy of the syncytium show the arms approaching the nerve cord in bundles and each bundle corresponds to arms from one or two adyacent rows of cells. Intracellular recordings show that the electrical coupling between cells is more efficient in narrow circular bands perpendicular to the longitudinal axis than along the length of the animal. We suggest that synchronization of electrical activity and contractile wave propagation is due in part to sequential activation of well coupled functional units of contraction (cell rows) that are perpendicular to the longitudinal axis. Thus, longitudinally oriented cells may present circular patterns of contraction as a consequence of the gap junction coupling between them.

485.2

A LASER CONFOCAL MICROSCOPIC STUDY OF THORACIC INTERSEGMENTAL INTERNEURONS IN THE MOTH, *MANDUCA SEXTA*. K. A. Mesce and K. A. Klukas*. Dept. of Entomology and Graduate Program in Neuroscience, University of Minnesota, St. Paul, MN 55108.

A population of intersegmental interneurons has been identified whose cell bodies are located in the adult pterothoracic ganglion and whose axons descend posteriorly through the unfused abdominal ganglia. Particular neurons within this population are important in controlling adult-specific ecdysis behavior and regulating selective neuronal death.

A variety of retrogradely transported neuronal tracers have been used to determine the number of neurons present, their morphologies and projection patterns. Smaller molecular weight tracers, such as Cobalt-Lysine and Biocytin, were found to label a number of putative 2nd order interneurons. These neurons were not filled, however, with higher molecular weight tracers such as Dextran Biotinylated Lysine and Dextran Tetramethyl Rhodamine, suggesting the occurence of trans-neuronal dye transfer through gap junctions.

To visualize small fluorescently labeled interneurons (somata less than 10 um in dia.) above background ganglionic autofluorescence, we used various dyes of cyanin derivation, some of which are not yet commercially available. Neuronal fluorescence was much increased above background by using a Bio-Rad Krypton/Argon laser to excite these fluorophores which had peak excitations at 647nm (red), far removed from excitation wavelengths in the blue and yellow ranges where autofluorescence is most apparent. We are currently examining whether these small intersegmental interneurons are generated *via* post-embryonic neurogenesis.

485.3

THE CONTRIBUTION OF VISUAL INTERNEURONS TO DIRECTION-SELECTIVE RESPONSES OF A FLIGHT MUSCLE. J.J. Milde, II. Zoologisches Institut, University of Cologne, Weyertal 119, D-5000 Koeln 41, F.R.G.

In the sphinx moth *Manduca sexta*, appropriate visual stimuli evoke compensatory body and limb movements. Intracellular stainings and recordings demonstrate that numerous brain interneurons responding to optomotor stimulation are present in the optic lobes (medulla, lobula and lobula plate) as well as in the posterior midbrain or the protocerebral bridge. To find out whether a recorded interneuron is really participating in behavior or not requires a simultaneous analysis of neuronal and motor responses.

In this study, the tonic unit of the mesothoracic third axillary muscle [Rheuben MB, Kammer AE (1987) J exp Biol 131:373], which has been shown to respond to visual stimuli even in non-flying moths [Dombrowski UJ (1991) Dissertation, University Cologne] is used as monitor for the motor output. The contribution of an interneuron to the motor activity is further evaluated by current injections. For example, a lobula plate neuron, which corresponds well with the muscle activity if the direction-selective responses are compared, can be shown by hyperpolarization to be obviously not involved in the generation of the muscle activity.

This approach is an important step towards an identification of neuronal elements underlying visually guided behavior.

485.4

SEGMENT-SPECIFIC FATES OF PROLEG MUSCLES AND MOTONEURONS DURING METAMORPHOSIS IN *MANDUCA SEXTA*. D.J. Sandstrom and J.C. Weeks. Graduate Group in Neurobiology, Univ. of Ca., Berkeley, CA 94720, and Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

The abdominal prolegs of *Manduca* are larval locomotory appendages that are lost at pupation. In the proleg-bearing segments, A3-A6, the APR motoneurons (MNs) innervate the larval proleg retractor muscle, APRM. Apparent homologs of the APRs and APRMs are also present in the non-proleg-bearing segments, A1 and A2. To better interpret other experiments investigating metamorphic changes in synaptic inputs to the APRs [*J. Comp. Neurol.* (1991) **308**:311], we have examined these MNs and muscles in more detail. In larvae, each APRM is innervated by a pair of APRs, which appear identical by electrophysiological and anatomical criteria. Typically, the anterior fibers of an APRM are innervated by one APR and the posterior fibers by the other APR, with middle fibers being dually innervated. Synaptic potentials from the two APRs have similar amplitudes and shapes, and exhibit similar activity-dependent plasticity. During the larval-pupal transformation, the APRMs degenerate in all segments except A2 and A3, whereas the APRs die one day after pupation in all segments except A2, A3 and A4. The dendritic arbors of APRs in the different segments regress to a similar extent regardless of whether the APR, or its target muscle, is fated to die. The surviving APRs and APRMs persist through the pupal stage, with the APRs showing dendritic regrowth. During the first two days of adult life the APRs and APRMs degenerate, presumably after participating in adult emergence behaviors. Thus, the degeneration of the APRs and APRM is segment-specific, while the dendritic regression of the APRs is not.

CALCIUM-DEPENDENT PLATEAU POTENTIALS IN THE LEG MOTONEURONS OF MANDUCA. R.B.Levine and J.M.Ramirez, Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721

Larval leg motoneurons (MNs) in *Manduca* persist to innervate the new adult legs. We are interested in the intrinsic properties of these MNs that may be important for locomotor activity. Using whole-cell patch-clamp techniques in primary cell culture it was shown that the leg MNs express two types of putative Ca^{++} currents: the dominant current has a low-threshold (-40 mV) and is slowly inactivating, the smaller one has a higher threshold and is resistant to inactivation (Levine and Hayashi, S.N.Abs. 1990). To examine whether these Ca^{++} currents reflect properties expressed *in situ*, intracellular recordings were obtained from leg MNs in intact ganglia. Following perfusion with saline containing TTX and TEA, plateau-like potentials could be evoked with short depolarizing current pulses and could be terminated prematurely with short hyperpolarizing pulses. Two components of the plateau-like potentials were distinguished:(1) transient, large amplitude potentials evoked at negative DC offsets and suppressed at more depolarizing offsets, (2) smaller, persistent potentials activated from depolarizing offsets. The plateau-like potentials occurred only in the presence of TEA and disappeared following perfusion with normal saline. They were TTX-insensitive, enhanced by replacing Ca^{++} with Ba^{++}, and suppressed by Co^{++} and Ni^{++}. The significance of these potentials for normal function is unclear, but they may augment rhythmic synaptic input during locomotion, perhaps after being revealed by neuromodulatory substances.

485.6

REORGANIZATION OF SENSORY REGULATION OF LOCUST FLIGHT AFTER PARTIAL DEAFFERENTATION. A.Büschges, R.Driesang, J.M.Ramirez and K.G.Pearson. Dept. of Physiology, University of Alberta, Edmonton, Canada.

Previous investigations have shown that the flight motor pattern of the locust relies heavily on activity in the hindwing tegulae but not on activity in the forewing tegulae. Removal of the hindwing tegulae results in a decrease of the wingbeat frequency by about 20% and an increase in the interval between the hindwing depressor and elevator activity by about 50%. However, these changes are not permanent since the flight motor pattern returns to normal during a period of about two weeks after the operation. This recovery is due to a functional substitution of the hindwing tegulae by the forewing tegulae. The following physiological changes in the connections of the forewing tegulae were found to be associated with recovery: 1) the probability of the forewing tegulae connecting to flight interneurons was significantly increased (e.g for interneuron 566 it increased from 0.58 (n=12) to 1.0 (n=16)), and 2) the average amplitude of the compound EPSP evoked in elevator interneurons by electrical stimulation of the forewing tegula afferents was significantly increased. This increase in amplitude was due to previously unconnected forewing tegula afferents developing synaptic contacts onto the elevator interneurons during the period of recovery. These physiological changes were paralleled by sprouting of the forewing tegula afferents in the metathoracic ganglion and by sprouting of the dendritic processes of flight interneurons.

THE PROBLEM OF RELIABILITY IN INSECT NEUROMUSCULAR CONTROL.
Jim H. Belanger and Ian Orchard. Department of Zoology, University of Toronto, Toronto, Ontario, Canada M5S 1A1.

The force which a muscle is capable of generating is proportional to its cross-sectional area, while the mass which it must accelerate is proportional to the volume of the organism. This means that, compared to vertebrates, insect muscles are relatively 'oversized'. It also implies that, in order to achieve a given level of control over its output (muscle tension), the insect neuromuscular system must exercise a greater degree of control over its input (motoneuronal signalling). We wanted to discover: 1. How reliably does a given insect neuromuscular system transduce a given motoneuronal input?; 2. What roles (if any) are played in maintaining reliability by neuromodulatory substances?

We approached this question using an *in vitro* preparation we have developed based on the locust (*Locusta migratoria*) ovipositor opener muscle. This preparation allows simultaneous monitoring of motoneuronal input, muscle electrical activity, and muscle force generation while the muscles are being driven spontaneously by a central pattern generator located in the terminal abdominal ganglion (K.J. Thompson, *J. Exp. Biol.* ***122***:387, 1986). In spontaneously active preparations, EMG activity is significantly correlated with neuronal input, but neither of these is correlated with the force produced by the muscle. When the spontaneous input is removed (by removing the ganglion), electrical stimulation of the opener nerve reliably predicts both the EMG and the force produced by the muscle, but only if single impulses are given. If trains of pulses are given, the summed EMGs are not significantly correlated with muscle force, even when the same population of axons is recruited with every stimulus. We are currently examining the possibility that proctolin acts to reduce this variability between axonal input and muscle output.

485.8

MOTOR PATTERNS IN COCKROACH LEGS DURING WALKING ON A SLIPPERY SURFACE.
F. Delcomyn. Department of Entomology and Neuroscience Program, University of Illinois, Urbana, IL 61801.

Intact cockroaches (*Periplaneta americana*) show a stereotypic pattern of activity in leg muscles during free walking. After amputation of a leg, free-walking insects show a pattern of motor activity that differs from normal mainly in the shifted timing of bursts in the leg in front of the amputated one during slow walking (Delcomyn, J. Exp. Biol. 156, 483-517). When suspended intact insects walk on a slippery surface, the pattern of motor activity is like that shown by intact insects walking freely. Amputation of a leg in suspended insects produces a motor pattern somewhat similar to that seen in free-walking amputee insects. However, this pattern has a reduced shift of timing of bursts in the leg in front of the amputated one, and a strong shift in timing of bursts in the leg behind it during slow walking. The differences between the motor patterns seen in free-walking and suspended amputee insects are likely due to the mechanical uncoupling of the legs during suspended walking. It is inferred that sensory feedback from leg mechanoreceptors is normally used by the leg of origin as well as by adjacent legs to coordinate motor activity.
Supported by a grant from the Whitehall Foundation.

NEURAL ACTIVITIES OF THE MUSHROOM BODIES OF THE COCKROACH DURING LOCOMOTORY BEHAVIOR.
M. Mizunami and N. J. Strausfeld. Arizona Research Laboratories, Division of Neurobiology, University of Arizona, Tucson, Arizona 85721.

In insects, two discrete sensory pathways supply premotor descending neurons, one via deutocerebral interneurons, the other via higher centers (mushroom bodies, MBs) in the protocerebrum. In 1960, Huber (Z. Vergl. Physiol. 44: 609-632), using electrical stimulation, concluded that MBs control complex behavioral repertoires. We have refined experimental techniques to re-examine this hypothesis.

Neural activities from MB neurons of the cockroach, *Periplaneta americana*, were recorded while animals were walking freely, using wire recording and staining techniques which reveal intact neurons at the vicinity of the electrodes (Mizunami & Strausfeld, Soc. Neurosci. Abstr. p759, 1990). Tactile stimulations were used to induce locomotory behaviors. Units from MBs were classified into (1) sensory units responding to mechanical stimulation of the body, (2) arousal units which exhibit long-lasting bursts after tactile stimulation, (3) locomotory units. Units recorded at MB input regions (the calyces) of MBs were exclusively sensory, whereas output regions (pedunculi and lobes) were characterized by arousal and locomotory units. Focal electric stimulations at the pedunculi and lobes induced complex locomotory sequences.

Although MBs are clearly indicated in spatial memory processing (see accompanying abstract; Weibrecht et al, 1991), and although lesions of MBs perturb this property, bilateral lesions of MBs do not perturb spontaneous motor actions. This suggests that motor activity per se can be independent of the participation of MBs and that MBs may specifically govern acquisitive motor repertoires. **Supported by NIH grant F05 TW 04390.**

THE MUSHROOM BODY OF COCKROACH BRAIN PARTICIPATES IN SPATIAL MEMORY PROCESSING.
J. M. Weibrecht, M. Mizunami and N. J. Strausfeld. Arizona Research Laboratories, Division of Neurobiology, University of Arizona, Tucson, Arizona 85721.

Social insects, such as bees and ants, can use complex spatial cues for orientation and navigation in environmental space. Here we present evidence suggesting that (1) cockroaches have a well developed spatial memory and (2) mushroom bodies (MBs) participate in the processing of spatial memory.

The ability of cockroaches to use spatial memory to identify a covert target was tested using the "Tenessee Williams" paradigm: cockroaches were placed in an arena, the floor of which was noxiously hot (50-55•C) except for a small invisible cool area (target). The wall of the arena was decorated with either visual patterns or olfactory cues having specific geometrical relationships with respect to the target. After five trials, cockroaches reached the target significantly faster with such cues than in their absence.

Effects of MB lesions on the ability to reach the target using spatial cues were tested. Small pieces of aluminum foil (width: 150-200 μm, length: 350 μm) were implanted into a selected area using relevant surface features. Subsequent histology determined the location and extent of lesions. In tests using visible targets, cockroaches with bilaterally lesioned MBs reached the target as fast as unoperated cockroaches (5 trials). When the target was invisible, however, the time taken for MB-lesioned cockroaches to reach the target was significantly longer than in unoperated cockroaches (5 trials). Unilateral MB lesions, or lesions of neuropils adjacent to MBs, did not significantly affect spatial learning, suggesting that MBs are indeed involved in spatial memory processing. **Supported by the Howard Hughes Undergraduate Biology Research Program and NIH grant F05 TW 04390.**

STRUCTURE OF OUTPUT NEURONS OF THE MUSHROOM BODIES IN HONEYBEE BRAINS.
B.A. Hurley*, W. Gronenberg, and N.J. Strausfeld, Arizona Research Laboratories, Division of Neurobiology, University of Arizona, Tucson, AZ, 85721 USA

Mushroom bodies (MBs) are protocerebral neuropils implicated in learning and memory [Erber J, Masuhr T & Menzel R (1980) Physiol Entomol 5:343-358; Mizunami M & Strausfeld NJ (1990) Soc Neuro Sci Abstr 16:759]. Each MB comprises a pair of calyces supplying a pedunculus branching into an α and ß lobe. Palisades of K-cells in the calyces receive a distributed afferent representation of olfactory, visual, and mechanosensory centers. This arrangement has been interpreted as reflecting multimodal sensory integration at K-cells [Mobbs PG (1982) Phil Trans Roy Soc Lond B. 298:309-354] whose axons go on to supply the pedunculi and lobes beneath. However, little is known concerning the pathways and targets of pedunculi and α-ß lobe outputs. The structure, arrangement, and targets of neurons leaving the α and ß lobes has now been analyzed using a modified Golgi technique and cobalt iontophoresis. Serially sectioned neurons were reconstructed using camera lucida at high power. In each α lobe, output neurons ("extrinsic neurons"; ENs) have elaborate dendritic arborizations characteristically interacting with specific configurations of the many thousands of parallel K-cell axons. Most EN axons extend around the α lobe and then terminate in specific premotor nuclei of the deutocerebrum. However, a substantial population of ENs project back to the calyces, comprising a "feedback" loop. Such reafferent supply may be important for memory acquisition, permitting information processed by the lobes to cycle back to their afferent supply (K-cells) for further processing [Schürmann FW (1974) Exp Brain Res 19:406-432]. **Supported by the Center for Insect Science (NSF DIR 82-20082) and NSF BNS 9011012**

THE MODULATION OF WING PHASE DURING TURNING RESPONSES OF DROSOPHILA.
M.H. Dickinson. Dept. of Organismal Biol. and Anatomy, Univ. of Chicago, Chicago, IL 60637.

The turning response of Drosophila to visual stimuli consists of several behavioral components including abdominal steering, leg position, and alteration of wing-beat amplitude. Here, I report an additional mechanism: the modulation of wing phase.

At the end of the downstroke flies rapidly rotate their wings before initiation of the upstroke. This rapid rotation is termed the ventral reversal. The timing of the ventral reversal can be precisely measured using pairs of photo-diodes (Götz, 1987). During optic stimulation in the open loop condition, flies actively modulate the timing of the ventral reversal such that the wing on the outside of the turn is in advance of the wing on the inside of the turn. The amplitude of the wing phase modulation is on the order of 5°. The phase response is much greater during stimulation with a single vertical black stripe (figure), than with oscillation of a large field pattern (ground). Wing phase modulation is greatest during oscillation frequencies near 1 Hz.

A NEURAL MODEL FOR OPTOMOTOR CONTROL AND THE LANDING REACTION IN FLIES. H. Öğmen. Dept. of Elect. Eng., University of Houston, Houston, TX 77204.

We present a neural model for the general optomotor control problem and test its predictions on a well-documented paradigm, viz. the landing reaction of the fly. The front-end of the model consists of elementary motion detectors (EMDs) (Öğmen & Gagné, *Neural Networks*, 3:487-505, 1990). EMDs are directionally selective and exhibit temporally adapting responses. The outputs of EMDs are pooled by wide-field directionally selective cells. The pooling takes into consideration the retinotopic position of EMD receptive field centers, their preferred direction axis, and binocularity. The pooling is an opponent process in that EMDs with opposite preferred directions undergo a shunting competition. Moreover, this opponent competition has sensitization and habituation properties. In addition to visual inputs, the wide-field integration cells receive other sensorial inputs such as mechanoreceptor outputs from legs and antenna. These sensorial inputs undergo habituation at their originating site before they modulate the pooling process. Finally, the opponent agonist antagonist outputs from the integration stage affect muscles controlling visually guided behaviors. The model will be compared with alternative models. It will be shown that there is a good agreement between model predictions and data from the landing reaction of flies.

NEURONAL CONTROL OF OPTOKINETIC NYSTAGMUS IN FLIES Cole Gilbert, Wulfila Gronenberg, and Nicholas J. Strausfeld. Center for Insect Science and Arizona Research Labs, Div. Neurobiology, Univ. of Arizona, Tucson AZ 85721

In insects, panoramic or small-field visual stimuli elicit optomotor head and body movements which stabilize the visual surround or the image of tracked objects on the retina. In tethered flies we optoelectronically quantified head yaw movements elicited by moving contrast gratings or small objects. These visually-induced saccadic head movements are suited to stabilize retinal images moving at velocities exceeding 3000°/s. Visual stimuli of the same spatio-temporal characteristics also elicit excitatory responses in 1) simultaneously extracellularly recorded motor neurons innervating the head/neck muscles which generate the observed behavior; 2) intracellularly recorded and dye-filled visual projection neurons, and 3) premotor descending neurons (DNs) which target the neck-muscle motor neurons. Recordings made with biocytin-filled electrodes often reveal dye-coupling between visual interneurons and DNs as well as between DNs and neck motor neurons. In the dorsolateral deutocerebrum of the brain these DNs are postsynaptic to 1) several wide-field motion-sensitive lobula plate neurons and 2) many motion- or flicker-sensitive small-field retinotopic elements originating in the lobula and lobula plate. Anatomical and physiological evidence suggests that each motor neuron integrates input from several DNs which, in turn, combine small- and wide-field visual input. We conclude that dorsal DNs integrate information about panoramic motion and movement of small objects and distribute this information to sets of neck muscle motor neurons which, in turn, control the muscles that produce the appropriate optokinetic head movements. **Supported by NIH Grant R01 EYO 7151-01, NSF Grant Dir 82-20082, and DFG Grant Gr 933 /2-1**

HYPOTHALAMUS II

486.1

DIVERGENT AXON COLLATERALS ORIGINATING IN THE RAT VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS. S. Truitt, C. Ulibarri, and T.R. Akesson, Department of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Cells of the ventrolateral part of the ventromedial nucleus of the rat (VMHvl) are perhaps the best characterized of neurons that influence female sexual behavior. Lesioning the VMH prevents and estrogen implants stimulate lordosis behavior. In addition to having their own estrogen receptors, neurons of the VMHvl also project to other steroid target nuclei, such as the medial preoptic nucleus (MPN), the medial nucleus of the amygdala (MeA), and the midbrain periaqueductal gray (PAG). One way in which a response to estrogen could be amplified is if an estrogen-receptive neuron sent collaterals to other nuclei involved in a particular function. This possibility prompted us to test for the presence of collateral projections by neurons of the VMHvl.

Female Long-Evans rats were iontophoretically injected in the PAG with a 3% aqueous solution of Fluoro-Gold using a 20 µm ID tip and 10 µa of positive current for 20 minutes. An incremental pressure injection (0.01-0.1 µl steps with 0.5-2 min pause to make a total of 0.05-0.5 µl) of a suspension of red and green latex spheres (LumaFluor, NY) were used to label the MPN and MeA respectively.

Ascending projection neurons (to MPN and MeA) were more numerous in the VMHvl than in central and dorsomedial parts of the nucleus but descending projection neurons (to PAG) were more uniformly distributed throughout the VMH. The vast majority of labeled cells in the VMH had only a single projection to either the MPN, MeA, or the PAG. A small but evenly distributed population of VMHvl neurons projected to both the MPN and MeA. In contrast, neurons which projected to the PAG were only occasionally found to also project to the MPN or MeA. Supported by HD22869.

A SUBPOPULATION OF NEURONS IN THE PARAVENTRICULAR NUCLEUS THAT PROJECT TO LOWER LUMBAR SPINAL CORD CONCENTRATE ^{3}H-ESTRADIOL IN THE MALE RAT. C.K. Wagner[1], L.G. Clemens[1] and C.L. Sisk[2]. Neuroscience Program and Departments of Zoology[1] & Psychology[2], Michigan State University, East Lansing, MI 48824

The paraventricular nucleus (PVN) of the hypothalamus sends projections to the lower lumbar spinal cord (*Brain Res.* 539:254, 1991). This level of the spinal cord is sexually dimorphic and contains the androgen concentrating motoneurons of the spinal nucleus of the bulbocavernosus and dorsolateral nucleus that innervate the sexually dimorphic perineal muscles involved in penile reflexes. PVN is known to play a role in the modulation of these reflexes. The purpose of the present study was to determine if neurons in PVN, that project to this region of the spinal cord, also concentrate steroids.

Sections through the PVN from male rats that had received injections of the retrograde tracer, Fluorogold, into the lower lumbar spinal cord, were prepared for steroid autoradiographic labelling using ^{3}H-estradiol. The results demonstrate that many neurons in the PVN of the male concentrate estrogen. The majority of these neurons are found in the anterior and lateral parvocellular subnuclei. Neurons that project to lower lumbar spinal cord are found primarily in the dorsal and lateral parvocellular subnuclei. A subpopulation of the neurons in the lateral parvocellular subnucleus that project to lower lumbar spinal cord also concentrate estrogen.

These findings suggest that androgen concentrating motoneurons of the lower lumbar spinal cord may receive steroid sensitive afferent input from the PVN.

HORMONE-SENSITIVE SEXUALLY DIMORPHIC NEURONS IN THE ANTEROVENTRAL PERIVENTRICULAR NUCLEUS PROJECT TO THE ARCUATE NUCLEUS OF THE HYPOTHALAMUS. B.S. Reinoso and R.B. Simerly. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

The anteroventral periventricular nucleus of the hypothalamus (AVPv) is a nodal point in the neural circuitry that controls ovulation in rodents (See Simerly and Swanson, J. Comp. Neurol. 270:209 for review). We previously determined that this important nucleus contains 3-4 times more dopamine cells, and approximately 4 times as many cells that contain prodynorphin (PDYN) mRNA in female rats, relative to male animals. Conversely, there are 2-3 times as many cells that express the opioid peptide precursor proenkephalin (PENK) in the AVPv of male rats compared with females; treatment of newborn female animals with testosterone reverses each of these neurochemical sexual dimorphisms. Moreover, sex steroid hormones appear to downregulate the expression of tyrosine hydroxylase in both male and female rats, and upregulate PDYN gene expression in female, but not male, rats. Thus, the maintenance of PENK cells, and the reduction in the number of hormone-sensitive dopaminergic and PDYN cells, in the AVPv may represent important developmental influences of perinatal androgens on the sexual differentiation of gonadotropin secretion. In the present project we used *in situ* hybridization in combination with retrograde transport and immunohistochemical methods to demonstrate that subpopulations of these sexually dimorphic neurons express estrogen receptors and project to the arcuate nucleus of the hypothalamus. These findings suggest a possible neural substrate whereby hormone-sensitive neurons in the AVPv provide sexually differentiated hormonal information to neurons in the arcuate nucleus, and may thereby influence the release of luteinizing hormone from the anterior pituitary.

ASYMMETRICAL VARIATIONS OF THE CHOLINERGIC SYSTEM OF THE PREOPTIC-HYPOTHALAMIC ANTERIOR AREA (PO-HAA) DURING THE OESTRUS CYCLE OF THE RAT. M.A. Sánchez*, J.C. López*, L. Huerto*, M.E. Cruz*, R. Tapia and R. Domínguez*. Instituto de Fisiología Celular, UNAM; Instituto Mexicano de Psiquiatría and Escuela Nacional de Estudios Profesionales Zaragoza, UNAM; Mexico.

It has been proposed that the PO-HAA participates asymmetrically in the ovulation process and a major role for its cholinergic system has been suggested. In this work, we studied the asymmetrical variations in muscarinic receptors and in choline acetyltransferase activity in both sides of the PO-HAA during the oestrus cycle of the rat. We observed that the activity of the enzyme varied along the oestrus cycle (Left: Oestrus (O)=32.6, Dioestrus 1 (D1)=24.3, Dioestrus 2 (D2)=30.1, Proestrus (P)=27.2; Right: O=39.1, D1=24.5, D2=20.5, P=26.6; nmol/min/mg protein). One way-ANOVA revealed that only the right side of the PO-HAA showed a significant variation during the cycle. Labeled n-methyl scopolamine binding constants also varied during the cycle, although only the Kd showed a marked asymmetry during the two dioestrus days (Left: D1=1.29, D2=0.95; Right: D1=0.4, D2=0.48; nM).

These data support the idea that the cholinergic system is involved in the asymmetric function of the PO-HAA in the ovulation process.

486.5

PRESENCE OF CALBINDIN (CB) AND LACK OF PARVALBUMIN (PV) IN PROGESTERONE RECEPTOR-CONTAINING (PR) NEURONS OF THE PRIMATE HYPOTHALAMUS T.L. Horvath,* F. Naftolin, C. Leranth. Dept. of Obstetrics & Gynecology, Yale University, School of Medicine, New Haven, CT 06510

In primates progesterone (P) decreases the frequency of luteinizing hormone (LH) pulses, but LHRH neurons do not contain PR. This suggests that P acts indirectly on the LHRH system. In the primate hypothalamus a large number of neurons contain PR and all of these cells are GABAergic (Leranth et al. '91). A large population of GABA neurons contain calcium-binding protein. In order to further characterize the PR-containing GABA cells we searched for their calcium-binding proteins. Experimental: Three out of 4 adult female ovariectomized vervet monkeys (*Cercopithecus aethiops*) received estradiol valerate. Thirty six hours later monkeys were sacrificed. Double immunostaining was performed for CB or PV and PR on hypothalamic sections. CB and PA was labeled by a Ni-DAB reaction, while PR with a DAB reaction. Results and Conclusion: In the ventromedial nucleus 41% of the PR cells were immunopositive for CB. The majority (78%) of the CB cells did not contain PR, and 59% of the PR cells did not exhibit immunoreactivity for CB. In the arcuate nucleus none of the PR cells were immunoreactive for CB. The hypothalamic PV cells, seen only in estrogen treated animals, did not contain PR. These results indicate that hypothalamic calcium-binding protein-containing GABA neurons can have different functions. These may be defined by their response to estrogen treatment and/or their PR-content. (Supported by NIH grants HD 23830, C.L. and HD 13587, F.N.)

486.6

TOPOGRAPHY OF HYPOTHALAMIC PROJECTIONS TO THE PERIAQUEDUCTAL GREY (PAG) IN THE RAT: A PHA-L STUDY. J.G. Veening*, L.M.G. Geeraedts*, G.J. Ter Horst**, P.G.M. Luiten** and T.A.P. Roeling*. Dept of Anatomy and Embryology, University of Nijmegen; **University of Groningen; The Netherlands. (SPON: European Neuroscience Association)

Descending projections have been studied in about 40 rats, with small iontophoretic injections of the anterograde tracer PHA-L in different parts of the hypothalamus. Projections from the paraventricular nucleus (PVN), dorsomedial nucleus (DMH), rostromedial and caudolateral parts of the ventromedial nucleus (VMH), intermediate hypothalamic area (IHA), ventrolateral and lateral hypothalamic area (LH) and the zona incerta (ZI), have been studied in detail. In addition, the structure of the PAG itself was investigated from its rostral, mesencephalic, to its caudal, pontine extension.

From all origins, mentioned above, fibers are distributed over the PAG in an intricate pattern of overlapping longitudinal columns. Rostrally, most projections, except LH, tend to converge in the dorsal PAG. More caudally, most descending fibers are present in the ventrolateral PAG, except the VMH-projection to the dorsal, the ZI-projection to the lateral and the LH-projection to the ventral PAG, including the dorsal raphe nucleus. Most caudally, some projections disappear (VMH, IHA), while others are mainly directed at the locus coeruleus (PVN, DMH, LH), or the adjoining nucleus of Barrington (ZI). Except for the projections from VMH and ZI, the central PAG is generally more densely innervated than the peripheral parts of the PAG.

486.7

THE NEURAL SUBSTRATE OF HYPOTHALAMICALLY INDUCED BEHAVIOURS IN THE RAT.
T.A.P. Roeling*, A.M.M. Van Erp*[1], W.H.M. Bressers*[2], E. Meelis*[2], M.R. Kruk*[1] & J.G. Veening*. Dept. Anatomy & Embryology, Univ. of Nijmegen, [1]Ethopharmacology Group, Univ. of Leiden, [2]Inst. for Theoretical Biol., Univ. of Leiden, The Netherlands.

On the basis of electrical brain stimulation, the hypothalamus of the rat has been divided into behavioural subregions. The anatomical correlates underlying this subdivision were investigated using local chemical brain stimulation for detecting the involvement of cell bodies and neuroanatomical tracers (PHA-L & HRP) for efferent and afferent connections.

Behaviour: A detailed analysis has been made of grooming behaviour elicited by microinjections into the hypothalamic paraventricular nucleus and adjacent dorsal hypothalamic area with glutamate agonists. Increases in boutlength and frequency of bouts were observed. The structure of the elicited grooming was similar to control situation. A brain cannula system was developed for experiments in a social environment. Microinjections into the subfornical region of the hypothalamus with bicuculline methiodide elicited digging, gnawing, agonistic behaviour and flight.

Anatomy: The efferent projections of the "grooming area" have been carefully mapped. Main projection areas are: lateral septum, medial amygdala, paraventricular thalamic nucleus, central gray, ventral tegmentum, locus coeruleus and nu. solitary tract. In comparison with other hypothalamic sites, many identical projection areas have been found. Within some of these areas, eg. septum and central gray, different spatial distributions can be distinguished.

THE POSTOPERATIVE HYPERACTIVITY OBSERVED FOLLOWING ELECTROLYTIC LESIONS OF THE LATERAL HYPOTHALAMUS IS ATTENUATED BY mCPP, BUT NOT HALOPERIDOL. T.R. Stratford and D. Wirtshafter, Univ. Illinois at Chicago, Dept. of Psychology, Box 4348, Chicago, IL 60680

Intense locomotor activity is often observed in rats awakening from anesthesia following electrolytic lesions of the lateral hypothalamus (LH). The hyperactivity usually persists for 2-3 hours and the magnitude of this phenomenon is often quite impressive. The mechanism underlying the locomotor activity may involve the non-specific release of dopamine at the target structures of damaged mesotelencephalic and/or mesolimbic axons which traverse the lesion site. In order to test this hypothesis we anesthetized rats with ether, lesioned the LH, and observed this postoperative activity in both an open field and in photocell activity cages following injections of the dopamine antagonist haloperidol (1.0 or 2.0 mg/kg, sc). Neither dose of haloperidol blocked the activity, although at the higher dose some jumping was introduced and the activity was directed increasingly in an upwards direction. In contrast, injections of another activity suppressing drug, the 5-HT agonist mCPP (1.0 or 5.0 mg/kg, sc), dose-dependently attenuated the activity, effectively blocking it at the higher dose. Therefore, it appears that dopamine release is not involved in the expression of this locomotor activity which can, however, be completely suppressed by mCPP.

486.9

EFFECTS OF REPEATED ELECTRICAL STIMULATION OF THE DORSOMEDIAL OR PARAVENTRICULAR NUCLEI ON GASTRODUODENAL EROSION FORMATION. D. Novin and N.S. Morrow. Depts. of Psychology and Psychiatry, Brain Research Institute, UCLA, Los Angeles, CA 90024.

Changes in the myoelectric activity of the stomach and the duodenum were recorded from freely-moving rats during electrical stimulation of the dorsomedial (DMH) or paraventricular (PVN) nuclei of the hypothalamus. Under pentobarbital anesthesia, a unipolar electrode was positioned stereotaxically and silver-chlorided recording electrodes were sutured underneath the serosa of the stomach and duodenum. Following postoperative recovery, rats were food deprived (16 h) and the DMH or the PVN stimulated (25-100 ua, 50 Hz, .5 ms) for 1 h; 3 stimulation sessions were given. Myogram activity was recorded preceding, during and for 2 h after stimulation. Rats stimulated in the DMH had significantly more gastric erosions than rats stimulated in the PVN. Duodenal damage was observed only in the PVN stimulated animals. Stomach and duodenal electrical activity was correlated with erosion formation. These results provide further support that changes in contractility mediate gastroduodenal damage.

CENTROMEDIAL AMYGDALOID LESIONS ATTENUATE GASTRIC EROSION FORMATION DURING ACTIVITY-STRESS. N.S. Morrow[1], C.V. Grijalva[1], D. Novin[1], and P.J. Geiselman[1]. Depts. of Psychiatry[1], Psychology[1], UCLA, Los Angeles, CA 90024, & Dept. Psychology[1], Louisiana State Univ., Baton Rouge, LA 70803.

To examine the role of the centromedial amygdala (CMA) in gastric erosion formation and running activity, rats with electrolytic CMA lesions and sham-operated controls were housed in Wahman activity cages. Following a 3 day baseline period (food and water, ad libitum), rats were restricted to eating for 1 h each day for 21 days. Running activity, body weight, body temperature, and food and water were monitored daily. Rats with CMA lesions exhibited significantly less gastric erosions compared to sham-operated controls or rats with damage outside the CMA. No other significant differences were observed between groups. The results support the view that the CMA is a crucial structure for the maintenance of gastric mucosal integrity. The results also suggest that the extensive gastric damage normally viewed in activity-stress rats is not solely responsible for their eventual inanition and ultimate demise.

VASOPRESSIN INNERVATION OF THE MEDIAL PREOPTIC AREA IN GERBILS ORIGINATES IN THE SUPRACHIASMATIC NUCLEUS. B.J. Crenshaw, and G.J. De Vries. Dept. of Psychology and Prog. of Neurosci. and Behav., Univ. of Mass., Amherst.

This study investigated the origin of vasopressin-immunoreactive (AVP-ir) fibers in the medial preoptic area (MPOA) in the gerbil hypothalamus. The MPOA contains a sexually dimorphic area (SDA) that has a subgroup of cells--the SDA pars compacta (SDApc)--which is absent in females in Nissl-stained preparations. We previously found that AVP-ir fibers were clustered in a sexually dimorphic manner in the region that houses the SDApc in males: the clusters were much larger in males than in females. We wanted to determine whether these AVP-ir fibers came from the AVP cell bodies in the bed nucleus of the stria terminalis (BST), whose efferents to the SDA are sexually dimorphic, or from the suprachiasmatic nucleus (SCN). Animals in one group received cuts dorsolateral to the SDA and ventromedial to the BST, which would transect efferents from the BST. A second group of animals received cuts ventral to the SDA and immediately dorsal to the SCN, which would transect efferents from the SCN. We found that cuts dorsal to the SCN eliminated AVP-ir fibers to the medial SDA (mSDA) and the SDApc, whereas cuts ventromedial to the BST left intact the AVP-ir innervation of the MPOA. These results suggest that the mSDA and the SDApc receive their AVP innervation from the SCN.

SUPRACHIASMATIC NUCLEUS OF NORMAL HUMAN BRAIN. K.Arima*, B.S.Kolachana, M.F.Casanova*, T.M.Hyde, J.E.Kleinman. Clinical Brain Disorders Branch, NIMH Neuroscience Center at St.Elizabeths, Washington, D.C. 20032.

Despite its modulatory role on circadian rhythms, little is known about the human suprachiasmatic nucleus (SCN). In this study we analyzed 14 normal brains using serial Nissl stained coronal sections to establish the topography and cellular characteristics of the human SCN.

The SCN measured about 1-1.8 mm in length along its rostrocaudal axis, and about 1 mm in diameter in the central coronal plane. At the caudal levels of SCN, the supraoptic nucleus appeared laterally. Nissl stain revealed two types of neurons; one with nuclei of 7-10 um in diameter and dark granular nucleoplasm, the other type with nuclei of 10-14 um, prominent nucleoli and clear nucleoplasm. Both types of neurons were occasionally invaginated into the underlying optic chiasm.

Qualitative and quantitative analysis of neurons in the left and right SCN and in the subfields will be discussed.

EFFECT OF NOCICEPTIVE STIMULI ON TIME ESTIMATION. B.E. Thorn, P.L. Hansell* and S. Keith.* Dept. Psychology, Univ. AL, Tuscaloosa, AL 35487. The effect of cold pressor & ischemic pain on Ss response to unexpected time estimation requests was examined. Time estimation has been proposed to be based on stimulus complexity, attentional demand, or arousal in an interval (Ornstein, 1969; Thomas et al., 1975). Pain should increase complexity, attentional demand *and* arousal, but Ss experiencing headache *underestimate* duration of an interval (Isler et al., 1987). We reasoned that a specific goal (SG) given to Ss in pain would mitigate downward distortion of time judgments, but Ss with an unspecified goal (UG) would show the distortion. Results from cold pressor confirmed the hypotheses: At 120 sec, time estimations of the UG groups (M =70.7 +43) were lower than the SG group (M =105.3 +46.4), t(25) =2.33, p<.05 or the non-pain control groups. Results from the ischemic pain showed that at 360 sec, time estimations of the *SG* group (M =260 +63.4) were lower than the *UG* group (M =357 +218.7) or the non-pain control groups. Results suggest that type of nociception &/or time frame of the test are factors in understanding the interaction of pain & goals on time estimation.

LEVELS OF BINDING IN PERCEPTION AND COGNITION. E.Pöppel, K.Schill*, N.v.Steinbüchel*. Institut für med.Psychologie, Universität München, 8000 München, Goethestr. 31, FRG

Each perceptual or cognitive act is characterized by the simultaneous activity of several neuronal modules. Specific mechanisms are necessary to bind the distributed activities together. Furthermore, successive activities have to be linked together as well to account for perceptual reality. Five different kinds of binding on different levels can be distinguished: 1. spatial binding of identical features within one sensory quality (like the establishment of connectedness in the visual modality); 2. object binding within one sensory modality for different qualities (such as surfaces with colors); 3. object binding for several modalities (such as the establishment of one object by visual and auditory information); 4. temporal binding for separate temporal events (as necessary in motion or speech perception); 5. semantic binding for the content of consciousness (such as the establishment of continuity of thought that might be lost in schizophrenia). The different binding processes are predicted to be implemented by different neuronal algorithms as is suggested by special defects. Supported by DFG and BMFT.

EVENT-RELATED BRAIN POTENTIALS ELICITED BY ADDITION PROBLEMS. P. J. Holcomb, J. Allen*, S. Ballerini*, D. Rosner*, & J. Anderson. Dept. of Psychology, Tufts University, Medford, MA 02155.

Numerous studies have reported a late negative ERP component (N400) that is larger to semantically incongruent or unexpected words in visual and spoken language tasks. While waves with a similar time course and morphology have been reported for stimuli in other cognitive domains it is unclear to what degree this and similar ERPs are specific to language comprehension processes. The current study compared ERPs to correct and incorrect answers in a mental addition experiment.

Six subjects (3 male) were run in two blocks (words and digits) of a task (120 trials/block) where 3 to 5 numbers had to be summed prior to the presentation of a target answer number. Fifty percent of answers were the correct sum of the previous addition problem and 50% were incorrect. Subjects indicated whether the answer was correct or incorrect by rapidly pressing one of two buttons. Artifact free ERPs were recorded from 13 scalp sites to each answer number.

All answers were characterized by a large positive going component between 300 and 600 ms in latency. However, incorrect answers were less positive than correct answers between 275 and 500 ms, with a notable negative going peak between 300 and 400 ms at some electrode sites. Moreover, incorrect word problems elicited a more N400-like negativity then did incorrect digit problems. The relevance of these findings to models of N400 and language processing will be discussed.

CROSS-MODAL SEMANTIC PRIMING USING DIFFERENT STIMULUS ONSET ASYNCHRONIES: AN EVENT-RELATED POTENTIAL STUDY. J. Anderson and P. J. Holcomb. Dept. of Psychology, Tufts University, Medford, MA 02155.

Previous electrophysiological and behavioral studies have found similar but not identical semantic priming effects within the auditory and visual modalities. This study compared priming effects between modalities in a cross-modal lexical decision task in order to investigate the possibility of common or independent language systems for auditory and visual modalities.

One group of 12 subjects was presented with visual primes and auditory targets and another 12 subjects with auditory primes and visual targets. The stimulus list consisted of 360 word pairs with equal proportions of semantically related, semantically unrelated, and word/pseudoword pairs. Three stimulus onset asynchronies (SOAs; 0, 200, and 800 msec) were randomly mixed across the experiments.

When the prime was visual and the target auditory, there were large N400 effects (i.e., greater negativity for unrelated targets) at all SOAs. However, when the prime was auditory and the target visual, there were N400 effects at the 200 and 800 SOAs, but not at the 0 SOA. Similarities in the semantic priming effects in the cross-modal conditions indicate that there are common underlying priming processes in the two modalities. However, differences in the time course of the effects and in the morphology of the components indicate that semantic priming in the two modalities may not be identical. The results have implications for models of language comprehension that assume similar or different systems for the two modalities.

487.5

ELECTROPHYSIOLOGICAL EVIDENCE FOR INDIVIDUAL DIFFERENCES IN SYNTACTIC PROFICIENCY DURING SENTENCE COMPREHENSION. S.A. Kotz, L. Osterhout* & P.J. Holcomb, Dept. of Psychology, Tufts University, Medford, MA 02155.

Evidence from previous ERP research has shown that syntactic anomalies (e.g. verb subcategorization and phrase structure errors) elicit a positive-going component (P600) quite distinct from the N400 found for semantic anomalies. Behavioral measures were used to assess the relative stability of previously established ERP components and possible variability due to individual differences. Subjects were ranked as high and low in syntactic proficiency based on their scores from a standardized grammar test. Subsequently, event-related potentials were measured during a sentence judgement task in which subjects were required to evaluate sentences that varied in length and syntactic difficulty.

Distinct P600 effects were found for the two types of syntactic anomalies. Subcategorization violations elicited a broadly distributed P600 in the low proficiency group, while the high proficiency group displayed no differences. The P600 elicited by phrase structure violations was larger at right hemisphere sites for the high proficiency group and posterior on the midline and at left hemisphere sites for the low proficiency group.

These results confirm the existence of distinct components for semantic and syntactic anomalies and indicate that the distribution of these components can be affected by the proficiency and individual processing strategies of the individual speaker.

BRAIN POTENTIALS EVOKED BY DIRECTIONAL CUES DIFFERENTIATE POOR AND GOOD READERS.
L. Anllo-Vento. Dept. of Psychology , Univ. of North Carolina at Greensboro, NC 27412.

The relationship between selective spatial attention and reading ability was studied with a paradigm that included both directional and non-directional cues. The children in the study were selected in kindergarten as being at risk of developing a reading disability, and were attending the 4th grade when tested.

The task included two successive stimuli: a central cue and a peripheral target. The cue, which was either directional (a left or right arrow) or non-directional (a circle), was followed 600 ms later by a target flash appearing randomly 8° in the left or right visual field. Children were asked to respond every time the target appeared in the cued visual hemifield.

Brain potentials differed between good and poor readers starting 120 ms after arrow onset, increased over time, and were most pronounced immediately before target presentation. Good readers exhibited distinct ERP patterns in response to left and right arrows, which were greatly reduced or absent in lower readers.

Cue-related potentials starting 320 ms after cue onset, but prior to target presentation, were correlated with reading ability, and helped explain subsequent response speed and accuracy.

PERISYLVIAN ANOMALIES IN DYSLEXIA: AN MR STUDY. C.M. Leonard[a], G.W. Hynd*[b],K.K.S. Voeller*[c], A.W. Alexander*[d], H. G. Andersen*[d], and J. Mao*[e], Depts of Neuroscience[a], Psychiatry[c], and Radiology[e], Univ. Fl. Coll. of Medicine, Morris Center[d], Gainesville, Fl. 32610, and Dept. of Special Ed., Univ. of Ga., Athens, Ga. 30602[b].

Dyslexia, or specific reading disability, may be due to anomalous development of the language areas surrounding the Sylvian fissure. Although the planum temporale is normally larger on the left, Galaburda and others have found that it is symmetrical in dyslexics.

We have examined other aspects of perisylvian morphology in two groups of dyslexics: four children with an IQ/reading discrepancy and four adults diagnosed by family history and interview. We scanned 15 age matched controls for comparison. All subjects were right handed. The adults were scanned using a volumetric acquisition that produced a gapless series of 1 mm thick sagittal images. The dyslexic children and their age matched controls were scanned with a standard T1 sequence (5 mm sagittal images). Sulcal patterns were classified with Steinmetz' method (Brain Lang. 38:515-533, 1990) as either normal (present in 82% of Steinmetz' sample and 14 out of 15 of our controls) or anomalous (extra or missing sulci).

Anomalous sulci were unexpectedly frequent in the dyslexics. Five dyslexics had extra sulci on the left while three had missing sulci on the right. Only two had normal patterns on both sides. These results support a role for anomalous brain development in the etiology of dyslexia. We conclude that thin sections in the sagittal plane afford an excellent view of the anatomical regions critical for language and that MR imaging can be used to identify behaviorally significant neuroanatomic variants.

NEUROANATOMICAL AND NEUROPSYCHOLOGICAL CORRELATES OF ACQUIRED AGRAPHIA. S.W. Anderson, J. Saver*, H. Damasio, and D. Tranel. Div. of Behav. Neurology & Cognitive Neuroscience, U. Iowa College of Medicine, Iowa City, IA 52242.

The neuroanatomical networks which subserve writing may vary considerably from individual to individual due to factors such as differences in learning history, but should have certain constancies due to neural constraints. In this study, motor and linguistic aspects of writing were evaluated in subjects with focal damage in 3 regions of the left hemisphere detected by CT/MR: 1) dorsolateral frontal lobe sparing primary motor cortex (n=13), 2) parietal lobe without extension into frontal or temporal cortices (n=8), and 3) posterior temporal lobe (n=8). Writing was evaluated for grapheme formation, spatial arrangement, spelling, word selection, perseveration, and grammar. The presence, nature, and severity of agraphia varied between and within the 3 groups, although frontal damage caused relatively severe impairments of grammar and grapheme formation. Motor and linguistic impairments of writing did not covary consistently with constructional apraxia or aphasic symptoms. These findings reflect the multifaceted nature and anatomically distributed basis of writing.

PRESERVED ACCESS AND PROCESSING OF SOCIAL KNOWLEDGE IN ACQUIRED SOCIOPATHY CAUSED BY VENTROMEDIAL FRONTAL DAMAGE. J. Saver*, A.R. Damasio, R.D. Jones. Div. of Cognitive Neuroscience, University of Iowa, Iowa City IA 52242

Damage to ventromedial frontal cortices produces abnormalities of decision making, especially in the realm of social conduct. To test the hypothesis that EVR-318, a prototypical patient with bilateral ventromedial frontal injury and "acquired sociopathy", would fail to access and process social knowledge, we investigated his performance and that of 5 controls matched for education, gender, and age, on standardized tasks which measure the abilities to (1) generate response alternatives to social dilemmas; (2) consider the consequences of pursuing each response option; (3) conceptualize effective means to achieve given social objectives; (4) predict the outcome of a particular response; and (5) perform moral reasoning at an advanced developmental level. The results revealed, unequivocally, that EVR exhibited normal or superior performance, being comparable to or better than controls on all tasks. The capacity to access and manipulate verbally the implications of social stimuli is not impaired in EVR. This result offers further indirect support to the alternative hypothesis that the mechanism underlying disordered social conduct in patients with ventromedial frontal lesions resides in an inability to mark with a specific somatic state (negative or positive) a future outcome that is otherwise normally evoked.

487.10

LAUGHTER: SONIC STRUCTURE AND CONTAGION. R. R. Provine. Dept. of Psychology, Univ. of Maryland Baltimore County, Baltimore, MD 21228.

Laughter is an ancient mode of pre-linguistic vocal communication performed in parallel with modern speech. A Sonographic analysis showed laughter is characterized by stereotyped laugh-note duration ("ha," X = 75 ms) and internote interval ("ha-ha," X = 210-218 ms), and a decrescendo. The simplicity and temporal symmetry of laugh-note structure and internote interval was demonstrated by reversibility; recorded laughter played backward sounded laugh-like. Contagion is another significant feature of laughter; most subjects laughed in response to 18 s of recorded laughter. Although the contagious response is well-known and the basis of "laugh tracks" on broadcast comedy shows, the implications of this potent and extraordinary behavior for brain function are unappreciated.

It is proposed here that stereotypic laughter is produced by a motor pattern generator that, in the case of contagious laughter, is triggered by a laugh-specific acoustic feature detector. Although the existence of human auditory feature detectors is debated, detectors are more likely for simple, species-typical laughter than for complex and culturally variable speech. Laughter and its contagion have numerous implications for theories of speech perception, the evolution of speech and language, the neural basis of social behavior, and cognitive neuroscience.

487.11

CATECHOLAMINE DEPLETION AND COGNITIVE PERFORMANCE: EFFECT OF SLEEP DEPRIVATION. U. McCann, D. Penetar*, Y. Shaham*, D. Thorne*, J.C. Gillin*, and G. Belenky. Dept of Behavioral Biology, Walter Reed Army Institute of Research, Washington, DC 20307-5100

Disturbances in CNS catecholamine systems have been postulated to underlie cognitive deficits in patients with a variety of conditions, including subcortical dementia, schizophrenia, and major depression. The effect of catecholamine depletion on cognitive performance in 40 healthy adult males was tested by preventing synthesis of catecholamines with AMPT, an inhibitor of tyrosine hydroxylase. Subjects were randomized to sleep deprived (no sleep for 40.5 hrs) or rested (7 1/2 hrs/night) conditions. In both sleep conditions, subjects received oral AMPT (or lactose placebo) at a dose of 750 mg QID over two days, for a total of 7 doses. Cognitive performance was measured repeatedly during the two days of drug administration and the day following the last drug dose, using a computerized battery of seven cognitive tasks. AMPT treatment alone, like sleep deprivation alone, was associated with decrements in cognitive performance. Furthermore, the combination of sleep deprivation and AMPT treatment was associated with greater performance decrements than either treatment alone. These findings support the view that catecholamines play a role in normal cognitive processes. Further, they suggest that decrements in cognitive performance associated with sleep deprivation may be mediated by the catecholamine neurotransmitters. Sleep deprivation may be a useful tool for detecting subclinical cognitive dysfunction in patients with a suspected cognitive deficit.

EXPOSURE TO HYPOBARIC HYPOXIA: A METHOD FOR THE COMPARISON OF NEUROPSYCHOLOGIC TESTS IN HUMANS
H.R. Lieberman, B. Shukitt-Hale, L.E. Banderet* and J.F. Glenn
Military Performance and Neuroscience Division, U.S. Army Research Institute of Environmental Medicine, Natick, MA 01760.

A common problem in psychopharmacology and neuropsychology is the absence of a reliable method to compare the sensitivity of behavioral tasks employed in human studies. Most environmental, behavioral and psychopharmacologic manipulations do not consistently produce readily detectable, graded deficits in human performance and mood. However, human cognitive function is sensitive to changes in oxygen availability and exposure to hypoxia should produce a continuum of effects as altitude level and duration are increased. We evaluated the behavioral effects of hypoxia as a function of time of exposure and altitude level with various standardized tests of cognitive function and mood-state. Twenty-three males were tested in an altitude chamber during a 4.5 hour exposure to hypobaric hypoxia. All subjects were exposed to two levels of hypoxia (4200 m and 4700 m) and a near sea level (550 m) control condition. Prior to altitude exposure, extensive practice was given on all tests. Cognitive function was significantly impaired on most tests. Even on relatively simple performance tasks, such as simple and choice reaction time, as well as complex tests of cognition, such as the Tower of Hanoi, function was significantly reduced in a graded manner. Mood-state, which was assessed using several standardized tests, such as the Profile of Mood States, was also impaired in a graded manner. In general, the magnitude of the effects observed was a function of exposure duration and altitude level. The robust and consistent effects observed and their graded, relatively non-specific nature, suggests that graded exposure of to hypobaric hypoxia may be a useful method for comparing the sensitivity of various tests of human performance, cognition and mood.

MOTOR DYSFUNCTION IN EARLY ASYMPTOMATIC HIV INFECTION. R.A. Stern,* N.G. Singer,* S.G. Silva,* H.J. Rogers,* D.O. Perkins,* C.D. Hall,* C.M. van der Horst* and D.L. Evans. Depts. of Psychiatry, Medicine, and Neurology, Univ. of North Carolina Sch. of Med., Chapel Hill, NC, 27599.

AIDS frequently results in CNS dysfunction. It remains unclear, however, whether asymptomatic HIV seropositive individuals exhibit neurobehavioral deficits early in the course of infection, prior to other symptoms and signs. The goal of this study was to assess the impact of several potential co-factors on the early presentation of cognitive and/or motor disturbance in HIV. Subjects included 35 asymptomatic HIV seropositive gay men and 44 seronegative gay male controls. Strict exclusion criteria were used to preclude the confounding effects of zidovudine use, substance abuse, or CNS disorder, including mild head injury or learning disability. Neuropsychological evaluations were conducted as part of a larger, longitudinal study. Group differences in summary ratings and individual test scores were first assessed with analyses of variance. Education, SES, B12 level, CD4 count, and Hamilton Depression Rating Scale score were then controlled for, individually and together, using analyses of covariance. The level of significance was set at .05 for all tests. Without any covariates, significant group differences were found in a variety of areas, with the seropositive subjects performing worse than controls. When controlling for education, the only significant group differences were on measures of motor speed. These significant group differences remained after controlling for SES, CD4 count, B12 level, and depression. In gay men without confounding factors of substance abuse, past CNS disorder, or zidovudine use, mild motor slowing was the only neurobehavioral deficit associated with early HIV infection.

Absence of Neurobehavioral Effects of High Dose Aspartame in Phenylketonuric Heterozygotes (PKUH). L.M.J. de Sonneville, B. Lanz-Englert*, F.K. Trefz*, Ch. Benninger, P. Matthis* and H. Bickel*. University of Heidelberg, Heidelberg, Germany.

The effects of aspartame (APM) on neuropsychological and biochemical parameters were evaluated in 48 adult (21 male, 27 female) PKUH whose carrier status had been proven by DNA analysis. Subjects received APM (either 15 or 45 mg/kg/day) and placebo in capsules in a randomized, double-blind, placebo-controlled, crossover study for twelve weeks on each treatment. A computerized battery of neuropsychological tests, the de Sonneville Visual Attention Tasks (SVAT), was evaluated at weeks -2, -1, 6, 12, 18, and 24. Through a series of complex reaction time paradigms, the SVAT evaluates cognitive changes in the main stages of information processing (encoding, memory search, decision, and response organization), in sustained and focused attention, and in short term memory. Notwithstanding increases in plasma phenylalanine concentrations after the morning dose in the 45 mg/kg/day APM group, there were no significant differences in any of the SVAT measures when APM was compared to placebo. Moreover, evaluation of individual SVAT scores did not reveal any changes from baseline. In addition, there were no significant differences in adverse experiences, urinary organic acids, and electroencephalograms when APM was compared to placebo. These results reaffirm the safety of APM in PKUH and refute the speculation that APM affects cognitive performance.

LEARNING AND MEMORY—PHARMACOLOGY: ACETYLCHOLINE II

488.1

CENTRAL CHOLINERGIC BLOCKADE BY SCOPOLAMINE DISRUPTS CLASSICAL CONDITIONING OF THE HUMAN EYEBLINK RESPONSE . P.R. Solomon, M.E. Groccia-Ellison, K.R. Edwards, and M.E. Stanton, Southwestern Vermont Medical Center, Bennington, VT 05201 and Williams College, Williamstown, MA 01267

The cholinergic system has been implicated in both normal and disordered memory. We have previously demonstrated that the anticholinergic drug scopolamine disrupts a simple form of learning and memory (Classical or Pavlovian eyeblink EB conditioning) in rabbits. Studying simple forms of learning and memory such as EB conditioning may be particularly useful for understanding mechanisms of memory disorders because the identical learned response can be studied in both humans and animals (rabbits). Recently, we have demonstrated that this form of memory is also disrupted in patients with Alzheimer's Disease (AD). This may be of some significance because of the hypothesized link between acetylcholine and disordered memory in AD. We now report that scopolamine disrupts human EB conditioning in a manner similar to that seen in AD patients. Human volunteers between the ages of 18 and 50 received oral administration of either scopolamine (SCOP) hydrobromide (0.6 or 1.2 mg), a peripheral cholinergic blocker, glycopyrrolate (GLY, 0.2 mg) or saline (SAL). Subjects then underwent classical conditioning of the EB response. Subjects receiving the low dose of SCOP or GLY conditioned at about the same rate as SAL controls. Subjects who received the high dose of SCOP conditioned significantly slower.

488.2

THE REVERSAL OF SCOPOLAMINE'S EFFECTS ON RESPONSE ERRORS BY MUSCARINIC AGONISTS IN RATS. V.L. Coffin, M.L. Libonati, and M.B. Latranyi*. Schering-Plough Research, Bloomfield, NJ, 07003

Rats were trained on a fixed-ratio (FR) discrimination procedure. Rats were required to complete one of two FRs on the center bar followed by a choice on the right lever if the ratio was low (FR 8) or on the left lever if the ratio was high (FR 16) for a food reward. Scopolamine produced dose-related decreases in response rates and increases in response errors (.003-.01 mg/kg sc). Arecoline and physostigmine reversed the effects of scopolamine on response errors and failed to reverse the decreased response rates. Doses of these agonists which reversed scopolamine, had no effect on this schedule when administered alone. Oxotremorine failed to reverse any of the effects of scopolamine on this schedule.

Methylscopolamine produced a similar decrease in response rates as scopolamine but with smaller changes in response errors over the same dose range. Muscarinic agonists did not reverse the effects of methylscopolamine on response errors.

In conclusion, scopolamine produces centrally mediated deficits on accuracy which can be selectively reversed by arecoline and physostigmine but not oxotremorine.

488.3

LACK OF AMNESIC EFFECT OF SCOPOLAMINE IN UNDER-REINFORCED PASSIVE AVOIDANCE. G. L. Quirarte*, S. Rivas-Arancibia* and R. A. Prado-Alcalá. Psych. Sch., Univ. Guadalajara and Physiol. Dept. Med. Sch., Natl. Univ. of México, México, D.F. 04510, México.

Experimental data indicate that in conditions of overtraining or over-reinforcement central nervous system cholinergic activity is not needed for memory consolidation. The aim of this work was to determine if the same holds true for consolidation of passive avoidance, trained with low levels of footshock (under-reinforcement). Rats were submitted to one-trial passive avoidance and were given one footshock during training (0.0, 0.3, 0.4, 0.5, 0.6, 0.7, or 0.8 mA). Half the groups was given one ip injection of scopolamine (8 mg/kg), 5 min after training and the other half was not injected. Scopolamine-induced amnesia was found only in the animals trained with 0.7 and 0.8 mA. These data suggest that muscarinic cholinergic activity is not involved in memory consolidation of under-reinforced tasks.

BEHAVIORAL MICROANALYSIS OF SPATIAL DELAYED ALTERNATION PERFORMANCE: REHEARSAL THROUGH OVERT BEHAVIOR, AND EFFECTS OF SCOPOLAMINE AND CHLORDIAZEPOXIDE. P. Dudchenko and M. Sarter. Dept. Psychology, The Ohio State University, Columbus, OH 43210.

Rats were trained in an operant spatial delayed alternation task employing various delays ranging from 2 - 32 seconds. In addition to response accuracy, operations of the levers during retention intervals were recorded and analyzed. In untreated animals, the relative number of correct responses and correct rehearsal operations (operation of the forthcoming correct lever during retention intervals) varied with the length of the retention intervals, and these measures were correlated. The response rate for rehearsal operations increased with the length of the retention intervals. It is speculated that the delay-dependent increase in response rate reflects an effect of delayed reward that was also associated with an increasing tendency to alternate between levers. These effects may have contributed to the delay-dependency of correct responding. Scopolamine-hydrobromide (0.01, 0.03, 0.1, 0.3 mg/kg) and -methylbromide (0.1, 0.3 mg/kg) produced main effects on correct responding, but did not interfere with the relative number of correct rehearsal operations. As both scopolamine-derivatives did not affect the relative number of correct rehearsal operations but of correct responses, it is speculated that these treatments increased the probability that the onset of the panel light (that was assumed to indicate lever activation) triggered a repositioning response, yielding a delay-independent reduction in the number of correct responses. These results suggest that in tasks that potently allow the development of rehearsal operations, delay-dependent response accuracy does not represent a sufficient condition for conclusions on task demands on memory. Furthermore, it seems likely that drug-induced changes in performance in such tasks may be a result of alterations within peripheral functions.

MUSCARINIC ACTIVITY OF A NOVEL M_1 AGONIST, YM796 AND ITS OPTICAL ISOMER. F. Wanibuchi, T. Konishi*, K. Hidaka*, H. Akiho*, Y. Nakamura*, K. Takahashi*§, S. Tsukamoto* and S. Usuda* Central Res. Labs., § Applied Pharmacol. and Develop. Labs., Yamanouchi Pharmaceutical Co., Ltd., 21 Miyukigaoka, Tsukuba, Ibaraki 305, Japan.

(±)-YM796 exhibits M_1 agonistic activity (Eur.J. Pharmacol. 187(1990) 479-486). We herein report the further characterization of its (-)-isomer, YM796 ((-)-2,8-dimethyl-3-methylene-1-oxa-8-azaspiro[4.5]decane, (-)-YM796) and its (+)-isomer on biochemical and behavioral studies. YM796 (0.016 - 0.25 mg/kg, po) like the racemate reversed the cognitive impairment induced by nucleus basalis magnocellularis (NBM) lesion in rat passive avoidance tasks, whereas (+)-YM796 was ineffective in the experimental amnesia. In addition, YM796 ameliorated the memory deficit of NBM-lesioned rats in Morris water maze. YM796 was weaker than RS86 in the induction of tremor, hypothermia and contraction of ileum which are mainly mediated by M_2 and/or M_3 receptors. YM796 like the racemate inhibited [^{3}H]pirenzepine ([^{3}H]PZ) binding to rat cerebral cortical membranes in the micromollar range and stimulated phosphoinositide (PI) hydrolysis in rat hippocampal slices. The (+)-isomer have essencially no agonistic activity in PI hydrolysis and behavioral changes in spite of inhibiting [^{3}H]PZ binding. These results indicate that YM796 but not its (+)-isomer is a potent and selective muscarinic M_1 receptor agonist.

BEHAVIORAL AND MICRODIALYSIS STUDIES OF A NEW AChE INHIBITOR, 3-PYRIDINOL DIMETHYLCARBAMATE, IN THE RAT

L.J. Cote, M.E. Bach, A.B. Naini, R. Burke, T. Oo, M. Sano, S. Ginsburg*, J.L. Bach*† & R. Mayeux*. Dept. of Neurology, College of P&S, Columbia University, New York, NY 10032 and †Ciba-Geigy Co., Summit, NJ 07901

In a previous study we found that rats with unilateral nucleus basalis magnocellularis (nbm) lesions (quinolinic acid-120nmol in 1 ul) displayed a learning deficit on the repeated acquisition task. In each session of the repeated acquisition task, the rat is required to learn in 10 trials, which new 4 arms, of an 8-arm radial maze, are baited with food. This study compared the effectiveness of the novel acetylcholinesterase (AChE) inhibitor 3-pyridinol dimethylcarbamate ("Norpyridostigmine") to physostigmine at enhancing repeated acquisition performance in the lesion rat. Norpyridostigmine tosylate at 5, 10, or 20 mg/kg and physostigmine salicylate at 0.6, 0.9 or 0.12mg/kg were administered i.p., 15 min prior to behavioral testing. The performance of AChE inhibitor treated lesion rats was compared to untreated lesion, sham and control rats. Both AChE inhibitors enhanced learning in a dose response manner. Also, Norpyridostigmine tosylate (30mg/kg, i.p.) increased the release of acetylcholine (ACh) from the striatum by about 80% above baseline, in an awake, free roaming rat. Peak ACh level occurred 2 hours following administration. In conclusion, Norpyridostigmine enhances repeated acquisition performance and increases ACh levels in vivo.

SCOPOLAMINE PRODUCED IMPAIRMENT OF REPEATED ACQUISITION PERFORMANCE BY THE NBM LESIONED RAT IS REVERSED BY THE NOVEL AChE INHIBITOR 3-PYRIDINOL DIMETHYLCARBAMATE M. Sano, M.E. Bach, A.B. Naini, L.J. Cote, S. Ginsburg*, J.L. Bach*† & R. Mayeux*. Dept. of Neurology, College of P&S, Columbia University, NY, NY 10032. and †Ciba-Geigy Co., Summit, NJ 07901.

Learning and memory impairments in Alzheimer's disease have been attributed to the disruption of the cholinergic system. We have demonstrated in rats that unilateral lesions (quinolinic acid-120 nmol in 1 ul) of the nucleus basalis magnocellularis (nbm) produced cholinergic cell loss and learning deficits in repeated acquisition performance. We hypothesized that the performance of the lesion rats would be more vulnerable to a disruption by scopolamine, a muscarinic antagonist, than sham and control rats. Scopolamine (0, 0.1, 0.2, & 0.4mg/kg, i.p.) administration began when the repeated acquisition task had been learned. In each session of this task, across 10 trials, the rat is required to learn which new set of four arms, of an 8-arm radial maze, are baited with food. Lesion, sham and control groups received scopolamine 20 minutes prior to testing. Across all doses, the lesion group was more impaired than the sham and control groups, who were similarly effected. Scopolamine impaired accuracy and increased reference and working memory errors in a dose-response manner with the former error type more effected. To determine if acetylcholinesterase (AChE) inhibitors could reverse the scopolamine impairment, 3-pyridinol dimethylcarbamate, "Norpyridostigmine" (5, 10 & 20mg/kg) and physostigmine(0.6, 0.9 & 0.12mg/kg) were administered i.p., 5 min following a scopolamine injection (0.4mg/kg). Both inhibitors consistently reversed the impairment. Initial studies suggest that Norpyridostigmine improves performance in a dose-response manner. These results support the hypothesis that cholinergic deficits produce memory impairments and suggest that AChE inhibition may serve as a viable treatment for cognitive/behavioral deficits.

USE OF RESPONSE STRATEGIES DURING RADIAL MAZE PERFORMANCE BY NBM LESIONED RATS. M.E. Bach and S.L. Teitelbaum*, Depts. of Neurol.& Rehab. Medicine, College of P&S, Columbia University, NY, NY 10032. In a previous study, we found that rats with unilateral nucleus basalis magnocellularis (nbm) lesions (quinolinic acid-120nmol in 1ul) displayed a repeated acquisition (RA) task learning deficit. They required 22 days to learn the task as compared to controls who needed 7 days. In the RA task, the rat is required to learn, across ten trials, which four arms of an 8 arm radial maze are baited with food; a new set of 4 baited arms is randomly selected for each session. During data collection, it was observed that lesioned rats followed response strategy rules more frequently than control rats. The observed strategies included: 1) response patterns: arm entries (AE) which follow a spatial pattern rule e.g. always enter arm at a right (90°) angle or always enter adjacent (45°) arm, 2) response sequences: repeated use of the same set of AE which are entered in the same sequential order and 3) entering arms in a predominantly clockwise (CW) or counterclockwise (CC) direction. To determine if lesioned rats (N=8) were more apt to use response strategy rules during the learning deficit period (sessions 11-20), we compared their AE choices to those of the controls (N=8). For response pattern analysis, the frequency of right angle, adjacent, nondescript (135°), across and reentry AE was assessed along with the prevalence of CW and CC moves. Response sequence analysis included: 1) examination of the first four arm choices from each trial for repetitions of a specific sequence of AE and 2) determination of which baited 4 arm sequence was used the most in each session. Using the Mann-Whitney U test we found that lesioned rats made significantly more right angle AE ($p<.02$) and also entered arms in a predominantly CW or CC direction ($p<.0001$). The two groups did not differ in any of the response sequence analyses. We propose that lesioned rats may employ response strategy rules because they make minimal demands on memory while still enabling the rat to solve the RA task.

488.9

EFFECT OF RX77368 AND SCOPOLAMINE ON 8-ARM RADIAL MAZE PERFORMANCE IN THE RAT. C.D.Watson*, M.J.Hewitt*, K.C.F.Fone*, G.W.Bennett*, & S.L.Dickinson[1]*. (SPON: Brain Research Association). Dept. of Physiol.& Pharmacol., Queen's Medical Centre, Nottingham NG7 2UH, UK. [1]Reckitt & Colman Psychopharmacol. Unit, University Walk, Bristol BS8 1TD, UK.

Thyrotrophin-releasing hormone (TRH) analogue RX77368 (dimethyl-Pro-TRH), is known to reverse an atropine-induced water maze deficit. We evaluated whether RX77368 could attenuate a scopolamine-induced deficit in the radial arm maze. Rats were cannulated i.c.v., placed on a 23hr food-deprivation schedule then tested on days 12-16, 19-23 and 26-30 post-surgery in a radial maze. Four groups of rats (n=8 each) were pretreated (-40min) with either saline (SAL; groups A and B; 2µl i.c.v.) or RX77368 (groups C and D; 2µg i.c.v.) followed 10min later with either SAL (A and C; 1ml/kg i.p.) or scopolamine (SCP; B and D; 0.3mg/kg i.p.). After the last trial, TRH levels in the septum, hypothalamus, nucleus accumbens, hippocampus and medial-parietal cortex were determined by radioimmunoassay. Performance of all groups significantly improved over time, as measured by unrepeated arm entries (UAE, $P<0.001$), total arms entered (TAE, $P<0.01$) and total maze time ($P<0.01$). UAE were significantly reduced by SCP alone ($P<0.05$, days 13-29), indicating a SCP-induced learning deficit. SCP alone also showed significantly fewer repeated arm entries (RAE) at the start of the trials ($P<0.05$) and significantly more at the end ($P<0.05$), suggesting SCP had non-cognitive effects. RX77368 significantly attenuated the SCP-induced deficit on days 13-21 but not on later days. RX77368 alone significantly increased UAE ($P<0.05$, days 12, 15) compared to SAL, suggesting that the TRH analogue either alone or in combination with SCP improved performance. Hypothalamic TRH levels (SAL; 169.2±18.2pg/mg protein) were significantly elevated in the SAL/SCP (580.5±106.6, $P<0.01$), RX77368/SAL (378.5±75.4, $P<0.05$) and RX77368/SCP (354±94, $P<0.05$) groups. Changes in other areas were less pronounced. Taken together these results suggest that SCP-induced radial maze performance deficit may result from a reduction in locomotion rather than solely a learning impairment and that RX77368 may improve performance by increasing arousal and exploration.

IMPROVEMENT OF MEMORY IN NORMAL AND IMPAIRED MICE BY BMY 21502: A COMPARISON WITH HYDERGINE® AND PHYSOSTIGMINE. H. Lal, K. C. Retz, and M.J. Forster. Dept. of Pharmacology,Texas College of Osteopathic Medicine, Fort Worth, TX 76107

BMY 21502, a substituted pyrrolidinone, was tested in three animal models for its potential to reverse age-related memory dysfunction. In two of the models, efficacy of BMY 21502 was compared with physostigmine and hydergine®. BMY 21502 treatment prior to training improved the ability of mice to learn a goal arm discrimination in a T-maze. In addition, the BMY 21502-treated mice showed improved recall one week following initial discrimination learning. Physostigmine and hydergine® also facilitated retention of discriminated escape in the young mice. Pre-treatment with BMY 21502 (from 0.64 to 10 mg/kg) was effective in reducing or eliminating amnesia induced by treatment with the anticholinergic, scopolamine. Hydergine was less effective than BMY 21502 in the drug-induced amnesia paradigm. In the third model, daily injections of BMY 21502 prior to testing improved acquisition of an active avoidance response in 4-month-old NZB/BINJ mice, a genotype noted for accelerated age-related decline of learning/memory capacity (Forster & Lal, *Br. Res. Bull.*, *25*:503-516, 1990). These results suggest that BMY 21502 may be effective in improving cognitive ability in both normal subjects and individuals with age-related memory impairment. (Supported by a research grant from Bristol Myers Squibb Company and NIH grant AG06182)

EFFECT OF ORAL ADMINISTRATION OF REVERSIBLE INHIBITORS ON BLOOD ACETYLCHOLINESTERASE IN HUMANS: E2020 AND TACRINE. **K.A.Sherman, Dept. Pharmacol., SIU Sch. Med., Springfield, IL 62794-9230**

Reversible, allosteric inhibitors of acetylcholinesterase (AChE), e.g. tacrine (THA) and E2020, a novel piperidine derivative developed for dementia treatment (Yamanishi et al. Soc.Neurosci.Abst. 14:59, 1988), slow phosphorylation of AChE by organophosphates, e.g. diisopropylfluorophosphate (DFP). A modest dose of E2020 (2 mg/kg, s.c.) produced marked and sustained DFP antagonism in rat cortex (>90% for 3 hr; >50% at 5 hr); AChE inhibition *ex vivo* at minimal tissue dilution (5-fold) was less (70% maximum; <10% by 5 hr) (Sherman, Soc.Neurosci.Abst. 16:137, 1990). The ability to protect AChE against irreversible inhibition by DFP *in vitro* thus provides a sensitive, new approach for quantifying the pharmacodynamics of these reversible inhibitors. In the present studies, we show that phosphorylation of AChE in red blood cells (RBC) is also antagonized after oral administration of E2020 or tacrine in humans. In 34 dementia patients, the effect of E2020 was selective; plasma ChE activity was not altered. E2020 produced dose-dependent antagonism of DFP which increased dramatically with duration of treatment up to 2 wk (1 mg daily) or 4 wk (2 mg). In pre-drug control samples, the conditions selected [25 µl of 4.5 µM DFP per 100 µl cells; 30 min at 37°C] resulted in 84.8 ± 0.8% inhibition of AChE activity subsequently measured at 262.5-fold dilution to prevent further action of DFP and to fully dissociate E2020. The effect of DFP was reduced by 30% or more (maximum 45%) in 43% of the RBC samples from patients treated with 2 mg/d E2020 for 1 to 3 mo. After ≥ 2 wk treatment, the degree of DFP antagonism in RBC was closely correlated to log concentration of E2020 in plasma. With chronic dosing, the relation of DFP antagonism to plasma [E2020] became progressively steeper; less than half as much drug level was required to achieve the same degree of DFP antagonism compared to the first week of E2020. A single oral dose of THA inhibited plasma ChE maximally at 1½ to 2 hr by 39 ± 2.5 % (range 29 to 55%) in 12 elderly controls. The effect in RBC was less and was variable ($\bar{x}$ = 18.7 ± 3.0%; range: 5.6 to 43%), but correlated well with peak plasma inhibition.

BIOCHEMICAL AND BEHAVIOURAL CHARACTERISATION OF HEPTYLPHYSOSTIGMINE (HPS): A POTENT ANTICHOLINESTERASE WITH LONG DURATION OF ACTION. **S.B.Freedman, G.R Dawson*, L.L. Iversen, S.D. Iversen*, P.L.Rugarli* and E.A.Harley*. Merck, Sharp and Dohme Research Laboratories, Terlings Park, Harlow, Essex CM20 2QR, England and Mediolanum Farmaceutici Research Laboratories, Milan, Italy.**

HPS was a potent inhibitor *in vitro* of both human acetylcholinesterase (ACHE)(IC_{50} 20nM) and horse serum butyrylcholinesterase (IC_{50} 5nM). In comparison to physostigmine (PHY), HPS had a slower association rate and dissociation rate. In an *ex vivo* assay in mouse brain HPS (ED_{50} 3.8mg/kg i.p.) had a significantly longer duration of action compared with PHY, tacrine and E-2020 with ACHE inhibition for up to 18 hours. In contrast, the inhibition with PHY (0.3 mg/kg) rapidly decayed over a 90 min period. HPS administered s.c. 80 min prior to testing fully reversed a scopolamine (0.2mg/kg) induced deficit in mouse and rat passive avoidance at doses of 3.0 and 8.0 mg/kg respectively. In the same rat passive avoidance experiment a dose of 0.6 mg/kg PHY (s.c 5 min pretreatment) only partially reversed the deficit. In a working memory test (DMPT), 4.0 mg/kg HPS partially reversed a scopolamine induced deficit whereas PHY was without effect. The longer duration of action and greater efficacy of HPS, compared with traditional ACHE inhibitors in rodent models of cognition, may mark a major development in drug treatment for dementia of the Alzheimer's type.

BUTYRYLCHOLINESTERASE PROTECTS AGAINST NERVE AGENT EXPOSURE IN RHESUS MONKEYS TRAINED ON A SERIAL PROBE RECOGNITION TASK. C.A.Castro, A.V.Finger, D.M.Maxwell, R.P. Solana, D.E.Lenz and C.A.Broomfield. USAMRICD, Aberdeen Proving Ground, MD 21010-5245.

Soman is a highly toxic nerve agent capable of producing death in humans and experimental animals within minutes of exposure. It has recently been demonstrated that exogenously administered enzymes such as equine butyrylcholinesterase (EBuChE) can prevent death and physical incapacitation in non-human primates exposed to multiple-lethal doses of soman. We report here that EBuChE can also prevent soman-induced behavioral incapacitation in rhesus monkeys as measured by performance on a Serial Probe Recogntion (SPR) task. Four monkeys were trained to perform a six-item SPR task at an 80% correct performance level. Next, all monkeys received 27500 U (503 nmol) of EBuChE followed 1.2-1.4 hr later by 220-260 nmol of soman (2 MLDs; a lethal dose in untreated animals). All monkeys survived the soman challenge and none showed any clinical signs of nerve agent intoxication. SPR performance was depressed after enzyme administration and 1 hr after soman challenge. By 8 hr after soman challenge, however, all monkeys performed the SPR task at pre-soman challenge levels. These findings indicate that EBuChE can protect against the behavioral as well as the lethal effects of nerve agent intoxication.

NICOTINE-INDUCED ATTENUATION OF SPATIAL MEMORY DEFICITS IN RATS WITH SEPTAL LESIONS. M. W. Decker and M. J. Majchrzak. Neuroscience Research, Pharmaceutical Products Division, Abbott Laboratories, Abbott Park, IL 60064.

The septohippocampal system is important for spatial memory. Septal lesions impair performance on a variety of spatial memory tasks in rats, and septal rats have been used as an animal model of Alzheimer's disease (AD). In this experiment, we found that pretraining administration of nicotine improved spatial discrimination learning in rats with septal lesions.

Rats with radiofrequency or sham lesions of the medial septum were required to learn which of two visible platforms in a pool of water provided a means of escape. The platforms were identical in appearance but could be distinquished on the basis of spatial location. Six trials were given for 5 consecutive days. On each of the first 4 days of training, the rats received an injection of (-)nicotine (0, 0.1, or 0.3 mg/kg, i.p.; 9-10 rats per group) 15 min. before training. Nicotine did not significantly alter the performance of sham-lesioned rats. However, nicotine markedly improved the performance of septal rats, such that on the 5th day of training, septal rats who had received a 0.3 mg/kg dose of nicotine performed as well (0.9 ± 0.3 errors) as control animals (0.7 ± 0.4 errors), whereas septal rats who had received only pretraining saline injections performed essentially at chance levels (3.1 ± 0.5 errors).

These findings suggest that nicotine can enhance spatial memory in rats in which septohippocampal function is disrupted. In that impaired septohippocampal function has been implicated in the memory deficits associated with AD, our findings further suggest that nicotinic receptor stimulation might be useful in the treatment of these cognitive deficits.

488.15

DIFFERENTIAL EFFECTS OF CHLORISONDAMINE AND MECAMYLAMINE ON NICOTINE INDUCED CHANGES IN LOCOMOTION AND LEARNING. M.J. Majchrzak, and M.W. Decker, Neuroscience Research, Pharmaceutical Products Division, Abbott Laboratories, Abbott Park, IL 60064.

Nicotinic agents have been implicated as modulators of learning and memory. Agonists tend to enhance, while antagonists tend to disrupt learning and memory. This study compared the ability of mecamylamine (MEC) and chlorisondamine (CHLOR), two central nicotinic antagonists, to disrupt nicotine's (NIC) agonist effect on locomotion and cognition. Post-training NIC administration (0.3 mg/kg max effect) enhanced 24 hour retention of an inhibitory avoidance task. Chronic CHLOR pretreatment (10 µg, icv), did not antagonize the enhanced retention produced by NIC. Pretraining administration of the central and peripheral antagonist MEC (1.0 mg/kg), did effectively block the enhancement produced by post-training NIC. Pretraining administration of the peripheral nicotinic antagonist hexamethonium (5.0 mg/kg), was not able to block the memory enhancing effect of nicotine. Animals from the previous experiments were then challenged with an acute dose of NIC (0, 0.1, 0.3 or 1.0 mg/kg, ip) and placed in activity monitors for 60 min. CHLOR blocked both the depressant and stimulatory effects of NIC. In a separate group of animals MEC (1.0 mg/kg, ip) was administered 10 minutes prior to the challenge with NIC. MEC produced a comparable blockade of NIC. CONCLUSION: CHLOR appears to be a very potent antagonist of NIC with respect to locomotor activity, yet does not disrupt the enhancement of cognition by NIC. However, MEC is able to disrupt cognition at doses that are as effective as CHLOR in blocking NIC's locomotor effects. Therefore, the ability of a nicotinic antagonist to block the locomotor effects of an agonist does not appear to predict its ability to disrupt the effects of an agonist in a cognitive task. The present findings suggest that these nicotinic antagonists may act at different sites, and could be useful tools in differentiating nicotinic receptor subtypes.

CLASSICAL NICOTINIC AGONISTS DIFFERENTIALLY AFFECT COGNITION, CORTICAL CEREBRAL BLOOD FLOW (CBF) AND DOPAMINE (DA) RELEASE. J.D. Brioni, D.G. Linville, E.D. Cadman, S. Williams *, M Buckley, D.J. Anderson and S.P. Arneric, Neuroscience Dept., Pharmaceutical Discovery, Abbott Laboratories and Dept. of Pharmacology, Southern IL University, Springfield.

Molecular biological evidence supports the existence of multiple neuronal nicotinic receptors in the brain. This study sought to determine whether potent classical nicotinic agonists differentially affect nicotinically-mediated events, possibly through subtype-mediated specificity. (-)Nicotine (NIC), (-)Cytisine (CYT), and (-) Lobeline (LOB) each potently displaced 3H-NIC and 3H-CYT binding from rat brain membranes (Ki= 0.1-1.1 nM). In contrast, NIC and CYT (EC50= 26.2 & 10.3 nM), but not LOB, enhanced the release of tritium from slices of rat striatum prelabeled with 3H-DA. Behaviorally, a consistent pattern was observed in the inhibitory avoidance task (IA) in mice. NIC and CYT (0.03-0.3 mg/kg, IP) but not LOB, induced a significant enhancement of retention. When the effects on cortical CBF were evaluated in urethane-anesthetized rats using laser-doppler flowmetry, NIC and LOB (less potently) enhanced basal forebrain-elicited increases in cortical CBF (350% increase). CYT had a biphasic effect with high doses inducing a 50% inhibition. CONCLUSIONS: 1) The memory facilitating effect of NIC and CYT correlate with the 3H-DA release effect; 2) Enhancement of cortical CBF mediated by the basal forebrain does not translate directly into enhancement of cognition in tasks such as IA.

NICOTINE-INDUCED FACILITATION OF RADIAL-ARM MAZE PERFORMANCE IN RATS. E.D. Levin, F.H. Brucato* H.S. Swartzwelder* and J.E. Rose. Departments of Psychiatry and Neurology, Duke University Medical Center, Durham, N.C. 27710

Abundant research has demonstrated the importance of muscarinic acetylcholine (ACh) receptors for cognitive function. Nicotinic ACh receptors have received less attention, but they are also appear to be important for cognitive function. We have found that like muscarinic blockade nicotinic blockade impairs choice accuracy in the radial-arm maze. Stimulation of nicotinic receptors with nicotine improves radial-arm maze choice accuracy after either acute subcutaneous injection of 0.2 mg/kg nicotine ($p<0.01$) or chronic subcutaneous infusion of 12-14 mg/kg/day for 3 weeks ($p<0.025$). Our most recent study has shown that facilitation of radial-arm maze choice accuracy also occurs after intraventricular infusion of 4 µg of nicotine. In a radial-arm maze exploration paradigm female Sprague-Dawley rats (N=13) averaged 3.95±0.48 (mean±sem) entries to repeat after control infusions and 4.87±0.31 after nicotine infusions ($p<0.05$). The dose of the nicotinic antagonist mecamylamine tried thus far (200 µg) did not significantly alter choice accuracy. Alzheimer's patients show decreased cortical nicotinic receptor binding. Additional nicotinic stimulation may help to reverse their cognitive impairment. (Supported by an Alzheimer's Association/Neil Bluhm Research Grant and NIDA grant 02665)

EFFECTS OF CHRONIC NICOTINE ADMINISTRATION ON THE COGNITIVE PERFORMANCE OF AGED RATS. G.W. Arendash and G.J. Sengstock, Department of Biology and Institute for Biomolecular Science, University of South Florida, Tampa, Florida 33620.

Aged rats have been shown to be impaired in the acquisition and/or retention of a wide variety of cognitive tasks. Despite reports showing that nicotine administration to *young adult* rats can affect cognitive performance, the effects of nicotine in *aged* rats have not yet been investigated. The purpose of this study was, firstly, to characterize the effects of aging on three dissimilar tasks and, secondly, to elucidate the effects of daily nicotine administration on the performance of *aged* rats in these tasks. To accomplish this, male Sprague-Dawley rats aged 2-3 months (young) and 22-24 months (aged) were tested in one of the following tasks: 17-arm radial maze, one-way active avoidance, or Lashley III maze performance. Aged rats received an i.p. injection of either nicotine (0.2 mg/kg) or saline vehicle 15 minutes prior to daily behavioral testing; young control rats received saline vehicle injections. Compared to young controls, aged vehicle-treated rats were significantly impaired in the general learning and reference (long-term) memory components of **17-arm maze performance**; working (short-term) memory was not affected. In contrast, nicotine pretreatment resulted in a significant improvement in both general learning and reference memory of aged rats in this task. An age-related impairment in the acquisition of **one-way active avoidance** pole jumping was also found. Nicotine pretreatment of similar aged rats was able to markedly improve overall learning and rate of learning compared to aged controls. In **Lashley III** maze testing, aged control rats made substantially more errors than young control rats; aged rats pretreated with nicotine made less errors than aged controls. These results indicate that chronic nicotine administration can improve the impaired learning/memory abilities of aged rats in several different tasks.

MEMORY IN THE MONKEY: AN AUTOMATED PARADIGM AND THE EFFECT OF NICOTINE. J.W. Ashford and H. Edwards*. Department of Psychiatry, University of California, Davis, VA Medical Center, Martinez, CA., 94549.

This study examined the formation of memory which is not disrupted by interference. The study used rhesus monkeys in a new automated testing paradigm. Monkeys learned to push a joystick lever to the left or the right in response to a video screen letter stimulus (7cm x 5cm) for a juice reward. Four animals learned to discriminate 12 letters: ABCD were given constant directional assignments (LRLR, respectively); EFGHIJKL were varied in their assignments for each day (4 for each direction). Letters were introduced in directionaly opposed pairs, 10 consecutive correct responses for one pair required to proceed to the learning of the next pair. If the animal learned all of the pairs in less than an hour, he was tested for the remainder of the hour on the sequence EFGHIJKL. One animal could learn the associations within 30 min, then score 99% correctly during the remaining 30 min (314 correct trials/320 total).

To test the effect of nicotine in this paradigm, doses up to 10ug/kg i.m. were administered 5 minutes before the task began. Nicotine improved task performance in all four animals: the optimal dose for 1 animal was 2.5ug/kg, and for the other 3 was 5ug/kg. Such automated tasks will facilitate analysis of memory in primates. (Supported by a donation from R.J. Reynolds Tobacco Co.)

488.20

NICOTINE REPLACEMENT AFTER 12-HR ABSTINENCE REDUCED MIRROR-TRACING TIME BUT DIFFERENTIALLY AFFECTED SUPRASPAN DIGIT LEARNING IN TYPE A AND B SUBJECTS. K.-T. Kao, S. Amick* and D. Moss*. Dept. of Psychol., Wabash College, Crawfordsville, IN 47933.

A supraspan (18) digit learning (SDL) and a mirror-tracing (MT) task were studied with five repetitions each. Computerized visual signal detection and Type A and B personality (TA & TB) were also assessed. Male college student smokers (N=18) and chewers (N=16) were randomly assigned to one of three treatment conditions after 12-hr abstinence: no replacement, low dose, and high dose (1/2, and 1) cigarette, or nicotine gums (2, and 4 mg), respectively. The two replacement groups were combined, as were the smokers and chewers, for analyses. Nicotine replacement had no effect on signal detection but reduced MT time during the initial trials without affecting MT error; nicotine also enhanced supraspan digit learning in TA subjects (8.05 ±.67, and 10.27 ±.45) but impaired it in TB subjects (13.63 ±.77, and 11.18 ±.84). The results suggest that studies of cognitive effects of nicotine should take into account their subjects' personality factors associated with coronary heart disease risks.

489.1

DORSOMEDIAL HYPOTHALAMIC LESIONS FAIL TO DISRUPT SELF-STIMULATION OF THE CAUDAL MFB.
M. Waraczynski, K. Conover, and P. Shizgal. Concordia Univ., Montreal, Quebec H3G 1M8

It has been proposed that the dorsomedial hypothalamic nucleus (DMH) gives rise to most or all of the substrate for the rewarding effect of stimulating the medial forebrain bundle (MFB) (Glimcher and Gallistel, Soc. Neurosci. Abstr., 1989, **15**, 33). To test this hypothesis, a caudal MFB stimulation electrode and an ipsilateral DMH lesioning electrode were implanted in male Long Evans rats. Rate-frequency curves were collected at each of 2-3 stimulation currents. For some subjects, the minimum effective stimulation current was also determined. Neither measure of rewarding effectiveness was altered by DMH damage in 6 rats. Some decrease in rewarding effectiveness was noted in the case of two rats in which the lesions extended beyond the DMH to invade the perifornical lateral hypothalamus and caudal MFB. These results challenge the notion that the DMH gives rise to all or most of the substrate for MFB reward. Nonetheless, they do not rule out the possibility that reward fibers in some part of the caudal MFB arise in the DMH.

489.2

ATTENUATION OF MFB REWARD BY ROSTRAL LH LESIONS DEPENDS ON STIMULATION SITE AND CURRENT.
B. Murray and P. Shizgal. Concordia Univ., Montreal, Quebec H3G 1M8

We have previously reported that electrolytic lesions of the antero-lateral portion of the lateral hypothalamus (LH) can reduce the rewarding impact of electrically stimulating more posterior MFB sites (Soc. Neurosci. Abstr., 1988, **14**, 1101); in one subject, the effect of the lesion varied with the stimulation current. To further investigate these phenomena, electrodes were implanted in male rats at 3 levels of the MFB: the anterior LH, middle LH, and anterior ventral tegmental area (VTA). Rate-frequency curves were collected using 3 currents at each middle LH and VTA site. Electrolytic lesions (anodal, 1.0 mA for 10 sec) were made through the anterior LH electrode. In 4 subjects, lesions of the anterior LH produced long-lasting increases of up to 78% in the frequency threshold for self-stimulation of the middle LH and/or VTA sites. The magnitude of these effects was highly dependent upon the stimulation site and current. The lesions failed to alter the frequency threshold in 5 other subjects. These data suggest a precise spatial relationship between reward-relevant neural elements in the anterior, middle, and posterior MFB.

489.3

THE EFFECT OF PERIPHERALLY ADMINISTERED BOMBESIN ON LH STIMULATION-INDUCED FEEDING AND SELF-STIMULATION.
T. Harris, C. Bielajew, and Z. Merali. School of Psychology, Univ. of Ottawa, Ottawa, Ontario, Canada.
Bombesin's purported role in satiety mechanisms prompted this investigation of its effect on lateral hypothalamic (LH) stimulation-induced feeding (SIF) and self-stimulation (SS); these behaviors can be elicited from the same site and may share some common neuronal elements. Using a Latin Square design, SIF and SS thresholds derived from the same electrode were assessed in five rats following four doses of bombesin: 0, 2, 4, and 8 µg/kg i.p. An additional dose of 16 ug/kg was tested in three of the animals. In SIF trials, a 20 sec on/20 sec off alternating cycle of pulse periods was delivered on an ascending logarithmic scale; the threshold was defined as the first period that failed to elicit feeding. SS period thresholds were interpolated from descending rate/period functions using a constant response criterion. For each behavior, thresholds were collected at six current values, ranging from 80 µA to 800 µA. Bombesin at any dose had no effect on SS thresholds but slightly lowered SIF period thresholds at the higher concentrations. These results suggest that unlike other satiety factors (e.g.CCK), periperal bombesin mechanisms are less involved in LH induced reward and feeding.

MORPHINE MICROINJECTION INTO THE VENTRAL TEGMENTAL AREA (VTA): EFFECTS OF REPEATED ADMINISTRATION ON LATERAL HYPOTHALAMIC BRAIN STIMULATION REWARD.
P. Bauco, Y. Wang* and R.A. Wise. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Canada, H3G 1M8.

While some of the behavioral properties of opiates show tolerance following repeated administration, the locomotor effects of morphine injections into the VTA show sensitization or "reverse-tolerance." VTA morphine also facilitates the rewarding effects of lateral hypothalamic electrical stimulation; we assessed the effects of repeated injections to determine whether there is sensitization of this opiate action. Unilateral injections of VTA morphine (2.5µg/0.5µl) were given on alternate days for a total of 10 treatments. These treatments caused leftward shifts in the function relating response rate to stimulation frequency, lowering the "dose" of stimulation required to maintain responding at pre-treatment levels without altering the maximum rates of responding seen with high stimulation doses. There was no apparent sensitization of the ability of morphine to potentiate the rewarding effects of brain stimulation reward. If anything there was a decrease in effectiveness over the course of treatments. This decrease in effectiveness may reflect some degree of pharmacological tolerance or it may reflect local tissue changes caused by the repeated central injections.

489.5

VENTRAL TEGMENTAL NUCLEI OF GUDDEN: A "SEROTONERGIC" REWARDING SITE?
M. Sarkar, D.L. Rosene and C. Kornetsky. Boston University School of Medicine, Boston, MA 02118.

The medial forebrain bundle (MFB) at the level of the lateral hypothalamus (LH) is probably most commonly studied in brain-stimulation reward (BSR) experiments. Although the MFB is rich in dopaminergic (DA), cholinergic (ACh), adrenergic, and serotonergic (5-HT) fibers of passage, current work has mainly implicated the DA system for the rewarding effects of BSR, with ACh and 5-HT serving a complementary inhibitory role. Among the sources of 5-HT fibers in the MFB is a brainstem nucleus, the ventral tegmental nucleus of Gudden (VTg) which gives rise to ascending fibers to the median raphe nucleus, VTA, MFB and other structures. The majority of studies suggesting an inhibitory role for 5-HT in self-stimulation behavior used the MFB-LH as the stimulation site. To investigate the possible role of direct stimulation of 5-HT in BSR, bipolar electrodes were implanted in the VTg and the MFB-LH, respectively, in each of four male F-344 rats. BSR thresholds were determined at each site. The results suggest that VTg stimulation is as effective as MFB stimulation in learning and maintenance of reinforcing behavior. We conclude that VTg is a novel reinforcing site suggesting that 5-HT may have rewarding properties (Supported in part by NIDA grant DA02326 and Research Scientist Award DA00099 to CK).

489.6

THE EFFECTS OF REPEATED PHENCYCLIDINE (PCP) ON LATERAL HYPOTHALAMIC BRAIN STIMULATION REWARD (BSR) AND LOCOMOTION IN RATS.
W. A. Carlezon, Jr. and R. A. Wise, Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia Univ, Montreal, Quebec, Canada H3G 1M8.

It has been suggested that the rewarding effects of psychomotor stimulants are intimately associated with forward locomotion in rats. Phencyclidine (PCP), like most drugs that are rewarding in their own right, potentiates lateral hypothalamic brain stimulation reward (BSR). In rats trained to lever press for electrical stimulation of the medial forebrain bundle (MFB), this facilitation was demonstrated after acute systemic administration of PCP (2.5 and 5.0 mg/kg) by leftward shifts in the functions that related response rate to stimulation frequency; that is, a lower than normal level of stimulation was sufficient to maintain baseline responding in phencyclidine-treated animals. When animals were tested in the BSR paradigm once per week for 8 weeks, no progressive changes in the facilitating effects of these doses of PCP were observed. On the other hand, another group of animals administered PCP (5.0 mg/kg) in a chamber outfitted with photocells demonstrated a progressive increase in sensitivity to the locomotor-stimulating effects of the drug with repeated testing. Thus, these data suggest that the reward-facilitating and at least one of the psychomotor stimulant effects of this drug can be dissociated.

489.7

FAILURE OF CHRONIC ESTROGEN TO ALTER LATERAL HYPOTHALAMIC BRAIN STIMULATION REWARD. C.M. Pudiak & M.A. Bozarth, *Department of Psychology, University at Buffalo, Buffalo, NY 14260.*

The threshold tracking procedure was used to determine the effect of chronic estrogen replacement after ovariectomy on brain stimulation reward (BSR). Female, Long-Evans rats were implanted with monopolar electrodes aimed at the lateral hypothalamic level of the medial forebrain bundle. After 5 to 10 days recovery from surgery, rats were trained to lever press for monophasic cathodal stimulation pulses during 60-min daily test sessions. The threshold tracking procedure determined the minimum stimulation frequency that maintains a predetermined response rate (i.e., 30 presses/min).

Following ovariectomy, 20 μg of 17-β-Estradiol was subcutaneously injected for 4 days followed by 4 days of vehicle injections; this injection series was repeated for 3 cycles. Chronically administered estradiol had no effect on BSR thresholds. These data along with previous data examining the effect of acute estrogen (Pudiak & Bozarth, *Soc. Neurosci. Abstr.*, 1990) suggest that estrogen does not influence the rewarding impact of lateral hypothalamic BSR.

EFFECTS OF LATERAL PREOPTIC AREA KNIFE-CUTS ON POSTERIOR HYPOTHALAMIC SELF-STIMULATION REWARD J.R. Stellar and Hugh Albert*, Psychology Dept., Northeastern University, Boston, MA 02115

Previously we reported that coronal knife-cuts placed in mid-lateral hypothalamus could be effective in reducing posterior hypothalamic self-stimulation reward in the rate-frequency paradigm using multiple stimulation currents. This effect was particularly strong at low currents (Stellar et al. NS Abst 16:591, 1990).

This year we extended these findings to coronal knife-cuts placed farther anterior, in the lateral preoptic area, keeping electrode placement the same. Half-maximal rate-frequency reward thresholds were raised (reward decrease) about 0.1 - 0.4 log Hz and were related to the size of the knife cut. Cuts ranged from minimal ventral damage just above the optic chiasm to a medial forebrain bundle transection that ran the entire dorsal-ventral length of the lateral preoptic area. Reward thresholds were less dependent on current than previously reported, suggesting that electrode/knife-cut alignment was not as important with these placements.

MODELLING DRUG SELF-ADMINISTRATION WITH SELF-ADMINISTRATION OF BRAIN STIMULATION (SABS): STABILITY OF SABS WITH PARTIAL REINFORCEMENT SCHEDULES. Marino Lepore*, Keith B.J. Franklin and Frances V. Abbott., McGill University, 1205 Dr Penfield Ave, Montreal, Que., Canada H3A 1B1

We have previously shown that rats trained on conventional self-stimulation will self-administer trains of brain stimulation that rise and fall in pulse frequency with a time course that mimics the rise and fall of drug concentrations in the brain. We now report that rats will spontaneously acquire such self-administration of brain stimulation, and that the pattern of behaviour is stable when "doses" of brain stimulation are delivered on a partial reinforcement schedule. As response requirement is increased from FR5 to FR15, the mean response rate increases while the mean frequency of stimulation (analogous to mean plasma drug concentration) decreases. This relationship is also found in drug self-administration. Another characteristic feature of drug self-administration is that the rate of self-administration decreases as the elimination half-life of the drug increases. This characteristic is also mimicked by SABS on a partial reinforcement schedule. Using single frequency modulated 16 sec trains of brain stimulation as reinforcers on an FI60 sec schedule we have shown that the rate of "absorption" contributes to the overall reinforcing effect of a stimulation train.

EFFECTS OF MOTIVATIONAL STATE ON OPERANT BEHAVIORS DIFFERENTIALLY SENSITIVE TO CHANGES IN REINFORCER VALUE. M. Vigorito, J.C. Carretta*, C.B. Kruse* and S.A. Radice*. Dept. of Psychology, Seton Hall University, South Orange, NJ 07079.

Rate-reducing effects of neuroleptic drugs on operant behaviors reinforced with food have been interpreted as resulting from the reduction in the reward value of the reinforcer. However, operant response rates are not always sensitive to changes in the value of the reinforcer. We previously found that in well-trained hungry rats VR rates were more sensitive to reductions in the value of a sucrose reward than VI rates; increases in the value of the reinforcer did not elevate response rates in either schedule. In the present experiment we replicated our earlier findings when rats were hungry and found that when the rats were not hungry sensitivity to reinforcer reductions was enhanced in both schedules. Moreover, an increase in the reinforcer value under the ad libitum condition elevated VI rates but not VR rates. We suggest that the pharmacological manipulation of operant behaviors that are differentially sensitive to changes in reinforcer value can be useful in understanding how drugs alter behaviors motivated by food reward.

489.11

SELF-ADMINISTRATION OF ELECTRICAL SELF-STIMULATION OF THE BRAIN.
E.O. McCaskill, R. Allen*, J.R. Stellar, Dept. of Psychology, Northeastern University, Boston, MA 02115.

Striking response differences have been observed between Intracranial Electrical Self-Stimulation (ICSS) and Intravenous Drug Self-Administration in rats. Recently these differences have been attributed to temporal parameters (Franklin et al. NS Abstracts:15:1092,1989). In our study, ICSS was delivered in a "cocaine-like" waveform in which pulse frequency changed each second over a 50-150 second period, rising quickly to a peak and then decaying slowly. Responding during a waveform triggered a new waveform which was added to the ongoing one.

As with cocaine, rats responded with periods of high lever press rates alternating with periods of abstinence. Decreasing ICSS current, or "dose", resulted in increased responding with some rats following the standard ICSS psychophysical trade-off between current and self-selected pulse frequency. Decreasing the duration of the waveform also resulted in increased responding.

LOCUS COERULEUS STIMULATION-INDUCED PLACE PREFERENCES ARE PREVENTED BY PRETREATMENT WITH THE DOPAMINE ANTAGONIST PIMOZIDE. C.L. Duvauchelle, L.A. MacConell*, A. Eremia* and A. Ettenberg, Behavioral Pharmacology Lab, Dept. of Psychology, University of California, Santa Barbara, CA 93106.

Electrical stimulation of the norepinephrine cell bodies in the locus coeruleus (LC) has been shown to support self-stimulation behaviors in rats. The present study employed a Conditioned Place Paradigm to test the hypothesis that dopamine antagonism can attenuate the reinforcing properties of LC stimulation. Animals were pretreated with pimozide (0.0, 0.5, 1.0 mg/kg) prior to exposure to one of two distinctive environments paired with rewarding LC stimulation. While LC stimulation resulted in reliable preferences for the stimulation-paired environment, this effect was dose-dependently attenuated by pimozide pretreatment. Since pimozide alone does not result in place aversions, it was hypothesized that dopamine neurotransmission may be important for the brain stimulation reward resulting from activation of cell bodies even far removed from dopaminergic fiber systems.

489.13

AUTOTITRATION SELF-STIMULATION ANALYSIS OF INDIVIDUAL DIFFERENCES IN THE RAT'S RESPONSE TO AMPHETAMINE. D. B. Neill and R. Puett*, Dept. of Psychology, Emory University, Atlanta, GA 30322.

It has recently been reported that it is possible to predict the "vulnerability" of rats to self-administration of amphetamine by their locomotor response to a novel environment. Rats showing a high locomotor response ("high responders") will acquire self-administration at doses below those necessary for "low responders." We examined the reaction of "high responders" and "low responders" to amphetamine using medial forebrain bundle/lateral hypothalamic self-stimulation. Rats were selected on the basis of their 1 hr locomotor response to a novel environment (Digiscan activity device). Those in the top and bottom one thirds of the activity distribution were implanted with a bipolar electrode in the lateral hypothalamus. All were trained to self-stimulate using the autotitration procedure where intensity dropped every 5 responses but could be reset to the maximum by a response on a second lever. We found that "high responders" showed greater responding and faster reset times; the responses significantly correlated with the previously determined locomotor activity. However, there was no difference between the two groups in response to amphetamine sulfate over a dose range of 0.5-2.0 mg/kg. Thus the "vulnerability" to self-administer amphetamine does not seem related to the functioning of the medial forebrain bundle "reward system."

CHRONIC DESMETHYLIMIPRAMINE ADMINISTRATION ATTENUATES STRESSOR INDUCED ICSS ALTERATIONS FROM THE PREFRONTAL CORTEX. C. Wolfe and R. M. Zacharko. Department of Psychology, Carleton University, Ottawa, Ontario, K1S 5B6.

Uncontrollable stressors have been found to induce a decline in responding for previously rewarding intracranial self-stimulation (ICSS) from a number of mesocorticolimbic sites. The stressor provoked attenuation of the rewarding properties associated with electrical brain stimulation has been proposed to be reminiscent of the anhedonia evident in clinical depression. In the present study, ICSS was assessed from the prefrontal cortex in CD-1 mice immediately, 24-hrs and 168-hrs following exposure to uncontrollable footshock. Marked reductions in ICSS rates were observed in all mice immediately following stressor exposure. Animals in which the ICSS deficits were still evident 1-week post stressor were administered either saline or desmethylimipramine (DMI) twice per day for a 20 day period. Chronic DMI administration ameliorated the stressor induced deficits in ICSS from the prefrontal cortex. Potential explanations for the stressor provoked variations in ICSS and the effects of DMI are discussed.

489.15

EFFECT OF INTRACRANIAL SELF-STIMULATION ON SELECTED PHYSIOLOGIC PARAMETERS IN RATS M.L. Burgess*, J.M. Davis*, T.K. Borg* and J. Buggy. Depts. of Exercise Science, Pathology and Physiology, University of South Carolina, Columbia, SC 29208.

The purpose of this investigation was to characterize selected metabolic, cardiovascular and hormonal responses to reinforcing intracranial self-stimulation (ICSS) of the ventral tegmental area (VTA) in rats. Ten, male Sprague Dawley rats were stereotaxically implanted with bipolar electrodes aimed at the VTA, origin of the dopaminergic mesolimbic projection, and trained to lever-press for ICSS. They were then adapted to the experimental environment (a metabolic operant chamber) for 30 min/d, 5 d/wk for 12 wks during which they were connected to the electrode cable but did not lever-press. At the end of 12 wks, all rats were instrumented with indwelling arterial catheters and performed a 30 min lever-pressing session in the metabolic operant chamber. Oxygen consumption, heart rate, blood pressure and rectal temperature increased with the onset and continuation of ICSS over 30 min ($p<0.05$). Plasma norepinephrine, epinephrine and corticosterone increased significantly over resting values ($p<0.05$). The results suggest that ICSS elicites heightened sympathetic, metabolic and neuroendocrine activity. These responses provide important information for studies that use ICSS as a motivator of behaviors, such as physical exercise in rats. They also provide valuable information about the physiologic consequences that may be related to inappropriate reinforcing behaviors, such as addictive drug abuse.

489.16

CAN METAL SELF STIMULATION WIRES BE USED IN AN ELECTROMAGNETIC FIELD? C. J. Sherry[1]*, T. J. Walters[1]*, P. A. Mason[2], J. M. Ziriax[2]*, C.J. Gonzales[1]*, M. H. Berent[3]*.
[1]Systems Research Laboratories, [2]Operational Technologies, [3]Armstrong Laboratory, Brooks AFB, Tx 78235-5301.

Most investigators appear to believe that metal wires, typically used to stimulate the brain or record its electrical activity, cannot be used in animals that will be exposed to radio frequency radiation (RFR) since RFR could couple to the wires, causing current flow (stimulating the brain) or a local temperature increase (causing a les ion).

Following an approved protocol, under aseptic conditions, a twisted pair of insulated nicrome wires (dia. 250 μm) were implanted in the central gray within the brains of rats (AP -6.9, L 3.28 (30°),D 5.76 mm). Stimulating (or lesioning) this site causes a species specific withdrawal response (WR). After recovery, the electrical stimulation threshold was determined and the rats were exposed to 9.3 GHz pulsed RFR in the near- and far-fields. During the RFR exposure rats did not display the WR, but did display thermoregulatory behavior (spreading saliva on face/ears). The rats did display WR when stimulated during RFR exposure. The stimulation threshold did not change after exposure, which suggests that exposure did not cause a lesion; this was confirmed histologically.

MANDUCA NEURAL ANTIGENS REVEALED BY ANTIBODY TO *DROSOPHILA PERIOD* PROTEIN. Kathleen K. Siwicki and Jessica L. McGrew*. Biology Department, Swarthmore College, Swarthmore, PA 19081

The *period* (*per*) gene of *Drosophila melanogaster* regulates the periods of behavioral circadian rhythms. An antibody to the *per* protein was used previously to localize its expression to specific cellular sites in the fly nervous system, and to monitor a circadian rhythm in the protein (Siwicki et al., 1988, Neuron 1: 141-150; Zerr et al., 1990, J. Neurosci. 10: 2749-2762). We have used the same antibody to study *per*-related proteins in a larger insect, the hawkmoth *Manduca sexta*, with the long-term objective of investigating the effects of *per* on cellular physiology.

In *Manduca* larvae, anti-*per* staining was found in 2 pairs of large (40 μm) dorsomedial brain neurons. In adult moth nervous systems, a variety of cellular sites were labeled, including nuclei of many small cortical cell bodies, cytoplasmic granules in some large neurons, and glial nuclei in neuropil regions. Many aspects of this staining pattern are reminiscient of the distribution of the *per* protein in *Drosophila*. We are now extending these studies to developing adults, in hopes of finding structures that might be involved in the circadian gating of eclosion.

Also, in immunoblots with protein extracts of moth brains, 44 kD and 110 kD *per*-like antigens were detected. We are now looking for daily rhythms in the levels of these antigens as a possible indication of functional homology with *per*.

Supported by NSF grants BNS-9010691 and BNS-9057703, and the Swarthmore College Faculty Research Fund.

490.2

LABELLING OF CELLS IN THE CNS OF THE CRICKET TELEOGRYLLUS COMMODUS BY AN ANTIBODY TO THE DROSOPHILA PER-PROTEIN. H.W. Honegger, W. Leser, W. Loher* and K.K. Siwicki**. Inst. of Zoology, TU Munich, D- 8046 Garching, Germany, *Dept. of Entomology, Univ. of California, Berkeley, CA 94720, **Biology Dept. Swarthmore College, Swarthmore, PA 19081.

The cricket Teleogryllus commodus shows a clear circadian rhythm of its calling song. We have stained sections of the CNS of Teleogryllus with an antibody against the Drosophila period (per) protein, which has been used previously to label the sites of per expression in Drosophila and putative circadian pacemaker neurons in the eyes of Aplysia and Bulla. Singing male crickets were sacrificed at four time points of a 12h:12h light-dark cycle. The brain with the retrocerebral complex, the suboesophageal ganglion, and occasionally the ventral nerve cord were fixed in 4% paraformaldehyde. Frozen sections were stained with affinity-purified anti-per antibody and the avidin-biotin-HRP method.

The anti-per antibody consistently labelled two somata (approximately 20 μm in diameter) on each side of the lateral protocerebrum, with their axonal branches in all areas of the CNS (including the optic lobes, the mushroom bodies, and the central body). Two fibers project via each NCCII into the corpora cardiaca, the corpora allata and the hypocerebral ganglion. In the cell bodies and the corpora cardiaca, the intensive staining was independent of the phase of the light-dark cycle or the crickets' state of activity. But in the labelled projections throughout the CNS, staining was distinctly lower at "lights-on" than at other times of day, suggesting that they may be involved in daily rhytmic functions.

490.3

AN ANTIBODY AGAINST AN APLYSIA EYE-SPECIFIC 48K PROTEIN RELATED TO THE PERIOD-PROTEIN OF DROSOPHILA SPECIFICALLY STAINS THE APLYSIA RETINA AND OPTIC PROJECTIONS INTO THE BRAIN. S. Strack* and J.W. Jacklet, Dept. Biology and Neurobiology Research Center, SUNYA, Albany, NY 12222.

We have partially sequenced the 48K protein, the major Aplysia eye antigen recognized by a Drosophila *period*-protein antibody (Neuron 3:51-58). Preparative 2-D gel electrophoresis followed by V8 digestion and sequencing yielded a 20 residue and a 10 residue sequence. Sequences are not similar to the *period*-protein but the short sequence shows homology to cAMP-dependent protein kinases. By metabolic labeling, we have found that the 48K protein is synthesized exclusively in the retina and transported along retinal afferents. Subcellular localization experiments show that 48K is likely to be associated with the cytoskeleton or cell surface. An antibody raised against the long sequence recognizes a family of 47K-48K, Pi 5.9-6.1 spots on 2-D Westerns, and on Aplysia tissue sections stains fibrous structures in the retina and optic nerve. Retinal somata are not stained. The projections of retinal afferents into the cerebral ganglion stained, revealing extensive terminal fields of afferents in the "optic ganglion". Some stained fibers cross over to the contralateral half of the cerebral ganglion, or follow the tentacular and other nerves. Other fibers form tracts and terminal areas in the ganglion. Some continue to the pleural and pedal ganglia and beyond to the abdominal ganglion. These results agree with previous optic tract tracing studies using tritiated markers (J.Neurosc. 5:3214) and identify the putative primary brain synaptic areas of retinal afferents. Localization of anti-48K on the EM level is being done. The visual system of Bursatella, a close relative of Aplysia, is stained by anti-48K, but not the visual system of Bulla, a more distantly related ophistobranch. (Supported by NSF grant BNS 8819773 to JWJ)

TYROSINE PHOSPHORYLATION AFFECTS THE CIRCADIAN PACEMAKER IN THE EYE OF THE MARINE SNAIL, BULLA GOULDIANA. M.H. Roberts and J.A. Towles*. Department of Biology, Clarkson University., Potsdam, NY 13699.

Previously we have shown that inhibition of kinase activity lengthens the period of the circadian rhythm recorded from the isolated eye of Bulla gouldiana (Roberts, et al., 1989). We now report the results of additional inhibitor studies.

The circadian rhythm in optic nerve impulses is unaffected by chronic treatment with okadaic acid (0.5 uM), a specific inhibitor of 1 and 2A protein phosphatases in vivo (Haystead et al. 1989). This raises the possibility that serine/threonine phosphorylation/dephosphorylation is not involved in rhythm regulation. In order to investigate this possibility, we found that phenylarsine oxide, a tyrosine phosphatase inhibitor (Bernier et al. 1987), irreversibily blocks impulse activity (5–100 uM).

In spite of the interpretive difficulties caused by the irreversibility of the treatment, we have further explored the role of tyrosine phosphorylation with genistein, a reversible inhibitor of tyrosine kinase activity (Akiyama, et al., 1987). Chronic moderate doses of genistein (11 uM) eliminate impulse activity; upon drug removal impulses return as do light responses, although the circadian rhythm is absent. At lower doses (3.7 uM) period is lengthened while even lower doses (0.37 uM) have no effect on the rhythm. Genistein's actions are phase dependent. When applied from CT 2–6 phase delays (–3.0 hrs) are induced. From CT 22–2 the rhythm is damped and phase advanced (+1.5 hrs) or completely eliminated, although impulses and light responses remain. Taken together, these results suggest that tyrosine phosphorylation/dephosphorylation plays a role in circadian rhythm regulation in the Bulla eye. Supported by NS26272 to MHR.

POTASSIUM CHANNELS MEDIATE CIRCADIAN CONDUCTANCE CHANGES IN PACEMAKER CELLS OF *BULLA*

S. Michel and G.D. Block, Department of Biology, Gilmer Hall, University of Virginia, Charlottesville, VA 22901

The eyes of the marine snail *Bulla* express a circadian rhythm of compound action potentials (CAP) in vitro driven by endogenous changes in membrane potential of basal retinal neurons (BRN), which are believed to be the pacemaker cells. Intracellular recordings and conductance measurements reveal circadian and light-induced changes in membrane conductance of the BRN. We used the current clamp technique to measure the current-voltage relationship of the cell membrane. Before dawn (circadian time = CT 23) the conductance of BRNs decrease followed by depolarization to -55 mV. During the early subjective night (CT 13-15) the conductance increases again and the membrane potential returns to hyperpolarized values (-65 mV). Bath application of the K^+ channel blocker TEA (100mM) at CT 20 leads to a reversible decrease of conductance and a depolarization of the cell membrane by 10 mV. The current-voltage curve in TEA at CT 20 is similar to the one measured after dawn (CT 3) in normal seawater. When TEA is given at this time (CT 2) no additional decrease in conductance was observed. The results suggest that K^+ currents, which are activated at hyperpolarized membrane potentials, like the inward rectifier, are involved in the circadian changes of membrane conductance. K^+ blockers like TEA are able to simulate the conductance changes near dawn, but have little effect after dawn when the channels are supposedly already closed. We are currently investigating the effect of other K^+ channel blockers like Ba^{2+}, 4-Ap and Quinine to describe the pharmacology of this inward rectifier in order to further characterize and identify the type of channel, which probably is an essential part of the output pathway of the circadian pacemaker in *Bulla*. Supported by NS 15264 to GDB and DFG-Mi328/1-1 to SM

490.6

THE ROLE OF EXTRACELLULAR Ca^{2+} IN THE GENERATION OF THE CIRCADIAN RHYTHM IN *BULLA* EYE. S.B.S. Khalsa, M.R. Ralph & G.D. Block. Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

The eye of *Bulla* contains a population of electrically coupled retinal cells which functions as a competent circadian pacemaker, expressing a rhythm in compound action potential (CAP) activity which can be recorded from the optic nerve in artificial seawater (ASW). Previous studies have indicated that extracellular Ca^{2+} is involved in the entrainment of the pacemaker; in this study we assess its role in the generation of the circadian rhythm.

To assay the state of the pacemaker during low Ca^{2+} treatment, various long duration pulses of low Ca^{2+} ASW (no added Ca^{2+}, 10 mM EGTA) were applied, and the phase of the subsequent rhythm was measured. All pulses started at CT 6 during the first cycle and pulse durations to different preparations ranged from 4 to 72 hrs. Although no phase shifts were apparent following pulses that ended before subjective dawn (CT 24, pulse durations 4-16 hrs), phase shifts of about 4 hrs were observed for those pulses that ended after subjective dawn (durations 20-36 hrs). Furthermore, for longer pulses that included the next subjective dawn (durations > 40 hrs), phase shift magnitude increased to about 8 hrs.

These data suggest that the pacemaker was not stopped by the treatment, since the subsequent phase remained correlated to the phase of untreated control eyes, and was not solely determined by the timing of the treatment. Furthermore, although most CAP activity records showed no evidence of rhythmicity during low Ca^{2+} treatment, some did show clear circadian rhythms with a phase indistinguishable from that of controls. Together, these data suggest that extracellular Ca^{2+} is not an essential requirement for rhythm generation; the phase shifts observed to long pulses of low Ca^{2+} ASW may be a specific effect of the pulsatile treatment. *Support by NS15264.*

490.7

OPSIN-LIKE IMMUNOREACTIVITY IN THE PUTATIVE PACEMAKER NEURONS OF THE BULLA EYE. M.E. Geusz, R.G. Foster, M.D. Lawrence*, and G.D. Block. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

A circadian rhythm in the frequency of compound action potentials in the optic nerve of the mollusk Bulla gouldiana is believed to be generated by the basal retinal neurons (BRNs) of the eye. Light responses from the BRNs persist in eyes with the distal photoreceptor layer surgically removed, and the circadian rhythm can still be phase shifted with light. In addition, artificial seawater with low $[Ca^{2+}]$ and high $[Mg^{2+}]$ fails to block the light response. However, further evidence that the BRNs are intrinsically photosensitive has been lacking.

An antiserum generated against the cone opsin of chickens has now been found to preferentially label the BRNs and their processes, suggesting that the protein involved in photoreception is present in the BRNs. In one group, eyes were treated with the antibody following lens removal, fixation, cryoprotection, sectioning at -20°C, and treatment with normal goat serum (NGS). In a second group, desheathed retinas were treated with the antibody after fixation and treatment with NGS, but prior to dehydration and embedding in the resin Durcupan. The retinas and eye sections were processed according to the avidin-biotin-HRP procedure. In both groups, the BRNs were stained with the diaminobenzidine (DAB) peroxidase product. Control retinas and eye sections, incubated with NGS alone, lacked staining. The anti-cone opsin antibody failed to label the distal photoreceptors, suggesting possible differences between the photopigments of the BRNs and the distal photoreceptors. Supported by NS08806 to MEG and NS15264 to GDB.

490.8

IS THE OCULAR CIRCADIAN CLOCK LOCATED IN PHOTORECEPTORS? G.M. Cahill and J.C. Besharse, Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS 66103.

An ocular circadian oscillator regulates retinal melatonin synthesis in cultured *Xenopus* eyecups, which include the retina, pigment epithelium (RPE), choroid and sclera. Several lines of evidence suggest that melatonin is produced in photoreceptors. We report here on tissue reduction experiments that suggest that photoreceptors are also capable of circadian rhythm generation. Isolated neural retinas, maintained in darkness in superfusion culture, produce circadian rhythms of melatonin for up to 3 cycles. The peak:trough relative amplitudes of these rhythms are normal, but melatonin levels are reduced 75-90%, suggesting that an oscillator is located in the neural retina, but that interaction with the RPE is necessary for maximal melatonin production. Eyecups without neural retina do not produce melatonin. We have developed methods that produce nearly complete lesions of the inner retina, but leave the photoreceptor layer largely intact. The vitreal surface of the retina within an eyecup is washed sequentially with detergent (1% Triton X-100 or SDS), deionized water, and culture medium. This results in lysis of inner retinal cells and splitting of the retina within the inner nuclear layer (INL). The inner retina can then be peeled away, leaving intact photoreceptors adhering to the RPE. These lesioned eyecups, some with >97% of INL cells destroyed, produce circadian rhythms of melatonin for 3 days. Although contributions from other cells can't be ruled out, these data suggest that photoreceptors can generate circadian melatonin rhythms.

490.9

TAIL PHOTORECEPTORS IN *LIMULUS* ENTRAIN THE VISUAL CIRCADIAN RHYTHM OF THE LATERAL COMPOUND EYES. George H. Renninger and W.J. Brad Hanna, Biophysics Group, University of Guelph, Guelph, Ontario N1G 2W1

Electroretinograms (ERGs) of the anterior photoreceptor organs [lateral compound eyes, median ocelli (1), and ventral eye (2)] of the horseshoe crab, *Limulus polyphemus*, exhibit a circadian rhythm in amplitude, driven by efferent optic nerve activity from the brain to the anterior photoreceptor organs during subjective night (1). Light pulses to these photoreceptor organs can shift the phase of the rhythm (1,3). Illumination of the tail alone can also shift the rhythm's phase (4).

We report here that periodic illumination of just the tail can entrain the rhythm in the ERG amplitude of the lateral eyes. The threshold light intensity for entrainment is consistent with that observed for light pulses to the tail to shift the phase of the rhythm (4). Illumination of the anterior photoreceptors alone can also entrain the rhythm.

While the tail and the anterior photoreceptor organs separately can entrain the lateral eye rhythm, there are differences in their influence on the rhythm: (i) the phase relation of the entrained rhythm to the entraining light depends on which photoreceptors (tail or anterior) are exposed to light; and (ii) the anterior photoreceptors produce larger phase shifts than the tail, when exposed to long light pulses (up to 12 h) of similar intensities.

TRANSCRIPTION AND TRANSLATION APPEAR CLOSELY COUPLED IN THE OCULAR CIRCADIAN SYSTEM OF *Aplysia*. C. Koumenis*, U. Raju, and A. Eskin. Dept. of Biochem. and Biophys. Sci., Univ. of Houston, Houston, TX. 77204

A model of the circadian system in the eye of *Aplysia* suggests that proteins are elements of the oscillator mechanism. Regulation of the synthesis of these proteins can occur at the transcriptional or translational level, or both. Translation inhibitors such as cycloheximide (CHX) have been shown to phase-shift the rhythm and also to block some of the effects of entraining agents.

Previously, we have shown that pulse treatments of isolated eyes with the reversible transcription inhibitor 5,6,1-b-d-dichlororibobenzimidazole (DRB) phase-shift the rhythm, while continuous treatments of DRB lengthen the free-running period of the rhythm. Camptothecin (a transcription inhibitor with a different site of action from DRB) also caused phase-shifts and period lengthening.

Is there a relationship between the effects of transcription and translation inhibitors on the rhythm? The onsets of the sensitive periods of the phase-response curves to CHX and DRB coincide. This similarity indicates that transcription and translation are closely coupled processes in the regulation of the rhythm. This conclusion is also supported by the rapid appearance of delay phase-shifts following DRB treatment.

To further investigate the roles of transcription and translation, we looked for proteins whose synthesis was affected by DRB. Overall protein synthesis as measured by leucine incorporation was not affected during a 2h DRB pulse. However, using 2D gel electrophoresis, we found that DRB altered the incorporation of ^{3}H-leucine into a small number of proteins. Some of these proteins may mediate the effects of DRB on the rhythm. A more detailed role for transcription and translation in the regulation of the oscillator will require the identification and study of these important proteins and their mRNAs.

490.11

CIRCADIAN BILATERAL EQUALIZATION OF CRAYFISH RETINAL SENSITIVITY. J.A. Barral*, E. Barrera-Calva*, O.A. Barrera Calva*, and B. Barrera-Mera. Proyecto y Maestría en Neurociencias. ENEP-Iztacala-U.N.A.M.; E.N.P. No.2-U.N.A.M. and Fisiología-Medicina-U.N.A.M.-A.P. 70-250, 04510 México, DF

As the crayfish processes the visual information of environmental movements and shapes, an instantaneous adjustment in photosensitivity of retina simultaneously occurs, as measured by the amplitude of electroretinogram (ERG). The last phenomenon is caused by an efferent clock-work program from the central nervous system. Anatomical, as well as enzimatic changes induce the neural modifications to become the main event revealing circadian photosensitivity. Aside from such a central regulation, however, a peripheral source of modulatory action arises from contralateral retinal photoreceptor. Its activity is explained by its own temporal course over the bilateral equalization of retinal photosensitivity, which suggests reciprocal left and right modulation of crayfish retina operating in a sustained manner. In order to determine its retinal origin, as well as its direct and indirect pathways through the protocerebral and the subesophageal ganglion respectively, we tested the effects of sustained light stimulation upon the contralateral eyestalk in all animals: intact, lesioned, with protocerebrum only, and splitbrain. A long latency time of 90 to 115 min to diminish ERG in the last animals but not in the rest suggests contralateral modulatory influences which travel throughout subesophageal ganglion.

490.12

THE CRAYFISH CAUDAL PHOTORECEPTOR IN VITRO, SHOWS A CIRCADIAN PATTERN IN THE RESPONSE TO LIGHT. M. L. Fanjul-Moles, J. A. Prieto-Sagredo* and A. Bernal-Moreno*. Lab. de Invertebrados, Fac. de Ciencias, U.N.A.M., Ap. Postal 70-371, México D.F., o4510, MEXICO.

In order to investigate a possible circadian rhythm in the caudal photoreceptor (CPR) of the crayfish, in vitro, spontaneous (SA) and light evoked activity (LEA) were recorded. The abdominal nerve cord was isolated from a group of 10 adult crayfish maintained previously in L:D 12:12. Henceworth the preparation was immersed in Van Harreveld solution at least 72 hours under constant temperature and darkness. The SA and LEA relayed by a suction electrode to a Grass P511 AC preamplifier were registred with an oscilloscope and captured in a PC computer to be analyzed. As a control, every hour during 72 hours the SA was recorded for 10 s. Afterwards, a 10 s light stimulus of 6500 lux was delivered to the CPRs and LEA was recorded. The results indicate a circadian pattern both in the SA and in the LEA. The rhytm showed a peak between 18 and 21 hours (external time) and a period value of approximately 21 hours.

ASYMMETRICAL PHOTOPERIODS SYNCHRONIZE THE ERG CIRCADIAN RHYTHM IN CRAYFISH. E. Moreno-Sáenz and B. Fuentes-Pardo. Depto. de Fisiología, Facultad de Medicina, UNAM. A.P. 70250, México 04510, D.F.

The ERG circadian rhythm (CR) of the crayfish can be synchronized by both complete photoperiods (PPc) and skeleton photoperiods (PPs) (data from our laboratory). These facts led us to study the effect of asymmetrical skeleton photoperiods (PPa) on the characteristics of the ERG CR. The ERG from adult crayfish Procambarus digueti, of either sex, housed individually in a constant temperature chamber was recorded by conventional procedures for periods up to 8 days. The PPa used were equivalents to the following PPc: 8:16, 11:13, 12:12, 13:11, 16:8 and 20:4. Each PPa consisted of two light signals of 4 and 1 h duration, respectively, the first one applied at the beginning and the second one at the ending of each PP. After the animals were stimulated with PPa, they were left in free run. The results suggest that the ERG CR is synchronized to all the PPa adjusting its phase of maximal amplitude to the longer dark time. This means that, through a phase jump, the crayfish, as many other species, modifies its subjective night phase in order to increase the night duration when the time between the two light signals, determining the night length, is too short.

EFFECTS OF FEEDING SCHEDULES ON LABELLED 2-DEOXYGLUCOSE UPTAKE IN RAT BRAINS. G.J. Coleman, J. Redman[1] and M. Brown[1] Dept Psychology, La Trobe Univ. Bundoora 3083, Australia and Dept Psychology, Monash Univ. Clayton 3168 Australia[1].

The anatomical location of the postulated food-entraind oscillator in rats has not been identified. This study was designed to compare ^{14}C-labelled 2-DG uptake in the brains of rats exposed to either a feeding schedule or to random feeding.

Rats were maintained on either a random or fixed 2-hr daily meal schedule under an LD cycle for 59 days. Rats were then killed, their brains frozen then later sectioned, filmed and subjected to densito-metric analysis.

Random-fed rats showed substantial disruption of wheel-running activity while meal-scheduled rats showed the usual activity anticipatory to the meal. In the brain areas analysed, differences between treatments were only observed in the SCN and VMH where random-fed rats showed lower levels of 2-DG uptake than did meal-scheduled rats.

These data are preliminary, but suggest that there is no evidence yet for an anatomically distinct site for a food entrained oscillator.

SUPRACHIASMATIC NUCLEI AND PHOTOINDUCED TESTICULAR DEVELOPMENT IN SIBERIAN HAMSTERS. K.Kelly*, J.Dark, & I.Zucker. Dept. of Psychology, University of California, Berkeley, CA 94720.

Light influences the mammalian neuroendocrine system by altering the duration of pineal melatonin secretion. The suprachiasmatic nucleus (SCN) is a melatonin target tissue involved in the neural innervation of the pineal gland. The present study assessed whether changes in SCN activity beginning several days after animals received a single inductive light stimulus are essential for gonadal growth in photoregressed Siberian hamsters. A single long day at 19 days of age produces sustained testes growth over the course of the next two weeks in male animals maintained in short daylengths. At 35 days of age testes weights of light-treated hamsters were significantly greater than those of untreated animals (143±43 vs 31±4 mg). Hamsters that sustained complete ablation of the SCN 3 days after the light treatment had testes weights of 291±35 mg ($p<0.001$ relative to untreated controls); those that received SCN lesions only, had testes weights of 147±45 mg. These results indicate that changes in SCN neural activity are not necessary for photic stimulation of gonadal growth once the light stimulus has been perceived and neuroendocrine changes initiated. Endocrine sequelae of SCN damage, including hyperprolactinemia, may account for the greater than normal testes weights of light-stimulated hamsters with SCN damage.

CHANGES IN PROLACTIN AND CORTICOSTERONE ASSOCIATED WITH PUBERTY AND PHOTOPERIOD IN THE COLLARED LEMMING, DICROSTONYX GROENLANDICUS. B. Gower, T. R. Nagy* and M. H. Stetson*. School of Life & Health Sciences, Univ. of Delaware, Newark, DE 19716 (BG, MHS), and Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112 (TRN).

The effect of photoperiod on the onset of puberty and associated neuroendocrine changes was examined in male collared lemmings, Dicrostonyx groenlandicus. Animals were gestated in either a 16:8 or an 8:16 photoperiod. Those from the 16:8 photoperiod were switched to either a 20:4 or an 8:16 photoperiod at weaning, while those from the 8:16 photoperiod remained in 8:16 throughout the experiment. At 33, 38, 43, and 48 days of age, groups were sacrificed and individuals examined for body, testes, and seminal vesicle weights and the presence of epididymal sperm. Serum was collected and later analyzed for prolactin, corticosterone, and testosterone. Maturation occurred significantly earlier, by 5 d, in the 20:4 group than in the group switched to 8:16; the group raised in 8:16 was not different from either of the other 2 groups. Testes and seminal vesicle weights were similar in the 20:4 group and the group raised under 8:16, while those animals switched to 8:16 had significantly lower tissue weights. Serum prolactin was significantly depressed by short photoperiod (both 8:16 groups), as was serum corticosterone. These data suggest that, although significant, the effect of photoperiod on reproductive development is slight. Photoperiod does, however, influence the neuroendocrine system during the peripubertal period. The low levels of prolactin observed in the 8:16 animals suggest that this hormone is not important for reproductive development, but may play a role in the annual pelage cycle.

DO SIBERIAN HAMSTERS RESPOND TO CHANGING PHOTOPERIODS? M.L. Tubbiola, E.L. Meyer*, S. Matsumoto* and E.L. Bittman, Dept. of Zoology and Program in Neuroscience & Behavior, Univ. of Massachusetts, Amherst.

Photoperiodic cues received during gestation determine the reproductive and body weight responses of Siberian hamsters to intermediate daylengths after birth. When pregnant dams are maintained in 12L:12D and transferred with their litters to 14L:10D at birth or 15 days later, their offspring mature rapidly. Puberty is delayed in pups gestated in 16L:8D but moved to 14L:10D after birth. In nature, however, pups are exposed to increasing or decreasing photoperiods rather than constant 14L:10D. We tested the possibility that steadily changing postnatal daylengths would override gestational cues.

Beginning on postnatal day 15, pups gestated on 16L:8D or 12L:12D were exposed to constant 14L:10D (groups A and D, respectively), or to daylengths which decreased 8.57 min/day from 16L:8D to 14L:10D (groups C and F) or increased at the same rate from 12L:12D to 14L:10D (groups B and E). Body weight and testis dimensions were measured at laparotomy on day 30. Pups were then held on 14L:10D until sacrifice on day 35.

As expected, postnatal exposure to 14L:10D induced larger final body, epididymal, and testes weights in pups gestated in 16L:8D than those gestated in 12L:12D (groups A vs. D, $p<0.01$). Gestational daylength also determined responses to steadily increasing or decreasing photoperiod (groups B vs. E and C vs. F, $p<0.01$). In general, pups responded more to the absolute amount of light than to the direction of photoperiod change. Increasing daylengths were no more inductive than constant 14L:10D. Decreasing daylengths stimulated less testis growth, however, than constant 14L:10D in pups gestated in 12L:12D (groups D vs. F, $p<0.01$). The results suggest that photoperiodic threshold might be set close to gestational photoperiod and/or that a period of particular sensitivity to daylength may occur shortly after day 15. KNIFE CUTS DORSAL TO THE PARAVENTRICULAR NUCLEUS (PVN) PREVENT TESTICULAR REGRESSION BUT NOT THE EFFECTS OF SHORT DAYS ON PROLACTIN SECRETION IN HAMSTERS. A.A. NUNEZ, L.L. BADURA and C.L. SISK. Dept. of Psychology/Neuroscience Prog. Michigan State University, East Lansing, MI 48824 and Dept. of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06268.

Male Syrian hamsters kept in a long-day photoperiod (16L:8D) received horizontal hypothalamic knife cuts just dorsal to the PVN or underwent sham stereotaxic surgery. Following surgery, animals with knife cuts and a subset of the sham-operated animals were transferred to a short-day photoperiod (6L:18D). The width of all the animals' right testes was measured 2 weeks and again 12 weeks after the hamsters were placed in short days. At the same sampling times, blood was drawn from all animals via cardiac puncture. Prolactin (PRL) concentration for each plasma sample was assessed via a RIA. At the time of the first sample, all groups had large gonads (mean=11.5mm) and PRL levels typical of animals kept in stimulatory photoperiods (mean=78.2ng/ml). At the 12-week sampling time, the sham-operated animals kept in 6L:18D had regressed gonads and low plasma PRL levels. As previously reported (Brain Res. Bull, 15:149, 1985), the knife cuts completly prevented gonadal regression. However, they failed to block the short-day induced reduction in PRL secretion (mean=8.3ng/ml). These results indicate that damage to the dorsal connections of the PVN blocks testicular regression without disrupting photoperiodic modulation of PRL. Supported in part by grants BNS8908576 to A.A.N. and HD21588 to C.L.S.

SEASONAL NEUROENDOCRINE RESPONSES IN MALE TURKISH HAMSTERS: MODULATION BY HYPOTHALAMIC PATHWAYS. L.L. Badura and B.D. Goldman. Dept. Physiology & Neurobiology, Univ. of Connecticut, Storrs, CT 06269.

The role of the hypothalamus in the modulation of neuroendocrine responses to photoperiod was investigated in Turkish hamsters via placement of horizontal knife cuts in the paraventricular nucleus (PVN) region. Adult male hamsters maintained under a long-day (16L:8D) photoperiod received knife cuts aimed either ventral to the PVN (VKC) or dorsal to this nucleus (DKC), or sham surgery (SHAM). Following surgery, approximately half of the animals in each group were transferred to a short-day (8L:16D) photoperiod. Blood samples and testicular measurements were taken at various times over a 16 week period. The testes were then removed and weighed, the brains prepared for histological evaluation of the extent of the lesion sites, and the serum assayed for prolactin (PRL) and follicle-stimulating hormone (FSH).

Similar to the effects of pinealectomy in this species, VKC lesions induced a significant decrease in testicular size, as well as accompanying declines in circulating PRL and FSH, under both photoperiod conditions. In contrast, DKC lesions induced a maintenance of testicular size and circulating FSH levels under both photoperiods that closely resembled the values obtained for SHAM animals in 16L. However, for animals in 8L, PRL levels were markedly reduced to values indistinguishable from SHAM animals. These data add further support for the importance of PVN projections in the modulation of pineal-dependent reproductive responses to photoperiod. Furthermore, they suggest that knife cuts dorsal to the PVN may prevent some photoperiodic responses by disrupting a neuroendocrine pathway responsible for inhibition of FSH release under short photoperiod conditions.

491.7

HYPOTHALAMIC INVOLVEMENT IN THE SEASONAL NEUROENDOCRINE RESPONSE IN SIBERIAN HAMSTERS. A.M. Snyder and L.L. Badura, University of Connecticut Health Center, Farmington, CT 06032 and Dept. Physiology and Neurobiology, University of Connecticut, Storrs, CT 06269.

Photoperiodic modulation of neuroendocrine activity in the Siberian hamster is dependent upon the integrity of the pineal gland. To further identify the functional neuroanatomy of the photoperiodic system in this species, female hamsters received horizontal knife cuts in the hypothalamus aimed between the suprachiasmatic (SCN) and paraventicular (PVN) nuclei. The animals were then transferred to short days and were blood sampled and scored for pelage condition at various times over a 14 week period. Uteri were then removed and weighed, and the brains prepared for histological evaluation of the lesion sites. PRL and FSH levels were determined via RIA.

The animals were divided into two groups based upon placement of the knife cuts: 1) cuts located ventral to the PVN leaving the SCN intact or 2) through the extent of the SCN. Similar to pinealectomized animals, animals in the SCN group maintained stimulated uteri and high levels of FSH and PRL as compared to control animals. These animals also retained the pigmented pelage coloration characteristic of long days. In contrast, animals in the PVN group maintained stimulated uteri and high FSH; however, they showed a marked reduction in PRL and a concurrent molt to the winter-type pelage. These results suggest that not all effects of photoperiod on neuroendocrine activity in this species are mediated directly by the pineal gland, and that the PVN region of the hypothalamus may contain an important pineal-independent neuroendocrine pathway that is responsible for the stimulatory modulation of PRL, but not FSH, release.

CONVERGENCE OF RETINAL AND OLFACTORY PROJECTIONS WITH LHRH NEURONS. H.M. Cooper*, G. Mick*, M. Magnin, F. Jourdan*. Vision and Motricité, I.N.S.E.R.M. U-94, 69500-Bron, FRANCE

The neuropeptide LHRH, secreted in a pulsatile manner in the basal hypothalamic region, stimulates the release of LH by the pituitary. Although the secretion of LH is known to be modulated by sensory information of both visual and chemosensory origin, the anatomical pathways involved in relaying this input to the LHRH system are unknown. LHRH containing neurons and fibers have been shown to be diffusely distributed in several diencephalic and telencephalic regions. Immunohistochemical demonstration of LHRH, combined with anterograde tracing methods, was used to examine the possibility of direct sensory input to the LHRH neuroendocrine population. Intraocular injections of tritiated amino acids or CT-HRP, in both primates and non-primates, showed that several structures containing LHRH positive cells and/or fibers also receive retinal projections: medial preoptic region, anterior and lateral hypothalamus, sub-paraventricular zone, medial septal nucleus, bed nucleus of the stria terminalis, medial amygdaloid nucleus, olfactory tubercle. Simultaneous injection of the anterograde tracer fluoro-ruby in the main and accessory olfactory bulbs showed converging visual and chemosensory projections in the BNST, lateral hypothalamus and basal telencephalon. Injections of retrograde tracers into the BNST and lateral hypothalamus confirmed that projection fibers mainly arise from the accessory olfactory bulb.

These convergent pathways could thus provide an anatomical basis for a monosynaptic relay of visual and/or chemosensory information to LHRH neurons. Work is currently in progress to confirm this hypothesis at the ultrastructural level. This sensory neuroendocrine convergence would be functionally analagous to the olfacto-retinalis system of teleosts, in which the LHRH neurons directly connect the retina with olfactory bulbs.

ACTIVITY OF DESCENDING BRAIN NEURONS IN WALKING CRICKETS. H.Böhm* and K.Schildberger MPI f. Verhaltensphysiologie 8130 Seewiesen, Germany.

In order to study the neural mechanisms involved in the course control of crickets we recorded intracellularly from descending brain neurons (DEBs), while the animals walked on an air-supported sphere and oriented toward various stimuli like calling song, moving gratings or air streams directed to the cerci.

DEBs responding to only one of the presented stimuli often showed a selectivity for the direction of the stimulus and were in most cases not influenced by walking activity. DEBs responding to all tested stimuli showed in most cases strong habituation, no directional selectivity and a strong influence of walking on their activity.

Moreover, there seem to be single DEBs responsible for specific aspects of walking. The activity of one DEB was increased before walking started and was linearly correlated with the forward but not with the turning speed of the animal. Another DEB seems to be a command neuron initiating walking. Hyperpolarizing the neuron immediately stopped walking while depolarizing above a certain firing rate always elicited walking. Further enhancing the firing rate did not produce faster walking and there was no correlation of the neuron's activity and the animal's turning tendency.

492.2

THE BIASING EFFECT OF PRIOR MATE OR COMBAT EXPERIENCE ON COURTSHIP AND AGGRESSION IN THE CRICKET, *GRYLLUS BIMACULATUS*. S.A. Adamo and R.R. Hoy. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853

In crickets, naive, sexually receptive males normally respond to tactile contact from conspecific males with aggressive behavior, but will court similarly presented females. A male cricket's response to conspecifics is not fixed, however, but varies depending on its previous behavior. 15 min. after an aggressive encounter, both winning and losing males exhibited increased aggressive behavior towards sexually receptive females ($p<0.05$, $G=3.85$, $n=29$ males). A losing male also required more time and more contact with a sexually receptive female before it would begin to court ($p<0.004$, Wilcoxon, $n=19$ males). Previous aggressive encounters did not inhibit courtship initiation in winning males. Losing males were also less likely to win their next aggressive encounter (15 min. later) even if they were paired with a smaller opponent ($p<0.01$, $G=8.65$, $n=35$ pairs). Losing males, unlike naive or winning males, fled from the tactile contact of other males ($P<0.01$, $G=8.8$, $n=35$).

Immediately after courtship, males tended to respond to male tactile contact with courtship song ($p<0.001$, $G=17.22$, $n=35$), at least initially. 15 min. after a bout of courtship, males showed an enhanced response to tactile contact with females, requiring less time to initiate courtship ($p<0.001$, Wilcoxon, $n=16$ males).

These results suggest that a cricket's prior behavioral performance can result in physiological changes lasting many minutes which alter its behavioral response to tactile contact from conspecifics. Current experiments are exploring the possible role of neuromodulators such as serotonin and octopamine in mediating this change.

492.3

NEURAL STUDY OF THE "PRECEDENCE EFFECT" IN NEGATIVE PHONOTAXIS OF THE CRICKET *TELEOGRYLLUS OCEANICUS*. R.A. Wyttenbach and R.R. Hoy. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

Tethered flying crickets make steering movements away from pulses of ultrasound. These movements include forewing tilt, abdomen swing, and metathoracic leg swing, all of which are lateralized relative to the sound source. A bilateral pair of ascending prothoracic auditory interneurons (int-1) has been shown necessary and sufficient to elicit these responses: stimulation of an int-1 (electrically or by ipsilateral ultrasound) causes steering to the contralateral side, while hyperpolarization prevents steering in response to sound. To correctly localize a sound source in the presence of echoes, directional information must be taken only from the first-arriving wavefront (precedence effect) and subsequent wavefronts cannot be treated as coming from additional sources (echo suppression).

Using EMGs of metathoracic leg abductors as an indicator of turning, previous work in our lab showed that the precedence effect and echo suppression occur for delays of 4 to 75 ms between a pulse of ultrasound and a simulated echo. For shorter delays, a random turn is made, while longer delays give rise to separate turns in response to each pulse of ultrasound. Bilateral recordings from the two int-1s show no difference in spike number or frequency between the int-1 receiving the first pulse and the one receiving the echo. Therefore, the behavioral effects cannot be accounted for by patterns of activity of the two int-1s.

We have begun recording from another pair of prothoracic auditory interneurons, the omega cells. These are thought to be involved in localization of calling song, but also respond to ultrasound. The omega cells are mutually inhibitory, inhibit the contralateral int-1s, and are respond to a broad spectrum of frequencies. Furthermore, these cells have a long-term delayed intensity-dependent self-inhibition that increases their directionality. These effects have so far been studied only for the calling song frequencies, but may also occur in ultrasound. If so, this would be evidence that the same mechanisms are used to localize both calling song and ultrasound.

492.4

POSSIBLE ROLES FOR JUVENILE HORMONE BINDING PROTEINS IN THE REGULATION OF CRICKET PHONOTACTIC BEHAVIOR. J. Stout, D. Zacharias*, and G. Atkins. Dept. of Biology, Andrews Univ., Berrien Springs, MI 49104.

In response to models of the males calling songs, young (0-2 day-old) female crickets have higher auditory thresholds (80-90dB) for positive phonotaxis than do older (4-21 day-old) females (45-55 dB). Changes in the firing threshold of the L1 auditory interneuron parallel the changes with age in the phonotactic threshold of these females. In 1 day-old females, topical application and microinjection of juvenile hormone III (JHIII) demonstrate that JHIII decreases (25-40 dB) both behavioral and neuronal thresholds within several hours, and that the site of JHIII action on neurons and behavior is within the prothoracic ganglion. The results of the JHIII microinjection experiments strongly suggest that the soma of L1 is the locus for this hormonal effect.

Juvenile hormone binding proteins have been isolated from the hemolymph and, apparently for the first time in insects, from protein extracts of nerve tissue of crickets by labeling them with the tritiated photoaffinity analogs for JHIII (EFDA) or methoprene (MDK), separating them using SDS- or native PAGE and identifying them by autofluorography. JHIII binding proteins with a weight of about 23 and 38 kDa were isolated from the pro- and metathoracic ganglia. The 38 kDa protein was found in both ganglia, while the 23 kDa binding protein was much more apparent in extracts from the prothoracic ganglia.

If JHIII were to directly influence the response properties of auditory interneurons by regulation of the expression of an appropriate gene(s), then binding proteins should be present in the somata of these neurons. We are presently attempting to localize JHIII binding proteins in these somata.

492.5

EXPRESSION OF NICOTINIC ACETYLCHOLINE RECEPTORS IN THE AUDITORY NEURONS OF CRICKETS - A POSSIBLE ROLE IN THE REGULATION OF PHONOTAXIS. G. Atkins, V. Hayes*, J. Henley* and J. Stout. Dept. of Biol., Andrews Univ., Berrien Springs, MI 49104.

Two auditory interneurons (L1 and L3) in the prothoracic ganglion of the cricket *Acheta domestica*, are involved in phonotaxis and have been shown to be influenced by Juvenile hormone III (JHIII). L1's threshold to 5 kHz calling songs decreases as JHIII levels increase either naturally with increasing age, or in response to topically applied hormone. This change correlates with a similar decrease in phonotactic threshold with age and JHIII application. Transcription inhibitors block JHIII effects. L3's threshold does not change, but its decrementing response which is syllable period selective, changes in response to natural or artificially changing JHIII levels, and correlates with changes in phonotactic selectivity under similar conditions .

We are using *In situ* hybridization to identify transmitter receptor mRNA present in these cells with the goal of determining whether the regulation of response properties of auditory neurons might involve regulation of the production of their ligand-gated channels. Ganglia containing iontophoretically labeled neurons were sectioned (20 um). Sections containing the labeled somata were exposed to an oligonucleotide probe and later visualized using a phosphatase detection system. We have demonstrated the presence of alpha1-like nicotinic receptor mRNA (Marshall et al. 1990) using three different 27mer oligonucleotide probes. We are presently determining whether changing JHIII levels might influence the expression of mRNAs for nicotinic receptors in these neurons.

492.6

HIGH FREQUENCY ACOUSTIC SENSITIVITY IN *ACHETA DOMESTICUS:* ROLES IN COMMUNICATION AND PREDATOR AVOIDANCE. T.G. Nolen, C. Lam*, J. Wong*, L. Luayon* and J. Aracena*, Dept. of Biology, University of Miami, P.O. Box 249118, Coral Gables, FL 33124.

Male crickets employ acoustic signals to establish and defend their territories and to attract mates. In *Acheta domesticus* the RIVALRY SONG is crucial for a male's territorial success: Muting the dominant, or deafening the subordinate male reduces the dominant's chance of gaining or keeping a territory. [Nolen and Lam, (1990)].

Spectral analysis of *A. domesticus* songs reveal three pulse types: LF, with significant energy at 4-5 kHz, but little above 20kHz (e.g. the CALLING SONG); LF-HF, with a 4-5 kHz fundamental and a high frequency component 10-40kHz; and HF, nearly exclusively high frequency (10-40kHz). The COURTSHIP SONG contains both LF and LF-HF pulses (HF peak at ~17-21kHz). The RIVALRY SONG is bimorphic: RSa is mostly LF and LF-HF, whereas RSb, which is sung primarily by the dominant male, is mostly HF (short, low amplitude pulses, usually > 30kHz). Both the CALLING SONG and RSa are relatively loud, and should travel greater distances than either the COURTSHIP SONG or RSb. The pressure component, rather than the near field (wind) component of the RS song is critical for the dominant male's success: Cercal ablation had no effect on territorial success [p>0.2, Wilcoxon SR test], whereas muting (HF reduced more than 30dB) did.

HF pulses are aversive to *A. domesticus* in a different behavioral context: During flight, this cricket steers away from high frequency pulses (analogous to the bat avoidance behavior of other species of crickets [Nolen and Hoy, 1986]). Recordings from ascending auditory neurons reveal sensitivity to HF; this HF response demonstrates two-tone suppression by 4-5kHz. Thus, the HF network in *A. domesticus* is not as strongly activated by LF and LF-HF pulses (CALLING, COURTSHIP and RSa) as by HF pulses (RSb and bat sonar). *A. domesticus*, is sensitive to the HF pulses of bat sonar (as are other crickets) and to the rivalry song of the dominant male. We hypothesize that in both behavioral contexts, HF pulses could activate the same general aversion circuit, mediating the avoidance of a predator or the avoidance of aggressive, territorial males. [Supported by NSF]

492.7

HABITUATION OF ULTRASONIC ACOUSTIC STARTLE IN FLYING CRICKETS. R.R. Hoy and M. L. May. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

The acoustic startle response (ASR) is a rapid, highly stereotyped motor reaction to a loud, transient sound. The survival value of the ASR is reflected in its wide phylogenetic distribution among animals that have a sense of hearing, ranging from insects through all vertebrates, including humans. In mammals, the ASR shows classical habituation. Using Thompson and Spencer's nine criteria for mammalian habituation, we show habituation of the ASR in crickets.

Tethered flying crickets (Teleogryllus oceanicus) steer away from ultrasound, by making lateralized movements of wings, legs, and abdomen. We investigated habituation in the ultrasound-induced metathoracic leg kick; eight of nine of Thompson and Spencer's critera were satisfied. Habituation of the ASR showed: (1) exponential decline of the response; (2) spontaneous recovery; (3) stimulus generalization; (4) dishabituation to a novel stimulus; (5) habituation of the dishabituating stimulus with repetition; (6) sronger and more rapid habituation with weak sounds than with more intense sounds; (7) stronger and more rapid habituation with repeated trials; and (8) stronger and more rapid habituation if the interstimulus interval is decreased.

By standard criteria, the ASR in crickets shows classical habituation. It is now possible to explore the neural basis of this relatively simple fixed act in a restricted neural network composed of identifiable neurons.

We acknowledge funding from NIH DC-00103-18, a Javits/Pepper Neuroscience Award.

ANATOMICAL AND FUNCTIONAL CHARACTERIZATION OF THE CENTRAL COMPLEX IN THE BRAIN OF THE LOCUST *SCHISTOCERCA GREGARIA*. U. Homberg. Fak. für Biologie, Universität Konstanz, FRG

The central complex (CC) comprises a group of neuropils in the center of the insect brain. Its subdivisions, including the protocerebral bridge and the upper and lower divisions of the central body constitute a system of horizontal layers, each beeing partitioned into a series of 8 or 16 vertical columns. This study investigates the anatomical organization of the CC and physiological properties of CC neurons in the locust *Schistocerca gregaria*.

Single-cell injections of Lucifer Yellow and neurotransmitter immunocytochemistry revealed two principal categories of CC-neurons. Tangential neurons innervate single layers of the CC. They connect the CC to visual pathways from the two compound eyes and to neurosecretory areas in the superior protocerebrum. Subtypes of tangential neurons are immunoreactive with antisera against GABA, serotonin, dopamine, octopamine, and neuropeptides including FMRFamide and locust adipokinetic hormone. Columnar neurons interconnect columns of the right and left CC hemispheres in a highly ordered fashion, suggesting a role of the CC in the coordination of neural activity between the two hemispheres. Systems of columnar neurons exhibit immunoreactivity with antisera against substance P, serotonin, and crustaceen cardioactive peptide.

In electrophysiological experiments, CC neurons responded to visual stimulation but more often to wind stimuli eliciting flight. Simultaneous recordings from flight muscles suggest that at least some CC neurons monitor flight motor activity. These data suggest that the CC plays a role in bilateral visual integration, receives information about ongoing motor activity and may be even involved in the control of the neuroendocrine system. Supported by DFG grant Ho 950/4-1.

LOCUSTS IN A FLIGHT SIMULATOR: THE ROLE OF HEAD MOVEMENTS DURING STABLE FLIGHT AND AVOIDANCE MANOEUVRES. D. Robert, Institute of Zoology, Basel University, Rheinsprung 9. CH-4051 Basel, Switzerland.

Flying insects strongly rely on vision to detect deviation from course and to maintain flight stability. Visually perceived deviations can have diverse causes: 1) aerodynamical disturbances and motor errors, and 2) active steering manoeuvres. The former (unintended) deviations activate the optomotor (compensatory) steering system while the latter (self-induced) do not. How can a locust initiate intentional turns without being restabilized to the original course by the optomotor system? Tethered locusts were flown in a flight simulator that electronically converts the steering force of the animal (measured by a torque meter) into the motion of a surrounding visual pattern driven by a servomotor. The locusts were in control of their visual environment (reafference control), and actively stabilized the panorama over long periods of time by means of compensatory steering manoeuvres. Under closed-loop conditions, preventing compensatory head (thus eye) movements impaired both the precision and the temporal coordination of stabilization manoeuvres.

This closed-loop paradigm allows one to test the robustness of the optomotor system to external or self-induced visual instabilities. Flying locusts exposed to pulsed ultrasound (resembling bat echolocation cries) actively steer away from the ultrasound source, thus provoking shifts of the panorama that were not compensated by the optomotor response. Compensatory and avoidance steering involved the same steering effectors, e.g. abdominal and hindleg ruddering and wingbeat modulation. In both cases, ruddering was directed to the side of the turn. During compensatory steering, the head moved to the side of the turn, while it moved to the side *away* from the turn during avoidance steering. For both reactions, head movements occurred 30-40 ms after torque production began and thus cannot be considered as initiating steering. Head turns during avoidance steering were shown to occur in the dark and to be independant of the sign of the visual reafference. This indicates a momentary cessation of visual control during avoidance steering. Head movements are proposed to proprioceptively assist opto- and audiomotor steering.

STEERING TORQUES GENERATED BY COLLISION AVOIDANCE MANOEUVRES DURING FLIGHT IN THE LOCUST. A. G. Johnson, R.M. Robertson and D.W. Lywood*. Departments of Biology and Biomedical Engineering, Queen's University, Kingston, Ontario, K7L 3N6, Canada.

When presented with objects in their immediate flight path, tethered flying locusts make asymmetrical movements of the wings on either side of the body. The side of the asymmetry correlates with the line of approach of the object. For objects approaching on the right of the midline, the right forewing is more elevated and separate from the right hindwing while the left forewing is more depressed and comes down in conjunction with, or in advance of, the left hindwing. These wing movements have been interpreted as steering movements. However it is unknown whether the described wing asymmetries generate the steering torques that would direct the animal around the closest edge of the object. We tested this by measuring the forces generated by flying locusts in response to approaching objects.

Locusts were attached to a tether which was mounted on a force transducer modified after an original design by Blondeau (J. Exp. Biol. **92**:155 1981). This device measured thrust, lift, side-slip, yaw, pitch, and roll forces. The locusts were suspended in the centre of a wind tunnel (20 cm square section, air speed 3 m/s). Objects (10 cm squares of black or patterned cardboard) were transported towards the head of the locust from 1.5 m away and 5 cm on either side of the sagittal midline at 1, 2, 3, 4 or 5 m/s. Wing movements were recorded using a video camera (60 frames/s) and could be correlated with the forces generated during the presentation of objects in the flight path. Preliminary results confirm that the wing asymmetries result in steering torques which would direct the animal around the closest edge of the approaching object.

VENTRAL GIANT INTERNEURON WIND FIELDS IN THE COCKROACH MODELED WITH CONSTRAINED BACK-PROPAGATION. R.D. Beer, G.J. Kacmarcik*, S. Chai*, R.E. Ritzmann and H.J. Chiel. Dept. of Comp. Eng. and Sci. and Dept. of Biology, Case Western Reserve University, Cleveland, OH 44106.

We are attempting to construct a physiologically accurate model of the escape system of the cockroach. At last year's meeting, we presented the basic components of a model constructed with the back-propagation training technique. Our model of the ventral giant interneurons (vGIs) was trained on the normal wind field responses and constrained by published patterns of connectivity from cercal afferents (Daley and Camhi, J. Neurophysiol. **60**:1350).

We have now refined this model by incorporating additional training data and constraints. The model is now trained on wind field data from both normal animals and animals with cercal ablations (Westin et al., J. Comp. Physiol. **121**:307; Volman and Camhi, J. Comp. Physiol. **162**:781). In addition, the sigmoidal responses of the model vGI neurons were fit to firing characteristics of actual vGI neurons. A series of intracellular experiments characterized current - frequency relationships of individual vGIs. Mean number of action potentials for varying levels of injected current were plotted.

A particularly interesting aspect of this system is the adaptation that occurs within vGI response patterns as a result of unilateral cercal ablation. With our more physiologically accurate model, we can now simulate this adaptation by retraining a lesioned model to the recovered wind fields. By comparing connection strengths before and after simulated adaptation, we hope to gain insight into possible loci of plasticity.

492.12

INFLUENCE OF NON-GIANT SENSORY INPUTS ON THE ESCAPE RESPONSE OF THE COCKROACH R.E. Ritzmann, A.J. Pollack* and Sue E. Hudson*. Dept. of Biology, Case Western Reserve University, Cleveland, OH 44106.

The wind mediated escape system of the cockroach has become an important neuroethological model for orientation movements. Although it is clear that activity in the ventral giant interneurons (vGIs) is a primary determinant of the direction of the escape turn, there are several lines of evidence to suggest that other information is also factored into the decision.

We are investigating the influence of non-GI sensory modalities on electrophysiological parameters of the thoracic interneurons that receive vGI inputs (TI_As) and on escape movements. In the absence of vGI inputs, we have recorded vigorous responses in TI_As to wind directed at the head of the animal. We have also recorded responses to auditory stimulation that persists after the thoracic ganglia are isolated from both abdominal and anterior connectives. Responses to light have been recorded in at least one TI_A. Although the light response was labile, lasting for only 7 trials, it returned after 1 hour in darkness. A previously published account (Murrain and Ritzmann, J. Neuorbiol. **19:552**) demonstrated that proprioceptors also excite TI_As. Behaviorally, we have now shown that in response to ablation of the mesothoracic legs, a cockroach will alter its leg movements. As a result, after 2 days the animal can direct its turn in response to wind as well as a normal animal can.

Our data indicate that, although wind direction encoded in vGIs is critical to the escape movements, this information is interpreted in the TI_As in the context of a plethora of other sensory information. We are presently expanding on both the physiological and behavioral aspects of this study.

EXPANDING THE BOUNDARIES OF THE COCKROACH "ESCAPE CIRCUIT": LESIONS AT THE CERVICAL LEVEL ALTER ESCAPE BEHAVIOR EVOKED BY TOUCH AND ALSO RESPONSES ELICITED BY WIND. A.P. Keegan, E. Mara, and C.M. Comer Dept. of Biological Sciences, University of Illinois at Chicago, Chicago, IL 60680.

The escape behavior of the cockroach (Periplaneta americana) has been known for many years to be triggered by wind stimulation of the caudal cerci, and to involve giant interneurons (GIs) ascending to the thoracic level of the CNS. We recently found that some predators appear not to be detected by wind cues, but rather by direct touch (Soc. Neurosci. Abst. 15:349) and that some of these tactile responses [e.g. those derived from the antennae] involve novel interneuronal pathways descending from the head ganglia to thoracic levels (Brain Res. 535:347).

We have now made lesions between the head ganglia and thoracic circuits and used high-speed videography to characterize both wind and tactually elicited behavior. We have found that such lesions alter antennal tactile escape responses, and also modulate cercal wind-evoked escape responses. When one neck connective was transected, animals responded less consistently to antennal tactile stimuli and the directionality of their turning was shifted: they often turned toward rather than away from stimuli on the side opposite the lesion. Animals with this type of lesion responded to cercal wind stimuli at normal levels, but the orientation of their turning was shifted in the same way as for touch.

This demonstrates lateralization of descending tactile pathways for escape, and also implies that pathways from head ganglia influence how thoracic circuits use ascending GI signals to initiate turning movements. Our data suggest that rostal modulation of GI-to-motor circuits is not likely to involve a phasic wind-derived signal, but rather a more tonic signal that can bias premotor and/or motor cells. NEUROETHOLOGY OF SOUND PRODUCTION IN ARCTIID MOTHS: RHYTHMICITY AND CENTRAL CONTROL. J.H. Fullard. Insect Behaviour Group, Department of Zoology and Erindale College, University of Toronto, Mississauga, Ontario, CANADA L5L 1C6.

As part of their in-flight anti-predator defences, certain species of tiger moths (Arctiidae) emit trains of high frequency clicks when they hear the intense echolocation calls of an attacking bat. Sound production serves as a convenient and stereotyped response to acoustic stimuli that can be used to study the neural control of this adaptive behaviour. The moth produces its sounds by rhythmically buckling a tymbal on each side of its thorax once activated by auditory input. By monitoring the motor nerve that leads to the tymbal musculature a large single spike proceeds each tymbal sound emission by 3 - 10 ms. This motor neuron output continues in the absence of actual sound emission and persists when all nerves have been severed from their tymbal muscles. Since rhythmicity is preserved in deefferented preparations, I conclude that arctiid sound production is controlled by a central pattern generator (CPG), located in the moth's thoracic central nervous system and is independent of sensory influence. One-eared moths initiate sounds from the tymbal opposite to the stimulated ear and once the cycle is initiated it continues without interference from the other side. This indicates the presence of auditory invoked inhibitory effects on the contralateral CPG allowing the rhythmicity of the motor output to proceed without disruption. The period and phase characteristics of the deefferented preparation suggests a pair of asymmetrical CPGs, each of which contains an additional synapse on the side ipsilateral to the stimulated ear. A model for the tymbal CPG is provided.

FLIGHT MUSCLE ACTIVITY UNDERLYING PHEROMONE-MODULATED ZIGZAGGING FLIGHT IN MALE MOTHS, *Manduca sexta*. MA Willis & EA Arbas. ARLDN, Univ. of Arizona, Tucson AZ 85721.

Male *M. sexta* approach females for mating by flying a characteristic side-to-side zigzagging path. This upwind path results from self-steered maneuvers initiated and modulated by wind-borne pheromone released by the female.

To characterize motor patterns underlying flight maneuvers, we have recorded electromyograms (EMGs) from flight muscles of *M. sexta* males flying freely in female pheromone. EMG activity was synchronized with a video record of the zigzagging flight track in a laboratory wind tunnel (closed-loop conditions). We have also recorded the activity of these muscles, in the same individuals, during tethered flight activated by visual stimuli or pheromone (open-loop conditions). We recorded from three muscles: the left dorsal longitudinal muscle (DLM), a main wing-depressor; and the left and right third axillary muscles (AxM), which have been identified as "steering" muscles in earlier studies. Parameters measured from the EMGs were: burst period (ms), burst duration (ms), and spikes/burst for all three muscles; and the phase of AxM activity with respect to each DLM burst.

Characteristic asymmetries between bilateral AxMs were identified during zigzagging turns in free flight. The most typical is the appearance of an additional spike at a later phase of the wing beat cycle in the AxM on one side of the animal, but not the other. These may occur during only one, or a few wing beat cycles in a turn. We have observed similar, additional spikes during attempted turns in tethered males stimulated by air-borne pheromone alone. Phase shifts in AxM firing were observed during attempted turns activated with visual flow fields alone. These changes in AxM firing may contribute to the temporally regular turns that make up pheromone-modulated flight. [Supported by NIH grants DC-00348 and NS-07309.]

DIGGING BY THE SAND CRAB *BLEPHARIPODA OCCIDENTALIS*. Z. Faulkes*, D.H. Paul & S.M. Pellis[1]. Dept. Biol., U. Vic., Victoria, B.C. V8W 2Y2; [1]Dept. Psych., U. of Leth., Lethbridge, AB T1K 3M4.

The spiny sand crab, *B. occidentalis*, digs into the sand using its thoracic legs. We hypothesize this is homologous to walking in other crustaceans. We hope to understand how the crabs dig, how digging has evolved from walking, and how the nervous system generates the digging motor pattern. We are studying digging with Eshkol-Wachman movement notation (EW) and by EMG analysis. Leg movements of crabs held in water were videotaped from the side and below, and analyzed with EW.

Digging resembles walking in two respects. 1) Contralateral legs, including the chelae, move out of phase (but become synchronized when the crab is almost dug in). 2) Ipsilateral legs move in a metachronous front to back sequence of power strokes. Digging differs from walking in several ways. 1) Leg 4 plays a special role in digging and its control may be different from the others: a) the power stroke of Leg 4 is backward while those of Leg 2 and 3 are forward; b) the sequence of joint movements is proximal-distal in Leg 4, but distal-proximal in Legs 2 and 3. 2) Most joints make active movements; in walking, distal segments are largely carried along. 3) Each leg moves in different directions relative to the body; in forward walking legs move parallel to the midline. 4) The abdomen and the chelae move and contribute to locomotion. The abdomen cycles at about twice the rate of the thoracic legs; its small size and rapid movement suggest that it acts by "puddling," making the sand more fluid.

CORRELATION OF APOMORPHINE- AND AMPHETAMINE-INDUCED TURNING BEHAVIOR WITH NIGROSTRIATAL DOPAMINE DEPLETION. J.L. Hudson*, C. G. vanHorne, I. Stromberg1, J. Clayton, S. Brock*, J. Masserano, B.J. Hoffer and G.A. Gerhardt. Depts. of Pharmacology and Psychiatry, Univ. Colorado Health Sci. Ctr., Denver, CO 80262 and Dept. of Histology1, Karolinska Institute, Stockholm, Sweden.

In the unilaterally 6-hydroxydopamine (6-OHDA)-lesioned rat model of Parkinson's Disease, some controversy exists concerning the use of apomorphine (APO)- vs. amphetamine (AMP)-induced rotations as indicators of nigrostriatal dopamine (DA) depletion. APO produces rotations contralateral to a lesion and is dependent upon the development of receptor supersensitivity, while AMP produces rotations ipsilateral to a lesion due to indirect DA agonist actions on the intact side. Our objective was to evaluate if either drug-induced behavior is more predictive of the extent of nigrostriatal DA depletion. Male and female Fischer 344 and Sprague-Dawley rats were unilaterally injected with 6-OHDA (9 micrograms/4 microliters/4min) into the medial forebrain bundle. The animals were tested twice each on APO (0.05 mg/kg) and AMP (5.0 mg/kg). Following the behavioral tests, right and left striatum (STR) and substantia nigra (SN) were analyzed for catecholamine content by HPLC-EC. The results showed that an animal that had greater than 99% (maximal) depletion of DA rotated well on either APO (500/hr) or AMP (300/hr). However, many sub-maximally lesioned rats were seen to rotate adequately on AMP but not on APO. We believe that APO-induced rotation behavior may be a better predictor of maximal DA lesions as compared to AMP. (Supported by USPHS grants NS09199 & AG06434)

DOPAMINE UPTAKE IN PREFRONTAL AND CINGULATE CORTEX AFTER CHRONIC AMPHETAMINE TREATMENT. M.A. Segall, G.A. Gerhardt, J.M. Masserano, Depts. of Pharmacology & Psychiatry, Univ. of Colorado Health Science Center, Denver, CO 80262.

Amphetamine (3mg/kg) given for 7 days to male rats induces a behavioral sensitivity to a single injection of amphetamine (1mg/kg) seven days after the last injection. In this study we found a 50 - 80% increase in the uptake of dopamine (DA) in prefrontal/cingulate cortex synaptosomes in rats chronically treated with amphetamine compared to saline controls. The increase in DA uptake is not seen 1 day after the last injection. There is also no increase in DA uptake into striatal or nucleus accumbens synaptosomes of chronically treated rats. Amphetamine blocks the uptake of DA in the control and chronically treated rats without any apparent change in sensitivity. With $1x10^{-7}$ M desipramine (DMI) blocking norepinephrine uptake sites, the increase in DA uptake in cortex was only about 30%. While with $1x10^{-7}$ M GBR 12909 blocking DA cells, there was a 70% increase in uptake of DA into norepinephrine sites. These data indicate that DA uptake into both DA and NE synaptosomes is increased in the medial prefrontal /cingulate cortex by chronic amphetamine treatment. (Supported by USPHS grants MH41551 and NS09199.)

FUNCTIONAL EFFECTS OF REPEATED APOMORPHINE ADMINISTRATION. L.J. Porrino[1] and F.E. Pontieri[2]. [1]Bowman Gray School of Medicine, Winston Salem, NC 27157 USA, [2]Department of Neurology, University of Rome, ITALY.

The repeated administration of apomorphine (APO) produces a progressive enhancement of its effects on motor behavior, in that stereotypic movements become more intense with repeated treatment. Using the 2-[^{14}C]deoxyglucose method, the distribution of alterations in functional activity associated with the repeated administration of APO was determined and compared to the distribution of changes associated with its acute administration. Male rats were treated with saline or APO (1 mg/kg, s.c.; x3). One week later APO or saline was administered and rates of glucose utilization measured in 3 groups: controls, pretreated and tested with saline; acute APO, pretreated with saline and tested with APO; and chronic APO, pretreated and tested with APO. The acute APO selectively increased rates of metabolism in portions of the nigrostriatal system, e.g. the globus pallidus, substantia nigra reticulata, and entopeduncular nucleus, and decreased metabolism in the lateral habenula, as reported previously (cf. McCulloch et al, 1982). In contrast, repeated APO treatment decreased metabolic rates in limbic areas, e.g. the nucleus accumbens, basolateral amygdala, hippocampus, and prefrontal cortex. Elevations in rates of metabolism, similar to those observed with acute APO treatment, were also seen in the nigrostriatal system, although these increases were somewhat attenuated when compared to the acute changes. The metabolic effects of repeated APO administration, then, are different from those of acute administration, and chronic APO treatment produces differential functional effects in the nigrostriatal and mesolimbic systems. Finally, the augmented behavioral response to repeated APO is not paralleled by corresponding increases in functional activity in any brain area examined.

ENVIRONMENTAL ENRICHMENT ALTERS AMPHETAMINE-STIMULATED DOPAMINE RELEASE AND SYNTHESIS IN THE NUCLEUS ACCUMBENS S.L. Bowling*, J.K. Rowlett & M.T. Bardo, Department of Psychology, University of Kentucky, Lexington, KY 40506.

In two experiments, rats were raised from postnatal day 21 to about day 60 in either an enriched (EC) or isolated (IC) condition. In the first study, amphetamine-stimulated release of dopamine (DA) was assessed in vitro from slices of the nucleus accumbens and striatum. DA and dihydroxyphenylacetic acid (DOPAC) levels were measured by high pressure liquid chromatography (HPLC). EC rats had less total DA and DOPAC than IC rats in the nucleus accumbens, but not the striatum. EC rats also released less DA than IC rats when stimulated by amphetamine (10^{-6}, 10^{-5} M). In the second study, an inhibitor of dihydroxyphenylalanine (DOPA) decarboxylase, NSD-1015 (100 mg/kg, i.p.) was administered after amphetamine (0, 0.5 or 2.0 mg/kg, s.c.). Tissue samples were assayed for DOPA using HPLC in order to estimate in vivo DA synthesis. In the nucleus accumbens, but not striatum, EC rats demonstrated less DOPA accumulation than IC rats. It was concluded that EC rats have a lower functional activity of the mesolimbic DA reward pathway relative to IC animals.

IN VIVO MECHANISM OF ACTION OF DEPRENYL: BIOCHEMICAL AND BEHAVIORAL STUDIES. C. Okuda, R. Kuczenski and D. S. Segal. Dept. of Psychiatry (0603), Univ. of California, San Diego, La Jolla, CA 92093.

In vivo microdialysis was used to concurrently measure the behavioral and striatal dopamine (DA) response following the administration of the irreversible type B selective monoamine oxidase (MAO) inhibitor, deprenyl (10 mg/kg), and its effects were contrasted to the action of an irreversible MAO-A inhibitor, clorgyline (4 mg/kg). Clorgyline administration demonstrated a response indicative of irreversible MAO inhibition, i.e., a gradual and enduring increase in extracellular DA and 3-methoxytyramine and a decrease in DOPAC and HVA which lasted for at least six hours. In contrast deprenyl administration produced rapid and transient changes in DA and its metabolites. This pattern of deprenyl effects closely resemble the neurochemical response following amphetamine administration (Kuczenski and Segal, J. Neurosci., 9:2051, 1989). Furthermore, our behavioral data demonstrated a stimulant-like increase in locomotor activity following deprenyl which was not observed following clorgyline. Taken together, these data suggest that systemic administration of deprenyl does not augment striatal extracellular DA by irreversible inhibition of MAO-B, but rather produces its effects on behavior and DA dynamics as a consequence of its conversion to amphetamine. (Supported by DA04157 and DA01568.)

THE ROLE OF DOPAMINE AND CALCIUM CHANNELS IN AMPHETAMINE-CONDITIONED LOCOMOTION. S.L. DiLullo*, K.F. McKenna, and M.T. Martin-Iverson. Neurochemical Research Unit, Dept. of Psychiatry, University of Alberta, Edmonton, Alberta, Canada T6G 2B7

Previous research has shown that dopamine (DA) D1 and/or D2 antagonists cannot block the establishment of amphetamine (AMP) -induced conditioned locomotion (Martin-Iverson and McManus, Br. Res. 521: 175, 1990). However, one DA receptor antagonist, pimozide, which is equipotent at blocking calcium (Ca) channels, has been shown to block stimulant-conditioned locomotion (Beninger and Hahn, Sci. 220: 1304, 1983). We directly tested the possibility that presynaptic catecholamine mechanisms are conditioned in rats by blocking the AMP-induced presynaptic release of DA and norepinephrine (NE) by pretreatment with alpha-methyl-para-tyrosine methyl ester (MPT, 50mg/kg,SC), or chemical lesioning of NE terminals with N-(2-chloroethyl) -N-ethyl-2-bromobenzylamine (DSP4, 50 mg/kg,IP). Secondly, we blocked L-type calcium channels with nimodipine (NIM, 10 mg/kg,SC) together or separately with DA D2 receptor blockade with haloperidol (HAL, .05-.2mg/kg,IP). All drug treatments were given during conditioning with AMP (1.5mg/kg, SC) but not on the test day. Both MPT and HAL blocked unconditioned AMP-induced locomotion and defecation, but did not block AMP-conditioned responses. DSP4 had no effect on either AMP-unconditioned or conditioned locomotion. NIM attenuated AMP-unconditioned but not conditioned locomotion. NIM and HAL treatments combined blocked AMP-unconditioned locomotion and attenuated AMP-conditioned locomotion. These results indicate that DA but not NE mediates the unconditioned effects of AMP. Actions on DA receptors alone, calcium-independent AMP-induced DA release, and NE do not mediate the establishment of AMP-conditioned behaviors. However a combination of DA D2 receptor blockade and blockade of L-type Ca channels attenuates the AMP-conditioned responses. Funding by AMHRF.

493.7

BEHAVIORAL CLAMPING ANALYSIS OF AMPHETAMINE-INDUCED EFFECTS ON STRIATAL SINGLE-UNIT ACTIVITY IN FREELY MOVING RATS: ROLE OF CORTICAL AFFERENTS. J.L. Haracz, J.T. Tschanz*, Z.R. Wang*, K.E. Griffith*, and G.V. Rebec. Prog. Neural Science, Dept. Psychology, Indiana University, Bloomington, IN 47405.

Our recordings of striatal single-unit activity in freely moving rats showed that amphetamine (AMP) typically excites motor-related and inhibits nonmotor-related neurons (Haracz et al., Brain Res., 489:365, 1989). Because motor-related cells regularly increase activity during movement, AMP-induced excitations may reflect a behavioral feedback response rather than a primary drug effect. This possibility was assessed with a new behavioral clamping method in which rated videotapes were used to match pre-AMP exploratory behaviors with similar post-AMP behaviors. Firing rates were compared within each match. AMP (1.0 mg/kg, sc) significantly enhanced movement-related activity of motor-related cells, suggesting a direct drug effect in exciting striatal neurons independent of behavioral feedback. This effect is abolished in rats with bilateral ablations of frontal and sensorimotor cortex, but not in sham-lesioned animals. Thus, AMP-induced excitations of striatal neurons require intact corticostriatal projections. Preliminary data from striatal nonmotor-related cells, however, indicate that such projections are not required for AMP-induced striatal inhibitions. These results suggest that AMP, possibly by enhancing dopamine neuromodulation, facilitates or inhibits the activity of striatal neurons that respectively receive substantial or little cortical input. [Supported by USPHS grant DA 02451.]

INCREASES IN EXTRACELLULAR DOPAMINE AND LOCOMOTION AFTER DIRECT INFUSION OF PHENCYCLIDINE INTO THE NUCLEUS ACCUMBENS OF THE RAT: A DIALYSIS AND BEHAVIORAL STUDY. L. D. McCullough and J. D. Salamone. Dept. of Psychology, Univ. of Connecticut, Storrs, CT 06269-1020.

Two studies were conducted to provide a further characterization of the neurochemical and behavioral effects of phencyclidine (PCP). The first experiment utilized in vivo microdialysis to measure extracellular dopamine (DA) concentrations after PCP administration into the nucleus accumbens (ACC). Rats were implanted with dialysis probes into the ACC and were tested for two days. Rats received either PCP (0.4×10^{-4} M dissolved directly into the perfusing medium) for two 45 min sessions, or continued perfusion with the normal medium, in a random order. PCP significantly increased extracellular DA levels. In a second experiment, chronic indwelling cannulae were implanted bilaterally into the ACC. Rats were injected with 1.0 µl of either saline or PCP (30.0 µg or 60.0 µg) in random order on 3 separate days, and placed in a motor activity chamber. PCP caused a dose-related increase in locomotion, with 60 µg causing the largest increases in motor activity. Little or no headweaving or ataxia was observed after injection of PCP. These results suggest that PCP can elevate extracellular DA concentrations by actions on the terminal regions of the DA neurons, and that these effects are related to some of the stimulant properties of PCP.

493.9

THE EFFECT OF INTRA-ACCUMBENS AMPHETAMINE ON LATENT INHIBITION USING AN ON-BASELINE, WITHIN-SUBJECT DESIGN. A.S.Killcross* and T.W.Robbins,(SPON: Brain Research Association). Dept. of Exp. Psychology, University of Cambridge, Cambridge, CB2 3EB, UK.

Latent inhibition (LI) is a phenomenon in which repeated, non-reinforced exposure to a stimulus retards subsequent conditioning to that stimulus. This is generally considered to be the result of learning to ignore or not to attend to the preexposed stimulus, and as such LI is commonly used to assess the influence of drugs and lesions on attentional processes. Several recent experiments have demonstrated that low doses of amphetamine, given acutely during preexposure and conditioning, abolish LI in a subsequent test session. These effects have been attributed to amphetamine-induced changes in mesolimbic dopamine (DA) function. The aim of this experiment was to test this hypothesis directly by examining the effects of intra-accumbens amphetamine on LI. In a within-subjects design with rats, LI was mapped across four conditioning trials using a conditioned suppression procedure. Animals that received bilateral infusions of d-amphetamine (1µl, 10µg/µl) immediately prior to preexposure and conditioning sessions showed a single trial retardation in conditioning, but subsequently developed a LI effect comparable to that of animals receiving control infusions of vehicle. These results provide no support for the hypothesis that the mesolimbic DA system plays a role in the attentional processes producing LI. It is likely that the decrements in LI found following acute, peripheral injections of amphetamine are due either to non-specific behavioural effects of the drug, or to effects of the drug on non-mesolimbic systems.

493.10

EXTRACELLULAR MONOAMINE LEVELS ARE DISSOCIATED FROM CHANGES IN LOCOMOTOR ACTIVITY FOLLOWING MEDIAL PREFRONTAL CORTEX ABLATION. E. Castañeda, D. Fiorino*, G. Mittleman and I.Q. Whishaw. Dep'ts. of Psychology, Arizona State University, Memphis State University & University of Lethbridge, Lethbridge, Alberta T1K 3M4.

Evidence suggests that some of the behavioral changes that follow cortical injury are produced by compensatory changes in the striatum. We examined the motor activity of rats that had received bilateral medial frontal cortex lesions and also examined extracellular monoamine levels in caudate nucleus and nucleus accumbens using *in vivo* microdialysis. Medial prefrontal cortex damaged rats displayed an attenuation in locomotor behavior during baseline measures and after an amphetamine injection (1.5 mg/kg, s.c.) one day after injury. In contrast, after two weeks recovery animals displayed heightened locomotion in relation to controls in response to amphetamine. There were no changes in extracellular levels of mesotelencephalic catecholamines (dopamine, DOPAC & HVA) at any time; and the serotonin metabolite, 5-HIAA, displayed a significant enhancement in nucleus accumbens extracellular levels, but only after an amphetamine challenge given on the day following medial prefrontal cortex lesions. The implications for non-dopaminergic mechanisms that might be responsible for recovery of behaviors traditionally thought to be mediated by mesotelencephalic dopamine systems will be discussed.

493.11

IBOTENIC ACID LESIONS OF THE MEDIAL PREFRONTAL CORTEX, DORSAL OR VENTRAL HIPPOCAMPUS DIFFERENTIALLY AFFECT RESPONSE TO FG-7142 IN THE RAT. Barbara K. Lipska, George E. Jaskiw, Daniel R. Weinberger. Clinical Brain Disorders Branch, IRP, NIMH, Neuroscience Center at St. Elizabeths, Washington, DC 20032.

The mechanism by which the anxiogenic ß-carboline FG-7142 reduces exploratory locomotor activity in rats is not known. FG-7142 has been shown to selectively enhance DA release within the medial prefrontal cortex (MPFC) and to reduce 5HT transmission in the hippocampus. Both these regions have been implicated in the control of exploratory activity. To assess the anatomical specificity of FG-7142-induced reduction of locomotion, we evaluated its effects in rats with ibotenic acid (5-6 µg/0.5 µl) lesions of MPFC, dorsal (DH) or ventral hippocampus (VH) as compared to the corresponding sham-operated animals (infused with buffered saline). We found that FG-7142 suppressed the locomotor behavior in control and VH lesioned rats. Its effect on locomotor reduction was potentiated in MPFC lesioned rats, but abolished in DH rats. These results suggest a specific role of the DH in mediating FG-7142-induced attenuation of exploration, possibly related to specific serotonergic projections to this region.

493.12

DISCRIMINATORY ACTION OF GABA AND VIGABATRIN ON ISOLATION-INDUCED OFFENSIVE BEHAVIOR IN MICE. M.Y.Hasan,R.D.E.Sewell and P.J.Nicholls. SPON: Brain Research Association, Division of Pharmacology, Welsh School of Pharmacy, UWCC, PO Box 13, Cardiff CF1 3XF,UK

GABA is involved in modulating mood and behavior and inhibition of GABA-transaminase reduces offensive behavioral expression in mice. Vigabatrin is an irreversible inhibitor of GABA-transaminase and increases GABA levels in the CNS. This study compares the effects of Vigabatrin with GABA on several behaviors including locomotion, non-social, social and in particular offensive profiles. These behaviors were assessed in male ICI-GB1 mice starting weight (20-25g,n=10) using a modified isolation procedure previously described by this laboratory. The behavioral interaction was observed between 3 week-isolated and group-housed individuals over a test period of 10 min. Pretreatment with GABA (<400mg/kg ip) or Vigabatrin (<600mg/kg ip) gradedly reduced the incidence of offensive encounters/animal, % animals displaying offense and delayed the onset of offense without modifying social, non-social and locomotor behaviors. Thus GABA and Vigabatrin anti-offensive activity is comparable and occurs at behaviorally selective doses.

PREVENTION BY MORPHINE OF PENILE ERECTION AND YAWNING INDUCED BY APOMORPHINE AND OXYTOCIN. M.R. Melis, R. Stancampiano* and A. Argiolas. B.B. Brodie Dept. of Neurosciences, Univ. of Cagliari, Via Porcell 4, 09124 Cagliari (Italy).

The effect of morphine administered systemically or into the paraventricular nucleus of the hypothalamus (PVN) on penile erection and yawning induced either by oxytocin or by the dopaminergic agonist apomorphine was studied in male rats. Systemic morphine (0.5-5 mg/kg i.p.) prevented in a dose-dependent manner penile erection and yawning induced by oxytocin (30 ng i.c.v.) or by apomorphine (80 μg/kg s.c.). Morphine (0.1-5 μg), but not U-69,593 (5 μg), injected into the PVN 10 min before oxytocin or apomorphine, prevented penile erection and yawning induced by the unilateral PVN microinjection of oxytocin (10 ng) or apomorphine (50 ng). The morphine effect was abolished by naloxone (1 and 3 mg/kg i.p.) 15 min before morphine. The results suggest that morphine prevents apomorphine- and oxytocin-induced responses by inhibiting the activity of oxytocinergic neurons through μ-type receptors in this hypothalamic nucleus. The finding raise the intriguing possibility that opiates inhibit sexual behavior by inhibiting central oxytocinergic transmission.

DRUGS OF ABUSE—AMPHETAMINE AND NICOTINE

ROTATIONAL BEHAVIOR AND CONCURRENT STRIATAL DOPAMINE OVERFLOW FOLLOWING AMPHETAMINE, PHENCYCLIDINE AND MK-801. A. Mele, D.J. Fontana, and A. Pert. BPB / NIMH, Bethesda, MD.

It has been suggested that some of the behavioral and pharmacological effects of PCP, like amphetamine, are determined through increases in dopaminergic (DA) function. The purpose of this study was to compare the effects of PCP, amphetamine, and the NMDA antagonist, MK-801, on rotational behavior and on concurrent striatal DA overflow in rats with unilateral nigrostriatal lesions. Rats were lesioned in the left MFB with 6-OHDA and implanted with a guide cannula in the striatum contralateral to the lesion. One week following surgery, a microdialysis probe was inserted into the striatum through the implanted guide. The animals were placed in a rotometer which had been modified to allow the collection of dialysate. Levels of DA and its metabolites were measured in the dialysate with HPLC-EC procedures at 20 min intervals. Following stabilization of DA levels, the animals were injected i.p. with either PCP (10 mg/kg), amphetamine (1 mg/kg), or MK-801 (0.25 mg/kg). All three drugs produced significant increases in rotational behavior ipsilateral to the lesion. Only amphetamine and PCP, however, elicited increases in striatal DA overflow. The effects of PCP on striatal DA were rather modest (approximately 50% increase over baseline at peak effect), whereas its effect on rotational output was quite dramatic (approximately 60 rotations/20 min at peak effect). Amphetamine, on the other hand, produced a more robust effect on DA (approximately 150% increase at peak effect) at the same time elevating rotational output to only 40 rotations at peak. MK-801 had behavioral effects similar to amphetamine, but did not produce any alterations in striatal DA. Thus, there appears to be a significant dissociation between the effects of these drugs on rotational behavior and their ability to alter striatal DA function. It is suggested that the modest DA actions of PCP contribute little to determining its effects on nigrostriatal functions.

METHAMPHETAMINE-INDUCED STIMULUS PROCESSING DEFICITS. B.G. Cooper*, A.E. Butt, D.J. Hardy*, & G.K. Hodge. Psychology Dept., University of New Mexico, Albuquerque, NM 87131-1161.

Neurotoxic doses of methamphetamine (MA) resulted in cognitive deficits in rats tested in an operant discrimination task. Animals were shaped to bar-press and then received four s.c. injections (2 hours between injections) of either saline or MA (10 mg/kg or 12 mg/kg). One week post-injection, animals were tested in an operant discrimination task. The first phase of the task required animals to press a bar for a food reward during the presentation of a 10-sec target light. A 10-sec period of darkness followed the target light; bar-presses during this period were recorded as errors. During the second phase of testing, a 10-sec distractor light followed the target light instead of darkness. Errors were penalized in this phase by delaying the onset of the target light by an additional 10 sec. During the third phase of testing, the target window was reduced to 3 sec, with distractor light and penalty conditions remaining constant. Results from the second phase of testing showed an initial increase in errors in the 10 mg/kg group, followed by rapid recovery; the 12 mg/kg group showed a more prolonged increase in errors with subsequent recovery. The third phase of testing was characterized by a pronounced increase in errors in both MA groups. Results suggest the inability of MA-treated rats to alter response patterns as task parameters change.

MDMA'S EFFECTS ESTABLISH A CONDITIONED PLACE PREFERENCE AND ELICIT SIGNS OF SEXUAL AROUSAL AMONG RATS. E.J. Bilsky* and L.D. Reid. Rensselaer Polytechnic Institute, Troy, NY 12180.

Studies of methylenedioxymethamphetamine (MDMA) are of interest because of its potential addiction liability and its neurotoxicity. Previously, we have demonstrated that MDMA establishes a positive conditioned place preference (CPP) among rats. Doses of 30 microgram/kg MDL 72222, a selective serotonin 5-HT3 antagonist, and 30 mg/kg CGS10746B, two compounds that attenuate the release of dopamine, blocked the establishment of a MDMA CPP. The data lead to the suggestion that MDMA's ability to elicit positive affect (and, thereby, positive reinforcement) is modulated by dopaminergic pathways. In observing rats being conditioned with a 6.3 mg/kg dose of MDMA, the ejaculation of seminal plugs was noted. With the first injections, in one experiment: (a) rats receiving saline or naltrexone (56 mg/kg, SC, 4 hr before conditioning) almost never left plugs in the place of conditioning, while (b) 7 of 12 rats receiving only MDMA, and (c) 12 of 12 rats receiving MDMA and naltrexone left plugs.

***IN VITRO* METABOLISM OF 6-HYDROXY-3,4-(METHYLENEDIOXY)METHAMPHETAMINE TO THE NEUROTOXIN, 2,4,5-TRIHYDROXYMETHAMPHETAMINE.** H.K. Lim*, W. Stevens and R.L. Foltz*, *Center for Human Toxicology, Dept. Pharmacology and Toxicology and Dept. Anatomy, University of Utah, Salt Lake City, UT 84112.

Since O-dealkylation has been reported as a primary *in vivo* metabolic pathway for 3,4-(methylenedioxy)methamphetamine (MDMA) in the rat, it is likely that the previously identified aromatic hydroxylated metabolites of MDMA (Lim and Foltz 1990) are further metabolized by O-dealkylation to compounds similar in chemical structure to the potent neurotoxin, 6-hydroxydopamine. Thus, this study examines the *in vitro* rat liver metabolism of 6-hydroxy-3,4-(methylenedioxy)methamphetamine (6-OH-MDMA) to 2,4,5-trihydroxymethamphetamine (THM). THM was found to cyclize to 5,6-dihydroxy-1,2-dimethylindole (DHDMI) when incubated in fortified rat liver S-9 fraction (Lim and Foltz, 1990). Selected reaction monitoring of the daughter ion at m/z 218 from DHDMI provided a highly sensitive method for the detection of THM. Comparison of the daughter ion profiles corresponding to the *in vitro* incubate containing 6-OH-MDMA and control indicated the presence of a peak not found in the control. Conclusive identification of this peak as DHDMI was from co-injection with synthetic DHDMI. Addition of SKF-525A, 1-aminobenzotriazole and quinidine resulted in 100, 76 and 100 % inhibition of the*in vitro* metabolism of 6-OH-MDMA. This study conclusively identified THM as an *in vitro* metabolite of 6-OH-MDMA. Furthermore, the metabolism of 6-OH-MDMA to THM is cytochrome P-450 dependent; the specific cytochrome P-450 isozyme P450IID6 appears to be involved. (Supported by NIDA grant 1RO1 DA 05860-01).

EFFECT OF 2,4,5-TRIHYDROXYAMPHETAMINE ON MONOAMINERGIC SYSTEMS IN THE RAT BRAIN. I.M. Elayan*, M. Johnson, G.R. Hanson, K.H. Lim*,R.L. Foltz* and J.W. Gibb. Department of Pharmacology and Toxicology. University of Utah, Salt Lake City, Ut 84112.

This study was designed to test the effect of a new amphetamine derivative, 2,4,5-trihydroxyamphetamine (THA), on the monoaminergic systems in the rat brain after intraventricular injection. In the long-term study, male Sprague-Dawley rats (200-280 g) were sacrificed one week after the injection of three different doses of THA (0.25, 0.5, or 1.0 µmole in 20 µl of 0.1% ascorbate in saline). A control group was injected with the same volume of the vehicle. Hippocampal tryptophan hydroxylase (TPH) activity was markedly reduced to 5%, 1%, and 7% of control by 0.25, 0.5, and 1.0 µmole THA, respectively. TPH activity in the striatum was decreased to 74%, 81%, and 56% of control and sriatal tyrosine hydroxylase (TH) activity was reduced to 67%, 10%, and 19% of control, with the same doses, respectively. Hippocampal norepinephrine levels were reduced to 10%, 18%, and 16% of control. In the short-term experiment, the rats were sacrificed 3 hours after the injection of THA (1.0 µmole) or saline. Hippocampal and striatal TPH activity were decreased to 8% and 79% of control, respectively. Striatal TH activity was reduced to 75% of control. Hippocampal norepinepherine was reduced to 16% of control. This study demonstrates that THA is a potent compound that decreases hippocampal and striatal TPH and TH activity when administered intraventricularly. (Supported by USPHS grants DA 00869, DA 04222 and DA 05860).

494.6

FUNCTIONAL INTERACTIONS OF LIMBIC AFFERENTS TO THE VENTRAL STRIATUM WITH MESOLIMBIC DOPAMINE: STUDIES OF CONDITIONED REINFORCEMENT AND LOCOMOTOR ACTIVITY IN THE RAT. L.H. Burns*, B.J. Everitt, and T.W. Robbins. Depts. of Experimental Psychology and Anatomy, Univ. of Cambridge, Cambridge, U.K. (SPON: European Brain and Behaviour Society).

Intra-accumbens d-amphetamine enhances the behavioral control of reward-related stimuli (or conditioned reinforcers) via dopaminergic mechanisms. This study examines the contributions of different limbic afferents to the ventral striatum in the amphetamine-induced potentiation of conditioned reinforcement. Rats were trained to associate a light+noise stimulus (the CR) with reward and then tested in extinction for the acquisition of a new response, maintained by this conditioned reinforcer. Excitotoxic lesions of either the basolateral amygdala or the ventral subiculum suppressed responding maintained by the conditioned reinforcer, with the greatest effect at the higher doses of intra-accumbens d-amphetamine. Similar results were found following excitotoxic lesions of the ventral striatum itself or following intra-accumbens infusions of low doses of NMDA receptor or quisqualate/AMPA receptor agonists and antagonists. Control experiments assessed the effects of these treatments on sucrose consumption and locomotor activity. The results suggest that the behavioral control of reward-related stimuli is mediated by limbic afferents and their interaction with dopaminergic mechanisms in the ventral striatum.

494.7

INFLUENCE OF CORTICOSTERONE ON AMPHETAMINE SELF-ADMINISTRATION. P.V. Piazza, V. Deroche*, S. Maccari*, J.M. Deminière*, M. Le Moal and H. Simon. Lab. des Comportements Adaptatifs INSERM U259 - Univ. Bordeaux II. Domaine de Carreire 33077 Bordeaux Cedex-France.

Individual vulnerability to the reinforcing properties of drugs of abuse appears to be an essential characteristic predisposing humans to addiction. In rat we have previously shown that individuals with a higher locomotor reactivity and a longer corticosterone release in response to novelty (High Responders, HR) have a higher predisposition to acquire amphetamine self-administration (SA)(Science 1989 245:1551-1513). Animals with weak behavioral and endocrinological responses to novelty (Low Responders, LR) do not develop SA. In the present study we have investigated whether corticosterone levels have a direct influences on amphetamine SA. When animals naturally resistant to develop amphetamine self-administration where injected with corticosterone they developed this behavior. Such an effect was present both when corticosterone (0.36mg/Kg i.v.) was administered after 8 days of testing for SA ($P<0.01$), during which resistant animals do not develop SA, and when the hormone (50lg/20µl) was present in the SA solution in addition to amphetamine (10lg/20µl) ($P<0.05$). Corticosterone also modified SA of individuals that spontaneously acquired this behavior. In this case, and with both the protocols described above, the hormone decreased the intake of the drug of HR animals. This apparent opposite effect of corticosterone in the two groups of individuals is similar to the phenomenon observed when the amount of drug delivered for each injection is increased: there is a faster acquisition of this behavior and a decrease of the number of drug injections during SA. Thus, it is suggested that corticosterone acts on SA by increasing the reinforcing properties of amphetamine. The possible direct reinforcing effect of corticosterone is under investigation and will be discussed.

CENTRAL CORTICOSTEROID RECEPTORS AFFINITY IS REDUCED IN RATS PREDISPOSED TO DEVELOP AMPHETAMINE SELF-ADMINISTRATION. S. Maccari*, P.V. Piazza, J.M. Deminière*, L. Angelucci, H. Simon and M. Le Moal. INSERM U.259, Rue Camille St Saëns, 33700 Bordeaux, France, and Farmacologia II, Univ. Roma, P.le A. Moro,2 00185 Rome, Italy.

Recently, we suggested that reduced corticosterone feedback in the rat may be involved in the predisposition shown by some individual animals to develop amphetamine self-administration (SA) of amphetamine. This hypothesis was based on the following observations: i) animals which are predisposed to acquire SA have a longer secretion of corticosterone after stress; ii) life events, which induce a longer secretion of corticosterone after stress, also increase likelihood to acquire SA; iii) an experimental increase of corticosterone levels also increase the propensity to amphetamine SA. Since corticosteroid receptors are involved in corticosterone feedback sensitivity, we examined the relation between individual differences in amphetamine SA and characteristics of corticosteroid receptors in hippocampus, amygdala and hypothalamus. Rats were selected on the basis of reactivity to novelty and designed as: 1) High Responder (HR) rats, with high locomotor reactivity, prolonged corticosterone secretion in response to novelty, and fast acquisition of amphetamine SA; 2) Low Responder (LR) rats, with low locomotor response and short corticosterone secretion in response to novelty, which fail to acquire amphetamine SA. The HR animals showed a lower affinity of type I receptors in the hippocampus ($P<0.01$) and amygdala ($P<0.01$), and a reduced affinity of type II receptors only in the hippocampus ($P<0.05$). The receptors in hypothalamus were not different in the two groups. These data suggest that a reduced affinity of corticosteroid receptors in hippocampus and amygdala may be responsible for the longer secretion of corticosterone after stress observed in the HR animals. Thus, it is suggested that pharmacological manipulations of corticosteroid receptors may open new therapeutic strategies for compulsive drug use.

INFLUENCE OF CORTICOSTERONE ON INDIVIDUAL BEHAVIORAL FEATURES PREDICTING THE PROBABILITY TO ACQUIRE AMPHETAMINE SELF-ADMINISTRATION V. Deroche*, P.V. Piazza, S. Maccari*, J.M. Deminière*, M. Le Moal and H. Simon. Lab. des Comportements Adaptatifs INSERM U259 - Univ. Bordeaux II. Domaine de Carreire 33077 Bordeaux Cedex-France.

In previous work (Science, 1989,245:1551-1513), we have shown that rats with a higher predisposition (High Responders, HR) to acquire amphetamine self-administration (SA) show higher locomotor activity in response to novelty and to amphetamine administration and also during the nocturnal period. Indeed animals with a weak behavioral response to these environmental and pharmacological challenges (Low Responders, LR) did not develop SA. HR animals also have a longer corticosterone secretion in response to novelty than LR groups. In the present study we have investigated whether corticosterone levels may have a direct influence on locomotor activity and on locomotor responses to amphetamine. The higher locomotor activity of HR animals seems to be partially dependent on plasma corticosterone levels. Thus, when HR animals are adrenalectomized and implated with corticosterone pellets, which maintain corticosterone levels in a physiological but fixed range, the locomotor activity of HR animals drop to the level of the LR's ($P<0.05$). Moreover, the addition of corticosterone (50mg/ml) to the drinking water of LR's increased their nocturnal locomotor activity to the level of HR animals ($P<0.01$). Corticosterone levels also may influence the locomotor response to amphetamine. Thus, when HR and LR animals do not differ in corticosterone levels amphetamine administration induces in the two groups the same increase in locomotor activity. Conversely when HR animals show higher corticosterone levels (i.e. after 120 min of exposure to novelty) amphetamine induces in this group of rats a greater increase of locomotor response ($P<0.01$). Furthermore, the addition of corticosterone in drinking water for 15 days (50mg/ml)induced an increase of locomotor response to amphetamine ($P<0.01$).These results suggest that corticosterone levels is an important biological feature determining individual differences in behaviors related to the predisposition to psychostimulant SA.

494.10

THE BEHAVIORAL EFFECTS OF ACUTE AND CHRONIC ADMINISTRATION OF 4-METHYLAMINOREX (4-MAX) ON ACTIVITY IN THE RAT. Batsche, K., Ashby, C. R. Jr, Pan, H. S., Kimura, C., Schwartz, J., and Wang, R. Y. Department of Psychiatry, SUNY Stony Brook, Putnam Hall, South Campus, Stony Brook, N.Y. 11794-8790.

The compound 4-methylaminorex is a phenylisopropylamine derivative with 4 isomers: trans 4R, 5R; trans 4S, 5S; cis 4S, 5R; and cis 4R, 5S. This compound produces sympathomimetic, stimulant, and anorectic effects similar to amphetamine and psychological effects similar to amphetamine and cocaine. We show here that acute subcutaneously administration of the cis 4R, 5S isomer of 4-MAX (.3, 1, and 3 mg/kg) in rats caused dose-dependant increases in horizontal activity. The drug effect for 3 mg/kg lasted for more than 3 hrs with the peak of activity around 1.5 hrs following injection of the drug. The locomotor activity for the dose 10 mg/kg was reduced relative to that of 3 mg/kg but was still larger than any other dosage assessed. At 10 mg/kg stereotyped sniffing was markedly increased. Our preliminary results show that the acute effects of the 4R, 5S isomer at 3 mg/kg were significantly attenuated by the dopamine D2 receptor antagonist eticlopride at .5 mg/kg IP. Chronic treatment with 4R, 5S isomer (3 mg/kg) for 7 days and rechallenged following 1 day drug withdrawal caused a marked desensitization in the horizontal activity. By contrast, in the same treatment paradigm followed with 10 days withdrawal and rechallenged with 4-MAX (4R, 5S), no desensitization was observed. In fact, the horizontal activity peaked earlier in this group than the control indicative of a sensitizing response. In conclusion, similar to amphetamine, 4-MAX dose-dependently increases locomotor activity. Unlike amphetamine, however, there was a sign of desensitization following chronic treatment.
(supported by USPHS grants MH-41440 and MH-00378).

494.11

EFFECT OF 4-METHYLAMINOREX ON MIDBRAIN DOPAMINE CELLS. C. Vogel, C.R. Ashby, Jr., H. Pan, L. Fishkin, Y. Minabe and R.Y. Wang. Dept. of Psychiatry and Behav. Sci. SUNY at Stony Brook, Putnam Hall-South Campus, Stony Brook, NY 11794-8790

4-methylaminorex (4-MAX, U4Euh), a phenylisopropylamine derivative, is a potent psychostimulant and anorectic agent, similar to amphetamine. It consists of four isomers: trans 4R, 5R, trans 4S, 5S, cis 4R, 5S and cis 4S, 5R. The aim of the present study was to compare the potency and efficacy of isomers of 4-MAX to inhibit the firing of midbrain dopamine (DA) cells. Single cell recording techniques were used to record DA cells in both the substantia nigra pars compacta (A9) and the ventral tegmental area (A10) in chloral hydrate anesthetized Sprague Dawley rats. All 4-MAX isomers dose-dependently suppress the firing of both A9 and A10 DA cells. In A10 DA cells the most potent isomer was trans 4S, 5S (IC50 = 0.56 mg/kg, i.v.) followed by the cis isomers (IC50s for cis 4S, 5R and 4R, 5S were 6.5 and 6.1 mg/kg, respectively) and the trans 4R, 5R isomer (12.8 mg/kg produced 43% inhibition). The same rank order of potency holds for the A9 DA cells. However, the trans 4S, 5S appears to be 6.6 fold less potent in inhibiting A9 compared to A10 DA cells. This result is surprising because the S(+)amphetamine stimulus generalized to all 4-MAX isomers and S(+)amphetamine appears to suppress equi-potently both A9 and A10 DA cells. Although systemically administered S(+)amphetamine has been shown to stimulate DA release more effectively in the nucleus accumbens as compared to the caudate, whether the latter finding can be extended to 4-MAX isomers remains to be demonstrated. In conclusion, our results show that similar to the action of S(+)amphetamine, 4-MAX isomers dose-dependently suppress the firing of both A9 and A10 DA cells. Unlike S(+)amphetamine, 4S, 5S isomer at low doses appears to exert its action preferentially upon A10 DA cells. (Supported by USPHS grants MH-41440 and MH-00378.)

494.12

REPEATED ADMINISTRATION OF AMPHETAMINE, AT LOW DOSES, CAUSES SUBSENSITIVITY OF A10 SOMATODENDRITIC DOPAMINE AUTORECEPTORS. R.S.J. Nassar and F.J. White. Wayne State Univ. Sch. Med., Dept. Psychiatry, Cellular and Clinical Neurobiology Program, Neuropsychopharmacology Laboratory, Lafayette Clinic, Detroit, MI 48207.

Repeated administration of amphetamine (AMPH), at low doses, produces an enhancement of its locomotor stimulating effects. This sensitization involves enhanced transmission within the mesoaccumbens dopamine (DA) system, including increased DA releasibility. Recent evidence indicates that an additional action of repeated AMPH within the ventral tegmental area (VTA) is necessary for the initiation of sensitization. We have suggested that subsensitivity of impulse-regulating somatodendritic DA autoreceptors, and the resulting increased activity of A10 DA neurons within the VTA, may be important triggering events leading to other, more persistent, neuronal alterations responsible for maintaining sensitization. Previous studies of DA autoreceptor subsensitivity have used AMPH doses which are higher than those necessary for the induction of sensitized locomotion. Therefore, the present study determined the ability of a low d-AMPH dosing regimen (1.0 mg/kg/day, i.p., 5 days on/2 days off/5 days on), known to produce locomotor sensitization, to cause subsensitivity of A10 DA autoreceptors. Anesthetized rats that had received either repeated AMPH or saline were prepared for single cell recording 3-4 days after the last injection. The inhibitory effects produced by i.v. challenge with either the mixed D1/D2 receptor agonist apomorphine or the D2/D3 receptor agonist quinpirole on A10 DA cell firing were significantly reduced in the AMPH-treated rats. Thus, somatodendritic A10 DA autoreceptor subsensitivity occurs following repeated administration of AMPH at doses which produce sensitization to its locomotor stimulant effects. (Supported by MH-40832 and DA-04093).

DIFFERENTIAL BRAIN REGIONAL DISTRIBUTION OF [^{3}H]D-AMPHETAMINE AFTER PERIPHERAL ADMINISTRATION R. Zaczek, C. Dersch and N.M. Appel. NIDA Addition Res Ctr, Balto., MD 21224

While much work has been done on the pharmacokinetic and distribution profiles of d-amphetamine (d-AMPH) subsequent to peripheral administration, controversy remains as to whether d-AMPH accumulates uniformly or unevenly across brain regions. We examined the in vivo accumulation of [^{3}H]d-AMPH after peripheral administration and found that both dose and time can be confounding factors when addressing the question of its brain distribution. At times up to 12 min post subcutaneous injection of 5mg/kg [^{3}H]d-AMPH , the regional distribution of d-AMPH appeared uniform. However, after 30 minutes a distinct differential distribution d-AMPH in brain became apparent. At 45 minutes, the areas with highest levels of d-AMPH were the neocortex and hippocampus (38 ± 7 and 38± 4 pmoles/mg wet wt, respectively). Areas with the lowest levels of d-AMPH were the pons-medulla and the cerebellum (26 ± 3 pmoles/mg wet wt). At lower doses (0.5mg/kg) of [^{3}H]d-AMPH, the distribution of the drug in brain appeared uniform. We found two reasons for the discrepancy between the distribution of tritium after injections of 0.5 and 5 mg/kg [^{3}H]d-AMPH. First, unmetabolized [^{3}H]d-AMPH made up a much smaller percentage of the total tritiated compounds found after 0.3 mg/kg (30 ± 18%) than after 3 mg/kg [^{3}H]d-AMPH (80 ± 15%). Second, rats injected with 0.5 mg/kg [^{3}H]d-Amph and subsequently subjected to perfusion fixation possessed identical brain regional distributions of [^{3}H]d-AMPH as rats injected with 5 mg/kg [^{3}H]d-Amph. These data suggest that the apparent uniform regional distribution after the low dose was due to serum contaminating brain. We conclude that d-AMPH accumulates differentially into various brain areas after peripheral administration. The rostro-caudal gradient of d-AMPH accumulation is reminiscent of the phenomenon of AMPH sequestration we have previously described.

ALTERATIONS IN MESOLIMBIC AND NIGROSTRIATAL DOPAMINE OVERFLOW FOLLOWING CHRONIC AMPHETAMINE. K.M. Wozniak, A. Mele, M. Linnoila and A. Pert.LCS/NIAAA and BPB/NIMH, Bethesda, MD 20892.

Certain behavioral effects of amphetamine increase in intensity and duration with repeated administration. The precise mechanism underlying this phenomenon of "behavioral sensitization" is unknown, although there is evidence for enhanceed synaptic accumulation of dopamine (DA) in chronically treated rats following an acute challenge. Using in vivo microdialysis, we have examined and compared the effect of various doses of amphetamine, applied both to the terminal regions and systemically, on DA overflow in rats chronically treated with amphetamine as compared to saline. Focal application of amphetamine into the striatum resulted in similar increases in DA in both treatment groups when administered 24 hr. after cessation of a 7-day (3 mg/kg, i.p., daily) treatment regimen. Similarly, there was no difference in either the n. accumbens or striatum between the two treatment groups following a systemic challenge of amphetamine (1 mg/kg, s.c.), either 24 hr. or 72 hr. after the chronic regimen. In contrast, a lower challenge dose of amphetamine (0.25 mg/kg, s.c.) elicited a larger increase in extracellular DA in the amphetamine-pretreated rats than in the control group, when administered 3 days after the chronic treatment regimen. Hence our preliminary data suggest that a pharmacological sensitization of dopamine systems after chronic amphetamine, which is apparently absent following certain acute challenges, can be unmasked following a systemic dose that produces relatively modest changes in dopamine. We are further investigating the exact nature of this process.

494.15

CORTICOSTERONE ACCELERATES THE DEVELOPMENT OF TOLERANCE TO NICOTINE-INDUCED ANALGESIA IN RATS A.R. Caggiula, L.H. Epstein*, S.M. Antelman*, S. Knopf* S. Saylor* and K.A. Perkins*. *Depts. of Psychology and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260*

We have previously shown that conditioned tolerance develops to some of the behavioral and endocrine effects of nicotine and Collins et al (1990) have recently suggested that a conditioned release of corticosterone (CORT) may contribute to this form of tolerance since chronic CORT reduces nicotine responsiveness in mice. Two studies tested the feasibility of this idea in male rats. In one, a single sc injection of 0.75 mg/kg of CORT prevented the analgesic response to sc 0.66 mg/kg of nicotine bitartrate (free base) given 5 min later, when compared to untreated controls. In a second study, males were given CORT (1 mg/kg), vehicle (ETOH + distilled water) or no injection 10 min before nicotine (.75 mg/kg) and tested for nicotine-analgesia every other day for 10 days. Significant tolerance developed more rapidly (1st vs 3rd injections) in the CORT pretreated rats compared to animals given only nicotine. A similar acceleration was produced by the vehicle pretreatment, which induced a significant release of endogenous CORT. These data are consistent with the hypothesis that a conditioned CORT response could contribute to the development of tolerance to some of nicotine's effects.

EXPOSING RATS TO A SINGLE BRIEF STRESSOR TWO WEEKS EARLIER MODIFIES THE RESPONSE OF PLASMA ACTH AND GLUCOSE TO ETHANOL (ETOH). S.M. Antelman*, A.R. Caggiula, S. Knopf*, D.J. Edwards and H. Barry III *Depts of Psychiatry, Psychology and Pharmacology/Physiology, Univ. of Pittsburgh, Pittsburgh, Pa. 15213*

We have shown that one exposure to a stressor can induce an extremely long-lasting alteration in the subsequent responsiveness of the organism to pharmacological or nonpharmacological stressors. This effect progresses with time since the first stressor and has been demonstrated using CNS, endocrine and immune endpoints, among others. The present study inquired whether one exposure to a stressor [an injection of isotonic saline or 200 or 750 mg/kg, 2-deoxy-d-glucose (2DG)] 2 weeks earlier would alter the effect of ETOH (1g/kg) on the stress-responsive hormones, ACTH, corticosterone (CORT) and glucose. These were measured at 5, 15 & 30 min. following ETOH, as were adrenal weights. At 5 min., ETOH itself significantly elevated both ACTH and glucose and this elevation was prevented in animals injected with saline 2 weeks earlier. At 15 min., significant elevation of ACTH and glucose occurred only in rats preexposed to 1 or both of our stressors 2 weeks earlier. Earlier stress failed to influence either the CORT response to ETOH or adrenal weights. Supported by MH24114 from NIMH & P50AA08746 from NIAAA.

RE-EXAMINATION OF PENTYLENETETRAZOL (PTZ)-LIKE EFFECT OF NICOTINE (NIC) AND ITS WITHDRAWAL. C.M. Harris, Dept. Pharmacol., New York Col. Osteo. Med., Old Westbury, NY. 11568

Two groups of rats were trained in a 2-lever choice task with food reward to discriminate the anxiogenic drug PTZ (12 mg/kg or 20 mg/kg) from saline. NIC substituted fully for PTZ and this effect depended upon both dose of NIC and training dose of PTZ. Tolerance to this subjective effect of NIC was evident during chronic infusion of NIC via osmotic pump for 7 days at 0, 10, 20 and 30 mg/kg/d. Chronic NIC dose-dependently reduced lever-pressing, food consumption, weight, and defecation. The magnitude of the weak PTZ-like stimulus previously found during withdrawal (Harris et al., Psychopharmacol. 90:85, 1986) depended neither on dose of chronic NIC nor on training dose of PTZ. These results indicate that NIC-withdrawal is not detected in a systematic manner by the PTZ discrimination. In contrast, the direct PTZ-like effect of NIC is both robust and systematic, suggesting that the acute anxiogenic effect of NIC may be mediated by a mechanism common to PTZ, while the withdrawal symptom "anxiety" is not.

PEMPIDINE-INDUCED ANTAGONISM OF PHYSIOLOGICAL AND BEHAVIORAL RESPONSES TO NICOTINE. W. Cao, S. Borch*, M.J. Marks, A.C. Collins. Institute for Behavioral Genetics, Univ.of Colorado, Boulder, CO 80309

Previous studies have demonstrated that pempidine both competitively and noncompetitively antagonizes central actions of nicotine. The purpose of the present study was to determine if genetic factors influence the sensitivities of mouse strains to pempidine blockade of the effects of nicotine in vivo. Both time course and dose response relationships for pempidine antagonism of effects of nicotine were determined. C57BL and DBA mice were pretreated with saline or pempidine (0.5-6.0 mg/kg, ip) at various time points prior to nicotine administration (1.5 mg/kg, ip). The responses to nicotine were measured using a battery of physiological and behavioral tests that includes alterations in respiratory rate, acoustic startle response, Y-maze activity, heart rate and body temperature. Dose response experiments (15 min. preinjection) indicated maximal inhibition at a pempidine dose of 1.0 mg/kg. Possible toxicological actions were seen at higher doses. The 1.0 mg/kg dose of pempidine was used to determine a time course for nicotine antagonism; maximal antagonism was seen 20 min following pempidine injection. Pempidine antagonism of nicotine's effects persisted for at least 90 min following acute treatment. Strain differences in sensitivity to pempidine-induced antagonism of nicotine's actions were defined. The results indicate that pempidine is very similar in potency to the classical nicotine antagonist, mecamylamine, and that is a useful agent for determining the function of brain nicotine receptors. Supported by DA-00116 and DA-03194.

ANIMAL MODEL OF NICOTINE DEPENDENCE AND ABSTINENCE SYNDROME P.N. Maultsby*, J.R. Lake, C.W. Cortes*, J.G. Lanier*, L.K. Roberts*, O.B. Wilson and D.H. Malin. Univ. of Houston-Clear Lake, Houston, TX 77058 and Baylor College of Medicine, Houston, TX 77030.

Very few animal models are currently in use for the recognized clinical problem of nicotine dependence and abstinence. This study introduces a rapid and convenient model using the rat. Male rats (250g) were continuously infused s.c. for 7 days via Alzet osmotic minipump with 0, 3 or 9 mg/kg/day nicotine tartrate in saline. Rats were observed before, during and after drug infusion on a modified checklist of opiate abstinence signs based upon a pilot experiment with nicotine-abstinent rats. All 3 groups showed few signs both before infusion and at the end of infusion, but there were large, significant and dose-related differences 16 hours after pump removal. ANOVA showed significant drug, time and interaction effects.

OVERALL ABSTINENCE SIGNS (M ± SEM)			
Nicotine Tartrate (mg/kg/day):	0	3	9
Last Infusion Day:	1.7±0.3	2.2±2.0	1.7±1.0
16 Hours Post-Withdrawal:	10.7±2.9	23.4±5.2	43.6±8.3

Most frequently observed signs during withdrawal included: teeth chatter, writhes/gasps, ptosis, tremors, shakes, and yawning. Sharp post-nicotine drop in locomotor activity and increases in food consumption and weight gain provided additional evidence of an abstinence syndrome. (Supported by Neuromedical Technology, Inc.)

ABNORMAL GANGLIOSIDE GD3 SYNTHESIS IN MUTANT MOUSE EMBRYOS. Seyfried, T.N. and Novikov, A.*, Boston College, Biology Dept., Chestnut Hill, MA 02167.

Gangliosides are a family of sialic acid-containing glycolipids that are proposed to function in cellular differentiation and adhesion. Although present in most cells and tissues, ganglioside concentration is greatest in neurons of the CNS. It is generally agreed, that neuronal ganglioside composition is regulated through two main metabolic pathways. The "a" pathway (comprising gangliosides GM3, GM2, GM1, and GD1a) and the "b" pathway (comprising GD3, GD2, GD1b, GT1b, and GQ1b). We previously found significant ganglioside abnormalities in E-11 and E-12 t^{w1}/t^{w1} mutant mouse embryos. The t^{w1} mutation is part of the T-locus complex on chromosome 17. These mutants express failed neural differentiation in the developing neural tube. The mutant ganglioside abnormalities involve reductions in "b" pathway gangliosides (especially GQ1b) and elevations in "a" pathway gangliosides. We proposed that these abnormalities could arise from a biosynthetic defect in the "b" pathway. To test this hypothesis we examined the in vitro activity of sialyltransferase 2 (SAT-2: EC2.4.99.8) in the normal (+/+ and $+/t^{w1}$) and t^{w1}/t^{w1} mutant embryos at E-12. This enzyme catalyzes the initial step for the synthesis of "b" pathway gangliosides. The enzyme assay was conducted for 4 hours at 37°C and contained (in 50 µl), substrate (GM3, 5 nmol), detergent (CF-54, 50 µg), donor (CMP-[^{14}C]-NeuAc, 25 nmol) cacodylate-HCl buffer (pH 6.43, 10 µmol containing 1 µmol MnCl2) and P2 embryo protein (50-100 µg). The labeled ganglioside products were separated using HPTLC and quantitated using liquid scintillation. The relative specific activity of SAT-2 (expressed as pmol ^{14}C-NeuAc incorporated into GD3/mg protein/hr) was significantly lower in the t^{w1}/t^{w1} embryos (227 ± 7, n=3) than in the +/+ (536 ± 24, n=6) or $+/t^{w1}$ (618 ± 33, n=6) embryos. The absence of an intermediate activity in the $+/t^{w1}$ embryos suggests that the reduced activity in the t^{w1}/t^{w1} mutants may be a pleiotropic effect of the mutation. (Supported by NIH grant 24826)

VITAMIN A INDUCED ALTERATIONS IN SECONDARY NEURULATION. T. Inagaki*, W. Goossens*, R.G. Higbee, D.G. McLone, and P.A. Knepper. Div Neurosurgery, Children's Memorial Med Center, Northwestern University, Chicago, IL 60614.

Vitamin A, in the proper amount and correct time, is crucial for embryonic development but if administered in excess, is a potential teratogen. To test the effects of vitamin A on secondary neurulation and canalization process, pregnant C-57 BL/6J mice were given IP injections of 5000 IU (Aquasol A) on gestation day 8.5 and 9.0 (during the time of closure of the posterior neuropore). On successive days, embryos were examined for neurulation defects and were processed for fluorescence microscopy using a battery of FITC-lectins and low light video microscopy. The majority of vitamin A embryos were abnormal, with absent tails (18%), kinked/short tails (64%) or caudal neural tube defects (2%). Light microscopy of tail-less embryos revealed alterations in the deposition of the basal lamina, delays in expression of sialic acid-containing glycoconjugates on the apical neuroepithelium and, in most embryos, the presence of multiple neuroepithelial rosettes with morphological features of neural tubes. These results suggest that excess vitamin A (or its active metabolites) altered the pre-set developmental timetable responsible for secondary neurulation.

DIFFERENTIATION PROCESS OF IV VENTRICLE OUTLETS IN MICE. K. Wang*,W. Goossens*, R.G. Higbee, D.G. McLone, and P.A. Knepper. Div Neurosurgery, Children's Memorial Med Center, Northwestern University, Chicago, IL 60614.

The differentiation process of the outflow mechanisms of cerebrospinal fluid (CSF) depends on remodeling of the primitive ventricular system. To examine the time at which the outlets of the IV ventricle become functional, embryonic C-57 BL/6J mice (gestation days 13, 14, 15, and 16) were investigated by: 1) injection of a CSF marker (0.5% potassium ferrocyanide-0.5% ammonium citrate [1:1] into the lateral or mesencephalic ventricles, followed by fixation and treatment with 2% hydrochloric acid (Prussian Blue reaction) and vibratome sections; or 2) injection of methyl methacrylate:monomer:catalyst: promoter (90:10:10:1, respectively) into the central canal, followed by fixation and scanning electron microscopy. The results of the Prussian Blue reaction product indicate that the outlets of the IV ventricle are functional by gestation day 15, and SEM revealed that a ciliated slit-like opening appeared in the lateral recesses of the IV ventricle. Studies are in progress to apply these approaches to determine whether the IV ventricle outlets and arachnoid development occur normally in genetic models of hydrocephalus (hy 3/hy 3) and the Chiari II malformation (dSp/dSp) in mice. (Supported in part by Kiwanis.)

495.4

LACTOSAMINE-CONTAINING GLYCOPROTEINS IN EMBRYONIC NORMAL AND ABNORMAL (NTD) SPINAL CORD. C.S.K. Mayanil*, W. Niforatos*, R. Higbee, D.G. McLone, and P.A. Knepper. Div Neurosurg, Northwestern Univ, Chicago, IL 60614.

Carbohydrates play roles in many cellular functions involved in neurulation, including cell recognition, adhesion, and differentiation. The tomato lectin, which recognizes lactosamine-containing glycoconjugates, was used to isolate glycoproteins from embryonic normal and abnormal (neural tube defect [NTD]) spinal cord. Neuroepithelial proteins were extracted in phosphate-buffered saline-2 mM EDTA-4 mM 2-mercaptoethanol-0.3 M lactose, followed by centrifugation at 100,000 x g for 1 hr. Supernatants were concentrated in centricon-10 to remove the lactose; 2 mg of protein was applied onto a pre-equilibrated tomato-lectin Sepharose 4B column. The bound proteins were eluted with chitotriose and chitotetraose in a ratio of 5:1. To date, we have analyzed bound fractions from rostral and caudal spinal cord proteins of normal and abnormal gestation day 14 delayed splotch embryos with NTD. As ascertained by SDS-PAGE, a set of lactosamine-containing proteins is characteristic of normal versus abnormal spinal cord; notably, a 15 kD and a 60 kD protein were not observed in the caudal NTD spinal cord. Studies are in progress to further characterize these glycoproteins and determine whether they function as carbohydrate-binding proteins. (Supported in part by Kiwanis.)

EFFECTS OF ACUTELY ADMINISTERED NALTREXONE ON SOCIAL BEHAVIOR OF AUTISTIC CHILDREN. I.F Borghese*, B.H. Herman, G.S. Asleson*, I. Chatoor*, M.B. Benoit*, P. Papero* & G. McNulty*. Brain Res Cen, CHNMC & Dept Psychiat, GWUSM, Washington, DC 20010.

Our group has hypothesized that heightened brain opioid activity and a dysregulation in POMC may underlie autism (Chamberlain & Herman, Biol. Psychiat 28:773 (1990)). Accordingly, we investigated the acute effects of placebo(P) and the opiate antagonist, naltrexone(N) (0.5, 1.0, 1.5, 2.0 mg/kg) in 13 autistic children (2F, 11M, 3-12y.o.).

The Childhood Autism Rating Scale(CARS) was used as an autism measure. Social behavior was assessed using the BRC Social Proximity Test where each subject was tested for two 10min sessions ("No Toys", "Toys") in a playroom with a volunteer(V) and a third 10min with mother(M). The room was divided into four quadrants(Q) (V in Q2).

CARS scores (n=5) were significantly lower in response to N (1.0, 1.5, and 2.0 mg/kg) than P ($p<.001$). ANOVA failed to indicate any significant effect of N on eye contact in either "No Toys" or "Toys" (n=13). We analyzed the effects of P vs N (1.0) on the pattern of Qs crossed (n=7). In the "No Toys" and "Toys" session, no significant effect of N (1.0) was obtained on the % time spent in Q2 with V. These data suggest that significant effects of N in autistic children can be obtained on a well established rating scale for autism. However, both eye contact and social proximity data failed to confirm the hypothesis of opioid involvement in the social dysfunction characteristic of autistics. Supported by grants from FDA, NICHD, and DuPont (to BHH)

PROLONGED ADMINISTRATION OF PIRACETAM TO DEVELOPING MICRENCEPHALIC RATS HAS LITTLE SALUTARY EFFECT ON MAZE LEARNING. A. Rabe, D. Dobrogowska*, A. Heaney*, and M.H. Lee. NY State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314.

Rats with severe micrencephaly (induced by a single in utero exposure to 30 mg/kg of methylazoxymethanol acetate on gestation day 15) have a life-long impairment in maze learning. In search of early interventions that could ameliorate the defect, we tried the cognition-enhancing drug piracetam which improves learning in adult rats with MAM-induced micrencephaly. We injected 18 micrencephalic and 17 normal Long-Evans rats with piracetam from day 2 to 2 mo of age. Two doses of the drug (50 or 100 mg/kg) or vehicle were injected s.c. five days a week. Body weight, developmental landmarks, and reflexes were monitored. Animals were trained to find a hidden platform in a water tank between the ages of 50 to 60 days. Piracetam had no effect on development in either group of rats. The drug had no effect on learning in the controls. Its effects on the micrencephalic animals (who were impaired on this task) were not clear-cut even though the high dose appeared to speed acquisition and lower the asymptote.

PATTERNS OF IMPAIRMENT IN DEVELOPMENTAL DYSCALCULIA. S.M. Sokol, P. Macaruso* and T.H. Gollan*. IHP Neurolinguistics Laboratory, Massachusetts General Hospital, Boston, MA 02108.

Utilizing a cognitive model developed in studies of acquired dyscalculia, we analyzed the number processing and calculation performance of several developmentally impaired children. Associations and dissociations of function in these children's data support the general architecture of the model as well as provide insight into the computational structure of individual sub-components.

Specifically, the ability to process numbers dissociated from the ability to calculate. Within the number processing system, Arabic and verbal subsystems proved functionally distinct, and within these subsytems, syntactic and lexical components were isolated which possess different representational properties. Finally, within the calculation system, mechanisms responsible for fact retrieval were found to be autonomous of those responsible for procedural planning and execution.

In addition to providing new data on the incidence and nature of developmental dyscalculia, our studies highlight the utility of a cognitive neuropsychological approach to the study of developmental impairments.

SUDDEN INFANT DEATH SYNDROME: POSTNATAL CHANGES IN THE NUMERICAL DENSITY AND TOTAL NUMBER OF NEURONS IN THE HYPOGLOSSAL NUCLEUS. J.R. O'Kusky and M.G. Norman*. Dept. of Pathology, Univ. of British Columbia, Vancouver, B.C., Canada V5Z 1M9.

It has been suggested that sudden infant death syndrome (SIDS) results from an abnormal development of neurons in brainstem nuclei involved in respiratory control. Tissue samples of brainstem were taken at autopsy from 27 SIDS victims and from 14 control infants without neurological disease (36-94 postconceptional weeks). Morphometric analyses were performed on serial Nissl sections through the hypoglossal nucleus. The volume of the nucleus, the numerical density (N_V, cells per mm^3) and total number of neurons, and the average neuronal profile area were measured. Normal development was characterized by increases in volume and neuronal profile area. The N_V of neurons decreased, while the total number of neurons remained relatively constant. In SIDS cases the rate of increase in volume was greater than in controls (36%). The rate of increase in neuronal profile area was greater for motoneurons (42%), but not for interneurons. The N_V of neurons decreased more rapidly than in controls, but the total number of neurons did not differ. These abnormalities in growth indicate a greater volume of neuropil in the hypoglossal nucleus of SIDS cases. Synapse counts by electron microscopy are in progress. (Supported by the MRC of Canada)

A DOUBLE BLIND STUDY OF FOLINIC ACID (LEUCOVORIN) FOR THE TREATMENT OF FRAGILE X SYNDROME. W. J. Pizzi, C.M. Strom* and R. Brusca*. Northeastern Illinois University & Illinois Masonic Hospital, Chicago, IL 60625.

Fragile X Syndrome is the most common inherited disease that causes mental retardation. Symptoms routinely include mild to severe retardation and hyperactivity with attention deficits, and reports of autistic-like behavior. Several uncontrolled case studies have reported dramatic remediation of symptoms following folic acid therapy; however, double blind, controlled studies have failed to report positive effects. We conducted a study of 19 Fragile X males whose diagnosis had been confirmed by karyotype analysis. Subjects were administered dl-Leucovorin, 15 mg/day by mouth or a placebo for 3 months, followed by a crossover phase. There were no significant differences between placebo and Leucovorin in the behavior of subjects evaluated on the Vineland Adaptive Behavior Scales; Peabody Picture Vocabulary Test; ACTERS, and; parent questionnaires. There were no significant differences in blood parameters or side effects for the duration of the study. While formal measures were negative, 50% of the parents reported improvement in their sons.

495.10

AGE-RELATED RESPONSES TO OXYGEN DEFICIENCY IN PRETERM AND FULLTERM NEONATAL RATS. M. Dyer and C. R. Almli. Develop. Neuropsychobiol. Lab., Wash. Univ. Sch. Med., St. Louis, MO, 93110

Perinatal oxygen deficiency is associated with neural and neurobehavioral pathology. Behavioral responses of pre- and fullterm neonatal rats to acute oxygen deficiency were investigated.

Oxygen deficiency was produced by placing fullterm (P0; vaginal delivery) and preterm (E20, E21; Cesarean section delivery) neonates in chambers until they reached a criterion of 3 successive gasps separated by at least 15 sec each. Control rats were placed in unsealed chambers. Pups were resuscitated by brushing. The procedure was repeated for E21 and P0 rats. Time to reach gasping criterion and survival through 24 hrs postnatal were studied.

Results showed age-related differences in response to oxygen deficiency. Younger rats took significantly more time to reach the criterion. Pups born at less than 4 grams body weight showed lower survival rates. Neuropathology and transmitter changes due to oxygen deficiency are under study. (Conducted under NIH Guide for Care and Use of Laboratory Animals).

EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS II

496.1

AMYGDALAR SCLEROSIS: A NOVEL PATTERN IN TEMPORAL LOBE EPILEPSY. L.P. Hudson, D.G. Munoz, J.P. Girvin and L. Miller. Departments of Pathology and Clinical Neuroscience, University of Western Ontario, London, Canada.

Mesial temporal sclerosis (MTS), a stereotyped pattern of hippocampal cell loss and gliosis, is the sole pathological abnormality in approximately 65% of temporal lobectomies for intractable temporal lobe seizures. Although a small portion of the remaining cases can be related to vascular, malformative, or neoplastic lesions, up to 22% of these resections demonstrate no recognizable pathology. We report a novel pattern of temporal lobe pathology associated with the development of temporal lobe epilepsy. Four en bloc temporal lobe resections without any evidence of hippocampal damage demonstrated cell loss and gliosis in the amygdala. This group of patients exhibited significant preoperative clinical differences from those patients found to have MTS in terms of age at onset of seizures, and performance on standard neuropsychological tests. Although MTS is invariably accompanied by a severe degree of amygdalar pathology, there have been no previous reports of isolated amygdalar pathology in temporal lobe epilepsy.

496.2

ELECTROPHYSIOLOGICAL COMPARISON OF HUMAN AND RODENT DENTATE GRANULE CELLS MAINTAINED IN VITRO. A. Williamson, G.M. Shepherd and D.D. Spencer, Sections of Neurobiology and Neurosurgery, Yale University School of Medicine, New Haven, CT 06510.

We have studied the electrophysiological properties of dentate granule cells in both human and guinea pig hippocampi using intracellular recording techniques in slices maintained in vitro. The human tissue was removed for treatment of extrahippocampal lesions and is morphologically normal compared to autopsy controls. There were no differences in any of the membrane properties examined including the membrane potential, input resistance, slope conductance and membrane time constant.

However, we noted differences in the response to depolarizing current injections. The guinea pig granule cells showed robust spike frequency adaptation, and directly evoked spike trains were followed by long afterhyperpolarizations (AHPs) which had both fast and slow components. By contrast, the human cells showed very little spike frequency adaptation and had prominent fast AHPs but the slow AHPs were very small. When 100 msec long depolarizing current pulses which produced four action potentials were given from membrane potentials between -60 and -65 mV, the AHPs were between 5 and 10 mV in amplitude (mean 6.52 mV, n=27) and were 2.5 sec long in the guinea pig but only 2 to 3 mV in amplitude (mean 2.23 mV, n=15, from 8 patients) and 0.5 sec long in the human cells. The conductance underlying the slow AHP was present in the human cells as prolonged trains were followed by an AHP which could be reduced by NE, as has been shown for the slow AHP in rodent granule cells. This may represent an important species difference as the slow AHP is modulated by a number of neuroactive compounds. These data suggest that human granule cell activity may be modulated to a lower degree than the guinea pig cells by compounds such as ACh, NE, 5-HT and HA. Supported by NIH NSO6208 (AW and DDS) and NIH DC00086 and ONR N00014 (GMS)

496.3

PARVALBUMIN AND CALBINDIN IMMUNOREACTIVE NEURONS IN EPILEPTIC AND NORMAL HUMAN HIPPOCAMPAL FORMATION. M. Vonau* and I. Török, School of Anatomy, University of New South Wales, Kensington, NSW 2033, Sydney, Australia.

The parvalbumin and calbindin-D28K immunoreactive (P-IR and C-IR) cells and terminals were examined in hippocampal tissue removed from patients with temporal lobe epilepsy and postmortem controls. A differential distribution of both calcium binding proteins was found in the various cytoarchitectonic regions. The highest density of P-IR neurons was found in the CA1 region in small to large multipolar neurons. Many of the latter had extensive dendritic processes across the full depth of the CA1 cortex. While CA2 contained moderate numbers of P-IR cells there was a conspicuous paucity of such cells in CA3. In CA4 there were numerous large P-IR multipolar cells with dendrites radiating in all directions. The pyramidal layer in CA1-3 contained a dense plexus of P-IR terminals with specially high density in the superficial sublayer in CA1. In the dentate gyrus, P-IR neurons were present in the molecular and polymorphic layers while there was a distinct and dense terminal labelling in the granule cell layer. C-IR was present in the majority of granule cells, clearly delineating their dendrites in the molecular layer. In addition, medium to large multipolar cells were labelled throughout the dentate gyrus. In CA1 of the hippocampal cortex, large numbers of pyramidal and non-pyramidal neurons were weakly C-IR. Terminal labelling was mostly discernible in the stratum radiatum in the CA3 area. Comparison of the sclerotic and non-sclerotic regions with each other and with normal controls clearly demonstrated the loss of P-IR and C-IR neurons together with the pyramidal and granule cells. Supported by the Australian Brain Foundation.

496.4

TYPICAL ABSCENCE LIKE ATTACKS INDUCED BY SIMULTANEOUS BILATERAL STIMULATION OF THE CENTROMEDIAN (CM) THALAMIC NUCLEI IN MAN. F. Velasco, M. Velasco*, L. Coronel*, A.L. Velasco*. Functional Neurosurgery Service. Hospital General, S.S. and Division of Neurophysiology, Nat. Med. Cent IMSS. México, D.F. P.O. Box 73-032.

This work was performed on epileptic patients with intractable generalized seizures and with recording/stimulating electrodes implanted in both CM nuclei as part of a neuroaugmentive procedure for seizure control. Prior to the onset of chronic electrical stimulation the correct placement of the electrodes was corroborated by electrophysiological studies. Simultaneous bilateral electrical stimulation of CM (3/s, 1.0 ms., 1.2-1.5m Amp and trains of 20s or more) induced a lapse of blank store, arrest of spontaneous ongoing activily, initial increase in reaction time, followed by blocking of single responses and "Number Cancellation" test. Concomitant 3/s spike and wave complexes appeared in the EEG at the frontal and central regions time locked to the individual stimulus presentation spike (P15 N20) and wave (N60) components had an amplitude relation of 1:5-10 uV. Unilateral stimulus induced ipsilateral spike and wave scalp discharges without clinical correlations.

Subcortical (centroencephalic) vs. cortical theories have been proposed to explain the physiopathology of generalized non convulsive seizures. Present results favors the centroencephalic theory.

496.5

ENHANCED PAIRED-PULSE INHIBITION IN HUMAN EPILEPTOGENIC AMYGDALA AND HIPPOCAMPAL PATHWAYS. S.U. Khan, C.L. Wilson, G.J. Kricorian* and M.F. Levesque. Department of Anatomy and Cell Biology, Department of Neurology, Division of Neurological Surgery and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Both the animal kindling model of epilepsy and depth recordings of seizure onsets in human temporal lobe epilepsy implicate the amygdala nucleus in epileptogenesis. Wilson et al. (Neurosci. Abst. 1989, 15:236) demonstrated greater paired pulse suppression of stimulation evoked population EPSPs in the epileptogenic hippocampal formation (HF) than in the nonepileptogenic HF. They attributed this suppression to enhanced GABAergic inhibition produced by principal neuron loss in the hippocampus. Since amygdala and HF have multiple connections, we decided to examine the excitability of these pathways.

For this purpose, we employed paired stimuli in a study of 13 medically intractable complex-partial epilepsy patients with depth electrodes implanted in the amygdala and the HF for diagnostic monitoring prior to surgery. Conditioning and test stimuli were delivered to five specific HF sites while recording evoked field potentials from microelectrodes in the amygdala. Stimulation was also delivered to the amygdala during recording from microelectrodes in the HF sites. Paired-pulses were delivered at inter-stimulus intervals of 20 to 1600 msec, and response depression or facilitation was measured by dividing the test by conditioning evoked response slope. The epileptogenic sites were defined as those on the side of all recorded seizure onsets and the nonepileptogenic sites as those on the side of no seizure onsets.

The slope of evoked field potentials was significantly suppressed on the epileptogenic side in comparison to the slope on the nonepileptogenic side ($F = 9.07$, $df=1$, $p < .005$), at interstimulus intervals of 20 to 200 msec. These results indicate interictal inhibition is enhanced in the epileptogenic amygdala, a functional difference consistent with that observed in the nonepileptogenic HF.

Supported by NIH grant NS02808.

496.6

INTERACTION OF ORTHODROMIC AND ANTIDROMIC STIMULI IN THE DENTATE GYRUS OF EPILEPTIC PATIENTS IN VITRO. K. Uryno, M.J. O'Conner* and L.M. Masukawa. Departments of Neurology, Research and Surgery, Graduate Hospital and Departments of Neurology and Neurosurgery, University of Pennsylvania Medical School, Philadelphia, PA. 19146.

Neuronal loss and mossy fiber reorganization occur during the course of epilepsy. Alterations in circuitry are thought to be associated with functional changes. In order to elucidate changes in function and circuitry, field responses of granule cells to paired pulse stimuli were examined in the dentate gyrus of hippocampal slices from temporal lobe epilepsy (TLE) patients and normal rats. Paired pulse stimuli (orthodromic pair, antidromic pair and combinations of orthodromic and antidromic pulses) were applied at various interstimulus intervals (ISI) via electrodes placed in the molecular layer and in the hilus.

In slices of TLE patients, the first stimulus (either orthodromic or antidromic) inhibited the second antidromically evoked population spike at short ISIs. This inhibition was stronger in the slices which showed hyperexcitability of granule cells. The inhibition was enhanced by bicuculline, and blocked by 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). 2-amino-5-phosphonovalerate (APV) partially reduced the inhibition. Neither the inhibition nor its enhancement by bicuculline was significant in rat slices. Orthodromic paired pulse inhibition was well preserved in some slices that showed antidromic paired pulse inhibition in TLE patients. These results suggest that mossy fibers make functional synapses with inhibitory interneurons (possibly non-GABAergic), in addition to excitatory synapses with granule cells. Presence of the new inhibitory synapses may precede the progressive decrease or loss in orthodromic paired pulse inhibition observed in TLE patients.

Supported by NIH grant NS23077 to LMM.

496.7

RELATIONSHIPS BETWEEN EVOKED FIELD RESPONSES AND TIMM-SULFIDE STAINING IN THE DENTATE GYRUS OF TEMPORAL LOBE EPILEPTIC PATIENTS. L.M. Masukawa, K. Uruno, L.J. Burdette and M.J. O'Connor*. Depts. of Neurology and Surgery, Graduate Hospital, Philadelphia, PA 19146.

To address the question of the functional significance of changes in mossy fiber termination, we examined the relationships between Timm-sulfide staining and evoked field responses to orthodromic and antidromic stimuli in *in vitro* brain slices from the dentate gyrus of epileptic patients who underwent temporal lobe resective surgery. We used the same population of patients for these measures to account for variation in their clinical histories. The following physiological parameters were significantly correlated with the intensity of Timm-silver staining in the molecular layer or hilus: 1) early and late inhibition as measured by paired pulse stimulation; 2) change in the orthodromic response during 1 Hz stimulation; and 3) abnormality of the antidromic waveform. These results are consistent with the possibility that reorganization of mossy fiber terminals from the hilus into the molecular layer may underlie the recorded physiological parameters. Supported by NIH Grant NS-23077 to LMM.

496.8

DYNAMIC ANALYSIS OF CARDIAC RATE DURING COMPLEX PARTIAL SEIZURES. R.C. Frysinger, S. Garg*, M. Levesque and R.M. Harper. Dept. of Anatomy and Cell Biology, Div. of Neurosurgery and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Heart rate has been shown to change dramatically and systematically during epileptic seizures. Such changes may involve mesial temporal structures such as hippocampus and amygdala, which have been shown to play a role in autonomic control as well as epileptogenesis. Heart rate patterns can thus serve as identifying features of seizure discharge. We examined peri-ictal beat-by-beat cardiac interval records of patients undergoing continuous seizure monitoring. Poincaré plots (RR_{n+1} vs RR_n) of intervals were calculated, and these plots indicated marked dynamic changes in interval to interval variation during a seizure. To quantify variability at low (0-.03 Hz), mid (.03-.15 Hz) and high (> .15 Hz) frequencies, cardiac interval records were interpolated to provide a linear time series, and FFTs were calculated on successive 16.38 second periods around each seizure. We derived two measures from each period: broad-band power (a measure of total variability), and the ratio of low to high frequency variation (an inferential measure of the relative contributions of sympathetic and parasympathetic sources). Results indicate that preictal cardiac variability is state-dependent, moderate and variable in frequency dominance. At seizure onset a large increase in broad-band power and in the low/high ratio occurs, suggesting a dramatic increase in sympathetic input. Low frequency power decreases over the course of the seizure, while higher frequencies increase, probably reflecting significant co-activation of sympathetic and parasympathetic sources. These techniques provide quantitation of degree and type of autonomic activation associated with seizures, an important factor in seizure characterization and cardiovascular risk assessment. The computationally simple Poincaré plots provide a qualitative display of the dynamic characteristics of the variability which could be provided in real time.

ULTRASTRUCTURAL ORGANIZATION OF SOMATOSTATIN INTERNEURONS IN THE FASCIA DENTATA OF HIPPOCAMPI FROM PATIENTS WITH EPILEPSY. M. F. Philips*, C. Pappas*, D. D. Spencer and N. C. de Lanerolle. Section of Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT. 06510

Hippocampi surgically removed from patients with medically intractable Temporal Lobe Epilepsy (TLE) can be classified into two groups. Those from subjects with an extra-hippocampal temporal lobe lesion (TTLE) have a relatively normal hippocampus in contrast to those who have no identifiable lesion (CTLE) [de Lanerolle et al., Brain Res., 495: 387-395, 1989]. Somatostatin-like immunoreactivity (SLI) in the fascia dentata (FD) of TTLE was localized in interneuron-like cell bodies in the hilus. Dendrites and axonal processes of these somata ramify in the hilus and some extend through the granule cell layer into the molecular layer (ML). The density of fibers in the inner ML is low compared to the outer ML. In CTLE, SLI somata in the hilus are reduced, but there is an increase in immunoreactive fibers throughout the width of the ML. The participation of SLI elements in the synaptic organization of the FD was studied by an electron microscopic analysis of SLI elements. In TTLE immunostained dendrites were located in the hilus and inner molecular layer. SLI dendrites were often the center of simple to complex glomeruli with several unlabeled, mostly round vesicle containing terminals. SLI myelinated axons and terminals were commonly seen only in the outer molecular layer and the hilus. The labeled terminals usually contained round vesicles. One main difference in CTLE was the presence of labeled terminals in all regions of the ML. (Supported by NS 27081)

CARBACHOL STIMULATED PHOSPHOINOSITIDE TURNOVER IN HUMAN BRAIN TISSUE FROM PATIENTS WITH EPILEPSY. E. W. Johnson, D. D. Spencer, and N. C. de Lanerolle. Section of Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510.

Using [^{3}H]cytidine as a precursor, it has been demonstrated that PI turnover in tissue slices can be stimulated by a variety of compounds resulting in the accumulation of membrane bound [^{3}H]cytidine diphosphate diacylglycerol ([^{3}H]CDP-DAG)(Science 249: 802 (1990)). The non-specific levels of non-membrane bound precursor and radiolabeled nucleic acids are reduced by washing. The autoradiographic images generated from these labeled sections reflects the degree of PI turnover in fairly discreet neuroanatomical regions.

Living human brain tissue was obtained from patients undergoing surgery for medically intractable temporal lobe epilepsy. Slices were prepared from either hippocampus or neocortex and preincubated with [^{3}H]cytidine. The slice was then incubated with LiCl +/- carbachol. The slice was cut into 20um sections before being washed and apposed to film.

The addition of carbachol resulted in an overall increase in [^{3}H]CDP-DAG accumulation in the hippocampus compared to LiCl stimulation alone. The increase was greatest in the dentate gyrus and in some parts of the CA fields. Carbachol stimulation of the neocortical tissue also resulted in increased labeling particularly in the outer layers of the cortex. (Supported by NS27081)

STIMULATION EVOKED POPULATION SPIKES IN HUMAN EPILEPTOGENIC HIPPOCAMPAL FORMATION SHOW ENHANCED INHIBITION. C.L. Wilson, S.U. Khan, H.C. Hu*, and M.F. Levesque. Department of Anatomy and Cell Biology, Dept. of Neurology, Div. of Neurological Surgery and Brain Research Inst., UCLA School of Medicine, Los Angeles, CA 90024.

Previous studies have shown that more pronounced paired pulse suppression of stimulation evoked population (pop) EPSPs occurs in the human epileptogenic hippocampal formation (HF) than in the nonepileptogenic HF (Wilson et al. 1989, Neurosci. Abst. 15:236). Similar results were obtained during perforant path stimulation in the kindled rat (e.g.Tuff et al. Brain Res. 1983, 277:79-90). However, the animal studies were based on measures of increased inhibition of the perforant path pop *spike*, not on pop *EPSPs*, (the latter show less modulation in seizure models; Sloviter 1991 Hippocamp,1:31-40).

In the present study, 6 HF sites were implanted with depth electrodes for surgical diagnostic recording in 23 complex partial seizure patients. Paired stimuli were delivered to one or more of these sites, in turn, while adjacent sites were monitored for pop spikes. Pop spike amplitude was the average of spike positivity and negativity. Paired pulse interval was varied from 20 to 800 msec and response suppression or facilitation compared between the epileptogenic vs nonepileptogenic HF as defined by depth electrode seizures.

Population spike amplitude in the epileptogenic HF was found to be significantly more suppressed than in the nonepileptogenic HF ($F=14.867$ $df=1$ $p<.0002$), further supporting the finding of enhanced inhibition in the epileptogenic hippocampus observed in pop EPSP studies. Supported by NIH grant NS02808.

Electrocorticography and simultaneous recording of regional cerebral blood flow with laser doppler technique from the human epileptic focus.

H. Carlson[1*], E. Ronne-Engström[1*], S. Blom[2*], R.Flink[2*], B.Gazelius[3*], B.Spännare[1*], L.Hillered[1], Depts.of Neurosurgery[1], Clin. Neurophysiology[2] University of Uppsala and Dept.of Pharmacology[3], KI, Sthlm, Sweden.

In comparison with normal brain tissue epileptic zones are characterized by altered metabolism and blood flow as visualized with PET and SPECT technique, respectively. Intracerebral microdialysis has been used in epilepsy patients to correlate levels of aminoacids and energy related metabolites to *i.a* seizure activity (Ronne-Engström et al 1991, J Cereb Blood Flow Metab, in press).The relationships between seizure activity, blood flow and biochemical events are unclear. In order to investigate the relation between the corticographic(ECoG) pattern and the regional cerebral blood flow with a high spatial and temporal resolution a combined subdural strip electrode and single fiber laser doppler probe was designed. The "lasertrode" was utilized in patients with focal epilepsy subjected to preoperative ECoG and videomonitoring of seizures. Relative flowmetry (Pf3, Perimed, Sthlm,Sweden) was performed intermittently in periods of eight hours/day. Six partial seizures have been recorded with ECoG and flowmetry. All started in the medial subtemporal region and had a duration of 1-3 min. Significant changes of the regional blood flow occurred in strict correlation to the ECoG seizure pattern.The flow returned to pre seizure levels within 1 min after termination of the seizures.Thus,as investigated by laser doppler flowmetry, there is no evidence for prolonged changes of the regional cerebral blood flow in the epileptic focus as defined by ECoG.The results indicate that this new method can be employed for investigations of the dynamics in regional cerebral blood flow in relation to the neuronal activity.

THE FREEZE LESION EPILEPSY MODEL ADAPTED TO RATS. W.D. Knowles and W.R. Barrett. Epilepsy Basic Research Program, Cleveland Clinic Foundation Research Institute, Cleveland, OH 44195.

The cortical freeze lesion epilepsy model has been used to study epileptogenesis primarily in cats. We report the successful adaptation of this model to rats, which have practical advantages.

Three Sprague-Dawley rats received neocortical freeze lesions and two rats received sham treatments. The lesions were located approximately in the motor cortex (1.5 mm posterior to bregma and 3.4 mm lateral.) The lesions were made by applying a 1 mm stainless steel probe that was in contact with a dry ice/95% ethanol slurry, to the dura for 30 seconds, then flushing with room temperature saline to remove the probe. Chronic EEGs were recorded from epidural skull screws embedded in an acrylic headpiece/connector.

No abnormal EEG or seizures were observed in the sham treated rats. EEG spikes and polyspikes could be recorded in freeze lesioned rats as early as one day post lesion. Behavioral seizures were observed starting 5-7 days post lesion, and continued as long as the animals were observed (1-3.5 months.) The seizures began with motionless staring, followed by clonus of the vibrissae, mouth, head, and eyes (Racine stages 1 or 2.) The seizures lasted from 5 seconds to 3.5 minutes, and were followed by restlessness, grooming and chewing. The EEG showed widespread low amplitude fast signals, followed by wide spread rhythmic high amplitude spikes and oscillations. Seizure frequency varied from one every 5 to 10 minutes to one every 15-20 minutes.

496.14

A SYSTEM FOR PRODUCING BENZODIAZEPINE TOLERANCE IN MICE USING OSMOTIC PUMPS. **C.D. TORCHIN*, I.M. KAPETANOVIC, AND H.J. KUPFERBERG*. Epilepsy Branch, NINDS, NIH, Bethesda, MD 20892.**

Tolerance to the anticonvulsant effects of benzodiazepines limits their use in epilepsy treatment. Animal models demonstrating tolerance have been developed, but they require repetitive injections over several days or use silastic capsules which must be made for each drug and do not provide a constant infusion rate. Alzet® 2001 osmotic mini-pumps deliver at a constant rate (1 μl/hr) and dosage can be easily adjusted. Various solvents; PEG400, propylene glycol, 2% Tween, 50% DMSO, saline, Molecusol®, and 0.5% methyl cellulose, were tried and were found unsuitable because diazepam was not maintained in solution or proconvulsant activity was seen. Tetraglycol was chosen as it did not demonstrate these shortcomings. Anticonvulsant activity was evaluated by PTZ iv tail infusion using forelimb clonic seizures as the endpoint. For naive NIH:NGP(S) mice, an infusion of 15 mg/ml at 0.2 ml/min produces forelimb clonus in about 30 seconds. All mice challenged with PTZ received an ip bolus of diazepam, 7.5 mg/kg, 30 minutes pre PTZ. Pumps containing vehicle, 15 μg/μl, 30 μg/μl, or 60 μg/μl diazepam were implanted sc in groups of six mice. Along with 6 naive mice, each group was challenged with PTZ 24 and 72 hours post implantation. There was no difference in the amount of PTZ required for clonus in naive or vehicle mice at 24 or 72 hours. Comparing 72 hours to 24 hours, protection was reduced by 15% in 15 μg/μl mice, 40% in 30 μg/μl mice, and 50% in 60 μg/μl mice. These decreases in protection show that tolerance to the anticonvulsant effects of diazepam developed while using osmotic mini-pumps. This model could be useful to screen putative anticonvulsant drugs for development of tolerance.

EPILEPSY: ANTICONVULSANT DRUGS

THE GABA UPTAKE INHIBITOR TIAGABINE INCREASES EXTRACELLULAR BRAIN LEVELS OF GABA IN AWAKE RATS. A.Fink-Jensen, M.D.B.Swedberg, M.E.Judge, P.Suzdak, L.Hansen* and P.G.Nielsen*. Novo Nordisk A/S, CNS Division, Denmark.

Tiagabine (NO-328) is a selective GABA uptake inhibitor in-vitro (IC50=67nM) and a potent anticonvulsant in rodents. Tiagabine is currently in Phase II clinical trials as an antiepileptic. The present study examined the in-vivo mechanism of action of tiagabine using microdialysis to measure changes in the extracellular brain levels of GABA in awake Sprague Dawley rats. Tiagabine was administered at 11.5 or 21.0 mg/kg i.p. (these doses of tiagabine correspond to the ED50 and ED85 doses, respectively, for inhibiting pentylenetetrazole-induced seizures). A microdialysis probe was placed in either the globus pallidus or the substantia nigra (two areas previously shown to receive a strong GABAergic innervation). Tiagabine produced a significant increase in extracellular GABA levels in globus pallidus with peak values of 310% of basal level (after 21.0 mg/kg) and 240% of basal level (after 11.5 mg/kg). A significant increase in extracellular GABA levels was also found in the substantia nigra - one of the major output channels of the basal ganglia - where the ED85 dose of tiagabine (21.0 mg/kg) produced a peak value of 200% compaired with basal level. The present microdialysis study shows that tiagabine increases extracellular brain levels of GABA demonstrating that it also in-vivo acts as a GABA uptake inhibitor.

497.2

ANTICONVULSIVE ACTIVITY OF ANTAGONISTS AT THE GLYCINE MODULATORY SITE ON THE NMDA RECEPTOR COMPLEX. **Alfred C. Nichols and K. Lemone Yielding*. Dept. of Pharmacology, Univ. of Texas Medical Br., Galveston TX, 77550.**

Halogenated derivatives of indole-2-carboxylic acid (Salituro et al., 1990) and kynurenic acid (kyn) (Kemp et al., 1988) can act as antagonists at the glycine modulatory site on the NMDA receptor complex. Twenty-two kynurenic acid derivatives were synthesized, and, along with nine indole derivatives and two pyridine dicarboxylic acids, were tested for anticonvulsive activity in the Antiepileptic Drug Development Program of NINCDS. In addition, each compound was tested for glycine receptor binding at a concentration of 10uM using the method of Snell et al. (1988). Although twelve of the kynurenate derivatives showed glycine receptor binding under the conditions of this assay, only four demonstrated any anticonvulsant activity (at 300 mg/kg). These were 7-Cl-8-methyl-kynurenate, 5,7-dichlorokynurenate, the ethyl ester of 7-Cl-kyn, and the ethyl ester of 5,7-difluoro-kyn. Three indole derivatives demonstrated anticonvulsant activity at the 100 mg/kg dose level: the ethyl ester of 5-methoxy-indole-2-carboxylic acid, 5-fluoro-indole-2-carboxylic acid and its ethyl ester. The two 5-fluoro derivatives showed competition binding in the glycine assay. However, the 5-methoxy-indole compound was inactive in this assay suggesting that its anticonvulsive activity is not due to interactions with the glycine site of the NMDA receptor complex.

497.3

VALPROIC ACID ENHANCES THE IPSP IN THE RAT AMYGDALA. L.-M. Tian and K. A. Alkadhi. Department of Pharmacology, University of Houston, Houston, TX 77204-5515.

Valproic acid (VPA) has been widely used clinically as an antiepileptic drug, but the mechanism of its action has not been established. In this study, we have examined the action of VPA on rat amygdala neurons *in vitro* using intracellular recording techniques. Amygdala slices (500 μm) were prepared from male Sprague-Dawley rats and bathed in artificial cerebrospinal fluid (ACSF).

The resting membrane potential and input resistance of the amygdala basolateral nucleus neurons were -65 to -70 mV and 40 to 80 mΩ respectively. Addition of VPA (30-100 μM) to the superfusate caused hyperpolarization (3-5 mV) and an increase in the membrane input resistance of amygdala neurons. Stimulation of the amygdalo-fugal pathway evoked inhibitory postsynaptic potentials (IPSP). This IPSP could be eliminated by hyperpolarizing the membrane to -75 mV or by addition of the $GABA_A$ antagonist bicuculline (10 μM) in the superfusate. The IPSP amplitude increased 1-3 fold after 10 minutes of superfusion with VPA (100 μM) when the membrane potential was artificially held at the resting level.

When slices were bathed in bicuculline (10 μM) for 5 min, an epileptiform burst of action potentials was observed upon subthreshold stimulation of the amygdalo-fugal pathway. The bicuculline-induced epileptiform response was completely abolished 15 minutes after addition of VPA (100 μM). These preliminary results suggest that VPA changes the membrane properties of the amygdala basolateral nucleus neurons probably by modifying the $GABA_A$ receptor function.

497.4

PD117302, AN OPIOID KAPPA AGONIST, AND MK801 PARTIALLY BLOCK MAXIMAL ELECTROSHOCK CONVULSION-INDUCED INCREASES IN *c-fos* mRNA IN RAT BRAIN. J.R. Dave*, L. Robles, K. Miller*, E.W. Bernton* and F.C. Tortella. Neuropharmacology Branch, Walter Reed Army Institute of Research, Washington, DC 20307 and Medicis Pharmaceutical Corp. New York, NY 10017.

It has been known that seizure activity is associated with increases in the proto-oncogene *c-fos* mRNA and *c-fos* protein in brain. The present study was undertaken to determine if the novel anticonvulsant kappa opioid drug, PD117302 (Tortella et al, Life Sci., 46, PL 1, 1990), and the NMDA antagonist MK801, would block seizure-induced *c-fos* mRNA in rat brain. *c-fos* mRNA levels, measured by Northern blot analysis, were greatly increased in a time-dependent manner following maximal electroshock (MES). Increased levels were measured within 15 min after MES, reaching a maximum in 30 min and declining to control levels within 2 hr post-convulsion. A maximal stimulation in *c-fos* mRNA of 10-15 fold was observed in the cerebellum, followed by hippocampus (5-7 fold) and cerebral cortex (4-6 fold). Administration of anticonvulsant doses of PD117302 (16 and 32 mg/kg, s.c.) and MK801 (0.2, 1.0 and 2.0 mg/kg, s.c.) alone produced no significant changes in *c-fos* mRNA levels in these three brain areas. However, both drugs (PD117302, 32 mg/kg; MK801, 0.2 mg/kg) administered 30 min prior to MES significantly blocked *c-fos* mRNA induction with the greatest effect observed in the cerebellum and a minimum effect in the cerebral cortex. Seizure-induced increases in *c-fos* mRNA levels and its partial blockade by anticonvulsant drugs suggest a possible role of *c-fos* in the mechanism of action of these drugs.

497.5

CARAMIPHEN ANALOGS: RELATIONSHIP OF σ BINDING AFFINITIES WITH ANTICONVULSANT ACTIVITY. J.T. Allen[1], D.L. DeHaven-Hudkins[1], J.F. Stubbins[2,*], R.L. Hudkins[2] and F.C. Tortella[3]. [1]Dept. Enzymology & Receptor Biochemistry, Sterling Research Group, Malvern, PA 19355, [2]Dept. Medicinal Chemistry, Medical College of Virginia, Richmond, VA 23298 and [3]Walter Reed Army Institute of Research, Washington, DC 20307.

Caramiphen is an antimuscarinic agent which is a more effective antidote to organophosphate poisoning than atropine, and also potently blocks MES-induced seizures in mice and rats. The anticonvulsant mechanism of caramiphen has been hypothesized to be due to high-affinity binding to dextromethorphan (DM)-labelled σ recognition sites in brain. We initially examined four properly chosen para-substituted caramiphen analogs to determine the influence of aromatic substituent parameters (i.e. σ, π) on σ receptor binding and also to determine if there was a correlation of σ binding affinity with anticonvulsant activity. Some of the analogs potently inhibited σ binding but were devoid of anticonvulsant activity. Of the compounds evaluated in MES only the 4-amino derivative showed anticonvulsant activity (ED_{50} = 3 mg/kg), although in σ binding assays its affinity was less than that of caramiphen. Comparable structure-activity data has previously been reported for 3-substituted DM analogs. In both series, while no apparent correlation exists between σ affinity with anticonvulsant activity, this information may reveal the common modes of binding of caramiphen and DM analogs to the σ recognition site.

497.6

CROSS TOLERANCE BETWEEN CARBAMAZEPINE AND VALPROATE IN AN AMYGDALA KINDLED SEIZURE PARADIGM. S.R.B. Weiss, R. Lewis*, E.Sohn*, A. Berger*, R.M. Post. Biological Psychiatry Branch, NIMH, Bethesda, Md. 20892

We have previously demonstrated the importance of the peripheral-type benzodiazepine receptor (P-BzR) in carbamazepine's (CBZ) anticonvulsant effects on amygdala kindled seizures. In order to evaluate potential common mechanisms of action, we evaluated cross-tolerance between CBZ and other anticonvulsant drugs. When tolerance to CBZ was induced, animals showed a lack of anticonvulsant response to PK-11195 (an antagonist at the P-BzR) and sodium valproate (VPA), but not to diazepam (DZP). Since the P-BzR is found in greatest concentrations in the olfactory bulb in rats, and VPA has recently been shown to be distributed almost exclusively in this area following *in vivo* administration (Hoeppner, 1989), we examined what effect lesions of the olfactory bulb would have on anticonvulsant responsivity. Rats with lesions of the olfactory bulb developed amygdala kindled seizures at rates equivalent to rats with sham lesions, and they showed equal anticonvulsant responses to CBZ, VPA, and DZP.

Our results suggest that while the P-BzR is important for the anticonvulsant efficacy of carbamazepine, receptors in the olfactory bulb are not critical for this effect. Similarly, although radiolabeled VPA is highly localized to the olfactory bulb, this structure is not necessary for the anticonvulsant effects of VPA. Potential common mechanisms of anticonvulsant action of CBZ and VPA are suggested by our findings of cross tolerance and require further investigation.

497.7

LAMOTRIGINE AND PHENYTOIN INTERACTIONS ON IONIC CURRENTS PRESENT IN N4TG1 AND GH3 CLONAL CELLS. D.G. Lang* and C.M. Wang. Division of Pharmacology, Burroughs Wellcome Co., Research Triangle Park, NC 27709.

Lamotrigine (LTG) is a novel anticonvulsant with a unique chemical structure; it has a pharmacological profile similar to phenytoin (PHT; Miller, et al., *Epilepsia* 27:483-489, 1986). LTG, like PHT, inhibits veratrine-induced glutamate release from rat brain cortical slices, presumably by inhibiting Na^+ channels (Leach, et al., *Epilepsia* 27:490-497, 1986).

We have examined the tonic effects of LTG and PHT on voltage-dependent Na^+ currents in N4TG1 mouse neuroblastoma cells and voltage-dependent Ca^{2+} and K^+ currents in GH3 rat pituitary cells using the whole cell mode of the patch clamp technique. Both LTG and PHT produced an inhibition of the Na^+ current with IC_{50} values of 90 μM and 58 μM, respectively. Low threshold, transient Ca^{2+} currents were inhibited by PHT (IC_{50} = 50 μM), but 100 μM LTG caused only a 15 ± 7.0% inhibition. High threshold, sustained Ca^{2+} currents were not significantly affected by either 100 μM LTG (+9.5 ± 4.9%) or 100 μM PHT (-8.0 ± 8.7%). Ca^{2+}-activated K^+ currents were not significantly affected by either 100 μM LTG (-3.0 ± 4.2%) or 100 μM PHT (-7.0 ± 7.0%). Transient, rapidly inactivating voltage-dependent K^+ currents were significantly inhibited by 100 μM LTG (-19 ± 3.8%) and by 100 μM PHT (-25 ± 3.6%). These data support the hypothesis that the primary site of action of the inhibition of glutamate release by LTG is Na^+ channels and not Ca^{2+} or K^+ channels.

497.8

MEMANTINE AND ATROPINE PROTECT AGAINST SOMAN-INDUCED SEIZURES. W.-D. Dettbarn, M.J. McLean, R.C. Gupta* and A.W. Wamil. Neurology Dept., Vanderbilt Univ. Med. Ctr., Nashville, TN 37212

A single sublethal dose of the nerve agent, SOMAN (100 μg/kg, sc), produced limbic seizures in rats. Pretreatment with memantine (MEM, 18 mg/kg, sc) ± atropine sulfate (ATS, 16 mg/kg,sc), but not ATS, prevented seizures. MEM, but not ATS attenuated seizure activity in progress. MEM±ATS or ATS had no effect on acetylcholinesterase (AChE) activity in crude brain homogenates. Pretreatment with MEM reduced inhibition of AChE activity by SOMAN, but not edrophonium (cationic site) or decamethonium (peripheral site inhibitor), suggesting action at a different modulatory site. MEM limited action potential firing frequency, and both MEM and ATS blocked ACh responses recorded intracellularly from cultured neurons. Thus, protection against SOMAN seizures by MEM ± ATS resulted from a combination of biochemical and pharmacological effects.

497.9

VOLTAGE-SENSITIVE CALCIUM CHANNELS (VSCC's) OF MOUSE CORTICAL ASTROCYTES ARE ATTENUATED BY PROTOTYPE ANTICONVULSANTS. J.A. Edwards[1], D.M. Woodbury[2] and H.S.White[1]. [1]Dept. of Pharmacology & [2]Dept. of Physiology, University of Utah, Salt Lake City, Utah 84108

Previous investigations in this laboratory have demonstrated that primary cultures of mouse cortical astrocytes express VSCC's which are effectively blocked by the L-type channel blocker nimodipine and the N-type channel blocker Ω-conotoxin. Since a number of anticonvulsants have been shown to block VSCC's of neurons, the present study was initiated in order to assess the effect of these drugs on VSCC's of cultured astrocytes using the fluorescent probe indo-1. Astrocytes grown on 25 mm cover slips and maintained in tissue culture for 20-31 days were "loaded" with indo-1 (5 μM) for 20 min. and fluorescence measured according to the method of Peeters et al. Depolarization of differentiated astrocytes with elevated KCl (55 mM) resulted in a significant increase in the free $[Ca^{2+}]_i$ concentration as estimated by an increase in the 410/480nm fluorescence intensity ratio (Grynkiewicz et al.,J.Biol.Chem.260:3440-3450, 1985). Pretreatment for 5 min. with therapeutic concentrations of phenobarbital (10 μM); valproate (1 μM); diazepam (1 μM); ethosuximide (100 nM); phenytoin (3 μM) and flunarizine (10μM) attenuated the peak KCl-induced Ca^{2+} transients by 84, 82, 81, 78, 71, and 60%, respectively. Whether these drugs are blocking Ca^{2+} influx through a direct interaction with the channel (L or N) or through an effect on second messenger systems is currently under investigation. In summary, the present results suggest that the VSCC's of astrocytes are amenable to pharmacological manipulation by anticonvulsant compounds. Supported by a grant from the NINDS of the NIH (2R01-NS-22200).

497.10

ANTICONVULSANT EFFICACY OF CALCIUM ANTAGONIST AGAINST CHEMICALLLY-INDUCED SEIZURES IN DEVELOPING RAT. S.K. Sobrian, N.L. Robinson* and L.E. Burton*. Dept. Pharmacology, Howard Univ. Col. Med., Washington, DC 20059.

Calcium channel antagonists (CAs) are effective anticonvulsants in several reflex and generalized models of epilepsy. The present study determined if nifedipine (NIF) and verapamil (VER) would protect Sprague-Dawley rats from convulsions induced by pentylenetetrazol (PTZ), picrotoxin (PIC) or bicuculline (BIC). At 15 or 30 days of age, pups were pretreated i.p., with either phenobarbital (15 mg/kg, 45 min), NIF (20 mg/kg, 30 min) or VER (20 mg/kg, 10 min) prior to s.c. injection of PTZ (50 mg/kg), PIC (3.15 mg/kg) or BIC (2.7 mg/kg). Controls received 0.1 ml/10G body weight DMSO. Three indices of convulsive behavior were measured for 30 minutes. At PND 15, NIF reduced head/limb movements (HLM) and body rotation (BR) induced by PTZ, BIC and PIC; in contrast, NIF pretreatment enhanced seizure-like activity (SLA) induced by PIC and BIC but not PTZ. VER reduced HLM movements induced by all 3 chemical convulsants and BR following BIC and PIC; PIC induced SLA was enhanced by VER pretreatment. At PND 30, NIF pretreatment enhanced SLA of PTZ and PIC; it was ineffective in reducing other indices. VER had no effect on PTZ, BIC or PIC convulsions. The results suggest that in developing rats CAs exhibited limited anticonvulsant efficacy and may exascebrate some chemically induced seizures. (Supported by PHS Grant #5RO1NS20725).

A ROLE FOR SEROTONIN IN THE ANTICONVULSANT EFFECT OF ANTIEPILEPSIRINE IN GENETICALLY EPILEPSY-PRONE RATS. Q-S. Yan*, P.C. Jobe and J.W. Dailey. Department of Basic Sciences, University of Illinois College of Medicine at Peoria, Peoria, Illinois 61656.

Previous reports from our laboratories demonstrate that antiepilepsirine (3,4,-methylenedioxycinnamyl piperine, AE), which is a clinically used antiepileptic agent in China, is an effective anticonvulsant in genetically epilepsy-prone rats (GEPRs) and that the anticonvulsant effect of AE in moderate seizure GEPRs (GEPR-3s) might be mediated, at lesst in part, by activation of CNS serotonergic neurons (FASEB. J. Abs. 3: A292, 1989; Neurosci. Abs. 15: 24.8, 1989). In order to further test this hypothesis linking the anticonvulsant action of AE in GEPRs to enhanced serotonin release, we evaluated the effects on dialyzable serotonin of i.p. AE in severe seizure GEPRs (GEPR-9s) and of i.v. AE in GEPR-3s. Under anesthesia, guide cannulae were stereotaxically placed over hippocampi of both GEPR-3s and GEPR-9s. To inject i.v. AE without stress, the GEPR-3s were also implanted with a jugular catheter. After recovery from surgery, dialysis probes were inserted into the guides of the conscious and unrestrained animals and the hippocampus was dialyzed with artificial CSF. Either AE (120 mg/kg i.p. in GEPR-9s; 40 mg/kg i.v. in GEPR-3s) or vehicle was administered after establishing basal release and dialysis was continued for 5 hours. Significant increases in dialyzable serotonin (approximately 200-250% over the basal values) were seen after the injection of AE in both GEPR-3s and GEPR-9s. The peak increases in serotonin produced by i.p. AE corresponded temporally with the time of peak anticonvulsant effect for this drug. These results confirm our earlier observation and are consistent with a role for serotonin in the anticonvulsant effect of AE in GEPRs. (Supported in part by a grant from Tsumura Juntendo Fdn.)

CESSATION OF BICUCULLINE-INDUCED FOCAL SEIZURES VIA LIDOCAINE: BEHAVIORAL AND ELECTROPHYSIOLOGICAL QUANTIFICATION. S.E. Krahl, E.J. Barea, and D.C. Smith. Department of Psychology, Southern Illinois University, Carbondale, IL 62901.

Earlier investigations in our laboratory have shown lidocaine to be an effective agent in the cessation of ongoing seizures when microinfused into an experimentally-produced focus. While the effectiveness of this technique has been verified behaviorally (1), quantification of the ECoG has not been performed to date. Although behavioral measures are useful in assessing abnormal discharges which have spread to the motor cortex, ECoG measures provide information about seizure activity occurring in other cortical and subcortical areas as well as about ictal events which may not be expressed as motor seizures. The present study used both behavioral and electrophysiological measures to quantitatively evaluate the effectiveness of the lidocaine technique.

Ten Long-Evans rats (250-274 g) were implanted with bilateral cannulae in the area tempestas (AT), and with cortical electrodes overlying the frontal and parietal cortices. Seizures were induced via a unilateral microinfusion of 0.5 μl of bicuculline (200 ng/μl) into the AT. Fifteen minutes later, 1 μl of either lidocaine or saline was microinfused into the same area. The results showed that lidocaine significantly reduced both the behavioral seizure, as measured on the Racine motor rating scale (2), and the integrated ECoG amplitudes to baseline levels. Saline did not cause a deviation in either measure from seizure levels. These results indicate that lidocaine may prove to be a useful means by which to arrest ongoing focal seizures.

CLASSIFICATION OF SUBSTANTIA NIGRA PARS RETICULATA (SNpr) NEURONS BASED ON RESPONSES TO IONTOPHORETIC GABA AND FLURAZEPAM. H.C. Rosenberg, H. Zhang and X. Weng*. Dept. of Pharmacology, Med. Coll. of Ohio, Toledo OH 43699.

Previous work showed that intranigral GABA agonists and benzodiazepines (BZs) had different effects on some experimental seizures (Zhang et al., 1989,1991). It was suggested that SNpr neurons might be differentiated based on their responses to GABA and BZs. Male, Sprague-Dawley rats were anesthetized, and anesthesia maintained by a constant i.v. infusion of chloral hydrate. Multi-barreled glass electrode assemblies were used to record spontaneous activity of single SNpr neurons. GABA and flurazepam (FZP), a benzodiazepine, were applied iontophoretically, using several currents for each agent. Recording sites were marked for histological confirmation. As expected, both FZP and GABA, as a function of increasing current, decreased the rate of neuronal discharge. Based on the maximum effect obtained with increasing currents of each agent, the neurons could be divided into categories. Most SNpr neurons could be completely silenced by GABA, though their sensitivities varied widely. About half the SNpr neurons were inhibited >90% by GABA, but could be inhibited only about 50% by FZP. Most of the other neurons were inhibited >90% by both FZP and GABA. A few neurons were relatively insensitive to FZP and GABA, and a few others could be inhibited more by FZP than by GABA. The data suggest that SNpr neurons can be differentiated by their relative sensitivities to FZP and GABA. Histological examination suggested some anatomical segregation according to BZ sensitivity. Supported by DA02194.

BIDIRECTIONAL CONTINGENT CROSS TOLERANCE BETWEEN THE ANTICONVULSANT EFFECTS OF PENTOBARBITAL AND ETHANOL IN AMYGDALA-KINDLED RATS. C.K. Kim, J.P.J. Pinel and N.R. Roese. Department of Psychology. University of British Columbia, Vancouver, B.C. V6T 1Y7

The amygdala-kindling model of epilepsy was used to examine contingent tolerance and cross tolerance to the anticonvulsant effects of pentobarbital (15 mg/kg, IP) and ethanol (1.5g/kg, IP) in male Long-Evans rats. In Experiment 1, rats received a pentobarbital injection and a convulsive stimulation once every 48 hr on each of 10 trials. Pentobarbital was injected either 1 hr before or 1 hr after each stimulation. Only rats receiving pentobarbital before each stimulation became tolerant to pentobarbital's anticonvulsant effect. Cross tolerance to the anticonvulsant effect of ethanol was also found to be greater in the pentobarbital-before-stimulation rats. Experiment 2 assessed the transfer of tolerance from ethanol to pentobarbital. Results mirrored those of Experiment 1: Convulsive stimulation during the periods of ethanol exposure facilitated the development of tolerance to the anticonvulsant effect of ethanol and its transfer to pentobarbital. The development of tolerance and cross tolerance to anticonvulsant drug effects is facilitated by the administration of convulsive stimulation during periods of drug exposure. This supports the drug-effect theory of tolerance. (MRC and NSERC grants to JPJP)

REDUCED BLOOD FLOW IN THE TEMPORAL LOBES IN ALZHEIMER'S DISEASE. J.L. Eberling, W.J. Jagust, B.R. Reed*, M.G. Baker, Donner Laboratory, Lawrence Berkeley Laboratory, University of California, Berkeley, CA 94720.

Alzheimer's disease (AD) is characterized by reduced cerebral blood flow and metabolism, especially in parietal and temporal cortex. This has been reported with both single photon emission computed tomography (SPECT) and positron emission tomography (PET). While some studies report more severe involvement of the parietal cortex, others report that the temporal cortex is most severely affected. We used SPECT to study regional cerebral blood flow (rCBF) in 50 mildly and moderately demented AD patients and nondemented control subjects in order to evaluate rCBF as a function of disease severity. Subjects were scanned at two tomographic levels using the blood flow tracer [123I] -N-isoproyl-p-iodoamphetamine (IMP). Regions of interest (ROIs) were quantitatively analyzed by constructing ratios of the regional radioactivity count density for each ROI to the average radioacitivity count density in occipital cortex. Data were analyzed with multivariate analyses of variance (MANOVA) and post-hoc tests to evaluate group differences for each ratio. Pearson product moment correlations were used to evaluate the relationship between disease severity, as measured by the MMSE, and rCBF for the AD patients. Results of the MANOVA showed that rCBF in temporal cortex was significantly ($P<0.0001$) lower than controls for both the mild and moderate AD patients, while rCBF in parietal cortex was significantly ($p<0.0001$) lower than controls for the moderate AD patients only. Disease severity was associated with rCBF in dorsolateral frontal and parietal cortex ($r = .51$ and $r = .48$, respectively), but not with rCBF in temporal cortex. These results suggest that temporal cortex is affected earliest and most severely in AD, and that other cortical areas become involved as the disease progresses.

498.2

PROLONGED MR T2 TIMES IN THE HIPPOCAMPUS AND AMYGDALA MARK THE PRESENCE AND SEVERITY OF ALZHEIMER'S DISEASE. S.J. Kirsch, R.W. Jacobs, L.L. Butcher, and J. Beatty. Behavioral Neuro-science Program, Department of Psychology, UCLA, Los Angeles, CA 90024.

Magnetic resonance (MR) imaging is a well-accepted visualization tool that produces high quality macroscopic images of body tissues based on the excitation of hydrogen nuclei. Three fundamental aspects of the precessing hydrogen nuclei contribute to an MR image: proton density, T1 relaxation, and T2 relaxation. Thus, the data from which those macroscopic images are constructed arise from molecular properties of the tissue. By quantitatively estimating such properties, information concerning molecular characteristics of tissues can be deduced.

Taking this approach, we measured T2 relaxation times in the left and right hippocampus (HC) of 13 patients with Alzheimer's disease (AD), 9 subjects with multi-infarct dementia (MID), 11 elder normals (EN), and 23 young normals (YN). Using an Insturmentarium Magnaview MRI operating at 0.04T (SE: 1000/130 and 1000/200), T2 values for all AD patients exceeded that of any nondemented individual, regardless of age. Further, HC T2 values were normal for the 9 subjects with MID. Finally, the degree of T2 prolongation was highly correlated with the severity of functional and cognitive impairment of the AD patients. A second study is now underway in which preliminary observations show that T2 times are also prolonged in the amygdala of AD patients, but not YN,EN, or MID subjects. These results suggest that HC, and possibly amygdala, T2 prolongation may provide a specific anatomical marker by which AD pathology may be characterized and followed *in vivo*.

498.3

COMPARISON OF NEURODEGENERATION IN ALZHEIMER'S DISEASE AND COGNITIVELY IMPAIRED STATES USING MRI. J.P. Kesslak, S.F. Nagata*, C.W. Cotman, and O. Nalcioglu*. Departments of Neurology, Psychobiology & Radiological Sciences, Univ. California, Irvine, CA 92717

Magnetic resonance imaging (MRI) is a non-invasive method that can be used to monitor and quantify neuroanatomical changes. Neural degeneration in Alzheimer's disease (AD) and cognitively impaired (CI) patients affects a variety of structures, including the hippocampus and parahippocampal gyrus. Structural changes may be associated with behavioral deficits. MR images of AD (n=27), CI (n=19) and age-matched controls (n=12) were used to quantify volumes of discrete brain areas and correlated with a measure of general cognitive function, the Mini Mental State Exam (MMSE). The CI group included vascular dementia, Wernicke-Korsakoff, multi-infarct dementia, and age-related memory impairment. Scanning was done on a 1.5 Tesla GE Signa Unit using a head coil. Three series of scans were taken: Spin Echo-1) sagittal, T1 weighted; 2) transverse T2 weighted; and 3) coronal T1 weighted Inversion Recovery (IR). The coronal IR images provided high resolution and contrast to best visualize structures. Peliminary analysis, using ANOVA, indicated AD and CI subjects had significantly smaller hippocampus and parahippocampus, and larger ventricles than controls ($p > 0.05$), but AD and CI did not differer from each other. AD subjects also had significantly smaller parietal lobes than controls and smaller temporal lobes (excluding hippocampus and parahippocampus) than CI and controls ($p > 0.05$). Hippocampal and temporal lobe volumes had a high correlation with MMSE ($r = .51$ and .50, respectively). Ventricle volumes had an inverse correlation (-.58) with MMSE scores. The results support previous observations indicating the integrity of the hippocampus and parahippocampus is important for cognitive functioning. MRI is useful in determining the neuroanatomical changes associated with dementia, but limited for differentiating between AD and CI which requires a battery of neurological and neuropsychological tests. MRI provides an excellent means to examine brain structure-function relationships and assessing the potential cognitive capacity with respect to the degenerative state.

Education provides a cognitive reserve against the clinical manifestations of Alzheimer's Disease: Evidence from regional cerebral blood flow. Y. Stern, G. Alexander*, I. Prohovnik* and R. Mayeux. Depts. of Neurology and Psychiatry, College of Physicians and Surgeons of Columbia Univ., New York, NY 10032.

The finding that dementia is most prevalent in individuals with fewer years of education has suggested the specific hypothesis that education protects against the consequences of Alzheimer's disease (AD). We tested this hypothesis by asking: do individuals with more years of education have a more advanced state of the underlying dementing process before it is clinically evident? In AD, there is a specific pattern of cerebral blood flow reduction in the temporoparietal area. We measured regional cerebral blood flow, using the ^{133}Xenon inhalation technique, in 3 groups of patients with probable AD matched for severity of dementia, but with varying levels of education (N=58). Although global flow was comparable across the three groups, the temporoparietal perfusion deficit was significantly greater in the group with the highest level of education ($p<.01$). This suggests that AD was more advanced in the higher education group although measures of the clinical severity of the dementia were comparable across groups. We conclude that increased education is associated with a reserve which compensates for the neuropathological changes of AD and delays the onset of its clinical manifestations.

498.5

ATP UTILIZATION IN DORSAL PREFRONTAL CORTEX OF ALZHEIMER'S DISEASE BRAIN IS CORRELATED WITH SEVERITY OF DEMENTIA. K. Panchalingam, J. W. Pettegrew, G. Branthoover*, M. Tretta*, Laboratory of Neurophysics, Dept. of Psychiatry, U. of Pittsburgh, Pittsburgh, Pa 15261.

Both *in vitro* and *in vivo* ^{31}P NMR studies have shown increased brain levels of phosphomonoesters (PME) in early stages of Alzheimer's disease. Phosphodiesters (PDE) are elevated in late stages of the disease. In this study, we report results of *in vivo* studies that demonstrate possible correlations between the degree of dementia and energy metabolism in the dorsal prefrontal cortex of mildly to moderately demented (Mattis 92-125, Blessed 1.5-13, MMS 16-24) male and female patients (N=14,ages over 65 years) with probable AD (NINCDS-ADRDA criteria). The results shows significant increase in ATP with degree of dementia (Blessed $p=0.03, r=0.4$, Mattis $p=0.02$, $r=0.4$). Female patients 63 years and older show similar correlations (Mattis $p=0.01, r=0.7$, Blessed $p=0.05$, $r=0.5$). In addition, the results indicate that the PME levels first increase and then decrease as the disease progressed. Normal controls show no change in membrane phospholipid metabolism or energy metabolism. These results support an important role for altered energy metabolism in the clinical symptoms of AD. ^{31}P NMR is non-invasive and therefore ideally suited to follow the natural course of the disease and response to therapies *in vivo*.

498.6

PATTERNS OF INTERCORRELATIONS OF REGIONAL CEREBRAL METABOLIC RATES OF GLUCOSE (rCMRglc) IN PATIENTS WITH DEMENTIA OF THE ALZHEIMER TYPE (DAT). N.P. Azari, S.I. Rapoport, C.L. Grady, M.B. Schapiro* and B. Horwitz. Lab. of Neurosciences, NIA, NIH, Bethesda, MD, 20892.

A correlational analysis of resting rCMRglc data obtained using positron emission tomography (PET) with [18F]flurodeoxyglucose, examined differences between DAT and control (CTRL) subjects. 22 age- and sex-matched CTRLs and 19 mild/moderate DATs were scanned with a Scanditronix PC1024-7B tomograph. The brain was divided into 65 regions of interest (ROIs). DATs had lower metabolic rates than CTRLs, and a greater variability of metabolic asymmetry. Correlations were performed on normalized (to whole-brain) values. DATs had fewer total correlations than CTRLs and showed decreased fronto-parietal, frontal-sensorimotor, frontal-limbic, and sensorimotor-parietal correlations. ROIs most involved in the decreased DAT correlations were dorsal left premotor, ventral left sensorimotor, right/left inferior parietal, right/left insula, and anterior cingulate. The results, confirming and extending a prior correlation analysis using a lower resolution PET scanner and different DAT and CTRL subjects (Horwitz et al., 1987), demonstrate decreased corticocortical interactions in DAT.

498.7

DETECTION AND MEASUREMENT OF NEURAL THREAD PROTEIN (NTP) IN CEREBROSPINAL FLUID (CSF): A POTENTIAL ANTEMORTEM MARKER FOR ALZHEIMER'S DISEASE. J. Chong, L. Cantrell*, B. Miller, M. Husain*, S. Riesing*, H. Ghanbari. Neuropsychiatric Markers R&D, Abbott Laboratories, Abbott Park, IL 60064.

Elevated levels of pancreatic thread protein (PTP)-immunoreactivity have been reported in brains of patients with Alzheimer's Disease (AD). Antibodies to PTP showed cross-reactive epitopes with a protein in AD brains. Further analysis of this neural thread protein-like immunoreactivity (NTP) revealed a larger protein species (20 KD) both in the brain and cerebrospinal fluid (CSF) as compared to the pancreatic form of the protein (14kD). We have developed an automated microparticle enzyme immunoassay (MEIA) for NTP. The reagents for this assay have been optimized and stabilized. Up to 22 samples can be analyzed within 45 minutes with a sensitivity of 60 picogram/ml. Titration curves of both normal and AD CSF demonstrated a linear relationship as did normal and AD brain extracts. Preliminary results indicate that clinically diagnosed probable AD CSF specimens have much higher NTP levels than those of non-AD CSF.

498.8

DETECTION AND MEASUREMENT OF ALZHEIMER'S DISEASE ASSOCIATED PROTEIN (ADAP) IN CEREBROSPINAL FLUID (CSF): AN ANTEMORTEM MARKER FOR ALZHEIMER'S DISEASE. H. Ghanbari, B. Miller, G. Robertson*, J. Chong, S. Riesing*, M. Hardey*. Neuropsychiatric Markers R&D, Abbott Laboratories, Abbott Park, IL 60064.

Alzheimer's disease (AD) is a neurodegenerative disease characterized by a chronically deteriorating course of impaired intellectual function and memory loss. The definitive diagnosis of AD is made by pathological examination of postmortem brain tissue in conjunction with a clinical history of dementia. The antemortem diagnosis of AD, however, is by exclusion. The misdiagnosis rate is about 30%. We have demonstrated in a large population of patients (n > 400) that ADAP is present in AD brain tissues and not in non-AD. Studies involving the distribution of ADAP in the brain have revealed that ADAP is elevated in the brain regions associated with memory processing/storage. Hence, we expect ADAP in CSF to be a good antemortem marker for AD. The ADAP concentration in CSF is in the femtomole/-ml range. Using ADAP extracted from brain tissue as a model, we have developed a chemiluminescent immunoassay (CLIA) suitable for measuring ADAP in CSF. Preliminary results indicate that ADAP level is significantly higher in AD CSF specimens as compared to non-AD CSF specimens.

498.9

LABELLING OF ACTIVATED MICROGLIA AND NEURAL MACROPHAGES BY ANTIBODY PRESENT IN THE CSF OF ALZHEIMER'S DISEASE PATIENTS. A. Dahlström[1], E.A. Ling*[2], R. Polinsky*[3] and A.McRae[1] Dept. of Histology[1], Univ. of Göteborg, Göteborg Sweden, Dept. of Anatomy[2], Nat. Univ. of Singapore, Singapore 0511, NINDS NIH[3], Bethesda MD USA.

Cerebrospinal fluid from Alzheimer's disease patients (AD-CSF) contains an antibody that recognizes amoeboid microglial cells, an activated form of microglia and macrophages in the developing rat brain. This study examined if AD-CSF would mark (A) the activated microglia, and (B) neural macrophages induced experimentally in adult rats. In (A), minute amounts of (2µl) of the toxic lectin Ricinus communin agglutinin (RCA-60, 0.05%) was injected into the sciatic nerve in anesthetized adult rats. This caused a selective destruction of the ventral horn neurons in the lower lumbar cord. The rapid neuronal cell death elicited a drastic response of the indigenous microglia. In (B), trace amounts of Kainic acid (KA) was applied extradurally over the sensorimotor cortex. Underlying cortical neurons were destroyed, which attracted a massive influx of neural macrophages. Rats were overdosed with barbital and perfusion fixed with 4% paraformaldehyde, 1-3 weeks after the operations. Tissue samples were incubated with non-diluted AD-CSFs and processed for immunocytochemical visualization with the avidin-biotin method. In RCA-treated samples, the activated microglia associated with the ventral horn neurons undergoing lysis were intensively stained. Many neuronal cell 'ghosts' were surrounded by AD-CSF positive cells. Contralateral microglial cells were not stained. In KA-treated samples, numerous active neural macrophages most probably derived from monocytes were also strongly stained. Electron microscopic studies showed that the immunoreactivity was detected at their plasma membrane. Some of the immunoreactive cells showed features indistinguishable from microglia. AD-CSF contains an antibody that specifically marks membrane antigens in the activated microglia and neural macrophages induced by experimental procedures, which strongly suggest the immunological involvement of monocytic cell lineage in AD.

PARKINSON'S DISEASE: HUMAN STUDIES

499.1

THE EFFECT OF ENZYME INHIBITORS ON THE APPARENT AUTOXIDATION RATE OF DOPAMINE AND RELATED CATECHOLS OF THE BRAIN.

B. Fornstedt and A. Carlsson*, Dept. of Pharmacology, University of Göteborg, Göteborg, Sweden.

The occurrence of 5-S-cysteinyl-dopamine (5-S-cysteinyl-DA), 5-S-cysteinyl-3,4-dihydroxyphenylalanine (5-S-cysteinyl-DOPA) and 5-S-cysteinyl-3,4-dihydroxyphenylacetic acid (5-S-cysteinyl-DOPAC) in dopaminergic brain areas of several mammalian species has been reported by this laboratory. The data indicates that DA and related catechols undergo *in vivo* autoxidation to reactive quinone forms, which then interact with thiol groups as that in cystein.

A substantial increase in 5-S-cysteinyl-DA has been found in the striatum following different time periods of reserpine treatment (5 mg/kg, i.p.). It was suggested that reserpine's inhibition of vesicle storage caused an increase in autoxidation of the unsheltered cytosolic pool of DA. Co-administration of pargyline (75 mg/kg, i.p., 18 h) did not change the elevation in 5-S-cysteinyl-DA levels, although DA available for autoxidation must have been increased. However, following pargyline treatment alone 5-S-cysteinyl-DA levels rised significantly.

The turnover rate appears to be lower for the 5-S-cysteinyl adducts than for their parent catechols as indicated in studies on enzyme inhibition as well as in other studies. Following 1 h of monoamine oxidase or tyrosine hydroxylase inhibition the levels of DOPAC and DOPA, respectively, decreased significantly whereas no effect was oberved for the correlated adduct's levels. Following 18 h of pargyline treatment the 5-S-cysteinyl-DOPAC concentration had decreased drastically, although not as much as the concentration of DOPAC. Alpha-Methyltyrosine treatment for 8 h (250 mg/kg, i.p.) of reserpine pre-treated animals resulted in significantly decreased levels of all three cysteinyl adducts.

499.2

LOCALIZATION OF SUPEROXIDE DISMUTASE AND GLUTATHIONE PEROXIDASE IN ANATOMICAL AREAS ASSOCIATED WITH NEURODEGENERATIVE DISORDERS. F.J. Denaro and J.S. Schneider. Dept. of Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Dept. of Neurology, Hahnemann University, Philadelphia, PA 19102.

Superoxide dismutase and glutathione peroxidase are two key enzymes which protect cells from destructive oxygen radicals. There is a growing body of evidence which implicates potentially damaging oxygen free radicals in disease processes. Examples of such diseases could be the neurodegenerative disorders of the brain, such as Parkinson's Disease and Alzheimer's Disease. Previously we developed antibodies to these enzymes (*J. Cell Biochem.* 12A, pp 44, 1988) and by means of immunocytochemistry identified superoxide dismutase and glutathione peroxidase containing cells in the human and rodent brain (Soc. for Neuroscience Abs., 1989). In the present study, we focus on areas strongly correlated with two important neurodegenerative disorders, Alzheimer's Disease (hippocampus, nucleus basalis) and Parkinson's Disease (substantia nigra and ventral tegmental area). It has been possible to identify the protective enzymes of interest in melanin-containing cells of the substantia nigra in primates and in cells of the cortex and hippocampus (granule cell layer). The sub-regional localization of these enzymes in these anatomical regions may have important implications for the pathophysiology of these neurodegenerative diseases.

499.3

ALLELIC VARIATIONS IN MAO GENES MARK ACTIVITY STATES AND MAY PREDICT VULNERABILITY TO PARKINSON DISEASE. C. Konradi (1), G.S. Hotamisligil (1,2),* A.S. Girmen (1),* S. Fink (1), J. Baenziger (3),* J. Sullivan (3),* J. Growdon (1), & X.O. Breakefield (1,2). (1) Neuroscience Ctr. & Neurology Dept., Mass. General Hosp., Boston, MA; (2) Dept. Genetics & Neuroscience Prog., Harvard Med. Sch., Boston, MA; (3) Depts. Psychiatry & Pathology, Alcohol Research Ctr., Indiana Univ. Med. Ctr., Indianapolis, IN.

Monoamine oxidases A and B are involved in degradative deamination of biogenic amines, including catecholamine neurotransmitters. These isozymes are encoded in homologous genes near each other on chromosome Xp11.3. Alleles for the MAOA gene are marked by several RFLP's, as well as a (GT)n repeat (Black et al, NAR, 1991); those for the MAOB gene, by a (GT)n repeat. A strong association has been found in control males between levels of MAO-A activity, measured in human skin fibroblasts, and specific alleles for the MAOA gene. Similar comparisons are underway for MAO-B activity, measured in platelets, and MAOB alleles. Individuals inherit widely varying levels of MAO-A and MAO-B activities. These different activity states may predispose individuals to certain diseases, like Parkinson disease, where drug models have implicated MAO in the pathogenic process. We have found a statistically significant difference in the frequency of alleles for MAOA and MAOB in over 60 Parkinson patients and 60 controls. This finding implicates endogenous levels of MAO-A and MAO-B activity in the disease process, and suggests that allelic status for these genes may be an index of susceptibility.

499.4

CALBINDIN-D_{28K} IN THE HUMAN HYPOTHALAMUS: RELATIONSHIP TO TYROSINE HYDROXYLASE (TH) IMMUNOREACTIVE NEURONS. M.K. Sanghera and D.C. German. Dept. of Psychiat., UT Southwestern Med. Cntr., Dallas, TX.

Calbindin-D_{28K} (CaBP), a calcium-binding protein, is localized within the midbrain dopaminergic (DA) neurons in the same regions that are spared in Parkinson's disease (PD) (German et al., Neurosci. Abstr. 16:696, 1990). Hypothalamic DA neurons do not appear to be degenerated in PD (Matzuk & Saper, Ann. Neurol. 18:552, 1985). The present experiment sought to determine if CaBP is localized in the same hypothalamic nuclei as the DA neurons. Immunocytochemical staining, with antibodies against TH (1:1000) and CaBP (1:1000), and computer imaging techniques were used to map the distribution of CaBP- and TH-containing cells. CaBP cells were located throughout the hypothalamus, however, often not confined within specific hypothalamic nuclei. The TH-containing cells were found within such nuclei as the arcuate, peri- and paraventricular nuclei. There was no substantial overlap in the distributions of CaBP- and TH-containing cells. These data suggest that CaBP does not protect the hypothalamic DA neurons from degeneration in PD. Supported by American Parkinson Disease Association, and AG-08013.

DOPAMINE DEPENDENT DECREASE IN ENKEPHALIN AND SUBSTANCE P LEVELS IN BASAL GANGLIA REGIONS OF POSTMORTEM PARKINSONIAN BRAINS. S. P. Sivam. Dept. Pharmacol./Toxicol., NW Ctr. for Med. Ed., Indiana Univ. Sch. Med., 3400 Broadway, Gary Indiana 46408-1197.

This study examined whether a relationship exists between the degree of dopamine (DA) loss and the changes in opioid (Met-enkephalin, ME; dynorphin A (1-8), DYN) or tachykinin (substance P, SP) peptidergic systems in basal ganglia (caudate and putamen) and limbic (frontal cortex) regions of postmortem tissue samples derived from patients who died of Parkinson's disease (PD). The levels of peptides were determined by radioimmunoassays. The levels of DA, 5-hydroxytryptamine (5-HT) and their metabolites were determined by HPLC. The degree of loss of DA in PD tissues was classified into two major categories, those with less than 80% and those with more than 80% DA loss as compared to control. It was found that the samples with more than 80% of DA loss exhibited lower levels of ME in caudate and SP in putamen; no changes were observed in DYN levels. A decrease in 5-HT level was also observed in caudate and putamen of samples that showed more than 80% DA loss. The frontal cortical region exhibited no changes in the levels of peptides. It appears that there is a DA-dependent secondary loss of enkephalin and tachykinin peptides in PD. In view of the involvement of these peptidergic systems in the regulation of behavior, movement and memory, derangements in these peptidergic systems should be considered as additional factors in the progression of symptoms of PD. Supported by USPHS grant NS 26063

DISTRIBUTION OF BINDING SITES FOR [^{3}H]CP-96,345 , A NONPEPTIDE NK_1 RECEPTOR ANATAGONIST IN HUMAN BRAIN: ALTERATIONS IN PARKINSON'S AND ALZHEIMER'S DISEASE. L. Rioux, B.S. Neal and J.N. Joyce. Departments of Psychiatry and Pharmacology, Univ. of Penn. Sch. Med., Philadelphia , PA

CP-96,345, a nonpeptide substance P antagonist, has been tritiated and determined to have high affinity (1.9 nM) for NK_1 receptors in guinea pig (McLean et al, Science 251:437, 1991). We have examined the distribution of this compound in postmortem human brain and examined alterations in Parkinson's (PD, n = 3) and Alzheimer's (AD, n=4) disease. Tissue sections were pre-incubated for 15 min at 22°C in 50 mM tris-HCl, containing 5mM $MnCl_2$ and 0.02% BSA (pH 7.3). Tissue section wre incubated in the same buffer with 5 nM [^{3}H]CP-96,345 at 4°C for 30 min with adjacent sections incu-bated in the presence of 5 µM CP-93,009-1. Following rinses and drying, the slides were apposed to ^{3}H-sensitive film for 60 days. Computer aided analysis indicated that nonspecific binding was 50% of the total binding at this concentration and certain regions of the human brain contained relatively high numbers of sites. The regions with the highest densities included the caudate (CN), putamen (PUT) and nucleus accumbens (NAS) (200-225 fmol/mg protein). Lower binding was observed in globus pallidus (40 fmol/mg P) and frontal cortex (100 fmols/mg P). The nucleus basalis (50 fmols/mg P) and regions of the medial temporal lobe, including the amygdala (50 fmol/mg P); entorhinal cortex (150 fmol/mg P), subiculum (175 fmol/mg P), CA1-CA3 (175 fmol/mg P), and dentate gyrus (200 fmol/mg P), showed high levels of binding. Binding was decreased in all regions of the striatal complex in PD and AD. In AD cases the binding was decreased by 17% in CN , 52% in PUT and by 32% in NAS and globus pallidus. In the PD cases the loss 68% in CN, 46% in PUT and 72% in NAS. Analysis of the medial temporal lobe is pending. **Funded by a grant from Pfizer Central Research.**

DISTURBANCES IN PRE- AND POSTSYNAPTIC DOPAMINE SYSTEMS IN PARKINSON'S AND ALZHEIMER'S DISEASE. A.M. Murray, F. Weihmueller*, J. F. Marshall*, and J.N. Joyce. Departments of Psychiatry and Pharmacology, Univ. of Penn. Sch. Med., Philadelphia , PA ; *Dept. Psychobiology, Univ. California, Irvine CA.

Parkinsons disease (PD) is most clearly associated with disturbances of motor function such as bradykinesia, tremor and rigidity. Increasing attention has been paid to the contribution of post-synaptic dopamine (DA) systems within the striatum to the development of the motor symptoms and the loss of responsiveness to treatment regimens. Many patients also develop severe dementia, which may also be related to disturbances in DA function. Patients developing Alzheimers disease (AD) also may develop PD symptoms, but only some of them show Lewy bodies or significant losses of pigmented neurones in the substantia nigra. In order to explore the role of pre and post-synaptic elements of the DA system to the clinical picture associated with AD, we utilized quantitative autoradiography to identify alter-ations in the density of high-affinity uptake sites for DA ([^{3}H]mazindol), and two DA receptor sub-types, D1 ([^{3}H]SCH23390) and D2 ([^{125}I]epidepride), in post-mortem tissue from patients with PD, AD, PD with AD and age-matched controls. Loss of pigmented neurons in PD was associated with a 90% loss of DA uptake sites in the motor region of the striatum (putamen) with less significant reductions seen in the caudate (40% rostral and 60% caudal). In contrast only a 20% loss of sites was seen in the putamen of the AD cases with a greater loss in the caudate (30-35%). In PD cases, an increase (46-51%) in D2 receptor density was seen in the region of almost complete loss of DA uptake sites (putamen) with a 10% reduction in the caudate nucleus. AD cases showed a 12-20% decrease of D2 receptors in the putamen. Preliminary analysis of D1 receptors showed slight decreases in AD striatum with no significant differences in PD brains. **Funded by MH43852, MH 43880, AG 09215.**

MITOCHONDRIAL FUNCTION IN PLATELETS AND MUSCLE IN PARKINSON'S DISEASE. D. Bravi*, J.J. Anderson, F. Dagani*, T.L. Davis*, R. Ferrari*, M. Gillespie*, and T.N. Chase, Experimental Therapeutics Branch, NINDS, NIH, Bethesda, MD 20892 and Institute of Pharmacology, University of Pavia, Pavia, Italy.

Recent evidence suggests that reductions in mitochondrial metabolism exist in substantia nigra, platelets, and skeletal muscle in Parkinson's disease (PD). However, it is unclear if these alterations occur in all cells of the body or specifically in dopamine cells of the substantia nigra. In this investigation, mitochondrial respiration and electron transport chain enzyme activity was studied in both platelets and muscle isolated from seven subjects suffering from PD and matched normal controls. Oxygen consumption rate in the presence of ADP induced by NADH-generating substrates (Complex I activity), succinate + rotenone (Complex II-III activity), and TMPD + ascorbate (Complex IV activity) in digitonin permeabilized platelets and isolated muscle mitochondria were not significantly different between control and PD subjects. Likewise, activities of the enzymes succinate cytochrome c reductase (Complex II-III activity) and cytochrome oxidase (Complex IV activity) in platelet and muscle mitochondria were not significantly different between control and PD subjects. These results suggest that there are no differences in mitochondrial function in peripheral tissues in Parkinson's disease and any mitochondrial defect may be localized to the substantia nigra.

ANTI-NEURONAL ANTIBODIES AND OTHER MARKERS OF IMMUNE SYSTEM ACTIVATION IN PARKINSON'S DISEASE. D.A. Loeffler[1]*, C.M. Brickman*[1], G. Kapatos[3], J.B. Peter*[2], P.A. Lewitt*[1] Dept. of Psychiatry, Wayne State University[3], Detroit, MI 48201 and The Clinical Neuroscience Program[1], Sinai Hospital, Detroit, MI 48235 and Specialty Labs, Inc.[2], Santa Monica, CA 90404-3900.

Anti-neuronal antibodies have been reported in serum and cerebrospinal fluid (CSF) from patients with Parkinson's Disease (PD), though further clues for immune mechanisms in this disorder have not been explored. With CSF from unmedicated PD subjects (n=17), normal controls (n=13), and patients with multiple sclerosis (n=10) and other medical disorders (n=18), we measured several indicators of immune system activation, including interleukin-1-beta (IL-1b), soluble interleukin-2-receptor (sIL-2R), tumor necrosis factor-alpha (TNF), and beta-2-microglobulin (B-2-M). Two methods were investigated for evaluating possible anti-neuronal immunoglobulins: an enzyme-linked immunosorbent assay (ELISA) detecting antibodies against plasma membrane antigens of a human neuroblastoma cell line (Sk-N-Mc), and an immunocytochemical technique for detecting antibody binding to neurons in sections of fixed rat midbrain. Three of the PD CSF samples produced detectable staining of rat midbrain cells; no antibodies against neuroblastoma antigens or cardiolipin were found in these samples. IL-1b, sIL-2R, and TNF were not detected in PD CSF samples; B-2-M was detected in all PD CSF samples but did not differ from B-2-M in normal CSF. Our data do not indicate that local immune system activation is present in PD.(Supported by the Student Fellowship Program of the Michigan Parkinson Foundation and NIH grants NS-27892, PAL, and NS-26081, GK).

FORCE CONTROL IN PARKINSONIAN HANDWRITING. H.L. - Teulings*, Nijmegen Institute for Cognitive Research, Nijmegen, The Netherlands, and G.E. Stelmach, Department of Exercise Science, Arizona State University, Tempe, AZ 85287-0404, USA.

The aim of this study was to quantify motor control deficits in Parkinsonian handwriting. Using a digitizing tablet, and performing signal-to-noise analyses and computer simulations, six idiopathic Parkinson's disease subjects and matched controls were examined as they executed a writing pattern. The analysis revealed that the movement deficits, often noted in Parkinsonians, were primarily due to an impaired force-amplitude component rather than to an impaired stroke-duration component. Computer simulations which altered the force-amplitude and force-duration components supported the signal-to-noise analysis. Applying the simulations as predictors, Parkinsonians were found to have few problems with sharp movement reversals during cursive script while exhibiting difficulty in maintaining a straight baseline over the writing pattern. The data are interpreted as demonstrating that Parkinson's disease alters the ability to regulate force amplitude.

SLEEP DEPRIVATION IMPROVES OCULAR AND MOTOR DEFECTS OF PARKINSONS DISEASE. E.M. DeMet, C. Reist, E. Coskinas*, A. Chhoeu*, C.-C. Chen*, K. Sokolski*. Depts. Psychiatry, Univ. California, Irvine, CA 92717 and Long Beach VA Hospital, Long Beach, CA 90822.

The retina and substantia nigra arise from a common embryological source. Degenerative changes in both tissues occur in Parkinsonism. Retinal function may be assessed through the use of electrooculograms obtained under conditions of light and dark adaptation. Some evidence suggests that sleep deprivation (SD) may improve the motor dysfunction of Parkinsonism. The present study sought to determine if similar changes also occur in retina. Motor function and ocular potentials were measured in patients with Parkinsons disease prior to and following SD. This treatment substantially improved motor function (>40%) and significantly increased ocular potentials. Improvements in these measures were highly correlated (r>0.9) and were approximately equally distributed over the range of the group response. The results confirm that SD therapy may provide temporary relief of motor disabilities. Parallel actions in retina and striatum, and the anatomical isolation of these tissues, further suggest that the SD effect may be expressed through induction of an endogenous humoral agent. Such an agent could provide a basis for the development of more effective treatments for Parkinsons disease.

DOPAMINE DEPENDENT SPATIAL WORKING MEMORY DEFICITS IN PARKINSON'S DISEASE.

A.M.Owen*, M. Beksinska*, M.James*, K.W.Lange*, B.A.Summers*, P.N.Leigh, N.P.Quinn, C.D.Marsden* & T.W.Robbins. Institutes of Psychiatry and Neurology, London, U.K. and Dept. of Expt. Psychol., Univ. of Cambridge, Cambridge, U.K.

Groups of patients with idiopathic Parkinson's disease (PD), either medicated or unmedicated, were compared with matched controls on a computerised battery of tests designed to assess different aspects of visuo-spatial memory and learning. In a test of spatial working memory known to be sensitive to frontal lobe damage, significant impairments were found only in the medicated PD patients and particularly in those patients with more severe clinical symptoms. These medicated patients 'later in the course' of the disease were also impaired in both a delayed matching to sample procedure and at learning the locations of a number of patterns on the screen. In contrast, spatial recognition was significantly impaired in medicated PD patients with both mild and severe clinical symptoms.

In a parallel experiment, this same battery of tests was given to 10 PD patients 'on' and 'off' L-Dopa therapy. Significant impairments following withdrawal of medication were only evident in the test of spatial working memory.

These results suggest that there are multiple memory impairments in PD which may differentially depend on the clinical severity of the disease. In addition, the selective impairment in spatial working memory following L-Dopa withdrawal suggests that those tests of memory function most sensitive to frontal lobe damage also depend most heavily on dopaminergic substrates.

PATIENTS WITH HEPATIC ENCEPHALOPATHY SHOW ALTERATIONS OF BRAIN ACTIVITY THAT APPEARS TO RELATE TO EXTRAPYRAMIDAL SYSTEMS. J. F. Rodriguez-Sierra, N. A. Norton*, J. R. McConell* and C. B. Greiner*. Departments of Anatomy, Radiology and Psychiatry, University of Nebraska Medical Center, Omaha, NE 68198.

Hepatic Encephalopathy (HE) is an alteration in mental state due to chronic liver disease. Although the etiology of HE is varied the expression of the disease is fairly typical: from subtle abnormalities of intellectual and motor function to coma and death. During the progression of the disease, we have noted that the patient displays signs of agitation with accompanying extrapyramidal signs of activity. We investigated whether HE patients might have some changes in their extrapyramidal system by using Magnetic Resonance Imaging (MRI) in 4 patients diagnosed with HE. The HE brain MRIs were compared to the MRIs of patients that did not have HE. All the images were scanned and the reflectances were analyzed by densitometry using the JAVA (Jandel Scientific) software system. Our results show that there were significant differences in areas of the extrapyramidal system, but that in addition some major fiber tracts were also affected: particularly the corpus callosum and the cerebral peduncles. The tectal area showed a significant effect using both axial (A) or sagittal (S) approaches. There were no significant differences in areas of the cerebral cortex, nor in the thalamus. There was some changes in the hippocampus and anterior portion of the internal capsule, but due to our small number of patients, the differences were not statistically significant. It appears that the HE patient is experiencing some alteration in the extrapyramidal pathways as well as in interhemispheric pathways. It remains to be determined whether the small effects in the hippocampus can be replicated as they would explain some of the behavioral deficits experienced by these individuals. (This work was partially supported by a grant from the NIH HD-13219 and funds from the University of Nebraska Medical Center Department of Radiology).

A SENSITIVE AND SPECIFIC RADIOIMMUNOASSAY (RIA) FOR THE QUANTIFICATION OF PERGOLIDE. R. R. Bowsher*, J. A. Compton*, J. M. Apathy*, R. L. Wolen* and D. P. Henry. Lilly Lab. for Clinical Research, Eli Lilly & Co., Indianapolis, IN 46202.

Pergolide mesylate, [(Methylthio)methyl]-6-propylergoline monomethanesulfonate (LY127809), is a synthetic ergot alkaloid with potent dopaminergic (D1 and D2) activity and is marketed under the trade name Permax ® for use in the treatment of Parkinson's Disease. The low level of pergolide found in plasma (≤1 ng/ml) after oral dosing has complicated the development of analytical methodology for pergolide. Accordingly, we developed and validated a monoclonal antibody-based competitive RIA specifically optimized for the measurement of pergolide in plasma (Table I). Briefly, samples (0.5 ml) are incubated 20 h at 10 C with 75 ng of tritiated pergolide (0.1 ml) and anti-pergolide MoAb diluted 1:50,000 (0.1 ml). Separation of bound and free labelled pergolide is achieved by adsorbing the free fraction with 1% dextran-coated 5% charcoal. Plasma levels are then estimated from a standard curve of reference pergolide ranging from 5 to 5,000 pg/ml.

Table I

Sensitivity	< 25 pg/ml
ED50	168 pg/ml
Inter-assay %CV	11.3-15.5%
Recovery	82-97%

Displacement experiments involving 4 pergolide metabolites found during animal studies and 5 synthetic analogs indicated the RIA is specific for pergolide and permitted defining the MoAb binding epitope. We conclude the RIA is a valid method for quantifying therapeutic concentrations of pergolide in plasma from man, rat and monkey.

THE USE OF MICROWAVE (MW) FIXATION FOR THE DETERMINATION OF MOUSE BRAIN METABOLITES DURING HIGH +Gz (HEAD-TO-FOOT) EXPOSURE IN A SMALL ANIMAL CENTRIFUGE (SAC). A. R. Shahed, B. B. Stavinoha*, J. A. Barber* and P. M. Werchan*. Up. Tech. Corp., UTHSC, San Antonio, Krug Life Sci. and Armstrong Laboratory, Brooks AFB. TX 78235

The mechanism or effects of acceleration induced loss of consciousness (G-LOC) observed in pilots of high performance aircraft are not fully understood. It has been proposed that cerebral blood flow may cease due to zero carotid artery pressure within 2s after >5 +Gz exposure. **HYPOTHESIS:** G-LOC may result from global ischemia and subsequent energy depletion. **METHODS:** A SAC equipped with a 2450 MHz, 10 KW, MW system with rotating waveguide was used for brain fixation. Mice were exposed to either varying +Gz (15 to 35) forces or duration (0-35s) and brains were fixed at specific time points during and 60s post run. Brain glycolytic and high energy phosphates were measured. **RESULTS:** The G-tolerance data show that the levels of glucose, C-P and ATP decreased and lactate accumulated as +Gz force increased. The time curve shows significant changes in glucose (-85%), C-P (-73%) and ATP (-22 %), lactate (+220%), AMP (+67%) and adenosine (+10 fold) 35s after the onset of 35 +Gz. The level of these metabolites were not restored 60s after the SAC run. **CONCLUSIONS:** (1) MW is an ideal tool for brain fixation during +Gz exposure. (2) G-LOC may occur to conserve energy resources during the cessation of cerebral blood flow in a high +Gz environment.

EFFECT OF LOW FREQUENCY PULSING ELECTROMAGNETIC FIELDS (PEMFs) ON FOCAL CEREBRAL ISCHEMIA. G.A. Grant, R. Cadossi*, and G.K. Steinberg. Dept. of Neurosurgery, Stanford Univ. Sch. of Med., Stanford, CA 94305

There is evidence that electromagnetic stimulation may accelerate the healing of tissue damage following ischemia. We studied the effect of exposure to PEMFs on cerebral injury in a rabbit model of transient focal ischemia (2 hr. occlusion of left ACA, ICA, and MCA, followed by 4 hrs. of reperfusion). PEMF exposure(240 V, 75 Hz) was initiated 10 min. after the onset of ischemia and continued throughout reperfusion(6 exposed, 6 controls). Magnetic resonance imaging(MRI) and somatosensory evoked potentials(SEPs) were used to measure the degree of ischemic injury. Exposure to the PEMF did not significantly reduce the area of MRI injury (exposed, 16.1 vs. control, 17.1). Although exposure showed a trend toward recovery of SEPs, this finding was not statistically significant (exposed, 54.9% vs. control, 27.7%). Preliminary data suggest that exposure to a PEMF of short duration has no beneficial role in the treatment of stroke, although more prolonged exposure might prove efficacious. (AHA Grant 881069 and IGEA).

PROTEIN OXIDATION AND INHIBITION OF GLUTAMINE SYNTHETASE IN THE CEREBRAL CORTEX FOLLOWING CARDIAC ARREST AND RESUSCITATION. G. Fiskum[1,2], R.E. Rosenthal[2*], and P.E. Starke-Reed[3*]. Dept. of Biochemistry and Molecular Biology[1], Emergency Medicine[2], and Medicine[3]. George Washington Univ. Medic. Center, Wash., D.C. 20037.

Proteins, e.g. glutamine synthetase, are an important site of attack by free radicals and metal-catalyzed oxidation systems. In this study, site-specific protein oxidation, as reflected by generation of carbonyl groups (CG), and glutamine synthetase activity (GS) were measured in protein extracts from the temporal cortex of chloralose-anesthetized, adult female beagles subjected to: A. sham-procedure (SP); B. 10 min of electrically-induced cardiac arrest (CA); C. 10 min CA followed by defibrillation and 2 hour of restoration of spontaneous circulation (CA/2 hr ROSC) and; D. 10 min CA followed by 24 hr ROSC (CA/24 hr ROSC). The following results were obtained: (values represent means ± S.E., n = 5).

	SP	CA	CA/2hr ROSC	CA/24hr ROSC
CG (nmoles mg^{-1} protein)	3.1±0.2	2.4±0.2	5.7±0.3	4.4±0.4
GS (units mg^{-1} protein)	87±4	84±8	59±8	75±3

These results suggest that free radical-mediated protein oxidation and associated inhibition of the activity of GS, an important enzyme in glutamate metabolism, may contribute to the molecular basis of brain damage in a clinically-relevant model of global cerebral ischemia and reperfusion. (Supported by a grant from Sigma Tau, S.p.A.).

LITHIUM EFFECTS ON DECAPITATION-INDUCED RELEASES OF INOSITOL PHOSPHATES, DIACYL-GLYCEROLS AND FREE FATTY ACIDS IN MOUSE CEREBRUM. T-A Lin*, J-P Zhang* and G.Y. Sun, Biochem. Dept. Univ Missouri, Columbia, MO 65212.

Decapitation-ischemia is known to cause a rapid hydrolysis of poly-phosphoinositides with concurrent increases in inositol phosphates, free fatty acids (FFA) and diacylglycerols (DAG) in brain. In this study, the effects of lithium administration on these events were examined. Adult C57Bl/6J mice were administered i.p. either lithium (8 meq/kg body wt) or saline 4 hr prior to decapitation and then subjected to decapitation ischemic treatment (5, 35, 65, 125, 305 sec). The cerebrum was taken for analysis of inositol phosphates by ion chrmatography, Ins(1,4,5)P_3 by radioreceptor binding assay and FFA and DAG by gas-liquid chromatography. In control mice, decapitation induced a sequential turnover of Ins(1,4,5)P_3 to Ins(1,4)P_2 and Ins(4)P with peak activities at 35, 65 and 125 sec, respectively. Lithium administration did not alter the turnover of Ins(1,4,5)P_3 but increased the levels of Ins(1,4)P_2, Ins(1)P and Ins(4)P. Decapitation resulted in an immediate increase in the levels of DG but the increase in FFA levels showed a lag time of 35 sec. Lithium treatment resulted in a decrease in the initial phase of FFA release which was reflected in an increase in the level of DAG. These results suggest that lithium may interfere with the release of FFA in brain through the DG-lipase pathway.

500.5

EFFECTS OF RAT FOCAL CEREBRAL ISCHEMIA ON LEVELS OF INS(1,4,5)P_3 G.Y. Sun, T-A Lin*, T-N Lin*, Y.-Y. He*, and C.Y. Hsu. Biochem Dept, Univ Missouri-School of Medicine, and Div. Restoratory Neurology, Baylor College of Medicine, Houston, TX.

Severe and mild focal cerebral ischemia in the right and left middle cerebral artery (MCA) could be induced by temporary occlusion of the right MCA and both common carotid arteries. Poly-phosphoinositide (PI) breakdown in the MCA cortex was dependent on the severity of the ischemic insult (Stroke 22: 495, 1991) and is marked by a transient increase in the level of Ins(1,4,5)P_3, followed by rapid conversion to Ins(1,4)P_2 and Ins(4)P. In this study, the levels of Ins(1,4,5)P_3 in the left and right MCA cortex were determined using the radioreceptor binding assay. Ischemia for 60 min resulted in marked decreases in levels of Ins(1,4,5)P_3 in the right (2.7 ± 1.9 nmol/g wt, n=7) and to a lesser extent, the left (7.1 ± 2.8, n=7) MCA cortex as compared to sham-operated controls (16-18 nmol/g wt). After 60 min ischemic treatment, reperfusion for 24 hr failed to restore the levels of Ins(1,4,5)P_3 in the right MCA cortex. On the other hand, ischemia for 30 min followed by reperfusion resulted in complete restoration of the levels of Ins(1,4,5)P_3 to control levels in both the right and left MCA cortex. The biochemical findings in this study are in agreement with earlier observation of irreversible neuronal injury to the right MCA cortex following severe ischemia for 60 min or longer (Am J. Physiol. 256:H589, 1989).

500.6

PERSISTENCE OF SEROTONIN AND CHOLECYSTOKININ IMMUNOREACTIVE NERVE FIBERS IN THE GERBIL HIPPOCAMPAL FORMATION FOLLOWING CEREBRAL ISCHEMIA. T. Kondoh[1], J. Howard[2], P.L. Faris[2], B.K. Hartman[2], Y.J. Li[1], S.M. Onifer[3], and W.C.Low[1], Depts. of [1]Neurosurgery and [2]Psychiatry, Univ. of Minnesota Medical School, Minneapolis, MN 55455 and [3]Dept. of Neurological Surgery, Univ. of Miami School of Medicine, Miami, FL 33101.

Serotonin (5HT) and cholecystokinin (CCK) -immunoreactive nerve fibers were studied in the hippocampal formation following the induction of transient forebrain ischemia in the mongolian gerbil. Transient cerebral ischemia was produced by occluding bilaterally the carotid arteries for a period of 10 min. Nerve fibers within the ischemic hippocampus were visualized using antibodies raised against 5HT and CCK. Pyramidal neurons in the dorsal CA1 region of the hippocampal formation had degenerated extensively 6-12 months after the ischemic episode. 5HT- and CCK-immunoreactive fibers were found to persist throughout the ischemic CA1 field in the absence of their post-synaptic targets. These observations suggest that 5HT and CCK fibers are resistant to ischemic injury. Moreover their persistence after ischemia suggests that they may be available to establish host-to-graft fiber connections with transplanted hippocampal pyramidal cells in attempts to reconstruct neural circuits that are damaged following ischemic injury.

CEREBROVASCULAR AND EVOKED POTENTIAL EFFECTS OF NEONATAL HYDROCEPHALUS. U.S. Vasthare*, J.P. McAllister, P.M. Hale* R.H. Rosenwasser* and J.S. Way. Depts. of Physiology, Anatomy and Neurosurgery, Temple University School of Medicine, Philadelphia, PA 19140.

This study was designed to assess the effects of infantile hydrocephalus and surgical decompression on cerebral blood flow (CBF) and somatosensory evoked response (SSER). Hydrocephalus was induced in 10 day old kittens by intracisternal injection of kaolin and verified with ultrasound; saline-injected or normal animals served as age-matched controls. Radiolabelled microspheres were used to measure CBF in severely hydrocephalic animals; standard SSER measurements were performed on control and hydrocephalic animals, as well as hydrocephalics that were decompressed with ventriculoperitoneal (VP) shunts at 6-13 days post-kaolin. Significant (p less than 0.05) decreases in CBF were detected in cortical areas 4 (61% below control), 22 (54%) and 17 (55%), as well as the thalamus (46%), midbrain/pons (54%) and caudate nucleus (64%); non-significant decreases occurred in the hippocampus (41%) and cerebellum (40%). Since mean CBF never fell below 23 ml/min/100g in any area, ischemia may not play a major role during hydrocephalus. Hydrocephalics exhibited pre-shunt increases in the SSER cortical peak latency, which was not reveresed immediately by VP shunting. Latency did return to normal by 7 days post-shunt. This early recovery suggests that axons are not structurally impaired during hydrocephalus.

NEURONAL DAMAGE IN THE SUBSTANTIA NIGRA RETICULATA IS DELAYED AFTER REPETITIVE FOREBRAIN ISCHEMIA. A. Shuaib, S. Ijaz,*J. Kalra,*W. Code, S. Mantha,*T. McConnell,* W. Howlett,*S. Lim.*

Neuronal damage after repetitive cerebral ischemia is more severe compared to a similar degree of exposure to a single ischemic insult. In the gerbil model of forebrain ischemia, in addition to damage in the striatum, cortex and the hippocampus, frequent damage is also seen in the medial geniculate nucleus, substantia nigra reticulata (SNr) and inferior colliculus, regions not supplied via the carotid arteries. We postulated that damage in the SNr was a result of loss of inhibitory input from the striatum and was therefore delayed in onset. Three, three minute transient forebrain ischemic insults were produced with one hour of reperfusion interval between episodes. Animals were sacrificed 2 days and 7 days after the insult and silver staining was used to assess neuronal damage. Beginning within two days of the insult, there was extensive damage in the hippocampus, striatum and thalamus. Damage in the SNr was apparent after 3 days and was maximum in the 7 day survival animals. This delay in the onset of damage in the SNr offers a window of 48 hours where proper intervention may prevent neuronal damage.

500.9

BLOOD FLOW THRESHOLD FOR ISCHEMIC DEPOLARIZATION OF RAT NEOCORTEX Y. Takeda*, M. Jacewicz and W. Pulsinelli. Dept. of Neurology and Neuroscience, Cornell University Medical College, New York, NY

To determine the ischemic blood flow threshold below which rat neocortex depolarizes, we implanted a DC potential electrode (DCPE) in the neocortex of halothane-anesthetized Spontaneously Hypertensive rats (n=27) and occluded their middle cerebral (MCA) and ipsilateral common carotid (CCA) arteries. The DCPE was inserted 800 μm below the cortical surface at 2 mm posterior and 3 mm lateral to bregma. This location represents a previously-determined transition zone between moderate and mild ischemia. To assure the second-to-second stability of CBF in the vicinity of the DCPE, a laser-Doppler flow probe was positioned within 1 mm of the DCPE. Approximately 10 minutes after MCA/CCA occlusion ^{14}C-iodoantipyrine (^{14}C-IAP) was injected intravenously and the animals were decapitated 5-6 seconds later. CBF was measured at the site of the DCPE using autoradiographies of frozen, dried coronal brain sections and image analysis (Quantimet 970). The DCPE site was located by injecting 0.15 μl of fluorescein (0.9 mg/ml) through the DCPE just prior to injecting ^{14}C-IAP. Statistical analysis of 27 rats (13 with depolarization, 14 without) using logistic regression and the jack-knife method indicated that 10% of rats depolarized at a CBF of 72.7 ± 5.3, 50% at 47.8 ± 1.5 and 90% at 22.9 ± 3.0 ml/100 gm/min. The results are consistent with our observations that the CBF in the border zone of focal cerebral infarction is approximately 45-50 ml/100g/min (Jacewicz et al, Soc. Neurosci. Abst., 16:1278, 1990). We conclude that the threshold for ischemic depolarization in the SHR and therefore the threshold for ischemic brain injury in this species lies at approximately 50 ml/100g/min.

500.10

ISCHEMIA IN GERBIL FOREBRAIN: POST-ISCHEMIC TREATMENT OF DI- CALCIPHOR PREVENTS CALCIUM-MEDIATED DEGRADATION OF SPECTRIN AND MAP2. **D. F. Matesic, T.M.Devlin*, A.Kalenak*, R. J. McKenzie* D.K.J.E.von Lubitz*, and R.C.S.Lin, Depts.of Physiol.& Biophys., and Biochem. Hahnemann University, Philadelphia, PA 19102**

To elucidate the mechanism of selective cell death in the ischemic forebrain, degradation of spectrin and MAP2, which is known to be mediated by the calcium-activated protease calpain I was studied using both immunohistochemical and immunoblotting techniques. Previously, we have shown that Di-Calciphor has calcium ionophoretic activity and that post-ischemic treatment reduces mortality. Therefore, the effects of this drug on the breakdown of spectrin, MAP2 and other structural proteins after ischemia were studied.

Immunoblot analyses of proteins from both dorsal hippocampus (DHP) and lateral striatum (LStr) in gerbils subjected to a 20 min. occlusion vs controls revealed 2 major spectrin degradation products (150-160 kD; Seubert, BR:492,1989) in day 1 and up to day 4 post-ischemia, with a corresponding decrease in spectrin (240 kD). These 2 bands were indetectable in control animals. Decrease of MAP2 on immunoblots in the DHP and LStr was observed 1 day and 4 days post-ischemia which correlated with the loss of immunohistochemical staining of MAP2. Levels of actin showed no major differences in control vs ischemic tissues, suggesting that breakdown of calpain I substrates preceeds breakdown of other structural proteins.

Degradation of both spectrin and MAP2 in DHP and LStr was prevented in animals treated with Di-Calciphor (10 mg/kg at 30 min. and 24 hrs after ischemia). These results provide evidence that Di-Calciphor may be a useful tool in studying calcium- mediated mechanisms of neuronal damage. **(supported by ONR grant N00014-89-J-1738 and Harvard Apparatus).**

CEREBRAL ISCHEMIA IN GERBILS: THERAPEUTIC EFFECTS OF DELAYED TREATMENT WITH CALCIPHOR (DIMER OF 16'16-DIMETHYL PROSTAGLANDIN B1). Dag K.J.E.von Lubitz*, T.M.Devlin*, A.Kalenak*, R.C.S.Lin, D.F. Matesic, R.J.McKenzie*.Depts.of Biochem.and Physiol. and Biophys., Hahnemann Univ. Sch. Med., Philadelphia, PA 19102

We demonstrated previously that immediately postischemic application of Di-Calciphor resulted in a pronounced improvement of survival in gerbils, and in enhanced quality of neurological recovery. We now describe the actions of Di-Calciphor on normal animals and the resuscitative effect of the drug following a delayed postischemic application.

Bilateral carotid occlusion (20 min) in female gerbils was followed by Di-Calciphor given I.P. at 5 or 10 mg/kg at 30, 60 or 180 min and 24 hrs postischemia (N=25/group). Ischemic controls (N=25) were injected with the vehicle. A group of nonischemic gerbils (N=25) was injected with 10 mg/kg Di-Calciphor. Rectal and epicranial temperature (RT,ET), mean arterial blood pressure (MABP), and cardiac rate (BPM) were noninvasively monitored in all animals. Epicranial platinum electrodes were used to record EEG. Postinjection/postischemic RT, RE, MABP, BPM and EEG were monitored at 60 min intervals for 6 hrs. Postischemic locomotor activity was monitored for 56 hrs and postischemic survival for 14 days.

Minimum postischemic life expectancy was 9 days in the animals treated at 5 mg/kg at 60 or 180 min postischemia, or 10 days at 10 mg/kg at 180 min, and 5 days in the controls ($p<0.05$). Postischemic recovery of the treated animals was characterized by EEG slow-down, reduction of the severity and frequency of seizures, and a reduction of the hyperactive period. Neuronal preservation was significantly improved in the hippocampus and striatum ($p<0.05$). Following injections of the drug, the postischemic/ postinjection RT, RE, MABP and BPM did not differ from the preischemic level.

Our experiments indicate that, although its mechanism of action is not fully known, Di-Calciphor is a compound of interest as a potential agent in treatment of cerebral ischemia. (supported by ONR grant N00014-89-J-1738, assistance of Harvard Apparatus is also acknowledged)

EFFECTS OF ACUTE VERSUS CHRONIC PRE-ISCHEMIC HYPERGLYCEMIA ON POSTISCHEMIC MORTALITY IN THE RAT. TX Gionet*, DS Warner, MM Todd. Department of Anesthesia, University of Iowa, Iowa City, IA 52242

Acute hyperglycemia (i.e., i.v. glucose infusion) prior to global ischemia often results in brain edema, seizures and death. To determine if chronic pre-ischemic hyperglycemia has similar effects on mortality, 3 groups of male Sprague-Dawley rats were subjected to 10 mins of bilateral carotid artery occlusion combined with systemic hypotension (MAP = 30±5 mmHg) and allowed 5 days recovery. The control group (n = 5) were healthy rats fasted from food for 12-18 hrs prior to ischemia. The acute hyperglycemic group (n = 7) were similarly fasted but also administered 1.5 ml of 25% glucose in saline, i.v., over 30 mins immediately prior to ischemia. The chronic hyperglycemia group were given 45 mg/kg streptozotocin subcutaneously 5-7 days prior to ischemia. These rats were fasted 6-8 hrs prior to ischemia and further studied if plasma glucose was between 300-400 mg/dL after surgical preparation (n = 9). Postischemic mortality rates were compared by Chi-square analysis. Blood gases, pericranial temp. and blood pressure were similar between groups. Plasma glucose values at onset of ischemia were 129±28, 379±66, and 358±33 mg/dL for the control, acute and chronic hyperglycemic groups respectively. There were no deaths in the control group, and one death in the chronic hyperglycemia group (11%), while 4 of 7 (57%) acute hyperglycemia rats died ($p<.03$). These results are consistent with human observations made by Woo et al. (Arch Neurol 47; 1990, 1174-7) and suggest a possible effect of duration of pre-ischemic hyperglycemia on relevance of this variable to postischemic outcome.

TRANSIENT FOREBRAIN ISCHEMIA IN THE CFW MOUSE.

R.N. Willette, R.K. Clark, E.V. Lee* and F.C. Barone, Division of Pharmacology, SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406.

The effects of bilateral common carotid artery occlusion on local cortical perfusion, EEG power and forebrain histopathology were examined in CFW mice. Under chloral hydrate anesthesia transient bilateral occlusion of the common carotid arteries elicited an immediate and sustained reduction in local cortical perfusion. The maximal reduction in perfusion (85±2%) was reached within 1 min and was maintained throughout the occlusion period (5 to 10 min). Similarly, the concomitant deterioration of the EEG power reached a minimum (-82±7%) within 1 min and remained depressed during ischemia. A histopathologic evaluation of the forebrain performed 7 days following 5 and 10 min periods of bilateral common carotid artery occlusion revealed significant neuronal damage in the cortex, dentate, and CA1 and CA3 fields of the hippocampus. The degree of damage in these areas were related to the duration of the ischemia. A carbon black study of the posterior communicating arteries in 16 mice indicated that 25% had patent arteries bilaterally, 37.5% had only one patent artery and 37.5% had no patent arteries. We conclude that the posterior cerebral circulation in the CFW mouse provides inadequate forebrain perfusion following bilateral common carotid artery occlusion. Hence, the CFW mouse may provide a useful model for the study of transient forebrain ischemia.

CALPAIN INHIBITION AND NEUROPROTECTION. L. Kent*, C. Zobre*, M.S. Miller, Neurosciences Dept., Sterling Drug, Rensselaer, NY 12144.

Excitatory amino acids (EAAs) released by neurons during ischemia may interact with **NMDA** receptors of nearby cells to induce Ca^{++} influx. Increased cytoplasmic Ca^{++} can activate calpain (**CAL**) which can hydrolyze cytoskeletal proteins, such as fodrin. Degradation of the cytoskeleton may contribute to ischemic and EAA-induced neuronal injury. This study determined if **NMDA**-stimulated **CAL** activation in cultured neurons precedes neuronal injury and whether inhibition of **CAL** attenuates injury. Appearance of a 155 kD fragment of fodrin in cells was a marker of **CAL** activity. Release of **LDH** was a measure of neuronal injury. Exposure of cultured mouse cortical neurons to 500 uM **NMDA** for 30 min induced **CAL** activity which was minimally elevated 30 min after **NMDA** exposure and maximally increased (10-20 fold) by 2 hrs. Maximal **LDH** release was observed 6-8 hr after **NMDA** exposure. Leupeptin (100 uM) inhibited both **CAL** activity and **LDH** release when measured 4-8 hr after **NMDA** exposure, but not at 24 hours. Thus, a temporal correlation existed between **CAL** inhibition and neuronal protection. Inhibition of **CAL** may reduce excitotoxic neuronal injury.

CALPAIN INHIBITORS AS UNIQUE THERAPEUTICS FOR ISCHEMIC BRAIN DAMAGE. [1]R.T. Bartus, [1]R.L. Dean, [1]D.D. Eveleth, [1]D.L. Lutz, [1]M.E. Harris*, [2]J. Powers. [1]Cortex Pharmaceuticals, Irvine, CA 92718, [2]Georgia Institute of Technology, Atlanta, GA 30332.

Abnormal elevations in intracellular calcium has been strongly implicated in the neurodegeneration that follows brain ischemia. Moreover, disassembly of the neurons' cytoskeleton has recently been shown to be an early event in their neuronal death, while activation of calcium-mediated proteases (calpains) appears to represent a final common pathway for the neurons' destruction.

For these reasons, inhibition of calpain provides a novel and potentially powerful means of reducing neuronal death due to ischemia and other neurotoxic perturbations.

Several novel inhibitors have been identified which are more potent, selective and efficacious than standard compounds. We evaluated the ability of these compounds to protect hippocampal neurons from transient global ischemic damage induced in the rat 4 vessel occlusion model. These studies demonstrated the superior efficacy of the novel, non-aldehyde inhibitors, providing more effective protection of pyramidal cells. They therefore provide the clearest evidence, to date, that despite the likely involvement of other events in the pathogenic cascade, inhibition of calpain is sufficient to protect a large number of vulnerable hippocampal neurons from the damaging effects of ischemia. Moreover, these data provide the first evidence that complete protection of certain hippocampal neuronal populations can be achieved, even when the inhibitors are administered well after the ischemic event is over.

500.16

NOVEL CALPAIN INHIBITORS OFFER GREATER HYPOXIC PROTECTION OF SYNAPTIC TRANSMISSION IN HIPPOCAMPAL SLICES. [1]H.T. Ton*, [2]A. Arai*, [1,2]D. Eveleth, [1,2]G.S. Lynch and [1,2]R.T. Bartus. [1]Cortex Pharmaceuticals, Irvine, CA 92718, [2]Univ. of California, Irvine, CA 92717.

Activation of the calcium dependent cysteine protease calpain has been implicated in long-term potentiation, excitatory amino acid-induced neurodegeneration and ischemic brain damage. This study was conducted to evaluate the efficacy and membrane permeability of four recently developed non-aldehyde calpain inhibitors (CX216, CX217, CX218 and CX233), versus the standard aldehyde inhibitors, Calpain Inhibitor 1 (CI1) and Leupeptin (LEU) in protecting synaptic transmission of hippocampal slices from hypoxic insult.

Hippocampal slices (400 um) were maintained in chambers perfused with artificial CSF and 95% O^2 : 5% CO^2. Hypoxic exposure involved substituting nitrogen for oxygen (i.e., 95% N^2 : 5% CO^2). Evoked field potentials were measured by stimulating the Schaeffer collaterals and recording from the apical dendritic region of CA1. Survival rate following 10 minutes hypoxia and recovery of synaptic transmission from hypoxia were measured.

While the standard aldehyde calpain inhibitors were only modestly effective in protecting hippocampal slices from hypoxia, all four novel non-aldehyde inhibitors were found to be more potent, efficacious and membrane permeant. For example, 100 micromolar of all four CX compounds, preincubated for either 30 minutes or 1 hour, produced a 40% to 80% survival rate, respectively. CX218 (at 100 uM) and 1 hour preincubation improved the recovery of synaptic transmission to 62% following hypoxia. In contrast, CI1 and LEU were ineffective under similar conditions. CI1 required 200 uM with a 2 hour preincubation period, while LEU required 1 mM with a 3 hour preincubation period to provide even modest protective effects. These results provide clear evidence that inhibition of calpain can reliably ameliorate functional damage in hippocampal slices induced by hypoxia. Moreover, recently developed non-aldehyde inhibitors are much more effective than the commercially available aldehyde inhibitors.

500.17

ADENOSINE AGONISTS AND NEUROPROTECTION; ISSUES RELATED TO BLOOD-BRAIN BARRIER PERMEANCE. [1]R.L. Dean, [1]D.L. Lutz, [1]M.E. Harris*, [1]J.E. Foreman*, [2]K.S. Lee, [3]K.A. Jacobson, [1]D.D. Eveleth and [1]R.T. Bartus. [1]Cortex Pharmaceuticals, Irvine, CA 92718. [2]Univ. of Virginia, Charlottesville, VA 22908, [3]National Institutes of Health, Bethesda, MD 20892.

Adenosine has been characterized as a natural modulator of glutamate neurotransmission and adenosine analogs have therefore been explored as possible neuroprotective agents for excitatory amino acid toxicity. However, attempts to develop effective peripherally administered adenosine agonists for neuroprotection have been confounded by two key issues. The first is that at efficacious doses, moderate side effects (i.e., hypothermia, sedation, hypotension) are seen. These side effects, alone or in combination with effects on synaptic transmission, can protect neurons from damage in several animal models of global ischemia. The second issue is whether adenosine analogs even penetrate the blood-brain barrier (BBB). It has been suggested that the neuroprotection attributed to adenosine agonists is due primarily to their peripheral side effects rather than a direct effect on central neurons.

In a series of experiments, we addressed a number of issues related to these points. We have shown that: 1) when non-BBB penetrating adenosine analogs are administered centrally (ICV), hypothermia and sedation are still observed, demonstrating the likelihood of both PNS and CNS mediated side effects; 2) brain levels of certain adenosine analogs can be detected following IP and IV administration using an HPLC method, demonstrating penetrance, albeit modest, through the BBB; and 3) direct infusions of A1 agonists into the CA1 region of the hippocampus following global ischemia (4 vessel occlusion procedure in rats) protected hippocampal neurons, demonstrating centrally mediated neuroprotective effects of adenosine analogs in the absence of confounding side effects.

INTRACELLULAR EVENTS RELATED TO THE DELAYED NEURONAL DEATH FOLLOWING TRANSIENT GLOBAL ISCHEMIA. D.L. Lutz, R.L. Dean, M.E. Harris*, J.A. Miotke, H.T. Ton*, B.K. Miyazaki*, D.D. Eveleth and R. T. Bartus. Cortex Pharmaceuticals, Irvine, CA 92718.

Delayed neuronal death has been reported in the gerbil two vessel occlusion model and in the rat 4 vessel occlusion model of global ischemia. To better understand this phenomena, the temporal damage of hippocampal neurons following transient global ischemia in the 4 vessel occlusion rat model was studied using biochemical, histological and electrophysiological markers.

Male Sprague-Dawley rats were sacrificed at various time periods following the occlusion (6 hours - 7 days). The brains were removed and 400 um sections of hippocampus were harvested for *in vitro* electrophysiological characterization of CA1 field potentials. A portion of the same hippocampus was immersion-fixed and stained with cresyl violet (Nissl stain) or silver (for degenerating neurons), while the remainder of fresh tissue was used in a Western assay to quantitate spectrin breakdown.

Ischemic-induced degeneration was first observed with the Nissl stain at 48 hours post-occlusion and peaked at 7 days. For silver stain, evidence of degeneration was first seen at 24 hours and peaked at 4 days. Breakdown of spectrin, a major substrate for the calcium stimulated protease, calpain, occurred very early in the neurotoxic cascade, preceding histological evidence of neuronal death by days. Electrophysiological changes also preceded the evidence of histological cell death. These observations suggest that a number of interdependent intracellular events participate in the delayed cell death phenomenon which follows transient global ischemia and add further support for the idea that calpain-mediated spectrin breakdown may play a causal role in this neurodegenerative cascade.

ELECTRON MICROSCOPIC STUDY OF THE CEREBRAL CORTEX AFTER TRANSIENT CEREBRAL ISCHEMIA IN GERBILS.
H. Tomimoto* and T. Yanagihara, Dept. of Neurology, Mayo Clinic, Rochester, MN 55905

Prompt dendritic damage and its central propagation have been observed in the periphery of dendrites in the gerbil hippocampus after transient cerebral ischemia. We examined the frontoparietal cortex of gerbils after bilateral carotid occlusion for 20 min and reperfusion for 72 hrs. During ischemia without reperfusion, progressive swelling of the periphery of ascending dendrites with swelling of mitochondria, disintegration of microtubules and formation of microvacuoles occurred in layer I and less notably in layers II and III. After reperfusion for 3 hrs, swelling of dendritic terminals and mitochondria receded but disintegration of microtubules and formation of microvacuoles propagated to deeper layers. Swelling of glial processes also became apparent in many layers after 3 hrs, causing indentation in dendrites. Neuronal perikarya showed disaggregation of polyribosomes and occasional fragmentation of rough endoplasmic reticulum after reperfusion for 3 hrs. Disintegration of mitochondrial cristae and formation of microvacuoles occurred after 6 hrs, particularly in layers III and Vb, and some neurons became clumped and electron-dense. While the number of these degenerated neurons increased progressively, surviving neurons with reaggregation of polyribosomes also increased beyond reperfusion for 12 hrs. The present study showed central propagation of dendritic damage and progressive structural disintegration of neuronal perikarya before "delayed neuronal death" became apparent with light microscopy.

ISCHEMIA: EXCITOTOXICITY

7-CHLOROKYNURENIC ACID REDUCES CA1 CELL LOSS IN A RAT MODEL OF CEREBRAL ISCHEMIA IN VIVO.
E.R.Wood, T.J.Bussey* & A.G.Phillips. Dept. Psychology, Univ. British Columbia, Vancouver, B.C., Canada, V6T 1Z4.

Transient cerebral ischemia results in loss of selectively vulnerable neurons, including hippocampal CA1 pyramidal neurons. A prominent hypothesis is that ischemic damage is mediated in part by the action of glutamate at NMDA receptors which causes pathological Ca^{++} influx, and cell death by subsequent Ca^{++}-mediated processes. However, although extracellular glutamate levels increase during ischemia, there is a close correlation between the areas of the brain which suffer cell loss and those in which glycine (and not glutamate) is elevated during ischemia and reperfusion. Binding of glycine at the strychnine-insensitive glycine binding site associated with the NMDA receptor-channel complex is required in combination with glutamate binding for channel opening. Prevention of glycine binding might therefore be expected to attenuate the cell loss associated with ischemia.

Preliminary results show that bilateral intraventricular administration of 2ul 500uM 7-chlorokynurenic acid--a potent competitive antagonist at the strychnine-insensitive glycine binding site--immediately before the induction of ischemia significantly reduces cell loss in CA1. Rats were subjected either to ischemia induced by 20 minutes bilateral carotid occlusion combined with hemorrhagic hypotension, or to sham surgery. Half of the rats in each group received 7-chlorokynurenic acid immediately before carotid clamping while the other half received the same volume of saline. 6 weeks following surgery there were significantly fewer viable CA1 pyramidal neurons in the ischemia with saline group than in all other groups. The ischemia with drug group did not differ from either of the sham surgery groups. These data suggest that elevated levels of glycine contribute to ischemic damage, and that antagonism of the glycine site associated with the NMDA receptor provides one means of attenuating cell loss.

501.2

NECESSITY OF CONTINUED INFUSION FOR NEUROPROTECTIVE EFFECT OF NMDA ANTAGONISTS IN CEREBRAL ISCHEMIA

D.M. Kunis, G.H. Sun* A. Poljak* and G.K. Steinberg
Dept. of Neurosurgery, Stanford University, School of Medicine, Stanford, CA 94305

While both competitive and noncompetitive NMDA antagonists have been shown to protect against focal cerebral ischemia, it is not clear whether a single dose or continued maintenance infusion of these drugs is necessary to achieve neuroprotection. We studied this issue using dextromethorphan (DM), dextrorphan (DX), and MK801 in a rabbit model of transient focal ischemia. Thirty rabbits underwent two hour occlusion of the left internal carotid, anterior cerebral, and middle cerebral arteries followed by four hours of reperfusion. Ten minutes after occlusion, the rabbits were treated with DM 20 mg/kg or 20 mg/kg followed by 10 mg/kg/h; DX 16.7 mg/kg or 16.7 mg/kg followed by 8.35 mg/kg/h; MK801 1 mg/kg or 1 mg/kg followed by 0.75 mg/kg/h or normal saline. The loading dose was given over 30 minutes. Ischemic injury was assessed using somatosensory evoked potentials, magnetic resonance imaging and histopathology. For DM and DX, maintenance infusions were necessary to achieve neuroprotection, whereas a loading dose only was protective for MK801. Maintenance infusion of MK801 tended to worsen ischemic injury, possibly by lowering blood pressure. The need for continued dosing of NMDA antagonists may depend on their serum and brain half lives.

Supported by AHA grant 881069, NIH grant R01 NS 27292-01A2, and the Valerie K. Bernhardt Cerebral Ischemia Fund.

501.3

POSTISCHEMIC ADMINISTRATION OF AMPA- BUT NOT NMDA-RECEPTOR BLOCKERS DECREASES NEURONAL DAMAGE FOLLOWING TRANSIENT CEREBRAL ISCHEMIA IN THE RAT.
T. Wieloch* and B. Nellgård Laboratory for Experimental Brain Research, Lund University, S-221 85 Lund, Sweden.

Glutamatergic transmission is an important factor in the development of neuronal death following transient cerebral ischemia. The effect of NMDA and non-NMDA receptor antagonists on neuronal damage were studied in rats exposed to 10 min of transient cerebral ischemia induced by bilateral common carotid occlusion combined with hypotension. Blockade of the AMPA-receptor by 2.3-dihydroxy-6-nitro-7-sulmamoyl-benzo (F) quinoxaline (NBQX), given post-ischemia as an i.p. bolus dose of 30 $mg \cdot kg^{-1}$ followed by an i.v. infusion of 75 $\mu g \cdot min^{-1}$ for 6 h, decreased neuronal damage in the hippocampal CA1 area by 44-69%, with the largest relative decrease in the temporal part of hippocampus. Neuronal damage in neocortex also decreased. Blockade of NMDA-receptors by either the non-competitive receptor antagonist dizocilipine given 1 $mg \cdot kg^{-1}$ i.p. at recirculation and 3 hours post-ischemia, or the competitive receptor antagonist DL-(E)-2-amino-4-methyl-5-phosphono-3-pentenoic acid (CGP 40116), 5 $mg \cdot kg^{-1}$, given i.p. at recirculation. did not provide any protection.

Our data demonstrate that AMPA- but not NMDA-receptor antagonists decrease neuronal damage following transient severe cerebral ischemia in the rat, and that the protection by NBQX may be dependent on the severity of the ischemic insult.

501.4

EXTRACELLULAR pH AND K^+ GRADIENTS IN FOCAL ISCHEMIA OF RAT CORTEX.
M. Chesler and Z. Hassan.
Dept. of Neurosurgery NYU Med Ctr, 550 1st Ave, NY, NY 10016.

Decreases in extracellular pH (pHo) below 6.6 abolish NMDA-gated currents (1). Thus, in ischemia, the behavior of pHo may determine the extent of excitotoxic injury. We studied pHo in rat cortex following middle cerebral artery (MCA) occlusion. Non-fasted, female, Long Evans-Hooded rats were anesthetized with pentobarbital, paralyzed and ventilated on O2-supplemented air. pH microelectrodes were inserted through a 300 μm hole in a silicone sheet, covering a 2 mm parietal craniotomy. Control pHo was 7.31 ± 0.02 with no cortical gradient. Mean arterial pH, pCO2 and O2 (torr) were 7.43/39/130 (pre-occl.) and 7.40/33/82 (post-occl.) respectively. Within 15 min. of MCA occl., minimum pHo (6.62 ± 0.05, n=5) consistently occured at cortical depths of 1000-1500 μm. At 250 μm, mean pHo was 6.87 ± 0.09, which decreased by 0.20 ± 0.05 pH units/mm depth. Below the point of maximum acidity, pHo increased by 0.47 ± 0.13 pH units/mm, with mean pHo of 6.94 ± 0.19 at 2000 μm. Decreases and increases in pHo were accompanied by neg. and pos. shifts in DC potential respectively. Preliminary measurements of $[K^+]o$ revealed similar U-shaped gradients, with troughs at upper and lower depths.

These data indicate that in non-fasted rats, MCA occl. can cause a pHo fall sufficient to protect against NMDA receptor-mediated injury. Vulnerability of superficial neurons may be related to higher pHo. Proximity of CSF, preservation of blood flow and CO2 egress might account for these gradients, however, their cause remains to be determined. (1) Tang, C.M. *et al.* (1990). *PNAS*, 87(16):6445. 501.5

PROTECTION FROM OXYGEN-GLUCOSE DEPRIVATION INJURY IN CORTICAL CULTURES BY GLUTAMATE ANTAGONISTS COMBINED WITH EXTRACELLULAR ACIDITY. D.A. Kaku, R.G. Giffard and D.W. Choi. Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305.

NMDA antagonists reduce neuronal vulnerability to hypoxic neuronal injury both in vivo and in vitro. However, prior in vitro studies have taken place at normal pH, whereas hypoxia-ischemia in vivo is associated with extracellular acidity, a perturbation that attenuates NMDA receptor activation, glutamate neurotoxicity, and hypoxic injury in vitro. We investigated whether acid pH would abolish the value of glutamate antagonists against a combined oxygen- and glucose-deprivation insult in murine cortical cell cultures.

Near-complete protection from insults lasting up to 60 min was produced by dropping extracellular pH to 6.4. The neuronal death produced by longer insults (80-120 min) was still reduced by the addition of the NMDA antagonists MK-801 or CGS-19755. Even further injury reduction was produced by addition of CNQX to saturating concentrations of MK-801, consistent with earlier reports of synergy at normal pH. Thus whereas brief exposure to extracellular acidity was neuroprotective, additional protective effects were produced by glutamate antagonists. When both NMDA and AMPA/kainate receptors were maximally blocked, dropping pH to 6.4 produced additional injury reduction. Extracellular acidity may have neuroprotective effects in hypoxic neuronal injury independent of glutamate neurotoxicity.

501.6

PROTECTION FROM EXCITOTOXIC BRAIN DAMAGE BY DRUG-INDUCED METABOLIC SLOWING AFTER STROKE. B.E. Morton and D.T.Shirae, Dept. Biochem-Biophys, Univ. Hawaii Sch. of Med., Honolulu, 96822.

In Mongolian gerbils, ten minutes of bilateral carotid artery clamping, followed by reperfusion, causes forebrain ischemia, glutamate release, and permanent injury to NMDA receptor-bearing brain areas after a 24 hour window of vulnerability. During this time, use of NMDA receptor antagonists, or blockers of the NMDA-regulated calcium channel, such as MK-801 which binds to PCP receptors within these channels, markedly reduces extent of brain damage present one week later.

Based upon the idea that sigma opiate ligands might also block the calcium channel, we tested the sigma ligand, progesterone, whose level increases greatly by birth, a time fraught with threat of anoxia, for its ability to reduce brain damage due to ischemic insult. We also tested another sigma opiate ligand, haloperidol. Both were injected, i.p., one hour after the above ischemic insult.

In gerbils injected with high concentrations of either progesterone (30 mg/kg) or haloperidol (30 mg/kg), there was almost complete absence of necrotic brain damage in the hippocampus and caudate, compared to saline injected controls one week after carotid artery clamping. Each of these animals had shown marked sedation from its drug, suggesting that their protection from the excitotoxic injury of anoxic insult was not directly due to sigma opiate receptor binding. Animals readily recovered from haloperidol, but not progesterone treatments.

As a test of an alternate hypothesis, that metabolic inhibition of the brain by pharmacologic means, could, like hypothermia, reduce ischemic brain damage, Δ^9-tetrahydrocannabinol was administered, 5 mg/kg, i.v., one hour after ischemic insult. This dose of THC, which had been reported to greatly reduce global brain metabolism in rats, potently prevented any visible brain damage from 10 minutes of bilateral carotid artery clamping when assessed one week later. Thus, certain of these and other compounds which reduce global brain activity appear promising for use in minimizing excitotoxic injury due to anoxic brain insult.

501.7

COMBINED TREATMENT WITH MK-801 AND A D1/D2 DOPAMINE ANTAGONIST REDUCES CEREBRAL ISCHEMIC DAMAGE. S. M Nurse*, D. Corbett and S.J. Evans*. Basic Medical Sciences, Fac. of Medicine, Memorial Univ., St. John's, NF, CANADA, A1B 3V6.

During ischemia extracellular levels of both dopamine(DA) and glutamate rise substantially, an event which may contribute to ischemic injury. This study examined the therapeutic efficacy of DA antagonists alone and in combination with MK-801.

Global ischemia was induced in gerbils by 5 min carotid artery occlusion, at 38°C. MK-801, 5 mg/kg, was given 1 hr prior to surgery; cis-flupenthixol, 0.4 and 1.2 mg/kg, 3 hr prior to surgery; and SCH-23390, 1 mg/kg, 0.5 hr prior to surgery. MK-801 but not. cis-flupenthixol reduced CA1 cell loss. Together these drugs were slightly more effective than MK-801 alone.SCH-23390 was ineffective.

Combined drug therapy with D_2 DA and NMDA antagonists may be a useful treatment strategy in cerebral ischemia.

Supported by the MRC of Canada.

DELAYED TREATMENT WITH NBQX ATTENUATES NEOCORTICAL INFARCTION. D. Xue*, Z.G. Huang*, K.E. Smith*, H. Lesiuk and A.M. Buchan. Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Canada, K1Y 4E9.

NBQX, a non-NMDA glutamate receptor antagonist protects against neuronal injury following forebrain ischemia. This study was done to determine whether NBQX attenuated neocortical infarction in a well characterized rodent model of transient MCA occlusion.

METHODS: 19 male SHR rats were subjected to 2 hours of reversible ischemia by permanent right common carotid artery and transient right middle cerebral artery occlusion, followed by reperfusion. 90 minutes following the onset of ischemia. Saline or NBQX (30 mg/kg) was administered i.p. Subsequent doses were given at the time of reperfusion (RP)(120 mins) and 30 minutes following RP. Animals were kept normothermic throughout ischemia and RP, and sacrificed at 24 hours. A priori power analysis predicted 7 animals per group would be needed to detect a 30% infarct reduction (α=0.05, β=0.2). Cortical infarct volume was calculated and expressed in mm^3. A Student-T test was used.

RESULTS:

Group	Mean volume of cortical infarction ± S.D.
Saline (n=10)	181 ± 31
NBQX (n=9)	125 ± 19*

* p<0.001

CONCLUSION: Treatment with MBQX reduces infarct size by 33% even when administered 90 minutes after the onset of ischemia.

501.9

ISCHAEMIA INDUCED RELEASE OF GLUTAMATE, ASPARTATE AND GABA FROM RAT RETINA IN VITRO: POSSIBLE INVOLVEMENT OF FREE-RADICALS. M.J. Neal and J.R. Cunningham.* Dept Pharmacology, St Thomas's Hospital, London, SE1 7EH, UK

We have examined the effects of "ischaemia" on the release of amino acids from the rat retina *in vitro*. Isolated retinas (dark-adapted or exposed to room light) were incubated at 32°C in Krebs bicarbonate medium gassed with 95% O_2/5% CO_2 (controls) or in glucose-free medium gassed with 95%N_2/5% CO_2 (ischaemia). Retinas were incubated for 10-90 min and the amino acids in the medium measured by HPLC.

When control retinas were incubated in the light for periods up to 90 min there was a steady release of glutamate (GLU) aspartate (ASP) and GABA (1.5±0.2; 0.19±0.026; 2.1±0.15 nmol/retina/30 min respectively, mean ±SEM n=5). Release was similar from control dark-adapted retinas. The release of GLU, ASP and GABA from retinas incubated in the light under ischaemic conditions for 90 min was increased 14.0, 19.1 and 9.5 fold respectively. The release of GLU and especially ASP from dark-adapted retinas incubated under ischaemic conditions was significantly higher than that from retinas in the light.

Remarkably, the ischaemia-induced release of GLU, ASP and GABA from retinas incubated in the light was not Ca-dependent, whilst the release from dark-adapted retinas was reduced by approximately 60% in high-Mg/low-Ca medium. The NMDA antagonist MK801 totally prevented the ischaemia-induced release of GLU and ASP at 30 min and reduced the increase in GABA release by about 75%. This inhibitory effect on release was less striking after 60 min of ischaemia and not significant after 90 min.

When control retinas were incubated for 30 min in medium containing xanthine and xanthine oxidase, the release of GLU, ASP and GABA was increased to levels similar to those caused by ischaemia, suggesting that free-radical formation might be involved in the ischaemia-induced release of amino acids.

501.10

THE EXCITOTOXICITY OF QUINOLINIC ACID IN HYPOXIC RAT HIPPOCAMPAL SLICES. A. Schurr, C.A. West* and B.M. Rigor, Dept. of Anesthesiology, Univ. of Louisville Sch. of Med., Louisville, KY 40292.

Quinolinic acid (2,3-pyridine dicarboxylic acid, QA), an NMDA receptor agonist, has been shown to induce excitatory, neurotoxic, and convulsant effects in both mice and rats. It is the most potent endogenous excitotoxin known to date.

The aims of this study were to explore the structural essentials of QA agonistic properties and to define certain conditions that potentiate its excitotoxicity. Orthodromically evoked CA1 population spikes were recorded from rat hippocampal slices. QA's ability to enhance hypoxic neuronal damage (lack of recovery of evoked response after 30-min reoxygenation) was compared with that of different QA derivatives. In addition, the effect of changes in the concentration of several ions in the perfusion medium on the excitotoxicity of QA was tested.

QA enhanced hypoxic neuronal damage in dose-dependent fashion, an effect that was blocked by the NMDA antagonist APV. None of the five other pyridine dicarboxylic acids tested could enhance hypoxic damage. Doubling of $[Mg^{2+}]$ or depletion of Ca^{2+} from the perfusion medium blocked the effect of QA.

QA is a weaker agonist than NMDA in enhancing hypoxic damage despite the structural resemblance between the two. Other structurally related compounds were innocuous. Both Ca^{2+} and Mg^{2+} play a role in QA excitotoxicity.

501.11

CYSTEIC ACID ENHANCES HYPOXIC AND HYPOGLYCEMIC NEURONAL DAMAGE IN VITRO. C.A. West*, A. Schurr and B.M. Rigor, Department of Anesthesiology, University of Louisville School of Medicine, Louisville, KY 40292.

L-Cysteic acid (CYS) is classified as a relatively weak analogue of NMDA in terms of its excitatory potency.

We have selected the rat hippocampal slice preparation and its electrophysiology as the in vitro system most suitable for studies on the involvement of excitotoxins in the mechanism of hypoxic and hypoglycemic neuronal damage. The combined effects of CYS and compromised energy metabolism on the degree of neuronal damage is the focus of this investigation.

Under normoxic and normoglycemic conditions (95% O_2, 10 mM glucose) CYS was harmless at 1 mM. However, this concentration of the agonist reduced the recovery rate of neuronal function (evoked, CA1 orthodromic population spike) after either 10-min hypoxia (95% N_2) and 30-min reoxygenation or 75-min hypoglycemia (0 mM glucose) and 30 min glucose repletion in a dose-dependent fashion. At 0.2 mM, the NMDA antagonist APV did not block the effect of CYS on hypoxic slices.

The present results indicate that CYS is as potent as glutamic and aspartic acid in enhancing either hypoxic or hypoglycemic neuronal damage but 10- to 100-fold weaker than quinolinic acid or NMDA, respectively.

PROTECTIVE EFFECT OF CCK-8 AND CERULETIDE AGAINST GLUTAMATE AND ISCHEMIA-INDUCED NEURONAL DAMAGE. G. Katsuura, S. Shinohara*, M. Eigyo*, H. Shintaku*, T. Shiomi* and A. Matsushita*. Shionogi Res. Labs., Osaka 553, Japan

Glutamate is now recognized to play a pivotal role in learning/memory processes and neuronal damage. Recently, there is increasing evidence suggesting the interaction between glutamate and neuropeptides. In the present study we examined the effect of CCK-8 and a potent analogue, ceruletide(CLT), on glutamate-induced neuronal death in neuron cultures and neuronal damage in the hippocampus of ischemic gerbils in vivo. By means of LDH efflux, CCK-8 ($>10^{-9}$M) and CLT ($>10^{-10}$M) markedly prevented glutamate (5×10^{-4}M)-induced neuronal cell death in neuron cultures. Gastrin-I ($>10^{-9}$M) showed the same effect. The response of CLT was completely blocked by an antagonist for CCK-B receptors, (+)L-365,260. These peptides significantly suppressed the increase in cytosolic free Ca^{2+} levels induced by glutamate. In ischemic gerbils, CLT(30 and 100μg/kg: sc) significantly attenuated the ischemia-induced neuronal damage in the hippocampus and amnesia, when injected 30 min before and immediately after ischemia. These findings clearly indicate that these peptides may be useful in the therapeutic treatment of neuronal deficits caused by cerebral ischemia.

501.13

BASIC FIBROBLAST GROWTH FACTOR (bFGF) PROTECTS AGAINST ISCHEMIC NEURONAL DEATH IN VIVO. D.J. Berlove, C.G. Caday*, M.A. Moskowitz and S.P. Finklestein. Massachusetts General Hospital, Boston, MA 02114.

Basic fibroblast growth factor (bFGF) promotes neuronal survival and blocks excitatory amino acid (EAA) toxicity in CNS neurons in vitro. EAA toxicity is thought to play a major role in delayed neuronal death after cerebral ischemia in vivo. We tested the neuroprotective effects of bFGF after temporary (3 min.) global forebrain ischemia in the Mongolian gerbil. Core temperature was kept constant during and after surgery. Animals were untreated, or received vehicle (artificial CSF) alone, or vehicle plus bFGF (1.2 ugm/day) through continuous infusion via osmotic pump into the right lateral ventricle for 3 days before and 7 days after ischemia. The degree of neuronal damage in the CA-1 field of hippocampus was scored on a 0-3 scale (0=no damage, 3=severe damage).

	Right Hippocampus	Left Hippocampus
Untreated (N=6)	3.0 ± 0.0	3.0 ± 0.0
Vehicle-treated (N=4)	3.0 ± 0.0	2.5 ± 1.0
bFGF-treated (N=6)	0.8 ± 1.2*	1.2 ± 1.3*

(Data are means ± SD; * = values differ from untreated by $p<0.01$) These data suggest that pretreatment with bFGF protects against ischemic cell death in vivo. Whether this represents a direct neuronal effect or is mediated through other cellular processes (e.g., glial activation, or angiogenesis) requires further study.

501.14

PHENYTOIN ATTENUATES HYPOXIA-INDUCED CHANGES IN GLUTAMATE AND ACETYLCHOLINE RELEASE FROM RAT HIPPOCAMPAL SLICES P.E. Potter[1], P. Detwiler[2]* and J.R. Moskal[3] Depts. Anesthesiology[1] and Neurosurgery[2], Albert Einstein College of Medicine, Montefiore Medical Center, Bronx, NY 10467, and Chicago Inst. Neuroscience and Neuroresearch[3], Chicago, IL

The effects of the anticonvulsant drug diphenylhydantoin (phenytoin) on hypoxia-induced changes in release of ^{3}H-glutamate and ^{3}H-acetylcholine were studied in superfused rat hippocampal slices. Hypoxia (25 min perfusion with Krebs buffer gassed with 95% O_2:5% CO_2) caused a large release of glutamate which lasted for 15-20 minutes. Re-oxygenation caused a second large release of glutamate, which persisted for at least 20 minutes. Both the hypoxia and re-oxygenation induced release of glutamate were decreased significantly by adding 20 μM phenytoin before or after hypoxia. The evoked (electrical stimulation, 4Hz, 2 min) release of ^{3}H-acetylcholine was halved by hypoxia; this decrease was reversed by 20 μM phenytoin. These results indicate that phenytoin reduces hypoxia-induced release of the excitatory amino acid glutamate, while allowing cholinergic neurons to remain functional. Thus, phenytoin may protect neurons from stroke-induced toxicity and may also reduce re-perfusion injury and delayed neuronal damage. Supported by the Health Foundation.

THE EFFECTS OF DIFFERING LEVELS OF HYPOGLYCEMIA ON HYPOXIC NEURONAL INJURY OF CEROBROCORTICAL CELL CULTURES. G.J. Birrell*, A.W. Probert, and F.W. Marcoux. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, 2800 Plymouth Road, Ann Arbor, MI 48105.

Calcium accumulation and neuronal injury of rat cortical cell cultures in vitro were examined following temporal exposure to hypoxia under conditions of normal and low glucose. Two-hour hypoxic (89% N_2/10% CO_2/1% O_2) exposures were performed on mixed glial cultures in a test medium of HBSS containing 4.0, 0.3, 0.1 and 0 g/l (22.2 - 0 mM) D-glucose. Normoxic (70% N_2/10% CO_2/ 20% O_2) controls were incubated at the same temperature, humidity and pH (7.2-7.6).

Measurements of $^{45}Ca^{2+}$ uptake and lactate dehydrogenase (LDH) release were measured immediately following and at 12 and 24 hours after hypoxic exposure. Normoxic cultures or hypoxic cultures exposed to 4g/l D-glucose displayed only small increases in Ca^{2+} uptake and LDH release with time. In hypoxic cultures exposure to low glucose (0.3 or 0.1 g/l) resulted in a delayed (12 hours) increase in Ca^{2+} accumulation associated with a rise in LDH release at 24 hours. Although those cultures experiencing hypoxia combined with zero glucose displayed both immediate (2 hours) and delayed increases in Ca^{2+} accumulation, little associated rise in LDH release at 24 hours was observed.

These results suggest that while low glucose potentiated hypoxic neuronal damage, severe hypoglycemia was surprisingly neuroprotective under the conditions of the present study.

501.16

HIPPOCAMPAL GLUTAMATE RELEASE DURING 'IN VITRO ISCHEMIA' IS CALCIUM-INDEPENDENT AND TTX-SENSITIVE. S.P. Burke and C.P. Taylor. Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI 48105.

Excess neurotransmitter release may cause neurodegeneration following CNS ischemia. The mechanism(s) of such release may differ from classical exocytosis. We examined overflow of amino acids from slices of rat hippocampal CA1 area (Nadler et al., 1990) during superfusion with media lacking glucose and gassed with nitrogen ('in vitro ischemia', IVI). Slices were held at 37°C and fractions of superfusate were frozen for analysis by HPLC.

Within 10', IVI evoked a large overflow of glutamate, as well as aspartate and GABA, which was maximal at 20' and returned to baseline 5' after the reintroduction of normal media. Taurine levels increased more gradually but remained elevated after IVI. Glutamine steadily decreased during IVI. Increases in amino acid levels were comparable to those evoked by 50mM KCl. Substitution of calcium by magnesium had little effect upon IVI release, but virtually eliminated KCl evoked release. Reduction of the bath temperature to 31°C reduced IVI release by half.

TTX (1μM) completely blocked IVI release for the first 15'. With continued TTX, overflow eventually rose to control IVI levels. Our results agree with in vivo studies (Yamasaki et al., 1991) showing focal TTX in rat hippocampus to mitigate neuronal damage from cerebral ischemia. The calcium-independence and TTX-sensitivity of glutamate release from IVI suggest that it may be driven by a reversal of plasma membrane transporters subsequent to cellular sodium loading.

501.17

THE EFFECT OF NMDA ANTAGONISTS ON EARLY ULTRASTRUCTURAL CHANGES IN NEURONAL CULTURE AFTER HYPOXIA. M.L. Weber, F.W. Marcoux, A.W. Probert and M.A. Dominick, Departments of Pharmacology and Pathology and Experimental Toxicology, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI, 48105.

Mixed cortical neuronal-glial cultures isolated from fetal rat brain were exposed to hypoxia for 5 hours. Some plates were treated with the competitive NMDA antagonist 4-(3-phosphonopropyl)-2-piperazinecarboxylic acid (CPP) prior to hypoxic exposure. Cultures were fixed with 1% glutaraldehyde immediately after hypoxia and then processed for transmission electron microscopy. Early ultrastructural changes were evident in neurons immediately after hypoxia at a time when only slight neuronal swelling was seen at the light microscopic level. Glial cells showed no apparent damage at 5 hours. Swollen mitochondria with disrupted cristae and vacuolization of the neuronal cytoplasm were seen at 5 hours. Control cultures subjected to 5 hours normoxia showed none of these changes. These changes paralleled early changes reported in vivo shortly after ischemia. Neurons treated with CPP showed no swelling grossly and ultrastructurally were identical to normoxic neurons. These results demonstrate NMDA antagonists ability to prevent the early intracellular changes in neurons consequent to hypoxia.

501.18

ISCHEMIC RAT SPINAL CORD INJURY INDUCED BY DYNORPHIN A INVOLVES ELEVATIONS IN EXTRACELLULAR EXCITATORY AMINO ACIDS. M.A. Oleshansky and J.B. Long. Dept. of Med. Neurosci., Walter Reed Army Inst. Res., Wash. D.C. 20307.

Lumbar subarachnoid injection of dynorphin A (DYN) causes dose-dependent ischemia, neuronal degeneration, and persistent hindlimb paralysis in rats. Excitatory amino acids (EAAs) have been implicated as mediators of DYN-induced spinal cord injury in this model due to the protective effects of selective antagonists for the NMDA receptor complex, as well as 2-chloroadenosine (2-CA), an inhibitor of glutamate release. To further characterize the involvement of EAAs in DYN-induced rat spinal cord injury, extracellular amino acid levels were measured in spinal cord CSF samples removed after injection of paralytic doses (20 and 40 nmoles) of DYN. DYN was injected through 30 ga needles inserted between the L4 and L5 vertebrae into the spinal subarachnoid space of rats transiently anesthetized with halothane. CSF was collected through similarly placed needles at 15 and 45 minutes postinjection. Amino acids were separated by reverse-phase HPLC and quantitatively detected by fluorometry after OPA derivatization. By 15 minutes postinjection, DYN selectively elicited 5-6 fold elevations in the EAAs glutamate and aspartate that were substantially reduced by 45 minutes postinjection. Coinjection of protective doses of 2-CA failed to alter the DYN-induced increases in the EAAs. These results indicate that DYN-induced ischemic spinal cord injury is associated with an endogenous release of glutamate and aspartate at potentially neurotoxic levels which does not appear to be altered by 2-CA.

501.19

IN VIVO ACTIVATION OF NMDA RECEPTORS DURING AND AFTER ISCHEMIA MEASURED BY *IN VIVO* ^{3}H-MK-801 BINDING. P.H. Schwartz and C.G. Wasterlain. Epil. Res. Lab., VAMC, Sepulveda, CA 91343.

Several lines of evidence implicate activation of NMDA receptors as a mechanism of ischemic neuronal necrosis and of delayed neuronal death. While it has been shown that post-ischemic antagonism of NMDA receptors confers neuroprotection, *in vivo* microdialysis experiments indicate that extracellular levels of glutamate return to normal after the end of ischemia. In this study, 15 min after a hypoxic-ischemic insult (bilateral coratid ligation and exposure to 6% O_2 for 1hr) in the 7-day-old rat, pups were injected s.c. with [3-^{3}H]-MK-801, with or without a prior injection of cold MK-801, and were sacrificed 10, 30, or 60 min later. The brains were rapidly removed and the cortices were frozen. Binding was determined by the filtration technique. Three additional groups were examined: untreated controls and pups decapitated 10 min after ^{3}H-MK-801 injection with the heads kept at either 37 or 0°C for up to 60 min before dissection. Both total brain concentrations and non-specific binding were linearly related to dose. In control pups specific ^{3}H-MK-801 binding was 0.251 ± 0.044 pmol/g wet weight after 10 min and rose to 0.395 ± 0.042 pmol/g after 60 min. Decapitation ischemia at 37°C induced a rapid increase in binding to 1.685 ± 0.092 pmol/g by 30 min ($p<0.001$ vs controls) while binding during decapitation ischemia at 0°C was similar to that of controls. Binding in the post-hypoxic/ischemic brains was 1.737 ± 0.060 pmol/g after 30 min ($p<0.001$ vs controls). These results indicate that ischemia induces a dramatic activation of NMDA receptors and that this activation persists in the post-ischemic state. This may account for the efficacy of post-ischemic neuroprotection by NMDA antagonists and for delayed neuronal necrosis.

501.20

EFFECT OF QUISQUALATE AND HYPOXIA ON NEURONAL CELL INJURY. J. A. Kelleher and P. H. Chan University of California CNS Injury and Edema Research Center, Dept. of Neurology, M-794, Box 0114 San Francisco, California 94143 U.S.A.

Excitatory amino acid receptors are coupled to both ionic channels and signal transducing mechanisms. Excessive presynaptic release of glutamate (Glu), coupled with inhibition of reuptake in astrocytes, following ischemia is implicated in neurotoxicity. The non-NMDA receptor quisqualate/AMPA (Quis) is coupled to both Na channels and phosphatidylinositide (PPI) turnover. We have studied the response of the Quis receptor on hypoxic and normoxic neuronal cultures. At 7-8 days in vitro the production of inositol phosphate induced by Quis treatment is only observed with hypoxia. The PPI turnover is correlated with cell swelling (^{14}C-urea space) and cell death (fluorescein diacetate staining). Hypoxia followed by Quis (250uM) caused cell death at two hours post-treatment, which was not observed with hypoxia or Quis (normoxia) alone. At similar post-treatment time periods, a reduction in cell volume was observed for hypoxia/Quis neurons compared to hypoxic treatment alone. Increased inositol phosphate production, cell death and decreased swelling at this later time period due to Quis plus hypoxic treatment could be reversed by preincubating the cells with the AMPA-insensitive, quisqualate antagonist d,l-2-amino-3-phosphonopropionate (AP3). Immediately following the Quis exposure (zero time), hypoxic cells exhibited greater cell volume than normal cells. This swelling could be inhibited by addition of either the non-NMDA receptor antagonist DNQX or AP3. Our data suggest swelling and injury due to Quis and hypoxia in combination is associated with the inositol phosphate production.

SYNAPTIC STIMULATION EXACERBATES HYPOXIC INJURY IN PENUMBRAL NEURONS. P.R. Trueblood, R.A. Wallis, K.L. Panizzon and C.G. Wasterlain . Sepulveda VAMC, Depts. of Neurology and Kinesiology, UCLA Sch. of Medicine, and Sepulveda, CA 91355.

Early physical therapy is recommended in cerebral ischemia, yet the effect of the resulting synaptic firing on survival of neurons in the ischemic penumbra has never been studied. We examined the effects of synaptic stimulation on hypoxic CA1 neurons unable to generate an evoked potential upon Schaffer collateral stimulation. After hypoxic disappearance of evoked responses, paired slices were stimulated at 2 or 20 Hz (for an average duration of 2.2 min. ± 0.3 SE) until the appearance of the hypoxic injury potential (HIP) in the 2 Hz slice. With the disappearance of the HIP in the 2 Hz slice, oxygenation was restored. 20 Hz slices showed significantly reduced recovery of mean population spike (PS) amplitude (9% ± 5.3) compared to 2 Hz slices which received less stimulation during hypoxia (64% ± 14.8). In a similar paradigm, slices receiving orthodromic stimulation showed a significant decrease in the mean percent CA1 PS amplitude recovery (11% ± 3.4) compared to slices receiving antidromic stimulation (83% ± 17.0), presumably because the latter releases less neurotransmitter. In low calcium medium, increased stimulation did not increase hypoxic injury significantly. These results suggest that synaptic stimulation can be detrimental to hypoxic penumbra neurons and that this damage is mediated by transmitter release.

502.1

ROLE OF INTRACELLULAR CALCIUM IN HYPOXIC/ISCHEMIC INJURY IN CULTURED ASTROCYTES. R. S. Goldman, Department of Neurology, Medical College of Wisconsin, Milwaukee, WI 53226

A substantial body of evidence suggests that an elevated level of intracellular calcium is associated with the neuronal response to hypoxia. I have investigated the role of intracellular calcium changes in the astrocytic response to hypoxia. Primary cultures of rat astrocytes were exposed to sodium cyanide (CN; 1mM), an inhibitor of oxidative metabolism, and to iodoacetic acid (IAA; 0.25mM), an inhibitor of anaerobic metabolism, for various lengths of time. The cells were then washed, and incubated overnight. Cell viability was determined by a two color fluorescence assay. Cell survival was related to duration of exposure to CN and IAA; all cells were killed by a 16 minute exposure. Survival was increased by similar exposure in the absence of extracellular calcium. Additionally, astrocytes were preincubated with the intracellular calcium chelator BAPTA-AM (50uM). This should cause a significant blunting of any hypoxia-induced intracellular calcium increase. This also resulted in increased cell survival.

Relative changes in the intracellular calcium concentration of cultured astrocytes were assessed using digital fluorescence microscopy, and the calcium indicator dye, fluo-3. A 10 minute incubation with CN and IAA produced a rapid rise in intracellular calcium. Calcium levels did not return to baseline following washout. The rise in calcium was significantly abated by incubation in low calcium buffer. Cells preincubated with BAPTA-AM showed little change in intracellular calcium levels during the first 5 minutes. However, with continued exposure, calcium levels did increase.

These results indicate that elevated levels of intracellular calcium are correlated with hypoxic injury in cultured astrocytes. Some of the proposed therapies for stroke based upon limiting the hypoxia-induced rise in intracellular calcium in neurons may also have a beneficial effect upon astrocyte survival.

502.2

HYPOXIC DEPOLARIZATION IN DIFFERENTIALLY VULNERABLE HIPPOCAMPAL PYRAMIDAL CELLS. K.S. Lee, T. Lowenkopf*, P. Brooks* and L. Arlinghaus. Dept. of Neurological Surgery, University of Virginia, Charlottesville, VA 22908 and Jefferson Med. Col. Philadelphia, PA 19107.

A precipitous depolarization during ischemia and hypoxia marks the severe compromise of membrane polarization and widespread entry of calcium into neurons. It has been suggested that the latency to onset of hypoxic depolarization (HD) is a critical determinant of the fate of a neuron. In support of this concept, vulnerable CA1 neurons exhibit a shorter latency to HD than relatively resistant dentate gyrus granule cells (Balestrino et al., Brain Res. 497, 1989) and, treatments that delay the onset of HD reduce post-hypoxic pathophysiology. We examined whether variations in HD latency characterize the responses of differentially vulnerable hippocampal pyramidal cells.

In vitro hippocampal slices were prepared from adult gerbils. In each experiment, simultaneous recordings were made in two of the following regions: CA1a, CA1b and CA3. Slices were maintained at interface with the atmosphere of the recording chamber and hypoxic treatment consisted of substituting 99% N_2 for the normal 95% O_2 in the atmosphere. To verify viability of the slices, evoked synaptic responses were tested prior to and following the hypoxic event in each region. The average delay to HD was virtually identical in areas CA3 and CA1b. Experiments in which DC potentials were monitored simultaneously in these two regions showed that one area usually underwent HD slightly before the other with CA3 being first in 46% of the cases and CA1b first in 54% of the cases (n=50 slices). The CA1a region consistently exhibited longer delays to HD than CA3 or CA1b (n=33). The relative, regional latencies to HD (CA1b=CA3<CA1a) do not parallel the relative vulnerabilities of these regions (CA1a>CA1b>CA3, from most to least sensitive). It therefore appears that regional variations in the latency to HD do not explain the differential vulnerability of subpopulations of hippocampal pyramidal cells. (Supported by NINDS grant NS24782).

MEASUREMENT OF INTRACELLULAR CALCIUM IN RAT CEREBRAL CORTICAL TISSUE DURING HYPOXIA AND AGLYCEMIA Keith J. Brooks & Philip I. Aaronson*. Departments of Pharmacology and Medicine, UMDS, St Thomas's Campus, London SE1 7EH, U.K.

Intracellular Ca ($[Ca]_i$) has been implicated as a probable mediator of neuronal damage during cerebral ischemia. In order to study the effects of ischemia on $[Ca]_i$ in rat cortex, we loaded cortical slices (350 µm thickness) with fura 2 AM (10 µM + 0.1% pluronic F-127 for 1 hour at room temperature). Tissues were subsequently superfused with Krebs solution, gassed with 95%O_2, 5%CO_2, at 37 °C. Tissues were judged viable if depolarisation with 40 mM K solution caused a substantial increase in $[Ca]_i$. When glucose was removed from the solution, there was a delayed rise in $[Ca]_i$; if hypoxia was induced by gassing with N_2 instead of O_2 there was little change in [Ca]i. If, however, tissues were made both hypoxic and aglycemic, $[Ca]_i$ rose rapidly and markedly. This result suggests that it is necessary to induce both of these insults simultaneously in order to cause immediate disruption of the $[Ca]_i$ regulating mechanisms in cortical tissue.

The Contribution Of Excitatory Amino Acid Transmission In The Activation Of Inward Currents During Hypoxia: A Patch Clamp Study. S. Veregge and N. Hershkowitz. Dept. Neurol., Georgetown Univ., Wash., DC 20007

Excitatory amino acid (EAA) transmission has been demonstrated to contribute to the neuronal injury that occurs as a result of hypoxia. We investigated the effects of alterations in EAA transmission on the resting leak current measured from CA1 pyramidal neurons during hypoxia. In vitro hippocampal slices were made hypoxic by exposing them to a gas mixture containing 95% N_2/5% CO_2. Whole-cell patch-clamp recordings were made from CA1 neurons with K-gluconate electrodes (V_H=-60 mV). In control neurons (n=11), hypoxia resulted in the development of a slowly increasing inward current within 60 sec of exposure to nitrogen gas. This current was interrupted by a rapidly developing, high-amplitude inward current (RIC) (mean latency=157+/-35 sec), which was typically associated with a negative shift in the field potential. Selective inhibition of non-NMDA glutamate receptors with 5 uM CNQX resulted in a moderate increase in the latency of the RIC (n=10, 522+/-38 sec), as did blocking propagated synaptic transmission with 1 uM TTX (n=5, 391+/-69 sec) or cutting the Schaffer collaterals (n=7, 485+/-48 sec). Selective inhibition of NMDA receptors with 5 uM CPP (n=8) or non-selective blockade of both NMDA and non-NMDA glutamate receptors with 5 mM kynurenic acid (n=5) resulted in a more marked increase in the latency of the RIC (752+/-135 sec and 787+/-118 sec, respectively). These data are consistent with previous studies in which hypoxia was evaluated with extracellular and current clamp techniques. In addition, they suggest that both non-NMDA- and NMDA-mediated events may be involved in hypoxia-induced cell injury. (supported by NINDS grant NSO1460-01).

502.5

Effects Of Hypoxia On Spontaneous And Evoked Synaptic Currents In The Hippocampus. N. Hershkowitz and S. Veregge, Dept. of Neurology, Georgetown Univ., Wash. DC 20007.

Little is known about the influence of hypoxia on synaptic transmission. We examined the effects of hypoxia on synaptic activity in CA1 neurons of the hippocampal slice using patch-clamp techniques (V_H=-60 mV, K-gluconate electrodes). A stimulating electrode placed in the stratum radiatum was used to elicit orthodromic synaptic responses. Slices were made hypoxic by exposing them to a gas mixture containing 95% N_2/5% CO_2. Orthodromic stimulation elicited an inward current (EPSC) followed by an outward current (IPSC). In addition to evoked currents, smaller spontaneous inward currents were also observed. Hypoxia resulted in a gradual decline in the evoked EPSC amplitude and a rapid decline in the evoked IPSC amplitude. Thus, after approximately 80 sec the IPSC was 15 ± 11% (mean ± S.E.) of control whereas the EPSC was 86 ± 7% of control (n=5). A pure NMDA response could be eliceited in two experiments carried out in the presence of CNQX (5 uM). Under these conditions, the orthodromically elicited inward current was rapidly inhibited with complete suppression occurring within 80 sec. Hypoxia also resulted in an increase in the frequency of spontaneous inward currents in many of the cells examined. Cutting the Schaffer collaterals did not abolish this increase, but kynurenic acid (5 mM, n=5) and TTX (1 uM, n=5) suppressed these spontaneous currents, identifying them as glutamate-mediated EPSCs. These results suggest that glutamate release during hypoxia may in part result from an increase in spontaneous EPSCs. In addition, the differential sensitivity of the IPSC and EPSC may represent the mechanism of hypoxia-induced seizures. (Supported by NINDS grant NSO1460-01).

METABOLIC ADAPTATIONS TO ANOXIA IN THE ISOLATED TURTLE CEREBELLUM. M. Pérez-Pinzón, J. Bedford, M. Rosenthal, P. L. Lutz and T.J. Sick. University of Miami Schools of Medicine and Marine and Atmospheric Sciences, Miami, FL.

Turtle brain can survive prolonged anoxia during which ion homeostasis (K^+_o) is maintained, evoked potential activity is depressed but not suppressed, and ATP levels are unchanged from control. Strategies for such anoxia tolerance likely include decreased ATP demand and increased anaerobic ATP production. Present goals were to account more precisely for such metabolic activity and to seek mechanisms controlling anaerobiosis during and subsequent to the transition to anoxia. Studies were conducted in isolated turtle cerebellum which demonstrates similar anoxia tolerance to that of the turtle brain *in situ*. Unlike in mammalian brain or mitochondria which are O_2 regulators (i.e. O_2 consumption was independent of O_2 availability over a broad range), O_2 consumption in turtle cerebellum varied sensitively with declines in bath O_2 tension from saturation. Parallel studies of heat output in turtle cerebellum by flow-through microcalorimetry demonstrated that ATP production decreased approx 50% during 2 hours of anoxia. Calculations from O_2 consumption and heat production indicated that oxidative metabolism provided approx 55% of normoxia ATP production and that anaerobic ATP production was increased within 30 min ('Pasteur effect') to account for energy demands not significantly altered by the transition to anoxia. After this time, however, anaerobic ATP production declined to level characteristic of a markedly hypometabolic state. These studies indicate that the turtle brain is an O_2 conformer and suggest sensitive endogenous regulation of anaerobiosis and ATP-consuming physiological activities such as by an O_2 sensor.

ELECTROPHYSIOLOGICAL ANALYSIS OF POST-ISCHEMIC CA1 NEURONS USING IN VITRO HIPPOCAMPAL SLICES. E. F. Cregan, E. W. Harris and G. C. Palmer, Biology Department, Fisons Pharmaceuticals, Rochester, NY 14623, USA.

Transient forebrain ischemia causes a loss of neurons in hippocampal area CA1 after a delay of 1-3 days. A leading candidate mechanism is the "excitotoxic hypothesis": CA1 excitatory afferent hyperactivity, which develops after ischemia, causes CA1 cell death. We have examined synaptic transmission along the major excitatory afferent to CA1 (the commissural/associational, or C/A, pathway) at different times after transient ischemia in rats (similar studies have been carried out in gerbil; Urban et al., Stroke 21: II-23, 1989).

Transient forebrain ischemia was induced using the "4-Vessel Occlusion" (4VO) model (Pulsinelli & Brierly, Stroke 10: 267, 1979). At select times after ischemia, slices of left & right hippocampus were prepared, and allowed recover semisubmerged at 36.5°C for 90 min. Two slices from septal and mid-septotemporal hippocampus from each side were examined. The C/A pathway was stimulated near CA2 at 8 fixed intensities, and the amplitude of synaptic field potentials and evoked cell firing were measured in CA1b. Trains of near maximal stimuli (20 stimuli at 2 Hz and 5 Hz) were used to test the ability to induce repetitive CA1 cell firing.

502.8

MECHANISMS OF ANOXIA-INDUCED DEPOLARIZATION IN BRAINSTEM NEURONS: IN-VITRO INTRACELLULAR STUDIES.

G. G. Haddad and C. Jiang, Dept. of Pediatrics, Sect. Respiratory Medicine, Yale Univ. Sch. of Medicine, New Haven, CT. 06510

We have previously shown that hypoglossal (HYP) and vagal (DMNX) motoneurons depolarize in a major way when exposed to short periods of low O_2 environment in adult rat slices. In addition, we have also demonstrated that extracellular Ca^{++} and Na^{+} decrease during anoxia. We hypothesized then that, under our experimental conditions, the anoxia-induced brainstem neuronal depolarization and ionic flux is due to increased extracellular levels of glutamate, data we recently obtained by microdialysis. We performed therefore blockade experiments in the adult rat slice preparation in which we measured the anoxia-induced depolarization before and after NMDA and non-NMDA receptor antagonists. During 4-5 min of anoxia, HYP or DMNX neurons depolarized by 35-50 mV and recovered with reinstitution of O_2 over 10-15 min. Neither MK801 (10-20 μM, n=3), Kynurenate (0.5-1.0 mM, n=3) nor CNQX (10-20 μM, n=2) changed the trajectory of the depolarization or the recovery from it. We then asked whether this depolarization is due to failure of energy-requiring processes. In order to answer this directly, we studied the anoxia-induced depolarization profile before and after iontophoresing ATP salt solution intracellularly for 20-30 min through the recording electrode. We found that after ATP iontophoresis, 6/7 HYP cells recovered totally from periods of anoxia that were 2 to 3x longer (up to 12 min in PO_2=0 Torr). In addition, the depolarization magnitude was $\leq$ than that before ATP, also in 6/7 HYP neurons. We conclude that: 1) NMDA and non-NMDA mechanisms are not essential in inducing the anoxic depolarization in brainstem neurons and 2) ATP-dependent mechanisms play a major role in altering membrane potential during O_2 deprivation.

MILD HYPOTHERMIA PROTECTS MAMMALIAN CENTRAL WHITE MATTER AGAINST ANOXIC INJURY. P.K. Stys, S.G. Waxman, B.R. Ransom, Dept. of Neurology, Yale Univ., New Haven, CT 06510 and Neuroscience Research Center, VA Hospital, West Haven, CT 06516.

Strokes cause disability by involving both gray matter and white matter (WM) structures of the CNS, and spinal cord injury can result in severe neurological disability by disrupting myelinated tracts. Extracellular Ca2+ ions play a central role in the production of irreversible anoxic injury in both gray and white matter. The mode of entry of Ca2+ into cells in WM, however, is different from that in gray matter; a large portion of the damaging Ca2+ influx occurs via reverse operation of the Na+-Ca2+ exchanger. Given the substatial temperature dependence of the Na+-Ca2+ exchanger, it could be expected that the degree of anoxic injury in WM would be very susceptible to temperature. To test the extent of temperature dependence of anoxic injury in WM, we used the in vitro rat optic nerve (RON) preparation, and studied the degree of injury produced by a 60 min anoxic insult at temperatures above and below the physiological range. At 37°C, the area under the compound action potential of the RON recovered to 35.4 ± 7.2% of control, following 60 min of anoxia and a 60 min period of re-oxygenation. Modest cooling to 34.5°C during anoxia increased recovery of CAP area substantially, to 64.6 ± 15.3% (SD, P<0.00001), and at 32°C CAP area recovered fully (100.5 ± 13.8%). Conversely, higher temperatures had a deleterious effect; at 39.5°C, recovery of CAP area was reduced to 22.3 ± 13.8, and at 42°C even more injury occurred (8.5 ± 7.0%). Our results indicate that even modest reduction in temperature during the anoxic insult can very significantly improve functional recovery of CNS WM from anoxia, and that the degree of injury increases substantially with increasing temperature above the physiological range. This mechanism likely reflects the temperature dependence of ion channel, transporter and enzyme kinetics.

ANOXIC INJURY AND EARLY POST-ANOXIC RECOVERY IN RAT OPTIC NERVE: ULTRASTRUCTURAL CORRELATES. S.G. Waxman, J.A. Black, P.K. Stys, B.R. Ransom, Dept. of Neurology, Yale University, New Haven, CT 06510 and Neuroscience Research Center, VA Hosptial, West Haven, CT 06516.

We have developed a reproducible, quantitative model of anoxic white matter injury using the rat optic nerve *in vitro*. In this model, action potential conduction is rapidly abolished by anoxia, and is restored with decreased conduction velocity in about 35% of axons, following a 60-min anoxic period. We have now examined the ultrastructural correlates of anoxic injury and early post-anoxic recovery in this model. Optic nerves examined following 60 min of anoxia, displayed large, distended myelin sheaths associated with empty zones located adjacent to the axon. Myelin remained compact and retained its periodicity. In some regions, the extracellular space was enlarged. There was mitochondrial swelling with loss of normal cristae and loss of microtubules and, to a smaller degree, of filaments in large-diameter axons. Nodes of Ranvier in anoxic optic nerves displayed detachment of terminal oligodendroglial loops and, in more severely affected fibers, retraction of the myelin from the node. In optic nerves that had been permitted to recover for 60 min in oxygenated Ringers, ultrastructural changes were less pronounced. Although some axons appeared swollen, empty zones were only rarely observed within myelin sheaths. Most nodes of Ranvier appeared normal, and only rare terminal oligodendroglial processes remained detached from the axon membrane. The axoplasm of large fibers continued to show loss of microtubules and filaments, as well as mitochondrial swelling. These findings provide support for the idea that, during anoxia, myelinated axons are damaged, likely by an influx of calcium. These results suggest that damage to paranodes leads to conduction block in the anoxic optic nerve, and that repair of paranodal axon-oligodendroglial terminal loops may provide a morphological basis for the early recovery of conduction that occurs after re-oxygenation.

Anoxic changes in rat CA1 pyramidal layer cells recorded with patch electrodes

L.Zhang[1] and K. Krnjević[2]. [2] Anaesthesia Research Dept, McGill University, Montréal, H3G 1Y6 and Neuroscience Unit, Toronto Western Hospital, Toronto M5T 2S8, Canada.

Recordings (with seals > 1GΩ) were made in 500 μm thick, partly submerged slices with electrodes containing 150 mM K gluconate, 2 mM $MgCl_2$, 0.2 mM Tris GTP and 10 mM HEPES (pH 7.25). Hypoxia was produced by switching to 0_2-free aerating gas and superfusing solution, typically for 4 min.

The overall resting potential (V_m) was -61.4 (S.E.1.44) mV and input resistance (R_N) 86.3 (±5.07) MΩ (for n=60): mean R_N was thus nearly 80% greater than in recordings with conventional microelectrodes.The presence or absence of 1 mM EGTA inside the electrodes made no significant difference to V_m (-1.0 ± 1.02 mV) or R_N (3.1 ± 7.82 MΩ); but in the presence of 2 mM ATP, V_m was significantly less negative (-59.8 ± 1.14 mV) and R_N higher (101.8 ±6.40 MΩ) than in its absence (V_m -63.1 ± 0.77 mV; R_N 70.7 ± 2.74 MΩ). These data indicate a substantial involvement of ATP in the regulation of V_m and R_N.

In general, anoxic changes in V_m and R_N were much smaller than previously observed with conventional intracellular electrodes: overall (n=68) mean ΔV_m was +2.4 ± 0.783 mV and ΔR_N -11.6 ± 2.42%. The presence (n=24) or absence (n=44) of ATP in the electrodes made no significant difference to anoxic ΔV_m and ΔR_N. However, a direct involvement of Ca^{2+} is suggested by the greater anoxic reduction in R_N in the absence of EGTA (-14.3 ± 3.78%, n=28) than in its presence (-8.1 ± 3.29%, n=30): when recording with ATP-containing electrodes, the magnitude of ΔR_N was significantly correlated with the absence of EGTA (r=0.38, p=0.05, n=24).

THE EFFECT OF FORSKOLIN ON CYCLOHEXYLADENOSINE INHIBITION OF COMBINED HYPOXIC / HYPOGLYCEMIC-INDUCED 45Ca UPTAKE BY NEOCORTICAL CULTURES. A.W. Probert and F.W. Marcoux. Parke-Davis Pharm. Research Division, Warner-Lambert Company, 2800 Plymouth Road, Ann Arbor, MI 48105.

Treatment of rat neocortical cultures with cyclohexyladenosine (CHA) inhibits ^{45}Ca uptake resulting from exposure to a combined hypoxic / hypoglycemic insult. CHA's potency (IC_{50}=60μM), however, differs markedly from its low nanomolar affinity for the adenosine A1 receptor site. This discrepancy in potency verses A1 receptor affinity may reflect activity at the low affinity, intracellular P site. Since activation of this site, as well as that for A1, has been reported to down regulate adenylate cyclase activity, we examined the adenylate cyclase activator, forskolin, for its ability to reduce CHA's inhibitory effects.

Cultures were exposed to 150 min of combined hypoxia (1% O_2) / hypoglycemia (0.2g/L D-glucose) in the presence of 1000μM CHA, 50μM FORSK, 50μM of the nonactivating FORSK analog, 1,9-dideoxyforskolin (dFORSK), or 100μM CPP. Inhibition of ^{45}Ca uptake by CHA, FORSK, dFORSK, or CPP were 81, -3, 64, and 59 percent, respectively. Combined treatment with FORSK reduced CHA inhibition to 10 percent while having little effect on CPP efficacy (63 percent inhibition). Inhibition was additive when dFORSK was combined with either CHA or CPP (99 and 102 percent, respectively).

These results suggest CHA's inhibitory activity is exerted through down regulation of adenylate cyclase activity, possibly by an action at an intracellular P site.

A CRITICAL TEST OF CHANNEL ARREST. C. J. Doll, P. W. Hochachka* and P. B. Reiner. Depts. of Zoology and Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 2A9.

One possible mechanism of anoxia tolerance is the "channel arrest" hypothesis which predicts that ion leakage across the plasma membrane is reduced during an anoxic episode. The reduction of ion leakage would reduce demand on ATP utilizing ion pumps, thereby conserving metabolic energy. We used the turtle (*Chrysemys picta*) as an anoxia tolerant model system, as this species has been shown to survive anoxia for over 6 months. To monitor changes in ion leakage, whole cell input resistance and specific membrane resistivity were measured under control and anoxic conditions using intracellular recording in cortical slices incubated at 25°C. There were no significant changes in measured parameters indicating that ion leakage was not reduced. These results do not support channel arrest as a mechanism of energy conservation during short term anoxia ($\leq$ 120 mins.).

EFFECTS OF COBALT AND NICKEL IONS ON SPREADING DEPRESSION IN RAT HIPPOCAMPAL SLICES. J. Jing*, P.G. Aitken and G.G. Somjen, Dept. Cell Biology, Duke Univ. Med. Center, Durham, NC 27710.

During spreading depression (SD) and hypoxic SD-like depolarization, interstitial calcium concentration ($[Ca^{2+}]_o$) decreases precipitously, presumably by influx into cells. The mechanism of the influx is not known. We used ion selective microelectrodes to test the effect, in the CA1 region, of ions which block voltage-gated Ca^{2+} channels on the drop of $[Ca^{2+}]_o$ as well as on the change in extracellular potential (V_o) and $[K^+]_o$. SD was induced by application of 1-2 µl 3M KCl solution to the slice surface, or by withdrawing oxygen. Co^{2+} and Ni^{2+} (2mM in the bathing medium) had similar effects; these effects were essentially identical in K^+-induced and hypoxia-induced SD. The decrease of $[Ca^{2+}]_o$, the increase of $[K^+]_o$, and the negative shift of V_o were curtailed but not abolished, more so in st. pyramidale than in st. radiatum. For example, in K^+ induced SD the average effect of Co^{2+} or Ni^{2+} was to reduce $\Delta[Ca^{2+}]_o$ to 72% of control value in st. pyramidale and to 94% of control value in st. radiatum. At the site of high K^+ application SD-related changes were only moderately depressed by Co^{2+} or Ni^{2+}, but at some distance from the focus the propagation of SD was powerfully suppressed. We conclude that (1) During SD some but not all Ca^{2+} enters cells through voltage-gated channels; (2) SD-related membrane processes in neuron somata can vary independently from those in the dendrites; (3) The mechanism of SD initiation may be different from that of SD propagation. SUPPRESSION OF PRESYNAPTIC CALCIUM CURRENTS BY HYPOXIA IN HIPPOCAMPAL TISSUE SLICES. J.N. Young*, G.G. Somjen, Dept. Cell Biol. and Div. Neurosurgery, Duke Medical Ctr., Durham, NC 27710.

During hypoxia of CNS synaptic transmission fails rapidly and, initially, reversibly. We tested the hypothesis that voltage gated calcium channels in the presynaptic terminals are inactivated by hypoxia, leading to failure of transmitter release. Rat hippocampal slices were studied in a dual-well interface chamber at 34.5°C. Interstitial calcium concentration ($[Ca^{2+}]_o$) was recorded with ion selective microelectrodes in st. radiatum of CA1 and sometimes also in st. pyramidale. Ortho- and antidromic stimulus trains (5s, 20Hz) were applied to evoke changes in $[Ca^{2+}]_o$. In order to record $[Ca^{2+}]_o$ responses due to Ca-influx into presynaptic axon terminals, postsynaptic responses were blocked by 10 µM 6,7-dinitroquinoxaline-2,3-dione (DNQX) and 20 µM 3-((±)-2-caboxypiparazine-4-yl)-propyl-1-phosphonic acid (CPP), or, in other experiments, by lowering bath Ca^{2+} to 0.12 mM. Oxygen was withdrawn until signs of spreading depression (SD)-like depolarization occurred. During hypoxia orthodromic (presynaptic) $[Ca^{2+}]_o$ responses in st. radiatum were extinguished before SD began; antidromically evoked $[Ca^{2+}]_o$ responses in st. pyramidale failed only at the moment of SD. "Resting" baseline of $[Ca^{2+}]_o$ declined first gradually, then, with the onset of SD, precipitously. In the presence of DNQX and CPP hypoxic SD occurred later, and during SD $[Ca^{2+}]_o$ decreased less, than in slices bathed in control solution. The findings are consistent with a failure of voltage gated Ca^{2+} channels in presynaptic terminals during hypoxia, possibly due to inactivation caused by a rise of $[Ca^{2+}]_i$. During hypoxic SD some but not all the Ca^{2+} appears to enter cells through glutamate-controlled channels. (Supported by grants NS 18670 and NS 06233)

CONSEQUENCES OF TRANSIENT ASPHYXIA IN CORTICAL AND HIPPOCAMPAL NEURONS IN CULTURE. J.L. Daval, F. Nicolas* and V. Koziel*, INSERM U.272, 30 rue Lionnois, 54013 NANCY, FRANCE.

Following a brief episode of oxygen deprivation, some neural cells, especially in cortex and hippocampus develop a so-called "delayed neuronal death", and a critical role for postanoxic release of excitatory amino acids has been proposed. The present study was designed in order to develop a reproducible model to study hypoxic damage in primary cultures of neurons. Functional response of cultured neurons from rat cortex and hippocampus to transient hypoxia/asphyxia was studied by the measurement of [^{3}H]2-deoxyglucose (2DG) specific uptake. Cell morphology, lactate dehydrogenase (LDH) efflux and protein contents were also examined. Hypoxia was induced by incubating the cells either in a 5% CO_2 -95% N_2 gas mixture or in 1 mM NaCN-containing culture medium for various periods of time. Twenty-four hours following hypoxia (6 to 8 h in an anaerobic atmosphere or 90 min in the presence of NaCN), 2DG transport was significantly enhanced, with a concomitant increase in LDH efflux, whereas no major morphological alteration could be noticed. Cell injury was more evident 3 days post-hypoxia, with a reduced rate of cellular metabolism and cell degeneration. The transient stimulation of 2DG uptake by the neuronal cells in culture indirectly suggests the participation of amino acid excitotoxicity.

Hypoglycemic injury in organotypic hippocampal culture is similar to NMDA neurotoxicity and is prevented by delayed MK-801. R. C. Tasker, J. J. Vornov and J. T. Coyle Depts. Anesthesiology, Neurology, Neuroscience and Psychiatry, The Johns Hopkins School of Medicine, Baltimore, MD 21205

In animal models of hypoglycemia, neurotoxicity is rapid and selectively involves CA1 and the dentate gyrus. Injury is attenuated by concomitant NMDA receptor antagonists. In organotypic hippocampal culture, which preserves the regional differentiation of the hippocampus, we have examined the time course of neuronal injury following *in vitro* "hypoglycemia" using propidium iodide fluorescence microscopy to observe directly the regional distribution of membrane injury in real time. Increasing duration of exposure to glucose-free media, for up to 3 hours, was associated with an increasing severity of injury. The pattern of propidium staining following 2 hours of hypoglycemia was the same as that observed following a 30 minute exposure to 10 µM NMDA: simultaneous staining of CA1 and the dentate gyrus with sparing of CA3, beginning after 4-6 hours of recovery. To facilitate further examination, a briefer "hypoglycemic" insult was achieved with the addition of 2-deoxyglucose (2-DG) to inhibit glycolysis. A 30 minute exposure to 5 mM 2-DG also produced propidium staining simultaneously in CA1 and the dentate gyrus after 4-6 hours of recovery. MK-801, during or up to 30 minutes after hypoglycemia, prevented propidium staining in CA1. At 24 hours, histologic evaluation confirmed the protective effect of MK-801 in CA1 and the dentate gyrus. Hypoglycemic injury appears to be mediated by acute, toxic NMDA receptor activation, which continues for at least 30 minutes into the recovery period in organotypic hippocampal culture.

502.18

EFFECT OF ANOXIA ON EXCITATORY AMINO ACIDS IN BRAIN SLICES OF RATS AND TURTLES: *IN VITRO* MICRODIALYSIS STUDY. R.S.K. Young, M.J. During, G.G. Haddad, D.F. Donnelly, W.J. Aquila*, V.L. Perry*. Yale University School of Medicine; New Haven, CT.

The purpose of this study was to utilize *in vitro* microdialysis to test the hypothesis that anoxia has a differential effect upon the concentrations of excitatory and inhibitory amino acids released from brain slices of rats compared to those of turtles. Ten minutes of anoxia (95% N_2 / 5%CO_2) produced signficiant elevation of glutamate (from 0.39±0.03 to 0.90±0.18 µM/L dialysate, Mean ± SE, $p < 0.05$, Anal. of Variance), aspartate (from 0.28±0.12 to 1.20±0.49, $p < 0.05$), glycine and alanine in the rat. During reoxygenation, alanine and glycine returned toward baseline values, whereas aspartate and glutamate did not. In contrast, prolonged anoxia (60 minutes) produced only a slight increase in aspartate (from 0.06±0.01 to 0.09±0.02, $p < 0.05$) and a decrease in glutamate (from 0.50±0.11 to 0.33±0.09, $p < 0.05$) in the turtle. Levels of glycine and alanine did not change. We speculate that the mechanism of anoxia-resistance in the turtle is at least partly due to the lack of increase in excitatory amino acids in response to severe oxygen limitation.

502.19

PROTECTION OF BRAIN SLICES FROM ISCHEMIC INJURY DURING PREPARATION BY HYPOTHERMIA, PHENYTOIN AND PENTOBARBITAL.
H. Qi, F. E. Hospod, K. Grundmann and G. C. Newman. Dept. of Neurology, SUNY at Stony Brook, Stony Brook, NY, 11777 and Northport VAMC.

Our goals are: 1) to test the hypothesis that ischemia due to decapitation is the primary cause of brain slice injury and 2) to improve slice quality.

We have studied histology of 500μ hippocampal slices incubated for 5 hours in K-R with 4 mM glucose by determining the number of normal appearing neurons in CA1 and the dentate. Male Sprague-Dawley rats (300g) were sacrificed without anesthesia (Control), after cooling to 31°C. with sedation using pentobarbital or a mixture of 1.5% halothane/NO_2 (Hypothermia), or after phenytoin (200mg/kg; PHT) or pentobarbital (60mg/kg; PB). The histologic effects of varying slice thickness from 350μ to 500μ or incubating at temperatures from 30°C. to 37°C. were also evaluated.

Approximately 20% of CA1 pyramidal cells appear normal in Control slices but hypothermia prior to sacrifice results in the normal appearance of virtually all CA1 neurons. Pre-treatment with PHT or PB increases the number of normals to over 50%. Incubation at 30°C. improved slice histology less than hypothermia prior to sacrifice while incubation at 35°C. produced no benefit. CA1 histology was improved only minimally by reducing slice thickness.

Dentate of Control 500μ slices show a zone of severe core injury beginning 90μ from the slice surface. This injury disappears completely in 350μ slices. Hypothermia shifted the onset of injury to a depth of 150μ. Pre-treatment with drugs or incubating in the cold had relatively little effect on dentate histology.

Hypothermia before sacrifice produces slices with near normal histology after 5 hours *in vitro* without introducing drugs or requiring changes in incubation temperature.

502.20

PROTECTIVE EFFECTS OF PHENYTOIN AND PENTOBARBITAL IN A THICK SLICE MODEL OF ISCHEMIA.
K. Grundmann, H. Qi, F. E. Hospod and G. C. Newman. Dept. of Neurology, SUNY at Stony Brook, Stony Brook, NY, 11777.

Thick brain slices (1000μ) differ from thin slices because they retain substances released into the extracellular space and thus create a more realistic model of ischemia. In this study we combine histology and brain slice glucose utilization (SGU) to further define the model and assess the effects of phenytoin (PHT, 10μM) and pentobarbital (PB, 100μM).

Hippocampal brain slices (500μ and 1000μ) were prepared from male Sprague-Dawley rats (250g). Histology and SGU were studied at multiple slice depths after 2 or 5 hours *in vitro*. CA1 histology was assessed by counting the percentage of neurons that were normal, shrunken, swollen or lysed. SGU was measured in the dendritic fields of CA1, CA3 and dentate.

In 500μ Control slices, normal cells in CA1 decreased from 32% at 2 hr to 20% after 5 hr and cell lysis increased from 6 to over 12%. SGU varied from 25 μmole/100g/min (U) in dentate to 38 U in CA1 str. radiatum after 2 hr and declined by about 20% after 5 hrs. PHT and PB had virtually no effect on 500μ slice histology but increased SGU in CA3 by 50%. In contrast, in 1000μ control slices, only 5% of CA1 neurons were normal after 2 hr and 1 % by 5 hrs while cell lysis increased from 8% to 28% after 5 hrs. SGU of 1000μ control slices was much higher than in thin slices, ranging from 35 U in dentate to 84 U in CA1 at 2 hr with a 50% decline after 5 hrs. Both PHT and PB increased the percentage of normal neurons slightly but significantly decreased cell lysis, especially after 5 hours *in vitro*. PHT and PB significantly increased SGU in all regions and reduced the relative decline after 5 hrs.

Both PHT and PB improve CA1 histology in this thick brain slice model of ischemia. This effect correlates with increased glucose utilization rather than the reduced metabolic rate expected from studies with non-ischemic tissue.

INFECTIOUS DISEASES

503.1

DIFFERENT MODES OF HIV-1 TRANSCRIPTION ACTIVATION IN GLIAL, AND IN PHORBOL ESTER (PMA)- AND RETRINOIC ACID (RA)-TREATED HUMAN NEURONAL CELLS.
D. Mondal* and O. Prakash. Dept. of Molecular Oncology, Alton Ochsner Medical Foundation, New Orleans, LA 70121.

A variety of neurological dysfunctions, collectively known as AIDS dementia complex, are observed in AIDS patients. Previously, it was considered that macrophages or microglial cells were the only cell types which carried the virus in the brain. However, recently it has been shown that HIV can also infect neuronal and glial cells. We carried out transient transfection experiments in order to assess the transcriptional activity of HIV-LTR in neuronal and glial cell lines.

HIV LTR expression was significantly higher in RA-treated compared to PMA-treated neuroblastoma (SHSY5Y) cells. The NF-kB responsive element did not appear to play a major role in this activation. In addition, the LTR expression was refractory to tat-mediated transactivation and induction by TNF-α, insulin and morphine. On the other hand, HIV-LTR expression in PMA-treated cells was inducible with tat, TNF-α, insulin and morphine. In the astrocytoma cell line U-373 MG, the LTR expression was inducible with TNF-α and tat but not with insulin and morphine. These results suggest that neuronal and glial cells have the capacity to induce cellular factors which can activate HIV expression and can contribute to neurological dysfunctions. Studies are underway in our laboratory to characterize these factors.

Recombinant gp120 causes astrocyte alteration.
L. Pulliam, D. West*, N. Haigwood*, R. A. Swanson Depts. of Laboratory Medicine and Neurology, VA Medical Center and Univ of CA, San Francisco, 94121 and Chiron Corp., Emeryville,CA

The gp120 of HIV has been reported to be neurotoxic to rat neurons; however, these results were not consistent with pathologic changes observed in patients with AIDS. In an effort to further characterize AIDS dementia and to define the role of gp120, we studied the effects of 2 recombinant gp120 preparations (SF2 and 3B) and 2 gp120 SF2 deletion mutant preparations on human brain cell aggregates. The 4 glycosylated recombinant gp120 molecules were used at concentrations of 1 pM or 1nM. The SF2 molecule binds to a CD4 receptor and 3B molecule does not. Using flow cytometry, we did not see a significant decrease in the neuron population nor was gp120 binding observed; however, there was a disruption of cellular matrix by histological exam. Using flow cytometry, there was a decrease in GFAP-staining cells treated with SF2 in 2 out of 4 brain preparations. By ultra-structure examination, cells consistent with astrocyte morphology but lacking cytoplasmic fibrils could be seen. To explore the possibility that altered astrocyte function may influence neuron viability, we measured glutamate uptake of gp120 treated human astrocyte cultures and did not find a significant decrease.

503.3

EVIDENCE FOR THE CELL-TO-CELL SPREAD OF HSV WITHIN THE TRIGEMINAL GANGLION AND ROOT AFTER CORNEAL INOCULATION.
J. H. LaVail and W. E. Johnson*. Dept. Anatomy and Neuroscience Program, UCSF, San Francisco, CA 94143.

We earlier used various antibody probes to characterize the classes of neurons in the V_1 division of the mouse trigeminal ganglion (TG) that become actively infected with Herpes simplex virus (Type 1) (HSV) 3 days after corneal infection (Margolis et al. 1989). Unspecified, however, were which classes of neurons in the TG became primarily infected following retrograde transport of virus from the cornea and which were infected secondarily, either after spread between cells within the ganglion or following transport to synaptic endings and reuptake by neighboring terminals. We now have identified neuron classes that innervate the cornea, based on their ability to transport FluoroGold (FG) from axon endings in the cornea back to cell somata in the TG and on their labeling with antibodies against Substance P (SP), Calcitonin gene-related peptide (CGRP) or monoclonal antibodies LD2 and SSEA3, that are directed against specific neuronal glycoconjugates. About 230 TG neurons innervate the central cornea of the mouse. About 44% of these are immunoreactive for SSEA3; about 45% contain CGRP and of these about half also contain SP. None of the FG+ cells label with LD2 antibody, although LD2+ neurons represent about 36% of the total neurons and 18% of HSV infected neurons in the V_1 division of the ganglion. We found in an earlier study that anterograde transported HSV does not appear in the trigeminal complex of the brainstem until 3 days after inoculation. Thus LD2+ ganglion cells observed on day 3 must have been infected with HSV following spread from nearby cells in the ganglion or proximal trigeminal root rather than by release at synaptic ending and reuptake by nearby terminals of other TG neurons.

503.4

DETECTION OF TAU-2 EPITOPES IN AIDS TEMPORAL LOBE.
S.X.Zhang*, L.C.Stanley, W.S.Metzer and W.S.T.Griffin. Departments of Anatomy, Neurology, and Pediatrics, UAMS, Little Rock, AR 72205

Tau proteins are low molecular weight microtubule-associated proteins found in the protease-resistant paired helical filaments of neurofibrillary tangles in neurons in Alzheimer disease (AD). Approximately 66% of all AIDS patients suffer from clinical dementia. The loss of cognitive function in AIDS is similar to that characteristic of AD dementia. We hypothesized that neuropathological changes similar to those in AD occur in AIDS, including the aberrant expression of Tau-2 epitopes. Using a specific monoclonal antibody, Tau-2 (gift from L.I.Binder), we examined formalin-fixed, paraffin-embedded, 10 μm thick, temporal lobe sections taken postmortem from AIDS, age-matched controls (AMC), and AD (positive control). We found a greater number of Tau-2 immunoreactive astrocytes, microglia, macrophages, neurons, and fibers in AIDS than in AMC. These immunoreactive cells and fibers were not as prevalent as in AD but had a similar appearance to those in AD. We conclude that the prominence of the immunohistochemical labeling is indicative of excessive expression of Tau-2 epitopes in AIDS temporal lobe. Our results provide evidence that a common cascade of neuropathological events occurs in AIDS as we postulate in AD. This work was supported in part by NS27414.

503.5

S100β IS ELEVATED IN BRAIN CELLS OF AIDS PATIENTS. W.S.T.Griffin, L.C.Stanley, R.E.Mrak, and L.J.Perrot*, Departments of Anatomy, Pathology, and Pediatrics, UAMS, Little Rock, AR 72205

We have recently reported an elevation of IL-1 in microglia in AIDS temporal lobe. Because IL-1 has been shown to stimulate astrogliosis in rats (Guilian et al., 1988), we proposed that elevated IL-1 induces astrogliosis, including synthesis of S100, in Alzheimer Disease (AD), Down Syndrome, and other neurodegenerative disorders, including AIDS, where gliosis is a characteristic neuropathology (Griffin et al., 1989). We have recently shown an elevation of the level and neurotrophic activity of S100β in AD and suggested that this elevation contributes to the overgrowth of neurites in senile plaques (Marshak et al., 1991). In order to determine if reactive astrocytes, containing elevated levels of S100β, are present in AIDS temporal lobe along with the elevated levels of microglia-derived IL-1, formalin-fixed, paraffin-embedded temporal lobe sections from HIV infected individuals (AIDS, n=8) and age-matched controls (AMC, n=6) were examined, using a specific antibody to S100β (gift from D. Marshak). The number of S100β immunoreactive astrocytes in AIDS was approximately 2 times that in AMC in both grey and white matter. Furthermore, these cells were enlarged and had prominent processes. We conclude that astrogliosis with elevated expression of S100β is associated with HIV infection and elevation of microglia-derived IL-1 in AIDS. If this elevation of S100β in AIDS is reflective of neurotrophic activity, as in AD, it could lead to the formation of dystrophic neurites and neuronal dysfunction. This work was supported in part by NS27414.

IL-1α AND IL-1β ARE ELEVATED IN BRAIN CELLS OF AIDS PATIENTS. L.C.Stanley, R.E.Mrak, L.J. Perrot*, and W.S.T.Griffin, Departments of Anatomy, Pathology, and Pediatrics, UAMS, Little Rock, AR 72205

The neuropathogenesis of an Alzheimer Disease-type dementia in AIDS is unknown but is likely due to HIV infection of brain cells (Navia et al., 1986). Numerous reactive microglia are infected with HIV in AIDS brain (Stoler et al., 1986; Michaels et al., 1988), and HIV preferentially infects and replicates in microglia rather than in other glia or in neurons (Watkins et al., 1990). We have previously shown an elevation of IL-1 in reactive microglia in Alzheimer Disease and Down Syndrome (Griffin et al., 1989). We hypothesized that numerous reactive microglia, containing elevated levels of IL-1, would be present in AIDS temporal lobe in response to HIV infection. We examined formalin-fixed, paraffin-embedded temporal lobe sections from HIV infected individuals (AIDS, n=8) and age-matched controls (AMC, n=6), using specific antibodies to IL-1α and IL-1β. The number of IL-1α immunoreactive cells in AIDS was approximately 5 times that in AMC. These cells were identified as reactive microglia based on their morphology and double labeling for IL-1α and GFAP which excluded the majority of these cells from the astrocyte population. The number of IL-1β immunoreactive cells in AIDS was approximately 9 times that in AMC but was only about 33% of the number of IL-1α+ microglia. Cells containing IL-1β immunoreactive product were identified as reactive astrocytes. We conclude that elevated expression of brain-derived IL-1 is associated with HIV infection and possibly contributes to the neuropathogenesis of dementia in AIDS. This work was supported in part by NS27414.

IDENTIFICATION OF UBIQUITIN-CONTAINING CELLS IN THE BRAIN FROM AIDS PATIENTS. H. Astle and F.J. Denaro, Dept. of Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

Ubiquitin belongs to a class of proteins produced by cells in response to physiological stress. Of central importance is ubiquitin's role in the formation of ubiquitin-protein complexes. These complexes are a signal for the degradation of atypical and short-lived proteins. To date, ubiquitin has been identified in neurofibrillary tangles, senile plaques, Lewy bodies, and cellular inclusions in other tissues. The brain, therefore, is capable of producing ubiquitin and this production appears to occur in association with various neuropathological states. Neurological problems and neuropathological lesions are associated with HIV infection. Work has been undertaken to clarify the role of HIV and opportunistic infections in the production of the neuropathology which is found in AIDS. In the present study, by immunocytochemistry we examined postmortem CNS tissue from AIDS patients. By this approach we have been able to identify ubiquitin in neurons in these brains. Opportunistic infections or HIV may be responsible for the production of ubiquitin in these cells. If so, the mechanism involved is not understood. For example, is the production of ubiquitin a consequence of direct neuronal infection by virus or is it an indirect result of the systemic effects of HIV or other opportunistic infections? Work is under way to examine the role of viral infections in the production of ubiquitin in the CNS.

NEUROTROPISM OF BORNA DISEASE VIRUS IS LINKED TO THE PRODUCTION OF NERVE GROWTH FACTOR AND OTHER SOLUBLE FACTORS BY NEURAL CELLS, K. M. Carbone, S. A. Rubin*, S. W. Park*, A. M. Sierra-Honigman*, R. W. Waltrip, II, W. I. Lipkin and R.H. Yolken*, Div. of Infectious Diseases, Depts. of Medicine & Pediatrics, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

Borna disease virus (BDV) is an RNA virus which causes immunopathological neurobehavioral disease. We examined the preferential replication of BDV in neural cells, assumed to be due to a receptor unique to these cells. We identified no increased binding of BDV to C6 cells, an astrocytoma cell line, as compared to the MDCK cells, a canine kidney cell line. C6 cells were extremely permissive to BDV replication, as 100% of the cells expressed viral antigens after BDV inoculation (C6-BDV) vs 2% of the MDCK cells. C6 conditioned medium (C6-CM) or NGF alone, when added to PC12 cells, a rat pheochromocytoma cell line, or to SHEP and SY5Y, human neuroblastoma cell lines, *after* inoculation with BDV, produced a 3 to 10-fold increase in BDV-infected cells and expression of BDV proteins, as compared to cells inoculated with BDV without NGF or C6-CM treatments. C6-CM or NGF treatment prior to inoculation with BDV had no effect. A comparison of C6-BDV and MDCK-BDV cell lines using immunoprecipitation and Northern Blot analysis revealed that the C6-BDV cell line produced more viral RNA and protein than the MDCK-BDV cell line. Thus, the neurotropism of BDV may be associated with the production of soluble factors by neural cells.

PCR AMPLIFICATION OF BORNA DISEASE VIRUS (BDV) SPECIFIC SEQUENCES IN NON NEURAL TISSUES AND BODY FLUIDS IN NEWBORN, CHRONIC AND ACUTELY-INFECTED RATS. A. M. Sierra-Honigmann*, W. I. Lipkin, J. W. Griffin, R. W. Waltrip, II, R. H. Yolken*, and K. M. Carbone.
Divisions of Infectious Diseases, Depts. of Pediatrics and Medicine, Dept. of Neurology, The Johns Hopkins University, School of Medicine, Baltimore, MD 21205.

Borna disease virus (BDV) is a neurotropic RNA virus that infects a wide range of species, including birds and mammals. BDV-infected cells can be identified immunohistochemically using serum from infected animals or by in situ hybridization with RNA probes from BDV cDNA clones. Previous studies in neonatally-infected rats (NB) indicated that viral antigen and infectious virus were found in neural and non-neural organs. In contrast, in adult infected rats, BDV was found to be restricted to the nervous system. We have developed a quantitative polymerization chain reaction assay (PCR) to measure BDV-specific sequences in NB, chronic (CH) and acutely (AC) infected rats. We amplified BDV RNA in brain and peripheral white blood cells as well as in CSF, saliva, nasal secretions, urine, and stool. BDV-specific sequences were not recovered from normal rats, nor from plasma from BDV-infected rats. Identification of BDV in body secretions in rodents suggests a possible mechanism for transmission of BDV in nature.

NUCLEIC ACID SEQUENCE FOR THE ORF ENCODING THE 38 kD PROTEIN OF THE BORNA DISEASE AGENT. Gus Ray*, W. Ian Lipkin, Neurology; Anatomy & Neurobiology; Microbiology & Molecular Genetics, University of California, Irvine, CA 92717.

The Borna disease agent (BDA) is an RNA virus characterized by tropism for pyramidal neurons of hippocampus and a wide vertebrate host range. Serologic data suggest that BDA or a related virus may cause neuropsychiatric disease in man.

BDA RNAs are transcribed in the nucleus and then transported to the cytoplasm. Histochemistry indicates that BDA antigens are primarily nuclear in location. Here we report nucleic acid sequence for the ORF encoding the major immunogenic protein of BDA. Predicted amino sequence for this 38 kD protein includes a putative nuclear import signal motif.

503.11

VIRAL GLYCOPROTEINS MEDIATE NEURONAL INFECTION BY PSEUDORABIES VIRUS. J.P. Card, M.E. Whealy*, A.K. Robbins* & L.W. Enquist*. Viral Diseases Group, DuPont Merck Pharmaceutical Co., Wilmington, Delaware 19880.

We have previously demonstrated that wild type pseudorabies virus (PRV-Be; Becker strain) and an attenuated strain of PRV (PRV-Ba; Bartha) differentially infect rodent visual circuits. Intraocular injection of PRV-Be results in two temporally separated waves of infection which ultimately target all known retinorecipient neurons. In contrast, PRV-Ba only infects a functionally distinct subset of these neurons. These data suggest that the wild type virus recognizes two receptors which are differentially distributed upon projection specific populations of retinal ganglion cells and that the mutations present in PRV-Ba prevent it from interacting with one of those receptors. In the present analysis we have examined the effects of defined glycoprotein mutations upon the pattern of central infection induced by PRV. PRV-Ba contains a deletion which removes two glycoprotein genes (gI and gp63) in the unique short (Us) region of the genome and also produces a defective gIII glycoprotein. Two strains of PRV lacking the gene for glycoprotein gI were examined; PRV-91 contains a single deletion of the gI gene on a Becker background while PRV-D is the Bartha strain with a rescued Us segment and a gI deletion. These strains of PRV exhibited reduced virulence and also produced a pattern of central transport essentially identical to that observed following injection of PRV-Ba. These data indicate that gI is necessary for infection of a functionally distinct subset of retinal ganglion cells and supports the contention that invasion of the central nervous system by alpha herpesviruses is the product of a complex interaction of multiple viral envelope glycoproteins and cellular receptors.

503.12

NEUROACTIVE KYNURENINES AFTER INTRASPINAL INOCULATION OF MACAQUES WITH LIVE POLIOVIRUS M.P. Heyes*, K. Saito*, S.P. Markey* and J.H. Vickers[2] Section on Analytical Biochemistry[1], NIMH and Pathobiology and Primatology Laboratory[2], FDA, Bethesda MD 20892.

Immune stimulation increases the concentrations of quinolinic acid (QUIN), an excitotoxic kynurenine pathway metabolite (*J. Neurochem.* 51 1946, 1988; *Ann Neurol.* 29 202, 1991). In the present study, 96 rhesus macaques received an intraspinal injection of poliovirus (PV) as part of a neurovirulence test for vaccine safety and compared to 6 sham and 6 uninjected controls. CSF QUIN concentrations increased between 3- to 550-fold on day 17 and were highly correlated ($r > 0.70$) to increases in indoleamine-2,3-dioxygenase (IDO) activity and QUIN levels in the spinal cord. CSF L-kynurenine (L-KYN), anthranilic acid and kynurenic acid levels were also increased and correlated with CSF QUIN levels and spinal cord IDO activity ($r > 0.70$). Smaller increases in IDO activity and QUIN levels were found in motor cortex (a PV target area) without changes in frontal cortex. The largest metabolic and histopathologic changes occurred in macaques with lower limb paralysis. Quantitative measures of neurologic damage and inflammatory responses in the spinal cord correlated with the magnitude of each of these metabolic responses in CSF and spinal cord ($r>0.78$). Serum QUIN and L-KYN levels were unchanged in the PV-inoculated macaques. We conclude that PV-inoculated macaques offer a primate model to determine the effects of intracerebral immune stimulation on kynurenine pathway metabolism and to investigate whether endogenous production of neuroactive kynurenines *in vivo* are associated with functional or neuropathologic consequences.

503.13

HISTOPATHOLOGICAL CHANGES IN THE PITUITARY OF FEMALE HAMSTERS INFECTED WITH THE 139H STRAIN OF SCRAPIE. X. Ye,[1] R.I. Carp,*[2] S. Callahan,*[2] J. Shek[2]. [1]CSI/IBR Center for Developmental Neurosciences, [2]New York State Institute for Basic Research for Developmental Disabilities, 1050 Forest Hill Road, Staten Island, New York, 10314.

Previous studies showed that the 139H strain of scrapie injected intracerebrally in hamsters caused obesity, a marked hypertrophy of the islets of Langerhans in the pancreas, generalized endocrinopathy and marked hypoglycemia-hyperinsulinemia. The extremely low scrapie infectivity levels in pancreas suggested that the changes noted in that organ were of neuroendocrine origin. In the current study, female, weanling, Syrian hamsters, strain LVG/LAK, were injected intracerebrally with scrapie strain 139H or with normal hamster brain. Coronal sections of the pituitary were stained with hematoxylin and eosin, and were examined with light microscopy. The scrapie strain 139H infected hamsters showed extensive vacuolization in the pituitary. Most vacuoles were located on the ventral and/or ventrolateral parts of the pars distalis. The pituitaries of scrapie infected hamsters also showed cellular hypertrophy, cellular atrophy, and cytoplasmic vesicles. There were nuclear pathological changes such as swelling, vesicular changes, chromatin increase, pyknosis and karyorrhexis. The cellular and nuclear pathological changes were most pronounced in the regions with vacuolation. We will also report on immunocytochemical studies of pituitary cells from these animals. These studies will help establish the relationship between the changes in the central nervous system and the pathological findings seen in the pancreas and other endocrine organs in 139H infected hamsters.

503.14

BRAIN LEVELS OF NEUROPEPTIDE Y IN EXPERIMENTAL PNEUMOCOCCAL MENINGITIS IN RABBITS. M.G. Täuber*, S.L. Kennedy*, R.A. Sheldon*, L. Guerra-Romero* and D.M. Ferriero. Departments of Medicine and Neurology, Univ. Calif. San Francisco, San Francisco, CA 94143.

Alterations of cerebral blood flow (CBF) have been documented in humans and experimental animals with pneumococcal meningitis (PM). Both the loss of CBF autoregulation and vascular inflammation resulting in spasm and thrombosis are likely to affect CBF, but little is known about other factors that affect regulation of vascular tone and CBF during meningitis. Neuropeptide Y (NPY), which is found in high concentrations in nerve fibres surrounding cerebral vessels, has been proposed to play a role in regulating CBF in CNS diseases. In the present study we examined whether NPY concentrations change in various regions of the brain during experimental PM. Rabbits were infected intracisternally with S. pneumoniae. At various time points after infection, levels of NPY were determined by RIA in the brain regions indicated (expressed as ng/g of protein):

	Cortex	Medulla	Caudate	Hippocampus
0 hr (n=4)	6.5±4.1	3.8±1.3	7.8±1.3	25.0±18.7
24 hrs (n=5)	17.6±15.2	3.8±0.8	20.4±19.5	51.2±36.1
48 hrs (n=7)	9.3±4.2	12.9±5.6*	13.9±16.5	27.6±37.0

While all brain regions showed increasing NPY concentrations, typically after 24 hrs of infection, changes were most pronounced in the medulla (*$p<0.001$), where NPY levels peaked after 48 hrs of infection. Immunocytochemistry confirmed these findings, showing markedly increased NPY-immunoreactivity in nerve fibres surrounding small vessels in the medulla in animals after 48 hrs of PM compared to controls. These results suggest that NPY may play a role in CBF alterations occuring during PM.

NEUROTOXICITY: MPTP

504.1

REDUCTION IN GLUCOSE LEVELS ENHANCES 2'ET-MPTP-INDUCED TOXICITY IN PC12 CELLS. A.N.Basma*, R.E. Heikkila, E.T. Browning[1], M.S. Saporito, H.M. Geller[1] and W.J. Nicklas. Depts. of Neurology & [1]Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

The active agent in MPTP neurotoxicity is thought to be its metabolite, MPP^+. MPP^+ and analogs such as 2'Et-MPP^+, are actively accumulated by mitochondrial preparations *in vitro* and block NADH dehydrogenase of complex I. This blockade results in biochemical sequelae which are cytotoxic. In certain model systems, the blockade of complex I is accompanied by an increase in glycolysis and a resultant stimulation in lactate formation. In this study, the catecholamine-containing PC12 cell line was used to investigate the effects of 2'Et-MPTP, 2'Et-MPP^+ and the complex 1 inhibitor, rotenone, on toxicity as well as the rates of glucose utilization and lactate production. Untreated PC12 cells utilized glucose and concomitantly produced lactate in a time-dependent manner at all concentrations of glucose studied. Treatment with 50μM 2'Et-MPP^+ or 50nM rotenone increased both rates significantly. Cell death caused by the toxins was also time-dependent and markedly attenuated by the availability of glucose in the medium. Iodoacetate (5μM), an inhibitor of glycolysis, was toxic to the cells suggesting that the glycolytic pathway is necessary for cell survival. The data further support the hypothesis that the ability of MPTP or its analogs to induce toxicity is dependent on the relative contributions of glycolysis and mitochondrial oxidation to the energy needs of a particular cell or model system.

504.2

INTRACELLULAR CALCIUM RESPONSES TO GLUTAMATE AND MPP^+ IN CULTURED CEREBELLAR GRANULE CELLS. A.M. Marini, Y. Ueda*, and C.H. June*. CNB, NINDS, NIH, and Naval Medical Research Institute, Bethesda, Maryland 20892.

The effects of glutamate on the intracellular calcium concentration were tested in cultured rat cerebellar granule cells loaded with fura-2 using digital image microscopy. During early culture times, glutamate (500 micromolar) elicited striking but transient increases in intracellular calcium levels. The response was rapid in onset (<10 sec) and the pattern of response heterogeneous in that only a subset of cells responded to glutamate. At later culture times (12-30 days in culture), glutamate caused no or only modest increases in intracellular calcium. The N-methyl-D-aspartate (NMDA) receptor antagonist, MK-801, caused a partial inhibition of the glutamate-induced calcium response; single cell analysis shows that the effects of MK-801 are complete on some cells and ineffective on other cells, suggesting that subsets of the cultured cells exist based on sensitivity to glutamate-induced calcium mobilization and the NMDA receptor antagonist.

We have shown previously that cultured cerebellar granule cells are susceptible to the neurotoxic effects of MPP^+. Exposure of cultured neurons to MPP^+ (50 micromolar) results in cell death by 72 to 96 hours. No significant increase in calcium was observed in MPP^+-treated cells for up to 48 hours, suggesting that signal transduction by calcium is unlikely to play a role in the initiation of MPP^+-induced neurotoxicity.

504.3

SENSITIVITY OF AN IMMORTALIZED DOPAMINERGIC CELL LINE TO MPP+ CYTOTOXICITY. H.K. Choi, L. Won, P.C. Hoffmann, and A. Heller
Dept. of Pharmacological and Physiological Sciences, The University of Chicago, Chicago, IL 60637

1-methyl-4-phenylpyridinium ion (MPP+) produces toxic effects on dopaminergic neurons of the substantia nigra in human, non-human primate, and mouse resulting in lesions similar to those found in human parkinsonism. The study of biochemical mechanisms underlying MPP+ toxicity is complicated by the heterogeneity of the cells obtained from dissection of the mesencephalon since dopaminergic neurons constitute less than 1% of the cells. Cell lines have simplified studies on diverse aspects of the nervous system. We have generated hybrid cell lines by fusion of cells from the mouse mesencephalic tegmentum at embryonic day 14 with a neuroblastoma cell line (N18TG2) (Choi et al., *Brain Res.*, in press). One of the monoclonal hybrid cell lines (MN9D) contains a high level of dopamine (DA). This line showed a marked sensitivity to the DA-depleting effect of MPP+ in contrast to a PC12 cell line. This report concerns the sensitivity of MN9D hybrid cells to the cytotoxicity of MPP+. Fifty thousand MN9D hybrid cells were plated per well in 48-well plastic culture plates with 500 ul of Eagle's basal medium containing 10 % fetal bovine serum and increasing concentrations of MPP+ from 1 uM to 1mM. Forty-eight hours later, the cells were trypsinized and counted. MN9D hybrid cells responded in a dose-dependent manner to the cytotoxicity of MPP+ with 1 uM MPP+ reducing the cell number to 65.9 ± 18.5 % of control. Ten uM MPP+ produced a reduction to 30.3 ± 12.2 % of control. Many of the cells detached from the plate and appeared non-viable. In contrast, the parental N18TG2 cells required an MPP+ concentration 2 orders of magnitude higher (100 uM) for a comparable level of cytotoxicity. The MN9D hybrid cell line therefore provides a useful model system for studying the mechanisms of toxicity of MPP+ as well as other cytotoxic substances affecting dopaminergic cells. Supported by MH28942 and GM07151.

ASSESSMENT OF THE NEUROTOXICITY OF A HALOPERIDOL PYRIDINIUM METABOLITE. H. Rollema, B. Subramanyam*, P. De Boer*, J. d'Engelbronner* and N. Castagnoli Jr*.
Dept. Medicinal Chemistry, University Groningen, 9713 AW The Netherlands and Dept. Chemistry, Virginia Tech, Blacksburg, VA 24061 USA.

The neurotoxic profile of the pyridinium metabolite derived from haloperidol, HALP+ (Subramanyam et al., BBRC, 166:238, 1990; Chem.Res.Toxicol., 4:123, 1991), was further characterized by intracerebral microdialysis studies of dopamine, serotonin and acetylcholine in rats. The extent of irreversible nerve damage was established by a standard MPP+ challenge perfusion one day after the intrastriatal infusion with HALP+. The almost similar toxic effects of HALP+ on serotonin (cortex) and acetylcholine (striatum) as on dopamine (striatum) suggest that HALP+ is less selective for dopaminergic neurons than MPP+. In vitro studies showed that HALP+ is a more potent inhibitor of respiration in intact mice liver mitochondria (RCR=12) than MPP+, the IC50 values being 35 uM and 113 uM respectively. Results of immuno-histochemical studies on the effects of unilateral intrastriatal infusions with HALP+, MPP+ and with the non-toxic N-methyl-pyridinium ion, via the dialysis probe, on the TH-ase activity in the ipsi- and contralateral substantia nigra will be presented. Until now our results show that HALP+ is a neurotoxin which may affect dopaminergic, serotonergic and cholinergic systems and that it, like MPP+, can inhibit mitochondrial respiration. Supported by NS23866, NATO-CRG890573 and the Peters Center, Virginia Tech.

ENHANCED MPTP TOXICITY IN THE RAT USING INTRANASAL ADMINISTRATION. C.C. Stahlbaum*[1], A. Giovanni, L. Manzino, R.E. Heikkila, and R.L. Doty*[1]. [1]Smell and Taste Center, Hosp. Univ. of Penn., Philadelphia, PA 19104 and Dept. of Neurology, UMDNJ-RWJ Medical School, Piscataway, NJ 08854.

Systemic administration of the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) induces a lesion of the dopaminergic nigrostriatal pathway in several species, including man, monkeys, mice and rats. Of these species, the rat is least suspectable to these neurotoxic effects, being relatively unaffected by a dose of MPTP which would produce an 80-90% loss of dopamine in the neostriata of mice. The present experiments compared the effects of MPTP administered intranasally or subcutaneously to rats. The acute behavioral effects associated with MPTP dosing appeared more quickly and at a lower dose under the intranasal condition. Additionally, the intranasal administration of MPTP results in an enhancement of dopaminergic neurotoxicity. For example, lower doses of MPTP can be used to produce similar decrements in striatal dopamine content. These data indicate intranasal administration of MPTP is a more effective means of inducing lesions of the dopaminergic nigrostriatal pathway than subcutaneous administration.

504.6

CHRONIC PARAQUAT ADMINISTRATION DECREASES DOPAMINE TURNOVER IN THE MOUSE STRIATUM R.J. Zavodny* K.A. Young and P.B. Hicks. Department of Psychiatry, Scott & White Hospital/Foundation; Departments of Medical Pharmacology and Medical Anatomy and Neurobiology, Texas A&M College of Medicine, Temple, TX, 76508.

The close structural resemblance of the herbicide paraquat to the neurotoxin MPTP prompted us to investigate the putative neurotoxicity of paraquat. We exposed mature pigmented mice (8 mo.-old C57BL) to paraquat injections for 5 and 28 days to determine effects on striatal monoamine pathways. After a 5-day exposure to various doses of analytical grade paraquat (0.05-10 mg/kg SC), DA turnover (DOPAC+HVA/DA) in the striatum was decreased dose-dependently. The highest dose decreased DA turnover by 46% (ANOVA $p<.01$), although at that dose animals also displayed weight loss and respiratory distress. Mice injected SC with 1 mg/kg paraquat for 28 days maintained normal weight and displayed normal spontaneous locomotor behavior after 28 days treatment. There were no histological signs of toxicity to the lungs, liver or kidney. DA, norepinephrine, serotonin (5-HT) levels and DA D2 receptor density in the striatum were not significantly affected by paraquat treatment. Levels of the DA metabolites DOPAC and HVA, however, were significantly ($p<.05$) decreased by 26% and 12%, respectively, in the striatum of the paraquat-treated group, and DA turnover was significantly ($p<.05$) decreased by 18%. The turnover of serotonin was significantly ($p<.05$) decreased by 9%. Chronic treatment with 1 mg/kg commercial grade paraquat product (Ortho) produced very similar effects on striatal neurotransmitters. Paraquat binds with high affinity to melanin which is found in high concentration in nigrostriatal DA neurons, a factor that may contribute to the development of changes in neurotransmitter function in these neurons. Thus, compared to earlier studies which found no effect of paraquat treatment on monoamine function in the striatum of younger mice, our findings suggest that age and length of exposure may be factors in the development of paraquat effects on brain monoaminergic pathways.

504.7

CALBINDIN-D_{28k} IS LOCATED IN THE MIDBRAIN DOPAMINERGIC NEURONS WHICH ARE RESISTANT TO MPTP-INDUCED DEGENERATION. K.F. Manaye, P. K. Sonsalla, B.A. Brooks, and D.C. German. Dept. of Psychiat., UT Southwestern Med. Cntr., Dallas, TX.; Dept. of Neurol., UMDNJ-Robert Wood Johnson School of Med., Piscataway, N.J.; Dept. of Physiol., UT Health Sci. Cntr. San Antonio, TX.

The calcium-binding protein calbindin-D_{28k} (CaBP) is localized within the same population of midbrain dopaminergic (DA) neurons that is spared by Parkinson's disease (German et al., Neurosci. Abstr. 16:696, 1990). The present experiment sought to determine whether CaBP-containing cells are spared in MPTP-treated Macaca fascicularis monkeys (4-32 mg/kg, i.v.), and C57BL/6 mice (4 X 20 mg/kg, i.p.). Sections through the midbrain were stained with antibodies against tyrosine hydroxylase and CaBP, forebrain dopamine was measured, and computer imaging techniques were used to map the cell locations. In both species, regions containing many CaBP cells exhibited minimal DA cell loss, and regions containing few CaBP cells exhibited extensive DA cell loss (>75%). These data support the hypothesis that CaBP protects midbrain DA cells from MPTP-induced degeneration. Supported by American Parkinson Disease Association, and AG-08013.

EFFECTS OF GANGLIOSIDE GD1a ON MPTP NEUROTOXICITY IN MICE. M. Gupta, X.L. Chen and F.J. Roisen. Dept. of Anatomical Sciences & Neurobiology, Univ. of Louisville Sch. Med., Louisville, KY 40292.

Previous studies from this laboratory have shown that intraventricular injections of a ganglioside mixture (BBG) prior to MPTP treatment reduces MPTP toxicity on tyrosine hydroxylase (TH)-positive neurons in the susbtantia nigra (SN). The present studies were undertaken to investigate if individual gangliosides (that were present in the BBG mixture), when injected prior to MPTP treatment, would have a similar effect on the dopaminergic neurons of the SN. Young adult male C57BL/6 mice were anesthetized and injected with ganglioside GD1a (that comprised 43% of the ganglioside mixture, 2µl in each lateral ventricle, conc. 200mg/ml in 0.1M PO4). Control animals received a similar volume of the vehicle injections. 17-20 hrs later, one half of the control and GD1a-treated mice received multiple injections of MPTP (total dose 90mg/kg) and were sacrificed three days later under anesthezia. Brains were processed for TH immunocytochemistry and the number of TH-positive neurons were quantitated in the SN. The results show that GD1a alone does not alter the number of TH-immunoreactive neurons in the SN. However, when given prior to MPTP treatment, it reduces MPTP-induced loss of dopaminergic neurons in the SN. These data suggest that GD1a alone might play a role in preventing neuronal degeneration. Supported by USPHS grant NS24291 and the Parkinson's Disease Foundation.

504.9

Species-specific action of gangliosides on MPTP toxicity in vitro. F.J. Roisen, J. Sosnowski, G. Yorke and M. Gupta. Dept. of Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, KY 40292.

Previously, we have shown that MPTP has a dose-dependent effect on the survival of PC12 cells and that pretreatment of these cells with a mixture of bovine brain gangliosides (BBG) can partially prevent MPTP toxicity. In these studies we examined the efficacy of individual gangliosides in the mixture to reduce MPTP cytotoxicity. PC12 cells were maintained in RPMI 1640 medium supplemented with 10% horse serum and 5% fetal bovine serum in the presence of Nerve Growth Factor (NGF, 40 ng/ml) and the test agents for 6 hr prior to incorporation of MPTP into the medium. Alternatively, the cells were maintained in the medium supplemented with NGF and GM1 or GM3 (not present in BBG) for 4 days prior to MPTP exposure and continued for 4 days. Cytotoxicity was examined morphologically on the basis of neurite development, confluency and an index of dying cells. In the undifferentiated model, GM1 increased MPTP cytotoxicity. In contrast, GM3 surprisingly reduced MPTP-mediated degeneration. Furthermore, in the presence of NGF and MPTP, GM3 (but not GM1) had a significant effect in preventing MPTP toxicity. Similar results were obtained with differentiated cultures. The neuritogenic potential of GM3 and the action of released ganglioside oligosaccharides is being assessed. GM3 was more effective in potentiating NGF-mediated neuritogenesis than GM1. These studies demonstrate an apparent species-related effect of gangliosides in promoting neuritogenic activity and in preventing MPTP cytotoxicity on PC12 cells. Supported by NIH NS24524 and the Parkinson's Disease Foundation.

EFFECTS OF AN MPTP ANALOG ON DIFFERENT COMPARTMENTS OF THE SUBSTANTIA NIGRA. X.L. Chen and M.Gupta. Dept. of Anatomical Sciences & Neurobiology, Univ. of Louisville Sch. Med., Louisville, KY 40292.

It has been shown that the caudal (lateral) portions of the substantia nigra (SN) is more severly afffected than the rostral (and medial) SN in idiopathic Parkinson's disease, resulting in an uneven dopamine loss in the striatum. We have recently shown that MPTP analog, 2'-CH_3-MPTP, produces a significant decrease in the number of tyrosine hydroxylase (TH)-positive neurons in the SN. The present studies were undertaken to investigate if there is compartmental (medial to lateral) effect of 2'-CH_3-MPTP on TH-positive neurons in the SN and gliosis in the striatum. Young adult male C57BL/6 were treated with 2'-CH_3-MPTP (total dose 45-60mg/kg, i.p.) over a two day period, anesthetized and perfused with the fixative three days after MPTP and adjacent 40µm thick serial sections through the brain were immunostained for TH and Glial Acidic Fibrillary Protein (GFAP). The SN was divided into a medial and lateral compartment and the number of TH-positive neurons were quantitated. The number of GFAP-positive astrocytes were quantitated in medial, lateral, dorsal and ventral compartments of the striatum. The results show that 2'-CH_3-MPTP produces a dose-dependent decrease of TH-positive neurons in both the compartments of SN and and an increase in GFAP-immunoreactive astrocytes in the striatum. The following will be discussed: Is the reduction in TH-positive neurons more significant in any one of the compartments of SN; Is there a compartmental effect on gliosis in the striatum. Supported by USPHS grant NS24291 to MG.

CATECHOLAMINES INHIBIT MITOCHONDRIAL COMPLEX I ACTIVITY IN RAT BRAIN. **V. Jackson-Lewis, A. Naini, S. Przedborski, S. Simonetti*, S. Fahn & J.L. Cadet. Columbia University, Dept. of Neurology, New York, N.Y. 10032**

Complex I of the electron transport chain is one of the two main sites of superoxide radical formation in the mitochondria (Feher, 1985). 1-Methyl-4-phenylpyridinium (MPP^+) which is toxic to the dopamine (DA) system blocks the rotenone-sensitive site of Complex I in mammalian mitochondria. Recently, it was reported that the substantia nigra of Parkinson's Disease (PD) patients has abnormalities of Complex I. These changes might be related to the production of either endogenous or exogenous toxins. We, thus, assessed possible inhibitory effects of other DA-related compounds on mitochondrial rotenone-sensitive Complex I activity in rat brain. Mitochondria were prepared according to the methods of Clark and Nicklas (1970) and preincubated with various concentrations (0.1-10uM) of dopamine (DA), 6-hydroxydopamine (6-OHDA), norepinephrine (NE) and 6-hydroxydopa (6-OHDOPA). All four compounds caused significant inhibition of Complex I activity except for the lowest concentrations of DA and 6-OHDA. Inhibition occurred in the following order: 6-OHDOPA> NE> 6-OHDA> DA. The DA receptor antagonist, fluphenazine (FLU), also blocked the activity of Complex I. Since these compounds generate oxygen-based radicals during their metabolism, it is possible that these oxygen-based radicals are toxic to some component of the Complex I. These preliminary results also suggest that the reported abnormalities in Complex I activity in the substantia nigra of PD might be related to inhibition by endogenous dopamine.

PUTATIVE VESICULAR LOCATION OF ^{3}H-MPP^+ BINDING SITES IN MOUSE STRIATUM. M.Del Zompo, M.P.Piccardi*, S.Ruiu*, A.Vaccari*, G.U.Corsini**. Dept. Neuroscience, Univ. Cagliari, I-09124 Cagliari, and *Inst.Pharmacology, Med.School, Univ. of Pisa, I-56100 Pisa, ITALY

MPP^+ is actively transported into dopaminergic neurons by the catecholamine uptake system, where its accumulation seems required for MPTP neurotoxicity. The site of long-term MPP^+ storage in brain of sensitive species is unknown. A specific binding was obtained in brain with an apparent KD of 20 ± 2 nM and a Bmax of 1800 ± 197 fmol/mg protein. Almost all density of binding sites was found in the synaptosomal fraction. The regional distribution showed the highest density of binding sites in the striatum. The binding of ^{3}H-MPP^+ (0.12-4 nM) to mouse striatal membranes was saturable, specific and of high affinity (KD 1.4 ± 0.4 nM; Bmax 168 ± 15 fmol/mg of protein). Dopamine, tyramine and d-amphetamine were found to potently compete with ^{3}H-MPP^+ for its sites. (-)-Norepinephrine, reserpine and tetrabenazine were slightly weaker, though potent, displacers. 6-OHDA lesion significantly reduced (60-70%) the number of ^{3}H-MPP^+ sites. Our data are consistent with a vesicular location of high affinity MPP^+ binding sites in dopaminergic nigrostriatal terminals. Any possible involvement of this site on MPP^+ neurotoxicity deserves further investigation.

NEUROTOXICITY: BIOGENIC AMINES

505.1

ORAL ADMINISTRATION OF MDMA PRODUCES SELECTIVE SEROTONERGIC NEUROTOXICITY IN THE NONHUMAN PRIMATE. S.F. Ali, G.D. Newport*, A.C. Scallet, Z. Binienda*, S.A. Ferguson*, J.R. Bailey*, M.G. Paule and W. Slikker, Jr*. Div. of Reprod. and Developmental Toxicology, National Center for Toxicological Research, Jefferson, AR 72079.

MDMA (3,4-methylenedioxymethamphetamine) is a recreational drug known as "Ecstasy" and also has been used as an adjunct to psychotherapy. Several reports indicated that MDMA produces serotonergic neurotoxicity in primates at doses as low as 2.5 mg/kg (1-2 times the human dose). This study was designed to evaluate whether this and a lower dose of MDMA causes any selective serotonergic neurochemical alterations in primates. Adult female rhesus monkeys (n=4/group) were dosed orally with 0, 1.25, 2.5 or 20 mg/kg MDMA twice daily for 4 days. One month after the last dose, animals were sacrificed and brains were dissected into several regions for neurochemical analysis. Biogenic amines and their metabolites were analyzed by HPLC/EC. MDMA produced no statistically significant (ANOVA) alterations in 5-HT or 5-HIAA concentrations in different brain regions after 1.25 or 2.5 mg/kg, although hippocampal 5-HT concentrations were only 68% of controls after 2.5 mg/kg. At 20 mg/kg, however, MDMA produced significant and marked decreases in 5-HT and 5-HIAA concentrations in several cortical and midbrain structures. Concentrations of 5-HT and 5-HIAA were, however, not changed significantly in brain stem. When combined with earlier data, these results indicate a selective dose-response relationship for MDMA-induced neurotoxicity in the nonhuman primate.

505.2

THE INTERACTION OF AMBIENT TEMPERATURE WITH REPEATED METHAMPHETAMINE (METH) EXPOSURE: EFFECTS ON REGIONAL BRAIN MONOAMINE LEVELS IN THE RAT. R.R. Holson, S.F. Ali, G.D. Newport*, W. Slikker, Jr.* and J.F. Bowyer. Division of Reproductive and Developmental Toxicology, National Center for Toxicological Research, Jefferson, AR 72079.

Adult male rats were exposed to four ip METH or saline injections at 2-hr intervals. Some animals were kept at room temperature (23°C), others were placed in a cold room (4°C) during the 8 hrs of METH exposure. Animals were killed 1 day, 3 days or 2 weeks after exposure. Monoamine levels in caudate nucleus (CN), olfactory tubercle (OT) and hippocampus (HC) were measured by HPLC-EC. The effect of 5.0 mg/kg METH 4X at room temperature was similar in all three brain regions. Levels of dopamine (DA) and serotonin (5HT) were depressed at 3 days and showed substantial or full recovery by 2 weeks. Major metabolites of 5HT and DA responded similarly. DA and 5HT depletion was least in OT. DA depletion was greatest in CN, and 5HT depletion was greatest in HC. Cold exposure protected completely against these METH effects at 5.0 or 7.5 mg/kg, but only partially at 10 mg/kg METH levels. There was no effect of cold exposure per se on DA or 5HT levels in any brain region, and again this pattern was seen across regions for both 5HT and DA. It is concluded that cold can protect completely against METH toxicity at moderate but not high doses, that METH is equally toxic for 5HT and DA, and that METH toxicity does not appear to depend upon regional DA or 5HT concentrations.

505.3

METHAMPHETAMINE-INDUCED DEPLETION OF STRIATAL DOPAMINE: IMPACT OF INDOMETHACIN. T.G. Hastings and M.J. Zigmond
Dept. Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260

The mechanism whereby methamphetamine causes the long-term depletion of striatal dopamine (DA) is unknown. However, there are parallels between methamphetamine- and ischemia-induced DA depletions. For example, both insults are accompanied by a large increase in extracellular DA, and the loss of tissue DA can be prevented by prior inhibition of DA synthesis. Thus, we hypothesized that other parallels might also exist and provide insights as to a shared mechanism for the neurotoxic events. Ischemic insult is known to increase free arachidonic acid as well as other fatty acids in whole brain and in striatum. This is accompanied by an elevation in arachidonic acid metabolites, such as prostaglandins and lipoxygenase products, and some of these products may contribute to the neurotoxic process. This proposal is supported by the observation that inhibition of arachidonic acid metabolism attenuates ischemic brain damage. To examine the role of arachidonic acid metabolism in methamphetamine-induced DA depletion, we examined the impact of pretreatment with an inhibitor of the cyclooxygenase component of prostaglandin synthase, indomethacin. Methamphetamine (3.25 - 25.0 mg/kg, s.c) was administered to male Sprague-Dawley rats (290-330 g) every 2 h for a total of 4 injections. When striatal tissue was analyzed by HPLC for DA content 7 days later, methamphetamine had caused a dose-dependent decrease in DA levels with a maximal effect observed at 12.5 mg/kg. When the drug effect was examined over time, DA depletion was maximal by 3 days and constant for at least 14 days. Indomethacin (5 mg/kg, s.c.) was then given 1 h before and 4 h after methamphetamine (4 x 12.5 mg/kg) and DA levels were measured 1 week later. Methamphetamine alone caused a 57% depletion of DA (saline, 157.3 ± 4.6 ng/mg protein; methamphetamine, 66.8 ± 18.6 ng/mg protein). This effect was not attenuated by indomethacin (methamphetamine + indomethacin, 38.4 ± 13.6 ng/mg protein). Thus, our initial results do not support the hypothesis that methamphetamine acts to deplete striatal DA via the cyclooxygenase component of arachidonic acid metabolism.

505.4

CALCIUM CHANNEL BLOCKERS ATTENUATE SEROTONIN NEUROTOXICITY INDUCED BY (±) 3,4-METHYLENEDIOXY-METHAMPHETAMINE (MDMA). M. Martello, A. Martello and G. Ricaurte. Department of Neurology, Francis Scott Key Med. Ctr., Johns Hopkins School of Medicine, Baltimore, MD 21224.

The finding that the N-methyl-D-aspartate (NMDA) receptor blocker, dextrorphan, prevents the serotonin (5-HT)-depleting effects of (±)3,4-methylenedioxymethamphetamine (MDMA) in rats (Finnegan et al., Neurosci. Lett. 105:300-306) has implicated excitatory amino acids (EAAs) in the neurotoxic action of MDMA. EAAs have been postulated to mediate neuronal injury by triggering excessive influx of calcium (Ca^{++}) into cells. The purpose of the present study was to test the hypothesis that Ca^{++} is involved in the neurotoxic action of MDMA. Rats were treated with MDMA alone and in combination with various doses of Ca^{++} channel blocking agents (flunarizine, nimodipine, verapamil). All of the Ca^{++} channel blockers examined afforded either partial or complete protection, depending on the dose of the blocker used and the regimen of MDMA employed. As none of the Ca^{++} channel blockers interfered with synaptosomal 5-HT uptake, it is unlikely that their neuroprotective effect is related to an interaction with the 5-HT transporter. These results suggest that Ca^{++} is involved in the neurotoxic action of MDMA. Further, they lend support to the view that the neurotoxicity of MDMA and related drugs may be mediated by endogenous EAAs.

PERSISTENT NEUROTOXIC EFFECTS OF METHAMPHETAMINE ON DEVELOPING DOPAMINE (DA) AND SEROTONIN (5-HT) NEURONS IN REAGGREGATE TISSUE CULTURE. L. Won, P.C. Hoffmann and A. Heller. Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637.

Methamphetamine (Meth) produces long-term reductions in brain DA and 5-HT levels in adult animals (Ricaurte et al., Brain Res. 193: 153-163, 1980). In order to study whether there is a similar persistence of Meth's effect on developing neurons, we have used reaggregate tissue cultures containing neurons of mesencephalic tegmentum and corpus striatum from embryonic mice. Reaggregates were exposed for an acute (4 hrs of treatment on day 22 of culture) or chronic period (7 days of treatment, between 15-22 days of culture) to 10^{-4} M Meth and then allowed to recover (7 days for acute; 20 days for chronic exposure) in drug-free media. During the recovery period, samples of drug-treated, as well as control reaggregates were collected for analysis of monoamine levels. At the end of the acute or chronic drug treatment period, DA and 5-HT levels in Meth exposed reaggregates were markedly depressed (DA and 5-HT levels were 39% and 64% of control, respectively, for the acute treatment; 28% and 15% of control for the chronic exposure). During the recovery period, DA and 5-HT levels increased in both acute and chronically-treated reaggregates, as well as in control cultures. Despite increases in the treated groups, neither DA or 5-HT attained the levels observed in control reaggregates by the end of the recovery period. As with adult neurons, it is clear that the effects of Meth on developing neurons are marked and persistent. Supported by MH42134 and NIDA#271-90-7404.

505.6

PRESYNAPTIC GLUTAMATE(GLU)-EVOKED DOPAMINE (DA) RELEASE IS TRANSIENTLY INHIBITED BY METHAMPHETAMINE (METH) PRETREATMENT. J.F. Bowyer[1], A.W. Tank[2], G.D. Newport*[1], S.F. Ali[1], W. Slikker Jr*.[1], and R.R. Holson[1] [1]Div. of Reprod. & Dev. Tox., Natl. Ctr. for Tox. Res., Jefferson, AR 72079 and [2]Dept. of Pharmacol., Univ. of Rochester Med. Ctr., Rochester, NY 14642.

Exposure to toxic doses of METH is often associated with decreased striatal levels of tyrosine hydroxylase and DA. These experiments were designed to determine post METH changes in the presynaptic regulation of DA release and uptake using superfused striatal slices from adult male rats. DA levels in the striatum contralateral to that used for *in vitro* release were determined to be 88% of saline control 1 day post, 38% of control 3 days post, and 70% of control 14 days post METH (4 doses [1 dose/2 hrs] of 5 mg/kg). There were no changes in either the 15 mM K^+-and 1 μM METH-evoked [^{3}H]DA release or the amount of [^{3}H]DA accumulated in striatal slices of rats pre-treated with METH compared to control at any time point. These results indicate that, although METH decreased striatal DA levels, DA terminals may not have been destroyed. A 30% decrease (relative to saline control) in the 100 μM GLU-evoked [^{3}H]DA release (no Mg^{2+} present) was observed in striatal slices from 1 day post METH but not from 14 day post METH rats. Therefore, a transient down-regulation in GLU/NMDA receptors may occur 1 day or less post METH. Since environmental temperatures of 4°C during METH exposure did not prevent a decrease in GLU-evoked DA release from striatal slices 1 day post METH but significantly blocked striatal DA level decrease 3 days post METH, the relationship between the initial changes in GLU-evoked DA release and METH toxicity is unclear.

505.7

EFFECTS OF AMBIENT TEMPERATURE AND REPEATED INJECTIONS OF METHAMPHETAMINE ON CAUDATE MONOAMINES AS MEASURED BY CEREBRAL MICRODIALYSIS. B. Gough, J. Bowyer, S.F. Ali, W. Slikker, Jr. and R. Holson. Division of Reproductive and Developmental Toxicology, National Center for Toxicological Research, Jefferson, AR 72079.

Female Sprague-Dawley rats were injected four times at 2-hr intervals with vehicle or 5 mg/kg methamphetamine (METH). Some rats were caged individually at room temperature (23°C), others were held individually in a cold room (4°C). Extracellular levels of dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), 5-hydroxy indole-acetic acid (5-HIAA), serotonin (5-HT) and homovanillic acid (HVA) were assayed in the caudate of these freely-moving rats using microdialysis and HPLC-EC. Dialysates were collected at 15 min intervals over the 8-hr course of dosing. METH reduced the classical effect on caudate monoamines. DA and 5-HT release was enhanced, while extracellular levels of their major metabolites (DOPAC and 5-HIAA) were reduced. Cold depressed extracellular levels of DOPAC, 5-HIAA and HVA, with or without METH exposure. The inhibitory effects of METH and cold on these metabolites was additive. This cold-induced depression of caudate monoamine metabolites may be related to the ability of cold to block toxic METH effects on caudate 5-HT and DA content.

505.8

PROTEIN SYNTHESIS INHIBITION BLOCKS THE NEUROTOXIC EFFECTS OF METHAMPHETAMINE IN RATS. KT Finnegan and R Karler. Depts. of Psychiatry and Pharmacology, Univ. of Utah Sch. Med. and the Salt Lake City VAMC, Salt Lake City, UT 84148.

Programmed cell death is a striking feature of normal embryonic growth and development. The CNS is a particularly common site, with an estimated one half of all neurons present during embryogenesis dying before adulthood. The survival of neurons appears to depend upon the continuous secretion of various tropic factors by target tissues. Historically, neurotropic factors have been thought to promote neuronal survivability by acting to sustain critical intracellular metabolic processes. Recently, however, it has been shown that inhibitors of protein synthesis prevent neuronal death induced by tropic factor deprivation. Cell death during embryogenesis thus appears to be an active process, involving the synthesis of new ("killer") proteins. Based on these findings, we examined whether protein synthesis might also be involved in the neuronal damaging effects of methamphetamine (METH) in the mature rodent CNS.

Male CF-1 mice were injected with METH, either alone or in combination with the protein synthesis inhibitors cycloheximide or anisomycin, and then killed one week later. Neostriatal DA, DOPAC, and HVA were assayed by HPLC-EC. METH alone induced a 50-60% depletion of neostriatal DA and its metabolites. Pretreatment with either cycloheximide or anisomycin, however, completely blocked the neurotoxic effects of METH. In other experiments, cycloheximide failed to alter either amphetamine-induced stereotypy or the threshold for convulsions induced by N-methyl-D-aspartate. The latter findings indicate that the neuroprotective effects of cycloheximide are unlikely to be explained by an antagonistic action at either DA or NMDA receptors. The findings suggest that programmed cell death during embryogenesis and METH-induced neuronal cell damage in the mature CNS involve similar biochemical mechanisms.

MK-801 PROTECTS AGAINST STRIATAL DOPAMINE TERMINAL DAMAGE AND REDUCES EXTRACELLULAR DOPAMINE OVERFLOW DURING A NEUROTOXIC REGIMEN OF METHAMPHETAMINE. F.B. Weihmuller, S.J. O'Dell and J.F. Marshall. Dept. of Psychobiology, University of California, Irvine, CA 92717.

Although the NMDA antagonist MK-801 prevents methamphetamine (m-AMPH)-induced damage to striatal dopamine (DA) terminals, the protective mechanism remains unknown. Using microdialysis in awake rats we show that a neurotoxic schedule of m-AMPH injections (4 x 4 mg m-AMPH/kg, sc, every 2 hrs) produced a massive overflow of striatal DA, peaking after the fourth injection. Also, total DA overflow was negatively related (r = -0.74) to remaining DA levels in striatal tissue measured one week later. Several pretreatment schedules with MK-801 (0.5 mg/kg, ip) provide protection against m-AMPH toxicity: 15 min before each m-AMPH treatment, before each of the last two m-AMPH injections, or before the first m-AMPH injection only. Each schedule of MK-801 pretreatment attenuated both the striatal DA overflow and the striatal tissue DA loss as measured one week later. In contrast, a single injection of MK-801 15 min before the fourth m-AMPH treatment produced only a modest decrease in total DA overflow and did not attenuate m-AMPH-induced injury to striatal DA terminals. These findings suggest: 1) that the large increase in striatal DA overflow is correlated with terminal damage and 2) that MK-801 might prevent this damage by reducing the amount of DA released.

505.10

DOPAMINE RECEPTOR ANTAGONISTS ATTENUATE METHAMPHETAMINE-INDUCED STRIATAL DOPAMINE OVERFLOW AND TERMINAL DAMAGE. S.J. O'Dell, F.B. Weihmuller and J.F. Marshall. Dept. of Psychobiology, Univ. of California, Irvine, CA. 92717

Four injections of methamphetamine (m-AMPH, 4 mg/kg, sc, at 2 hr intervals) produce a massive efflux of striatal dopamine (DA), peaking after the fourth injection and result in damage to striatal DA terminals. Moreover, the amount of DA overflow is positively correlated with the degree of subsequent DA depletion. We used microdialysis to examine m-AMPH-induced striatal DA efflux in rats treated concomitantly with the neuroprotective agents SCH 23390 (a D1 receptor antagonist) or eticlopride (a D2 receptor antagonist). Four injections of SCH 23390 or eticlopride alone induced modest increases in striatal DA overflow (reaching a maximum of 2-3 fold of pre-treatment values). However, when given 15 min prior to each m-AMPH treatment, either eticlopride or SCH 23390 reduced total DA overflow when compared to animals treated with m-AMPH alone. Additionally, pretreatment with eticlopride completely protected against m-AMPH-induced dopaminergic damage while SCH 23390 pretreatment afforded substantial, but not total protection. One mechanism by which DA receptor antagonists may attenuate m-AMPH-induced neurotoxicity is by reducing stimulant-induced increases in DA overflow.

505.11

EFFECT OF PARGYLINE PRETREATMENT ON P-CHLORO-AMPHETAMINE (PCA)-INDUCED NEUROTOXICITY TO SEROTONIN NEURONS IN RAT BRAIN ASSESSED USING [3H]CYANOIMIPRAMINE AUTORADIOGRAPHY. Saloua Benmansour* and David J. Brunswick, Dept. of Psychiatry, Univ. of Pa. Sch. of Med. and Dept. Vet. Affairs Med. Ctr., Phila., PA 19104.

A number of drugs with an amphetamine-like structure can produce long-term neurotoxic effects on serotonergic neurons in brain. It has been suggested that the weak monoamine oxidase (MAO) inhibitory properties of these amphetamines contribute to their neurotoxic effects. If so, then more complete inhibition of MAO might potentiate their neurotoxicity. In the present study, the effect of pretreatment of rats with the MAO inhibitor pargyline on pCA-induced neurotoxicity was examined by quantitative autoradiography using [3H]cyanoimipramine. This radioligand binds with high affinity and specificity to serotonin uptake sites. There were three groups of rats (n=6/group): 1) saline four hours prior to PCA (4mg/kg, s.c.); 2) pargyline (50mg/kg, s.c.) four hours prior to PCA; 3) saline four hours prior to saline. Rats were killed 7 days after drug administration. PCA treatment alone caused significant reductions (30-70%) in [3H]cyanoimipramine binding in all terminal fields receiving serotonergic innervation but not in cell body areas (dorsal and median raphe nuclei). Pargyline pretreatment significantly potentiated the neurotoxic effect of pCA in nine of the terminal field areas and produced a trend for greater toxicity than that seen with PCA alone in the other terminal areas. These results show that increasing the inhibition of MAO potentiates the neurotoxicity of pCA. (Research funds from the Dept. of Vet. Affairs & USPHS grant DA 05317).

DOPAMINERGIC NEUROTOXICITY IN RAT STRIATUM? F. Filloux and J.J. Townsend. Depts. Neurol., Pediatr., Psychiat. and Pathol., Univ. Utah Sch. Med., Salt Lake City, UT 84132.

Considerable evidence indicates that dopamine (DA) may play a neurotoxic role in brain under certain pathologic circumstances. To investigate this issue, a high concentration of DA (1000 nmoles/μl) was injected into the striatum of anesthetized 200 gm Sprague-Dawley rats. Control animals received injections of GABA or NaCl at identical concentrations (diluted in dH_2O, pH 7.0-7.7, as reported by others: Olney & Gubareff, Nature 271:557, 1978). Brains were removed 9 days later, frozen and sectioned (10μm) for histologic and autoradiographic analysis. DA injection resulted in a small volume (~3mm^3) lesion in comparison to control GABA and NaCl injections which produced only a needle track of < 0.6 mm^3 in volume ($p < 0.01$). Within the DA lesion, marked neuronal loss, macrophage invasion and glial proliferation was present. Acetylcholinesterase staining and D1 receptor binding were markedly reduced as well. [^{3}H] R05-4864 binding (to peripheral benzodiazepine receptors on astrocytes) was increased. The findings support the contention that dopamine may act as a low potency neurotoxin.

505.13

INDUCTION OF c-*fos* mRNA BY STIMULATION OF D_1-DOPAMINE RECEPTORS IN NS20Y NEUROBLASTOMA CELLS: EFFECTS OF MANGANESE CHLORIDE. S. Peña*, D.J. Minnema*, and G.P. Cooper. Dept. Environ. Hlth., University of Cincinnati, Cincinnati, OH 45267-0056.

D_1-dopamine receptors are coupled to stimulatory G-proteins that activate adenylate cyclase. Recently, it has been shown that selective D_1 dopamine agonists can induce the expression of c-*fos* mRNA in the rat striatum. However, the dose-dependency and time-course of this induction have not been characterized. For this purpose we are using NS20Y neuroblastoma cells, which express D_1 receptors. Cells were synchronized by serum depravation for 72 hours prior to treatments and were exposed to dopamine and/or manganese for 30 minutes. The effect of dopamine on c-*fos* mRNA expression is dose-dependent and ranges from 1 nM to 100 μM. The dopamine concentration giving maximal induction is ~1 μM. This effect on c-*fos* mRNA expression is specific, as shown by its inhibition by the selective D_1 antagonist SCH 23390. Induction of c-*fos* mRNA by manganese occurs at a concentration of 30 μM. Ongoing experiments involve determination of the effects of manganese on the dopamine dose-effect curve and time-course of induction. The effects of lead (Pb^{2+}) on c-*fos* expression are also being investigated.

505.14

DEVELOPMENTAL ONSET OF SEROTONIN ALTERATIONS IN THE CHRONICALLY HYPERAMMONEMIC SPARSE FUR MOUSE. S. Djali, B.A. McLaughlin, M.L. Batshaw and M.B. Robinson. Children's Seashore House; Depts. Ped. and Pharm., Univ. of PA; Philadelphia, PA, 19104.

Due to an X-linked genetic deficiency, the congenitally hyperammonemic sparse fur mouse (*spf*/Y), has only 5-20% of normal ornithine carbamoyltransferase activity. In the cortex of adult *spf*/Y mice, we previously demonstrated two-fold increases in the levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA). The purpose of this study was to evaluate the development of serotonin alterations in the *spf*/Y mouse. Brain glutamine (Gln) levels were used as an index of hyperammonemia. Cortical levels of tryptophan, serotonin, 5-HIAA, norepinephrine, homovanillic acid, γ-aminobutryric acid, glutamate, and glutamine were measured in one- and three-week old *spf*/Y mice and littermate controls (B6). In one-week-old *spf*/Y mice, there were no alterations in 5-HIAA levels (*spf*/Y, 1.97 ± 0.97; B6, 2.26 ± 0.60 pmol/mg, $p > 0.5$, mean ± SD, n=6), or Gln levels (*spf*/Y, 9.80 ± 2.35; B6, 8.95± 2.28 nmol/mg, $p > 0.5$). Glutamate levels were significantly decreased (*spf*/Y, 6.53 ± 0.69; B6, 7.53 ± 0.47 nmol/mg, $p < 0.01$). At three weeks of age, Gln levels were increased two-fold (*spf*/Y, 10.4 ± 4.50; B6, 5.35 ± 2.51, $p < 0.04$), and there was a trend towards an increase in 5-HIAA (*spf*/Y, 3.68 ± 0.54; B6, 3.09 ± 0.56 pmol/mg, $p < 0.09$) in preliminary studies. There were no alterations in the other neurotransmitters or their metabolites at either age. The finding that Gln correlates with 5-HIAA in three-week-old animals ($r = 0.758$, $n = 12$, $p < 0.01$) supports the hypothesis that the increase in 5-HIAA found in hyperammonemia may be due to increased brain Gln levels.

505.15

COCAINE INDUCED HYPOXIA *IN UTERO* RESULTS IN A CNS "AT RISK" FOR INJURY: GM1 REDUCES POSTNATAL DYSFUNCTIONS AND INCREASED VULNERABILITY TO CNS DAMAGE.

J MacDonall, A Stadlin*, S Suchday*, H Laev, A Ortiz, N Hernandez, J Bonheur*, SP Mahadik, SE Karpiak. NYS Psychiatric In.., Neuroscience, Dept. Psychiatry,Columbia U (P&S) NY,NY 10032. & Fordham U. Bronx, NY 10458.

Since GM1 (monosialoganglioside) treatment reduces CNS ischemic injury, this study was undertaken to assess if this neuroprotective agent might decrease CNS damage associated with *in utero* hypoxia that results from the vasoconstrictive effects of cocaine exposure. Pregnant rats (Wistar) were orally dosed (prenatal days 7-20) with cocaine hydrochloride (60mg/kg) and either GM1 (10mg/kg sub.cu.) or saline. Pups born from cocaine exposed dames [CEDs] had reduced ultrasonic vocalization rates & nipple attachment latencies, and increased activity levels. Pups born from GM1 treated CEDs did not show these dysfunctions, and were not different from vehicle controls. Primary neuronal cell cultures (cortical neurons harvested at pre-natal day 15 from CED fetuses) had reduced thresholds to glutamate toxicity as evidenced by associated increases in urea & Ca^{++} uptake. This increased vulnerability to injury was not seen in cells from GM1 treated CED fetuses. This increased vulnerability to CNS damage was also evidenced when cortical focal ischemia was induced in mature rats. In rats born of CEDs there were higher levels of edema found in primary & peri-ischemic cortices. These increased levels of injury were reduced in rats born from CEDs treated with GM1.

GM1's neuroprotective effects can occur *in utero* as evidenced by the reduced postnatal dysfunctions. We hypothesize that cocaine abuse during pregnancy may result in a CNS cell population whose injury threshold is markedly lower, resulting in a mature CNS that is "at risk" to injury (e.g. trauma, fever, neurotoxins etc.) for its entire life-span.

This work was supported in part by a grant from the FIDIA Research Foundation and a BRSG grant.

SYMPOSIUM. THE CANNABINOID RECEPTOR: BIOCHEMISTRY, ANATOMY AND PHYSIOLOGY. A.C. Howlett, Saint Louis Univ. (Chairperson); M. Herkenham, NIMH; S. Ward, Sterling Research Group; L. Matsuda*, NIMH; S. Deadwyler, Bowman Gray Med. Sch.

The cannabinoid receptor transduces the response to Δ^9-tetrahydrocannabinol (THC), the primary active constituent in marihuana extracts. This receptor couples to G_i to inhibit adenylate cyclase. The *in vitro* structure-activity profiles for a series of synthetic cannabinoid analogs parallel a number of biological responses in humans and animals. Novel aminoalkylindole analgesics also bind to this receptor and elicit cannabinoid biological activities. Certain compounds from this series behave as antagonists *in vitro*. Autoradiographic localization studies reveal a unique cytoarchitectural distribution of cannabinoid receptors which is similar across all species examined including human. Receptors are concentrated in motor systems (basal ganglia, cerebellum) and cerebral cortex (notably the hippocampus), and are sparse in the brainstem and spinal cord. Cannabinoid receptor mRNA is prominent in the hippocampus and other CNS structures. Physiological and behavioral effects of cannabimimetic drugs are being assessed in freely moving animals, particularly with respect to impairments in cognitive processing. In addition, analyses of cannabinoid actions on single cells in culture are being studied with regard to whole cell conductances and the nature of receptor-channel interactions.

SYMPOSIUM. SPECIFICATION OF CEREBRAL CORTEX DURING DEVELOPMENT. M. Sur, M.I.T. (Chairperson); P. Rakic, Yale Univ. Sch. of Med. (Chairperson); S.K. McConnell, Stanford Univ.; J. Bolz, Friedrich-Meischer Lab., Tubingen; R. Linsker, I.B.M. T.J.Watson Res. Ctr.

The development of an area of the cerebral cortex involves the specification of several features that characterize the area, including the location and composition of its cells (cytoarchitecture), its external connections (inputs and outputs), its internal connections (microcircuitry), and its molecular make-up (chemoarchitecture). This symposium will review recent results on the extent to which these features are regulated by intrinsic developmental programs and by extrinsic factors such as input activity. P. Rakic will describe the radial unit hypothesis for generation of cortical laminae, the role of thalamic afferents in specifying cortical areas, and the matching of retinal, subcortical and cortical "protomaps" during development. S. McConnell will describe the processes by which the cortex generates neurons and parcels them into different laminae and different areas, in the context of layer-specific and area-specific long-distance connections. J. Bolz will show that highly specific afferent and efferent cortical connections can form in vitro, in slice cultures of thalamus and cortex; these results indicate that the cortex guides its innervation by thalamic afferents by regulating molecules that facilitate proper target selection. M. Sur will describe how a visual field map and neurons with receptive field properties similar to primary visual cortex arise in auditory cortex in ferrets that have retinal input diverted into their auditory pathway, indicating that cortical microcircuitry is both intrinsically specified as well as regulated by input activity. R. Linsker will describe theoretical studies of the self-organization of cortical microcircuitry, and present modeling results to demonstrate how cortical mechanisms may generate ordered maps and receptive fields whose properties depend upon an area's external connections, its internal structure, and correlated input activity during development.

POTASSIUM CHANNELS: MOLECULAR BIOLOGY II

510.1

TEMPORAL AND SPATIAL DISTRIBUTION OF RAT BRAIN K^+ CHANNELS.

S.Verma and R.H.Joho[1]. Division of Neuroscience and [1]Dept. of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX 77030.

Recently a number of related mammalian K^+ channel cDNA clones have been isolated. The biological significance of this diversity is not understood. To examine this, we looked at the distribution of K^+ channels in various neonatal and adult tissues and throughout the rat brain by *in situ* hybridization. The following cDNA isolates, each representing a subfamily, were used in this study : DRK1, R-NGK2, RCK2, K13, and IK8. We found brain specific expression of RCK2 and R-NGK2; in contrast the other clones were also present in non-neuronal tissues. *In situ* hybridization with adult rat brain showed distinct but overlapping distribution patterns for each of the isolates examined. All channels were present in some of the cortical layers. DRK1, RCK2, and K13 were all expressed in the hippocampal cell layers, whereas R-NGK2 and IK8 were expressed at very low levels. Interestingly, in contrast to others, R-NGK2 has non-homogenous expression in the cortical and hippocampal cell layers. Only K13 and R-NGK2 were present in the pons and medulla. All channels except IK8 were expressed in the cerebellum. In particular R-NGK2 was very high in the Purkinje and granular layers and RCK2 was present only in the Purkinje layer.

Since R-NGK2 expression is mainly in the adult cerebellum (the level of expression is five times less in the rest of the brain), we decided to look at the time course of appearance of R-NGK2 during development. We have found that its expression starts at postnatal day 11 in the cerebellum and continues up to and past day 20.

510.2

GLIAL- AND NEURONAL- SPECIFIC K+ CHANNEL GENE EXPRESSION IN THE CNS OF THE MOUSE.

L. A. Adams*, K. M. Houamed, and B. L. Tempel. Departments of Medicine and Pharmacology, Univ. of WA, 98195; and GRECC, Seattle Veterans Affairs Medical Center, Seattle, WA 98108.

Voltage-gated potassium (K^+) channels are important modulators of membrane excitability in neurons and other electrically polarized cells. We have examined the cellular distribution of two different K^+ channel genes in the central nervous system (CNS) of the mouse. These genes, designated MK1 and MK2, each direct the expression, in injected Xenopus oocytes, of delayed rectifier channels with slightly different kinetic properties. Their respective patterns of CNS expression were analyzed using the technique of in situ hybridization, in which oligonucleotide probes directed against two different nonconserved regions of each gene were 3' end-labelled with ^{35}S-ATP and applied to 20 micron frontal sections of normal adult male mouse brains, using standardized protocols. We find that MK1 and MK2 have markedly different patterns of expression. MK1 is expressed in particular subsets of neuronal cell bodies, notably in regions of the brain which are known to produce high frequency actions potentials, i.e. the auditory pathway, vestibular pathway, and motor pathways, and the hippocampus. In contrast, MK2 is expressed in the major fiber tracts of the brain, and thus appears to represent a glial cell-specific K^+ channel gene.

510.3

MOLECULAR MECHANISMS OF IONIC SELECTIVITY IDENTIFIED BY SITE-DIRECTED MUTAGENESIS IN THE ShB K^+ CHANNEL. *Andrea Yool, Ross Vickery*, Robert Burgess* and Thomas Schwarz.* Molecular & Cellular Physiology, Stanford University, Stanford CA 94305-5426.

To identify the region of the K^+ channel that influences ionic selectivity, we used site-directed mutagenesis to change single amino acids in the ShB K^+ channel from *Drosophila*. Our data support the hypothesis that the H5 region (asp431 to thr449) lines the pore of the channel. A plausible model places H5 as a β-barrel in the center of a tetrameric complex of Shaker-encoded proteins. Properties of the mutant and wildtype channels, expressed in *Xenopus* oocytes, were assayed by single channel and macropatch electrophysiology in bi-ionic recording conditions with the test cation present externally, and K^+ internally (the reversal potential of the current-voltage relationship is a direct measurement of permeability of a test ion relative to K^+). In homomultimeric mutant channels, two amino acids (phe433 and thr441) each increased permeability to NH_4^+ when mutated to serine (Yool and Schwarz, 1991, *Nature* 349: 700-704). The increased permeation by NH_4^+ is consistent with the model that H5 lines the conductive pathway; both of these mutations reduce bulkiness, and maintain or increase the polar nature of the side chains. Mutations at residues outside of H5 had little effect on selectivity. Many of the mutations created within H5 produced nulls, yielding no detectable currents when expressed as homomultimers. Preliminary results have demonstrated that some of these nulls can be "rescued" by pairing the mutant subunits with wildtype subunits in tandem constructs that link the two subunits into a single polypeptide. These hybrid channels produce effects on selectivity that are consistent with the H5 hypothesis. The size of the pore in mutant channels can be probed with organic cations such as methyl-substituted ammonium derivatives, hydroxyamine and guanidine. Mutations that increase permeability to NH_4^+ also increase permeability to the larger organic cations. By the systematic mutation of residues within H5, we intend to identify the molecular mechanisms that generate the ionic selectivity of the K^+ channel. *(Supported by NIH 2HQZ-402 to TLS).*

REVERSIONS IN THE PORE OF A CHIMERIC POTASSIUM CHANNEL. J.A. Drewe, G.E. Kirsch, H.A. Hartmann, M. Taglialatela, M. De Biasi, A.M. Brown and R.H. Joho. Dept. Mol. Physiol. & Biophys., Baylor College of Medicine, Houston, TX 77030.

In the chimeric channel DRK-NGK (Hartmann, Science 1991), a stretch of cDNA encoding 21 amino acids was exchanged between the donor channel rat-NGK2 (Drewe, submitted) and the host channel DRK1 (Frech, Nature 1989). The exchange conferred upon the host channel the phenotype of the pore of the donor channel, rat-NGK2. Thus, DRK-NGK had the slope conductance of the donor rat-NGK2 channel which was about three times that of the host DRK1 channel and, DRK-NGK like NGK2, was blocked by the open channel blocker TEA at an external site whereas DRK1 was not blocked with external application but with internal application. It follows that the differences between DRK-NGK and DRK1 must have arisen from the nine amino acid differences exchanged between DRK1 and rat-NGK2. We reverted each of these nine amino acids using site specific mutagenesis and tested the results on conductance and TEA blockade. One reversion, L374V, restored an exaggerated version of the conductance of K^+ and Rb^+ by DRK1 although the TEA blocking profile was unaffected. Two reversions, Q382K and M387K, reduced inward current and blockade by external TEA. Supported by National Institutes of Health Grant Nos. NS08805 to J.A. Drewe, NS28407 to R.H. Joho, and HL39262, HL37044, HL36930 and NS23877 to A.M. Brown.

510.5

A CHIMERIC K^+ CHANNEL MUTANT WITH REDUCED SENSITIVITY TO TETRAPENTYLAMMONIUM BLOCKADE. M. De Biasi, M. Taglialatela, J. A. Drewe, H. A. Hartmann, A. M. Brown and G. E. Kirsch. Department of Molecular Physiology and Biophysics. Baylor College of Medicine, Houston TX 77030

Chimeric K^+ channels (DRK/NGK) formed by replacing the pore region of DRK1 with that of NGK2 were shown previously to have the TEA blocking profile of NGK2; extracellular TEA was much more potent than intracellular TEA. In the present study we tested a hydrophobic TEA derivative, tetrapentylammonium (TPeA) in DRK/NGK and mutant chimeras in which single amino acids in the pore region were restored to the corresponding DRK1 residues. Macroscopic K^+ currents were measured in Xenopus oocytes. External TPeA blocked DRK/NGK in a time- and voltage-dependent manner ($IC_{50} = 88\,\mu M$). Based on its voltage dependence, TPeA is thought to have an intracellular site of action. Consistent with this idea we found that TPeA sensitivity was unchanged in Q382K a mutant with markedly reduced sensitivity to external TEA. In contrast, L374V, a mutant with altered ion selectivity (Drewe, et al. this meeting), was found to be much less sensitive to TPeA (IC50 >5 mM) than DRK/NGK. Even though TPeA is an open channel blocker the observed reduction in sensitivity does not depend on decreased channel open time in L374V, since another mutant, V369I, was found to have decreased open time and high sensitivity to TPeA. Our results suggest that L374 interacts with a TPeA binding site near the intracellular mouth of the pore. This result is consistent with the idea that the pore lining is formed by a membrane-bound loop extending between two proline residues (P361 and P381) and includes L374.

510.6

GATING CURRENTS FROM A CHIMERIC K+ CHANNEL EXPRESSED IN *XENOPUS OOCYTES* [1]M. Taglialatela, [2]G.E. Kirsch, [1]A.M. Brown and [1]E. Stefani*. [1]Dept. Molecular Physiology and Biophysics and [2]Dept. Anesthesiology, Baylor College of Medicine, 1 Baylor Plaza, 77030 Houston, TX.

Structural rearrangements of the voltage sensor of voltage-dependent ion channels under the influence of the electric field generate gating currents. We have studied the gating currents of a chimeric delayed rectifier (DR) K^+ channel, DRK/NGK M3, in which the pore phenotype of the donor NGK2 was exchanged for that of the host DRK1. A single point mutation (L374V) caused a dramatic decrease in the single channel K^+ conductance of the chimeric channel. The experiments were performed with a novel open-oocyte vaseline gap method. Many properties of the DRK/NGK M3 gating currents were similar to those reported for the DR of the squid giant axon. A rising phase was resolved in the ON transient and it had little or no voltage-dependence. The gating currents appeared at more negative potentials than the ionic currents (15 mV shift) and saturated at positive potentials (+40). They showed no sign of charge immobilization during a 50-200 msec depolarizing pulse which did not inactivate the ionic current. The kinetics of the decay of the ON and OFF gating transient had the same time course of activation and deactivation of the ionic current. Hyperpolarizing conditioning pulses delayed the activation of the ON transient. The data are consistent with an early voltage-independent transition between the closed states followed by voltage-dependent transitions between later closed states and a final voltage-independent closed-open transition.

510.7

MUTATIONS IN THE LEUCINE HEPTAD REPEAT OF *SHAKER* 29-4 ALTER THE CHANNEL'S ACTIVATION WITHOUT ALTERING GATING CURRENTS

Nathan E. Schoppa,* Ken McCormack,* Mark A. Tanouye,# and Fred J. Sigworth.* *Dept. of Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, CT 06510, #Dept. of Entomology, University of California, Berkeley, CA 94720.

Mutating either of the first two leucines in the conserved heptad repeat region of *Shaker* cDNA 29-4 to valines causes a 60-100 mV depolarizing shift and a dramatic reduction in the voltage sensitivity of channel activation (McCormack et al., PNAS 88: 2931). In search of an explanation for these changes, we recorded "macroscopic" ionic currents and gating currents in membrane patches from oocytes injected with mRNA encoding non-inactivating wild-type and mutant channels. All recordings were made in the inside-out mode with an NMG-Aspartate pipette solution. Bath solutions contained K-Asp and TEA-Asp for measuring ionic and gating currents, respectively. Gating current measurements showed that the voltage dependence and kinetics of most of the charge movement were similar in the wild-type and mutant channels. Moreover, the number of effective charges displaced per channel opening appeared to be similar for the two channels. Lower bounds for z obtained from the limiting slopes of the activation curves (at $P(o) < 0.01$) were similar : 9.9 ± 1.3 (N=4) and 8.7 (N=2) for wild-type and mutant channels. These values were close to those obtained from experiments which directly evaluated z. First, the number of channels in a patch was estimated from noise analysis on ionic currents; then, following the replacement of K with TEA, the charge movement was measured in the same patch. From these measurements, z was calculated to be 8.9 ± 1.8 (N=5) and 8.6 ± 1.9 (N=5) for the wild-type and mutant channels. The mutation appears to affect steps in the activation process that follow most of the charge displacement.

510.8

STRUCTURE AND FUNCTION OF VOLTAGE DEPENDENT K^+ CHANNELS: SUBUNITS AND SUBCONDUCTANCES. A.M.J. VanDongen and A.M. Brown. Dept. Mol. Physiol. and Biophys., Baylor College of Medicine, Houston, TX 77030.

Voltage dependent K^+ channels are thought to consist of four identical subunits, containing 6 transmembrane segments (S1-S6) that surround a central pore, which is formed by the linker regions between S5 and S6. Every subunit contributes to the lining of the pore. Two mechanisms could underlie channel opening and closing: a change in the physical dimension or the chemical properties of the pore. No matter what the mechanism is, each individual subunit must undergo a conformational change when the channel opens. This results in 3 intermediate states, where 1,2 or 3 subunits are in the "open" conformation. In this paper we want to investigate the role of the individual subunits in channel opening and closing. Experiments were done using *Xenopus* oocytes expressing a delayed rectifier K^+ channel, *drk1*, and a chimeric *drk1* that contains the S5-S6 linker region of *ngk2*. Single channel data from *drk1* showed subconductance levels of 2.5, 5.0 and 7.5 pS in addition to the full (10 pS) conductance. These sub-conductance states were very short lived and usually occurred as shoulders at opening and closing transitions. These results suggest that (i) the intermediate states are conducting, (ii) they are very unstable and (iii) each subunit makes an equal contribution to the conductance of the fully open channel. In another set of experiments, *drk1* was coexpressed together with the chimeric channel, which has a single channel conductance that is three time as great. From the intermediate single channel conductances it appeared that different hetero-multimers were formed. The data is being analyzed in terms of the subunit-subconductance hypothesis.

510.9

Mouse photoreceptors express mShak family potassium channels.

D. J. Klumpp*, E-J. Song*† and L. H. Pinto† Department of Biochemistry, Molecular Biology and Cell Biology and †Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

Mouse potassium channels can be classified into at least four families by homology with the four potassium channel families of *Drosophila*. The most extensively characterized rodent potassium channel family, mShak, is expressed in the rodent brain. However, the diversity of expression of mShak channels within specific neronal populations is not yet known. To determine the diversity of expression of mShak channels within a specific neuronal type, RNA PCR was employed. Mouse retinas were enzymatically dissociated and individually identified photoreceptors were harvested with a broken patch pipette. Following cell lysis by detergent, mRNA was purified using bead-coupled oligo(dT). cDNA was then synthesized from purified photoreceptor mRNA. The polymerase chain reaction was used to amplify mShak sequences from photoreceptor cDNA employing primers specific for conserved mShak regions. The predicted amplification product was detected by gel electrophoresis. A control reaction without reverse transcriptase generated no such amplification product. Cloning and DNA sequence analysis of the putative photoreceptor mShak amplification products revealed the presence of MK2 sequences due to homology with RCK2 (Grupe *et al.*, EMBO J., 9: 1749-1756). Therefore, mouse photoreceptors express MK2 channels.

510.10

A *C. ELEGANS* POTASSIUM CHANNEL GENE WITH HOMOLOGY TO *DROSOPHILA Shaw*.

A. Wei, T. Jegla* and L. Salkoff. Dept. of Anatomy and Neurobiology, and Dept. of Genetics, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Four voltage-gated potassium channel gene subfamilies defined by the *Drosophila* potassium channel genes, *Shaker, Shal, Shab* and *Shaw* are represented in a wide variety of metazoans, including mammals. We now report the isolation of a *Shaw* potassium channel gene homologue from the nematode *C. elegans*. A screen of genomic DNA was performed by PCR utilizing degenerate synthetic oligonucleotides coding for highly conserved regions of the four *Drosophila* potassium channels. Though *C. elegans* is distantly related to *Drosophila*, having a common ancestor no later than six hundred million years ago, the deduced amino acid sequence of the nematode channel shares approximately 65% identity to the fly channel. Homology appears significantly greater to the fly sequence than to reported vertebrate *Shaw* homologues. The greater similarity of fly and nematode homologs is evident in an area presumed to be important in ion selectivity; ion selectivity differs between fly and mammalian homologs of *Shaw*. Functional studies of this channel by expression in *Xenopus* oocytes will reveal whether this property is conserved between fly and nematode. Efforts are underway to locate this gene on the physical map of *C. elegans*, and to identify potential mutants.

510.11

MOLECULAR CLONING OF A NEW K⁺ CHANNEL IN *APLYSIA*.

B. Zhao and E.R. Kandel Ctr. Neurobiol. & Behav., Columbia Univ., & HHMI, N.Y., N.Y. 10032.

Potassium channels are the major targets for neuromodulation and thus contribute to neural plasticity. Since a large number of K⁺ channels exists, and different K⁺ channels play different roles in defining various aspects of the electrical properties of a neuron, we have tried to clone new families of K⁺ channels. Toward this end we have cloned at least one new K⁺ channel in *Aplysia* using a PCR-based strategy.

We carried out PCR reactions with degenerate oligonucleotides that code for conserved regions of known K⁺ channels. The right-sized PCR products were subcloned into plasmid vector and subjected to sequence analysis. At least one new K⁺ channel was found from the PCR products. This putative K⁺ channel is almost identical to other cloned K⁺ channels in the H5 region. However, surrounding this region it is at most 50% identical to *Aplysia* homologues of shab, shak, shaw and *Drosophila* shal. This type of sequence identity suggests that it is a putative K⁺ channel and represents a structurally new family of K⁺ channels, distinct from shab, shak, shaw, and shal. We are currently trying to obtain the full-length sequence in order to express it.

510.12

OVEREXPRESSION OF AN *APLYSIA* SHAKER POTASSIUM CHANNEL CHANGES THE ELECTRICAL PROPERTIES AND SYNAPTIC EFFICACY OF IDENTIFIED *APLYSIA* NEURONS.

Y. Furukawa[1]*, B.-K. Kaang[1], T. Kubo[1]*, P.J. Pfaffinger[2], S.G.N. Grant[1]* and E.R. Kandel[1]. [1]HHMI, Columbia, N.Y., NY 10032, and [2]Div. Neurosci., Baylor College of Medicine, Houston, TX 77030.

To examine the properties of a cloned *Aplysia* K⁺ channel (AK01a) in its native neuronal environment, we microinjected into different identified *Aplysia* neurons a plasmid expression vector (pNEX, Kaang et al., this meeting) containing the AK01a nucleotide sequence (pNEX-AK01a). As early as seven hours after microinjection of pNEX-AK01a, we observed a large transient K⁺ current. This expressed current in *Aplysia* had the biophysical and pharmacological properties of one of the native transient K⁺ currents (I_{Adepol}). A similar current was obtained when AK01a was expressed in *Xenopus* oocytes. Thus, it appears possible to generate a native current with a channel that is simply a homomultimer. Moreover, by expressing the current at high level, we could redesign critical electrical properties of identified neurons. In the bursting cell R15, overexpression resulted in an increase of the afterhyperpolarization and a narrowing of the action potential which altered the bursting pattern. In the cholinergic neuron L10, overexpression and consequent spike narrowing decreased the amount of transmitter release from the terminals and greatly weakened the synaptic connections. In many cells, prolonged period of incubation (10-30 hr after injection) induced the additional expression of a more slowly inactivating or non-inactivating component in the current that modified still further the electrical properties of neurons. For example, it silenced completely the bursting of cell R15. We are now investigating how this change in expression is brought about.

VISUAL CORTEX: FAR EXTRASTRIATE CORTEX

511.1

A BODY CENTRED COORDINATE SYSTEM IN POSTERIOR PARIETAL CORTEX.

P. R. Brotchie and R. A. Andersen. Department of Brain & Cognitive Sciences, Massachusetts Institute of Technology, MA 02139.

Models of gaze shifts suggest the existence in the brain of a visual map in body centred coordinates. A distributed map of visual targets in head centred coordinates has previously been proposed for areas 7a and LIP of posterior parietal cortex in the monkey (Andersen et al., J. Neuroscience 10(4), 1990) since cells in these areas have a retinal receptive field, modulated as a linear function of eye position (termed a gain field). Head position would need to be incorporated into the activity of these cells to produce a body centred map of the visual world. We recorded cells from areas 7a and LIP in a monkey with its head free to rotate horizontally. The animal was trained to orient its head and eyes towards independent locations and make visually guided saccades from different initial eye and head positions. This allowed us to determine separately the modulation of activity during the visual saccade task caused by eye position and that caused by head position.

82 cells from areas 7a and LIP were recorded. Both eye and head position signals were observed, often in the same cell so that the cell's activity was encoding gaze position (eye plus head position). These signals were found to linearly modulate the visual or saccadic activity of 55 cells to produce gain fields to eye and head position ($P<0.05$). In 22 cells modulation of the neuronal response occurred with eye position but not head position whereas modulation of neuronal activity by head position was seen in 33 cells. The gain fields for these 33 cells were best described as a function of gaze position rather than just head position as virtually all cells with gain fields for head position had similar gain fields for eye position. In the vast majority of these cells the gain fields were oriented towards the contralateral side of the body.

These results suggest that cells in areas 7a and LIP are of two types. One type of cell incorporates the retinal location of a stimulus with the orbital position and can thus participate in encoding the location of a target in head centred coordinates. The other type of cell modulates retinal responses as a function of gaze position rather than eye position and is thus capable of participating in encoding the location of a target in body centred coordinates.

511.2

Electrical microstimulation delineates 3 distinct eye-movement related areas in the posterior parietal cortex of the rhesus monkey.

P. Thier and R.A. Andersen. *Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139, USA*

Previous work has subdivided the posterior parietal cortex (PPC) into distinct areas based on anatomical and recording results. We now demonstrate that this parcellation is also reflected in the effects of electrical microstimulation. Stimulation (500 Hz biphasic pulses, 0.1 msec, train duration 100 msec, max. current 200 μA) was delivered in 2 monkeys while the animals kept fixation of the remembered location of a visual target. The areas are designated on physiological criteria since the animals are still being used in experiments. **Area 7a:** Whereas many sites proved to be unexcitable, stimulation of other sites elicited eye blinks (threshold: 50-100μA), which at several sites were accompanied by fast and wavy eye movements. The eye movements were directed to a circumscribed zone in the visual field (goal-directed saccades). **Floor of IPS:** Goal-directed saccades into the contralateral hemifield were also elicited from the floor of the intraparietal sulcus (IPS). Unlike eye-movements elicited from area 7a, these saccades had straight trajectories. They were usually accompanied by brisk movements of the shoulders, pinnae and facial muscles (threshold: 25-50μA). **LIP:** microstimulation elicited saccades (threshold: 25-50μA) which were rarely accompanied by non-eye movements. Although varying initial eye position affected both the amplitude and direction of the saccades, these saccades did not show convergence to a goal within the oculomotor range. They were always directed into the contralateral hemifield with many more sites yielding upward component than downward component saccades. Our observations suggest that the function of area LIP is more confined to saccades than that of the other 2 areas.

511.3

NEURONES IN THE MACAQUE LATERAL INTRAPARIETAL CORTEX (LIP) APPEAR TO ENCODE THE NEXT INTENDED SACCADE.

R M Bracewell, S Barash, P Mazzoni & R A Andersen.
Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

LIP, a subdivision of inferior parietal cortex, has been implicated in the planning of saccadic eye movements on anatomical and physiological grounds. In a delayed saccade paradigm, many LIP neurones maintain an elevated level of activity after the offset of the visual target until the saccade is made in that direction. We have interpreted this "memory" activity as reflecting the monkey's plan to make the next saccade. Here we present further evidence for this hypothesis:

1. When monkeys make delayed saccades to auditory targets, some LIP neurones show memory activity. Generally, this memory activity is in the same direction as for visual delayed saccades.

2. Memory double saccade experiments: the two targets are flashed briefly, as in a "traditional" double saccade, but the fixation point remains on for several hundred milliseconds after the targets are flashed. Only after offset of the fixation spot may the saccades be made. For most LIP neurones, only sustained activity related to the first saccade to be made is manifest during the memory period, even if the second saccade target appeared within the receptive field of the neurone.

3. Change of motor plan paradigm: in a variant of the delayed saccade task, we unpredictably presented 1, 2 or 3 targets (either visual or auditory) in succession during the delay period. The monkey had to saccade to the last one presented. In those trials in which 2 or 3 differing targets were presented, the monkey had to change his plan during the delay period. Activity in LIP reflected the direction of the next planned saccade. Alterations of this plan, even in the absence of eye movements, were reflected in neuronal activity: e.g., a preferred target would evoke memory activity which would be "nulled" by subsequent presentation of a non-preferred target.

Thus it appears that activity in many LIP neurones reflects the monkey's *plan* to make the *next* saccade, regardless of how the saccade is evoked, whether it is part of a sequence, and whether indeed it is made.

511.4

NEURONS IN THE LATERAL INTRAPARIETAL AREA OF THE MONKEY REMAP VISUAL SPACE IN CONJUNCTION WITH SACCADIC EYE MOVEMENTS I. PRESACCADIC EVENTS.

J.-R. Duhamel, C. L. Colby and M. E. Goldberg Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

Accurate processing of visual space requires that the brain compensate for changes in eye position. To study this compensation we recorded from LIP neurons in a paradigm in which a visual stimulus is presented outside the receptive field (RF) and the monkey was required to make a saccade that moved the stimulus into it. We found that half of the visual neurons studied in two monkeys began to discharge with a latency significantly less than that predicted if the response were solely due to the reafferent effect of the saccade bringing the stimulus into the RF. Some cells began to discharge even before the beginning of the saccade. Control experiments show that these same neurons did not respond to the stimulus outside the RF when the monkey made no saccade, nor did they respond when the monkey made the eye movement in the absence of the stimulus. They also did not discharge in response to the stimulus when the monkey attended to the saccade target without making an eye movement to it. The phenomenon requires that the monkey make a saccade that will bring the stimulus into the neuron's RF. When the monkey made a saccade that removed the stimulus from the retinal RF, the discharge of such neurons was truncated as compared to the case when the stimulus disappeared while the monkey maintained fixation.

These results suggest that LIP visual neurons can be excited from any retinal location as long as an impending saccade will bring that retinal location into the receptive field of the neuron. They provide evidence for a process of dynamic remapping that combines eye movement and retinal information to generate the neuronal response. This mechanism ensures the continuity of visuospatial processing across eye movements.

511.5

NEURONS IN THE LATERAL INTRAPARIETAL AREA (LIP) OF THE MONKEY REMAP VISUAL SPACE IN CONJUNCTION WITH SACCADIC EYE MOVEMENTS II. REMAPPING OF A VISUAL MEMORY TRACE.

C. L. Colby, J.-R. Duhamel and M. E. Goldberg Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

Visual neurons in LIP show evidence for dynamic remapping of visual space. They respond to stimuli outside the classically determined receptive field when the monkey makes a saccade that will bring the stimuli into it. We now show that for most LIP neurons, dynamic remapping is a phenomenon which extends to the memory representation of a visual stimulus. We have tested neurons in a new paradigm in which a visual stimulus is briefly flashed (< 50 msec) outside of the receptive field and is followed by a target which elicits a saccade. The saccade brings the eye to a position where the stimulus, if it were still present, would be in the receptive field. We have discovered that virtually all LIP neurons discharge in this task at a rate that is about half of their response to an actual visual stimulus. Control experiments show that this activity is not related to onset of the saccade target or execution of the saccade. Cells respond to stimuli that were flashed as long as a second before the saccade. The spatial organization of the response is retinotopic. Any saccade which brings the eye to a final position such that the stimulus would have been in the receptive field will activate the response. It does not depend on the performance of a particular amplitude and direction of saccade.

These results suggest a novel mechanism for spatial processing of visual images. LIP neurons are sensitive to the retinotopic location of a visual stimulus, whether physically present or existing as a memory trace. The retinotopic coordinates assigned to the trace are updated at the time of a saccadic eye movement as though the stimulus were fixed in space and the eye swept over it. This mechanism ensures that visual information in parietal cortex is spatially accurate at all times.

AREA 7 AND THE SPONTANEOUS CAPTURE OF ATTENTION BY UNEXPECTED STIMULI

C. R. Olson. Department of Psychology, George Mason University, Fairfax, VA 22030.

Attention includes both top-down processes, in which an object is chosen voluntarily, and bottom-up processes, in which an object calls attention to itself. Area 7 is involved in top-down attention as indicated by the enhancement of neuronal visual responsiveness that occurs when an animal is actively prepared to process information from a stimulus. I ask here whether there is a similar enhancement of visual responsiveness when a behaviorally irrelevant stimulus succeeds in spontaneously capturing an animal's attention.

Single-neuron activity was recorded at 105 sites in Area 7 of two cats whose eye movements were monitored with surgically implanted scleral search coils. The cats were reinforced with periodic food reward for remaining in a state of general alertness and for tolerating head restraint. No other aspect of their behavior was reinforced. Visual stimuli were presented briefly at an eccentric visual-field location under computer control. The interstimulus interval was variable and was always greater than 60 sec.

Behavioral responses to the stimulus were bimodal. Cats either responded with a large eye movement directed toward the target or did not emit a detectable response. Neuronal visual responses in Area 7 were more prolonged and more intense on trials when a behavioral response occurred than on trials when there was no orienting eye movement. Whereas the visual response might begin at a latency as short as 30 msec, the enhancement was not apparent until around 80 msec following target presentation. Enhancement of the visual response was not attributable to simple superimposition of a motor burst on the visual burst because it occurred even on trials when the saccade was delayed by several hundred msec. I conclude that the strength of the neuronal visual response in Area 7 is a predictor of whether a stimulus will or will not capture attention.

MODULAR CONNECTIONS BETWEEN AREA V4 AND TEMPORAL LOBE AREA PITv IN MACAQUE MONKEYS.

D.J. Felleman and E. McClendon. Dept. of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX 77030.

Area V4 contains "modules" which receive input from either cytochrome oxidase thin- or interstripe compartments of V2 (DeYoe et al.,'88; Zeki and Shipp,'89). Tracer injections into these V4 modules produce segregated labeling patterns in posterior IT (Van Essen et al.,'91; and see DeYoe and Sisola, this meeting). In this study, we explore further the size, distribution, and specificity of the V4 inputs to posterior IT by making tracer injections into temporal lobe area PITv.

Anterograde and multiple retrograde tracer injections were made into loci separated by 2-6 mm in area PITv of 4 macaque monkeys. Single, 150-250 nl. injections of fluorescent dyes into PITv produced a variable labeling pattern in V4. In most instances, labeled cells were clustered in several distinct patches which ranged in size from 2x2 to 5x6 mm with an average width of 4 mm and separation of 4-7 mm. In 2 cases, 2 retrograde tracers were injected into separate loci in area PITv separated by 4-6 mm. These paired injections produced interdigitating patterns of retrogradely labeled cells in area V4. In other cases, the labeled zones in V4 were larger and irregularly shaped and may reflect labeling of several adjacent modules. Since a 4-6 mm separation between injections produce segregated clusters in V4, we suggest that "modules" in PITv are at least 4-6 mm wide. These data are consistent with the view that area PITv, like prestriate areas V2 and V4, contains a functional architecture which may reflect segregated processing of form and color information. Supported by a grant from the Whitehall Foundation and an Alfred P. Sloan Foundation Fellowship to DJF.

DISTINCT PATHWAYS LINK ANATOMICAL SUBDIVISIONS OF V4 WITH V2 AND TEMPORAL CORTEX IN THE MACAQUE MONKEY.

E.A. DeYoe and L.C. Sisola. Dept. of Anatomy, Medical College of Wisconsin, 8701 Watertown Plank Rd, Milwaukee, WI 53226.

Visual pathways originating in cytochrome oxidase thin- and inter-stripes of V2 remain segregated when terminating in V4 (DeYoe etal.'88). To determine if projections from other visual areas to V4 are also segregated, different fluorescent retrograde tracers were injected at 3 sites in V4 spaced 2-3 mm apart above the tip of the IOS. In two of three hemispheres injected, retrograde labeling by different tracers was overlapping but segregated within V2: thin stripes labeled by one tracer were interdigitated but separate from inter-stripes labeled by a different tracer. Within occipito-temporal cortex, cells labeled by each tracer were also markedly segregated. In one case, as many as 10 distinct patches of label ranging in size from 2X4mm to 4X8mm could be identified in the region extending from the lip of the STS ventrally to the parahippocampal gyrus. Area PITv, and possibly VOT and CITv appeared to contain more than one patch of label. Four additional foci were labeled on the lateral wall and floor of the STS though intermixing of different tracers was more common near the fundus and in all areas closer to the temporal pole. Alternating patches of different label were also observed on the anterior bank of the lunate sulcus. In a third hemisphere, comparably placed tracer injections produced significantly greater intermixing of label within both V2 and occipito-temporal cortex. These results (and those of Felleman & McClendon, this meeting) suggest that the functional division of visual pathways originat-ing in V2 is preserved in the connections of V4 with visual areas throughout occipito-temporal cortex. Supported by NIH grant RO1-EY08406.

NEURONS WITH RELATED STIMULUS SELECTIVITY ARE CLUSTERED IN THE MACAQUE INFEROTEMPORAL CORTEX.

I. Fujita, K. Cheng and K. Tanaka Lab. for Neural Information Processing, Frontier Research Program, RIKEN, Wako, Saitama , 351-01, Japan.

Neurons in the anterior 2/3 of the inferotemporal cortex (IT) of the macaque are selectively activated by visual stimuli with particular 'complex' features: 'complex' shape or combinations of texture or color with shape. Simultaneous recordings from multiple neurons with single electrodes have shown that adjacent cells have similar, but usually not identical, stimulus selectivity (Fujita et al., Soc Neurosci Abstr, 1990). To assess the spatial arrangement of neurons with similar stimulus preferences we made 2 kinds of penetrations in IT, one directed vertically and the other tangentially to the cortical surface.

Recordings were made in the crown of the anterior IT in anesthetized and immobilized monkeys (*Macaca fuscata*). For vertical penetrations, electrodes were advanced from the side at right angles to the midline of the head and tilted downward by 20°. For tangential penetrations, we directed electrodes from the side anteriorly at an angle of 45° to the midline and downward by 27°. We presented various paper cutouts and tens of 3-D objects to the monkey for the initial survey to find stimuli which activated a cell, and then determined the stimulus feature critical for the activation with the aid of a computer graphics system. We made a set of 8 to 18 stimuli ('test set') including optimal, suboptimal and ineffective stimuli for that cell. Other cells were sampled at 100 or 200 μm steps in that penetration and tested with this same set of stimuli.

Over a distance of 0.6-1.4 mm in vertical penetrations we obtained neurons which responded to related stimuli in the test set, i.e., the optimal and suboptimal stimuli for the first tested cell in each penetration. In tangential penetrations, cells with related stimulus selectivity were found within 0.2-0.5 mm. In some tangential penetrations, there existed 2 or 3 separate clusters of neurons showing similar selectivity. The gap between adjacent clusters was 0.4-1 mm. We suggest that the anterior IT is composed of modules, in which neurons with related selectivity cluster across cortical layers.

TRAINING AFFECTS TASK-RELATED PROPERTIES OF INFEROTEMPORAL NEURONS. R. Vogels and G.A. Orban. Lab. Neuro- en Psychofysiologie, KULeuven, GHB, 3000 Leuven, Belgium.

Last year we (Vogels and Orban, *Soc. Neurosci. Abstr.* 1990) reported on task related properties of inferotemporal (IT) units recorded in a monkey (Ronnie) that was extensively trained in a task in which it had to indicate whether or not two successive gratings (S1 and S2) differ in orientation. In order to determine whether the properties of IT units depend on the level of behavioral training in this task we recorded IT units at two stages of training in a second monkey (Adam). After determining orientation discrimination thresholds (6 months), we trained Adam in the same-different task for a restricted range of S1 orientations (4 months) and then recorded IT units (N=587) with S1 covering the full range of orientations (orientation difference S1-S2 26 degrees). After further intensive training (5 months) at a 15 degrees S1-S2 difference, we recorded again in the same area of IT cortex (N= 560). In the first recording session we found no significant difference in the average unit response level or response variance for learned versus unlearned S1 orientations. A comparison of the single cell responses to S1 between the two recording sessions yielded no significant difference in the response strength, response variance, response latency or orientation sensitivity. However, two task-related response properties changed in the course of training. First, significantly more cells responded stronger to S1 than to the physically identical S2 in the first than in the second recording session. In the second recording session the distribution of the difference in responses to S1 and S2 was similar to that of the extensively trained monkey Ronnie. Second, the number of cells that were responsive during the delay between S1 and S2 increased with the training. These results suggest that the properties of IT units are affected by behavioral training. Furthermore these results may lead to an understanding of the way the primate brain changes its stimulus- and task-related representations during learning.

A NEURAL CORRELATE OF RECENCY MEMORY IN INFERIOR TEMPORAL (IT) CORTEX. E.K. Miller, L. Li*, and R. Desimone. Lab. Neuropsychology, NIMH, Bethesda MD 20892

Several studies report that, in a matching-to-sample paradigm, IT neurons respond differently to a test stimulus depending on whether or not it matches an immediately preceding sample. Because an item can be actively held in memory even while viewing other items, in two rhesus monkeys we tested whether the memory of the sample influences the response of IT neurons to subsequent test stimuli, even when other stimuli intervene. On each trial, while the animal maintained fixation, the sample appeared first, followed by 0-6 nonmatching (NM) stimuli and then the matching (M) stimulus. For most cells, the responses to M stimuli were weaker than to the same stimuli presented as NM, and this difference was maintained even following 6 intervening NM stimuli. The time course of the response difference varied, but some cells discriminated between M and NM at very short latencies. Based on the response, a test stimulus could be correctly classified as M or NM on 60-90% of the trials and, for many cells, the specific sample stimulus used could also be identified from the NM response. The results suggest that many IT neurons retain short-term, dynamically updated memory traces and that their responses to stimuli are modulated according to their similarity to the trace.

511.12

INFERIOR TEMPORAL (IT) NEURONS DISTINGUISH NOVEL AND FAMILIAR STIMULI. L. Li*, E.K. Miller, and R. Desimone. Lab. Neuropsychology, NIMH, Bethesda MD 20892

In a companion study, we report that IT neurons respond differently to incoming stimuli that match items actively held in short-term memory. However, monkeys and people can also judge how well stimuli match items in a longer term store, i.e. judge familiarity. To examine this, two rhesus monkeys were trained to perform a matching-to-sample task while maintaining fixation. The sample and matching test stimuli were completely unfamiliar to the animal; a new set of 20 was used on each cell. The 4 nonmatching stimuli were familiar and held constant across cells. The responses of about a third of the cells in anterior IT cortex declined steadily with increasing familiarity, reaching a plateau by about 8 presentations of a given sample. The remainder showed either no change in response or (rarely) an increase. The response decrement was stimulus specific. For a given stimulus, the magnitude of cumulative response decrement on a given trial was related to the recency of presentation of that stimulus in the sequence of trials. A few cells were retested with a new set of stimuli, and they showed a recovery of response to the new set. The results suggest that as stimuli become familiar, connection weights in IT cortex adjust adaptively, resulting in a narrowing of activitation across the population.

PEPTIDES: PHYSIOLOGICAL EFFECTS IV

512.1

PITUITARY ADENYLATE CYCLASE-ACTIVATING POLYPEPTIDE (PACAP) INCREASES CYTOSOLIC FREE CALCIUM IN CULTURED RAT HIPPOCAMPAL NEURONS. T.Yada*, J.Tatsuno*, B.Shivers and A.Arimura. US-Japan Biomedical Research Laboratories, Tulane University Hebert Center, Belle Chasse, LA 70037; Departments of Medicine, Physiology and Anatomy, Tulane University School of Medicine, New Orleans, LA 70112.

PACAP, a 38-residue peptide, is a new member of the vasoactive intestinal polypeptide (VIP) / glucagon / secretin family of proteins and stimulates adenylate cyclase in primary cultures of rat pituitary cells, neurons and astrocytes. PACAP, derived from a 176-amino acid precursor, is expressed in primate, sheep and rat brains. Immunoreactive PACAP nerve fibers and PACAP binding sites have been detected in hypothalamic and extrahypothalamic areas suggesting that PACAP has a neurotransmitter/neuromodulator role in the brain. In the present study we investigated the effect of PACAP on cytosolic free calcium concentration ($[Ca^{2+}]i$) in hippocampal neurons. Rat hippocampal neurons were prepared from day 18 embryos and cultured on poly-L-lysine-coated coverslips for 1-10 days. Fura-2-loaded neurons were superfused at 37°C, and the effect of PACAP or glutamate on $[Ca^{2+}]i$ was determined by dual-wavelength microfluorometry with image analysis. Following a lag time of ~ 30 seconds, PACAP at 10^{-10} to 10^{-7} M elicited, in a concentration-dependent manner, an increase in $[Ca^{2+}]i$ from an 80 nM basal level to peak levels of 200-600 nM. Approximately half of the neurons responded to 10^{-8} M PACAP. The $[Ca^{2+}]i$ increase often appeared first near the plasma membrane and then spread inward. A VIP antagonist at 10^{-6} M did not alter the PACAP-induced increase in $[Ca^{2+}]i$. Glutamate at 100 μM also induced an increase in $[Ca^{2+}]i$; however, the PACAP-responsive neurons did not always respond to glutamate, and *vice versa*. These findings indicate that PACAP probably acts through a selective receptor to increase $[Ca^{2+}]i$ in hippocampal neurons and are consistent with a neurotransmitter/neuromodulator role for PACAP in the brain.

512.2

CORTICOTROPIN RELEASING HORMONE (CRH) AND ß ADRENORECEPTORS REGULATE GENE TRANSCRIPTION IN CEREBELLAR NEURONS J.P. Loeffler*, F. Barthel*, A.L. Boutillier* and P. Feltz. Institut de Physiologie et de Chimie Biologique URA 1446 du CNRS,21 rue René Descartes 67 084 STRASBOURG CEDEX FRANCE.

We demonstrate that granular neurons from rat cerebellum maintained in primary culture express functional ß adrenergic and CRH receptors. Activation of these receptors by Isoprenalin ($5 \cdot 10^{-6}$M) and CRH (10^{-8}M) increase cAMP levels and stimulate *c-fos* mRNA accumulation. The role of protein kinase A (PKA) was analyzed by gene transfer studies and expression of a mutated subunit of PKA lacking cAMP binding sites. Introduction of this dominant inhibitory mutation which inactivates PKA inhibits *c-fos* transcription from chimera genes bearing human *c-fos* promoter sequences. These results show an involvement of cAMP-dependent responses to CRH in the cerebellum and underline their importance in gene regulation in differentiated neurons.

PHE^6-TYR^7 IS NECESSARY AND SUFFICIENT FOR ALPHA-BAG CELL PEPTIDE INHIBITORY ACTION ON ABDOMINAL GANGLION LUQ NEURONS IN *APLYSIA*. D.F. Owens, J.G. Menon, and B.S. Rothman. Department of Biology, San Francisco State University, S.F., CA 94132.

Alpha-bag cell peptide (α-BCP[1-9], APRLRFYSL) mediates the bag cell-induced inhibition of left-upper quadrant (LUQ) neurons L2, L3, L4, and L6. The purpose of this study is to determine which residues of α-BCP are necessary for its inhibitory activity, so that cleavages of α-BCP produced by *Aplysia* peptidases that we have recently characterized can be assessed for their ability to inactivate this peptide. Up to three LUQ neurons were monitored concurrently by intracellular glass microelectrodes in individual isolated abdominal ganglia that were perfused at 10 μl/min and superfused at 670 μl/min at room temperature with artificial sea water (ASW). Spike rate in 1 min intervals and interburst intervals were quantified throughout the experiment, and their changes measured when α-BCP[1-9] or one of its fragments, dissolved at 10^{-7} to 10^{-3} M in ASW, was added to the perfusion stream for 4 min. Our results indicate that the Phe^6-Tyr^7 residues are both necessary and sufficient for α-BCP-mediated inhibitory activity. This conclusion is based on the following: 1) Of all fragments tested α-BCP[6-7] had the lowest threshold (10^{-7} M) for producing inhibition. 2) When perfused individually, seven α-BCP peptides containing residues 6-7 ([1-9], [1-8], [1-7], [3-9], [3-8], [6-9], [6-8]) produced inhibition with a threshold of 10^{-6} to 10^{-5} M. 3) In contrast, when perfused individually, six α-BCP fragments lacking an intact 6-7 bond ([1-5], [1-6], [7-9], [8-9], Phe, Tyr) did not produce inhibition. Based on biochemical studies conducted in our lab, these data strongly suggest that α-BCP is inactivated after release into the extracellular spaces of the CNS by the combined actions of three ganglionic ectopeptidases and one soluble hemal peptidase. *Supported by NIH grants RO1-NS-24046 (BSR) & K04-NS-01177 (BSR).*

512.4

INTRACEREBROVENTRICULAR NEUROPEPTIDE Y INCREASES BASAL GASTRIC ACID BY DECREASING CENTRAL ADRENERGIC INHIBITION OF ACID. J.G.Geoghegan*, C.A.Cheng*, S.S.Schiffman, T.N.Pappas*. Duke Univ. Medical Center, Durham, N.C.27710.

Intracerebroventricular (ICV) NPY increases basal acid output in dogs. ICV yohimbine also increases acid in dogs, suggesting there is tonic α_2-adrenergic inhibition of acid. In this study interaction between ICV NPY and central adrenergic control of acid was examined. Six dogs with chronic cerebroventricular guides and gastric fistulas received [Leu^{31}, Pro^{34}]-NPY (250,500 pmol/kg), a Y_1 post-synaptic receptor agonist, or control into the lateral ventricle. In separate studies NPY was given either before or after ICV desmethylimipramine (DES, 50μg/kg) or vehicle (VEH) as control. Acid output was measured for two hours (shown below in mmol/hr ± SEM, *p<0.05).

Results: [Leu^{31}, Pro^{34}]-NPY had no effect on acid output (control: 1.3 ± 1.0; [Leu^{31}, Pro^{34}]-NPY: 250 pmol/kg: 1.2 ± 0.8; 500 pmol/kg: 0.9 ± 0.6).

NPY+DES	NPY+VEH	DES+NPY	VEH+NPY
9.1 ± 2.3	7.9 ± 3.5	2.0 ± 1.3*	7.3 ± 2.1

Conclusions: The effect of ICV NPY on acid is not mediated at a post-synaptic site. DES, which slows uptake of norepinephrine (NE) from the synaptic cleft, inhibits NPY-induced acid secretion when given before but not after NPY. These studies suggest that ICV NPY may increase acid output by pre-synaptic inhibition of tonic release of NE in dogs.

512.5

THE SELECTIVE POTENTIATION OF NMDA-INDUCED NEURONAL ACTIVATION BY NEUROPEPTIDE Y INVOLVES AN ATYPICAL NPY RECEPTOR. G. Debonnel, F.P. Monnet, A. Fournier and C. de Montigny. Neurobiological Psychiatry Unit, McGill University, I.N.R.S.-Santé, Montréal Québec, Canada and Institut de Recherche Jouveinal, Fresne, France.

We have previously shown that neuropeptide Y (NPY) selectively potentiates NMDA-induced activation of CA_3 hippocampal pyramidal neurons *in vivo*, and that this effect is reversed by the high affinity σ ligand haloperidol *(Eur. J. Pharmacol. 182: 207, 1990)*. To characterize the type of receptor involved in this potentiation of NMDA by NPY, we have studied the effect of peptides related to NPY: [Leu^{31}, Pro^{34}]pNPY which possesses high selectivity for the Y_1 receptor *(P.N.A.S., 87: 182, 1990)*, $pNPY_{13-36}$, a selective ligand for the Y_2 receptor *(J. Biol. Chem., 264: 6648, 1989)*, and the pancreatic peptide (PP) and peptide YY (PYY) which both activate Y_1 and Y_2 receptors.

Five-barrelled micropipettes were used for extracellular recording of CA_3 hippocampal pyramidal neurons of anesthetized male Sprague-Dawley rats and microiontophoresis of [Leu^{31}, Pro^{34}]pNPY, $pNPY_{13-36}$, PP and PYY (0.1 mM in 150 mM NaCl and 0.1% BSA, pH: 8), NMDA (10 mM in 200 mM NaCl, pH: 8) and QUIS (1.5 mM in 400 mM NaCl, pH: 8).

[Leu^{31}, Pro^{34}]pNPY and $pNPY_{13-36}$ induced a marked and selective potentiation of NMDA-induced activation which was reversed by haloperidol (20 μg/kg, i.v.). In contrast, PP and PYY did not potentiate NMDA-induced activation.

Since [Leu^{31}, Pro^{34}]pNPY and $pNPY_{13-36}$ are selective for the Y_1 and Y_2 receptors respectively, and PP and PYY activate both receptors, the present results suggest that the selective potentiation of the NMDA response by NPY is mediated by a NPY receptor distinct from the Y_1 and Y_2 receptors. This NPY receptor might represente a subtype of σ receptors.

512.6

SPINAL AND PERIPHERAL MODULATION OF GASTROINTESTINAL (GI) MOTILITY BY THE PANCREATIC POLYPEPTIDE-FOLD PEPTIDES (NPY, PYY AND PP): ROLE OF THE ALPHA (α) ADRENERGIC SYSTEM. Wager-Pagé, S., B. Ghazali*, J. Davison* and W. Veale. Univ. of Calgary, Dept. of Medical Physiology, Calgary, Alberta.

NPY, PYY and PP are distributed in the spinal cord and GI tract. Work from this laboratory has shown that NPY, PYY and PP modulate GI tone and alter intraluminal pressure at peripheral and thoracic spinal sites in the rat. Others have shown that some of the physiological effects of NPY are via modulation of the sympathetic nervous system (SNS). The role of the SNS in the PP-fold peptide's modulation of GI pressure in the rat was studied. NPY, PYY, PP (200 pMole) were injected intra-venously (IV) or intrathecally (IT) following α-1(prazosin(0.1 mg/kg) IM) (PRZ) or α -2 (yohimbine (0.5 mg/kg)IM)(YOH) blockade.

Increase In Duodenal Pressure Change from Baseline (mmHg)				Increase In Colonic Pressure Change from Baseline (mmHg)			
	Alone	+YOH	+PRZ		Alone	+YOH	+PRZ
PP(IV)	3.7*	2.3*	3.5*	PP(IV)	6.2*	2.5*	8.2*
PP(IT)	3.0*	0.9†	0.8†	PP(IT)	3.7*	0.5†	2.0*
PYY(IV)	3.2*	4.8*	2.2	PYY(IV)	3.3*	2.9	2.4
PYY(IT)	2.1*	1.3	1.1	PYY(IT)	3.3*	0.9†	2.3
NPY(IV)	1.8*	0.9	1.7*	NPY(IV)	2.0*	4.2*	2.6
NPY(IT)	1.8	0.2	1.4*	NPY(IT)	2.2*	2.0*	0.4†

(*p<0.05, from BL)(†p<0.05 from peptide alone)

As previously shown, NPY, PYY and PP increase duodenal and colonic intraluminal pressure. Both α -1 and α -2 adrenergic mechanisms may be involved in the modulation of GI tone by the PP-fold peptides.

512.7

ENDOTHELIN ACTIONS AT THE SUBFORNICAL ORGAN. K.M. Wall, M. Nasr* and A.V. Ferguson. Dept. of Physiology, Queen's University, Kingston, ON K7L 3N6, CANADA.

Endothelin (ET) is a 21-amino acid peptide with potent vasoconstrictor properties. ET administered intravenously to dogs has been shown to cause increases in plasma levels of adrenaline, noradrenaline, renin, angiotensin, aldosterone and vasopressin (VP). Evidence suggests that ET acts as a neuropeptide, but central sites of action and regulatory functions of ET in the central nervous system remain to be determined. Our initial electrophysiological studies, using extracellular single unit recordings, demonstrated excitatory responses in 44% of magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus in response to circulating ET. Electrolytic lesion of the subfornical organ (SFO) reduced this value to 14%. In the present study, electrophysiological and micro-injection studies were performed to further assess the role of the SFO in mechanisms whereby circulating ET alters the activity of neurohypophysial VP and oxytocin (OXY) neurons.

Male Sprague-Dawley rats anaesthetized with 1.4 g/kg urethane and fitted with femoral arterial and venous catheters were placed in a stereotaxic frame for 1) micro-injection of 0.5 pmol (0.5 μl volume) ET-1 into SFO or 2) examination of single unit responses of SFO neurons, antidromically identified as projecting to PVN, to intravenous ET (50 pmol). Micro-injection of ET into SFO caused an increase in mean arterial pressure of 10.2 ± 2.0 mmHg, while similar administration of saline had no significant effect. Single-unit extracellular recordings from SFO neurons demonstrated an excitatory response to ET for 60% of the cells. These results support the suggestion that circulating ET causes release of VP and OXY through central nervous system actions at the SFO. *Supported by a grant from the MRC of Canada. KMW is a recipient of a HSF Fellowship.*

INHIBITION OF Ca^{++} CURRENTS BY A MU OPIOID IN AN ANATOMICALLY-DEFINED SUBSET OF RAT SENSORY NEURONS. J.E. Schroeder and E.W. McCleskey. Washington University, St. Louis, MO 63110.

Selective modulation of particular somatosensory sensations occurs in humans and animals but the basis of the selectivity is unclear. We asked if there is selective modulation at the level of the primary sensory neuron in rats by comparing electrophysiological properties of randomly selected dorsal root ganglia (DRG) neurons to those of identified subsets of DRG neurons in short-term cell culture. Subsets were identified in two ways: labeling with antibodies (provided by Drs. Jane Dodd and Tom Jessell) against heterogeneously expressed cell-surface antigens and retrograde transport of dye from the peripheral target to the DRG prior to cell preparation. The antibodies labeled cells that preferentially project to specific laminae in the dorsal horn of the spinal cord, implying that they label cells of particular sensory modality. Using whole-cell voltage clamp, the following properties were examined: cell capacitance, low-threshold T-type and high-threshold Ca^{++} current amplitudes, total to sustained high-threshold Ca^{++} current ratios, Na^+ current sensitivity to tetrodotoxin, and high-threshold Ca^{++} current sensitivity to mu opioids. Only the response to opioids was different in random and labeled cells. Of 73 randomly selected cells, 12% were insensitive to a saturating concentration of the mu opioid agonist DAGO and inhibition of Ca^{++} current in the remaining cells varied from 5% to 95%. In an identified population of 44 cells enriched in pain and temperature-sensing neurons, fewer cells lacked opioid sensitivity (4%) and Ca^{++} current was never inhibited by greater than 55%. The results show that an identified DRG subset responds in a predictable manner to mu opioids, whereas randomly selected cells show wide variation in their responses. Thus, selective opioid modulation can occur at the level of DRG sensory neurons.

512.9

SELECTIVE LOSS OF ß-ENDORPHIN NEURONS AND COMPENSATORY INCREASE IN μ OPIOID RECEPTORS IN THE HYPOTHALAMUS OF ESTRADIOL-VALERATE TREATED RATS. G.C.Desjardins,J.R.Brawer and A.Beaudet. Montreal Neurol. Inst.,Dept. of Anatomy,McGill Univ.,Montreal,Que.,Canada H3A 2B4.

A single injection of estradiol valerate (EV) in female rats induces a series of hypothalamic changes which ultimately result in an aberrant pattern of LHRH release and the development of chronic polycystic ovaries. We have previously demonstrated that EV treatment is associated with a selective increase in μ opioid binding in the medial preoptic nucleus (MPO), an area of high LHRH neuron density, and with a concomitant decrease in hypothalamic ß-endorphin content. In this study, we report using quantitative immunocytochemistry that EV treatment causes an average 60% decrease in the total number of ß-endorphin immunoreactive neurons across the arcuate nucleus ($p < 0.001$;$n=5$). Adjacent sections labeled with antibodies to somatostatin, neurotensin and tyrosine hydroxylase exhibited no differences in average immunopositive neuron numbers between control and EV-treated animals, suggesting that neuronal loss was relatively specific for ß-endorphin neurons. To determine wether this effect was responsible for increases in μ opioid binding detected in the MPO, μ opioid binding densities were quantitated by in vitro radioautography in the hypothalamus of rats deprived of arcuate neurons by neonatal monosodium glutamate treatment and found to be inversely correlated with hypothalamic ß-endorphin content ($r=0.8$). These results suggest that estradiol treatment results in either destruction of ß-endorphin neurons in the arcuate nucleus or decreased synthesis of ß-endorphin in these neurons and that this reduction in endogenous peptide causes a chronic up-regulation of μ opioid receptors in the MPO.

GENE STRUCTURE AND FUNCTION III

513.1

ALTERNATIVE SPLICING OF THE PARANEOPLASTIC OPSOCLONUS GENE WITHIN SPECIFIC REGIONS OF THE HUMAN BRAIN. R.B. Darnell Cotzias Lab of Neuro-Oncology, Memorial Sloan Kettering Cancer Center & Cornell Univ Med Ctr, NY, NY 10021

Paraneoplastic opsoclonus (PO) is a neurologic disorder in which brainstem and cerebellar dysfunction are associated with malignancy. In 8 PO patients an antibody (anti-Ri) directed against their own tumors and a nuclear neuronal antigen (Ann Neurol 1991;29:241-251) has been reported. We have now identified a cDNA encoding a fusion protein recognized by anti-Ri antisera, and additional clones encoding what is most likely the full length of the Ri protein.

Because the neurologic manifestations of PO are restricted, while Ri antisera recognizes an antigen expressed throughout the brain, we have characterized Ri cDNA's from different areas of the brain. A number of Ri cDNA's appear to result from splicing of novel exons into a common transcript. One such exon ("C1"), occurs within the coding region of the Ri fusion protein, encoding a peptide rich in serine and proline. This exon is absent from all subtentorial (cerebellar and brainstem) and present in all cortical (frontal and hippocampal) cDNA clones characterized. Thus the Ri gene transcript appears to be alternatively spliced in a regionally specific manner in the nervous system. If exon C1 alters the recognition of the Ri fusion protein by PO antiserum, it would suggest that regional variations in the Ri antigen might contribute to the specificity of the neurologic symptoms.

MOLECULAR CLONING OF IMMORTALIZED MOTOR NEURON HYBRID CELL-SPECIFIC cDNAs. S.H. Pasternak, N.R. Cashman, K.E.M. Hastings.* Dept of Neurology and Neurosurgery, McGill University, Montreal PQ H3A 2B4

We have pursued a strategy which could lead to the identification of motor neuron-specific genes based on immortal hybrid cell lines produced by the fusion of N18TG2 neuroblastoma X dissociated spinal cord cell fusions (Soc Neurosci Abs 1989). One of these hybrid cell lines, NSC34, expresses many motor neuron-like characteristics not found in the parental neuroblastoma, including the ability to extend processes, to contact cultured myotubes and induce aggregation of acetylcholine receptors, and to express choline acetyltransferase, neurofilament proteins and NCAM. A cDNA library was made from NSC34, and 10 clones were isolated from it using differential and subtractive screening strategies designed to isolate cDNA copies of RNAs expressed at higher levels in the hybrid cells than in the N18 parent. Sequence analysis indicates that three transcriptional components contribute to the NSC34-enriched RNAs. These are 1. mRNAs transcribed from the mitochondrial genome, 2. small RNAs, presumably transcribed by RNA polymerase III, which correspond to the B1 highly repetitive DNA sequence element, and 3. typical cytosolic mRNAs presumably transcribed by RNA polymerase II. Among the latter group (5 clones) two have been identified as mRNAs encoding chromogranin B (a component of neurosecretory vesicles and GAP-43 (important in axonal growth cone function), while the remaining three represent previously unreported sequences. We are currently investigating the tissue expression patterns of these isolated cDNAs in order to assess their expression in motor neurons.

513.3

EXPRESSION OF A FUNCTIONAL FOREIGN GENE IN ADULT MAMMALIAN BRAIN FOLLOWING IN VIVO TRANSFER VIA A HERPES SIMPLEX VIRUS DEFECTIVE VIRAL VECTOR. M.G. Kaplitt[1], J.G. Pfaus[1], S.P. Kleopoulous*[,1], B.A. Hanlon*[2], S.D. Rabkin*[2], D.W. Pfaff[1]. [1]Laboratory of Neurobiology and Behavior, Rockefeller University, N.Y., N.Y., 10021;[2]Program in Molecular Biology, Memorial Sloan-Kettering Cancer Center, N.Y., N.Y., 10021.

We have used a herpes simplex virus type 1 (HSV1) defective viral vector for the transfer and expression of a foreign gene in the adult rat brain *in vivo*. The vector genome consists of multiple copies of an HSV1 amplicon, a plasmid-based cloning and amplifying construct which contains HSV1 cis-acting sequences, allowing packaging into defective HSV1 virions upon superinfection with a helper virus. Our amplicon, pHCL, utilizes a human cytomegalovirus promoter and bacterial lacZ gene as a reporter. Helper functions were provided by a temperature-sensitive mutant HSV1 strain, which does not replicate at physiological temperatures. The resulting defective viral vector (dvHCL) was stereotaxically microinjected into rat hippocampus and hypothalamus, and cells expressing enzymatically active β-galactosidase were detected in both regions. Expression was confined to regions at or near the site of injection. Control animals injected with helper virus alone were completely negative. Positive neurons were identified as soon as 18 hrs following injection, and expression was still detectable after 2 weeks. All animals survived and there was no behavioral, gross or microscopic anatomical evidence of a virulent neurologic infection. The unique advantages of the defective vector system include amplification of the reporter gene, localized expression without virulent spread due to a lack of autonomous amplicon replication and simple manipulation of the defective viral genome as a plasmid. Attempts are underway to express lacZ *in vivo* under the control of the vasopressin and enkephalin promoters.

EXPRESSION OF CHLORAMPHENICOL ACETYLTRANSFERASE FROM THE HUMAN MAO B PROMOTER. R. M. Denney and Abha Sharma*. Dept. of Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, TX 77550.

Monoamine oxidase (MAO) B oxidizes dopamine and β-phenylethylamine and activates the neurotoxin, MPTP. The X-linked, MAO B gene exhibits cell type-specific expression which differs from the similar and closely-linked MAO A gene. The MAO B promoter has not been functionally characterized. A 174 bp genomic fragment, which extends from an upstream Pst I site to a Sau 3a site in the 5'-untranslated region of exon 1, and which contains a TATA box-like sequence and a GC-box, was ligated in native orientation immediately 5' to a promoterless chloramphenicol acetyltransferase (CAT) gene in each of two vectors, one containing and one lacking an SV40 enhancer. Transient expression of the enhancer-containing construct led to detectable CAT activity in HeLa cells, which express endogenous MAO B activity and mRNA. No CAT activity was detected in HeLa transfected with an enhancer-containing CAT plasmid lacking the MAO B promoter insert, or an enhancerless plasmid containing the promoter insert. CAT vectors containing DNA extending further 5' from MAO B exon 1 are being tested to further define the promoter and to search for possible linked enhancer activity in the DNA region 5' to the MAO B gene. [Supported by NS 19543 and funds from the John Sealy Memorial Endowment, UTMB.]

TRANS-ACTING ELEMENTS AND OLFACTORY NEURON GENE TRANSCRIPTION. C. Stein-Izsak, M. Grillo, C. Behn*, M. Sakai*, J. Corbin*, F.L. Margolis, Dept. of Neurosciences, Roche Inst. of Molec. Biol., Nutley, NJ 07110

Olfactory marker protein (OMP) is an abundant, phylogenetically conserved gene product of mature olfactory receptor neurons. The OMP-gene lacks introns and CAAT or TATA box motifs characteristic of genes transcribed by RNA pol II. The pattern of OMP expression argues that it may represent a class of neuron-specific genes with novel transcriptional regulation. Previously, we described a 5' segment of the OMP gene that interacts only with extracts of olfactory epithelium (OE) (C. Stein-Izsak, M. Grillo, F. L. Margolis: Soc. for Neurosci., Abstr. 16, 158, 1990). DNase footprinting has identified a novel 17 bp motif as the binding site of this OMP gene binding protein (OMP-GBP). OMP-GBP activity is developmentally regulated and responds to olfactory nerve lesion. OMP-GBP elutes from heparin-agarose chromatography at 0.4 M KCl. A putative SP-1 site is located just 3' of the OMP-GBP sequence, but nuclear protein enriched extracts from rat OE lack an SP-1 shift in gel mobility shift assays. These extracts do contain activities that bind to consensus sequences for Oct-1, NF_KB, NF-1, and AP-3. In transgenic mice 3 Kb but not 0.3 Kb of 5' upstream OMP sequence gives appropriate, cell-specific reporter gene expression. Since the 0.3 Kb upstream sequence includes the novel footprint motif additional upstream regulatory elements are being sought.

513.6

FUNCTIONAL REGULATION OF PROGESTERONE RECEPTOR TRANSCRIPTIONAL ACTIVITY BY PHOSPHORYLATION. L.A.Denner, N.L.Weigel*, O.M.Conneely*, W.T.Schrader* and B.W.O'Malley* Dept. of Cell Biology, Baylor College of Medicine, Houston, TX 77030.

Phosphorylation regulates transcriptional activity of the progesterone receptor (PR) by ligand-dependent and ligand-independent mechanisms. We have used single amino acid substitution mutagenesis of serine 530 (S530), the progesterone-induced phosphorylation site, to elucidate the precise role of phosphorylation in functional regulation of the PR. S530 was mutated to glycine (S530G) to prevent phosphorylation and to aspartic acid (S530D) to constitutively provide negative charge, thus partially mimicking the charge provided by phosphorylation. All receptor forms had equal hormone binding and expression levels in transient transfections of CV1 cells. S530 and S530D had similar maximal transcriptional activation of the PRE-tk-CAT reporter gene while S530G was reduced 25-50%. Gel retardation studies using the PRE showed that S530D had substantially higher DNA binding than S530 and S530G, which were similar to each other. Indirect immunofluorescence indicated that S530 and S530G were localized exclusively to the nucleus after treatment with either progesterone or okadaic acid, a phosphatase inhibitor that activates PR-mediated transcription in the absence of progesterone by the ligand-independent pathway. S530D was perinuclear under all conditions. These observations suggest that the ligand-dependent pathway for transcriptional activation of the PR occurs by phosphorylation of S530, resulting in an increase in DNA binding activity. The ligand-independent pathway occurs by phosphorylation of a site distinct from S530.

POSITIVE AND NEGATIVE REGULATORY CIS-ACTING ELEMENTS IN GLUTAMINE SYNTHETASE EXPRESSION. H.J. Purohit*, R.G. King, H. Haleem-Smith*, V.P. Kedar*, and J.F. Mill. Lab. of Molecular Biology, NINDS, NIH, Bethesda, MD 20892.

Glutamine synthetase (GS) gene expression is confined to astrocytes in the CNS. The gene for GS was cloned and the 5' flanking region isolated. A series of deletion and site-directed mutants of the promoter region were generated by PCR, cloned into pSV_0CAT, and expressed in various cell lines.

We identified three regions of importance for the regulation of GS expression, an AP2 site located at -222, an enhancer region at -315, and a silencer region at -797.

The deletion mutants show that the AP2 and enhancer sites are sufficient for cell type specific expression. Inclusion of only the AP2 site created a small increase in expression while a large increase was seen when the enhancer region was included. This elevation was suppressed by the inclusion of the silencer region.

Site directed mutation studies demonstrate that while the AP2 site has only a small effect by itself, the enhancer region requires the AP2 site for its induction. Mutation of the silencer site leads to an increase in expression, though dual mutation of the AP2 and silencer sites further increase the promoter activity, suggesting that all three sites are interacting in controlling GS expression.

513.8

IDENTIFICATION OF A NOVEL REPRESSOR ELEMENT RESPONSIBLE FOR NEURAL-SPECIFIC EXPRESSION OF THE RAT BRAIN TYPE II SODIUM CHANNEL GENE. S.D.Kraner, K.M.Dains*, J.A.A.Chong* and G. Mandel*, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794. The mammalian voltage-gated Na channnel is encoded by a multi-gene family, the members of which are expressed in a tissue-specific manner. The brain type II Na channel is expressed in a neural-specific manner, in a restricted pattern throughout the CNS. We wished to determine the molecular basis of this transcriptional specificity of the type II gene. Neural-specific expression is faithfully reproduced in cell lines transfected with fusion genes containing 5'regulatory sequences of the type II gene fused to a reporter gene (minigenes). These minigenes direct high level reporter activity in PC12 cells, a neuronal-like cell line; only minimal reporter activity of the minigene is detected in the skeletal muscle cell line, L6. By deletional analysis, we have identified a 68 base pair (bp) element within the type II Na channel gene's 5' flanking region which is responsible for the repression of minigene activity in L6 cells. The element does not repress the high level expression of the same minigene in PC12 cells. Proteins which bind specifically to DNA probes containing the 68 bp element were found in nuclear extracts prepared from L6 cells but not in those prepared from PC12 cells. Furthermore, these proteins protect 28 out of the 68 bp in DNase footprinting assays using L6 nuclear extracts. The 28 bp sequence appears to represent a binding site for novel transcription factors. These factors achieve neural-specific expression by repressing gene activity in non-neural cells. The generality of this mechanism for neural-specific gene expression remains to be determined. This work was supported by an NRSA award to SDK and an NIH grant to GM.

IDENTIFICATION OF A RETINOIC ACID RESPONSE ELEMENT IN THE HUMAN OXYTOCIN GENE PROMOTER WHICH OVERLAPS WITH AN ESTROGEN RESPONSE ELEMENT. Stéphane Richard* and Hans H. Zingg. *Laboratory of Molecular Endocrinology, Royal Victoria Hospital, McGill University, Montreal, Quebec, Canada H3A 1A1*

We previously identified an estrogen (E_2) response element (ERE) at position -164 in the human oxytocin (OT) gene promoter (JBC 265:6098). By transient expression of OT 5'-flanking sequences linked to the CAT gene, we now show that retinoic acid (RA) elicits a 7-fold stimulation of the transcriptional activity of the OT promoter in neuroblastoma cells co-transfected with either the human RA receptor (RAR) α,β or γ. We further demonstrate that the presence of 4 TGACC repeats, located at -162, -156, -103 and -83, is an absolute requirement for maximal RA induction. Since the TGACC repeats at -162 and -156 are contained within the ERE (GGTGACCTTGACC), we next determined the level of synergism and/or interference that occurs when both hormones are added together. In constructs containing an intact ERE and all 4 TGACC repeats, RA and E_2 had an additive effect. By contrast, in constructs in which the TGACC repeats at -103 and -83 were deleted, RA *decreased* E_2-induced stimulation by ~50%. A likely interpretation of these data is that, in the absence of the two downstream TGACC repeats, the RAR is forming a transcriptionally inactive complex with the ERE and is thereby preventing the ER from binding to the ERE. The overlapping elements in the human OT promoter create a natural molecular model system for the investigation of interactions between nuclear factors.

513.10

A SILENCER-LIKE ELEMENT DETERMINES CELL TYPE SPECIFICITY IN THE PROMOTER OF THE RAT CHOLINE ACETYLTRANSFERASE GENE. Håkan Persson and Carlos F. Ibáñez, Department of Medical Chemistry, Laboratory of Molecular Neurobiology, Karolinska Institute, S-10401 Stockholm, Sweden.

The cDNA coding for the rat choline acetyltransferase (ChAT) was isolated and used as a probe to investigate the developmental and regional expression of ChAT mRNA in the rat CNS. Expression of ChAT mRNA was also studied in rat peripheral tissues where high levels of two ChAT transcripts were found in the testis.

A genomic clone containing 7kb of 5' flanking sequences from the rat choline acetyltransferase (ChAT) gene was isolated and shown to contain a TATA box-like sequence and several consensus binding sites for the transcription factor AP1. Two constructs containing 450 and 1450bp, respectively of 5' flanking sequences promoted expression of a fused chloramphenicol acetyltransferase (CAT) gene when transfected into fibroblast FR3T3, Sertoli TM4, pheochromocytoma PC12 and cholinergic neuronal SN6 cell lines. In contrast, a longer construct containing 3850bp of 5' flanking sequence allowed CAT activity only in the cholinergic cell line SN6 (although at 2 to 3-fold lower levels than those seen with the shorter constructs), while CAT activity with this construct was suppressed in the three other cell lines, including PC12 cells. This result suggests that the the distal region of the ChAT promoter contains a cell type-specific silencer-like element that restricts ChAT gene expression to cholinergic cells. NGF treatment of PC12 cells increased the promoter activity of the -450 and -1450 constructs approximately 4-fold and allowed promoter activity from the -3850 construct, indicating that elements involved in NGF responsiveness of the ChAT promoter are contained in the first 450bp of upstream sequence. Taken together, our results support a model in which gene transcription controlled by cell type-specific regulatory elements contribute to the establishment, maintenance and plasticity of neurotransmitter phenotypes in the nervous system.

REGULATION OF TISSUE- AND TREATMENT-SPECIFIC ppENK RNA INITIATION. G. Weisinger, J.D. DeCristofaro and Edmund F. La Gamma. Department of Pediatrics and Neurobiology, SUNY at Stony Brook, Stony Brook, NY

We previously demonstrated that rat preproenkephalin (ppENK) RNA is initiated from at least 4 start sites by primer extension and S1 analysis of striatal RNA (JBC 265:17389, 1990). To further compare specificity of usage, we surveyed 12 tissues in the basal state using primer extension analysis. E3 + E4 start sites accounted for 80% of the 1.4 kb striatal RNA species compared to a preferential usage of the E2 site in all other tissues; including the 1.7 kb RNA species seen in testes and epididymis. To evaluate effects of induction on usage, rats were given cholinergic drug treatments (nicotine 5 mg/kg + oxotremorine 1 mg/kg; sc q 12h up to 4d). Adrenomedullary E2 transcripts peaked at 2d increasing 5-fold while newly induced E4 transcripts increased 80 fold. In contrast, after hypoglycemia (insulin 10/kg sc, rescue at 2h with 40% sucrose PO), only the E4 transcript was increased (16-fold). Interestingly, in both treatment paradigms, steady state levels of adrenal ppENK mRNA increased 50 to 100 fold. In the striatum of the cholinergic treated groups, RNA initiation increased 10-15 fold but not after insulin treatment (hypoglycemia). These studies demonstrate tissue and treatment specific differences in ppENK RNA start site usage and steady state levels of mRNA. (NSF #BNS8719872.)

513.12

EXPRESSION OF BOVINE VASOPRESSIN IN THE HYPOTHALAMUS OF THE TRANSGENIC MOUSE AND ITS REGULATION DURING OSMOTIC CHALLENGE. H.L. Ang*, J. Funkhouser*, D.A. Carter, M.Y. Ho* and D. Murphy. Neuropeptide Laboratory, Institute of Molecular and Cell Biology, National University of Singapore, Kent Ridge Crescent, Singapore 0511.

A 13.4 kilobase genomic fragment of the bovine vasopressin (VP) gene was micro-injected into mouse oocytes. Four independent transgenic mouse lines were derived and three lines had been assayed for tissue distribution of bovine VP RNA. All lines showed bovine specific ovarian VP expression. In addition, two lines showed bovine VP RNA in the hypothalamus. In-situ hybridisation of transgenic mouse hypothalamic sections identified bovine VP RNA expressing cells in neurons of the supraoptic nuclei. When the transgenic animals were subjected to an osmotic stimulus (2% NaCl in their drinking water for 7 days), the bovine message level increased 1.6 fold, similar to that of the endogenous murine message.

These studies show that the 13.4 kilobase bovine genomic vasopressin fragment contains at least some of the regulatory elements necessary to direct tissue-specific expression and physiological regulation in the transgenic mouse hypothalamus.

FORMATION AND SPECIFICITY OF SYNAPSES V

514.1

ROLE OF SYNAPSIN I IN THE MATURATION OF FUNCTIONAL NEUROMUSCULAR SYNAPSES. B. Lu, P. Greengard and M.-m. Poo, Lab. of Molecular and Cellular Neurosci., Rockefeller Univ., New York, N. Y. 10021 and +Dept. of Biol. Sci., Columbia Univ., New York, N. Y. 10027

The synapsins are a family of neuronal phosphoproteins associated with synaptic vesicles, and believed to be involved in the regulation of neurotransmitter secretion. In the developing nervous system, the expression of synapsin I correlates with neuropile development and synapse formation. Recent morphological evidence suggests that the synapsins may play a causal role in synaptogenesis. Thus, transfection of cultured neuroblastoma cells with synapsin IIb cDNA results in marked increases in the number of nerve terminals per cell, in the number of synaptic vesicles per nerve terminal, and in the number of synapse-like contacts. We have now found that synapsin I, loaded into Xenopus embryos, promotes the functional maturation of developing neuromuscular synapses in culture. Spontaneous synaptic currents occurred with higher frequency and their amplitudes showed an earlier appearance of bell-shaped distribution indicative of more mature quantal secretion. Impulse-evoked synaptic currents also showed a significant increase in amplitude. These results provide physiological evidence for the involvement of synapsin I in the maturation of neuromuscular synapses.

514.2

TARGET CONTACT REGULATES CALCIUM TRANSIENTS IN NEURITES DURING SYNAPTOGENESIS. L. R. Funte, and P. G. Haydon, Dept. of Zoology and Genetics, Iowa State University, Ames, IA 50011.

It is known that calcium channels aggregate at presynaptic terminals (Charlton, 1990), however, the mechanisms that give rise to this channel distribution are unknown. Using cultured *Helisoma trivolvis* neurons, our goal is to determine the regulatory mechanisms controlling calcium channel distribution during synaptogenesis.

Individual neurons were plated into culture, and, after 1-3 days, action potential- evoked calcium transients were imaged using Fura-2. Trains of action potentials reliably evoked homogeneous calcium transients throughout the neuritic arbor. Single, dissociated muscle fibers from the supralateral radula tensor (SLT) muscle, the normal effector muscle of neuron B19, were plated onto neurites and allowed to contact overnight. Action potentials in synaptically connected neuromuscular preparations evoked a heterogeneous pattern of calcium transients, with the largest calcium transient being localized to the site of muscle contact.

We have begun to address the mechanism(s) underlying the focal calcium transients by first determining the time course of the transition to the heterogeneous state. Neurons were plated alone, in culture, and the calcium transients shown to be homogeneously distributed. Single muscle fibers were then plated on to the neurites, and by imaging sequential calcium transients, a transition to focal heterogeneity was determined to occur within 30 minutes of muscle contact.

514.3

MOTOR NERVE TERMINALS ARE SELECTIVELY ELIMINATED FROM REGIONS OF NEUROMUSCULAR JUNCTIONS FOCALLY BLOCKED WITH α-BUNGAROTOXIN. R.J. Balice-Gordon and J.W. Lichtman, Dept. Anatomy & Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110

Following multiply innervated neuromuscular junctions over time in living mice has shown that the postsynaptic ACh receptor regions beneath one motor axon are selectively eliminated while those beneath the other motor axon are maintained. After postsynaptic ACh receptor loss, the overlying motor nerve terminal is eliminated and that motor axon withdraws from the junction. The precocious loss of ACh receptors from beneath one input but not the other may lead to a decrease in the efficacy of the terminals of one axon and alter the competitive balance between the two inputs.

We tested this by saturating the ACh receptors with α-bungarotoxin in a portion of a singly innervated junction in adult mice using a focal labeling technique. In this way we decreased the synaptic strength of a few branches of a motor nerve terminal arbor while the other branches of that axon within the same junction were unaffected. We then followed the fate of the synaptic sites in blocked and unblocked regions over time. Several days after focal blockade was begun we found that the density of ACh receptors in the blocked region decreased, because existing receptors were eliminated from that region and no new receptors were inserted there. Furthermore, motor nerve terminals were eliminated from blocked receptor regions but not from unblocked regions. These results suggest that nerve terminals rendered inactive by postsynaptic blockade are at a disadvantage when forced to compete with nearby terminals on the same muscle fiber which have normal activity. A number of controls ruled out alternative explanations for this experimental outcome. We conclude that blocking the ACh receptors in a small region of a singly innervated adult junction simulates developmental synaptic competition between two different axons with intrinsically different activity patterns. This predictable way of inducing synaptic competition will help us learn how activity mediates the cascade of events that underlie synapse elimination.

514.4

HETEROSYNAPTIC SUPPRESSION OF DEVELOPING NEUROMUSCULAR SYNAPSES: HEBBIAN MODULATION *IN VITRO*. Y. Lo and M-m. Poo, Dept. of Biological Sciences, Columbia Univ., N.Y., N.Y. 10027

We have developed a nerve-muscle culture in which a single muscle cell was co-innervated by two embryonic spinal neurones, and the effect of electrical activity on the synaptic efficacy was examined after electrical stimulation was applied to one or both neurons. We found that brief tetanic stimulation of one neuron (100 pulses at 2-5 Hz) results in immediate functional suppression of the synapse made by the other un-stimulated neuron co-innervating the same muscle cells, as shown by a reduction in the amplitude of impulse-evoked synaptic currents recorded in the myocyte. Heterosynaptic suppression was observed regardless whether the tetanized synapse showed stronger or weaker synaptic efficacy prior to the tetanus, although stronger synapses were found to be more effective in inducing suppression. Synchronous application of tetanic stimulation to both neurons resulted in little or no suppression of both synapses, while the same tetani applied asynchronously (with 100 ms delay) to the two neurons led to marked suppression of one or both synapses. Finally, the heterosynaptic suppression was found to be absent when the distance between the sites of innervation made by two neurons was larger than 50 um, suggesting that the competitive interaction underlying the heterosynaptic suppression occurs only among adjacent synapses. These results are consistent with Hebb's postulate of synaptic modulation and provides an *in vitro* demonstration of activity-dependent synaptic competition at single-cell level.

514.5

SUPPRESSION OF DEVELOPING NEUROMUSCULAR SYNAPSE BY FOCAL IONTOPHORETIC APPLICATION OF ACETYLCHOLINE. Y. Dan and M-m. Poo, Dept. of Biological Sciences, Columbia Univ, N.Y., N.Y. 10021

Brief tetanic stimulation of a presynaptic neuron leads to rapid functional suppression of synapses made by other co-innervating neurons on the same postsynaptic muscle cell (see preceding abstract). In the present study, we tested the hypothesis that such heterosynaptic suppression was due to repetitive postsynaptic activation of myocyte acetylcholine (ACh) receptors by the stimulated neuron. We have examined the effect of repetitive focal iontophoretic application of ACh on the synaptic efficacy at a singly-innervated myocyte in 1-d old *Xenopus* cultures, using whole-cell voltage-clamp recording. The amplitude, duration and frequency of iontophoretic currents were adjusted to produce ACh-induced membrane currents of similar characteristics as those generated by ACh release from a tetanized neuron. We found that application of 100 pulses of ACh (at 2 Hz), each induced an inward current of peak amplitude of 1 to 3 nA and a duration of about 50-70 ms, consistently led to suppression of the synapse if the site of the ACh application was within 10-15 uM from the synapse. The suppression was not due to the desensitization of the ACh receptors by the ACh released during iontophoresis. Both the proximity requirement as well as the persistence of suppression following the repetitive stimulation are similar to the heterosynaptic suppression induced by nerve stimulation. The cellular events underlying the ACh-induced synaptic suppression, the involvement of Ca influx through the activated ACh channels in particular, remain to be investigated.

514.6

NMDA RECEPTOR ANTAGONIST BLOCKS SYNAPSE ELIMINATION DURING CEREBELLAR DEVELOPMENT. Y. Bailly, S. A. Rabacchi*, N. Delhaye-Bouchaud and J. Mariani*. Inst. Neurosc., CNRS & Univ. P. & M. Curie, Paris, France.

The glutamate receptor of the NMDA type has been reported to be involved in axonal remodelling in the immature visual system. During the postnatal development of the rodent cerebellum, the granule cells and the Purkinje cells exhibit a transient sensitivity to NMDA. This occurs precisely when the redundant synapses made by several climbing fibers on each Purkinje cell are eliminated, sculpting the adult one-to-one relationship between these two partners. Therefore, the cerebellum offers a unique model to test the hypothesis that the NMDA receptor participates in synapse elimination. In the present study, a selective antagonist of this receptor, the D,L-APV(1-10mM) was released chronically from a slice of Elvax polymer implanted on rat cerebellar surface during the whole period of synapse elimination (PN4-PN17). The degree of innervation of Purkinje cells by climbing fibers was then analysed by in vivo intracellular recording.

On 183 Purkinje cells recorded from 31 rats treated with D,L-APV, 47.5% remained innervated by 2 or 3 climbing fibers. By contrast, only 17.3% of 75 Purkinje cells recorded in 10 rats treated with the inactive isomer L-APV remained similarly polyinnervated; the polyinnervation persisted also in only 11.1% of the 57 Purkinje cells recorded from 8 rats implanted with Elvax alone.

These data suggest that the NMDA receptor plays an important role in the synapse elimination process, probably related to the modulation of Purkinje cell electrical activity by their afferences.

514.7

A ROLE FOR POST-SYNAPTIC NEURONS IN DETERMINING PRE-SYNAPTIC TRANSMITTER RELEASE PROPERTIES. G.W. Davis*, and R.K. Murphey. Program in Neuroscience and Behavior, University of Massachusetts, Amherst, MA 01002.

Interneurons MGI and 10-3 of the Cricket terminal abdominal ganglion have different response properties. MGI responds phasically to a 100 Hz sound stimulus while 10-3 responds tonically. This phasic/tonic difference is believed to reside in the properties of the sensory to interneuron synapses since neither accommodation of the sensory receptor nor adaptation of the sensory neuron can account for the phasic response of MGI. EPSPs recorded in the dendrite of MGI initially facilitate dramatically and then show pronounced response decrement during high frequency, 100-150 Hz, stimulation of single sensory neurons. We believe this high frequency plasticity is the basis for the phasic response of MGI and that synapses on 10-3 lack this plasticity.

To determine how synapses with different release properties are specified from a single population of sensory neurons on two different interneurons we have examined an identified sensory neuron (SN 3c) which simultaneously contacts both MGI and 10-3. 100Hz stimulation of SN 3c evokes EPSPs in MGI which facilitate dramatically followed by pronounced response decrement, while EPSPs simultaneously evoked in 10-3 are more stable, neither facilitating nor decrementing dramatically. We hypothesize that the post-synaptic interneurons have a role in determining the release properties of their presynaptic terminals. We are currently attempting a quantal analysis of these synapses and investigating the role of post synaptic activity in determining pre-synaptic release properties. Supported by NSF grant # BNS 90-96180.

PARKINSON'S DISEASE

515.1

FERRITIN mRNA EXPRESSION IN RAT BRAIN: EFFECTS OF 6-HYDROXDOPAMINE LESIONS AND LEVODOPA ADMINISTRATION. OJF Foster, A Kingsbury*, DT Dexter*, S Blunt*, SL Lightman, CD Marsden* and P Jenner*. Neuroendocrinology Unit, Charing Cross Hospital, Department of Clinical Neurology, Institute of Neurology, Queen Square, and Department of Pharmacology, King's College, London, UK.

Post-mortem studies of patients with Parkinson's disease (PD) reveal decreased levels of brain ferritin, both in the substantia nigra pars compacta (SNc) which is known to be damaged by the disease process, but also in apparently unaffected areas such as cerebral cortex. The pathogenetic significance of these changes is unclear.

In situ hybridisation histochemistry was used to study the distribution of heavy ferritin mRNA in rat brain and the effects of SNc lesioning and levodopa administration on its regional expression. Heavy ferritin mRNA was expressed chiefly in neurons. Neurons of the dorsolateral septal nucleus, hippocampus and several other brain regions were strongly labelled, moderate labelling was found in the SNc and cerebral cortex, while labelling of striatal cells was low. Following unilateral 6-hydroxydopamine lesioning of the nigrostriatal projection, ipsilateral SNc ferritin mRNA expression was reduced. Oral L-dopa administration for one month had no effect on expression of ferritin mRNA in cerebral cortex, hippocampus or SNc.

These results suggest that loss of nigral dopamine cells in PD could contribute to decreased ferritin levels in the SNc, but that the widespread reduction in brain ferritin seen in PD cases is not due to L-dopa therapy and may reflect an underlying defect of brain iron metabolism in such patients.

VULNERABILITY OF STRIATAL DOPAMINERGIC NEURONS TO FREE RADICALS: THE PROTECTIVE EFFECTS OF ZINC AND METALLOTHIONEIN. R.F. Pfeiffer* and M. Ebadi. Depts. of Pharmacol. and Neurol. Univ. Nebr. Coll. Med, 600 S. 42nd St., Omaha, NE 68198-6260.

The hallmark of Parkinson's disease is a major loss of dopaminergic neurons, causing a marked reduction in the concentration of dopamine in the corpus striatum. The surviving neurons are able to compensate by enhancing the rate of dopamine synthesis. Furthermore, it has been postulated that this may result in accumulation of peroxide-generating cell toxins causing oxidative stress, which may predispose to an accelerated rate of destruction of the remaining neurons. The altered levels of iron and transferrin in the substantia nigra of Parkinson's patients, along with the beneficial effects of α-tocopherol and/or *L*-deprenyl are additional suggestive evidence. Our laboratory has discovered and characterized metallothionein (MT) in several regions of mammalian brain, including striatum. Zinc, which is able to remove superoxide and displace iron as redox catalyst on macromolecules, is selectively reduced in 6-hydroxydopamine (8 μg in 4 μl of 0.02% ascorbic acid)-lesioned rat striatum. Similarly, MT, with its nucleophilic sulfhydryl group able to interact with intectrophilic toxins in regulating the intracellular redox potential, is also depleted in conditions causing destruction of striatal neurons. Moreover, neuroblastoma IMR-32 cells, unable to synthesize large amounts of MT in culture, exhibit far greater vulnerability to metal toxicity when compared to Chang liver cells, which synthesize copious amount of MT. The results of these studies are interpreted to indicate that zinc and MT may be involved in oxidative stress in Parkinson's disease. (Supported in part by a grant from USPHS ES-0349).

28kd CALCIUM BINDING PROTEIN IN MIDBRAIN CATECHOLAMINERGIC NEURONS FROM CONTROL SUBJECTS AND PATIENTS WITH PARKINSON'S DISEASE. E.C. Hirsch[1], A. Mouatt[1*], A.M. Graybiel[2], M. Thomasset[3], F. Javoy-Agid[1] and Y. Agid[1]. (1) INSERM U289,Hosp. Salpêtrière, 75013 Paris, France; 2) Dept of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139, USA; (3) INSERM U120, Hosp. Debré, 75019 Paris, France.

Neurons expressing 28kd Calcium Binding protein (CaBP) and tyrosine hydroxylase (TH) were analyzed immunohistochemically in midbrains from 3 controls and 3 patients with Parkinson's disease (PD). Double staining experiments showed that all TH-positive neurons were CaBP-positive in the dorsal mesencephalon (central grey substance and catecholaminergic region A8) and that only 10 to 20% of the CaBP-positive neurons were TH-negative. In the ventral mesencephalon (substantia nigra and ventral tegmental area) only rare CaBP-positive TH-positive neurons were detected, whereas most TH-positive neurons were CaBP-negative.

In PD, the loss of TH-positive neurons was moderate in the dorsal part and severe in the ventral part of the mesencephalon. The number of CaBP-positive neurons was not different in the midbrain of controls and parkinsonian patients. The results suggest that CaBP may contribute to the protection of catecholaminergic neurons that are not affected by pathological process in PD. Supported by INSERM and NIH# (NIH NS 25529).

EARLY STAGES IN NERVE CELL DEGENERATION IN MPTP-INDUCED PARKINSONISM IN THE SQUIRREL MONKEY. L.S. Forno, L.E. DeLanney, I. Irwin*, P. Bolt* and J.W. Langston. From the VA Medical Center, Palo Alto, CA 94304, and the California Institute for Medical Research, San Jose, CA 95128.

Three 10-12 year old squirrel monkeys were anesthetized and perfused intracardially with paraformaldehyde-glutaraldehyde and examined by electron microscopy (EM) 2, 3 and 4 days after a single s.c. injection of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) 2.5 mg/kg. In all three animals the substantia nigra (SN) displayed distended dendrites and axons containing membranous structures. Mitochondria were generally better preserved than other organelles. Axonal swellings in myelinated fibers were observed in the 2 day animal. Some nerve cells appeared normal; others showed loss of or disorganization of Nissl substance. In the striatum focal vacuolization was noted, and some nerve cell processes contained membranous material. Immunocytochemistry with antibody to tyrosine hydroxylase (TH) revealed striking preservation of TH positive fibers in the striatum in the 3 day animal, with some decrease in the 4 day monkey. In the SN nerve cell loss was not observed, but proximal portions of the nigro-striatal pathway showed swollen axons in the TH-reacted tissue. These findings correlate well with the biochemical changes recently reported in squirrel monkeys that received a similar regimen of MPTP (Brain Res 1990;531:242-252).

515.5

COMPARISON OF NEUROTOXIC ACTIONS OF MPP^+ AND NH_2-MPP^+ ON THE SURVIVAL OF PERIPHERAL ADRENERGIC NEURONS OF THE CHICK EMBRYO. S.V. Bhave, J. Johannssen# and A.R. Wakade. Dept. of Pharmacology, School of Medicine, WSU, Detroit, MI 48201 and # FDA, Washington, D.C.

Central dopaminergic neurons are the potential targets for MPP^+ and its analogues. The neurotoxic effect depends on the uptake of MPP^+ through the dopamine carrier system. Since sympathetic neurons (SN) demonstrate the high affinity and desipramine (DMI) sensitive norepinephrine uptake we examined the effects of MPP^+ and NH_2-MPP^+ on their survival in culture. When MPP^+ or NH_2-MPP^+ was added to the medium along with NGF almost all the neurons died after 2 days in culture. Toxic effect of MPP^+ was evident at 3 nM and was maximum at 1 μM. ED_{50} for MPP^+ and NH_2-MPP^+ was about 20 nM and 200 nM, respectively. Pretreatment of SN with DMI prevented the toxic effects of MPP^+ and NH_2-MPP^+. Neurotoxic effect of MPP^+ was not evident when it was added to the medium 24 hours after the neurons were plated. NH_2-MPP^+ was toxic even when added 24 or 48 hours after the start of culture. Sensory neurons were unaffected by as high as 10 μM MPP^+ or NH_2-MPP^+. Our studies show that primary cultures of chick SN could serve as an effective model to explore the mechanism of neurotoxic action of MPP^+ and related compounds.

CHRONIC NICOTINE ENHANCES THE DOPAMINERGIC NEUROTOXICITY OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPRYDINE IN BLACK MICE. R.A. Behmand* and S.I. Harik. Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

There is low prevalence of Parkinson disease among cigarette smokers. Nicotine is a major component of cigarette smoke. Thus, we examined the effect of chronic nicotine on 1-methyl-4-phenyl-1,2,3,6-tetrahydroprydine (MPTP) neurotoxicity. Adult male C57 black mice (25 g) were implanted sc under general anesthesia with Alzet minipumps loaded with 15-70 mg nicotine, that discharge their loads over 14 days. Control mice were not given nicotine. Seven days later, MPTP was injected sc, twice daily (6 hr apart) for 2 days. The total dose of MPTP ranged from 20-80 mg/kg. Seven days after MPTP, mice were killed and their striata dissected and analyzed for dopamine and its metabolites by high-performance liquid chromato-graphy with electrochemical detection. We found that nicotine at all doses significantly enhanced MPTP-induced reduction in striatal dopamine and its metabolites. Also, at the higher MPTP doses, several of the nicotine-treated mice died while none of the control mice died. The results strongly suggest that nicotine accentuates rather than reduces MPTP neurotoxicity.

515.7

CHANGES IN BRAIN CATECHOLAMINES AND DOPAMINE UPTAKE SITES AT DIFFERENT STAGES OF MPTP PARKINSONISM IN MONKEYS. G.M.Alexander, R.J.Schwartzman, J.R.Grothusen*, S.Gordon* and D.L.Brainard*. Department of Neurology, Jefferson Medical College, Philadelphia, PA 19107.

1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine (MPTP) has been shown to produce parkinsonism in primates. We have studied the changes in brain catecholamines and the distibution of desipramine insensitive Mazindol binding sites in MPTP parkinsonian primates. Thirty five monkeys (Macaca fascicularis) were utilized in this study. Twelve naive animals received no treatment and served as controls. Twenty three animals were rendered parkinsonian with serial injections of MPTP. All animals were given scored neurologic examinations throughout the study. Their movement was quantitated in an activity box. The animals were sacrificed 30-180 days after their last MPTP injection. The clinical exam in the MPTP parkinsonian monkeys ranged from mildly to severely affected, with dopamine depletions of 67.6-99.7% in the caudate nucleus, 48.7-99.8% in the putamen, and 0-40% in the nucleus accumbens. Frontal cortex norepinephrine was depleted 0-48.8% in these animals. Mazindol binding was decreased 30-98% in the caudate nucleus, 20-97% in the putamen, 0-26% in the nucleus accumbens, 80-96% in the substantia nigra pars compacta and 49-94% in the ventral tegmental area. In the striatum, the decreased mazindol binding was more promounced lateraly and posterior.

515.8

GENETIC EFFECTS ON DOPAMINE UPTAKE SITES IN THE STRIATUM. S. Roffler-Tarlov and A.M. Graybiel, Neuroscience Program, Tufts Univ. Sch. Med., Boston, MA 02111 and Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139

Weaver is classified as an autosomal recessive mutation because its behavioral phenotype is visible only in homozygous weaver mice. However, many cellular and biochemical effects of weaver appear in less severe form in the heterozygote in both neuronal systems known to be affected.

This report describes a deficit in ^{3}H-dopamine uptake (an indicator of function for dopamine-containing terminals) in the caudoputamen of the heterozygous weaver in which all dopamine-containing cell bodies survive in the substantia nigra and striatal targets display little loss of dopamine unlike in mice homozygous for weaver. For these experiments, ^{3}H-dopamine uptake and dopamine content were measured in synaptosomal preparations of the dorsal and ventral caudoputamen of adult homozygous normal, heterozygous weaver and homozygous weaver mice. The measurements of dopamine and ^{3}H-dopamine uptake in the homozygous weaver confirmed and extended previous findings of massive depletion of dopamine and even greater reduction of uptake capacity especially in the dorsal striatum. In the heterozygote, little loss of dopamine occurred and that was confined to the dorsal striatum. In contrast, uptake capacity for ^{3}H-dopamine was severely reduced in both the dorsal and ventral caudoputamen. Loss of uptake capacity amounted to 41% in the dorsal and 53% in the ventral caudoputamen of the heterozygote compared to normal mice.

The results add to the evidence showing that weaver exerts effects on neuronal processes that are not accompanied by cell death in the midbrain of the heterozygote. We suggest that these defects may lead to cell death in the homozygote where they are present in two doses.

ROTATIONAL BEHAVIOR ALTERATIONS FOLLOWING INFUSION OF GABAERGIC AGENTS INTO THE SUBTHALAMIC NUCLEUS (STN). P.M. Carvey, J.S. Kroin, D.H. Lin*, H.L Klawans*, and R.D. Penn. Depts. Neurology and Neurosurgery. Rush U, Chicago, IL.

GABAergic fibers from the basal ganglia regulate activity in the STN which in turn regulates the internal segment of the globus pallidum (GPi) via glutaminergic fibers. Lesions of the STN have been shown to reduce MPTP-induced parkinsonism in primates. We infused GABAergic agents into the STN and monitored apomorphine-induced contralateral rotation (APO-CR) in five, 6-hydroxydopamine (6-OHDA) lesioned rats to test whether modulating output affects rotation in this model. Using 0.5 µl/2.5 min injections through implanted guide cannulae the STN was infused with normal saline (NS), the GABA-A agonist muscimol (200 ng), or the GABA-A antagonist bicuculine (200 ng) at 2 day intervals. Bicuculine decreased APO-CR 79%, NS did not alter APO-CR, while muscimol increased it 157%. It appears that GABA outflow neurons from the striatum regulate activity in the STN which, in turn, influences the outflow from the GPi. Reducing the activity of the STN in the parkinsonian brain using drugs may therefore be beneficial in the treatment of Parkinson's disease.

515.10

PATHOLOGICAL CORRELATES OF DEMENTIA IN PARKINSON'S DISEASE. R.M. Zweig, J.C. Hedreen, M. Cohen*, S. Giere*, and D.L. Price. University of Nevada, Johns Hopkins, and Case Western Reserve Schools of Medicine.

Dementia in idiopathic, Lewy body positive, Parkinson's disease (PD) has been reported to be correlated with neuronal loss in the nucleus basalis (NB), substantia nigra para compacta (SN) (medial part), and locus coeruleus (LC), and with the presence of Lewy body-like (LB) inclusions in neocortex. We counted neurons at selected anatomical levels of the LC and SN, and rated NB neuronal loss and LB numbers in the anterior cingulate (ubiquitin immunocytochemistry), in 13 patients with pathologically confirmed PD without concurrent Alzheimer's disease. Individuals with dementia (7 patients, mean age 76.0) had significantly fewer neurons at all levels of the LC, but not the SN, greater NB neuronal loss, and more anterior cingulate LBs than those without dementia (6 patients, mean age 71.5). In conclusion, dementia in PD reflects patterns of extra-nigral neuronal involvement.

515.11

CELLULAR EXPRESSION OF CATECHOL-O-METHYLTRANSFERASE (COMT) IN RAT CNS AND PERIPHERAL ORGANS REVEALED BY IN SITU HYBRIDIZATION HISTOCHEMISTRY. J.G. Richards, B. Bertocci,* M. Da Prada* and P. Malherbe.* Pharma Division, Preclinical Research, F.Hoffmann-La Roche Ltd, CH-4002 Basel, Switzerland

COMT (EC 2.1.1.6), a membrane-associated enzyme, catalyzes the metabolism of dopamine, noradrenaline, adrenaline and other catechol derivatives. In the brain, COMT is responsible for the extraneuronal inactivation of catecholamines released into the extraneuronal space. cDNA clones for human and rat COMT have been recently isolated and sequenced (Bertocci et al., Proc. Natl. Acad. Sci. USA (1991) 88, 1416-1420; Salminen et al., Gene (1990) 93, 241-247). In order to identify the cells expressing COMT in rat CNS and peripheral organs, we used ^{35}S-labelled oligonucleotide probes (nucleotide sequences 92-152 and 587-647) for in situ hybridization histochemistry. Transcripts were found in discrete regions of rat brain (ependyma, choroid plexus, circumventricular organs, dentate gyrus granule cells > hippocampal CA1-4 pyramidal cells, cerebellar granule cells, Bergmann glia, brain stem nuclei - facial n., vestibular n., olive n., pontine n., > cerebral coretex, olf. bulb), leptomeninges, intracranial blood vessels, pituitary, kidney and placenta. The results suggest that non-neuronal elements provide an enzymatic barrier to the transport of catecholamines between the CSF and the brain (see also Kaplan et al., Brain Research (1981) 204, 353-360). The identity of neurones in the hippocampal formation and brainstem nuclei expressing COMT mRNA is being further investigated.

515.12

NEOSTRIATAL DOPAMINE DENERVATION FOLLOWING INTRASTRIATAL 6-HYDROXYDOPAMINE RESEMBLES WEAVER MOUSE STRIATUM. C. A. Altar, L. B. Jakeman, I. N. Acworth[1], R. H. Soriano, and M. Dugich-Djordjevic. Endocrine Research Dept., Genentech, Inc., South San Francisco, CA, 94080 and [1]ESA, Inc., Bedford, MA, 01730.

Injury to dopamine (DA) neurons was characterized following delivery of 6-hydroxydopamine (6-OHDA) to the rat striatum. Two wks after injecting 8, 25, or 100 µg of 6-OHDA, the density of striatal DA terminals, defined by [^{3}H]mazindol autoradiography, was lowered by 22, 48, and 52% respectively. Losses predominated in dorsal striatum. Caudal-rostral (1.4-fold) and medial-lateral (1.7-fold) gradients of increasing [^{3}H]mazindol binding in the intact striatum were abolished by 8 or 25 µg of 6-OHDA. Striatal contents of DA, 3-MT, DOPAC, and HVA and [^{3}H]mazindol binding were each decreased by 57-86% at 1 and 4 wks after 25 µg 6-OHDA, with a partial recovery in all measures by 4 weeks. Little or no alteration in 5-HT, NE, and related compounds were observed from 1-4 weeks post-injury. 6-OHDA or vehicle increased the density of the glial marker [^{3}H]PK 11195 but only adjacent to the cannula tract. Immunocytochemical staining at 2 wks after 25 µg 6-OHDA showed a 31-50% decrease in the number of tyrosine hydroxylase-positive neurons at 3 levels of the central and medial pars compacta of the substantia nigra but not in the VTA. Intrastriatal 6-OHDA treatment produces a reproducible, DA neuron-selective, and anatomically limited depletion of DA nerve terminals and cell bodies that closely resembles these patterns in weaver mouse striatum. The sparing of DA cell bodies relative to terminals provides a model for neurotrophic factor rescue or sprouting of DA neurons.

515.13

PERSISTENT CONSEQUENCE OF LIMITED TREATMENT WITH L-DOPA IN RATS WITH UNILATERAL NIGRAL LESIONS. P.B. Silverman. Dept. of Psychiatry and Behavioral Sciences, Univ. of Texas Health Sciences Center, Houston, TX 77030.

Rats with a unilateral 6-hydroxydopamine lesion of substantia nigra not only rotate (circle) contralaterally immediately after administration of the direct acting dopamine agonist, apomorphine, but also weeks later when they are reintroduced to the environment in which apomorphine had been administered. Here, the ability of limited L-DOPA treatment to result in similar conditioned rotation was tested. Lesioned, but otherwise drug-naive rats were administered 5 mg/kg carbidopa (ip) 30 min prior to 10 to 50 mg/kg L-DOPA (ip) and placed in hemispherical plastic bowls. Rotations in each direction were counted via a video camera and image analyzer. Two weeks after a single drug exposure, most rats briefly made rapid contralateral rotations when placed in the rotation bowls. As previously found with apomorphine, lower doses of L-DOPA were more effective than higher doses in conditioning this behavior in a single trial. Rats administered carbidopa + L-DOPA on three consecutive days generally showed an increased response to successive administrations (sensitization). Some thrice-treated animals also exhibited explosively rapid rotation when returned, undrugged, to the environment associated with L-DOPA. This striking rotation developed progressively over several months after the last drug treatment and may prove to be a useful model for study of abnormal involuntary movements associated with parkinsonism. (Supported by NIDA grant DA06269).

516.1

NMDA RECEPTOR-MEDIATED MOBILIZATION OF INTRACELLULAR Ca^{2+} STORES IN PRIMARY CENTRAL NEURONS. Sizheng Z. Lei, Dongxian Zhang, and Stuart A. Lipton. Dept. of Neurology, Children's Hospital & Program in Neuroscience, Harvard Medical School, Boston, MA 02115.

NMDA receptor-mediated increases in $[Ca^{2+}]_i$ were examined using digital imaging techniques with the dye fura-2 in primary cultures of rat neonatal retinal ganglion cell or cortical neurons. Bath application of MK-801 (12 μM), APV (200 μM), magnesium (1 mM) or EGTA (2 mM) completely blocked NMDA-evoked increases in $[Ca^{2+}]_i$. Also, a 2 min preincubation with 30-100 μM dantrolene, a drug that blocks Ca^{2+} release from sarcoplasmic reticulum and possibly from neuronal intracellular stores (Hernandez-Cruz et al., *Soc. Neurosci. Abstr.* 1989;15:17), produced a dose-dependent inhibition of the NMDA-evoked $[Ca^{2+}]_i$ increase; maximal block was 60% of the Ca^{2+} response. In whole cell patch-clamp recordings, dantrolene did not inhibit NMDA-activated currents. This result is in agreement with receptor binding studies showing no direct interaction of dantrolene with glutamate receptors (Frandsen & Schousboe, *J. Neurochem.* 1991;56:1075). With 2 mM EGTA and no added calcium in the bath, 2 μM ionomycin produced a transient increase in $[Ca^{2+}]_i$, apparently depleting intracellular stores. This effect of ionomycin could be prevented by preincubation with dantrolene, consistent with an intracellular mode of action of dantrolene. Taken together, these results suggest that NMDA-stimulated Ca^{2+} influx through ion channels leads to the mobilization of intracellular Ca^{2+} stores. Hence, both extracellular and intracellular calcium pools may be important for NMDA receptor-mediated physiologic and neurotoxic events.

516.2

EFFECTS OF THE 1S,3R- AND 1R,3S- ISOMERS OF 1-AMINOCYCLOPENTANE-1,3-DICARBOXYLIC ACID (ACPD) ON METABOTROPIC EXCITATORY AMINO ACID (EAA) RECEPTOR COUPLING IN RAT BRAIN SLICES. D.D. Schoepp, B.G. Johnson, and J.A. Monn. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285

The selective metabotropic EAA receptor agonist (±)*trans*-ACPD is a racemic mixture of 1S,3R- and 1R,3S- stereoisomers. These ACPD isomers were characterized for efficacy and affinity at metabotropic EAA receptors using cross-chopped slices from regions of the adult rat brain. 1S,3R-ACPD was substantially more efficacious than 1R,3S-ACPD as a stimulator of ^{3}H-phosphoinositide hydrolysis (indexed by ^{3}H-IP formation) in rat hippocampus, cerebral cortex, and striatum (see table below, N.D. = not possible to determine).

	EC50 (μM)	MAXIMAL EFFECT (% OF BASAL HYDROLYSIS)	N
Hippocampus			
1S,3R-ACPD	40.1 ± 5.7	507 ± 26 @ 300μM	5
1R,3S-ACPD	N.D.	161 ± 13 @ 1000μM	6
Cerebral Cortex			
1S,3R-ACPD	80.9 ± 9.1	462 ± 13 @ 300μM	6
1R,3S-ACPD	N.D.	171 ± 10 @ 1000μM	6
Striatum			
1S,3R-ACPD	22.9	159 ± 9 @ 300μM	8
1R,3S-ACPD	N.D.	119 ± 5 @ 1000μM	8

Further studies in adult rat hippocampus showed that1R,3S-ACPD inhibited 1S,3R-ACPD (100μM) stimulation of ^{3}H-IP formation with an IC50 = 475 ± 24 μM and a maximal effect of 65 ± 2% inhibition @1000μM (n=3). Thus, in adult rat brain tissue 1S,3R-ACPD is a full metabotropic agonist. However,1R,3S-ACPD is a partial agonist with relatively low intrinsic activity, and therefore it acts as an antagonist at fully activated metabotropic EAA receptors.

516.3

ACTIVATION OF THE METABOTROPIC EXCITATORY AMINO ACID (EAA) RECEPTORS BY INTRASTRIATAL INJECTION OF 1S,3R-1-AMINOCYCLOPENTANE-1,3-DICARBOXYLIC ACID (1S,3R-ACPD) INDUCES CONTRALATERAL TURNING. A.I. Sacaan, J.A. Monn and D.D. Schoepp. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285

1S,3R-ACPD is a selective agonist at the metabotropic EAA receptor (see Schoepp et al., this issue). In this study we have investigated the consequence(s) of activating the metabotropic EAA receptor *in vivo*. Unilateral intrastriatal injection of 1S,3R-ACPD produced dose-related turning behavior as indexed by contralateral rotations (ED_{50} value = 0.59 μmole / 2 μl, 32 ± 4 rotations/5min at 1 μmole / 2 μl). This effect of 1S,3R-ACPD was not mimicked by saline vehicle (2 μl) or by the less active ACPD isomer at this receptor, 1R,3S-ACPD (2 μmole / 2 μl). Administration of the NMDA receptor antagonist LY274614 (2.5 mg/kg i.p.) did not significantly alter 1S,3R-ACPD (1 μmole)-induced rotations. However, coinjection of the metabotropic receptor antagonist L-AP3 (1 μmole) significantly reduced rotations by 1S,3R-ACPD (1 μmole). Maximally effective behavioral doses of 1S,3R-ACPD did not lead to loss of striatal GABA neurons, as indexed by glutamic acid decarboxylase (GAD) activity in the injected striatum. NMDA (0.2 μmole/ 1 μl) weakly induced contralateral rotations (3.5 ± 2.4 / 5 min), but unlike 1S,3R-ACPD, this was associated with severe clonic convulsions, and a 50 ± 9% loss of GAD activity. This suggests that 1S,3R-ACPD-induced rotations are a behavioral consequence of activating striatal metabotropic EAA receptors. Furthermore, unlike ionotropic EAA receptor activation, direct *in vivo* metabotropic EAA receptor activation is not associated with convulsions and / or excitotoxicity.

516.4

EVIDENCE THAT NMDA RECEPTORS STIMULATE DEPHOSPHORYLATION OF DARPP-32 BY CALCINEURIN IN STRIATAL NEURONS. S. Halpain, G. Snyder, and P. Greengard. Laboratory of Molecular & Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

DARPP-32 is enriched in the medium-sized spiny neurons of mammalian neostriatum. In most cases, dopamine and glutamate have opposite effects on the physiological activity of these cells. One mechanism for antagonistic interactions of glutamate and dopamine on these cells may involve DARPP-32. The phosphorylation state of DARPP-32 on a threonine residue (Thr-34) is increased by dopamine via activation of cAMP-dependent protein kinase. We recently showed that glutamate, via NMDA receptors, is able to antagonize this effect. We suggested that the calcium/calmodulin-dependent protein phosphatase (PP2B, also called calcineurin) might mediate this effect. NMDA receptor activation is known to trigger an increase in intracellular calcium. Both calcineurin and PP2A can dephosphorylate Thr-34 of DARPP-32 in vitro. Okadaic acid is a compound which selectively inhibits PP2A, but not PP2B. We have treated slices of rat brain striatum with okadaic acid in order to examine whether the NMDA effect is mediated by PP2A or by PP2B.

Okadaic acid increased the basal phosphorylation of DARPP-32 Thr-34 in a dose-dependent and time-dependent manner, suggesting that an okadaic acid-sensitive phosphatase does regulate DARPP-32 phosphorylation in vivo. However, okadaic acid did not inhibit the ability of NMDA to induce dephosphorylation of Thr-34. These results suggest that PP2B, but not PP2A, mediates the action of NMDA receptors on DARPP-32 dephosphorylation, and support our hypothesis that NMDA receptors are coupled, via calcium, to the activation of calcineurin.

NEW NON-NMDA ANTAGONIST DISCRIMINATES BETWEEN AMPA AND KAINATE RESPONSES ON CORTICAL NEURONES IN VITRO BUT NOT ON SPINAL NEURONES IN VIVO. M.G. Jones, A. Palmer and D. Lodge, Department of Veterinary Basic Sciences, Royal Veterinary College, NW1 OTU, U.K.

We have used bath application to cortical wedges and electrophoretic application to spinal neurones in halothane-anaesthetised rats, to characterise non-NMDA receptors in the mammalian central nervous system with a novel benzodiazepine compound, GYKI (Tarnawa et al, 1989). On cortical slices, GYKI had an IC50 vs AMPA (40uM) of 12 ± 1.5uM, whereas responses to KAIN (5uM) and NMDA (40uM) were reduced by 50 and 20% respectively. The AMPA dose-response curve was shifted in a more or less parallel manner. On spinal neurones in vivo electrophoretic GYKI reversibly reduced responses to AMPA, KAIN and NMDA by 58 ± 27, 43 ± 28 and 17 ± 18% respectively. Similar benzodiazepine analogues may prove to be useful non-NMDA antagonists with pharmacological and therapeutic benefits.

516.6

MULTIPLE QUISQUALATE UPTAKE SITES IN RAT HIPPOCAMPAL SLICES Ian C. Kilpatrick* and Peter S. Harrison* (SPON: Brain Research Association). *Department of Pharmacology, University of Bristol, Bristol, BS8 1TD, UK.*

Potentiation of the depolarising action of the excitatory amino acid (EAA) agonist, quisqualate (QUIS), by uptake blockers suggests the compound may be subject to uptake mechanisms. However, we have already shown an absence of active uptake of 16μM QUIS into rat hippocampal slices [Harrison & Kilpatrick (1991) *J. Physiol. (Lond).* **435**, 43P]. The aim of this study was to directly investigate the accumulation of higher QUIS concentrations. In addition, since active EAA transport appears to occur via 2 distinct sites: a high-affinity, Na^+-dependent carrier and a lower-affinity, Cl^--dependent/Ca^{2+}-potentiated site, the relative effects of replacement of Na^+ and Cl^- with impermeant ions has been examined.

Following incubation of 400μm slices with either 200μM or 2mM QUIS for 4 min at 25°C, homogenate levels of QUIS as measured by HPLC were 502 ± 53 and 2871 ± 128 pmol/slice (mean ± S.E.M; n=7 and 8, respectively). Both values were reduced to at least 60% of control after incubation at 2°C or by inclusion of 100μM ouabain. On complete replacement of the Na^+ content of the Krebs'-bicarbonate buffer by choline, QUIS accumulation at 200μM was greatly reduced (-83.8%, n=3; $P<0.01$, Student's *t*-test). Conversely, substitution of the medium Cl^- content by either ethanoate (CH_3COO^-) or methanesulphonate ($CH_3SO_3^-$) did not influence QUIS transport at this concentration (+0.4%, n=3 and +2.1%, n=3, respectively). At 2mM QUIS, however, Cl^- substitution with $CH_3SO_3^-$ but not with CH_3COO^- (+7.5%; n=3), induced a significant reduction in uptake of -22.7% (n=3, $P<0.05$), whereas replacement of Na^+ offset uptake by -72.2% (n=3, $P<0.01$).

It would appear that accumulation of QUIS at 200μM is predominantly via a Na^+-dependent transport site but at higher concentrations (*e.g.* 2mM), a lower-affinity, Cl^--dependent component augments uptake. The influence of medium HCO_3^- and Ca^{2+} content on QUIS uptake is presently under investigation.

We thank the Medical Research Council.

OPEN-CHANNEL BLOCK OF NMDA RESPONSES BY THE ANTIPARKINSONIAN DRUG MEMANTINE.

H.-S. Vincent Chen and Stuart A. Lipton. Depts. of Biol. Chem. & Molec. Pharm. and Neurology, Harvard Medical School, Boston, MA 02115.

Excessive activation of *N*-methyl-D-aspartate (NMDA) receptors is thought to mediate neurotoxicity during cerebral anoxia, stroke, and several neurodegenerative diseases. NMDA antagonists therefore have therapeutic potential for these diseases. One type of antagonist (e.g., MK-801) is a use-dependent NMDA open-channel blocker. Recently, memantine, an antiviral and antiparkinsonian drug, was also reported to be a use-dependent antagonist of NMDA-evoked current and to inhibit [^{3}H]MK-801 binding (Bormann, *Eur. J. Pharm.* 1989;166:591; Kornhuber & Bormann, *ibid.* 589). We used the whole-cell patch clamp technique on rat retinal ganglion cells to characterize further the mechanism of memantine block of NMDA-activated current. At a holding potential (V_H) of -60 mV, 12 μM memantine selectively and nearly completely inhibited the current elicited by 200 μM NMDA (n = 11) without affecting kainate (50 μM) and quisqualate (5 μM) responses. The memantine blockade was voltage dependent (little inhibition at V_H = +50 mV) and could be abolished by pre-exposure to 3 mM extracellular magnesium. The rate of recovery from memantine blockade was also voltage- and agonist-dependent. Taken together, the evidence suggests a mechanism of open channel block. Compared to MK-801, however, memantine has much faster macroscopic blocking and unblocking rates ($\tau \approx$ 1.1 s and 6.5 s, respectively; V_H = -60 mV, $K_d \approx$ 2 μM). With these fast kinetics at concentrations previously shown to be clinically tolerated, memantine-like drugs may eventually prove useful as NMDA antagonists for future therapeutic intervention.

EFFECTS OF POLYAMINES AND THEIR ANTAGONISTS ON NMDA-STIMULATED INCREASES OF INTRACELLULAR CALCIUM.

G.A. Pritchard*, C.M. Conaty and L.G. Miller. Div. of Clinical Pharmacology, Tufts-New England Medical Ctr., Boston, MA 02111.

The endogenous polyamines (PA) spermine and spermidine specifically modulate NMDA-receptor mediated events (e.g. [^{3}H]MK801 binding and ionic currents). Antagonists and inverse agonists suspected of interacting with this polyamine site have also been described. We have characterized the activity of various agonists, antagonists and inverse agonists at the NMDA-receptor in a system utilizing NMDA-stimulated changes in intracellular calcium (Cai) of cultured chick cortical neurons. Spermine and spermidine potentiated an increase in intracellular calcium.in the presence of maximally effective concentrations of NMDA (500 μM) and glycine (100 μM) (EC_{50}s: 346 μM and 734 μM, respectively). Both compounds demonstrated an inversion of the dose response curve for concentrations above 1.5 mM in the presence of NMDA and glycine. Both polyamines were moderately effective at elevating Cai in the absence of added NMDA and glycine (11 % of basal) likely due to endogenous glutamate and glycine. Contrary to previous reports, in the present system the purported antagonist diethyltriamine (DET) and the endogenous PA putrescine were virtually ineffective at the PA recognition site showing only moderate (12 %) reversal when administered at 2.5 mM. Arcaine and diaminodecane (DA10) were potent antagonists (250 μM, approx. 40 % reduction) of PA-stimulated increases in Cai. Arcaine and DA10 also displayed inverse agonist properties in the presence of NMDA and glycine (53 and 38 % decrease of maximal NMDA/glycine response, respectively. It is possible that the activity of Arcaine and DA10 in the absence of added PA agonists is due to interaction with endogenous polyamines.

DO PUTATIVE POLYAMINE ANTAGONISTS ACTUALLY ANTAGONIZE A FUNCTIONAL RESPONSE TO POLYAMINES: AN ANALYSIS IN THE RAT CORTICAL WEDGE MODEL

P. A. Boxer and L.J. Robichaud, Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

Recent evidence has suggested that polyamines such as spermine and spermidine bind to a site associated with the NMDA receptor-ion channel complex and act to enhance responses to excitatory amino acids. Previously, we have demonstrated that the rate of spontaneous epileptiform discharges (SED) in the rat cortical wedge model (in Mg^{++}-free buffer) is increased in the presence of spermine (30 μM to 1 mM). This increase in rate is both time and dose dependent; however, treatment with 1 mM for >90 min or exposure to 3 mM spermine blocks the discharges. Several compounds have been described as polyamine antagonists: arcaine (1,4-diguanidinobutane), putrescine (1,4-diaminobutane), the antihypertensive, ifenprodil, and DET (diethylenetriamine); as well as the inverse agonist 1,10-diaminodecane (DA10). Arcaine (30-100 μM) and putrescine (3 mM) increased SED rate, similar to spermine. These diamines both left shifted the dose-response curve to spermine, suggesting that they are agonists at the polyamine site. Ifenprodil produced a slight increase in SED rate at 10 μM and inhibition at higher concentrations. The inhibition could not be reversed by spermine nor was the enhancement at low doses additive with spermine. Based upon this data it would appear that ifenprodil does not interact in a competitive manner with spermine at the polyamine site. On the other hand DA10 at a concentration which had no effect on its own (100 μM) blocked the increase in SED rate produced by spermine . No evidence of inverse agonism was detected. In conclusion, in a model where polyamines clearly affect NMDA mediated responses only DA10 functioned as a polyamine antagonist.

COMPETITION BETWEEN Mg^{2+} AND PCP FOR BLOCK OF NMDA ACTIVATED CHANNELS IS REDUCED AT DEPOLARIZED POTENTIALS.

M.V.L.Bennett*, A.Garcia-Ballesteros, R.S. Zukin*, and J. Lerma. Instituto de Neurobiologia S. Ramon y Cajal, CSIC, Madrid, Spain and Albert Einstein College of Medicine, Bronx, NY 10461

We recently showed that physiological concentrations of Mg^{2+} greatly impede the ability of phencyclidine (PCP) to block NMDA activated channels. Receptors were expressed in *Xenopus* oocytes injected with rat brain mRNA and voltage clamped at -60 mV (Lerma et al., Neurosci. Lett. 123: 187-191, 1991). Block was competitive in that Mg^{2+} decreased the potency of PCP in blocking open NMDA channels without changing its maximum effect, i.e., complete block. Channel block by Mg^{2+} or PCP alone is reduced by depolarization, and since neurons are often depolarized, it was of interest to determine the effect of depolarization on the interaction of PCP and Mg^{2+}. PCP and Mg^{2+} applied together reduce NMDA-induced currents more than do either blocker alone. However, the degree of PCP block can be estimated by removal of NMDA and blockers, thereby trapping PCP in the channel, and reapplication of NMDA alone, which provides a test of the extent of PCP trapping and of the original degree of block. By this method we found that at -20mV Mg^{2+} (0.5mM) had almost no effect on PCP block of NMDA-activated channels. This result is not unexpected, given the greater charge on Mg^{2+} and the likelihood that a substantial component of PCP binding is due to non-electrostatic interactions. Our results suggest that neuronal activity will affect Mg^{2+}/PCP interaction *in vivo* and alter the pharmacodynamics of PCP. This factor may account for differences in behavioral effects of PCP receptor ligands and competitive antagonists at NMDA receptors.

NON-COMPETITIVE NMDA-CHANNEL BLOCKERS INCREASE MEMBRANE CONDUCTANCE AND GLUTAMATE RESPONSES IN CULTURED ASTROCYTES.

C.M. Müller, C. Kleingoor*[1] and H. Kettenmann[1]. Max-Planck Institute for Developmental Biology, Tübingen, FRG;[1] Dept. Neurobiol., University Heidelberg, Heidelberg, FRG

Astrocytes have been shown to express multiple transmitter-gated ion channels, including glutamate-gated kation conductances. We used the whole cell patch clamp technique to study the influence of the non-competitive N-methyl-D-aspartate (NMDA) channel blockers ketamine and MK-801 onto glutamate activated membrane currents of cultured rat cortical astrocytes. With caesium present in the recording pipette, glutamate (10^{-3}-10^{-4} M) activated an inward current ranging from 50 to 600pA. Concomitant application of MK-801 or ketamine (10^{-3}-10^{-4} M) resulted in a profound increase (up to 300%) in current amplitude. Application of the NMDA antagonists alone, also elicited a small inward current. However, the overall enhancement of the glutamate current could not be accounted for by a simple additive effect. The fact that responses elicited by glutamate, NMDA-antagonists, or the combination of both, reversed near 0 mV excludes the possibility that the currents reflect an uptake mechanism. In addition, we also observed a comparable potentiation of kainate currents by NMDA channel blockers. The data show that astroglial cells are targets of non-competitive NMDA antagonists and call for special care in the interpretation of experiments obtained with systemic application of these compounds. ALZHEIMER'S AND CONTROL BRAIN CONTAIN SOLUBLE ß AMYLOID PROTEIN PRECURSOR DERIVATIVES ENDING AT POSITION 15 OF THE ß AMYLOID PROTEIN. J. Pasternack[1], R. Cotter*[2], B. Greenberg[3], R. Heinrikson*[3], D. Lowry*[3], M. Usiak*[1], R. Wang*[2], H. Zurcher-Neely*[3], and S. Younkin[1]. [1]Case Western Reserve Univ., Cleveland, OH 44106; [2]Middle Atlantic Mass Spectrometry Facility, Johns Hopkins Univ., Baltimore, MD 21205; [3]Upjohn Laboratories, Kalamazoo, MI 49001.

To identify the carboxyl terminus of the ~125 and ~105 kDa soluble ß amyloid protein precursor (ßAPP) derivatives produced from full-length membrane-associated ßAPP, we purified these derivatives, digested with CNBr, separated the CNBr peptides by RPLC using a C18 column, identified putative C-terminal peptides by ELISA with anti-βAP_{1-40} (provided by D. Selkoe), and characterized these peptides. To implement this approach, we first analyzed the abundant soluble ßAPP derivatives secreted by Sf9 insect cells infected with baculovirus expressing full-length βAPP_{751} (Bac_{751}) or βAPP_{695} (Bac_{695}). Two ßAP-bearing peptides were readily separated and identified in the CNBr digest of these derivatives, and analysis by direct sequencing, amino acid composition, and mass spectrometry showed these peptides to be βAP_{1-16} and βAP_{1-15}. This indicates that Sf9 insect cells, like human embryonic kidney (293) cells (Esch et al., Science 248: 1122, 1990), produce soluble derivatives by cleaving full length ßAPP at βAP_{15-16}. Soluble ~125 and ~105 kDa ßAPP derivatives isolated from AD or control brain were analyzed in a similar fashion. In both the AD and control brain, C-terminal βAP_{1-15} was identified by RPLC in conjunction with direct sequencing and mass spectrometry. These data indicate that, in human brain, as in other cells, soluble ßAPP derivatives are produced by cleavage at βAP_{15-16}. It is not clear, however, that this is the only or even the major cleavage producing soluble derivatives in human brain. Additional analysis is needed to determine if cleavage producing soluble derivatives occurs at multiple sites producing the multiplicity of carboxyl-terminal ßAPP fragments that we have observed in human brain and cultured cells (see Estus et al., Golde et al., these meetings). It will be important, in particular, to determine if even a small fraction of the soluble derivatives in AD or control brain are potentially amyloidogenic forms containing the entire ßAP.

517.2

C-TERMINAL FRAGMENTS CONTAINING FULL LENGTH ß AMYLOID PROTEIN ARE PRODUCED DURING NORMAL PROCESSING OF THE ß AMYLOID PROTEIN PRECURSOR IN CULTURED CELLS. T. E. Golde, S. Estus, L. Younkin, M. Usiak, and S. G. Younkin. Institute of Pathology, Case Western Reserve University, Cleveland, OH 44106

Processing of the ß amyloid protein precursor (ßAPP) along a secretory pathway generates a soluble C-terminal truncated form and a membrane associated C-terminal fragment. Using a pulse chase paradigm followed by immunoprecipitation of cellular lysates with an anti-C-terminal ßAPP antibody (provided by D. Selkoe), we have studied the processing of the ßAPP in human embryonic kidney (293) cells overexpressing full length βAPP_{695}. Using Tris/tricine SDS PAGE, we have identified a set of at least five 8-12 kDa C-terminal fragments in these cells. These fragments appear to be derived from processing of the full length ßAPP because they appear after the synthesis of full length ßAPP. Two findings indicate that the two largest C-terminal fragments contain full length ß amyloid protein (ßAP): 1) labeling of these fragments with antibodies raised against the first 17 aa of the ßAP (provided by B. Greenberg) and 2) comigration of the second largest fragment with a band augmented in 293 cells transfected with constructs expressing the full length ßAP through the C-terminus of the ßAPP. Essentially the same set of at least 5 C-terminal fragments is present in control 293 cells (although at a much reduced level); in a variety of human cell lines including fibroblasts, neuroblastomas, and a teratocarcinoma; and in human brain (see Estus et al., these meetings) indicating that ßAPP processing in human brain is similar to that in cultured cells. However, marked quantititive differences in the proportions of these fragments are observed in various cell lines and tissues, and several cell lines produce additional fragments. We are currently investigating whether the multiple C-terminal fragments that we have identified are generated through the secretory pathway that produces soluble ßAPP derivatives or via an alternative metabolic route.

517.3

POTENTIALLY AMYLOIDOGENIC C-TERMINAL FRAGMENTS OF THE ß-AMYLOID PROTEIN PRECURSOR IN HUMAN BRAIN. S. Estus[1], T. Golde[1], T. Kunishita*[2], D. Blades[1], M. Eisen*[1], D. Lowery*[3], M. Usiak*[1], B. Greenberg[3], and S. Younkin[1]. [1]Case Western Reserve Univ., Cleveland, OH 44106; [2]Natl. Inst. of Neuroscience, Kodaira, Tokyo 187, Japan; [3]Upjohn Labs, Kalamazoo, MI 49001.

The 39-42 residue ß-amyloid protein (ßAP) deposited as amyloid in Alzheimer's disease (AD) is an internal peptide that begins 99 residues from the C-terminus of alternatively spliced, 695-770 residue, membrane-associated ßAP precursors (ßAPP). Previous studies in this and other laboratories have established that full-length ßAPPs are normally cleaved near their C-termini to produce large secreted derivatives and small C-terminal fragments. To isolate ßAPP C-terminal fragments from human brain, detergent extracts of a human cerebral cortical membrane fraction were passed over an immunoaffinity column containing a polyclonal antibody (anti-$\beta APP_{672-695}$) raised against the last 24 amino acids of full length ßAPP. Proteins eluted after extensive washing were separated using Tris/tricine SDS/PAGE, and immunoblotted. The superior resolution of small proteins afforded by Tris/tricine SDS/PAGE revealed at least 5 distinct proteins (~11.8, ~11.4, ~10.9, ~9.6, and ~8.7 kDa) migrating between the 6 and 12 kDa markers. Each of these proteins was specifically labeled with anti-$\beta APP_{672-695}$ as well as three other anti-C-terminal antibodies (provided by D. Selkoe). The ~11.4 kDa polypeptide comigrated with a 100 residue C-terminal fragment (which begins with $M\beta AP_{1-42}$) synthesized in a rabbit reticulocyte lysate system. Anti-βAP_{1-40} (provided by D. Selkoe) labeled the ~11.8 and ~11.4 kDa proteins, and this labeling was abolished by absorption with βAP_{1-15} and βAP_{1-17} as well as βAP_{1-40}. Anti-βAP_{1-17} also labeled the two largest C-terminal fragments. Using pulse-chase methodology (see Golde et al., these meetings), we identified an essentially identical set of at least 5 C-terminal ßAPP fragments in cultured 293 cells that are produced by metabolism of full-length ßAPP. Taken together these data indicate that multiple C-terminal ßAPP fragments are produced in human brain some of which contain the entire ßAP and hence are potentially amyloidogenic. Significantly, our preliminary data indicate that tissues showing marked amyloid deposition (e.g. temporal cortex) have high levels of potentially amyloidogenic C-terminal derivatives whereas relatively non-amyloidogenic tissues (cerebellum, liver, kidney) have predominantly the smaller C-terminal fragments.

517.4

CHARACTERIZATION OF β-AMYLOID PRECURSOR PROTEIN ISOFORMS.

M. Staufenbiel, C.P. Baur*, D. Ristig*, H. Lübbert, P. Frey*. Preclinical Research, Sandoz Pharma AG, CH-4002 Basel and Sandoz Research Institute, CH-3001 Bern, Switzerland.

Several secreted or membrane-bound isoforms of amyloid precursor protein (APP) exist which may contain or lack a Kunitz-type protease inhibitor or an extradomain. Using a sensitive protease inhibitor assay as well as antibodies against different domains we have purified isoforms of APP from PC12 cells after induction with bFGF. Biochemical characterization demonstrated differences in the glycosylation pattern of membrane and secreted APP forms. Furthermore, the major secreted form contained the Kunitz-type protease inhibitor but lacked the extradomain. The extradomain, however, was present in membrane-bound APP isoforms. As compared to secreted APP, Kunitz-type protease inhibitor containing isoforms were reduced in membrane-bound APP. These biochemical differences may contribute to different as yet unidentified functions of membrane-bound and secreted APP. Currently we are testing APP isoforms for their effects on growth and survival of distinct CNS neuron types.

517.5

Heterogeneity of Amyloid Precursor Expression in Olfactory Neuroblasts. B.L.Wolozin, D. Chung*, B. Leibovics*, B.B.Zheng*, I. Lieberburg and T. Sunderland. Lab. of Clinical Science, NIMH, Bethesda, MD 20892 and Athena Neurosciences, S.F., CA 94080.

Amyloid Precursor Protein (APP) expression was examined in cell lines of olfactory neuroblasts (ON) from human donors. In basal conditions of cell culture, ON protein and gene expression was found to consist of primarily APP_{770} and APP_{751}. PCR analysis indicates the ratio of APP_{770}:APP_{751}:APP_{695} is 65:100:7.50. The amount of APP detected by immunoblotting with antibody targetting the ß/A4 region of the molecule appeared to vary among individuals. Antibodies targetting the N and C termini also detected variation in APP immunoreactivity, but to a lesser extent. We have looked at cell lines from 10 donors less than 50 years old who died of non-neurologic causes and 3 donors with AD. APP was abundantly expressed in 7 of the young donors. However, 3 of the cell lines from young donors and all 3 AD cell lines expressed APP at much lower levels. Calcium stimulation of the cells increased APP immunoreactivity and resulted in approximate equalization of APP levels for all the cell lines. Because immunoprecipitation experiments show a calcium induced decrease (rather than increase) in APP levels, we suspect that the apparent calcium induced increase in APP levels seen by immunoblot is due to a post-translational modification of APP. Analysis of APP expression in a non-neuronal cell model (lymphoblasts) did not indicate any variation in baseline or calcium-stimulated APP levels between AD and controls.

517.6

ß-AMYLOID PEPTIDES DESTABILIZE CALCIUM HOMEOSTASIS IN HUMAN CORTICAL NEURONS AND INCREASE THEIR VULNERABILITY TO NEUROFIBRILLARY DEGENERATION. M. P. Mattson, R. Rydel, B. Cheng and I. Lieberburg, Center on Aging and Anatomy & Neurobiology, Univ. of Kentucky, Lexington KY 40536; Athena Neurosciences, South San Francisco, CA 94080.

Human cerebral cortical cell cultures were employed to test the hypothesis that ß-amyloid peptides (ßAPs) can render neurons more vulnerable to calcium-mediated excitatory amino acid (EAA) neurotoxicity. Synthetic ßAPs corresponding to amino acids 1-38 or 25-35 of the ß protein enhanced glutamate neurotoxicity, while a peptide with a scrambled sequence was without effect. ßAPs 1-38 and 25-35 alone had no effect on neuronal survival. ßAPs enhanced both kainate and N-methyl-D-aspartate (NMDA) neurotoxicity. The effects of ßAPs on EAA-induced neuronal degeneration were concentration-dependent (10nM - 40 µM) and required prolonged exposures. Measurements of intracellular calcium levels indicated that ßAPs made neurons vulnerable to EAA-induced calcium elevation. The ßAPs also rendered neurons more vulnerable to calcium ionophore neurotoxicity indicating that the ßAPs destabilize calcium homeostasis. Finally, the ßAPs made neurons more vulnerable to neurofibrillary tangle-like antigenic changes induced by EAAs or calcium ionophore (i.e., increased staining with tau and ubiquitin antibodies). Neuronal calcium destabilization leading to neurofibrillary degeneration was also seen with a peptide corresponding to amino acids 25-28 of the ß protein. We propose that in Alzheimer's disease, ß-amyloid destabilizes neuronal calcium homeostasis and so renders neurons more vulnerable to environmental insults. (supported by the Alzheimer's Association).

517.7

PLASMA AMYLOID PRECURSOR PROTEIN IS A MARKER FOR ALZHEIMER'S DISEASE. A.I.Bush*, R.D.Moir*, Q.-X.Li*, J.Currie*, D. Small, B. Rumble*, U. Mönning#*, K.Beyreuther#* and C.L.Masters. Dept. of Pathology, Univ. of Melbourne, Parkville, VIC, Australia and # Center for Molecular Biology, Univ. of Heidelberg, Heidelberg, Germany.

βA4 amyloid deposition in brain, characteristic of Alzheimer's disease (AD), may result from the failure of the amyloid precursor protein (APP) to be correctly processed. A blood marker reflecting this abnormal metabolism would be of predictive and diagnostic value, as well as provide a means of monitoring the efficacy of therapeutic interventions. We have previously sequenced APP from the human platelet where it is detected by Western blotting as 130 and 110 kDa proteins and may be released with the βA4 domain intact[1]. Plasma contained these and additional forms of 65 and 42 kDa. We analysed immunoblots of plasma APP from AD cases (n=26) and controls (n=34) and found a 60% increase of the 130 kDa species of APP in AD ($p< 0.001$), no differences in 110 and 65 kDa forms and a 35% decrease in the 42 kDa form ($p< 0.001$). Studies of protease action on APP indicated that plasma APP forms may be proteolytic cleavage products. The APP abnormalities in the circulation in AD may reflect a failure of constitutive proteolysis due to modifications of APP, or anomalies involving degradative pathways, co-factors or inhibitors. Abnormalities of constitutive APP proteolysis may allow APP to be processed through an alternative, amyloidogenic, pathway. Our studies show that the source of plasma APP and the mechanism responsible for the APP differences detected may lie outside the vascular compartment.

FORMS OF β-AMYLOID PRECURSOR PROTEIN (β-APP) IN HUMAN PLATELETS AND LYMPHOCYTES. M. Schlossmacher*, B. Ostaszewski*, I. Lieberburg+, K. Kosik, D. Selkoe. Brigham & Women's Hosp., Harvard Medical School, Boston,MA 02115;+Athena Neurosciences, San. Francisco 94080.

Amyloid-β-protein (AβP) is progressively deposited in cerebral plaques and meningocerebral vessels in Alzheimer's disease (AD). AD shares numerous features with amyloidoses of circulating origin. The soluble, C-truncated ~125 kDa form of βAPP (i.e., PN-II), which we have identified in plasma, has also been localized to platelet α-granules. Full-length (FL) βAPP has been reported to be released from agonist stimulated platelets as membranous microparticles. We have examined peripheral blood cells with regard to βAPP isoforms. After purification of platelets from contaminating leukocytes, we detected the mature, N- plus O-glycosylated ~140 kDa FL-βAPP in platelet membranes but only trace amounts of immature, N-glycosylated βAPP. In the cell-free releasate of activated platelets, we found abundant PN-II but failed to detect FL-βAPP associated with microparticles. Membrane extracts of resting and stimulated platelets also revealed comparable amounts of a ~10 kDa fragment, which probably represents the C-terminal portion of βAPP after cleavage of PN-II. B and T lymphocytes isolated from peripheral blood and cultured EBV-transformed B cells contained small amounts of internal membrane-associated mature and immature FL-βAPP. The presence of amyloidogenic FL-βAPP molecules in peripheral blood cells has potential relevance for the pathogenesis of AβP deposition in AD.

517.9

PROCESSING OF ß-AMYLOID PRECURSOR PROTEIN IN ASTROCYTES AND MICROGLIA FAVORS A LOCALIZATION IN INTERNAL VESICLES C. Haass*, A. Hung* E.H. Koo, and D.J. Selkoe. Center for Neurologic Diseases, Harvard Medical School, Brigham and Women's Hospital, Boston MA.

We report the expression of ßAPP in microglial cells and astrocytes in primary cultures of cerebral cortex of newborn rats. Both cell-types express substantial amounts of ßAPP 695, 751 and 770 as determined by metabolic labeling followed by immunoprecipitation and by PCR-mediated amplification of the corresponding mRNAs. Both cell types show a reduced secretion of soluble fragments of ßAPP into media compared to other cell types transfected with cDNAs coding for ßAPP. This can be monitored by using the remaining membrane-bound 10 kDa fragment following constitutive proteolytic cleavage as a marker. The amount of the 10 kDa fragment in both cell types is low, correlating with the relatively low amounts of the soluble ßAPP fragments in media. Immunocytochemistry reveals that ßAPP is located intracellularly in Golgi-like structures, with very little cell surface staining. From these data, we propose that at least in astrocytes and microglia cells, ßAPP may primarily occur in an intracellular, membrane-associated form rather than being cleaved and secreted or inserted at the cell surface. It may thus perform a principally intracellular function. We also present preliminary data showing that microglial cells secrete C-terminal-containing βAPP fragments into the media. These fragments are potentially amyloidogenic since they contain the C-terminus and ß the peptide epitopes.

517.10

EFFECTS OF BETA AMYLOID I: INDUCTION OF ALZ-50. J. Busciglio and B.A. Yankner. Dept. of Neurology, Children's Hospital and Harvard Medical School, Boston, MA 02115.

The β amyloid protein causes neuronal degeneration in primary rat hippocampal neurons after 3 days in culture (Yankner et al. Science 250:279, 1990). We have assayed for neuronal expression of the neurofibrillary tangle-associated Alz-50 immunoreactive proteins (Alz-50 i.p.s.) by quantitative immunoblot analysis and immunocytochemistry. The Alz-50 i.p.s. are expressed at low levels during neuronal development in primary hippocampal cultures as two isoforms with molecular weights 55 and 68 kD. Treatment with β amyloid induced a 4-5-fold increase in Alz-50 i.p.s. which was not observed after addition of control peptides or a reverse sequence β amyloid peptide. The levels of several other cytoskeletal proteins were unchanged. The β amyloid dose response for induction of Alz-50 i.p.s. was quite similar to the dose response for the neurotoxic effect. Treatment with the excitotoxin glutamate did not induce the Alz-50 i.p.s. In addition, coincubation of β amyloid with the excitatory amino acid antagonists kynurenate and APV did not affect the induction of Alz-50 i.p.s. Preincubation of neurons with cycloheximide prevented subsequent induction of Alz-50 i.p.s. by β amyloid. Thus β amyloid can specifically induce the altered cytoskeletal proteins associated with Alzheimer's disease by a mechanism which requires protein synthesis and which differs from that of excitatory amino acids.

517.11

EFFECTS OF BETA AMYLOID II: PROTECTION BY SUBSTANCE P. M. Flint Beal, Neil W. Kowall, Jorge Busciglio, Lawrence K. Duffy and Bruce A. Yankner. Neurology Service, Mass. General Hospital, and Children's Hospital, Boston, MA 02114.

The role of β amyloid protein in the pathogenesis of neuronal degeneration in Alzheimer's disease (AD) is a central issue in the illness. We found that focal deposition of β amyloid in adult rat cerebral cortex causes profound neurodegenerative changes including neuronal loss, degenerating neurites and induction of Alz-50-immunoreactive proteins associated with AD. In the present study we examined the effects of local or systemic administration of substance P on the neurodegenerative effects. β-amyloid (3 nmol) or control peptides were stereotactically injected into parietal cortex in a volume of 1 µl. Animals were sacrificed at 1 week and perfused for histologic evaluation. Neuronal counts were made in a 0.64 mm^2 square in the area of maximal neuronal degeneration. Coinjection of substance P (2-200 pmol) with β amyloid dose-dependently prevented neuronal loss. Induction of Alz-50 immunoreactivity by β amyloid as detected by either immunocytochemistry or immunoblot analysis, was also blocked by substance P. Peripheral administration of substance P in a dose of 2-200 nmol/kg i.p. 30 min before intracortical injection of β amyloid dose-dependently blocked the neurotoxicity. Administration of substance P for up to 24 hr after the β amyloid injection was effective in preventing neurotoxicity, but the effect dissipated by 72 h. These results show that β amyloid neurotoxicity in vivo is prevented by either local or systemic administration of substance P.

EFFECTS OF BETA AMYLOID III: THE PRIMATE BRAIN A.C. McKee, N.W. Kowall, M.F. Beal, J. Schumacher and B.A. Yankner Depts. of Neuropathology, Neurology and Neurosurgery, Massachusetts General Hospital, Children's Hospital and Harvard Medical School, Boston, MA 02114

Deposition of ß amyloid protein in the brain is a universal feature of Alzheimer's disease (AD). To determine the effects of ß amyloid deposition, we performed intracerebral microinjections of a ß amyloid peptide (ß1-40) in adult Cynomolgus monkeys. Bifrontal craniotomies were performed with the resection of a dural flap. Microinjections of ß1-40 and control peptides were performed under stereotactic guidance. After short survival intervals, the brains were perfusion-fixed, cryoprotected and cut at 50 µ on a freezing microtome. Sets of serial sections were processed for histopathology and immunohistochemistry with the monoclonal antibody Alz 50, and antibodies to tau, ß amyloid and ubiquitin. The ß1-40 peptide injections produced a defined ß amyloid-immunoreactive deposit surrounded by neuronal degeneration and abnormal ubiquitin and Alz 50 positive neurites. The extent of degeneration was dose-dependent. Control peptides produced cortical disruption at the injection site without a significant lesion. A substituted ß1-40 peptide produced a smaller lesion than that caused by native ß1-40. These findings suggest that ß amyloid protein is neurotoxic and may, therefore, be responsible for neuronal degeneration in AD.

GANGLIOSIDE GM1 MAY COUNTERACT THE MPTP-INDUCED UNILATERAL DECREASE IN NUMBER AND MEAN VOLUME OF PIGMENTED NEURONS IN THE SUBSTANTIA NIGRA OF THE PIG-TAILED MACAQUE. [1]A.M. Ianson,[2]A. Møller,[3]H. Nakashima,[4]G. Toffano*,[3]M. Goldstein and [1]K. Fuxe. [1]Dept of Histology and Neurobiology, Karolinska Institutet, S-104 01 Stockholm, Sweden; [2]NeuroSearch, Copenhagen, Denmark, [3]Dept of Psychiatry, New York, New York Univ. Medical Center, New York, USA, [4]Fidia Research Laboratory, Abano Terme, Italy.

Two female pig-tailed macaques (b.wt. 5.9 kg) were infused with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP, 2 mg/kg) in the left internal carotid artery. Starting 30 min before the MPTP injection one macaque was treated with the ganglioside GM1 (20 mg/kg) daily, i.m. for 18 days. The other macaque received saline injections. The day after the last GM1 injection the animals were sacrificed, perfused with 4 % paraformaldehyde and the brains were processed for immunohistochemistry after cryotome sectioning of the entire substantia nigra (35µm coronal sections). After Nissl staining the total number of pigmented neurons in the substantia nigra were estimated unbiased using the optical disector (Olympus) and the total volume of nigral pigmented neurons were estimated using Cavalieri's principle. The coefficient of error of the estimates was 4-7 %.

The degree of rigidity was milder in the GM1-treated animal, which sometimes used the right hand when eating, which was never the case in the saline treated macaque. The unbiased estimates of the total number of pigmented neurons in the substantia nigra were: saline treated animal: 89,000 (unlesioned side), 42,000 (lesioned side); GM1 treated animal: 101,000 (unlesioned side), 58,000 (lesioned side).

The estimates of the mean volume were: saline treated animal: 9,200 μm^3 (unlesioned side), 7,400 μm^3 (lesioned side); GM1 treated animal: 10,800 μm^3 (unlesioned side), 13,200 μm^3 (lesioned side).

This pilot study gives support for the previously observed effect of GM1 to counteract the MPTP-induced shrinkage of nigral tyrosine-hydroxylase immunoreactive neurons in the male C57 BL/6 mouse. Thus, ganglioside GM1 may exert anti-parkinsonian actions.

518.2

THE NEURONOTROPHIC ACTION OF N-METHYL-D-ASPARTATE (NMDA) IS ASSOCIATED WITH AN INCREASE OF IMMEDIATE EARLY GENE MESSENGER RNA IN CEREBELLAR GRANULE NEURONS. M. Favaron*, J. Rimland, S. Romanello*, N. Gabellini*, A. Leon and R. Dal Toso. Fidia Research Labs, 35031 Abano Terme, Italy.

In primary cultures of cerebellar granule neurons the stimulation of Excitatory Amino Acid (EAA) receptors leads to a rapid increase of immediate early gene messenger RNA (mRNA). The induction elicited by NMDA was dose-related and dependent on the concentration of extracellular KCl. At day 2 in vitro the NMDA EC50 for c-fos mRNA induction was 10uM at 10mM KCl, and 30uM at 25mM KCl. Higher levels of NMDA-mediated c-fos mRNA induction were observed at 10mM KCl compared to 25mM KCl. The differential activation related to KCl concentration was maintained up to 5 days in vitro, at which time the levels of c-fos induction reached a plateau independently of the extracellular concentration of KCl and NMDA. A similar trend was observed monitoring neurofilament mRNA, suggesting that the increased activation of c-fos mRNA elicited by NMDA results in a time-related pattern of activation of neurofilament mRNA. This system could provide a useful approach for examining the ability of compounds to effect neurotrophism.

EYE EXTRACT COMPONENTS PROMOTE ACETYLCHOLINE SENSITIVITY IN CHICK DORSAL ROOT GANGLION NEURONS. J. F. Margiotta. Dept. of Physiol. & Biophysics., Mount Sinai School of Medicine, NY, NY 10029.

Eye tissue extracts contain at least two activities that support the survival and development of chick ciliary ganglion neurons in culture: a neurotrophic activity and a 50-kDa fraction that increases acetylcholine (ACh) sensitivity. Recent studies indicate that the neurotrophic (growth promoting) activity can substitute for nerve growth factor (NGF) in supporting short-term survival of chick dorsal root ganglion (DRG) neurons (Eckenstein et al., Neuron 4:623-631, 1990), and that DRG neurons express both ACh receptor (AChR) mRNA and functional nicotinic AChRs (Boyd et al., J. Neurobiol. 22: 1-14, 1991). In order to examine factors influencing the appearance of functional AChRs on sensory neurons, embryonic day 13 (E13) DRG neurons were grown in basal culture medium supplemented with either NGF (10 ng/ml) or eye extract (3% v/v) for up to 7d, and examined for responses to 500 uM ACh using whole-cell recording methods. Close to 100% of the cells identified as neurons after 1d in NGF and eye extract-supplemented culture media survived for 6d, while <50% of neurons in basal medium survived. After 5-6 d, 95% of the neurons grown with eye extract displayed ACh responses well-above a criterion level of 2 pA/pF (geometric mean response=12±1 pA/pF, n=35) while only about 50% of the neurons grown in basal media alone or with NGF did so, and the responses were much smaller [2±1 pA/pF (n=20) and 3±1 pA/pF (n=25), respectively]. At an equivalent developmental age (E18,19) 95% of freshly dissociated DRG neurons were sensitive to ACh, identical to the proportion seen after 6d in culture medium containing eye extract, and representing a >2-fold increase from the proportion seen for neurons obtained at E13,14 (n=18). These results indicate that eye extract components, different from NGF, promote the ACh sensitivity of DRG neurons in culture, and suggest that similar components may influence AChR appearance *in vivo*. Supported by NIH NS24417 & March of Dimes 5-742.

DEVELOPMENTALLY REGULATED EXPRESSION OF THE CALCITONIN GENE-RELATED PEPTIDE (CGRP) IN THE MOUSE OLFACTORY SYSTEM S.Denis-Donini, B.Chini+ and M.Vitadello. Biology Department, University of Milan, 20133 Milan, Italy.

We have shown previously, using an in vitro system, that in the embryonic mouse olfactory bulb the expression of dopaminergic phenotypes is induced by the neuropeptide CGRP which is synthesized and released in vitro by the chemosensory neurons from the olfactory epithelium (Nature 339:701,1989). It was therefore interesting to study the expression of the peptide during development. Cells involved in the synthesis of CGRPα in the olfactory epithelium have been studied by using in situ hybridization and immunohistochemistry. Sections processed for in situ hybridization with the type αCGRP probe demonstrated specific mRNAs at the level of the growing olfactory axons at stages between E13-15 with a gradual decrease at E17-18 to reach the background level at birth. Immunostaining demonstrated specific CGRP also at the level of the olfactory axons with a kinetics closely matching that of its mRNA.

These results show that the expression of CGRP is developmentally regulated and confirm its role as a differentiation factor during olfactory bulb ontogenesis.

IBOTERNIC LEISON IN STRIATUM TRIGGERS EXPRESSION OF ONE NEW AND INCREASES FIVE EXISTING PROTEINS. F.C. Zhou., Y. Kim,* C.F. Pu, and B.S. Kwon,* Departments of Anatomy and microbiology, Indiana Univ. Sch. Med. Indianapolis, IN, 46202, USA.

Neuronal toxin, ibotenic acid (IB), injection caused neuronal degeneration and glial activation and proliferation in the adult rat brain. The region of non-neuronal and reactive glial environment was subsequently heavily invaded by serotonergic fibers beginning three days and prevailed after 20 days. Such an environment also fostered a high survival rate of transplanted fetal neurons as compared to normal striatal environment. A trophic signal was suggested in the injured area where the growth of 5-HT fibers and transplanted neurons was facilitated. A gel analysis was performed to detect protein expression in the injured brain region. Three and eight days after IB lesion in the striatum, a 10ul of 1137ci/mmole ^{35}S-methionine was injected in the same area to label the newly synthesized protein / peptide; injection into pair-caged normal animals were used as controls (n=5 each). Two hours (n=3 each) later the striatum was homogenized in the 0.5% Triton-added isotonic lysis buffer, and centrifuged. The protein in supernatant was precipitated and analyzed by 2D-polyacrymide gel electrophoresis. The expression of 5 peptides (IBNF1,2,6=49KD, IBNF3=35KD, IBNF4=30KD) significantly increased in 3- and 8-day-post-IB-lesion animals. A protein/peptide of 45KD newly appeared in the lesioned striatum. This study provides evidence that a group of proteins other than prominent glial proteins, GFAP (40KD) and S100 (32KD), increased their expression level in the brain where neurons were injured and 5-HT fibers grew responsively (supported by NIH grant NS23027 to FCZ).

BIOLOGICAL ACTIVITY OF THE SECRETED FORM OF AMYLOID β/A4 PROTEIN PRECURSOR I: SEARCH FOR THE APP RECEPTOR. J.-M. Roch[a], I.P. Shapiro[a], L.M. Refolo[b*], N.K. Robakis[b], and T. Saitoh[a]. [a] Dept. of Neurosciences, 0624, Univ. of California, San Diego, La Jolla, CA 92093 and [b]Dept. of Psychiatry, Mt. Sinai School of Medicine, NY, NY 10029

Amyloid β/A4 protein precursor (APP) is a transmembrane glycoprotein, the extracellular domain of which is secreted by different cell types. This process includes the cleavage of the β/A4 domain preventing formation of amyloid β/A4 protein. The secreted form of APP, with and without the Kunitz type protease inhibitor domain, is involved in growth regulation of fibroblasts (Cell 58:615-622, 1989). This biological activity is present in a bacteria-made fusion protein corresponding to the N-terminal two-thirds of APP-695 and the first 13 amino acids of CII protein of phage λ . This APP fragment has high affinity binding sites on the surface of fibroblasts and it presumably triggers the signal transduction mechanisms, resulting in alteration of PKC distribution. This supports the idea that the secreted form of APP-695 has a cell surface receptor. To further analyze APP and APP-triggered cellular signaling mechanisms, large quantities of pure APP are needed. Therefore, we used a prokaryotic expression vector allowing the production of large amounts of APP in bacteria. Specifically, we inserted into this plasmid the 1.7 kb KpnI-BglII fragment of APP-695 cDNA which encodes almost the entire secreted form of APP-695. Bacteria carrying this plasmid expressed high levels of APP which was detected by anti-APP antibodies and biologically active in terms of growth stimulation of fibroblasts. This bacteria-made APP was purified, labeled with ^{125}I and used as a radioligand in binding experiments. This is a first step toward the identification and isolation of APP receptor.

A FACTOR IN CONDITIONED MEDIUM FROM RETINAL PIGMENT EPITHELIUM (RPE) MEDIATES PHOTORECEPTOR SURVIVAL IN VITRO. V.P. Gaur*, A.J. Sweatt and J.E. Turner. Departments of Neurobiology and Anatomy and Ophthalmology, Bowman Gray School of Medicine, Winston-Salem, NC. 27157

Maintenance of visual gene expression in photoreceptor cells (PRC) of dystrophic RCS rat retinas by RPE transplants has been reported (Exp. Eye Res., 1991). These studies indicated that a RPE secreted factor mediated PRC rescue. We have used an in vitro PRC culture system to characterize this factor. We report PRC survival and neurite promotion by medium conditioned by cultured normal RPE (RPE-CM). Up to 87% of cells expressed immunocytochemically detectable opsin in RPE-CM. In RPE-CM from RCS retinas only 14% cells expressed opsin. Analysis of basic fibroblast growth factor (bFGF) levels (shown effective in achieving PRC rescue in vivo) in RPE-CM from normal and dystrophic rats indicated no significant differences by ELISA. Analysis of metabolically labeled proteins in normal and dystrophic RPE-CM indicated specific differences. Efforts are currently underway to test various components of the RPE-CM for PRC rescuing abilities.

INSULIN-LIKE GROWTH FACTOR I (IGF I) STIMULATES THE DIFFERENTIATION OF DOPAMINERGIC (DA) NEURONS *IN VITRO*

S.L. Bradshaw, A. Smith*, I. Reisert and V.K.M. Han*. MRC Group in Fetal and Neonatal Health and Development, Lawson Res. Inst., London, Ont, Canada N6A 4V2.

Insulin-like growth factors (IGFs) are potent mitogenic and differentiating promoters of many developing tissues including brain. To determine the role of IGF I on the differentiation of DA neurons in the developing mesencephalon , we have studied the effects of IGF I on primary DA neurons cultured in serum free medium. Mesencephalon of 14 d rat embryos were dissociated and cultured in 10% FCS for 48 hours, then maintained in SFM with or without IGF I. At 7 days *in vitro*, ^{3}H-dopamine total uptake, K^+ stimulated release and Ca^{2+} stimulated release were measured. Total uptake of ^{3}H-dopamine was increased from 861 dpm/min (SFM) to 1334 dpm/min (IGF I 100ng/ml), ($p<0.001$) indicating an increased capacity for uptake and storage of neurotransmitter with IGF I treatment. K^+ stimulated release of stored ^{3}H-dopamine was increased significantly ($p<0.05$) from 419 dpm/min to 715 dpm/min (IGF I 50ng/ml). Ca^{2+} stimulated release of ^{3}H-dopamine was not significantly altered upon treatment with IGF I. Immunocytochemistry with antiserum against tyrosine hydroxylase and morphometric measurements of the identified neurons demonstrated a significant increase in the soma size, and in the number and length of neurite processes, following treatment with IGF I. We conclude that IGF I promotes uptake, storage and K^+ mediated release of ^{3}H-dopamine, as well as neuronal morphology of DA neurons *in vitro*.

INSULIN-LIKE GROWTH FACTOR-I ENHANCED SECRETION IS BLOCKED IN PROTEIN KINASE C DEFICIENT CHROMAFFIN CELLS. M.K. Dahmer, C. Hardaway* and K.L. Leach. Dept. of Biochemistry, Univ. of Tennessee College of Medicine, Memphis, TN 38163 and Dept. of Cell Biology, The Upjohn Co., Kalamazoo, MI 49001.

We have previously shown that bovine chromaffin cells cultured in medium with 10 nM insulin-like growth factor-I (IGF-I) secrete ~2 fold more catecholamine when exposed to secretory stimuli than cells cultured without IGF-I. The purpose of these studies was to determine whether the effect of IGF-I on secretion from chromaffin cells might involve protein kinase C. High K^+-stimulated release of [^{3}H]norepinephrine previously loaded into the cells was used to assay secretion. We found that high K^+-stimulated secretion from cells cultured without IGF-I was unaffected by overnight treatment with 100 nM β-phorbol didecanoate (PDD), which depleted protein kinase C in the cells as determined by immunoblots, however, secretion from cells cultured with IGF-I was reduced by β-PDD treatment to a level comparable to that in cells cultured without the peptide. α-PDD (100 nM) had no effect on secretion from untreated or IGF-I treated chromaffin cells. Overnight treatment with 100 μM H7, but not HA1004, prevented the enhanced secretion normally seen in IGF-I treated cells. High K^+-stimulated $^{45}Ca^{2+}$ uptake in IGF-I treated cells was reduced to that seen in untreated cells when the cells were incubated overnight with β-PDD (200 nM). Immunoblots using antibodies to protein kinase C isozymes suggested that the ε-isozyme of protein kinase C is more abundant in IGF-I treated cells than in untreated cells, yet α-protein kinase C levels are relatively unchanged. These observations suggest that protein kinase C is required for IGF-I enhanced secretion from chromaffin cells and that ε-protein kinase C may be the specific isozyme involved in this effect.

518.10

DELAYED DELIVERY OF A CORTICALLY DERIVED TROPHIC FACTOR RESCUES AXOTOMIZED, SLOWLY-DEGENERATING NEURONS OF THE DORSAL LATERAL GENICULATE NUCLEUS (DLGN) AND IMPROVES VISUAL DISCRIMINATION. F. Haun, T. Jaret and T.J. Cunningham, Dept. of Anatomy & Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129

Visual cortex lesions in adult rats lead to cell death in two populations of dLGN neurons; in one population (generated late in neurogenesis) loss is maximal by 2wks. post-lesion, while for earlier generated neurons a similar maximal loss is not reached until 2mos. post-lesion. Using an implanted osmotic minipump, we delivered a 2-week supply of a neuron survival factor to the visual cortex lesion site beginning 2wks. post-lesion, and tested the animals behaviorally starting 2mos. post-lesion. This factor was was derived from an HPLC fraction of culture medium conditioned by embryonic occipital cortex explants. Animals receiving the factor learned a difficult visual discrimination more than twice as fast as animals with comparable lesions that received a control fraction of unconditioned culture medium. 3H-thymidine counts of labeled dLGN neurons showed that the factor rescued all neurons that otherwise die between 2wks. and 2mos. post-lesion. These results show that delayed delivery of a trophic factor following CNS injury can nonetheless rescue slowly degenerating neurons, with a resulting behavioral improvement.

Supported by NIMH grant MH44734 (FH) and NIH grant NS16487 (TJC).

518.11

A NOVEL PEPTIDE ENHANCES CHOLINERGIC STIMULATION ACTIVITY OF NGF IN MEDIAL SEPTAL NUCLEI CULTURE. K.Ojika, S.Kojima*, Y.Ueki*, N.Fukushima*, M. Taiji and M.Yamamoto*. Second Dep. of Internal Medicine, Med. Sch., Nagoya City Univ., Mizuho-ku, Nagoya, Japan 467 and Res. Inst. Sumitomo Pharma. Co.Ltd., Konohana-ku, Osaka, Japan 554.

A novel peptide(HCNP) that enhances acetylcholine(AcCho) synthesis of the medial septal nuclei(SEPT) culture has been purified from rat hippocampus. Structure of HCNP is acetyl-Ala-Ala-Asp-Ile-Ser-Gln-Trp-Ala-Gly-Pro-Leu.

To study the disparity of cholinergic stimulation activity between NGF and HCNP, saturable amount(1ng/ml) of mouse 2.5S-NGF and/or 30pg/ml of synthetic de-acetylated HCNP(free-HCNP) were applied to explant cultures of anterior spinal cord(SPC), corpus striatum(STRI) and SEPT, from 14, 15 and 16 day Wistar rat embryo, respectively. Compared with control or either component alone, application of both components to the same SEPT culture exerted a striking additive or more than additive enhancement of AcCho synthesis as well as choline-acetyltransferase activity at day 6 in vitro. However, neither NGF nor free-HCNP influenced AcCho synthesis of SPC culture, and only NGF stimulated AcCho synthesis of STRI culture.

518.12

GENERATION OF ANTIBODIES AGAINST NATIVE CHOLINERGIC NEURONAL DIFFERENTIATION FACTOR (CDF) WHICH BLOCK CHOLINERGIC-INDUCING ACTIVITY. Keiko Fukada and Marie F. Towle*. Anat./Cell Biol., SUNY-HSCB, Brooklyn, NY 11203.

A glycoprotein from heart cell-conditioned medium (CM), CDF, causes a transition from noradrenergic to cholinergic phenotype in cultured rat sympathetic neurons. We developed an efficient protocol for purification of naturally-occurring CDF from CM using antipeptide antibodies raised against a synthetic peptide homologous with the N-terminal region of CDF. Using this protocol we obtained ~ 44 nmoles of pure CDF from 150 liters of CM. Both amino acid composition analysis and N-terminal sequence analysis showed that this preparation was ≥ 96 % pure (the working accuracy of procedures used). This pure CDF was used to raise antibodies in three rabbits. All three antisera specifically immunoprecipitated CDF from a preparation where CDF constituted ~0.07 % of the total protein, while preimmune sera did not. Moreover, all three antibodies completely blocked the cholinergic-inducing activity of CDF when tested on cultured sympathetic neurons, although high concentrations of antipeptide antibodies also showed partial inhibition. When concentrated CM was used instead of pure CDF, the three antibodies at 100 ug/ml blocked ~95% of the cholinergic-inducing activity of the CM, whereas no inhibition was observed by the same concentration of antipeptide antibodies. These antibodies will be useful for assessing the physiological role of CDF. (NINCDS to KF.)

519.1

AUTORADIOGRAPHIC DISTRIBUTION OF CHOLINERGIC MUSCARINIC RECEPTORS IN OLFACTORY BULBECTOMIZED (OB) RATS AFTER CHRONIC TREATMENT WITH MIANSERIN AND DESIPRAMINE.

B. Earley[1*], M. Glennon[1*], M. Lally[1*], B. E. Leonard[1*], J-L. Junien[2*], J.G. Wettstein[2*]. Pharmacology Department[1], University College, Galway, Ireland and Institut de Recherche Jouveinal[2], 94265, Fresnes, France.

Bilateral removal of the olfactory bulbs in rats produces a behavioural syndrome that is defined by a retention deficit in a passive avoidance test and hyperactivity in the open-field test. This syndrome may be related to depression since these behavioural effects can be attenuated by antidepressant drugs. Moreover, abnormalities of the cholinergic system may be involved in the pathogenesis of depression. Thus, muscarinic receptor density was measured by autoradiography with [^{3}H]QNB after the bilateral removal of the olfactory bulbs from rats. In OB rats, muscarinic receptor density was decreased in several brain regions including the amygdaloid nuclei, the basal ganglia, hippocampus, hypothalamus, cortex and olfactory regions. When OB rats were treated chronically for 24 days with mianserin (5 mg/kg i.p.) or desipramine (7.5 mg/kg i.p.) the behavioural abnormalities in the passive avoidance and open field tests were reversed and muscarinic receptor density was increased in the hippocampus and cortical regions. The results are consistent with a cholinergic involvement in depressive illness and suggest that the cholinergic modulatory properties of antidepressant drugs may contribute to their therapeutic effectiveness.

519.2

EFFECT OF THE CHOLINESTERASE INHIBITORS SOMAN AND PHYSOSTIGMINE ON BRAIN MUSCARINIC RECEPTORS.

X-H. Yang, W. Li*, L. Erwin* and J.J. Buccafusco. Dept. Pharmacology & Toxicology, Medical College of Georgia & Dept. Vet. Affairs Med. Ctr., Augusta, GA

The ability of cholinesterase inhibitors (ChEI) to enhance the effects of endogenously released brain acetylcholine has often been reported to result in muscarinic receptor down-regulation. This is not always a consistent finding for different brain regions or for different inhibitors. In this study two dissimilar ChEI were employed in two species and under different conditions of acute and chronic administration. Soman, an irreversible organophosphorous ChEI, and physostigmine, a reversible carbamate ChEI were employed for the purpose of comparing their effects on regional muscarinic receptor regulation in synaptosomal fractions. Acute, s.c., administration of soman did not significantly alter the density of receptors as measured by [^{3}H]methylscoploamine binding in cortex, midbrain or hindbrain, at doses ranging from LD_{20} to LD_{90} in rats. Acute administration of soman to guinea pigs at doses in the $LD_{80\text{-}90}$ range also did not alter binding parameters in the respective brain regions. Chronic treatment once daily (7 days) of rats with soman at doses which resulted in 95% inhibition of ChE at the time of receptor measurement did not alter binding parameters. Physostigmine administration twice daily (25µg/kg,s.c.) for 7 days produced a significant decrease in the density of cortical muscarinic receptors of 28% without affecting the Kd, although this treatment did not alter binding parameters in the midbrain and hindbrain. These results support the concept that brain ChE inhibition is not the only factor which determines whether down regulation will occur and that receptor regulation may be different in the various brain regions.

PHARMACOLOGICAL CHARACTERIZATION OF A NOVEL MUSCARINIC PARTIAL AGONIST, (2,8-DIMETHYL-3-METHYLENE-1-OXA-8-AZASPIRO[4.5]DECANE (YM796) IN TRANSFECTED CELLS EXPRESSING THE m1 OR m2 MUSCARINIC RECEPTOR (mAChR) GENE.

H. B. Wei*, W. R. Roeske, J. Lai, F. Wanibuchi, K. Hidaka, S. Usuda and H. I. Yamamura. U. of AZ, Tucson, AZ 85724 and Yamanouchi Pharm. Co., Tsukuba, Japan.

To investigate the pharmacological effect of a novel compound YM796, we performed binding and correlative biochemical experiments using the transfected murine fibroblast B82 cells which expressed the m1 and m2 mAChR genes (defined as LK3-3 and M2LKB2-2 cell lines). [^{3}H](-)MQNB binding in these transfected cell lines was displaced by different optical isomers of YM796, atropine, pirenzepine, AF-DX 116, as well as selected agonists. (-)YM796, (+)YM796 and (±)YM796 displaced [^{3}H](-)MQNB from its binding site in LK3-3 cells with K_i values of 16.5, 30.4 and 21.9 µM and in M2LKB2-2 cells with K_i values of 43.3 , 93.2 and 79 µM, respectively. From functional assays we found the two isomers had different intrinsic activities for the M_1 and M_2 mAChRs. (-)YM796 stimulated IP_1 accumulation in LK3-3 cells with an EC_{50} value of 27.3 µM and inhibition of cAMP formation in M2LKB2-2 cells with an EC_{50} value of 91.2 µM although (-)YM796 failed to achieve a maximal response in either assay compared to carbachol (a full agonist). (+)YM796 showed no obvious efficacy for the M_1 and M_2 mAChRs. In conclusion, (-)YM796 represents a muscarinic partial agonist with selectivity for the M_1 mAChRs and may be potentially useful in Alzheimer's disease whereas (+)YM796 might be an antagonist at the M_1 and M_2 mAChRs.

519.4

PHARMACOLOGY OF THE M4 MUSCARINIC RECEPTOR MEDIATING CA CURRENT INHIBITION IN NG108-15 CELLS.

M.P. Caulfield and D.A. Brown. Dept. Pharmacology, University College, London WC1E 6BT, UK.

Molecular biological techniques have shown genes coding for five muscarinic receptors in neuronal tissue. NG108-15 cells express message exclusively for m4 receptors and ACh inhibits the Ca current (I_{Ca}) in these cells (Higashida et al., Proc. Roy. Soc. Lond.(B). 242:68-74, '90); we have studied the effects of some muscarinic agonists and antagonists on I_{Ca} inhibition to define the pharmacology of the m4 gene product in a functional assay. ACh (+ neostigmine), oxotremorine-M and carbachol were "full" agonists (max. inhibition 39.5% ± 1.9); -log EC_{50} values (±se) were 6.95 (0.1), 6.85 (0.18) and 5.7, respectively. Muscarine, methylfurmethide and APE were "partial" agonists, with -log EC_{50} values of 6.27 (0.3), 6.1 and 6.71 (0.28), respectively. The effect of ACh was blocked by omega-conotoxin (100nM), but not by nifedipine (5µM). Antagonist potencies (-log K_B ± se) were atropine, 9.8±0.39; pirenzepine, 7.74±0.23; methoctramine, 7.63±0.23; himbacine, 8.83±0.13. This antagonist profile is similar to that seen in binding studies on these cells (Lazareno et al., Mol.Pharmacol., 38:805-815, '90) and shows himbacine can distinguish M_4 receptors from M_1 receptors, as both are blocked by pirenzepine with high potency.

EVIDENCE THAT MUSCARINIC STIMULATION OF ADENYLATE CYCLASE AND GENERATION OF INOSITOL PHOSPHATES ARE MEDIATED BY DIFFERENT RECEPTOR SUBTYPES IN RAT OLFACTORY BULB.

P. Onali and M.C. Olianas, Department of Neurosciences, University of Cagliari, Italy.

Often agents that stimulate phospholipid hydrolysis increase cyclic AMP formation. We have previously shown that in rat olfactory bulb (o.b.) muscarinic agonists enhanced adenylate cyclase (a.c.) activity and stimulated phosphoinositide breakdown. In the present study we have examined whether the two responses were mediated by the same pharmacological receptor subtype. In miniprisms of rat o.b., carbachol (CCh) increased the accumulation of inositol phosphates (IPs) by about 110 % of basal level with an EC50 of 96 µM. Oxotremorine M behaved as a full agonist, whereas oxotremorine and arecoline exibited only 20 % of the CCh efficacy. In contrast, oxotremorine and arecoline were 70% and 90% as effective as CCh in enhancing a.c.. The CCh stimulation of IPs generation was potently antagonized by the M1 blocker pirenzepine (pA2=8.26), but was less sensitive to the M2 antagonist AF-DX 116 (6.12). Conversely, the muscarinic stimulation of a.c. showed the opposite sensitivity. Thus, in rat o.b. different muscarinic receptor subtypes stimulate a.c. and increase phosphoinositide hydrolysis.

IN VITRO LOCALIZATION OF A RADIOLABELLED VESAMICOL ANALOG IN THE HUMAN BRAIN.

S.M.N. Efange*, D.C. Mash, M.I. Basile, J. Pablo, and R.H. Michelson*, Dept. of Radiology, University of Minnesota, Minneapolis, MN 55455 and the Dept. of Neurology, University of Miami School of Medicine, Miami, Fl. 33136.

The prominence of the cholinergic lesion in Alzheimer's disease has provided the impetus for the development of novel radiotracers which can detect this lesion. The phencyclidine isomer 2-(4-phenylpiperidino) cyclohexanol (vesamicol) is a potent inhibitor of vesicular ACh transport. This ligand binds with high affinity to a cytoplasmically-oriented site, the vesamicol receptor (VR), on the cholinergic synaptic vesicle. Thus, the vesamicol receptor may be a potentially useful target for the development of novel tracers for mapping central cholinergic innervation. This study reports the characterization of a novel vesamicol-like radiotracer, (-)-2-hydroxy-3-(4-[^{125}I]iodo-phenyl)-1-(4 phenylpiperidino) -cyclohexanol (4-HIPP) in the postmortem human brain. Saturation analysis revealed that 4-HIPP binds to two sites in the human brain (KD = 3.5 nM, BMAX =42.5 pmol/g; KD = 31.1 nM, BMAX =102.1 pmol/g). We have used a low concentration of 4-HIPP (3 nM) to selectively label the high affinity site in slide-mounted sections of the human brain. Quantitative autoradiography demonstrates that [^{125}I]-4-HIPP binding sites are heterogeneously distributed throughout the human cortical mantle. The highest levels of binding sites were observed over the basal forebrain. High binding site concentrations were seen throughout the cortex, with lesser amounts in the the caudate, putamen and nucleus accumbens. Preliminary localization studies in Alzheimer's disease cerebral cortex indicate that this binding site persists despite the marked disruption of cholinergic synapses. Studies are underway in the human brain to characterize the residual binding sites in relation to the topography of cholinergic innervation. Funded by the AHAF.

LOCALIZATION OF CHAT mRNA IN THE RAT BRAIN AND SPINAL CORD. Justin D. Oh, Nancy J. Woolf, Ali Roghani, Robert H. Edwards, and Larry L. Butcher. Dept. Psychology and Neurology, UCLA, Los Angeles, CA 90024-1563, U.S.A.

Gene expression of choline acetyltransferase (ChAT) in the central nervous system was studied by use of *in situ* hybridization histochemistry. RNA probes against ChAT DNA templates were synthesized using *in vitro* transcription in the presence of digoxigenin-11-UTP. The probe was detected by an antibody against dioxigenin coupled to alkaline phosphatase. This method resulted in a large number of cell bodies and occasional proximal processes being intensely labeled against a virtually undetectable background. Telencephalic cells expressing ChAT mRNA were found in the following striatal and basal forebrain nuclei: the caudate-putamen, nucleus accumbens, olfactory tubercule, medial septal nucleus, vertical and horizontal diagonal band nuclei, substantia innominata, and nucleus basalis. Cortical cells were not labeled with this probe. In the diencephalon, only cells of the medial habenula were labeled with the ChAT mRNA probe, other thalamic areas and the hypothalamus did not contain labeled cells. In the brainstem, only the pedunculopontine and laterodorsal tegmental nuclei and motor cranial nuclei 3, 4, 5, 7, 9, 10, and 12 contained cells labeled with the ChAT mRNA probe. In the spinal cord, ventral horn neurons exclusively exhibited ChAT mRNA label. The distribution of ChAT mRNA labeled cells in this study corresponds conservatively to previously identified cholinergic cells. [Support: USPHS grant NS 10928 to L.L.B.].

THE RAPID KINETICS OF ACETYLCHOLINE RELEASE FROM RAT BRAIN SYNAPTOSOMES: ANALYSIS BY RAPID SUPERFUSION. L. B. Pearce, and E. Adamec* Department of Pharmacology, Boston University School of Medicine, Boston, MA 02118.

Spontaneous and evoked [^{3}H]ACh efflux from rat brain synaptosomes was investigated on the second and millisecond time scale using the technique of rapid superfusion. Synaptosomes, radiolabeled by preincubation with [^{3}H]choline, were superfused with Krebs-bicarbonate buffer, pH 7.4 at 0.3 to 0.5 ml/second. The mixing half-life was 119 milliseconds (ms) and efficiency of superfusion > 85%. Superfusion for 48 seconds with isoosmotic Krebs buffer resulted in 1.57, 5.68, 7.19, 8.80, and 18.32 percent release of tritium in the presence of 10, 20, 30, 50, 75, and 100 mM potassium ion, respectively. Kinetic analysis of net potassium-stimulated release revealed a single component of release that fit a single exponential function with a $t_{1/2}$ = 12.7, 13.1, 15.4, and 12.7 seconds for 20, 50, 75, and 100 mM KCl. Analysis of the area under the tritium efflux curves observed for serial collection of 50 ms samples over 750 ms revealed that 0.111, 0.550, 0.614 % net tritium release was evoked by superfusion with isoosmotic buffer containing 20, 50, and 100 mM KCl, respectively. Potassium-evoked release observed on both the second and millisecond time scales was totally calcium-dependent whereas, only a small fraction of spontaneous release was dependent on calcium. This work was supported by a grant from The Eppley Foundation for Research.

MUSCARINIC TYPE-2 ANTAGONISTS INCREASE HIPPOCAMPAL ACETYLCHOLINE RELEASE IN UNANESTHETIZED RATS.

M.J. Stillman*, B. Shukitt-Hale, R.M. Kong*, A. Levy, Ross H. Pastel and H.R. Lieberman.

Military Performance and Neuroscience Division, United States Army Research Institute of Environmental Medicine, Natick, MA 01760.

Hippocampal muscarinic receptors belong to two main pharmacologic subtypes, M_1 and M_2. The majority of the latter subtype is predominantly located presynaptically, where these receptors could modulate acetylcholine (ACh) release by functioning as inhibitory autoreceptors. M_2 antagonists may inactivate this receptor, leading to increased ACh release. The purpose of this study was to assess changes in extracellular ACh via *in vivo* microdialysis following administration of various M_2 antagonists. Microdialysis guide cannulae were implanted into the CA1 hippocampal region of male Fischer rats. After a minimum of two days to recovery from surgery, each rat was tested while awake and unrestrained. Drug or placebo was perfused via the microdialysis probe. High performance liquid chromatography with electrochemical detection was used for on-line analysis of the dialysates. M_2 antagonists significantly enhanced ACh release in a dose-dependent fashion as compared to placebo. The present data corroborate studies which show increased ACh levels *in vitro* following application of M_2 antagonists.

DOPAMINERGIC REGULATION OF STRIATAL ACETYLCHOLINE RELEASE: IMPORTANCE OF D1 AND NMDA RECEPTORS G. Damsma†, G.S. Robertson§, C. Tham§* and H.C. Fibiger§, †PF/CNS 70/310, Hoffmann La Roche, CH-4002, Basel, Switzerland; §Division of Neurological Sciences, Dept. of Psychiatry, University of British Columbia, Vancouver, B.C., Canada, V6T 1Z3

The dopaminergic regulation of striatal cholinergic activity was studied using *in vivo* microdialysis to measure the interstitial concentration of acetylcholine (ACh) and choline in the striata of freely moving rats. *d*-Amphetamine (2 mg/kg, s.c.) and nomifensine (5 mg/kg, s.c.) increased the concentration of ACh in the striatal dialysate by 40-60%. The selective D1 receptor antagonist SCH 23390 (0.3 mg/kg, s.c.) decreased the concentration of ACh in the striatal dialysate by 15-20%, while the selective D2 antagonist raclopride (1 mg/kg, s.c.) increased striatal ACh release by 50-60%. Raclopride blocked the increase in locomotor activity produced by *d*-amphetamine but did not interact with the stimulant to further enhance ACh release. In contrast, SCH 23390 completely antagonized both the increase in locomotion and the enhancement of striatal ACh release produced by *d*-amphetamine. SCH 23390 also blocked the raclopride-induced increase in ACh overflow. These results indicate that *d*-amphetamine increases ACh release in the striatum via a D1 receptor mechanism. Consistent with this hypothesis, the selective D1 receptor agonist CY 208-243 (1 mg/kg, s.c.) increased striatal ACh release by approximately 60%. Inclusion of the N-methyl-D-aspartate (NMDA) receptor antagonist MK-801 in the striatal perfusion solution significantly attenuated the increase in striatal ACh release produced by CY 208-243. Consequently, increased striatal ACh release produced by enhanced D1 receptor stimulation appears to be mediated, at least in part, by activation of striatal NMDA receptors.

CHOLINERGIC MICROSTIMULATION OF THE PERIBRACHIAL NUCLEUS: PROLONGED ENHANCEMENT OF PGO WAVES AND REM SLEEP. S.Datta, J.M.Calvo, J.Quattrochi and J.A.Hobson. Lab. of Neurophysiology, Harvard Med. School, Boston, MA 02115 and Instituto Mexicano de Psiquiatría, México D.F.

During REM sleep ponto-geniculo-occipital (PGO) waves are generated by cholinergic neurons in the peribrachial pons. We report here the effect of cholinergically stimulating this brain region. Five cats were chronically prepared for recording wake-sleep parameters. After recovery, carbachol (4.0 μg/250nl) was microinjected into the peribrachial PGO bursting cell zone. Carbachol produced an immediate onset of state-independent PGO waves lasting 4 days and the duration of state-dependent PGO waves remained high for 6 days (49.3±13.8%, $p<0.0001$) compared to control values (18.9±6.3%). Beginning on day-2, increased PGO activity was associated with a threefold increase in REM%. REM% also remained elevated for 6 days (22.2±6.4% , $p<0.001$) compared to control values (13.0±3.2%). We postulate that the immediate and sustained increase in PGO activity is due to cholinergic activation by carbachol of the PGO burst cells and the delayed, sustained increase in REM is a secondary consequence of membrane excitation. Supported in part by NIH grant MH-13923.

520.1

MOLECULAR CHARACTERIZATION OF A STRIATAL ENRICHED PROTEIN TYROSINE PHOSPHATASE.

P. Lombroso, G. Murdoch*, M. Brines and M. Lerner*. Child Study Center, Howard Hughes Medical Institute, Yale University, New Haven, CT 06510.

Modulation of tyrosine phosphorylation is one mechanism for regulating cell differentiation and is controlled by opposing actions of protein tyrosine kinases (PTKs) and protein tyrosine phosphatases (PTPases). A number of PTPases have been cloned and their amino acid sequence determined. Two classes have been identified. The first class is intracellular and the second class has extracellular regions linked to cytoplasmic, catalytic domains through single transmembrane regions. Although Northern analyses of different tissues indicate wide variability in the regional expression of PTPases, none have been nervous system specific.

Here, we report the isolation and characterization of a cDNA clone which encodes for a PTPase found predominantly in the brain. Within the brain, it shows further tissue specificity by appearing to be a STriatal Enriched Phosphatase and has been designated STEP. This new PTPase contains regions homologous to ones found in previously characterized PTPases, and appears to be a distinct member of the cytoplasmic class of PTPases. The deduced amino acid sequence predicts a protein of approximately 369 amino acids. *In vitro* translation produces a protein with an apparent molecular weight of 46 kDa. Northern analyses of various regions of rat brain reveal a 3 kb and a 4.4 kb mRNA. *In situ* hybridization experiments support the Northern analyses by showing a high degree of localization of the 3 kb message in the striatum.

TIME-COURSE OF PEPTIDE ALTERATIONS IN STRIATAL EFFERENT NEURONS AFTER UNILATERAL CORTICAL LESION BY THERMOCOAGULATION.

P.Salin, C. Gonzales, F. Szele and M-F.Chesselet,. Dept of Pharmacology. University of Pennsylvania, Philadelphia, PA 19104

We have previously reported (Chesselet and Salin, Neurosci. Abst. '90) a bilateral increase in the levels of mRNAs encoding enkephalin (ENK) and substance P (SP), two neuropeptides present in striatal efferent neurons projecting to the globus pallidus (GP) and entopeduncular nucleus (EP) respectively, 5 and 21 days after unilateral lesions of sensory-motor cortex by thermocoagulation in adult rats. Levels of ENK and SP were measured in GP and EP after similar lesions, by quantitative immunohistochemistry with 125I- secondary antibodies and film autoradiography. After an initial increase, ENK immunoreactivity in GP markedly decreased contralaterally at 6 weeks, and bilaterally at 3 months post-surgery, without a parallel loss of ENK mRNA-positive neurons in striatum. SP levels in EP were decreased, but to a lesser extend. The results suggest a delayed alteration in peptide synthesis or transport in striatal efferent neurons after cortical lesions in rats. The greater severity of effects in the side contralateral to the lesion points to a role of the contralateral cortex in these effects. Supported by BNS 86-16841 and NS 29230.

520.3

ULTRASTRUCTURAL CHARACTERIZATION OF DOPAMINE IMMUNO-POSITIVE FIBERS AND THEIR RELATION TO POSTSYNAPTIC STRUCTURES IN THE STRIATUM AND NUCLEUS ACCUMBENS OF THE LIZARD GEKKO GECKO.

J.M.L. Henselmans* and F.G. Wouterlood. Department of Anatomy, Free University, Amsterdam, The Netherlands.

In the lizard *Gekko gecko*, efferents of mesencephalic dopaminergic neurons project to the striatum (STR) and the nucleus accumbens (ACC). We studied this innervation by means of immuno-EM, using an antibody against dopamine (DA). DA-immunoreactivity in the striatal complex is localized in boutons which mainly contain clear round vesicles and a few dense-cored vesicles. The great majority of the DA-immunopositive boutons form symmetrical synapses with dendritic shafts. In addition, symmetrical axo-somatic contacts were found. Only a few synapses were found with dendritic spines. In STR, one DA-immunopositive bouton established both an axo-somatic and an axo-axonic contact. Occasionally, convergence on dendrites was observed of a DA-immunopositive terminal and an unlabeled axon terminal. Since symmetrical synapses have been associated with inhibition, the DA-immunopositive elements in the STR and ACC may be involved in an inhibitory action of dopamine. In the rat, asymmetrical, non-dopaminergic and symmetrical, dopaminergic synapses frequently converge on a common postsynaptic element. The absence of this phenomenon in the STR of *Gekko* suggests a different organization of inhibitory and excitatory inputs than in mammals.

DISTINCT SUBSETS OF NEUROTENSIN IMMUNOREACTIVE NEURONS REVEALED IN THE RAT STRIATUM FOLLOWING ANTAGONISM OF THE DOPAMINE-MEDIATED SUPPRESSION OF NEUROTENSIN IMMUNOREACTIVITY.

D.S. Zahm. Dept. of Anat. and Neurobiol., St. Louis Univ. Sch. of Med. St. Louis, MO, 63104.

The distribution of neurotensin immunoreactive structures in the rat striatum was evaluated after blockade of dopamine neurotransmission by drugs that act presynaptically (6-OHDA, reserpine) and postsynaptically, preferentially at the D-2 (eticlopride, haloperidol) and D-1 (SCH-23390) receptor sites. Calbindin-D 28 kD immunoreactivity was used to delineate patch(striosome) and matrix in the caudate-putamen and core and shell in the nucleus accumbens. Antagonism at the D-2 dopamine receptor and 6-OHDA lesions caused dense axonal immunoreactivity and moderate numbers of neurotensin immunoreactive neurons to be distributed preferentially in the matrix of the caudate-putamen. D-1 receptor antagonism was significantly less effective at eliciting neurotensin immunoreactive neurons in the caudate-putamen. Reserpine or co-administration of the D-1 and D-2 receptor antagonists produced many neurotensin immunoreactive neurons in both striatal compartments throughout the caudate-putamen and dense axonal neurotensin immunoreactivity in the medial patch compartment. This dense axonal neurotensin immunoreactivity may therefore be a site of convergence of neurotensin immunoreactive axons from nearby patch and matrix. To varying degrees, with SCH-23390 being least effective and reserpine most effective, all of the drug treatments elicited neurotensin immunoreactivity in neurons in the olfactory tubercle, rostral nucleus accumbens, accumbal shell and ventrolateral caudate-putamen, i.e., most of ventral striatum. Support: NS-23805.

520.5

THE SYNAPTIC CHARACTERISTICS OF Leu-ENKAPHALIN IMMUNOREACTIVE TERMINALS IN THE MARGINAL DIVISION OF THE MONKEY (Macaca Mulatta) STRIATUM.

S.Y.Shu and X. Bao. Dept. Neurobiol., Center Neuromed., Zhu-Jiang Hospital, Guangzhou, China.

A new subdivision, the marginal division has been found in the striatum of the monkey as well as in the rat striatum (Shu, et. al., J Chemical Neuroanatomy 1988). The marginal division is more densely filled with enkephalin(Enk) - and substance(SP) P -immunoreactive terminals than does the rest of the striatum. In the present study we examined the ultrastructure of L-Enk immunoreactive terminals in the monkey (Macaca Mulatta) striatum. A pre-embedding staining technique was used. The tissues of the darker stained marginal division were dissected out under a macroscope and processed for EM examination. The L-Enk immunoreactive product is deposited around the vesicles in the positive reacted terminals. Four types of synapses consisting of L-Enk immunoreactive terminals are observed in the marginal division of the monkey striatum. They are axo-dendritic(A-D), axo-somatic(A-So), axo-axonic(A-A) and compound synapses. Axo-spinous(A-Sp) synapses are found but not connecting with L-Enk reactive terminals. Most of the synapses with L-Enk immunoreactive terminals are compound with more than three components. The compound synapses are demonstrated in different ways: A-A-D, D-A-D, A-D-A, D-A-So, or A-A-So.

520.6

A SECOND INPUT SYSTEM FOR BODY REPRESENTATIONS IN THE PRIMATE STRIATAL MATRIX.

A. W. Flaherty[1,2] and A. M. Graybiel[1]. [1]Dept. of Brain and Cog. Sci., Mass. Inst. of Technol., Cambridge MA 02139. [2]Div. of Health Sci. and Technol., Harvard Medical School, Boston MA 02115.

Only one sensorimotor input system to the primate striatal matrix, the projection from ipsilateral sensorimotor cortex, has been mapped both anatomically and electrophysiologically. We show here the existence of a second system, from the contralateral motor cortex, which projects to a different set of interdigitating zones within the matrix. Intracortical microstimulation and multiunit recording guided deposits of distinguishable anterograde tracers in motor cortex (area 4) and SI somatosensory cortex (area 3b) in 4 squirrel monkeys. Striosomes and matrix were distinguished by enkephalin immunohistochemistry.

In one monkey we examined foot area inputs from ipsilateral motor cortex and from area 3b (which projects almost exclusively ipsilaterally). The regions innervated overlapping zones in the matrix of the putamen (cf. Fotuhi et al., *Soc.Neurosci.Abstr.* '89), zones that also receive input from corresponding parts of ipsilateral areas 3a and 1 (Flaherty and Graybiel, *J.Neurophys.*, in press). In two monkeys we deposited one tracer in nearly all of SI bilaterally, and the other tracer, on one side only, in the motor cortex leg representation. Ipsilaterally, the leg representations of motor cortex and SI projected to largely overlapping zones. In sharp contrast, contralateral motor cortex sent its strongest inputs to matrix zones that largely interdigitated with inputs from ipsilateral SI. In a fourth monkey we labeled motor cortex in each hemisphere with differentiable tracers. Ipsi- and contralateral motor cortex projected to largely interdigitating matrix zones.

These experiments suggest that inputs from cortex representing predominantly the contralateral and ipsilateral body alternate in the primate striatal matrix, an arrangement reminiscent of the alternating ocular dominance columns in visual cortex.

OROFACIAL MOTOR CONTROL IN THE VENTROLATERAL STRIATUM OF RAT: GLUTAMATERGIC-DOPAMINERGIC INTERACTIONS. M. Pisa. Dept. Biomed. Sci., Div. Neurosci., McMaster Univ., Hamilton, Ont. Canada L8N 3Z5.

Previous lesion studies indicated a role of the ventrolateral striatum in orofacial motor control (Pisa, Neurosci., 24:453, 1988). The aims of this research were to examine the roles of corticostriatal glutamatergic (GLU) and nigrostriatal dopaminergic (DA) transmission in orofacial motor control. Rats were administered microinfusions of kynurenic acid (KYN), an antagonist of GLU transmission, into the ventrolateral striatum through chronically implanted cannula guides (12 to 36 nmoles/0.2 ul PBS, pH 7.4), with or without prior infusion of the dopamine receptor blocker haloperidol (HAL: 0.1 to 0.5 ug/0.2 ul of 1% lactic acid), and their orofacial movements were videotaped for 1h. Data were number of grimacing movements and non directed (in vacuo) chewing movements. KIN injections produced a dose-dependent, significant increase of grimacing and chewing. HAL injections dose-dependently reduced the KYN-induced dyskinesias. These results indicate that 1) an impairment of corticostriatal GLU transmission can produce oral dyskinesias; 2) a concomitant blockade of nigrostriatal DA transmission can counteract this effect. The implications of these findings for normal brain function and mechanisms of oral dyskinesias in humans will be discussed. (Supported by the Scottish Rite Schizophrenia Res. Prog. M.P. is a Research Associate of the Ontario Mental Health Foundation).

520.8

ORGANIZATION OF NIGROSTRIATAL AND STRIATONIGRAL PROJECTIONS IN THE PRIMATE. E. L. Lynd-Balta, S.J. Mitchell, and S.N. Haber. Department of Neurobiology and Anatomy, University of Rochester, Rochester, N.Y. 14642.

The substantia nigra and striatum are reciprocally connected. Lesions of the nigrostriatal pathway result in profound deficits as seen in Parkinson's Disease. The striatum receives topographical inputs from cortex which impose a cortical map on the striatum. It has been hypothesized that striatal output projections maintain this topography so that different parallel circuits travel through the basal ganglia. We propose that the organization of efferent projections of the substantia nigra pars compacta does not maintain a strict topography in its relationship with the striatum and that some integration between regions such as dorsolateral (motor) and ventromedial (limbic) striatum may occur through the inputs and outputs of the substantia nigra.

A combination of retrograde and anterograde tracers were placed in the dorsolateral motor-related region and the ventromedial limbic-related region of the striatum. Results indicate that there is overlap in the substantia nigra between the inputs and outputs of these different regions. For example, terminals labeled from an injection of PHA-L into the ventral striatum overlap with retrogradely labeled neurons in the substantia nigra after an injection of HRP-WGA into the dorsal striatum. These results suggest that the substantia nigra may be an important integrator of striatal function by allowing different areas of the striatum to communicate via pathways through the substantia nigra. Supported by NIH NS22511.

520.9

HALOPERIDOL + SCH 23390 PREVENTS THE INCREASE IN RAT STRIATAL 'PERFORATED' SYNAPSES DUE TO EITHER DRUG ALONE: POSSIBLE INVOLVEMENT OF SEPARATE D-1/D-2 PATHWAYS. C.K. Meshul, A. Janowsky, D.E. Casey*, R.K. Stallbaumer*, B. Taylor*. V.A. Medical Center and Depts. of Pathology, Medical Psychology, Psychiatry, and Pharmacology, Oregon Health Sciences Univ., Portland, OR 97201

Haloperidol (0.5 mg/kg/d/14d), a neuroleptic associated with extrapyramidal syndromes (EPS) and tardive dyskinesia (TD), blocks dopamine (DA) D-2 receptors, while SCH 23390 (1 mg/kg/d/14d) blocks DA D-1 receptors. These drugs cause an increase in striatal DA D-2 and D-1 receptors, respectively, and in the percentage of 'perforated' synapses. Co-administration of haloperidol and SCH 23390 for 14 days prevented the increase in striatal perforated synapses while the DA D-2 and D-1 receptors were increased to the same level as if administered separately. We have shown that the perforated synapse originates from motor cortex and speculate that the increase is due to activation of the corticostriatal pathway. It has been suggested that many striatal neurons possess separate DA D-1 and D-2 receptors. The D-1 pathway projects to the thalamus via the entopeduncular nucleus and the D-2 pathway also projects to the thalamus via the globus pallidus, subthalamic nucleus, and substantia nigra-zona reticulata. Simultaneous blockade of both receptor subtypes with haloperidol and SCH 23390 could up-regulate the two DA receptors, while converging input to the thalamus could eventually decrease activation of the corticostriatal pathway. Administration of SCH 23390 could be effective in reducing the incidence of EPS and TD associated with haloperidol. Supported by the Dept. of Veterans Affairs and NIMH.

SEGREGATED EFFERENT PROJECTIONS FROM NEOSTRIATAL COMPARTMENTS TO THE ENTOPEDUNCULAR NUCLEUS IN THE RAT. N. Rajakumar, K. Elisevich and B.A. Flumerfelt. Dept. of Anatomy and Clinical Neurological Sciences, Univ. of Western Ontario, London, Canada, N6A 5C1.

The compartmentalization of afferent projections and neurochemical markers into well demarcated striosomes and matrix regions is an established feature of the mammalian neostriatum. The observation of distinct types of neuroactive substances, receptors and their interactions in striosomes and matrix suggests a functional segregation between these compartments. The present study was undertaken to determine the organization of efferent projections from each of the neostriatal compartments to the entopeduncular nucleus (EP), one of the main output centers of the striatum. Fluorogold, a fluorescent retrograde tracer, was placed into the lateral habenula (LH) or the ventrolateral nucleus of the thalamus (VLT) of adult Wistar rats to identify the topographical organization of neurons projecting to these two major output centres of the EP. Subsequently, fluorogold was placed into the rostral or caudal region of the EP, identified from the above experiment as areas that project to the LH or VLT respectively. The fluorescent retrograde labelling was combined with immunocytochemistry for calbindin, a specific marker for the projection neurons of the matrix. The results reveal that the rostral part of the EP projects to the LH and receives input exclusively from the striosomes, whereas the caudal part of the EP projects to the VLT and receives input exclusively from the matrix. These observations were substantiated by the finding that calbindin immunoreactive fibres lie in relation to those EP neurons that project to the VLT. The data suggest that the striosome is involved in a pathway through EP, LH and the dorsal raphe nucleus which in turn projects to the neostriatum, while the matrix is involved in a pathway through EP and VLT which projects to the cerebral cortex. LIMBIC INTERACTION IN THE ROSTRAL CAUDATE NUCLEUS: A NEUROANATOMICAL STUDY IN THE CAT. A. Rosell*, S. de las Heras*, B. Hontanilla*, P.Barreiro* and J.M. Giménez-Amaya. Dept. Morfología, Fac. Medicina, U.A.M., 28029-Madrid, SPAIN.

The limbic component of the basal ganglia has been mainly assigned to the so-called ventral striatum. The dorsal striatum has, however, a remarkable innervation from limbic territories located in the medial wall of the cerebral cortex (Powell et al.,1974). This study was designed to explore in detail the organization of these projections, and their hodological relationship with two other afferent striatal systems: the thalamus and the substantia nigra. Eleven cats were deeply anesthetized and stereotaxically injected with horseradish peroxidase free (HRP) and/or conjugated with wheat germ agglutinin (HRP-WGA) in different portions of the rostral caudate nucleus. Next, we focussed our anatomical evaluation of retrogradely labeled cells in the limbic areas of the medial wall of the ipsilateral hemisphere, rostral intralaminar nuclei of the thalamus (ILr) and the pars compacta of the substantia nigra (SNc). Adjacent sections processed for acetylcholinesterase and Nissl were used to complete, histochemically and cytoarchitectonically, our tracer study. The most prominent results of this study are: a) the anterior limbic area projects heterogeneously to the rostromedial striatum (RmS) following a dorsoventral topology, with rostral cortical portions projecting chiefly to more dorsal striatal aspects, and caudal territories to more ventral parts of RmS; b) the rostral and dorsal pole of the cingulate area (Cg) projects mainly to dorsal areas of RmS; c) more caudal zones of Cg project conspicuously to central portions of RmS; d) the rostral half of the retrosplenial area projects to dorsal, central and ventral fields of RmS; e) regarding the ILr, dorsal injections in RmS elicited a remarkable labeling in the central lateral and paracentral thalamic nuclei, central injections into RmS labeled noticeably the so-called central dorsal thalamic nucleus, and more ventral injections in RmS yield retrogradely labeled cells mainly in the midline thalamic nuclei; and, finally, f) the two caudal thirds of the SNc were most abundantly labeled after retrograde tracer injections in RmS. Supported by CICYT PB88-0177.

PHARMACOLOGICAL ACTIVATION OF DOPAMINERGIC PATHWAYS IN THE BABOON STUDIED WITH PET. C.C. Rowe* and J.S. Perlmutter. Washington University School of Medicine, St. Louis, MO 63110.

We developed an in-vivo method to measure regional cerebral blood flow (rCBF) responses to dopamine receptor manipulation in the anesthetized baboon. A surgically implanted skull cap that locks into a head holding device equipped with 3 orthogonal N-shaped fiducial markers for PET and MRI was employed for head fixation. Comparison of PET fiducial measurements to those from an MRI obtained in the same plane in each animal permitted precise anatomical identification of rCBF responses. Quantified CBF studies were performed using the bolus O-15 water method and regional responses were identified by subtraction of studies performed before and after I.V. drug administration. We found as much as a 25% reduction in rCBF in the lentiform nucleus and thalamus after i.v. injection of the selective D2 agonist quinpirole. These reductions were dose dependent over the range of 0.002 to 0.2 mg/kg and were reproducible within and across different animals. Furthermore, different regional responses occurred after the D1 agonist SKF 38393. Functional effects of specific dopamine pathways manipulation can be demonstrated in-vivo in primates with PET.

520.13

TASK SPECIFIC MOVEMENT INITIATION IMPAIRMENTS AND EFFECTS OF L-DOPA IN PATIENTS WITH BASAL GANGLIA DISEASE. V. J. Brown, E. M. Bowman, U. Schwarz, T. A. Zeffiro, D. L. Robinson, and M. Hallett*.
Laboratory of Sensorimotor Research, N.E.I. and *Human Motor Control Section, N.I.N.D.S., Bethesda, MD 20892.

The symptoms of Parkinson's disease include a slowness to initiate movement. However, the impairment may be task specific. It has been suggested that patients may be unimpaired when the responses are cued by stimuli which are compatible with the response, but when the stimulus-response (S-R) relationship is arbitrary, there is an impairment.

To test this hypothesis, two choice reaction time tasks were compared. In both tasks, the subjects responded by lifting the right or left index finger as rapidly as possible following a cue. In one task (S-R compatible), the stimulus was to the left or the right. In the other task (arbitrary S-R) the side of the required response was symbolically cued.

Performance of patients with idiopathic Parkinson's disease was compared with that of patients with Parkinsonian-like symptoms which were not responsive to L-dopa. Both groups were tested with and without L-dopa on each type of choice reaction time task. Only the patients with Parkinson's disease were differentially impaired in the two tasks, but it was the task with high S-R compatibility which was more impaired and not the task with an arbitrary S-R relationship. The differential deficit was ameliorated with L-dopa treatment. These results demonstrate a task specific impairment in reaction time performance with differential response to dopaminergic therapy.

INVERTEBRATE LEARNING AND BEHAVIOR III

521.1

BLOCKADE OF ADENYLATE CYCLASE INCREASES THE RATE OF SYNAPTIC DEPRESSION IN SIPHON SENSORY NEURONS IN APLYSIA. B.A. Goldsmith and T.W. Abrams Dept. of Biology & Institute of Neurological Sciences, Univ. of Pennsylvania, Phila., PA 19104.

We have found that an inhibitor of adenylate cyclase, 9-(tetrahydro-2-furyl)adenine (THFA or SQ 22,536) effectively blocks cAMP-mediated effects produced by 5-HT in siphon sensory neurons (SNs) including spike broadening, reduction of accommodation, and reversal of depression at SN synapses. We observed that synaptic depression occurred more rapidly in the presence of THFA. When SNs were stimulated at an ISI of 15 s, the second EPSP was 35 ± 6% (± SEM) of initial amplitude in THFA vs. 71 ± 6% in controls ($p<.001$). After 10 SN action potentials were elicited, EPSPs still showed significantly more depression in THFA experiments (29 ± 6% initial amplitude in THFA vs. 42 ± 3% in control, $p<.001$). In addition to acting as a cyclase inhibitor, THFA produces a modest broadening of SN action potentials, possibly by blocking K^+ channels. Comparable broadening of the SN APs by the K^+ channel blocker 3,4-DAP had no effect on the rate of synaptic depression. These results suggest that cAMP plays an important role in maintenance of normal levels of synaptic transmission.

POSSIBLE MOLECULAR BASIS OF THE ORDER REQUIREMENT FOR CS-US PAIRING DURING CONDITIONING: BACKWARDS PAIRING OF Ca^{2+} WITH FACILITATORY TRANSMITTER ACCELERATES THE DEACTIVATION OF *APLYSIA* NEURAL CYCLASE. H.E. Jarrard*, Y. Yovell, T.W. Abrams. Dept. of Biology & Inst. of Neurological Sciences, Univ. of Penn., Phila., PA 19104.

During classical conditioning of the gill and siphon withdrawal reflex of *Aplysia*, Ca^{2+}/calmodulin-sensitive cyclase serves as a molecular site of convergence within siphon sensory neurons for Ca^{2+} and serotonin, the cellular representations of the conditioned and unconditioned stimuli (CS and US). Using a perfused membrane cyclase assay, we previously found that a prepulse of Ca^{2+} resulted in both a faster rate of cyclase activation and greater peak activation by a brief pulse of 5-HT than did a backwards pulse of Ca^{2+}. These results suggested that Ca^{2+}/calmodulin binding to the cyclase might enhance the rate of activation by receptor and G_s. If Ca^{2+}/calmodulin binding influences the rate of G_s-cyclase coupling, we hypothesized it might also affect the rate of G_s-cyclase uncoupling once transmitter leaves the receptor. To test this possibility, we measured the time course of cyclase deactivation, in the presence and absence of a pulse of Ca^{2+} delivered after a transient exposure to 5-HT. The Ca^{2+} pulse, after 5-HT had been washed out, accelerated the rate of decay of cyclase activity to basal. These results suggest that the CS-US sequence requirement of classical conditioning may result from effects of Ca^{2+}/calmodulin on G_s-cyclase coupling and uncoupling.

521.3

A MOLECULAR MECHANISM FOR MEMORY IN *APLYSIA* : UBIQUITIN-MEDIATED PROTEOLYSIS OF REGULATORY SUBUNITS OF THE cAMP-DEPEDNDENT PROTEIN KINASE. Ashok N. Hegde and James H. Schwartz. Howard Hughes Medical Institute, Columbia University, New York, NY 10032

In *Aplysia*, behavioral sensitization of defensive reflexes and the underlying presynaptic facilitation of sensory-to-motor neuron synapses lasts for several min (short-term) or days to weeks (long-term). Short-term facilitation has been explained by cAMP-dependent modulation of ion channel function. Long-term facilitation requires additonal molecular processes including new protein synthesis. A key molecular event is persistent activation of the cAMP-dependent protein kinase (PKA). Greenberg et al (*Nature* **329:** 65-69, 1987) showed that regulatory (R) subunits are lost in long-term sensitization and this could account for persistent activation (Sweatt & Kandel, *Nature* **339:** 51-54, 1989). Despite dependence on new protein synthesis the loss of R results from proteolysis rather than diminished synthesis (Bergold et al, *PNAS* **87:** 3788-3791, 1990). In order to understand the molecular events that produce the loss of R in long-term facilitation, we investigated how R is degraded. A prominent degradation pathway (involved in stress, cell cycle and other developmental events) is mediated by ubiquitin. When several molecules of ubiquitin are conjugated to a protein, it is degraded. We find that *Aplysia* R subunits in nervous tissue (and early embryos) are degraded through the ubiquitin pathway. First, high molecular-weight *Aplysia* R-ubiquitin conjugates (ladders) form in cell-free rabbit reticulocyte lysates, suggesting that R subunits can be multi-ubiquitinated. Second, we observe ATP- and ubiquitin- dependent degradation of R. We suggest that the ubiquitin-mediated proteolysis of R operates constitutively in *Aplysia* neurons (which contain ubiquitin) and, further, that in facilitated sensory cells a protein targeting R for multi-ubiquitination is synthesized that is limiting in naive neurons. The *induction* of this postulated targeting protein would result in enhanced degradation of R, which in turn would *maintain* PKA in an activated form.

521.4

INHIBITORS OF PROTEIN AND RNA SYNTHESIS BLOCK STRUCTURAL CHANGES ACCOMPANYING LONG-TERM PRESYNAPTIC FACILITATION AND INHIBITION IN *APLYSIA* SENSORY NEURONS. S. Schacher, P.G. Montarolo, E.R. Kandel, Mary Chen, and C.H. Bailey Ctr. Neurobiol. & Behav., Columbia P&S, NYSPI, & HHMI, N.Y., N.Y. 10032.

Long-term presynaptic facilitation by 5-HT of sensorimotor synapses in culture is accompanied by increases in both the size of the EPSP evoked in the motor cell L7 and in a number of sensory neuron varicosities. By contrast, long-term presynaptic inhibition by FMRFamide of sensorimotor synapses is accompanied by a decrease in sensory neuron varicosities. Since in both cases the changes in the EPSPs are dependent on macromolecular synthesis, we now examined whether the structural changes also require protein or RNA synthesis. As previously reported, both transmitters evoked long-term changes in the EPSP in L7 that are paralleled by changes in the number of sensory neuron varicosities. Thus, the EPSP increased by 61% ± 10 and the number of varicosities by 46% ± 7 with 5-HT ($N = 15$), and the EPSP decreased -41% ± 4 and the varicosities decreased by -26% ± 5 with FMRFamide ($N = 10$). The protein synthesis inhibitor, anisomycin, and the RNA synthesis inhibitor, actinomycin-D, blocked both the changes in EPSP and in the number of varicosities evoked by each transmitter. The inhibitors alone had no significant effect on the structure of the sensory cell or the EPSP. These results indicate that structural changes require the expression of genes and proteins not required for the short-term changes, and suggest that the long-term structural changes are tightly coupled with long-term modulation in the efficacy of synaptic transmission.

521.5

EARLY STEPS IN LEARNING-RELATED SYNAPTIC GROWTH: 5-HT INDUCES ENDOCYTIC ACTIVATION AND INTERNALIZATION OF N-CAM RELATED CELL ADHESION MOLECULES IN *APLYSIA*: C.H. Bailey, M. Chen, F. Keller and E.R. Kandel. Ctr. Neurobiol. & Behav., Columbia P&S, NYSPI, & HHMI, NY, NY 10032.

We have found the synaptic growth that accompanies 5-HT induced long-term facilitation of the sensory to motor connection in *Aplysia* dissociated cell culture requires new protein and mRNA synthesis. This growth is associated with a down-regulation of cell adhesion molecules related to N-CAM (Ap CAM, Barzilai et al., 1989; Mayford et al., in prep). By combining thin section E.M. with gold-conjugated mAb specific to Ap CAM (Keller and Schacher, 1990), we have found that 5-HT leads, within one hour of its application, to a 50% decrease in the density of gold-labeled complexes at the surface membrane of the sensory neuron (9.4/ μm ± 0.7, SEM = 7) vs. Control (19.5 ± 1.4, $p<0.001$). Down-regulation is achieved by activation of the endosomal pathway, leading to internalization and subsequent degradation of Ap CAM. The endocytic activation and resultant internalization triggered by 5-HT increases the gold found within the cell seven-fold (29.4 ± 2 vs. 4.1 ± 0.3; n = 7, $p<0.001$), requires new protein synthesis and is particularly prominent at sites of homophilic interactions. These findings suggest that an early step in learning-related synapse formation involves endocytic activation and internalization of cell adhesion molecules via a clathrin-dependent pathway. The removal of cell adhesion molecules from the neuronal surface may lead to a destabilization of cell-cell contacts that might be important for disassembly. In addition, we suggest that endocytosis may lead to a redistribution of membrane components to sites of new synapse formation.

521.6

FURTHER BEHAVIORAL AND CELLULAR STUDIES OF DISHABITUATION AND SENSITIZATION IN *APLYSIA*. T.E. Cohen*, V. Henzi, E.R. Kandel and R.D. Hawkins. Ctr. Neurobiol., Columbia Univ., HHMI, NY, NY 10032.

We have developed an isolated mantle organ preparation for simultaneous behavioral and cellular studies of plasticity of the gill-withdrawal reflex in *Aplysia*. In our initial behavioral studies, we reinvestigated the effect on dishabituation and sensitization of test time, tap strength, and shock intensity. Sensitization occurred in most conditions, with significant effects of time, tap, and shock. By contrast, for dishabituation there were no effects of tap or shock level 2.5 min after the shock, and the post-test was always slightly less than the first (pre-habituation) test. 12.5 min after the shock there were significant effects of both tap and shock level (as in sensitization), and in most conditions the post-test was greater than the first test. This pattern of results suggests that at 2.5 min dishabituation of this reflex may be due to removal of habituation, whereas at 12.5 min it may also be due to sensitization. In our initial cellular studies we reinvestigated the contribution of the LE mechanosensory neurons. We used a mechanical tapper driven by a solenoid and varied force by varying the travel distance. In 9 out of 21 preparations, a tap that did not actually touch the siphon elicited a gill-withdrawal response. By contrast, 32 out of 32 LE cells in those preparations fired action potentials if and only if the tapper touched the siphon. Moreover, the latency of firing of the LE neuron was always slightly longer than the latency of the onset of the response in a motor neuron. We have obtained similar latency results in a second series of experiments with a controlled force stimulator. These results confirm that the LE cells participate in the reflex, and suggest that a second, unidentified population of sensory cells with lower thresholds and slightly shorter latencies may also contribute.

521.7

ACTIVITY-DEPENDENT ENHANCEMENT OF ELECTROPHYSIOLOGICAL MEASURES CONSISTENT WITH ENHANCED PRODUCTION OF cAMP IN PLEURAL SENSORY NEURONS OF *APLYSIA*. R.D. Hawkins, T.E. Cohen*, L.S. Eliot and E.R. Kandel. Ctr. Neurobiol. & Behav., Columbia Univ., & HHMI, NY, NY 10032.

Activity-dependent facilitation of synaptic transmission from sensory neurons to motor neurons in *Aplysia* is thought to be due in part to enhanced production of cAMP in the sensory neurons (Kandel et al., 1983; Ocorr et al., 1985). Recently, Eliot et al. (1989) demonstrated activity-dependent facilitation in isolated cell culture, using a modified one-trial training procedure. We have begun to investigate whether this training procedure also produces electrophysiological changes consistent with enhanced production of cAMP in isolated clusters of pleural sensory neurons. In a first series of experiments, we produced tetanic firing (20 hz, 2 sec) of the neurons with extracellular shock either 0.5 sec (paired) or 1 min (unpaired) before a 30-sec application of 5-HT and measured the excitability (number of spikes produced by a constant intracellular current pulse) of one cell in the cluster. Paired training produced a significantly greater maximum ($\bar{X}$ = 425 vs. 292%) and duration ($\bar{X}$ = 2.4 vs. 1.5 min) increase in excitability than unpaired training ($N = 12$, $t = 2.26$, $p < .05$). Tetanus alone had no effect. Preliminary results from a second series of experiments suggest that paired training also produces a greater increase in frequency-broadened spike width (12.8%) than either 5-HT alone (7.7%) or tetanus alone (-1.6%). These results are consistent with enhanced production of cAMP in the sensory neurons, and lay the groundwork for future experiments relating these electrophysiological changes to biochemical measurements in the same preparation.

521.8

ACTIVATION OF THE FACILITATORY INTERNEURON L29 PRODUCES INHIBITION OF REFLEX INPUT TO SIPHON MOTOR NEURONS IN *APLYSIA*. T.M. Fischer & T.J. Carew, Yale Univ., Dept. Psychology, New Haven, CT 06520.

The identified interneuron L29 has a well characterized facilitatory role in the siphon withdrawal reflex (SWR) of *Aplysia* (Hawkins et al.,1981). We report here that L29 can also transiently inhibit this reflex via recruitment of recurrent inhibition from the identified interneuron L30.

The SWR was elicited by siphon taps (5 min ISI) in an isolated mantle/abdominal ganglion preparation. As a measure of net SWR circuit activity, we integrated the initial 500 msec of the tap-evoked complex EPSP in LFS siphon motor neurons (hyperpolarized to prevent spiking). Intracellular activation of L29 (5 sec, rate ≈ 30 Hz) 10 sec prior to a tap produced a significant decrement of the complex EPSP ($\bar{x}$ = 79% of baseline, $N = 7$, $p < .001$) which recovered by the next trial. In separate experiments, L29 activation 20 sec prior to a tap still produced significant inhibition ($\bar{x}$ = 85%, $N = 11$, $p<.01$), whereas 40 sec prior did not ($\bar{x}$ = 89% , $N = 10$, n.s.), indicating that L29-induced inhibition has a time course of approximately 30 sec.

Several preliminary observations suggest that the mechanism of L29-induced inhibition involves, at least in part, L29 removing itself from the SWR circuit through recruitment of recurrent inhibition from interneuron L30. First, voltage clamping L29 during reflex activation significantly reduces the complex EPSP in LFS neurons ($\bar{x}$ = 85%, $N = 11$, $p < .05$). Second, intracellular activation of L30 20 sec prior to tap inhibits both LFS complex EPSPs ($\bar{x}$ = 83%, $N = 9$, $p < .05$) and L29 spiking ($\bar{x}$ = 62%, N=5). Third, the monosynaptic IPSP from L30 to L29 shows substantial post-tetanic potentiation both directly (by L30 activation) and indirectly (by L29 activation). These observations suggest that L29/L30 interactions can serve as a module providing use-dependent gain control in the neural circuit for siphon withdrawal.

521.9

A NETWORK MODEL OF INHIBITORY INFORMATION PROCESSING IN THE SIPHON WITHDRAWAL REFLEX OF *APLYSIA*. D.E.J. Blazis, D. A. Berkowicz*, E. W. Kairiss, and T.J. Carew. Dept. Psych. and Prog. Neuroscience, Yale Univ., New Haven, CT, 06520.

Two forms of inhibition have recently been described in the siphon withdrawal reflex (SWR) of *Aplysia:* (1) Tail-shock (TS) induces transient inhibition of the SWR (Marcus et al, 1988). This inhibition is mediated, at least in part, by inhibitory interneuron (INT) L16. L16 responds to TS, activation of L16 inhibits reflex-induced complex EPSPs in siphon motor neurons (MNs), and voltage clamping L16 abolishes this TS-induced inhibition (Wright & Carew, 1990). (2) Activation of excitatory INT L29 inhibits reflex-induced complex EPSPs in MNs; this inhibition arises in part from L29's recruitment of inhibition onto itself from inhibitory INT L30, and is modulated both by electrical coupling between the cells and by post-tetanic potentiation (PTP) of the L30-L29 inhibitory synapse (Fischer & Carew, 1991).

We have used the network simulator GENESIS to incorporate the connectivity and synaptic interactions described above into a biologically plausible model of inhibition in the SWR. Our model includes elements representing siphon and TS input, INT processing, and MN output. This network generates both forms of inhibition observed in the SWR: (1) Activation of the simulated L16 inhibits reflex-induced EPSPs onto MNs. Following TS, which activates L16, the EPSP is reduced by ≈ 75%. TS-induced inhibition is abolished under simulated voltage clamp of L16. (2) Activation of simulated L29 recruits inhibition onto itself via activation of INT L30, which in turn reduces excitation to MNs. We are currently examining the computational significance of the L29-L30 electrical connection and inhibitory PTP at the L30-L29 synapse.

As our model more completely simulates inhibitory interactions in the SWR circuit, it will be of interest to apply it to different forms of learning exhibited by this reflex.

521.10

LATERALIZATION OF LONG-TERM HABITUATION IN TAIL-INDUCED SIPHON WITHDRAWAL IN *APLYSIA*. M. Stopfer, X.V. Chen*, and T.J. Carew. Department of Psychology, Yale University, New Haven, CT.

The tail-induced siphon withdrawal reflex (T-SWR) in *Aplysia* is mediated by bilateral clusters of sensory neurons. Each cluster conveys sensory information from one side of the body, raising the possibility that learning mediated by these sensory neurons might be lateralized. Indeed, Scholz and Byrne (1987) have demonstrated lateralization of long-term sensitization in the T-SWR. In this study we report that another form of learning, long-term habituation, also can be lateralized in the T-SWR.

Aplysia were bilaterally implanted with silver wire electrodes so that weak electrical stimuli (behaviorally equivalent to tactile stimuli) could be delivered consistently to the same tail sites. All experiments were conducted blind in freely-moving animals. Animals first received a series of bilateral pre-tests at a non-habituating (10 min) ISI; the T-SWR duration was measured following each stimulus. Next, computer-controlled unilateral habituation training ensued: four stimulus blocks were spaced 90 min apart (each block= 30 stim at a 30 sec ISI). Finally, bilateral tests were conducted 24 hr after training. Two experiments were conducted: in Exp 1 (N=13) the control side received no stimuli during the training period; in Exp 2 (N=15) the control side received an equivalent number of stimuli as the trained side, but at a non-habituating (10 min) ISI. An ANOVA revealed a significant overall effect of training in both experiments (interaction: $p<0.001$ in each). Furthermore, trained side test scores indicated significant habituation relative to their own pre-scores (Exp 1: $p<0.05$; Exp 2: $p<0.001$) whereas control sides showed no habituation.

Our results show that long-term habituation can be lateralized in the T-SWR. Since this reflex is well suited for a cellular and molecular analysis of behavior, it should now be possible to use the within-animal control provided by our findings to explore the detailed mechanisms of long-term memory for habituation.

521.11

DIFFERENTIAL EFFECTS OF THREE STIMULI PRODUCING LEARNED CHANGES OF RESPIRATORY PUMP RATE IN *APLYSIA*. M. Levy* and A.J. Susswein, Dept. of Life Sciences, Bar-Ilan University, Ramat Gan 52 900, Israel

In *Aplysia*, the gill contracts during 2 behaviors: 1) the gill withdrawal reflex; 2) respiratory pumping. Learning affecting the withdrawal reflex has been intensively studied by others. We have examined learned changes in respiratory pumping.

Three stimuli affecting respiratory pumping were identified: 1) decrease in pH 2) increase and 3) decrease in salinity. Effects of all 3 have sharp thresholds. For any of the 3, threshold can be altered by pairing subthreshold stimulation (pH 7.0, 120% or 85% seawater) with head shock. Shock alone, pre-exposure to a sub-threshold stimulus, or unpaired exposure to shock *and* a sub-threshold stimulus lead to sensitization of respiratory pumping that is shorter-lasting than is effect of pairing. Thus, pairing may amplify sensitizing effects produced by shock and by the 3 stimuli.

The head ganglia and the abdominal ganglion contain neurons capable of sensitizing the gill withdrawal reflex. These neurons also could affect respiratory pumping. When the pleural-abdominal connectives were cut, thereby separating the abdominal and head ganglia, no response was seen to decreased pH, but responses were normal to increases and decreases in salinity. These data suggest that sensitizing neurons in the head ganglia respond to decreased pH, while neurons in the abdominal ganglion mediate responses to altered salinity.

We tested this hypothesis further, by examining generalization of learning between the 3 stimuli. When animals were shocked in 85% seawater and tested in 120%, and vice versa, there was complete generalization of learning between the 2 stimuli. By contrast, there was no generalization of learning when animals were shocked in decreased pH and tested in either 85% or 120% seawater. These data support the suggestion that a common sensitizing site in the abdominal ganglion is responsive to increases and decreases in salinity, while a different site in the head ganglia responds to decreased pH.

DEVELOPMENT OF CEREBRAL CORTEX AND LIMBIC SYSTEM III

522.1

Development of amygdaloid projection of the prefrontal cortex in the rat studied with Phaseolus vulgaris-leucoagglutinin (PHA-L). R.W.H. Verwer, J.F.M. van Uum and E.H.S. van Vulpen*. Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam, The Netherlands and *Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Canada. (Spon: European Neuroscience Association)

The amygdaloid innervation pattern in the prefrontal cortex (PFC) was studied at 3 early postnatal ages. PHA-L was injected in the rostral part of the basolateral amygdala at postnatal days (dpp) 1, 6 and 12 and the pups survived for 2 days. At 1 dpp a few diffusely distributed very thin fibers were observed throughout the PFC. The most rostral and caudal parts were void of fibers. At 6 dpp more fibers were present and in the medial PFC (mPFC) fibers showed a slight preferrence for layers I, II, III and VI. The caudal part of the prelimbic area was almost empty. In the lateral PFC (lPFC) the fibers were mainly in layers V and VI. At 12 dpp there was a marked increase of the fiber density and a distinct segregation into two bands. In mPFC the bands comprised layers (II, III) and VI, which were less pronounced more caudally. Again the density became less in the caudal mPFC. In lPFC the bands were II and (V, VI). In adult rats (day 34) the pattern seemed to stay more or less the same, while the density further increased as compared with 12 dpp.

522.2

POSTNATAL DEVELOPMENT OF THE SEROTONERGIC INNERVATION IN THE FERRET CEREBRAL CORTEX. T.Voigt and A. D. de Lima. Max-Planck-Institut für Entwicklungsbiologie, Spemannstr.35/I, 7400 Tübingen, Germany

We have investigated the serotonergic innervation of the ferret cortex from the day of birth to adulthood with immunohistochemical techniques. Due to the premature birth of ferrets, this period spans the entire generation of cells located within the upper cortical layers and their subsequent migration to their final positions. Already at birth, serotonergic fibers innervate the developing cortex. This innervation is most dense within the marginal zone, the subplate region and the lower portion of the cortical plate. As long as cell migration continues, serotonergic fibers enter the expanding portions of the cortex. Only the region just below the marginal zone where newly arriving cells are added to the cortical plate is not innervated by the ingrowing fibers. When the bulk of cell migration ceases, during the third postnatal week, this gap disappears and the fibers gradually form a continuous innervation from the pia to the ventricle. As the cortex matures the serotonergic fibers become successively confined to the upper layers, to generate the adult pattern. In the adult ferret cortex, the highest innervation density is found within layers 1, 2 and 3, with a much sparser innervation within the lower layers. The dense innervation in the deep cortical layers is only transient, virtually disappearing towards adulthood. These results suggest that serotonergic axons innervate cortical layers as soon as newly arriving cells reach their final positions within the cortex. This early innervation lends support to the idea that serotonin may play a role during development of the cerebral cortex.

522.3

ISOFORMS OF MICROTUBULE-ASSOCIATED PROTEIN 2 (MAP2) IN DEVELOPING CAT CORTEX AND CORPUS CALLOSUM. B.M. Riederer, and G.M. Innocenti. Institute of Anatomy, University of Lausanne, Rue du Bugnon 9, 1005 Lausanne, Switzerland.

MAP2, an essential protein for dendritic microtubules and morphogenesis, was shown on immunoblots to occur in only two isoforms, MAP2b and c, during cat brain development. *In cat cortex*, MAP2b was abundant during the first postnatal month, and decreased towards adulthood, while no or little MAP2b was detectable in corpus callosum during the same time. MAP2c, present in three forms of close molecular weights, changed composition in cortex and corpus callosum during the first postnatal month, possibly due to dephosphorylation, and then disappeared toward adulthood. In adult brain tissue, MAP2a could not be detected with different MAP2 antibodies. Immunocytochemical localization revealed the presence of MAP2 mainly in differentiating neurons in all cortical layers. *In corpus callosum*, axons were stained - probably containing MAP2c forms. In additon in the same tissue, MAP2b positive cells of different size and shape, and with neuronal characters (i.e. positive to neuron specific enolase and GABA) were identified. They were numerous at early postnatal ages, and remained in the frontal part, but decreased in middle and rostral parts of the corpus callosum towards adulthood. Function and fate of these cells are unclear. *In conclusion*, MAP2 isoforms differ in distribution and structural association, and change at a time of intense dendritic and axonal growth and reorganization. This work was in parts supported by Sandoz Foundation, the University of Lausanne, and SNF grants Nr. 31.26624-89 and 3.359-0.86.

522.4

DEVELOPMENTALLY TRANSIENT ACETYLCHOLINESTERASE ACTIVITY IN CORTICAL PYRAMIDAL NEURONS OF RAT BRAIN. C. Geula and M-M. Mesulam, Harvard Medical School, Boston, MA 02215.

Using a histochemical method for visualization of cholinesterase activity, we have observed transient expression of acetylcholinesterase (AChE) in cortical pyramidal neurons during postnatal development in the rat.

Practically no AChE-positive cortical pyramidal neurons are seen at birth. At 1-4 days postnatally (P1-P4), many of these neurons emerge and can be detected in most cortical areas. The emergence of these neurons occurs earlier in paralimbic cortical areas (P1-P2) as compared with other areas of the cerebral cortex (P2-P4). Between P5 and P8, the density of these neurons increases and a leveling off is observed at P8-P11. During this period of peak density, AChE-positive pyramidal neurons can be detected in all cortical areas. Their density and staining intensity, however, appear to be higher in paralimbic cortical zones as compared with other cortical areas. Thereafter, the density of AChE-positive cortical pyramidal neurons gradually decreases. At P21 and longer, very few of these neurons can be observed and this pattern continues into adult life.

The developmental pattern of AChE-positive cortical pyramidal neurons in the rat is quite different from that observed in the human, in which such neurons are absent in childhood and become established in adult life.

522.5

AN ANTISERUM TO THE LOW AFFINITY NERVE GROWTH FACTOR RECEPTOR LABELS SUBPLATE CELLS OF DEVELOPING NEOCORTEX IN THE MOUSE AND A SUBSET OF NEURONS AND GLIA IN TISSUE CULTURE. D.B. Wayne, A.A. Zupan, and A.L. Pearlman Depts. of Cell Biology, Neurology and Pharmacology, Washington University School of Medicine, St. Louis, MO 63110

The preplate cells of embryonic mammalian neocortex are a unique population of early-generated, predominantly transient cells that make up the subplate and marginal zone after cortical plate formation. They are closely associated with specific extracellular matrix components (Stewart and Pearlman, 1987; Chun and Shatz, 1988; Sheppard et al., 1990), and express the nerve growth factor receptor (NGFR) in the cat and ferret (Allendorfer et al., 1990). Many preplate/subplate cells are neurons that form synapses and extend the first efferent axons (McConnell et al., 1989), but some may be glia (Rickmann and Wolff, 1985). To define this important population further, we immunolabeled sections and dissociated cell cultures of the developing neocortex of the mouse with a new antiserum produced in the chicken to an extracellular domain of recombinant human NGFR (Zupan et al., Soc. Neurosci. Abst., 1991). The cell bodies and processes of subplate cells are clearly labeled by the antiserum on embryonic day (E) 16 and postnatal day 1. In cell cultures dissociated from cortex on E13 and double-immunolabeled three days later, the cell bodies and processes of a subset of the neurons identified with an antibody to neurofilaments (RM108 provided by Dr. V. Lee) are labeled with the NGFR antiserum, as are a subset of the glial cells identified with the monoclonal antibody RC1 (provided by Dr. M. Yamamoto). Taken together, these findings indicate that subplate neurons express an NGFR-like molecule on their surface, and that NGFR expression also defines a subset of embryonic glial cells.

522.6

ANATOMIC AND FUNCTIONAL CORRELATES OF THE SUBPLATE IN THE SOMATOSENSORY CORTEX OF KITTENS. S.L. Juliano, R.A. Code, D.E. Eslin Department of Anatomy & Cell Biology, USUHS, Bethesda, MD 20814.

In kittens less than 2 weeks of age, little stimulus-evoked functional activity (as revealed by 2-deoxyglucose [2DG] uptake) is seen in the somatosensory cortex. Dense metabolic label is present in these animals, however, as a band of increased activity at the interface between layer VI and the white matter. This region corresponds to the subplate, which is normally observed in developing animals. We found in kittens aged 3 days to 2 weeks, that the subplate was heavily labeled with 2DG uptake, whether or not a somatic stimulus was delivered. After this age, a metabolic correlate of the subplate was not visible and stimulus-evoked activity became gradually more apparent, until about 5 weeks of age, when it was adult-like. A dense band of cytochrome oxidase activity is also found in the same layer VI-WM location, normally not observed in the adult. Histologic evaluation of this region established an increased number of Nissl-stained cells at the layer VI-WM junction, which conformed in morphology to neurons of the subplate. In addition, the cortical laminar organization of cell bodies is immature with layers V and VI being easily distinguished, while layers II-IV are relatively indistinguishable. An immature pattern of acetylcholinesterase activity is also seen in animals less than 2 weeks of age. In the young kittens, a dense network of fibers extends from the WM to into layers V and VI. Cortical layers above this site possess only sparse AChE+ fibers, in contrast to the adult distribution, which displays a dense distribution of fibers in all cortical layers. These structural correlates indicate that the subplate is present and metabolically active in the somatosensory cortex of kittens up to 2 weeks of age. Further studies may interpret the significance of the subplate in forming a mature pattern of functional activity in the somatosensory cortex. Supported by NS-24014.

MODIFICATIONS IN MYSTACIAL VIBRISSAE AND THE BARREL CORTEX IN RAGGED MUTANT MICE. R.O. Kuljis. Department of Neurology, The University of Iowa College of Medicine, Iowa City, Iowa 52242-1053.

The functional and cytoarchitectonic units called barrels in the murine somatosensory cortex are among the most distinct examples of modular ensembles in the cerebral cortex. Postnatal cues from sinus hair receptors to this region are necessary for their development. However, since early prenatal vibrissal follicle ablation has so far been unsuccessful, virtually nothing is known about their role in the specification of barrels in embryos. The barrel cortex of 6 specimens of Ragged, opposum (Ra^{OP}) mutant mice and 4 controls was analyzed in coronal or tangential sections, using the Nissl, cytochrome oxidase and succinate dehydrogenase methods. Flat-mounted muzzle skin from each animal was analyzed in Bielschowsky and Masson's stains. The vibrissal pad of mutants has rows of small elevations or mounds in a location similar to that of sinus hair follicles and in a pattern identical to them in normal animals. Only 3-4 short and thin vibrissae originate from the most posterior of those mounds. Histology confirms that each mound - with and without vibrissa - is a sinus hair follicle. Barrels corresponding to the existing vibrissae are almost twice as wide as those not supplied by vibrissae, but exhibit about the same level of staining intensity for oxidative enzymes as the rest. Only barrels immediately surrounding the enlarged ones have a reduced diameter and a polygonal appearance, suggesting that they have either shrunk or grown less than their neighbors. These observations indicate that barrels can develop in the absence of pre- and postnatal vibrissal stimulation, but do not necessarily imply that they can develop in complete absence of cues other than action potentials from vibrissal receptors. It appears also that vibrissal stimulation may be a factor influencing the amount of cortex devoted to each barrel.

SPONTANEOUS ACTION POTENTIAL ACTIVITY AND SYNAPTIC CURRENTS IN THE EMBRYONIC TURTLE CEREBRAL CORTEX. Mark G. Blanton and Arnold R. Kriegstein, Department of Neurology and Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA 94305.

We used loose-patch and whole-cell recording techniques to study spontaneous action potential activity and excitatory and inhibitory synaptic currents in embryonic neurons in the cerebral cortex of turtles. Sporadic action potentials appeared early in development at stage 17. As the cortical plate matured in mid-embryonic stages, action potential activity became more regular and fell into one of two distinct patterns, slow waveform, tonically active neurons (pyramidal) and fast waveform, repetitively firing neurons (nonpyramidal).

Spontaneous synaptic currents with rapid rise and slow exponential decay were observed in embryonic neurons at stage 18. Spontaneous excitatory synaptic currents appeared first, and while IPSCs could be elicited by repetitive stimulation at this stage, spontaneous IPSCs appeared suddenly at stage 20 and soon surpassed EPSCs in frequency. These results, and the presence of inhibitory synapses ultrastructurally at stage 18 (Parnavelas, Blanton and Kriegstein, unpublished), indicate that the time of onset of spontaneous IPSCs is not determined by the formation of a functional synaptic apparatus but is dependent on a later developmental event. EPSCs increased in frequency, rise time, and tau, but amplitudes remained stable despite dendritic elongation. In contrast, IPSCs showed a significant change in mean amplitude, increasing from 9.0 ± 0.6 pA at stage 18 to 13.0 ± 2.2 at stage 26 at a holding potential of -20 mV, and showed no change in tau. EPSCs and IPSCs were sensitive to TTX, and were thus dependent on spontaneous action potential activity.

Spontaneous IPSCs appear just prior to the time excitatory synapses can synchronize epileptiform bursts, and after the time inhibitory activity can be evoked. Inhibitory synapses are therefore present in advance of their role in controlling excitability and are recruited as spontaneous excitatory activity increases. Spontaneous neuronal activity emerges in a characteristic sequence and provides a substrate for shaping development *in vivo*.

CHANGES IN GRAY AND WHITE MATTER VOLUME IN NORMAL DEVELOPMENT: AN MRI STUDY. A. Pfefferbaum, E. V. Sullivan, D. H. Mathalon*, B. B. Zipursky*, and K. O. Lim. Dept. of Psychiatry and Behavioral Sciences, Stanford University School of Medicine and Mental Health Clinical Research Center, Dept. of Veterans Affairs Medical Center, Palo Alto, CA .

Significant changes in brain morphology occur during childhood. The brain grows in size, white matter continues to be myelinated, and gray matter increases and then decreases with regressive processes, such as neuronal pruning. To track these changes in vivo, we quantified volumetrically MRI scans obtained from 40 children referred for a clinical scan. The group comprised 17 boys, age 2-18 yrs (mean=11.4 yrs) and 23 girls, age 1 mo-19 yrs (mean=9.7 yrs); children known to have CNS disorders were excluded. All scans were read clinically as normal. An automated image quantification procedure segmented each image into compartments of gray matter, white matter and cerebral spinal fluid (CSF). Volumes, based on 7, 5-mm thick sections, provided estimates of whole brain volumes of each compartment. Volumes, expressed as percentages of head size, measured changes in CSF and tissue proportions over age, controlling for head/brain size differences. Absolute volumes provided an index of growth patterns of each compartment, regardless of head size. Because sex differences were not significant, all data were pooled. Percentage gray matter decreased and white matter increased linearly with age ($r=-.86$, $r=.80$, $p<.0001$); percentage CSF increased curvilinearly from about age 10. Absolute volumes changed curvilinearly with age: white matter volume increased more steeply over the first than second decade; gray matter volume peaked around age 8-10 and then decreased over the second decade, complementary to an increase CSF volume. This pattern is consistent with neuropathological studies; thus, MRI may provide a valid tool for longitudinal developmental studies of the brain. *[Supported by MH30854, AA05965, Norris Mental Health Center, the Meyers Foundation]*

DIRECT MEASUREMENT OF PEPTIDE CO-TRANSMITTER RELEASE FOLLOWING INTRACELLULAR STIMULATION OF A SINGLE IDENTIFIED MOTORNEURON IN *APLYSIA*. F.S. Vilim[1], D.A. Price[3], W. Lesser[3], I. Kupfermann[1], and K.R. Weiss[2]. [1]Cntr. Neurobiol. & Behav., Columbia Univ., NYS Psych Inst., NY, NY, [2]Dept. Physiol. & Biophys., Fishberg Res. Ctr. in Neurobiol., Mt. Sinai School of Med., NY, NY, and [3]Whitney Labs St Aug. FL.

The accessory radula closer muscle (ARC) and its innervation provide a model system for studying the role of neuromodulation and co-transmission. Motorneuron B15, which innervates the ARC, synthesizes peptides that modulate ARC contractions when applied exogenously. These peptides fall into two classes (coded for by different genes), the SCPs and the buccalins. The SCPs potentiate (postsynaptically) and the buccalins depress (presynaptically) motorneuron induced ARC contractions. Previous work provided indirect evidence for SCP release in the ARC. We have developed a method for directly measuring SCP and buccalin release and provide evidence that they are co-released in response to physiological ranges of B15 stimulation. Radioimmunoassay, with femtomolar sensitivity, was used to detect buccalin and/or SCP in the perfusate of ARC muscle. B15 was intracellularly stimulated to fire at either 7.5 or 12 Hz for 3.5 sec every 7 sec for 10 min or continuously at 6 Hz for 10 min. The muscle was kept at 15°C which matched the temperature of the tanks housing the animals. Under these conditions, release of both SCP and buccalin was greater at 12 Hz than at 7.5 Hz. Continuous stimulation at 6 Hz for 10 min produced intermediate levels of release indicating that stimulus parameters other than frequency affect release. No release was observed if Mg++ was substituted for Ca++ in the perfusate. Blocking muscle contractions with 10^{-4}M hexamethonium had no effect on peptide release. The present findings, together with previous findings that SCP and buccalin are colocalized in the same dense core vesicles suggest that they are co-released. The results provide good evidence that the peptides are released in vivo when the animal feeds.

523.2

CHARACTERIZATION OF A cDNA CLONE ENCODING MULTIPLE MYOMODULIN-RELATED NEUROPEPTIDES IN *APLYSIA*. M.W. Miller, S. Stamm*, E.C. Cropper, F.S. Vilim, S. Beushausen, J. Brosius, I. Kupfermann, and K.R. Weiss. Center for Neurobiol. & Behavior, Columbia Univ., Coll. P&S and NYS Psychiat. Inst., NY, NY 10032; and Fishberg Res. Center for Neurobiol., Mount Sinai School of Medicine, 1 Gustave Levy Pl., NY, NY 10029.

The neuropeptide myomodulin A, originally purified and sequenced from the accessory radula closer (ARC) muscle of *Aplysia*, is present in one of the cholinergic motor neurons innervating this muscle, where it has been proposed to act as a modulatory cotransmitter (Cropper et al., 1987). Clones encoding myomodulin A were isolated from a buccal ganglion cDNA library using degenerate oligonucleotide probes. The sequence of the longest clone (≈1.4 kb) encodes a 370 amino acid open reading frame containing a potential myomodulin precursor. This sequence includes 10 contiguous copies of myomodulin A, each flanked by dibasic potential cleavage sites, and each ending with a C-terminus glycine amide donor. The precursor also contains 6 myomodulin-related peptides, each of which is present in a single copy. Four of these peptides, the heptapeptides myomodulin D, F, and G (Miller et al., 1990) and the octapeptide myomodulin B (Vilim et al., 1989), have been previously purified from the ARC muscle. Whereas all of the heptapeptides are flanked by dibasic (Lys Arg) residues, a single basic residue (Arg) is present at the carboxyl end of the octapeptide. The precursor sequence includes two novel related peptides, myomodulin H (GLHSMLRLa) and myomodulin I (SLSMLRLa). Synthetic myomodulin H and I were tested for bioactivity and found to modulate evoked contractions of the ARC. Probing Northern blots of *Aplysia* nervous system poly(A) RNA at high stringency revealed a single band approximately 1.5 kb in length, suggesting that this clone corresponds to a full length transcript. *In situ* hybridization experiments demonstrate that abundant expression of this messenger RNA occurs in specific neurons in each of the central ganglia. These results indicate that the myomodulins comprise a family of neuropeptides which may participate in diverse neural circuits in *Aplysia*.

523.3

RFa PEPTIDES ARE PRESENT IN THE ARC NEUROMUSCULAR SYSTEM OF *APLYSIA*. E.C. Cropper, F. Vilim, A. Vitek*, M.W. Miller, I. Kupfermann, and K.R. Weiss. Dept. Physiol. & Fishberg Ctr. for Neurobio., Mt. Sinai Med. Schl., NY, NY 10029; Ctr. Neurobio., Columbia Univ., NY, NY 10032.

A striking feature of the ARC neuromuscular system is its chemical complexity. The ARC motor neurons B15 and B16 each contain at least four neuropeptides in addition to their primary neurotransmitter ACh. All four of the B15 peptides appear to be packaged in the same dense core vesicles, and therefore are presumably coreleased. Thus, modulatory effects of the ARC neuropeptides are not likely to be exerted independently. When peptide cotransmission occurs, it is likely that multiple peptides are released, and that released peptides have interactive effects. This suggests that a comprehensive investigation of peptide cotransmission in the ARC neuromuscular system will be difficult unless all major bioactive peptides present in B15 and B16 are characterized. Towards this end, material was extracted from neuronal processes attached to 100 g of ARC muscle and was subjected to RP-HPLC. Bioactive fractions were purified and the following amino acid sequences were obtained: G-G-A-L-F-R-F, G-S-L-F-R-F, and S-T-L-F-R-F. To localize these peptides, and to verify their structures, B15 neurons were incubated in ^{3}H-Phe and chromatographic properties of radiolabeled peptides were compared to those of synthetic amidated versions of the above RFa peptides. B15 radioactivity and synthetic peptides coeluted through sequential chromatography, indicating that B15 contains the novel RFa peptides. All three RFa peptides decrease the size of muscle contractions elicited by motor neuron stimulation, presumably by acting presynaptically. They decrease the size of motor neuron-elicited EJPs, but have no effect on contractions produced by direct application of ACh to the ARC. Thus, a new family of bioactive neuropeptides has been localized to the ARC motor neuron B15.

523.4

SCP AND MYOMODULIN UTILIZE SEPARATE SIGNAL TRANSDUCTION PATHWAYS AND CONVERGE ON COMMON SUBSTRATES IN THE ARC MUSCLE OF *APLYSIA*. S.L. Hooper, W.C. Probst*, I. Kupfermann and K. Weiss. Dept. Phys. & Biophys., Mt. Sinai Sch. of Med., NY NY 10029; Cntr. Neurobiol. & Behav., Columbia Univ. and NYS Psych. Inst., NY NY 10032

The peptides SCP and myomodulin (MM) are contained in the ARC motorneurons B15 and B16 and increase ARC contraction amplitude and relaxation rate. SCP is known to increase ARC cAMP levels; the MM second messenger is unknown, but is not cAMP. Application of pcpt cAMP or forskolin, an adenylyl cyclase activator, resulted in dramatic increases in ARC contraction amplitude and relaxation rate; threshold concentrations for each were *ca.* 10^{-5} M. SCP application and B15 stimulation, but not MM application or B16 stimulation, increased the level of activated cAMP dependent protein kinase (PKA). SCP application to intact ARCs induced dose dependent increases in active PKA in the 12K supernatant of muscle homogenates. The threshold was 10^{-8} M and PKA was maximally activated (a 10 fold increase) at 10^{-5} M SCP, at which point 100% of total PKA was activated. This change was associated with an approximate two fold drop in total (activated + inactive) PKA levels in this fraction, suggesting that SCP translocates PKA to the pellet fraction. Protein phosphorylation was investigated in ARC muscle by back-phosphorylation after treatment with MM and SCP. The ability of cAMP to stimulate incorporation of ^{32}P from γ-^{32}P-ATP into proteins in homogenates of control and peptide treated (before homogenization) ARCs was assessed by SDS-PAGE and autoradiography. The incorporation of radiolabel into three protein bands (300 kD, 57 kD, and 41 kD) was dramatically reduced after treatment of intact muscles with either peptide, indicating increased phosphorylation of these proteins in intact ARC. This change in protein phosphorylation state indicates that even though SCP stimulates cAMP and MM does not, their second messengers converge on the same protein substrates.

523.5

MODULATION OF ION CURRENTS IN THE ARC MUSCLE OF *APLYSIA*: CONVERGENT ACTIONS OF SEROTONIN, SCPs AND MYOMODULINS. V. Brezina, C. G. Evans, I. Kupfermann & K. R. Weiss. Dept. of Physiology & Biophysics, Mount Sinai School of Medicine, New York, NY 10029, and Ctr. for Neurobiology & Behavior, N.Y. State Psychiatric Institute, New York, NY 10032.

Potentiation of feeding movements during food-induced arousal in *Aplysia* is implemented partly by release onto the accessory radula closer (ARC) muscles of small cardioactive peptides (SCPs) and myomodulins (MMs) from the muscles' own motorneurons and serotonin from separate modulatory neurons. Although acting via different second messengers (SCPs and serotonin via cAMP, MMs unknown), all of the modulators similarly increase both the size and the relaxation rate of ARC contractions, and phosphorylate common protein substrates in the muscle (Hooper *et al.*, these abstracts). We have characterized ion currents in voltage-clamped dissociated ARC muscle fibers to determine whether these effects might reflect modulation of a common set of ion channels. Differences in voltage dependence, ion selectivity and pharmacological sensitivity enabled us to distinguish several currents including a hyperpolarization-activated Cl, inwardly rectifying K, 'A'-like K, delayed rectifier-like K, and a depolarization-activated Ca current. Two currents were indeed modulated similarly by each of serotonin, MM and SCPs, as well as by elevation of intracellular cAMP. Modulation of the first, as yet unidentified, current (which could conceivably also represent the activity of an ion pump) appeared as a small outward current shift at potentials more positive than -80 mV. The second current modulated was the Ca current, which we usually studied as inward Ba current in TEA-containing solution; it was activated at potentials more positive than -40 mV, and eliminated by addition of 1 μM nifedipine, 1 mM Cd^{2+}, or replacement of extracellular Ba^{2+} with Co^{2+}. This current was increased by 50-100%, in a mutually occlusive manner, by 1 μM (a supramaximal dose) of each of serotonin, MM and SCP_B, and 50 μM forskolin. This enhancement of Ca current by the modulators may underlie their potentiation of the size of ARC muscle contractions.

523.6

A TYROSINE KINASE RECEPTOR FOR INSULIN IN *APLYSIA* BAG CELLS. D.H. Solomon*, A.M. Elste*, P.J. Bergold and J.H. Schwartz. Center for Neurobiology and Behavior, Howard Hughes Medical Institute, College of Physicians & Surgeons, Columbia University, New York, NY 10032.

In invertebrates, insulin-like peptides have been convincingly localized to neurons, and, in several instances, fulfill some of the criteria expected of neurotransmitters. Much less secure is the status of insulin and insulin-related peptides as neurotransmitters in vertebrate brain. In the marine mollusc *Aplysia*, Shapiro et al (*J. Neurobiol.* **22**, 55-62, 1990) provided evidence that vertebrate insulins can act on certain identified neurons to modulate ion channels through activation of a phospholipase C to release the complex sugar, inositol phosphate glycan (IPG). Using immunocytochemistry with an insulin-receptor α subunit antibody, we find strong immunoreactivity in *Aplysia* bag cell bodies and axon processes that extend into the neuropil of the abdominal ganglion. Immunoblot analysis using this insulin-receptor antibody, which was affinity purified with the peptide immunogen, reveals an M_r 130,000 protein in bag cell extracts similar in size to the *Drosophila* insulin-receptor α subunit (the α subunit is the extracellular insulin-binding component of the receptor). Using the polymerase chain reaction (PCR) with degenerative primers spanning a conserved domain in human and *Drosophila* insulin receptors, we obtained a partial cDNA sequence from bag cells with an inferred amino acid sequence similar to the tyrosine kinase domain of human and *Drosophila* insulin receptors. These two results suggest that both extracellular and intracellular domains of an insulin-type receptor are present in *Aplysia*. Our working hypothesis is that, in addition to their roles as growth factors and hormones, insulin-like peptides can function as peptide transmitters to modulate neuronal function through tyrosine specific protein phosphorylation.

523.7

FURTHER CHARACTERIZATION OF NEUROPEPTIDES THAT MIMIC PROLONGED INHIBITION OF BAG CELL TARGET NEURONS IN APLYSIA. S.M. Rajpara*, J.C. Eliassen* and E. Mayeri. Department of Physiology, University of California, San Francisco, CA 94143

The bag cell neurons of *Aplysia* are part of a neural system that utilizes four peptides as neurotransmitters. The peptides are derived from the egg-laying hormone/bag cell peptide (ELH/BCP) precursor and produce various effects in abdominal ganglion neurons following initiation of a bag cell burst discharge. In cells L3 and L6, bag cell activity produces inhibition that lasts for 2 or more hours. α-BCP mediates an early component of this prolonged inhibition.

To further characterize two peptides that are candidates for mediating the prolonged component of inhibition, we purified material from an acid extract of abdominal ganglia by molecular sizing HPLC, followed by one or more steps of reverse-phase HPLC on C4. One peptide is 4687 Da and consists of 40 amino acids, as determined by mass spectroscopy and amino acid composition analysis. A two min. application of the peptide at a concentration of 4 μM produced sustained hyperpolarization and a reduction in spontaneous spike activity that lasted 100 min. The second peptide has an apparent molecular weight of 3300 Da and was 5-fold less potent. Amino acid composition analysis suggests that neither peptide is derived from the ELH/BCP precursor. Since the 4687 Da peptide is effective at a lower concentration, it is the best candidate for the true inhibitory transmitter.

Supported by NIH grants NS 16490 and NS 16033.

523.8

MODULATION OF NEUROMUSCULAR EFFICACY BY EXCITATORY AND INHIBITORY MOTOR NEURONS IN *APLYSIA*. P. J. Church and P. E. Lloyd. Committee on Neurobiology, The University of Chicago, Chicago, Il 60637.

Buccal muscle I3a is innervated by two excitatory motor neurons, B3 and B38 and a newly identified inhibitory neuron, B47. B3, B38, and B47 synthesized FMRFamide, the SCPs, and myomodulin (Mm) respectively. Bath application of FMRFamide, SCPs or Mm (10nM) enhanced B3-evoked contractions. We monitored the modulation of B3-evoked muscle contractions in response to stimulation of B38 and B47 using paradigms designed to release conventional transmitters alone and with peptide cotransmitters. When B38 was stimulated in high frequency bursts during B3 interburst intervals, subsequent B3-evoked contractions were enhanced. We interpret these results as B38 releasing its peptide modulatory cotransmitters (SCPs) during high frequency bursts. Stimulation of B47 simultaneous with B3 inhibited the B3-evoked contractions. However, high frequency B47 stimulation during B3 interburst intervals enhanced subsequent B3-evoked contractions. It appears that B47 can have different effects on neuronally evoked muscle contractions depending on the temporal characteristics of stimulation. We interpret these results as B47 releasing its inhibitory conventional transmitter alone during low frequency bursts and along with its peptide cotransmitter (Mm) during high frequency bursts. Supported by NS 23569.

523.9

SEROTONIN AND FMRFamide INHIBIT THE RELEASE OF NEUROPEPTIDES FROM IDENTIFIED *APLYSIA* NEURONS IN CULTURE. M.D. Whim and P.E. Lloyd. Dept. Pharm. Physiol. Sci. & Comm. on Neurobiol. Univ. Chicago, Chicago, IL 60637.

To examine the modulation of the release of neuropeptide cotransmitters we have used *Aplysia* neurons B1 and B2 in primary culture which incorporate ^{35}S-met into 2 neuropeptides (SCPA and SCPB). The SCPs are transported into the regenerated neurites, and can be shown to be released in a stimulus- and Ca-dependent fashion (Lloyd et al, 1986). Initial experiments determined that stimulating individual B1 or B2s using intracellular microelectrodes at a frequency of 6 Hz for 500 msec with 500 msec interburst intervals, evoked a reproducible release of radiolabeled SCPs into the bathing solution which could be detected using a combination of HPLC and liquid scintillation counting. This release showed only a small decline wth repetitive stimulation periods. Bath application of FMRFamide and serotonin both transiently inhibited release. 1μM FMRFamide reduced the release of the SCPs to less than 5% of control. The effect of serotonin was dose-responsive, with a ~60% inhibition of release at 100μM. Although serotonin inhibited the release of the SCPs, it increased excitability as monitored by the number of spikes evoked by depolarizing current pulses. We are currently examining the possibility that the effects of serotonin are mediated via the actions of a second messenger. Supported by NS 23569.

523.10

NEURON SPECIFIC SPLICING OF FMRFamide GENE TRANSCRIPTS IN THE MOLLUSC *LYMNAEA*. J.F. Burke, S.E. Saunders*, K. Bright*, E. Kellett*, N. Santama* and P. Benjamin*. Sussex Neuroscience Research Centre, Biological Sciences, University of Sussex, Brighton, E. Sussex BN1 9QG, (U.K.)

The FMRFamide gene of *Lymnea* contains at least three exons. One encodes multiple copies of the cardioactive neuropeptide FMRFamide, another encodes the N terminal extended peptides GDP/SDPFLRFamide and the third exon encodes a common hydrophobic leader sequence. *In situ* hybridization data show that expression of the gene is limited to a discrete number of cells located throughout the major ganglia of the brain. The hydrophobic leader is expressed in all cells whereas the neuropeptide encoding exons are alternatively spliced. The neuropeptide encoding exon splicing pattern is mutually exclusive, such that a single neuron only expresses one class of neuropeptide.

As well as encoding the FMRFamide and GDP/SDPFLRFamide the neuropeptide precursor proteins encode a number of other potential peptides including EFLRIamide, EFFPLamide and a peptide ending in the C terminal sequence SEEPLY. Immunocytological studies will be presented showing that these peptides are syntheized in the brain of *Lymnaea*, and that in some cases they can account for the physiological activites of single identified neurons.

523.11

DISTRIBUTION OF THE NEUROPEPTIDE APGW-NH_2 IN THE CENTRAL NERVOUS SYSTEM AND MALE REPRODUCTIVE ORGANS OF *LYMNAEA STAGNALIS*. J. van Minnen, A.B. Smit* and R.P. Croll[1]. Faculty of Biology, Vrije Universiteit, 1081 HV Amsterdam, The Netherlands and [1]Department of Physiology & Biophysics, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

Recently, a gene has been cloned from neurons located in the anterior lobes of the cerebral ganglia of *Lymnaea stagnalis*.. The product of this gene is processed to become 10 copies of the neuropeptide APGW-NH_2 and a single copy of a 40 amino-acid polypeptide. The present study describes the distribution of neurons expressing the APGW-NH_2 gene by means of *in situ* hybridization and immunocytochemistry in the CNS and male reproductive organs. The majority of the neurons expressing APGW-NH_2 is located in the anterior lobes of the cerebral ganglia. The right lobe, which consists largely of motoneurons innervating the penis, contains 120-150 APGW-NH_2 neurons whereas the smaller left lobe, which possesses no penial motoneurons, contains only 15-20 APGW-NH_2 neurons. In addition, clusters of 4-6 small neurons are also found in the right parietal and visceral ganglia, and a total of 10-15 other cells are scattered elsewhere within the CNS. Neurites containing APGW-NH_2 can be traced throughout the CNS and into the periphery with particularly strong projections to the penial complex, vas deferens and prostate gland.

This study indicates a general, important role of APGW-NH_2 in the functioning of the gastropod nervous system. Furthermore, comparative studies on other molluscan species (*e.g.Helix, Aplysia, Mytilus*)indicate many similarities in APGW-NH_2 containing neurons and peripheral projections to male reproductive organs and suggest evolutionary conservation in the use of this neuropeptide.

524.1

THE ROLE OF HORMONES IN REGULATING THE MITOTIC ACTIVITY OF NEUROBLASTS IN THE MOTH, *MANDUCA SEXTA*. R. Booker and J. Kim Section of Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853.

The neurons generated by postembryonic neuroblasts (NBs) play an important role in shaping the nervous system of the adult *Manduca*. Each NB generates a discrete nest of progeny. The NBs are individually identifiable, and each NB generates a characteristic number of progeny, ranging from 10 to more than 100. We examined mitotic activity of the NBs, using immunocytochemical detection of the thymidine analog 5-Bromodeoxyuridine, in combination with a series of endocrine manipulations.

The mitotic activity of the NBs was not uniform throughout the larval stage. There was little change in the mitotic activity of the NBs throughout the feeding larval stage. However, at the onset of metamorphosis, which occurs on the first day of wondering (W-0), there was a 10 fold decline in the number of labeled cells counted within the nests. The next day (W-1) the mitotic rate of all the NBs rebounded.

A series of ligation experiments were used to isolate the NBs from the sources of hormones. The results suggest that the dramatic drop in mitotic activity on W-0 was induced by the small peak of ecdysteroids which occurs on the third day of the fifth larval instar (5-3) and marks the first time the ecdysteroids occur in the absence of the juvenile hormones (JH). The dramatic drop in NB activity was blocked by the application of JH mimics (JHM) to intact 5-3 animals. Instead of a rapid fall, the mitotic activity of the NBs dropped slowly over a period of 8 days in the JHM treated animals. The rebounding of NB mitotic activity on W-1 was correlated with the appearance of the large prepupal peak of ecdysteroids. Ligating abdomens on W-0 prevented this increase in mitotic activity. Replacing the ecdysteroids with an infusion of 20-hydroxyecdysone (20-HE) dramatically increased the mitotic activity of the NBs. However, infusion of 20-HE into animals treated for 14 days with JHM, which prevents the cessation of mitotic activty triggered by the small peak of ecdysteroids, did not result in an increase in mitotic activity. This suggests that the number of progeny a NB generates is determined by intrinsic cues. However, our endocrine manipulations suggest that hormones regulate the mitotic activtiy of the NBs at the onset of metamorphosis developmental.

CLONAL ANALYSIS SHOWS *NOTCH* IS REQUIRED FOR NORMAL SENSILLAR DEVELOPMENT IN THE WING OF *DROSOPHILA*. E.Rulifson and S.S.Blair. Neuroscience Training Program and Dept. Zoology, U. Wisconsin, Madison, WI 53706.

The techniques of mitotic recombination and enhancer-trap based cell marking were used to generate mosaic clones of a null allele of the *Notch* gene in the wing of *Drosophila*. It is thought that cell-cell interactions are required for the proper segregation of neural and epidermal lineages during embryonic and larval development. Clonal studies of *Notch* in the differentiation of bristles on the notum support the idea that *Notch* protein is a receptor for a lateral inhibitory signal; this signal is required to produce the normal number of correctly positioned sensilla within fields of competent cells. Our preliminary results showed that mutant clones of *Notch* in the wing produced supernumerary sensillar precursors surrounding the positions of normal campaniform sensilla. However, clones of mutant cells in positions not normally containing campaniform sensilla differentiated as epithelium. At later stages, after sensillar cells become immunoreactive for anti-HRP, clones of mutant cells were seen to contain clusters of supernumerary neurons. Thus, in the wing, as in the notum, *Notch* may be required by competent cells for the generation of the correct pattern of sensilla.

524.3

ANALYSIS OF A DROSOPHILA GENE CLUSTER EXPRESSED DURING CNS DEVELOPMENT. S. D. Zhang*, D. Mellerick-Dressler*, H. Gainer, W. Odenwald* and J. Kassis*[1]. Lab. of Neurochemistry, NINDS, NIH and [1]Ctr for Biologics Evaluation and Research, FDA. Bethesda, MD 20892

Enhancer-detection screening has led to the identification of a gene cluster located at 83c which is active during Drosophila neurogenesis. Thus far, two non-overlapping genes (*83c alpha* and *beta*) that are transcribed in converging directions have been partially characterized.

Genomic and cDNA analysis indicates the *83c alpha* gene may encode a transcription factor. The deduced protein sequence contains an acidic domain and four linked TF-IIIA -like zinc fingers. Whole mount *in situ* hybridizations reveal that the *83c alpha* gene is first activated at the time of neuroblast formation in clusters of cells within the cephalic neurogenic region. Simultaneously, *83c alpha* expression is also turned on in groups of three to four cells located in the ventral cord midline. Each group is positioned at the anterior portion of each parasegment. During ventral cord development the *83c alpha* gene displays successive anterior to posterior bilaterally symmetrical waves of activation in cells flanking the ventral midline. These cells may be neuroblasts. Late in CNS development there is an overall decrease in *83c alpha* gene expression in both the cephalic lobes and in the ventral cord. Except for four to six cells along the posterior boundary of the contracted ventral cord, no transcripts are detected in the abdominal ventral cord.

Sequence analysis of genomic and cDNA *83c beta* clones identifies an open reading frame of at least 2Kb. The encoded protein bears no homologies to previously described proteins. *83c beta* transcripts are detected in early embryos; suggesting this gene is maternally expressed. Late in embryonic development *83c beta* is expressed throughout the CNS. However, unlike *83c alpha*, expression of *83c beta* is not limited to the CNS.

POSTEMBRYONIC NEUROGENESIS AND DEVELOPMENT OF THE ANTENNAL LOBE IN THE TOBACCO HORNWORM *MANDUCA SEXTA*. K.A. Sorensen, N.T. Davis, and J.G. Hildebrand. ARL Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

Manduca sexta exhibits dramatic changes in its appearance and behavior during its metamorphosis from larva to adult. These changes are accompanied by extensive reorganization of the nervous system, involving the death and remodelling of subsets of larval neurons as well as the postembryonic addition of new neurons. We are studying the origins of neurons in the primary olfactory center, the antennal lobe, in the brain of *M. sexta*. We previously identified 5 neuroblast nests (3 lateral, A-C, and 2 medial, D,E) that, based on their positions adjacent to the larval antennal center, appeared likely to contribute to the reorganization of this structure into the adult antennal lobe. We are now interested in determining how these 5 nests relate to the 3 groups of neurons (lateral, medial, and anterior) found in the adult antennal lobe.

To determine the contribution of these neuroblast nests to development of the adult antennal lobe, successive stages of prepupal and pupal development were examined in histological and histochemical preparations. Cell death is evident within the nests from stage W0-W2; nest-cell processes appear as prominent tracts leading from each nest to olfactory neuropil from stage W3 forward. The olfactory neuropil remains larval in character (each nest having its own discrete tract and characteristic point of entry into the olfactory neuropil) until stage P2, after which somata and tracts associated with each of the lateral nests (A-C) appear to coalesce, forming a characteristic adult lateral cell group and input tract by stage P4. Medial nests retain their orientations and input tracts relative to the neuropil during metamorphosis, with nest E appearing to contribute to the medial cell group of the adult antennal lobe and nest D, to the anterior cell group. [Supported by NIH grant AI-23253]

CRITICAL PERIOD OF INTERACTIONS LEADING TO THE BIRTH OF PERIPHERALLY INDUCED CENTRAL (PIC) NEURONS DURING LATE EMBRYOGENESIS IN THE LEECH , *HIRUDO MEDICINALIS*. Thomas Becker and Eduardo R. Macagno. Dept. of Biological Sciences, Fairchild Center, Columbia University, NY, NY 10027.

PIC neurons are present only in the sex ganglia (those in the fifth and sixth body segments) in *Hirudo*. They appear late in embryogenesis as a result of an inductive interaction between the male genitalia and the CNS (Baptista et al., Nature **346**, 855-858; 1990). The induction requires intact nerves connecting the male genitalia and the sex ganglia. Male organ removal prior to embryonic day 13 (E13) prevents the appearance of PIC's entirely. Conversely, at E16, the removal of the peripheral target no longer prevents the birth of PIC's (Baptista and Macagno, J. Neurobiol. **19**, 707-726; 1988). To explore the basis of this critical period of PIC induction, we performed a series of male organ ablations at E10-11, followed by back-transplantation of male organs at later stages from donors of the same age. PIC neurons only appeared in animals that received a back-transplant up to E16. To test whether this resulted from the loss of inductive capacity of male organs after E16, as opposed to a loss of CNS responsiveness, we performed heterochronic transplantations. Organs from animals up to E40 were able to induce PIC's in E13-16 hosts, but those from older donors appeared to have lost this ability. Back-transplantation of 11-day-old male organs into animals older than 16 days that had their male organ removed at E10 never resulted in the appearance of PIC cells. We conclude (1) that the interaction can take place in as short a time as one day and (2) that the sex ganglia lose their sensitivity to the inductive signal after day 16, although the male organ retains its ability to induce up to E 40.

REGULATION OF NEURONAL NUMBER AND SIZE IN FROGS DEVELOPING FROM HALF EMBRYOS. Francesca Mariani* and Margaret Hollyday. Department of Biology, Bryn Mawr College, Bryn Mawr PA 19010.

The developmental processes which determine neuron number and its relation to body size are not well understood. To further explore this issue, we studied embryos developing from fertilized eggs of Xenopus laevis which were divided at the two-cell stage. Single blastomeres were isolated using microsurgical techniques. Detailed observations were made of sets of experimental embryos and their matched controls to compare cleavage patterns, rate of development and growth. Embryos were raised until they showed signs of impending death; they were then processed for light microscopic analysis. Quantitative estimates of body size were estimated from stained serial sections using a camera lucida attachment and digitizing tablet; cells counts were made of selected sections to estimate total neuron number. The oldest embryos studied to date were at stage 48-49 of Nieuwkoop and Faber.

Experimental embryos showed altered early cleavage patterns; the isolated blastomere displayed an additional, vertically oriented cleavage division before cleaving horizontally. Nevertheless, both experimental and control embryos underwent neurulation at the same time, despite the diminished size of the experimental embryo. The experimental embryos were consistently smaller than their matched controls thoughout the observation period. Analysis of body size and total neuronal number in the oldest tadpoles revealed that experimental embryos were approximately half-sized compared to control embryos and that their nervous systems contained half the number of neurons as did controls. These preliminary results suggest that both body size and neuronal cell number are heavily influenced by the volume of cytoplasm in the egg.

A TEMPORAL AND SPATIAL SHIFT IN THE REGULATION OF NEUROGENESIS. R.D.Heathcote and M.G.Larson. Department of Biological Sciences, University of Wisconsin, Box 413, Milwaukee, WI, 53201.

Environmental cues are known to influence the differentiation of neural crest cells and could also influence their genesis. We examined neurogenesis in a ganglion whose neurons continued to accumulate throughout a prolonged period of development. The cardiac ganglion of the frog *Xenopus laevis* contained a single type of neuron whose precursors continued to divide and differentiate long after neural crest migration had ceased. We located a source of these late neuronal precursors and determined that their proliferative ability differed from precursors that had just completed migration from the neural crest.

In order for new neurons to continue to be added to the ganglion, the source of neuronal precursors must shift from the neural crest to another site early in ganglion formation. When hearts were isolated in culture in the presence of ^{3}H-thymidine, some cells incorporated label into their DNA, divided and became neurons. Thus precursors to cardiac neurons were active in a germinal zone that included the heart. The neuronal precursors in the heart continue dividing long after precursors from the neural crest supply the first neurons to the ganglion. Regulation of proliferation in these 2 sets of precursors appeared to be different. Cytosine arabinoside (araC), blocked thymidine uptake (and cell division), but had different effects on the 2 types of neuronal precursors. When hearts from animals whose cells had just arrived from the neural crest were cultured in araC, they contained half the number of neurons of control hearts (cultured without araC). Following neural crest migration, araC had no effect on the number of neurons in cultured hearts. Thus, precursors from older hearts maintained in our culture conditions were not capable of the same amount of neurogenesis as precursors that had just arrived from the migrating neural crest. This difference likely reflected changes in the mechanisms regulating neurogenesis at these 2 different times and locations.

BIRTH AND MIGRATION OF CELLS IN THE CENTRAL POSTERIOR NUCLEUS OF WEAKLY ELECTRIC KNIFEFISH *(EIGENMANNIA SP.)* **DURING ADULTHOOD.** G.K.H. Zupanc[1,2] and M.M. Zupanc*[3]. [1]Scripps Institution of Oceanography, [2]Department of Neurosciences, and [3]Department of Biology, University of California at San Diego, La Jolla, CA 92093.

In *Eigenmannia sp.*, the central posterior nucleus (CP) is a bilateral diencephalic cell group, stretching from the third ventricle approximately 400 μm laterally. At its lateral extent, the CP fuses with the prepacemaker nucleus (PPn), which controls frequency modulations of the electric organ discharge. Recent morphological data have suggested that the PPn is much larger than assumed in earlier studies (e.g., M. Kawasaki *et al.*, J. Comp. Neurol. *276:* 113-131, 1988) and that it incorporates at least part of the traditionally defined CP (G.K.H. Zupanc and W. Heiligenberg, submitted). Furthermore, experiments employing 5-bromo-2'-deoxyuridine (a thymidine analogue which is incorporated into replicating DNA and which enables the detection of mitotic S-phase cells) in adult knifefish have revealed the generation of approximately 20-50 new cells per 12 hrs unilaterally in the periventricular zone of the CP (G.K.H. Zupanc, Soc. Neurosci. Abstr. *16:*128, 1990). In the present autoradiographic study, we examine the fate of these newborn cells.

Fish were injected with ^{3}H-thymidine and sacrificed after various lengths of survival time. While ^{3}H-thymidine labelling was highly concentrated in the periventricular zone after 12 hrs (m, median distance of labelled cells from ventricle = 8 μm; n = 135 cells examined), newborn cells appeared to migrate laterally on the following days (day 2: m = 17 μm, n = 106; day 4: m = 27 μm, n = 41). The median distance of labelled cells from the ventricle reached a plateau after about one week (day 5: m = 29 μm, n = 177; day 7: m = 29, n = 111; day 28: m = 29 μm, n = 38). Light and electron microscopic observations suggest that at least part of the newly generated elongated periventricular cells differentiate into round or ovoidal neurons of the CP during their lateral migration.

A NOVEL MARKER FOR CORTICAL SUBPLATE NEURONS AND SOME SUBVENTRICULAR ZONE CELLS IN EARLY POSTNATAL RAT BRAIN. Z-Y. Yu and J.E. Bottenstein. Marine Biomedical Institute, University of Texas Medical Branch in Galveston, Galveston, TX 77550

Our previous work has shown that conditioned medium (CM) from the B104 CNS neuronal cell line increases proliferation of O-2A glial progenitors and immature oligodendrocytes. We generated mouse monoclonal antibodies (mAbs) against a partially purified heparin-binding fraction of the CM from this cell line. One of these antibodies (AC3) was used in combination with mouse mAbs against 68 kD neurofilament protein (NF; a neuronal marker) or against G_{D3} ganglioside (a marker for immature neuroepithelial cells) to identify the cells expressing the AC3 antigen. A double immunoperoxidase method was used on 50 μm vibratome sections of early postnatal rat brain. Strong AC3 immunoreactivity was observed within cells of the **cortical subplate** in P0-1 and P7 (P, postnatal day) rat forebrain, but it disappeared by P14. The majority of these AC3-positive cells double stained with NF mAbs, indicating they were neurons. In the **subventricular zone (SVZ)**, especially in the medial portion beneath the lateral ventricle, strong AC3 immunoreactivity was detected at P0-1 and P7, which was weaker at P14. An apparent lateral migration of AC3-positive SVZ cells was seen at P7 and P14. Only a few AC3-positive cells in this region were double stained by G_{D3} mAbs. However, strongly G_{D3}-immunoreactive cells were observed in the cingulum, corpus callosum, and other parts of the SVZ. No double staining was detected for AC3 and G_{D3} in the cingulum, corpus callosum, or cortical subplate. Our results indicate that AC3 mAbs provide a novel marker for cortical subplate neurons and for some SVZ cells and may be useful in studies of the maturation and migration of cells in rat brain.

NOVEL cDNA CLONES DEFINE DEVELOPMENTAL SUBPOPULATIONS OF GRANULE CELLS IN MOUSE CEREBELLUM. S.G.Kuhar[1], L.Feng[1], S.Vidan[2], M.E.Ross[3], M.E.Hatten[2] and N.Heintz[1]. [1]Rockefeller Univ., New York, NY 10021, [2]Columbia Univ., New York, NY 10032,[3]Univ. of Minnesota, Minneapolis, MN 55455

The development of the mammalian cerebellum involves a complex system of cell:cell interactions which are controlled by both intrinsic genetic programs and epigenetic factors. To define the molecular events underlying cerebellar development, we have initiated a search for genes which mark specific stages in granule cell (GC) differentiation. Polyclonal antisera made in rabbits against purified postnatal days (P) 3-5 GC was adsorbed on PC12 cells and adult cerebellar tissue and used to screen a cDNA library made in λgt11 from purified P3-P5 GC (Ross et al., Soc. Neurosci. Abs., Vol.16 Pt.I p.151, 1990). Of 58 purified phage clones, 42 were found to be unique by restriction enzyme analysis of PCR amplified inserts. Search of all GenBank entries with 100-500 nucleotides of 5' sequence showed 36 novel clones. Northern blots of poly A(+) RNA made from cerebella of different aged mice and from various tissues have shown that six of the 26 clones analyzed thus far are developmentally regulated. Five of these six are brain-specific. In situ hybridization has shown localized expression of several of these subclones to cellular subpopulations in the mouse P8 cerebellum. For example, clones whose expression is restricted to superficial layers of the EGL, or to the outermost cells of the IGL have been identified. Our present efforts are directed toward identifying which of these novel genes require specific cell:cell interactions for expression, and toward understanding their role in cerebellar development.

MONOCLONAL ANTIBODIES AGAINST CELL NUCLEI IN THE DEVELOPING CHICK NERVOUS SYSTEM. A. M. Smith, L.C. Ellis* and T. N. Parks. Dept. of Anatomy, Univ. of Utah Sch. Med., Salt Lake City, UT 84132.

Recent studies have demonstrated that a subset of nuclear proteins which bind DNA are involved in the regulation of gene expression during development. It is our long-range goal to identify and characterize these proteins in the chick nervous system. Using both affinity chromatography to isolate DNA-binding proteins and hybridoma technology, we are producing monoclonal antibodies against cell nuclear proteins in the nervous system of the chick. We report here on four MAbs which were made against mouse brain nuclear protein (A60, A61, A18, F41; Smith et al., *Soc.Neurosci.Abstr. 16:* 642, 1990) and found to cross-react in the chick and two new MAbs (1F5 and 2D4) which stain chick neuronal cell nuclei. The new MAbs were produced by immunizing mice with protein isolated from chick brain nuclei. Total soluble nuclear protein was loaded onto a DNA-cellulose column and eluted with high molar salt. Silver stained gels of eluted fractions showed that most proteins were in the flow-through fraction, but that high salt elutions contained proteins predominantly in the 35-70 kDa range. Both 1F5 and 2D4 stain most neuronal nuclei in the chick brain as early as embryonic day (E) 19. Further immunohistochemical studies of several stages of development, as well as the results of immunoblot analyses will be presented. The four other MAbs all stain neuronal cell nuclei in the chick. The cognate antigens for A60 and A61 bind to a DNA cellulose column and are eluted with high molar salt, supporting our hypothesis that these proteins are DNA-binding proteins. A60 stains only neurons in the chick CNS and PNS and is detected as early as E2 in a few cells in the neural tube. With the exception of Purkinje cells, A60 staining is detected in most neurons by posthatching day (P) 5. A61 is detected as early as E1 and stains most cell nuclei at this stage. Later in development, A61 stains neurons and glia as well as several other cell types. Monoclonal antibodies A18 and F41 stain only neurons in the developing chick brain and are both detected as early as E10. Immunoblot analysis has been performed for these four antibodies in the chick and will be presented.

BIOCHEMICAL AND MOLECULAR CHARACTERIZATION OF THE 5A11 ANTIGEN, A NOVEL ADHESION MOLECULE OF THE NEURAL RETINA. P.J. Linser, J.M. Fadool and M.J Greenberg. The Whitney Laboratory and The Department of Anatomy and Cell Biology, University of Florida, St. Augustine, FL 32086.

The 5A11 antigen is a unique adhesion molecule identified in the neural retina that participates in neuronal-glial interactions. Three antibody probes have been prepared to this antigen to facilitate its characterization during retina development. Immunohistochemical analysis shows that the antigen is ubiquitous on retina cell plasma membranes early in development but later becomes restricted to Muller glial cells, photoreceptor cells and the pigmented epithelium. By Western blot analysis, all antibodies identify a doublet at 43-45kDa with and without reduction. An additional band at 68kDa is also recognized by the probes. Lectin and endoglycosidase analyses of the immunopurified antigen revealed several characteristics of the glycoprotein antigen: the antigen contains complex N-linked carbohydrates that comprise about 25% of the apparent molecular weight of the 43-45kDa doublet; the 43 and 45 kDa forms differ by the degree of sialation; differential digestions showed the presence of at least three biantennary carbohydrate moieties; the 68kDa band seems to be distinct from the others in its glycosilation and peptide core. Microsequencing of immunoisolated 43-45kDa material has produced sequences that show little homology with sequences in the available data bases. PCR was used to produce and then clone additional sequence from retina mRNA. Again the sequence appears to be unique.

525.1

Delayed Phosphorylation Of GAP-43 During Neurite Outgrowth in a Mouse Neuroblastoma Line J.T. Megerian, K.F. Meiri[1], W.L. Klein, Northwestern Univ. Inst. Neurosci, Evanston, IL 60208; Dept. Pharmacology, [1]SUNY Health Science Center, Syracuse, N.Y. 13210.

GAP-43 (aka neuromodulin, B50, pp46, F1), originally identified as an 'axonal growth associated protein', is a protein kinase C substrate thought to be involved in synaptic plasticity, neurite outgrowth, and neurotransmitter release (reviewed by Coggins P.J. & Zwiers, H., J. Neurochem. 1991 56:1095-1106). Previous studies from this laboratory using cell lines and primary nerve cultures have indicated that GAP-43 expression is neither necessary nor predictive for neurite outgrowth (Megerian & Klein, Soc Neurosci Abs, 1990; 1989). Others have reached similar conclusions (Baetge & Hammang, Neuron 1991, 6:21-30). Recently, Meiri et al (J. Cell Biol. 1991, 112(5):991-1005) have developed a panel of phospho-specific antibodies and have used them in vivo to show that phosphorylation of GAP-43 is temporally/spatially restricted to distal neurites in proximity of their targets. Using these same antibodies, we show that, in vitro, phosphorylated GAP-43 is absent from newly differentiating mouse neuroblastoma cells, despite an abundance of unphosphorylated GAP-43 in both differentiated and undifferentiated cells. Phospho-GAP is observed only in more differentiated cultures, in those cells having very long neurites. In these cells, P-GAP is punctate, localized to the distal neurite segment and is most prominent in the growth cone. Many of the growth cones containing P-GAP are in contact with other neurites and/or growth cones, suggesting that contact triggers GAP-43 phosphorylation. These results, along with our previous findings that GAP-43 is absent in early neuritogenesis, indicate that the protein has a late occurring function in neurite elongation, consistent with a role in growth cone-neurite interaction.

525.2

POST-TRANSCRIPTIONAL REGULATION OF GAP-43 mRNA LEVELS DURING NERVE GROWTH. L. H. Lin, B. Costello*, J. A. Freeman and J. J. Norden, Dept. of Cell Biology, Vanderbilt University, Nashville, TN 37232.

Elevation of GAP-43 expression has been correlated with neuronal growth states. A number of agents, including NGF, FGF, EGF, dBcAMP, KCl and TPA were reported to stimulate GAP-43 expression in PC12 cells. The regulation of GAP-43 expression, however, is not well understood. Nuclear runoff assays were performed in order to determine if the elevated GAP-43 mRNA levels in stimulated PC12 cells and developing rat brain arise via an increased transcription rate. PC12 cells were treated with NGF, FGF, EGF, dBcAMP, KCl, TPA or DEX for 6 hrs. None of the agents tested had any effect on GAP-43 transcription rate. The same results were obtained from PC12 cells treated with 4-day-old rat brain extract. When the transcription rate of GAP-43 mRNA of 4-day-old rat brain was compared to that of adult, no differences were noted. We then measured mRNA levels in PC12 cells treated with NGF, FGF or dBcAMP for 1 day, followed by treatment with the transcription inhibitor actinomycin D, with or without effector, for a second day. NGF was found to increase message stability. FGF and dBcAMP had no effect. Our data indicate that GAP-43 mRNA levels are regulated post-transcriptionally, both in PC12 cells and in developing rat brain. NGF stimulation in PC12 cells involves message stabilization whereas FGF and dBcAMP stimulation involve other post-transcriptional mechanism(s). (Supported by NIH Grants NS25150 to JJN and NS18103 to JAF)

525.3

NEURON-SPECIFIC PROMOTER CONSTRUCTS FOR OVEREXPRESSION OF B-50(GAP43) IN TRANSGENIC MICE.
J. Verhaagen[1], J.J. Plaizier[1], J.A.G. van Roon[1], J. Oberdick[2], J. I. Morgan[2], S. Forss-Petter[3], F. L. Margolis[2] [1]Rudolf Magnus Institute, Univ. Utrecht, NL,[2]Roche 8Inst. Molec. Biol. Nutley, NJ,[3]Scripps Clinic, La Jolla, CA.

A fundamental question regarding the function of the growth associated protein B-50 is: Is B-50 a determining factor in nerve fiber formation during neurodevelopment and after nerve damage? As a first necessary step to address this question in vivo three neurons-pecific promoter constructs have been prepared to study the effects of overexpression of B-50 in transgenic mice: 1. The olfactory marker protein (OMP) coding sequence in a 11kb OMP genomic clone was replaced by the B-50 coding sequence. With this construct B-50 can be targeted to mature olfactory neurons, cells that do not normally express B-50. The effect of B-50 expression in mature olfactory neurons on the lifespan of these neurons will be studied. 2. The Purkinje cell/retinal bipolar neuron specific L7 protein promoter has been fused to the B-50 coding sequence. This enables the study of the effect of B-50 overexpression on the development of these particular neurons in an otherwise unchanged brain. 3. A neuron-specific enolase (NSE)-B-50 transgene was prepared to express B-50 in virtually all neurons during adulthood. Since B-50 levels normally decline as development of the nervous system proceeds, NSE-B-50 transgenic animals offer an opportunity to study regeneration and synaptic plasticity in a number of CNS and PNS structures containing higher levels of B-50 than in non-transgenic mice.

525.4

APPROACH TO STUDY GAP-43 FUNCTION BY HOMOLOGOUS RECOMBINATION-MEDIATED GENE TARGETING IN EMBRYONIC STEM CELLS. J.D. Pollock, S.J. Engle*, J.A. Tischfield*, and L. Yu. Dept. of Med. & Mol. Genetics, Indiana Univ. Sch. of Med., Indianapolis, IN 46202.

GAP-43 (also known as neuromodulin and F1) is a neural specific phosphoprotein enriched in growth cones and axons. GAP-43 synthesis is increased during neuronal outgrowth and during axonal regeneration. It is phosphorylated during long-term potentiation in the hippocampus, suggesting its possible association with learning. However, despite many studies, little is known about the physiological role of GAP-43.

One way to analyze GAP-43's function is to generate a null mutation of the endogenous GAP-43 gene in animals and to observe the effects of such mutation. The development of the technique of gene targeting in embryonic stem cells via homologous recombination by Capecchi, Evans, and Smithies's groups makes it possible to achieve this goal. Using a GAP-43 cDNA clone as probe, we isolated genomic clones of the mouse GAP-43 gene. Two targeting vectors were constructed which contain thymidine kinase genes flanking the second exon of the GAP-43 gene. In one vector the exon is interrupted by the insertion of a neomycin-resistance gene, and in the other a lacZ gene is fused to the neomycin-resistance gene. Mouse embryonic stem cells are transformed with these vectors to generate targeted null mutation in the GAP-43 gene.

525.5

LOCAL REGULATION OF GAP-43 PHOSPHORYLATION IN GROWTH CONES OF NEURITES REGENERATING IN CULTURE. E.W.Dent* and K.F. Meiri, Dept. Pharmacology, SUNY Health Science Center, Syracuse, NY13210.

The nervous-system specific protein GAP-43 is highly enriched in the membrane skeletons of growth cones where it is a major substrate for protein kinase C. Previously, we have shown that induction of GAP-43 phosphorylation is precisely regulated during axonogenesis *in vivo* (Meiri et al., J.C.B., 112, 991-1005, 1991). Here we have used embryonic DRG neurons *in vitro* to study the regulation of GAP-43 phosphorylation between and within individual growth cones. Two major findings emerge: First, when dissociated E16-20 DRGS are cultured, GAP-43 phosphorylation is initially switched off and only gradually reestablishes its prior *in vivo* levels by about 20 hours, by which time a dense plexus of neurites has already been generated. This down-regulation does not reflect either levels or activity of kinase C and cannot be ameliorated with excess NGF, phorbol esters or conditioned medium from long-term cultures. Second, Phosphorylated GAP-43 has a restricted distribution in individual growth cones: Phospho-GAP-43 colocalizes with actin at the ruffling edge of lamellae and is also highly concentrated in filopodia. Additionally, discrete phospho-GAP-43 'hot spots' may appear within the body of individual growth cones. These results, which show that the induction of GAP-43 phosphorylation seen during development is also recapitulated during regeneration, and further confirm that phospho-GAP-43 is not required for initial stages of axon outgrowth, also demonstrate the local regulation of GAP-43 phosphorylation in individual growth cones.

525.6

ABNORMAL NEURITE EXTENSION IN GAP-43 DEFICIENT PC12 CELLS STABLY TRANSFECTED WITH MUTATED (SER^{41}-ALA^{41}) GAP-43. E.E. Baetge, L.E.Bickerstaff,° K.M. Felsenstein, J.P. Hammang and K.F.Meiri° CNSMol. Neurobiol. Bristol-Myers Squibb, Wallingford, CT 06495. Dept. Pharmacology,° SUNY Health Science Center, Syracuse NY 13210.

The nervous-system specific kinase C substrate GAP- 43 is localized to the membrane skeleton of growth cones and has been linked to both axon outgrowth and neurotransmitter release. However, in the PC12 line, PC12(B) axon extension can occur without normal levels of GAP-43 (Baetge & Hammang Neuron 6:21, 1990). Here we show that these PC12(B) cells actually extend neurites more readily and more rapidly, and are also less adhesive to substrates than 'GAP- 43-normal' counterparts. The PC12(B)cells were transfected with a GAP-43 cDNA in which the kinase C phosphorylation site at ser^{41} had been mutated to alanine, preventing phosphorylation at that site. Clones that stably expressed mutant GAP- 43 were more adhesive to substrates and to each other than either the parent line or 'GAP-43 normal' PC12 cells. The transfected cells also extended fewer neurites more slowly than controls. Under highpower Nomarski optics, alterations to the morphology of live transfected cells were also apparent: Massive elaborations of filopodia arose from cell bodies and neurites as well as growing tips. The membranes of cell bodies and neurites often appeared distorted and accumulations of large vesicles were seen throughout the cells. The magnitude of these effects correlated with the amount of mutant GAP-43 expressed. These results, which extend previous observations that GAP-43 is not necessary for axon elongation, further suggest that over-expression of non-phosphorylatable GAP-43 may interfere with cytoskeletal organization and membrane vesicle transport.

525.7

ALTERED ORGANIZATION OF INTERMEDIATE FILAMENT PROTEINS IN GAP-43 DEFICIENT PC12(B) CELLS. [1]J.P. Hammang, [2]K.F. Meiri and [1]E.E. Baetge. [1]Cell and Molecular Neurobiology, Bristol-Myers Squibb Company, Wallingford, Ct. 06492, [2]Department of Pharmacology, SUNY Health Sciences Center, Syracuse, N.Y. 13210.

Intermediate filaments are tissue specific cytoskeletal proteins that influence cell shape and function. To determine whether the growth-associated protein, GAP-43 is involved in intermediate filament organization in PC12 cells, we compared the pattern of intermediate filament expression in GAP-43 deficient PC12(B) cells (Baetge and Hammang, Neuron 6 p. 21-30, 1991) with lines of "GAP-43- normal" PC12 cells. Furthermore, GAP-43 expression in the PC12(B) cells was restored by transfecting the cells with vectors containing a rat GAP-43 cDNA together with the genes for hygromycin B or neomycin resistance. Cells were treated with NGF to induce neurite expression for 3-7 days. All cells were processed for immunofluorescence using antibodies to the neurofilament proteins and to peripherin. GAP-43 containing and GAP-43 deficient PC12(B) cells exhibit neurofilament immunoreactivity within the cell body and extending out to the end of the neurites. The distribution of peripherin was markedly different. In PC12(B) cells peripherin immunoreactivity was confined to the cell body and was absent in the neurite processes, whereas in "GAP-43-normal" PC12 cells, or in the GAP-43 transfected PC12(B) cells, the peripherin was distributed within the neurites. The GAP-43 deficient PC12 cells will be useful for the investigation of the role(s) of GAP-43 in neuronal development and function.

525.8

GAP-43 MESSAGE LEVELS IN A HUMAN NEUROBLASTOMA CELL LINE BEFORE AND AFTER DIFFERENTIATION BY RETINOIC ACID. M.Weisenhaus*, J.P.E.Tokeson*, K.E.Rogers, S.Sullivan, M.F.D.Notter, P.D.Coleman. Dept. Neurobio. and Anat., Univ. of Rochester, Rochester N.Y. 14642.

It has been shown that neuroblastoma cells can be differentiated *in vitro* to acquire many neuronal phenotypes that are absent prior to differentiation. These include the expression of neuronal surface markers, electrical properties, cessation of cell division, and induction of morphological characteristics, including the extension of neurites with growth cones. This latter property was investigated by slot blot quantification of GAP-43 message, both before and after differentiation with 10uM retinoic acid. GAP-43, a phosphoprotein, is a marker of neuritic sprouting *in vivo* both during development and during synaptic reorganization. Differentiation of LAN-1 cells by retinoic acid induced a 3.5 fold increase in GAP-43 message levels as compared with controls, normalized for oligo dT slot blot hybridization. Northern blot analysis ensured intact RNA and confirmed the specificity of the GAP probe, which was made by random priming a full length GAP-43 cDNA. It is suggested that this paradigm can be used to study neurite plasticity and the regulation of GAP-43 *in vitro*. Supported by LEAD AG 09016, R01 AG 01121, and NIH NS25778.

POST-TRANSCRIPTIONAL MECHANISMS DURING PROCESS OUTGROWTH II. Stabilization of GAP-43 and other neuronal mRNAs in TPA induced PC12 cells. V.V. Cansino*, D. T. Kohn* and N. I. Perrone-Bizzozero. Department of Biochemistry, University of New Mexico, Albuquerque, NM, 87131-5221, U.S.A.

Previous work from our laboratory showed that the expression of the neuronal growth-associated protein GAP-43 is induced by nerve growth factor (NGF) via a selective change in the rate of degradation of the mRNA (Perrone-Bizzozero et al, (1990) Neurosci. Abtr. 16, 814). To study this further, we have examined the effects of NGF and other agents that modulate neurite outgrowth on the steady-state levels and on the relative rates of decay of GAP-43 and other neuronal mRNAs. By Northern blot analysis, we found that GAP-43 mRNA levels in PC12 cells were increased in response to the phorbol ester TPA, but not by either dibutyryl-cAMP or the Ca^{2+} ionophore A23187, suggesting that GAP-43 expression in these cells depends on the activation of protein kinase C. Furthermore, TPA had a much greater effect than NGF on both the onset and extent of process outgrowth and on the levels of the mRNAs for the neuronal proteins GAP-43, β-tubulin II (β-tub) and actin. In mRNA decay studies, TPA was found to increase 3-4 fold the half-lives of GAP-43, β-tub and actin mRNAs but had no effect on that of the housekeeping enzyme glyceraldehyde-3-phosphate-dehydrogenase (G3PD). The effect of TPA on the stability of GAP-43 and β-tub mRNAs was blocked by dexamethasone but not by cycloheximide, suggesting that post-translational modification of a neuronal factor is required for these effects. In conclusion, our results indicate that in addition to transcriptional control, post-transcriptional mechanisms seem to play an important role in the regulation of gene expression during neuronal differentiation. Supported by NSF (BNS-9011199) and the American Paralysis Association (PBI-9006) to N.P.B.

IDENTIFICATION OF *CIS*-ACTING ELEMENTS REGULATING GAP-43 PROMOTER ACTIVITY. E. Nedivi*, G. S. Basi, and J. H. P. Skene. Dept. of Neurobiology, Stanford University Medical School, Stanford, CA 94305

One of the best characterized examples of a gene that exhibits both neural-specific induction and later axon-dependent repression in neurons is the single-copy gene encoding GAP-43. In order to analyze regulatory elements controlling transcription of this gene, we have now isolated a functional GAP-43 promoter from rat, and 5 kb of DNA flanking this promoter. A 386 bp fragment containing the GAP-43 promoter fused to a gene for chloramphenicol acetyltransferase (CAT) drives expression of this reporter gene when transfected into dissociated cells from embryonic rat cortex or into NGF-treated PC12 cells, but not in several non-neuronal cell lines. This indicates that *cis*-acting elements in or near the core GAP-43 promoter can account for a substantial degree of the gene's neural-specific expression.

The promoter activity of the 386 bp fragment is modulated by additional elements lying on either side of it. Addition of an upstream DNA fragment containing the repeating sequence (GT)17 to the 386 bp fragment strongly inhibits CAT expression in cortical cultures. A downstream fragment containing the repeating sequence (GA)35 mildly depresses expression when added to the 386 bp fragment alone, but strongly counteracts the repressive effects of the upstream region when both flanking elements are present. The repeating sequences have the potential to adopt unusual DNA conformations. A 230 bp fragment located further downstream of the promoter appears to stabilize fluctuations in the level of promoter activity. On its own, this downstream fragment can act in an orientation-independent fashion to direct low-level expression of a marker gene in transient transfection assays, behaviour reminiscent of some types of non-promoter regulatory sequences from other genes (e.g. Cell 32, 503). The 1 kb DNA fragment containing all of these functionally characterized elements also contains upstream of the promoter, a sequence motif common to several neural-specific genes. Preliminary experiments indicate that an additional 4 kb of more upstream DNA may contain two 'silencer' elements, differing in strength and size, that cumulatively repress GAP-43 promoter activity. Supported by grant EY 07397.

FUNCTIONAL CONSERVATION OF GAP-43 GENE REGULATORY ELEMENTS BETWEEN MAMMALS AND FISH. E. Reinhard*, E. Nedivi, J. Wegner*, J.H.P. Skene, and M. Westerfield. Inst. of Neurosci., Univ. of Oregon, Eugene, OR 97403 and Dept. of Neurobiol., Duke Univ., Durham, NC 27710.

Expression of the single-copy GAP-43 gene is confined to the nervous system, where GAP-43 is widely expressed during development and then decreases drastically as synapses are formed. Distal axon interruption reinduces GAP-43 expression in the CNS of fish and amphibians, but not in the mammalian CNS. To explore the phylogenetic conservation of *cis*-acting elements responsible for early neural-specific expression and the later repression of this gene, we have introduced the rat GAP-43 promoter and surrounding DNA into transgenic zebrafish.

Three DNA fragments from the 5' end of the rat GAP-43 gene, a 386 bp fragment containing a neural-selective GAP-43 promoter (Nedivi et al., this volume), and larger fragments of 1 kb or 5 kb encompassing the smaller piece, were fused to a gene for β-galactosidase and injected into one-cell zebrafish embryos. Expression patterns were analyzed at several developmental stages. The constructs were strongly expressed in the developing nervous system at stages when extensive neurite outgrowth takes place (20-60 h after fertilization). At 50 h, for example, 85% of the cells expressing the 1 kb construct were neurons, 6% pigment cells, 1% muscle, and 8% other cells. The 386 bp fragment alone also directed expression preferentially in neurons; more than 80% of cells expressing the transgene were in the nervous system. In contrast, an RSV-promoter directed β-galactosidase expression in muscle cells (38%), skin (31%), and various other cells (31%). In embryos older than 35 h, the 386 bp and 1 kb promoter fragments were active almost exclusively in the brain, whereas the 5kb fragment was activated also in more posterior regions of the nervous system. Therefore, the 5 kb fragment may contain additional regulatory elements.

Our results demonstrate that *cis*-acting control elements from the rat GAP-43 gene are specifically activated in zebrafish neurons, suggesting that elements controlling the neural-specificity of GAP-43 gene expression have been functionally conserved during vertebrate evolution. Supported by grants HD22486 and EY07397.

GAP-43 mRNA BINDING PROTEINS RELATED TO NEURAL DIFFERENTIATION. N. Irwin, N. I. Perrone-Bizzozero and L. I. Benowitz. Dept. Neurosurgery, Children's Hospital, Harvard Med. School, Boston MA 02115; Dept. Biochem., U. New Mexico.

Expression of the membrane phosphoprotein GAP-43 is closely linked to the development and reorganization of neuronal connections[1,2]. Although growth-related changes in GAP-43 are generally paralleled by changes in levels of the mRNA, nuclear run-on studies indicate that these mRNA changes do not reflect altered rates of gene transcription[3,4]. For a number of other mRNAs, regulation involves the binding of cytosolic proteins to defined nucleotide sequences, which either enhance or retard degradation by ribonucleases[5]. Using band-shift assays, we found that the migration of a 3' fragment of GAP-43 mRNA on non-denaturing gels was retarded when the mRNA was incubated with cytosolic factors from cells undergoing neurite outgrowth. Factors from undifferentiated cells caused the mRNA fragment to migrate to a different position. To identify these binding proteins, cellular proteins were separated by SDS-PAGE, transfered to nitrocellulose, and probed with a radiolabeled fragment of the 3' end of GAP-43 mRNA. NGF-stimulated PC12 cells contained a 17 kDa protein with high GAP-43 mRNA binding activity; this protein did not bind control RNA and was barely detectable in unstimulated PC12 cells. Another GAP-43 RNA binding protein was visualized by similar methods in the neonatal rat cortex. We are currently characterizing the identity and biological activity of these proteins. *Support: NIH EY 05690.*

POSSIBLE ROLE OF CALMODULIN BINDING TO B-50 (GAP-43) IN THE MECHANISM OF NORADRENALINE RELEASE.

P.N.E. DeGraan, J.J.H. Hens*, M. De Wit*, P. French*, A.B. Oestreicher* and W.H. Gispen*. Div. Mol. Neurobiol., Rudolf Magnus Inst. and Inst. Mol. Biol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, The Netherlands.

B-50 (also known as GAP-43, F1 and neuromodulin) is a neuron-specific protein kinase C (PKC) substrate and is thought to be involved in the mechanism of noradrenaline (NA) release (Dekker et. al., *Nature* 324, 74, 1989). In purified systems and in native synaptosomal plasmamembranes it has been shown that B-50 binds calmodulin in the absence but not in the presence of calcium. In this study we investigated the relevance of B-50/calmodulin interaction in the mechanism of NA release. Calcium-induced NA release from Streptolysin-O permeated synaptosomes was measured using ^{3}H-NA. B-50/calmodulin interaction was measured using the homobifunctional crosslinker disuccinimidylsuberate (De Graan et al., *J.Neurochem.* 55, 2139, 1990). Calcium induces a dose-dependent dissociation of the B-50/CaM complex (EC_{50} 10^{-6} M) in the presence or absence of 150 mM K^+). The EC_{50} for complex dissociation and calcium-induced NA release are identical. Both calcium-induced NA release and B-50/CaM complex formation (at 10^{-6} M calcium) can be inhibited by polymyxin B, but not by calmodulin inhibitors such as W7 and trifluoperazine. The sensitivity of these two parameters for polymyxin B is at least 10-fold higher than PKC-mediated B-50 phosphorylation. Our data show that the inhibition of NA release by polymyxin B is not due to inhibition of PKC. These results are in line with the hypothesis that calmodulin-binding to B-50 plays a role in the regulation of NA release.

525.14

TWO FORMS OF GAP-43 DISTINGUISHED BY MIGRATION ON SDS-PAGE CORRELATE WITH THE PALMITOYLATED AND NON-PALMITOYLATED ISOFORMS. Sean I. Patterson and J. H. Pate Skene. Department of Neurobiology, Box 3209, Duke University Medical Center, Durham, North Carolina 27710.

An abundant protein component of growth cone membranes, GAP-43, has been shown to undergo covalent, post-translational addition of fatty acid residues concurrent with its attachment to cellular membranes (J. Cell Biol. 108, 613-624). Incorporation of 3H-palmitate into GAP-43 by isolated growth cones suggests that cycles of acylation and de-acylation of the protein may occur *in vivo*. Using SDS-PAGE at high voltage (300V), we have resolved two closely migrating forms of GAP-43 (apparent molecular weights 48 and 50 kDa, respectively, on 12% acrylamide gels), which can be detected on Western blots with mAb 9-1E12. Under similar conditions, 3H-palmitoylated GAP-43 migrated as a single band detected by fluorography, corresponding in migration to the upper band detected by Western blotting. Sub-cellular fractionation of growth cone preparations shows that the lower, non-acylated form is found predominantly in a cytosolic fraction. The upper, acylated form of GAP-43 found in washed membrane preparations can be converted to the soluble, lower form by treating the membranes with hydroxylamine at pH 10, which removes the fatty acid from the protein. This is consistent with a role for covalenlty bound fatty acid in the binding of GAP-43 to growth cone membranes. It is not yet clear whether the lower isoform is produced by de-acylation alone, or by additional modification that follows de-acylation of GAP-43. The lower, non-acylated form produced by chemical treatment is highly hydrophilic and exhibits a substantially reduced binding to nitrocellulose membranes. One technical implication of this finding is that standard Western blotting of tissue samples will systematically underestimate the occurence of this form of GAP-43 *in vivo*, relative to the upper acylated form. With appropriate calibration, however, these results provide an assay for assessing the relative proportions of these two forms of GAP-43 under changing biological conditions *in vivo*. Supported by NIH grant NS 20178.

IDENTIFICATION OF THREE PHOSPHORYLATION SITES IN THE GROWTH-ASSOCIATED PROTEIN GAP-43. S.A. Spencer and M. Willard. Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

GAP-43, a protein that is concentrated in neuronal growth cones and certain presynaptic terminals, has been suggested to perform functions in axon outgrowth, transmitter release, and synaptic plasticity. It is a substrate for protein kinase C, which phosphorylates it at a single site, serine 41, and thereby changes its affinity for calmodulin. Previous experiments indicated that in cultured neurons, GAP-43 is phosphorylated at additional sites by other protein kinases. To identify these additional sites, dispersed superior cervical ganglion cells from rat were grown in culture for five days and then labeled with ^{32}P-orthophosphate for four hours. GAP-43 was immunoprecipitated from these cultures and then proteolyzed with trypsin or endoproteinase Asp-N; the resulting radiolabeled peptides were purified by reverse-phase HPLC. Sequential Edman degradation of these phosphorylated fragments produced three sequences corresponding to amino acids 38-43, 90-106, and 167-176 of GAP-43. The first peptide, IQASFR, was phosphorylated at serine 41, the site recognized by protein kinase C. ^{32}P-orthophosphate was released from the second and third peptides at the cycles of Edman degradation corresponding to serine 96 and threonine 172 respectively, demonstrating that these two sites, in addition to serine 41, are phosphorylated in cultured neurons. The similarity of the amino acid sequences surrounding these two sites, i.e. APAT S^{96a} PKAE, and AAAT T^{172} PAAE, suggests that they may be phosphorylated by the same enzyme. These sequences resemble those recognized by a recently described enzyme designated proline-dependent proline kinase. (Supported by NIH grant EYO2682.)

GAP-43 mRNA EXPRESSION IN THE RAT HIPPOCAMPUS. H.M.Chao and B.S. McEwen. Laboratory of Neuroendocrinology, The Rockefeller University, New York, NY 10021

GAP-43 (growth associated protein 43) is a neuron-specific phosphoprotein localized in growth cones, whose expression is closely correlated with axonal growth. GAP-43 is abundant throughout the brain during development, but in the adult brain its expression is greatly diminished and anatomically restricted. The hippocampus is an area in which GAP-43 persists in the adult, a reflection perhaps of the synaptic plasticity known to occur in this brain region. We have analyzed the expression of the GAP-43 mRNA in different subfields of the rat hippocampus by in situ hybridization. Our results indicate that there is a significantly higher level of GAP-43 mRNA in the CA3+4 region than in CA1+2, and an intermediate level of expression in the dentate gyrus. Since CA3 pyramidal cells have a dense projection to CA1 pyramidal cells, the relative abundance of GAP-43 mRNA in the CA3+4 region may account for the prominent immunostaining for GAP-43 observed in the CA1 subfield. In addition, in rats that have been bilaterally adrenalectomized for 7 days, there is an increase in the level of GAP-43 mRNA in several subfields of the hippocampus relative to sham-operated animals. These findings are consistent with previous reports describing negative regulation of the GAP-43 gene by glucococorticoids in vitro. We are currently investigating the effects of steroid replacement in adrenalectomized rats and of steroid treatment in adrenal-intact rats on the hippocampal expression of GAP-43 mRNA. (Supported by MH41256 and NS07080.)

ULTRASTRUCTURAL DISTRIBUTION OF B-50/GAP-43 IN CULTURED HIPPOCAMPAL NEURONS DURING VARIOUS DEVELOPMENTAL STAGES. M. Van Lookeren Campagne, C.G. Dotti[1], E.R.A. Jap Tjoen San, W.H. Gispen and A.B. Oestreicher. Rudolf Magnus Institute, University of Utrecht, Utrecht, NL, and [1]European Molecular Biology Laboratory, Heidelberg, FRG

The distribution of B-50/GAP-43 in hippocampal neurons *in vitro* has been studied at different stages of development by light and electron microscopy. Axons and dendrites are distinguished by morphological criteria and marker antibodies, using immunocytochemical detection by silver enhanced 1 nm gold particles. Particle density is quantitated by video imaging. Directly after plating the neurons extend several filo- and lamellipodia. Ultrastructurally, B-50 is mainly present in the cytosol of lamellipodia and associated with small clear vesicles in the perinuclear area. After 2 days *in vitro* (2 DIV), neurons have several neurites of equal length or one long axon and several short dendrites. B-50 is homogenously distributed at the plasma membrane of all neurites, their growth cones and the cell body. After 7 DIV the spacial distribution of B-50 varies. Where synaptic contacts are scarce or absent, B-50 is detected at the plasma membrane of axons and dendrites. In neurons receiving synaptic contacts, B-50 at the plasma membrane of dendrites is reduced compared to axons. In this developmental stage MAP2 is exclusively present in the microtubules of dendrites. In neurons maintained in culture for 14 to 21 days, cell density appears to play a crucial role in the plasma membrane distribution of B-50. In high density cultures the cell body and dendritic plasma membrane is almost devoid of B-50. The plasma membrane of axons and axon terminals is rich in B-50. In low density cultures of neurons without synaptic contacts, B-50 is present at the plasma membrane of axons, dendrites and the cell body. At all developmental stages B-50 is detected at vesicles of 100 nm, which are mainly present in growth cones. These results suggest that synaptogenesis, rather than functional polarization, determines the restricted localization of B-50 in the axonal domain.

THE PATTERN OF GAP-43 IMMUNOREACTIVITY IN POSTNATAL RAT SPINAL CORD. D.J. Stelzner and J.A. Strauss*. Dept. of Anatomy and Cell Biology, SUNY Health Science Center, Syracuse, New York 13210.

Monoclonal antibodies to a phosphorylated form of GAP-43 (2G12/c7) or to both phosphorylated and non-phosphorylated forms of GAP-43 (5E7/G2) (J. Cell Biol. 112:991) were used to study the distribution of GAP-43 during postnatal development within rat spinal cord (0,3,6,12,15,18,24,48,90d; N=4). Tissue was lightly fixed in Bouin's and embedded in paraffin. Blocks were transversely sectioned at 10 um, and tissue prepared for immunohistochemistry using HRP and avidin-biotin amplification. A similar distribution of immuno-staining was seen with both antibodies, although denser and somewhat broader immunoreactivity was seen with the 5E7 antibody in 15d and older tissue. Heavy staining filled much of the white matter and the neuropil of the intermediate and ventral gray matter at birth. Lamina I was labeled from birth on. At 3,6,and 12d, regions containing corticospinal (CS) axons became the heaviest labeled areas of the white matter as CS axons extended through the spinal cord and immuno-reactivity increased in dorsal horn. Gracile fasc. remained lightly labeled until 12d although little staining was found in the cuneate fasc. Axons in other areas of white matter became progressively less heavily labeled. Some axons remained immunolabeled in CS pathways until 24d. At 15d the upper laminae of the dorsal horn, CS projection areas in the medial dorsal horn, and a medial zone surrounding the central canal remained heavily labeled. Less immunostaining was seen in 18-24d material; little was seen at 48 and 90d, particularly with 2G12. (Supported by grant NS14096).

525.19

AUTORADIOGRAPHIC PATTERNS OF GAP-43 mRNA EXPRESSION IN ADULT RAT BRAIN. L. Kruger, Dept. of Anatomy and Cell Biology, UCLA Medical Center, Los Angeles, CA; C. Bendotti, R. Rivolta*, and R. Samanin*, Lab. Neuropharmacology, Mario Negri Institute, Milan, and M. Bentivoglio, University of Verona, Italy.

The neuron-specific protein associated with axonal outgrowth during development and nerve regeneration, GAP-43, is expressed in highly selective neuronal populations in the adult rat brain. We previously reported high levels of GAP-43mRNA expression in mature brainstem monoaminergic neurons (Bendotti et al., '91). A survey of the distribution of GAP-43mRNA throughout the adult CNS revealed highly specific localization patterns that differ from the distribution of immunoreactivity reported by others.

High mRNA levels are evident in the primary olfactory and in the secondary gustatory pathways. Low levels are found in the main visual, auditory and somatosensory relays, although "secondary," midline and intralaminar thalamic nn. exhibit high levels. In cerebral cortex, insular and parastriate fields exhibit highest levels. Other regions of high density include inferior olive and cerebellar granular layer, hippocampus CA_3, entorhinal cortex, amygdala, hypothalamic nn., bed n. of stria terminalis, n. basalis, lateral reticular, periaqueductal gray, and substantia gelatinosa. The variety of anatomical substrates provides a new basis for examining the propensity for synaptic "plasticity" in mature neurons.

GAP-43 RESPONSES TO NERVE INJURY AND PERIPHERAL INFLAMMATION. R.L. Nahin, M. DeLeon and M.A. Ruda, Neurobiology and Anesthesiology Branch, NIDR, NIH Bethesda MD 20892.

Dorsal root ganglia (DRG) levels of GAP-43 have been shown to increase after axotomy. In the present study we compare GAP-43 mRNA and peptide levels after: 1) complete sciatic transection; 2) a chronic constriction injury (CCI) that results in behavioral hyperalgesia (Bennett and Xie, Pain 33 (1988) 87-107); 3) peripheral inflammation and accompanying hyperalgesia produced by two unilateral hindpaw injections of complete Freund's adjuvant (CFA), 5 and 10 days prior to sacrifice. Total mRNA was extracted from L4-5 DRG, 7 days after nerve transection or CCI, and 10 days after induction of inflammation in a hindpaw. RNA blots were hybridized with a ^{32}P-labeled cDNA probe for rat GAP-43. For cellular localization, fixed DRG were processed for in situ hybridization using a ^{35}S-labeled cDNA probe, or for immunoreactivity using a monoclonal antibody to GAP-43. Despite the fact that nerve transection destroys all fibers while the chronic constriction injury spares 60-70% of unmyelinated fibers, RNA blot analysis revealed at least a 2-fold increase in GAP-43 mRNA after both nerve transection and CCI. Using in situ hybridization, we localized this increase in mRNA to both large and small DRG neurons. In contrast, peripheral inflammation did not produce any alteration in GAP-43 mRNA or peptide. We conclude that 1) complete axotomy is not necessary for induction of GAP-43 synthesis; 2) increased primary afferent activity following inflammation and hyperalgesia is not sufficient to alter GAP-43 levels.

NERVE GROWTH FACTOR VI

526.1

SPECIFICITY OF NGF-INDUCED CEREBROVASCULAR SPROUTING. L.G. Isaacson[1] and K.A. Crutcher[2]. [1]Dept of Zoology, Miami University, Oxford, OH 45056; [2]Dept of Neurosurgery, University of Cincinnati College of Medicine, Cinci OH 45267.

We have previously shown that intraventricular infusion of nerve growth factor (NGF) into the adult rat brain elicits sprouting from mature cerebrovascular axons associated with the intracranial internal carotid artery (ICA). A 3-fold increase in the total number of perivascular axons was found at the ultrastructural level (Isaacson et al.1990). Since the ICA receives innervation from sympathetic, sensory, and parasympathetic sources, we undertook the present study to determine: 1) to what extent the sprouted axons are sympathetic in origin and 2) whether non-sympathetic fibers respond to NGF in the absence of sympathetic fibers. One group of rats received bilateral superior cervical ganglionectomy after a 14-day infusion of either NGF (NGFsx) or cytochrome C (VEH sx) and was sacrificed 3 days later. The other group received ganglionectomy 3 days prior to the onset of the infusion and was sacrificed at the end of the 14-day infusion period (sxNGF or sxVEH). The total number of perivascular axons associated with the ICA was determined using electron microscopy. Bilateral ganglionectomy resulted in a significant (73%) reduction in the number of perivascular axons indicating that the majority of sprouted fibers are sympathetic in origin. Both sxVEH and sxNGF rats exhibited a significant decrease compared to nonganglionectomized VEH rats, but the decline was greater in the sxVEH rats (67%) than in sxNGF rats (47%) indicating that some non-sympathetic axons may be responding to NGF in the absence of sympathetic fibers. These results suggest that mature cerebrovascular innervation can be modulated by NGF infusion and that sympathetic axons apparently are more responsive than non-sympathetic fibers.

526.2

CHANGES IN NGF RECEPTOR AND GAP 43 mRNA ASSOCIATED WITH COLLATERAL SPROUTING AND REGENERATION OF DORSAL CUTANEOUS NERVES IN THE RAT. K.M. Mearow, G.M. Ross*, A. Gloster, M. Holmes* and J. Diamond. Dept. Biomedical Sciences, McMaster University Medical Centre, Hamilton, Ontario, Canada.

Previous studies have demonstrated that collateral sprouting of intact nociceptive nerves is NGF-dependent, while regeneration of the damaged fibres shows no such requirement (Diamond et al, 1987, PNAS 84:6596). In our approach to explain this difference, we have begun to look at the expression of NGF-R and GAP 43.

DRGs of regenerating, collateral sprouting and control dorsal cutaneous nerves were isolated and used for analysis. In situ hybridization (ISH) was used to examine changes in mRNA distribution at the cellular level. These changes were quantified by solution hybridization using total RNA and PCR amplification of the specific messages.

The results indicate that the mRNAs for NGF-R and GAP 43 are elevated in the DRGs of sprouting nerves at 1 day post-op, decreasing to control levels by 1 week post-op. The ISH results show that these changes are specific to the small DRG neurons. We are presently using the same approach to study "precocious sprouting" (e.g. Doucette & Diamond, 1987, J. Comp. Neurol. 261:592), a dramatic shortening in the latency of nociceptive collateral sprouting induced by impulse activity. (This work is supported by the Centres of Excellence for Neural Regeneration and Functional Recovery).

526.3

ANTI-NGF TREATMENT BLOCKS THE COLLATERAL SPROUTING OF CHOLINERGIC FIBERS IN THE HIPPOCAMPUS. E.E.M. Van der Zee, J. Fawcett, J. Stanisz, R. Racine and J. Diamond. Departments of Biomedical Sciences and Psychology, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5

Entorhinal cortex lesion leads to sprouting in the dentate gyrus of fibers from NGF-sensitive cholinergic neurons of the basal forebrain. We have now tested whether this sprouting is NGF-dependent. Eight days after a unilateral electrolytic lesion of the entorhinal cortex, the density of AChE positive fibers in the ipsilateral and contralateral outer molecular layers was compared. Either anti-NGF or non-immune serum was injected daily via a permanently implanted cannula in the ipsilateral lateral ventricle. In separate studies antibodies were shown to penetrate into predominantly ipsilateral brain tissue. The ipsilateral cholinergic sprouting was totally prevented by anti-NGF treatment; however the widening of the inner molecular layer (attributed to sprouting of commissural/associational fibers) seemed to be unaffected. The 8 d. anti-NGF injections did not reduce the density of AChE positive fibers in the contralateral dentate gyrus or in unlesioned brains. The findings thus implicate NGF, or a molecule that is recognised by the polyclonal anti-NGF, such as BDNF or NT-3, in the collateral sprouting of the cholinergic septohippocampal fibers. (This McMaster Node is a member of and supported by the Centres of Excellence for Neural Regeneration and Functional Recovery).

526.4

DEVELOPMENT AND CHARACTERIZATION OF CHICKEN POLYCLONAL ANTIBODIES TO NERVE GROWTH FACTOR RECEPTOR (NGFR) THAT INHIBIT LIGAND BINDING. A.A.Zupan, J.C.Pryor*, I.Leung*, L.Coussens* and E.M.Johnson,Jr. Dept. of Pharmacology, Washington Univ. Sch. of Med., St. Louis, MO 63110; Chiron Corp., Emeryville, CA 94608.

In this report we describe the development and characterization of a polyclonal chicken antibody against the recombinant extracellular domain of the human NGFR. This paradigm offers several distinct advantages. First, the evolutionary differences of antigen source and antibody producer enhance antigenic potential. Second, egg-yolk immunoglobulins are readily accessible, produced in large quantities, and conveniently packaged for facile storage. The purified antibody is novel in its ability to recognize receptor from a variety of species (including human, rat, mouse, and guinea pig), as determined by immunocytochemistry, immunoprecipitation and/or in vivo retrograde transport assays. Furthermore, this antibody has the capacity to block ligand binding to these receptors. To date this has only been demonstrated for the anti-human NGFR monoclonal antibodies, e.g., ME20.4-IgG. Because of the broad range of species reactivity we propose that this antibody will be useful in determining the role of the low-affinity NGFR in signal transduction, as well as contributing to improved receptor immunoassays (e.g., electron microscopy and immunoblotting.

526.5

INTRACEREBROVENTRICULAR (ICV) ADMINISTRATION OF NGF TO NEWBORN RATS INDUCES AN INCREASE OF ACETYLCHOLINESTERASE (AChE) ACTIVITY IN FOREBRAIN REGIONS. G. Vantini, N. Schiavo*, C. Cosi, N. Gabellini* A. Leon and M.A. Tria*. Fidia Research Labs, 35031 Abano Terme, Italy.

Forebrain cholinergic neurons respond in vivo to icv administration of NGF with a prominent and selective increase of choline acetyltransferase activity. We here report that, in the septal area and striatum, NGF administration also affects the enzymatic activity of AChE. A significant increase (about 50%) of AChE activity was observed in both septum and striatum of 10-day-old rats treated with NGF (10ug/injection) on postnatal days 2,4,6, and 8. In septal area this effect was associated with an increase of AChE mRNA. In adult animals, a modest increase (about 15%) of striatal AChE activity was observed after continuous icv infusion of NGF (100ug over two weeks). Since in forebrain regions AChE is largely associated with cholinergic neurons, and in view of the multiple roles that the molecular forms of AChE can exert in neuronal development and function (see for example Small D.H., TIBS, 15:213-216), the present observations confirm and extend the notion that NGF (or related molecules) acts in vivo by modulating both functional and structural properties of forebrain cholinergic neurons.

ACETYLCHOLINE RELEASE IN VIVO IN LESIONED ANIMALS GRAFTED WITH GENETICALLY MODIFIED CELLS IN THE CORTEX. PREVENTION OF NEURONAL DEGENERATION IN THE NUCLEUS BASALIS MAGNOCELLULARIS (NBM). D. Maysinger, P. Piccardo*, L. Lamarre*+, M. Goiny*+ and A.C. Cuello. Department of Pharmacology and Therapeutics, McGill University, Montreal, Canada H3G 1Y6. +Department of Pharmacology, Karolinska Institute, Stockholm, Sweden S-104-01.

Degenerative changes in the nucleus basalis magnocellularis (NBM) can be prevented by chronic treatment with trophic factors such as nerve growth factor (NGF). The aim of the our study was to investigate whether neuronal degeneration of the NBM could be prevented by grafting genetically modified fibroblasts in the cortex at the site of the lesion. Male Wistar rats (n = 26) were unilaterally lesioned by disrupting the blood vessels in the area of the fronto-parietal cortex. Following devascularization, fibroblasts (both secreting and non-secreting NGF) were placed onto the surface of the cortex. Cell suspension ($3.0 \times 10^5 - 3.0 \times 10^6$ cells per animal) was introduced into sterile, biodegradable gel-foam (0.8 x 0.8 x 0.1 cm; Upjohn) and layered over the damaged cortex. Thirty days following surgery, animals were anaesthesized and subjected to microdialysis. Our results demonstrated that, in animals grafted with NGF-secretor cells, there was a diminished decrease in ChAT enzymatic activity in the NBM and less neuronal cell shrinkage and loss of processes. Furthermore, microdialysis studies also showed an increased release of ACh in the remaining cortex proximal to the devascularizing lesion. Thus, fibroblasts, genetically modified to produce and secrete NGF and grafted to the CNS, prevented retrograde cholinergic degeneration, demonstrating a functional and morphological response to the grafted cells. (Funded by the Medical Research Council of Canada and the Centres of Excellence Network for Neural Regeneration and Functional Recovery.)

NERVE GROWTH FACTOR PRODUCING PRIMARY FIBROBLASTS GRAFTED INTO THE BASAL FOREBRAIN OF BEHAVIORALLY CHARACTERIZED AGED RATS. K. S. Chen and F. H. Gage. Dept. of Neurosciences, 0624, U.C.S.D., La Jolla, CA. 92093.

Rats exhibit behavioral and anatomical alterations as a function of aging. Previously, we have demonstrated that grafts of fetal basal forebrain cells into the hippocampus, cortex or nucleus basalis, as well as chronic unilateral infusions of nerve growth factor (NGF) into the lateral ventricles can partially reverse some of the age-related behavioral changes and basal forebrain cholinergic neuronal atrophy. In this study we grafted primary fibroblasts, genetically modified to produce NGF, bilaterally into the area of the nucleus basalis of aged (22 mos) Fischer 344 rats. The primary fibroblasts were obtained from Fischer 344 rats and infected with a retroviral vector containing the cDNA for mouse NGF. Either NGF-producing or control non-infected fibroblasts were grafted into aged and adult rats that had been behaviorally characterized on the Morris water maze. The aged animals, as a group, were impaired on the water maze compared to the adult animals, although not all aged rats exhibited deficits. Upon retesting following grafting, the aged rats that received grafts of NGF-producing cells had significantly improved their retention of the location of a hidden platform, though not to the level of the initially unimpaired aged animals, whereas the aged rats that received non-infected control cells did not show an improvement in their performance. In contrast, grafts of NGF-producing fibroblasts to adult rats resulted in a detriment in performance on this task. Grafts of both NGF-producing and control fibroblasts survived in the aged and adult brains. Immunohistochemical staining with an antibody to NGF-receptor (NGF-R) revealed the presence of NGF-R-positive processes within the NGF-producing grafts but not within the control grafts. NGF-R-positive process density appears greater within the grafts into the adult rats compared to the aged rats. Quantitative morphometric analysis of NGF-R-positive cells in the basal forebrain will be presented for each animal. These findings show that grafts of NGF-producing cells into the basal forebrain region of aged rats can survive and partially ameliorate observed behavioral deficits.

NGF ENHANCES CHOLINERGIC TRANSMISSION BETWEEN NUCLEUS BASALIS AND BASOLATERAL AMYGDALA IN RAT H.C. Moises, M.D. Womble, M.S. Washburn, and L.R. Williams+. Dept. of Physiology, Univ. of Michigan, Ann Arbor 48109 and + The Upjohn Co., Kalamazoo, MI., 49001.

Although it well-documented that administration of NGF stimulates transmitter-related functions in basal forebrain cholinergic neurons (BFCN), it is unknown whether this facilitates neurotransmission between BFCN and their postsynaptic target cells. To examine this possibility, we compared the ability of nucleus basalis (NBM) stimulation to elicit a muscarinic slow depolarization (slow EPSP) in pyramidal cells in basolateral amygdala (BLA) in slice preparations obtained from control and NGF-treated rats. Young adult Fisher 344 rats were treated i.c.v. with vehicle or NGF (1.2 μg/day) for 3 weeks. When recording in normal medium, NBM stimulation (30 Hz for 500 ms) elicited an atropine-sensitive slow EPSP in 15 of 24 neurons in slices (n=14) from NGF-treated rats, compared to only 5 of 27 cells in control slices (n=16). Although eserine (2 μM) increased the number of cholinergic responses that were recorded in both control (22/27) and NGF preparations (22/24), the frequency-response relationship for eliciting the slow EPSP in NGF-treated slices showed a significant leftward shift, compared to that of controls. In contrast, no differences in neuronal responsiveness to bath applications of carbachol were observed between control and NGF-treatment groups. These data suggest that NGF treament can enhance forebrain cholinergic transmission, possibly by increasing acetylcholine release.

NGF LEVELS, CHOLINERGIC SEPTAL NEURONS, AND SEPTAL CYTOSKELETAL MARKERS ARE PRESERVED FOLLOWING EXCITOXIC LESIONS OF THE HIPPOCAMPUS: M.A. Burke, J. Roback, B.H. Wainer and J.H. Kordower, Dept. of Anatomy, Univ. Illinois Sch. Med., Dept. Pharmacology, Univ. Chicago Sch. Med., Dept. Neurological Sci., Rush Presbyterian Med.Ctr., Chicago Ill. 60612 USA.

Cholinergic septal neurons persist following elimination of hippocampal neurons, their normal source of endogenous nerve growth factor (NGF; Sofroniew et al, *Science*, 247: 338-342, 1990). This suggests that either NGF is not required for the maintenance of basal forebrain neurons or that basal forebrain neurons utilize NGF from other sources following this lesion. To further characterize this phenomenon, rats received injections of ibotenic acid into the hippocampus and were sacrificed 2 weeks-7 months later. As seen previously, no reductions in ChAT-immunoreactive neurons were found ipsilateral to the lesion at any time point studied. Furthermore, antibodies which recognize phosphorylated neurofilaments that can normally label perikarya of axotomized neurons, did not stain septal perikarya ipsilateral to the lesion. RNA blot analysis revealed that despite a comprehensive loss of hippocampal neurons on the side of the injection, the hippocampal remnant expressed NGF mRNA levels comparable to the contralateral side. Since excitotoxic lesions primarily affect neurons, these data suggest that either hippocampal glia or residual hippocampal neurons upregulate NGF synthesis in response to the death of neighboring neurons and may still play a role in sustaining cholinergic basal forebrain neurons following hippocampal damage. DISTRIBUTION AND RELATIVE DENSITY OF NERVE GROWTH FACTOR RECEPTORS (NGFR) IN THE RAT BRAIN AS A FUNCTION OF AGE AND ANTI-NGF TREATMENT. B.A. Urschel and C.E. Hulsebosch. Dept. of Anat. and Neurosci., Marine Biomed. Inst., Univ. of Texas Med. Br., Galveston, TX 77550.

It is clear that Nerve Growth Factor (NGF) has a role in the central nervous system (CNS). In order to begin to determine the possible roles of NGF in the CNS, we gave neonatal rats daily subcutaneous injections of antibodies to NGF (ANTI-NGF) for a period of up to one month. By utilizing a monoclonal antibody (192-IgG), which recognizes the NGFR, and standard immunohistochemical techniques we have localized NGFR in various aged ANTI-NGF treated animals and compared the anatomic localization and relative density of the NGFR immunoreactive regions to same age untreated and preimmune sera treated littermates. We confirm previously reported localizations of NGFR immunoreactivity (NGFR-I) in the rat brain. In addition, we demonstrate that NGFR-I levels of ANTI-NGF treated rats in the molecular and Purkinje cell layers of the cerebellum, vestibular nuclei, spinal tract of V and cochlear nuclei remain at lower concentrations compared to same aged control animals. We also demonstrate that NGFR-I levels in the granular layer of the cerebellum are decreased and that NGFR-I in the basal nucleus is completely lost with ANTI-NGF treatment. We hypothesize that ANTI-NGF biologically inactivates NGF, which over a period of 30 days results in decreased NGFR-I. These results may be due to neuronal loss in these regions following ANTI-NGF treatment. Supported by Sigma Xi, NS11255, NS25450, NS01217, RR03979, Bristol Myers.

DIFFERENTIAL EFFECTS ON SENSORY NERVE PROCESSES AND BEHAVIORAL ALTERATIONS IN THE RAT AFTER TREATMENT WITH ANTI-NGF. C.E. Hulsebosch, P.N. Brown, and B.A. Urschel. Dept. of Anat. and Neurosci., Marine Biomed. Inst., Univ. of Texas Med. Br., Galveston, TX 77550.

Published work on the effects of antibodies to Nerve Growth Factor (ANTI-NGF) treatment on rats has shown an increase in the number of unmyelinated central processes of dorsal root ganglia (DRG) neurons. This increase is interpreted to be sprouting of the central projections of the DRG neurons. To test for sprouting of the peripheral DRG projections, we quantitated the number of peripheral DRG processes in the peripheral nerves of ANTI-NGF treated compared to untreated rats, following selective surgery to eliminate motor and sympathetic nerve fibers. We report the numbers of peripheral processes in an NGF deprived environment decrease by 48% compared to untreated controls and the decrease is selective for the unmyelinated fiber population. Since the majority of the unmyelinated population is nociceptive, two nociceptive behavioral measures, one reflexive (tail flick) and one nonreflexive (paw or skin pinch), were performed and demonstrated decreased response times in the ANTI-NGF treated compared to untreated and preimmune treated rats. These data suggest a directional effect primarily on the unmyelinated sensory population which results in altered nociceptive behavior, induced by the suppression of one endogenous factor, NGF. IN SITU LOCALIZATION OF NERVE GROWTH FACTOR AND ITS RECEPTOR IN THE DEVELOPING ORGAN OF CORTI AND *IN VITRO* EFFECT OF ANTI NERVE GROWTH FACTOR ANTIBODIES. T.R. Van DeWater, P.P. Lefebvre*, V. GalinovicSchwartz*, T. Weber*, G. Moonen. Depts. of Otolaryngology and Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461 and Depts. of Human Physiology-Pathophysiology and Otolaryngology*, University of Liege, 4020 Liege, Belgium.

Nerve growth factor (NGF) and nerve growth factor receptor (NGF-R) were immunolocalized in the peripheral auditory system of 5 day post partum (PP)rat pups. NGF protein was detected in both the inner (IHC) and outer (OHC) hair cells of Corti's organ, the somas as well as both peripheral and central axons of spiral ganglion neurons and in the sheath cells of the VIIIth cranial nerve. NGF-R antibody was not immunolocalized over the somas of either the IHC or OHC, however intense immunolabel was present over the neurons that compose the spiral ganglion and nerve endings at the bases of both the IHC and OHC. Explants of 5PP rat organ of Corti with attached spiral ganglion cells showed that antibodies directed against 2.5S NGF can disrupt the normal pattern of innvervation (detected by anti-neurofilament antibodies)when compared to normal serum control explants of Corti's organ. These findings strongly support a role for NGF or a member of the NGF family (i.e BDNF or NT3) in development of the peripheral auditory system.

NGF INCREASES THE SOMA PROFILE AREA AND THE COMPLEXITY OF DENDRITIC TREES OF CHOLINERGIC INTERNEURONS IN ORGANOTYPIC STRIATAL CULTURES OF NEWBORN RATS. C. Spenger+, K. Rufener+*, L. Studer* and H.-R. Lüscher. Dept. of Neurosurgery, Inselspital, CH-3010 Bern+; Dept. of Physiology, CH-3012 Bern Switzerland.

The influence of NGF on the development of cholinergic striatal interneurons in terms of cell number, cell size and complexity of dendritic tree was studied in vitro. The striatum was taken from newborn Wistar rats and chopped in 250 μm thick slices. From these slices identical circular pieces of 1.1 mm in diameter were punched out. 4 series of 20 cultures each were grown simultaneously by means of the roller tube method. The medium of the 4 culture series contained 5 ng/ml NGF, no NGF, 20 ng/ml anti-NGF antibody (AB) or 5 ng/ml NGF plus 20 ng/ml anti-NGF-AB respectively. After 13 days in vitro all cultures were fixed and stained for AChE. The number of AChE positive interneurons in cultures grown with NGF, without NGF, with anti-NGF-AB or with NGF plus ani-NGF-AB was 12.7 ± 10.2, 6.9 ± 7.8, 6.5 ± 9.7 and 4.4 ± 4.5, respectively. The soma profile area of the cholinergic neurons in cultures grown with NGF,without NGF and with NGF plus anti-NGF-AB were 698 μm^2 ± 228, 480 μm^2 ± 151 and 441,8 μm^2 ± 158, respectively. 5 cells each of cultures grown with and without NGF were reconstructed and the dendritic trees analyzed. The mean combined dendritic length of the cells grown with and without NGF was 5751 μm ± 2342 and 3737 μm ± 935, respectively. The mean number of stem dendrites was 5.6 ± 1.5 and 4.2 ± 0.4, respectively and the mean total number of branch points per cell was 47 ± 29 and 28 ± 5, respectively. The areas covered by the dendritic tree of the neurons grown with and without NGF were not different. These data demonstrate first, that NGF promotes survival and growth of the cholinergic striatal interneurons in culture and second, that cells of the same age in vitro grown with NGF possess a more complex dendritic tree than those grown without NGF.

NGF ATTENUATES NBM LESION-INDUCED CHOLINERGIC NEUROCHEMICAL MARKER DEFICITS IN YOUNG, BUT NOT IN AGED, F344 RATS. A.C. Santucci, P.D. Kanof, and V. Haroutunian. Psychiatry Service, Bronx VAMC & Dept. of Psychiatry, Mt. Sinai School of Medicine, New York, NY 10468.

This study's aim was to determine whether nerve growth factor (NGF) administration would enhance central cholinergic activity in aged animals that have sustained experimentally-induced cholinergic lesions. Accordingly, 14 young (3-4 months) and 13 aged (22-23 months) F344 rats were prepared with NMDA-induced unilateral lesions of the NBM. During the same surgical session, subjects were implanted with a subcutaneously placed osmotic pump filled either with 6 μg of ß NGF (young, n=7; aged, n=6) or artificial cerebrospinal fluid (young, n=7; aged, n=7) and connected to an indwelling cannula directed at the lateral ventricle. Animals were sacrificed and their brains dissected two weeks after surgery. Concentrations of CAT and AChE within the caudate, cortex and hippocampus were measured. Results indicated a significant lesion-induced depletion of CAT and AChE within the frontal cortex of both young and aged subjects ($p<.001$). Nerve growth factor attenuated these depletions by approximately 35%. However, this effect of NGF was observed only in young animals ($p<.05$). This finding contrasts a previous report from our laboratory indicating NGF's ability to increase cholinergic neurochemical markers in aged non-lesioned animals. Taken together, these data suggest that NGF's effect on cholinergic activity in the aged brain may depend upon the neurological integrity of the tissue.

TRANSCRIPTIONAL CROSSTALK IN THE STIMULATION OF GALANIN GENE EXPRESSION BY NERVE GROWTH FACTOR. S.C. Hooi, D.R. Abraczinskas* and L.M. Kaplan. Gastrointestinal Unit, Mass. General Hospital and Program in Neuroscience, Harvard Medical School, Boston, MA 02114.

Nerve growth factor (NGF) is an potent neurotrophic agent required for the differentiation and maintenance of neural crest-derived neurons. The PC12 rat pheochromocytoma cell line provides a useful model for examining mechanisms by which NGF induces cellular differentiation. NGF exposure causes these cells to adopt a neuron-like phenotype. This trans-differentiation is associated with stimulated expression of several neuropeptide genes including galanin. The induction of galanin expression in these cells is rapid, peaking 4 hours after NGF addition, with mRNA increased more than 100-fold. To study the transcriptional regulation of the galanin gene by NGF, galanin-luciferase reporter constructs were examined by transient expression in PC12 cells. Deletion analysis revealed 2 regions in the galanin 5'-flanking sequence that conferred NGF responsiveness to the transfected reporter gene. Dose-response analysis, transfections in protein kinase A- and C-deficient PC12 cells, and experiments using inhibitors of protein kinases indicate that the NGF response cannot be fully accounted for by either the cAMP-dependent or protein kinase C pathway alone. Rather, NGF acts cooperatively with agents that stimulate these activities. The simultaneous addition of forskolin, TPA and NGF caused a 50-fold increase in luciferase activity over untreated controls. Gel mobility shift analysis using the proximal NGF-responsive region revealed several discrete DNA-protein complexes. A major site of protein binding was located between bases -22 and +4, a GC-rich region with several GCGGC repeats. Methylation interference analysis confirmed protein binding in close proximity to G residues in this region. Protein binding was not competed by sequences known to bind previously characterized transcription factors including AP1, AP2, AP3, NF1, SP1 and zif-268. Efforts are underway to isolate and further characterize the protein that binds to this NGF-responsive element.

NERVE GROWTH FACTOR REGULATES THE EXPRESSION OF THE CALCIUM-BINDING PROTEIN S100α. D.B. Zimmer, R.H. Cochran and S.J. Strada. Dept. Pharmacol., Univ. S. Alabama, Mobile, AL 36688.

One mechanism by which nerve growth factor (NGF) induces differentiation in neuronal cells is to increase the expression of specific proteins such as 42C, a member of the S100 family of calcium-binding proteins. This study utilizes PC12 cells to examine the effect of NGF on the expression of other members of this protein family, S100α and S100β. Northern blot analysis revealed that PC12 cells express S100α and not S100β mRNA. In addition, the steady state level of S100α mRNA increased with NGF treatment. This mRNA increase was accompanied by a 2-fold increase in S100α protein in NGF-treated cells. While, NGF treatment resulted in increased S100α protein levels, it did not alter the S100α-binding protein profile or subcellular distribution of S100α. In both treated and untreated cells, S100α exhibited a punctate staining pattern in the cell body with no detectable staining in the cell processes. Altogether, these results demonstrate that NGF increases S100α expression and suggest that S100α may mediate cellular responses to NGF in neuronal cells.

NERVE GROWTH FACTOR SIGNAL TRANSDUCTION IN RAT SEPTAL NEURONS GROWN IN BILAMINAR CULTURE. L. Mudd*, M. Downen, J. Roback, J. Zucker, M. Wert*, B. Wainer and H.C. Palfrey*. Dept. Pharmacol. & Physiol. Sciences, University of Chicago, 947 E. 58th Street, Chicago, IL 60637.

We have developed a method for the preparation of primary neuronal cultures from rat septal nuclei dissected on embryonic day (E)16. Neurons are grown in defined medium in a bilaminar culture system consisting of a post-natal glial cell layer 1 mm away from the neuronal plane. Greater than 99% of the cells in the neuronal plane stain positively for neurofilament proteins (NFP), but less than 1% for glial fibrillary acidic protein (GFAP). A nerve growth factor receptor (NGFr) is expressed in 24 ± 8% of these cells. We have studied the mechanism of NGF signal transduction in these cultures and have demonstrated that NGF rapidly increases expression of the protooncogene c-fos, tyrosine phosphorylation, microtubule associated protein (MAP) kinase activity. Nerve growth factor transiently increases tyrosine phosphorylation in a subset of neurons with maximal stimulation 2 min after NGF treatment, followed by a return to basal levels within 10 min. A similar time course is observed for MAP kinase activation with phosphorylation of myelin basic protein (MBP) increasing to a maximum within 2 min and declining to basal levels within 10 min. The increase in fos expression shows a maximum in 17.8 ± 3.6% (mean ± SEM) of cells 30 min following NGF administration as demonstrated immunocytochemically. Fos levels decline to those of untreated cells within 4 hours. Thus NGF signal transduction in these post-mitotic neurons shows significant similarities to events previously demonstrated after NGF administration to PC12 cells. Preliminary investigations of long term effects of NGF in these neuronal cultures suggest that NGF alone cannot entirely account for the survival characteristics provided by the presence of a glial plane. These results indicate that other trophic factors released by glial cells support the long-term viability of the neuronal population. The bilaminar culture system should be a valuable tool for the evaluation of septal responses to neurotrophic agents.

CELL LINES DERIVED FROM INTESTINAL EPITHELIAL CELLS SYNTHESIZE NERVE GROWTH FACTOR IN CULTURE. G.W. Varilek*, G.A Neil*, B. Antisdel* and N.J. Pantazis. Depts. of Internal Medicine and Anatomy, Univ of Iowa College of Medicine, Iowa City, IA 52242.

Although nerve growth factor (NGF) has been detected in the gastrointestinal tract of adult rats (Weskamp and Otten, J. Neurochem., 48:1779, 1987), the cell(s) responsible for NGF synthesis in the tract have not been identified. Since intestinal epithelial cells are a major cellular component of the gastrointestinal tract, the aim of this study was to determine whether intestinal epithelial cells are a potential source of NGF. Two cell lines, Caco-2 and IEC-6, were selected for study since they are derived from intestinal epithelial cells and they display many characteristics of epithelial stem cells. Conditioned medium (CM) was obtained from confluent cultures of Caco-2 and IEC-6 and examined in two NGF bioassays. CM from both cell lines induced neurite outgrowth from rat pheochromocytoma (PC12) cells and sensory neurons (dorsal root ganglia). This outgrowth was similar to that induced by purified NGF and was inhibited by polyclonal anti-NGF antibody. In addition, an NGF-ELISA (Mobley et al., Neuron 3:655, 1989) detected NGF in CM from Caco-2 and IEC-6 cells. These data demonstrate that Caco-2 and IEC-6 cells synthesize and release NGF into the culture medium. This suggests that intestinal epithelial cells are a potential source of NGF in the gastrointestinal tract. Supported by the CCFA, Univ. of Iowa College of Medicine Grant, and Univ. of Iowa Aging Research Seed Grant.

RECAPITULATION OF THE DEVELOPMENTAL PATTERN OF NGF RECEPTOR IMMUNOREACTIVITY IN REGENERATING RAT OLFACTORY NERVE. [1,2]H. Vickland, [1,2]L.E. Westrum and [3]M.A. Bothwell. Depts. of [1]Biol. Struct., [2]Neurol. Surg., and [3]Physiol. & Biophys. University of Washington, Seattle, WA 98195.

We have previously described a differential pattern of expression of nerve growth factor receptor (NGFR) in the young and adult rat olfactory system (Vickland, et al., 1991, *Brain. Res.*, in press and Neurosci. Abstr. 1989). We found NGFR immunoreactivity (IR) along the young olfactory nerve (ON), possibly indicating the growth state of axons before they reach their targets and NGFR-IR in the glomeruli of the olfactory bulb (OB) of the adult, perhaps indicative of synaptic maintenance. Because many investigators have found NGFR-IR in regenerating peripheral nerve, we sought to determine if the regenerating rat olfactory system would show a recapitulation of the developmental pattern of NGFR-IR. Lesions to the ON were performed on adult rats and the olfactory tissue was taken after survival times of 3, 6, 10, 14, 20, 45 and 90 days. The shorter survival times showed a recapitulation of the developmental pattern: NGFR-IR began to be expressed along the regenerating ON and it disappeared in the OB glomerular layer. In longer survival times we observed a reestablishment of the typical adult pattern. As in our previous study, electron microscopy shows that NGFR-IR is localized to glial cells. These findings clearly indicate a role for NGFR in the regenerating rat olfactory system similar to its role during development. (Supported by NIH Grants NS09678, NS23343 and 2T32HD07183-11A1. NGF RECEPTORS IN THE OLFACTORY SYSTEM.
Mary S. Bailey, Qizhi Gong, Sarah K. Pixley, Michael T. Shipley. Dept. of Anatomy and Cell Biology, Univ. of Cincinnati, Cincinnati, OH 45267.

To address the possible role(s) of NGF in development and regeneration in olfactory system, we have assessed the cellular localization of NGFrs in adult and developing rats using two monoclonal antibodies directed against NGFrs (217C and 192).

NGFr-immunoreactivity (NGFr-IR) was observed on fibers in deep layers of the olfactory bulb late in development but was not apparent before E18. NGFr-IR was also observed in neurons of the basal forebrain and their axons coursing into the deep layers of the olfactory bulb. In the adult, NGFr-IR remains abundant in olfactory bulb glomeruli and in fibers in deeper layers of the bulb. These results suggest that NGFrs in the adult olfactory bulb glomeruli and deep layers is located on the cholinergic centrifugal afferents from the basal forebrain. This will be tested by lesioning the basal forebrain cholinergic neurons with ibotenic acid; we predict that this manipulation will eliminate NGFr from the adult olfactory bulb.

In developmental tissue there was high NGFr-IR in the epithelium and olfactory nerve which may be localized to Schwann cells. However, in contrast to perinatal animals, only a few streaks of NGFr-IR were present in the adult olfactory nerve. These "streaks" of NGFr seen in the adult nerve may represent fascicles transiently "denervated" by normal olfactory neuron turnover and replacement. Consistent with this hypotheses, NGFrs were robustly re-expressed in the olfactory nerve following lesion of the olfactory epithelium. [Supported by NIDCD DC00347 and NINDS NS29218]

HORMONES AND DEVELOPMENT: STEROID RECEPTORS

527.1

ONTOGENY OF THE HIPPOCAMPAL BINDING CAPACITY OF THE GLUCOCORTICOID AND MINERALOCORTICOID RECEPTOR.
D.M.Vázquez, M.I.Morano and H. Akil. Mental Health Research Institute and Department of Pediatrics, University of Michigan, Ann Arbor, MI
The developing HPA axis is hyporesponsive to stressful stimuli during early life. Once the adrenocortical response is established, failure to terminate the corticosterone rise is evident following certain stressors. The hippocampal (HC) glucocorticoid (GR) and mineralocorticoid (MR) receptors have been implicated in the modulation of glucocorticoid negative feedback. In order to investigate the emergence of this mechanism, we have studied the ontogeny of GR and MR binding capacity (Bmax) in the HC. Adrenalectomy (ADX) was performed on day: 6, 10, 14, 18, 22, 28, 35, 45 and adult animals. GR and MR Bmax HC analysis was done 12 hours after ADX using saturating amounts of ^{3}HCorticosterone. RU26938, a GR agonist, and corticosterone were used as ligands to calculate specific GR or MR Bmax. GR Bmax reached adult levels on day 10 and remained steady. In contrast, MR Bmax was greater than adult from day 6 until day 45; when it decreased and approached adult concentrations. Thus, GR:MR Bmax ratios increased with age (d6=1:1 to adult=6:1). Looking at the total HC, it was evident that the greatest absolute increase for both receptors occurred between days 22 and 45, at a time when failure to terminate the adrenocortical response is described. This suggests that an impaired glucocorticoid modulation during development is not the result of lower GR and MR hippocampal binding as has been reported in the aged animal. The difference in MR to GR ratio during this time may contribute to this phenomena. Alternatively, immature circuitry between HC and hypothalamus may explain the lack of feedback. Supported by MH422251.

527.2

DEVELOPMENTAL VS. ACTIVATIONAL EFFECTS OF GONADAL STEROIDS ON THE BINDING PARAMETERS OF CORTICOSTEROID RECEPTORS IN HIPPOCAMPUS OF MALE VS. FEMALE RATS.
B.B. Turner, M.S. Ansari*, T. Ansari*, L.I. Holtsclaw*, and X. Chen. Department of Physiology, James H. Quillen College of Medicine, East Tennessee State University, Johnson City, TN 37614-0002.

We have previously reported that female rats have fewer hippocampal Type I and Type II corticosteroid receptors than do males, and that the in vitro affinity of the Type I receptor from females is several fold less than that from males. In this study, we asked whether the presence of the gonads during development contributes to these differences or whether the short term presence of gonadal steroids is solely responsible. Male and female pups were gonadectomized either on day 1 or as adults. Each male group was injected (s.c.) with either vehicle alone or 250 ug testosterone propionate for 10 days. Likewise, females were injected with vehicle or 2.5 ug estradiol benzoate. Animals were adrenalectomized 12 hr before sacrifice. For each hippocampus, Type I binding was measured using a saturation plot (^{3}H-dexamethasone + RU 28362) and total binding was measured with a single, saturating concentration of ^{3}H-dexamethasone. Three-way analysis of variance showed a main effect of sex steroids on the Bmax of Type I receptors ($p < 0.01$): estrogen treated females had fewer Type I receptors than did other groups. No significant main effects were found with respect to the Kd of the Type I receptor; values were similar to those previously reported for males. Type II receptor number showed a main effect of sex ($p < 0.02$): female groups had fewer Type II receptors than did male groups. These results indicate that the presence of estrogen down-regulates the Type I receptor but does not influence its affinity. In contrast, expression of the Type II receptor may be developmentally influenced by gonadal steroids. Supported by NS 22158.

POSTNATAL DEVELOPMENT OF CORTICOSTEROID RECEPTOR IMMUNOREACTIVITY IN THE RAT CEREBELLAR CORTEX. A. Lawson*, R. Ahima, Z. Krozowski* and R. Harlan. Dept. Anatomy, Tulane Med. School, New Orleans, LA 70112 and Baker Med. Inst. Prahan, Australia 3181 (ZK).

Glucocorticoids are required for normal CNS development. High levels are neurotoxic and reduce myelination. The actions of glucocorticoids are mediated via either a high affinity Type I (mineralocorticoid) receptor or a low affinity Type II (glucocorticoid) receptor. MRNA and immunoreactivity (ir) of both receptors have been localized in the adult rat cerebellar cortex, a region which undergoes most of its development during postnatal life. We have studied the development of Type I-ir and Type II-ir in the postnatal rat cerebellar cortex using MINREC4 antiserum and BUGR2 monoclonal antibody, respectively. Type I-ir Purkinje cells were first observed at postnatal day 5 (P5) in contrast to Type II-ir cells which were first observed at P15. In the Purkinje cell layer, both receptor systems developed rapidly to adult levels by P20. Type I-ir and Type II-ir in the granular and molecular layers were first observed at P5 and P15 respectively; however, the rate of development was slower. By P30 the density of immunoreactive cells in these layers was still less than in the adult. The earlier development of the Type I receptor system suggests it may mediate most of the actions of corticosteroids in the cerebellum during early postnatal life. Supported by NS24148.

NEONATAL PRAZOSIN TREATMENT REDUCES CYTOSOLIC ESTROGEN RECEPTOR LEVELS AND OVARIAN WEIGHT IN ADULT FEMALE RATS. R. H. Fitch† and H. Feder^. †Center for Molecular and Behavioral Neuroscience, ^Biological Sciences Department, Rutgers University, Newark, NJ, 07102.

Exposure of primed adult female guinea pigs to the alpha-1 antagonist prazosin has been shown to reduce estrogen receptor levels in the hypothalamus and preoptic area. To further investigate this interaction between the noradrenergic and neuroendocrine axes, newborn female rat pups (<2 hours old) received a s.c. implant of prazosin (.0125 mg/day for 5 days) or placebo. After establishing the presence of regular estrus cycles by daily vaginal smears, subjects were sacrificed by perfusion with 30cc cold DMSO on the morning of proestrus. The ovaries and uterus were removed and weighed. Brains were removed and frozen, and later the medial preoptic area (POA), the corticomedial amygdala (AMG), mediobasal hypothalamus (HYP), and a cortical sample (CTX) were dissected out and analyzed for cytosolic estrogen receptors. Results showed that receptor levels in the POA, HYP, and AMG were reduced by 32%, 44%, and 35% respectively for the prazosin group ($p<.05$). Cortical receptor levels were low and showed no group differences. Ovarian weight was also significtly reduced in the prazosin group ($p<.0001$), although uterine weight was unaffected. Interestingly, prazosin treated females showed a post-pubertal increase in body weight characteristic of ovariectomized females, while controls showed no such increase. These results indicate that neonatal prazosin exposure affected ovarian development and reduced, either directly or indirectly, cytosolic estrogen receptor levels in the POA, HYP, and AMG.

COCAINE DECREASES HYPOTHALAMIC ESTROGEN RECEPTOR mRNA LEVELS IN NEONATAL FEMALE RATS. C. Benton*, H. Najmabadi*, W.J. Raum*, S. Bhasin* and D.H. Olster. Division of Endocrinology, Harbor/UCLA Medical Center, Torrance, CA 90509.

Neonatal exposure to testosterone or estradiol (E) androgenizes the rat brain. We have previously shown that cocaine interferes with this process, and decreases hypothalamic nuclear estrogen receptor (ER) binding. To examine if these effects of cocaine are mediated via changes in hypothalamic ER mRNA levels, 3 day old female rats were left untreated, received E (0.2 μMol/kg) or E plus cocaine (10 mg/kg). ER mRNA levels were quantified by hybridization of northern blots with a human ER cDNA probe. E treatment increased levels of hypothalamic ER mRNA; this effect was blocked by cocaine. Thus, cocaine antagonizes E-stimulation of ER mRNA in the hypothalamus, perhaps by influencing ER mRNA transcription or stability. This may result in fewer ERs available for interaction with DNA-responsive elements, and in this manner interfere with activation of E-responsive genes involved in androgenization of the brain. ONTOGENY OF ESTROGEN RECEPTOR-LIKE IMMUNOREACTIVITY IN THE BRAZILIAN SHORT-TAILED OPOSSUM BRAIN. C. D. Jacobson, L. R. Ross* and C. A. Fox. Department of Veterinary Anatomy, Iowa State University, Ames, IA 50011.

In this study, we have used the Brazilian short-tailed opossum (*Monodelphis domestica*) as a model to study the ontogeny of estrogen receptors in the mammalian brain. *Monodelphis* is a small, pouchless marsupial which breeds well under laboratory conditions and whose young are born in an immature sexually undifferentiated state. The Abbott H222 monoclonal rat estrogen receptor antibody (gift of Abbott Laboratories) was utilized in an indirect immunohistochemical procedure to detect estrogen receptors in the developing opossum brains. Estrogen receptors were first expressed in the dorsomedial and ventromedial hypothalamus of the opossum ten days after birth (10PN). Most regions that contained estrogen receptor immunoreactivity (ER LI) in the adult opossum contained ER LI at 15PN. These areas include the lateral septum, medial preoptic area, bed nucleus of the stria terminalis, periventricular preoptic area and hypothalamus, amygdala, dorsomedial and ventromedial hypothalamic nuclei, arcuate nucleus, ventral premammillary nucleus, and the midbrain central grey. The number of ER LI cells increased from 15PN-60PN in all regions of the brain that contain ER LI cells in the adult opossum. The time course of expression indicates that estrogen receptors are present in early development of the *Monodelphis* brain and may mark the beginning of a critical period for sexual differentiation of the opossum brain.

POST-NATAL DEVELOPMENT OF TARGET REGIONS FOR GONADAL HORMONES IN THE BRAIN OF THE CYNOMOLGUS MONKEY. R.P. Michael and R.W. Bonsall. Department of Psychiatry, Emory University School of Medicine and the Georgia Mental Health Institute, Atlanta, Georgia 30306.

To determine if the adult pattern of testosterone uptake and metabolism by brain develops before or after birth, 4 male and 5 female neonatal cynomolgus monkeys, gonadectomized 3 days earlier, were injected subcutaneously at 5-8 days of age with 500 μCi ^{3}H-testosterone (^{3}H-T). 60 min later, brains and other tissue samples were removed. Purified nuclear pellets and supernatants were prepared and analyzed by HPLC. The aromatized metabolite ^{3}H-estradiol (^{3}H-E_2) was found only in nuclear pellets from hypothalamus and amygdala where it represented 40-55% of the radioactivity. ^{3}H-T was the major androgen present in nuclear pellets from all 8 brain regions studied, and levels in both nuclear pellets and supernatant fractions were significantly higher in females than in males ($P<0.005$), suggesting a difference in clearance rates. Comparisons with orchidectomized fetuses at 122 days gestation and with fully adult male castrates showed that the largest developmental increase occurred in the amygdala after birth: nuclear levels of ^{3}H-E_2 were 4-fold higher in adults than in neonates. Nuclear concentrations of ^{3}H-T increased markedly during development in most brain regions except the cerebellar cortex where they were initially high and later declined. Major differences were also noted in brain supernatants: metabolic conversion of ^{3}H-T was much faster in fetuses and neonates than in adults. The development of the hormone-sensitive neural systems regulating behavior in adult primates may depend on changes in enzyme activities and receptor levels occurring after the neonatal period. Supported by USPHS grant MH 40420 and by the Georgia Department of Human Resources.

THE OCCUPATION OF NUCLEAR ESTROGEN BINDING SITES IN THE FETAL MACAQUE HYPOTHALAMUS BY STEROIDS OF TESTICULAR ORIGIN. R.W. Bonsall, D. Zumpe* and R.P. Michael. Department of Psychiatry, Emory University School of Medicine and the Georgia Mental Health Institute, Atlanta, Georgia 30306.

Previous results with macaque fetuses given ^{3}H-testosterone (^{3}H-T) at around 120 days of gestation demonstrated a sex difference in nuclear levels of the aromatized metabolite ^{3}H-estradiol (^{3}H-E_2) in hypothalamus. To determine if this might be due to prior occupation of receptors by endogenous steroids in the male, we have now compared the uptake of ^{3}H-T and its metabolites in intact male fetuses (plasma T 571.2 ± 215.5 ng/100 ml, N=5), sham-gonadectomized female fetuses (33.8 ± 25.2 ng/100 ml, N=5) and male fetuses orchidectomized *in utero* about 7 d earlier (14.6 ± 5.7 ng/100 ml, N=5). Fetuses were given 500 μCi ^{3}H-T s.c. and, 60 min later, brains were dissected to obtain the hypothalamus and 7 other samples. Purified nuclear pellets and supernatant fractions were analyzed by HPLC to identify radioactive metabolites. Hypothalamic nuclear concentrations of ^{3}H-E_2 in intact males (847 ± 195 dpm per mg DNA) were significantly lower than those in females (2,147 ± 542 dpm per mg DNA) and in orchidectomized males (2,233 ± 345 dpm per mg DNA) ($P<0.05$), but nuclear and supernatant concentrations of ^{3}H-T did not differ in the 3 groups. Thus, fetal orchidectomy eliminated the difference between males and females, supporting the original hypothesis that occupation of estrogen receptors is greater in intact male than in intact female fetuses at this stage of gestation. Aromatized metabolites of T acting via estrogen receptors during fetal life could, therefore, account for some of T's organizational effects on primate physiology and behavior. Supported by USPHS grant MH 40420 and by the Georgia Department of Human Resources.

ONSET OF ANDROGEN RECEPTOR mRNA EXPRESSION IN THE CNS OF *XENOPUS LAEVIS*; LOCALIZATION USING *IN SITU* HYBRIDIZATION. M.A. Cohen, L.M. Fischer, D.B. Kelley, Dept. Biol. Sci., Columbia Univ., NY, NY 10027

In the clawed frog, *Xenopus laevis*, male mate calling is controlled by testicular androgen secretion. Nuclei in the CNS calling circuit have been mapped; all have been shown to concentrate radiolabeled androgen, as does the effector organ, the larynx. Previous studies using tritiated dihydrotestosterone detected CNS androgen concentrating cells from tadpole stage 64 on; no labelled cells were detected at stage 60. The absence of labeled cells at stage 60 could be due to lack of androgen receptor (AR) expression or to competition for labelling by endogenous hormones. To determine the onset of AR expression in the calling nuclei, we localized AR transcripts in developing tadpole brains using *in situ* hybridization. A cloned AR cRNA probe, isolated from *X. laevis* laryngeal cDNA, was used. AR mRNA expression in neurons was detected as early as stage 56, when the gonads differentiate. At this and subsequent stages, transcripts were localized to motor nucleus of cranial nerves IX-X, medullary reticular formation, a presumed sensory nucleus of cranial nerve V, pretrigeminal nucleus of the dorsal tegmental area of the medulla, laminar nucleus of the torus semicirculus, anterior pituitary, ventral thalamus, and anterior spinal cord. The earliest stages of receptor expression and the hormonal control of this developmental program are under investigation.

DEVELOPMENTALLY REGULATED ECDYSTEROID BINDING AND IMMUNOCYTOLOGICALLY IDENTIFIED INSECT NEURONS. H.J. Bidmon,* W.E. Stumpf and N.A. Granger. Dept. of Cell Bio. and Anat., UNC, Chapel Hill, N.C. 27599.

To study the action of 20-hydroxyecdysone (20-HE) on the CNS of larval Manduca sexta, high affinity ecdysteroid binding sites ($K_D \leq 4nM$) in cerebral ganglia were labelled *in vitro* with ^{3}H-ponasterone A (PNA, a 20-HE agonist) or ^{125}I-PNA. Certain autoradiograms were immunostained for tyrosine hydroxylase or the prothoracicotropic hormone (PTTH). Analysis of autoradiograms revealed stage-specific expression of ecdysteroid receptors (ER) in the CNS during the 4th and 5th larval stadia. During the 4th stadium, the number of cerebral neurons with ER peaked on day 2 and decreased steadily until day 0 of the 5th stadium. In the 5th stadium, the number of target neurons peaked at the times of the two ecdysteroid peaks. ER during both stadia were present in neurosecretory centers of the protocerebrum, including the prothoracicotropes, and in certain neurons of the subesophageal ganglion (SEG). The prothoracicotropes exhibited nuclear ER only during periods of active ecdysteroid synthesis by the prothoracic glands. Similar developmental fluctuations in numbers of neurons with ER occurred in the SEG, where several target neurons stained for tyrosine hydroxylase. The results demonstrate stage-specific ecdysteroid binding in neurons with identified peptide and neurotransmitter functions.

ESTROGEN INCREASES PROENKEPHALIN mRNA EXPRESSION IN THE VMN OF JUVENILE MALE AND FEMALE RATS. Annabell C. Segarra, Jesus A. Angulo and Bruce S. McEwen. The Rockefeller University, Laboratory of Neuroendocrinology, 1230 York Ave., New York, N.Y. 10021.

Opioids have been implicated in sexual differentiation of the brain and in the regulation of reproductive behavior in adult rats. Previous studies indicate that estrogen administration in adults increases proenkephalin mRNA in the VMN of female, but not male, rats (Romano et al., Brain Res.1990; 536:63). We have determined proenkephalin mRNA expression in estrogen-treated juvenile male and female rats to investigate the developmental pattern of estrogenic regulation of enkephalinergic neurons in the VMN. Rats were gonadectomized at 16 days of age and treated with estradiol benzoate (40 μg/kg) or oil from day 21-23. Sections of the ventromedial nucleus (VMN) and preoptic area (POA) were studied by in situ hybridization histochemistry at the single cell level and quantified with the assistance of an image analysis system. Estrogen caused an upward shift in the amount of mRNA expressed per cell in the VMN of male and female juvenile rats. No significant sex difference was observed in oil-treated animals nor in the response to estrogen treatment. Taken together, these results indicate that there is a difference in the response of VMN enkephalinergic neurons of male rats according to the developmental stage studied. A similar situation has been reported in estrogen induction of spine density (Segarra & McEwen, 1991; Neuroendocrinol., in press) and of cytosol progesterone receptors (Bogic et al., 1988; Endocrinol. 112:2735) in the VMN of juvenile vs adult male rats. It is possible that the testosterone surge during puberty renders the male VMN unresponsive to estrogenic induction of enkephalinergic messsage (WS 07080 and F34 GM13001-01).

LOCALIZATION AND HORMONAL REGULATION OF THE c-raf-1 PROTO-ONCOGENE IN DEVELOPING RAT HYPOTHALAMUS. R.C. Whorf and S.A. Tobet, Dept. of Biochemistry, E.K. Shriver Center, Waltham, MA 02254 & Prog. in Neuroscience, Harvard Medical School, Boston, MA 02115.

In studying sexual differentiation of the brain, we examined the expression of the protein product of the proto-oncogene c-*raf*-1 (Raf-1). We have immunocytochemically and biochemically determined the localization of Raf-1 in embryonic rat brain regions and its regulation by hormonal stimulation using an affinity-purified anti-peptide antiserum specific for Raf-1 (NH-44). Western blot analysis revealed a 77 kD polypeptide isolated in the cytosol of developing rat brains. Female embryonic day 22 (E22) hypothalami (HYP) contained the highest levels of Raf-1, 2-fold (1.5-2.3) higher than male HYP by semi-quantitative western blot and quantitative protein dot blot analyses. HYP levels were greater than brainstem or cortex in western blots. To test hormonal regulation of Raf-1, testosterone propionate (TP) was administered to pregnant rats on E17; male and female fetuses were examined on E22. This treatment significantly decreased Raf-1 levels in female HYP, but not in male HYP, as determined by western blot analysis. No significant sex differences or response to hormone treatments were observed in either the brainstem or cortex. Administration of TP 3h after birth did not change Raf-1 levels examined 24h later. In summary, Raf-1 was localized within selective regions of the rat brain and its expression altered by exogenous prenatal hormonal stimulation. Raf-1 signal transduction may act to delimit hormonal critical periods in sexual differentiation of the brain.

IMMUNOCYTOCHEMICAL AND HISTOCHEMICAL ANALYSES OF GONADOTROPIN RELEASING HORMONE (GnRH), TYROSINE HYDROXYLASE (TH), AND CYTOCHROME OXIDASE (CO) ACTIVITY WITHIN THE SEPTAL, HYPOTHALAMIC, AND THALAMIC AREAS OF CHICKS SHOWING EARLY SEXUAL MATURATION. G. S. Fraley*, W. M. Saidel, and W. J. Kuenzel of University of Maryland at College Park, MD 20742.

A modified, retractable Halasz knife was used to produce parasagittal cuts isolating the hypothalamus from lateral connections in chicks two weeks of age. By five weeks of age, operated chicks which showed advanced development of secondary sex characteristics were selected, matched with sham-operated controls and prepared for immunocytochemical analysis of brain tissue. Three nuclei showed significant differences between knife-cut birds and controls: the bed n. of the pallial commissure (nCPa), the paraventricular n. (PVN), and the anterior lateral thalamic n. (LA). A greater number of both TH and GnRH perikarya were found in the nCPa of respondant birds compared to sham-operated controls. A greater number of GnRH neurons were also found in the LA of knife-cut birds. The PVN of experimental birds had densely staining cells when reacted with Cytochrome Oxidase indicating increased metabolic activity. These brain nuclei may be important for the control of gonadal development in birds.

USDA Grant #90-37240-5506.

CASTRATION AFFECTS THE GnRH NEURON SYSTEM OF MALE DJUNGARIAN HAMSTERS WITH DELAYED PUBERTY. S.M. Yellon and C.P. Haase*. Div. Perinatal Biology, Depts. Physiology, Pediatrics, and Anatomy, Loma Linda Univ., Sch. of Med., Loma Linda, CA 92350.

Puberty in the Djungarian hamster (age 25 d) is characterized by peak gonadotropin secretion and increased numbers of unipolar but not bipolar GnRH-immunoreactive (GnRH-i) cell bodies in the medial preoptic area (MPOA) and diagonal band of Broca (DBB), regions that contain the majority of GnRH perikarya. The pubertal increase in GnRH-i cell number can be blocked by exposure to short days (*Endo 124 Suppl:257A, 1989*). To determine whether the testes or testosterone (T) contribute to this photoperiod effect, males reared in short days (10L:14D) were castrated at 12 d (n = 10) and implanted with a blank or T-filled silastic capsule (5 mm s.c.). Testis-intact males (n = 5), as well as comparably treated males reared in long days (16L:8D; n = 15) served as control. Brain sections (60 μm) from the MPOA and DBB were processed for GnRH immunocytochemistry (LR1 from R. Benoit). In long-day reared males, regardless of treatment more unipolar GnRH-i soma were present at 25 d (71 ± 4) compared to that at 15 d (42 ± 3; $p < 0.05$, ANOVA). At each age (15 or 25 d), GnRH-i cell numbers were the same in castrates, blank or T-treated, as in testis-intact controls. Thus, the testes or T do not contribute to the pubertal increase in GnRH-i neuron number. In short days, similar numbers of unipolar GnRH-i cells were found in both 15 and 25 d testis-intact males and 15 d old castrates, comparable to that in 15 d males in long days. By contrast, castrate males in short days at 25 d (blank and T-treated) had significantly more unipolar GnRH-i cells (vs 15 d; $p < 0.05$), numbers equivalent to that in long-days males at 25 d. Bipolar GnRH-i cell numbers were the same regardless of age or treatment. Findings indicate that the testis but not testoster-one contribute to the mechanism by which short days block pubertal development of the GnRH neuron system in the Djungarian hamster.

SEX DIFFERENCES IN SYNAPTIC NUMBERS IN THE BINOCULAR AREA OF THE VISUAL CORTEX OF THE RAT. Silvia N. M. Reid and Janice M. Juraska. Neuroscience Program and Department of Psychology, University of Illinois, Champaign 61820.

We have previously found that male rats have more neurons in the binocular area of the primary visual cortex (Oc1B) and a larger Oc1B than female rats (Reid & Juraska, Neurosci. Abst., 1990). In the present study we investigate sex differences in synaptic connections. Synaptic density of layer II-III of the Oc1B was estimated from 7 littermate pairs of 90 day old Long-Evans hooded rats. The number and the length of synapses were obtained from 12 electromicrographs (40,000X) for each hemisphere of each animal. Synaptic length was used as a correction factor in estimation of synaptic densities.

Our preliminary data show that synaptic densities, the average synaptic length and the synapse-to-neuron ratio were not significantly different between sexes. Because layer II-III of Oc1B in the male rat was larger, it contained more asymmetrical synapses and total synapses (20%) than that of the female rat. More animals will be added. Supported by NSF BNS 89-09164.

EFFECT OF PERINATAL ESTROGEN ON THE CORPUS CALLOSUM OF ADULT FEMALE RATS. C. M. Mack*, R. H. Fitch, P. E. Cowell, L. M. Schrott, and V. H. Denenberg. Biobehavioral Sciences Graduate Program, University of Connecticut, Storrs, CT 06269 and Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102.

To determine the contribution of perinatal estrogen on adult callosal size, female rats were either ovariectomized (OVX) on postnatal day 12 (P12) or were OVX followed by chronic implantation of a 10mm silastic tube containing B-estradiol (E) on P25. Unmanipulated males and sham females served as controls. The corpus callosum was examined at 110 days of age. The software package Stereology yielded callosal parameters of area, perimeter, length and 99 widths taken perpendicular to the longitudinal axis. Seven regional width factors, derived from a prior factor analysis of the rat callosum, were used to analyze group differences. The factors are widths 1-5 (W1-5), W6-17, W24-38, W46-57, W62-72, W79-95 and W96-99. Males had a larger callosal area than females and were also larger for regions W1-5, W6-17, W62-72 and W79-95. OVX females had a larger callosal area than control females and were also larger for W46-57 and W79-95. These results confirm our prior findings. In addition, the callosal area of the OVX + E females was smaller than that of the OVX group. Regional analyses revealed a smaller callosum in W6-17, W24-38, W46-57, W62-72, W79-95. These findings indicate that the presence of perinatal estrogen contributes to the feminization of the rat callosum. In addition, the critical period of estrogenic effects upon the adult female callosum extends at least through P25.

ONTOGENY OF A SEXUALLY DIMORPHIC PREOPTIC NUCLEUS IN JAPANESE QUAIL (Conturnix japonica). R. Thompson and E. Adkins-Regan, Department of Psychology, Cornell University, Ithaca, NY 14851.

The nucleus preopticus medianus (POMn) is a sexually dimorphic nucleus that is critically involved in the hormonal activation of male copulatory behavior. The larger volume observed in adult males appears dependent upon circulating testosterone (Panzica, Viglietti-Panzica, Calcagni, Anselmetti, Schumacher & Balthazart, 1987). The present study is an attempt to determine exactly when during normal development this nucleus becomes dimorphic. POMn was drawn under a projecting microscope in Nissl stained coronal sections (40 um) from animals sacrificed at two weeks of age (n=3 per sex) and three weeks of age (n=3 per sex). Areas were measured by computerized planimetry from consecutive serial sections (n=10 per animal) immediately anterior to and including the final section in which the anterior commisure (CA) was observed, so chosen because the nucleus gradually increases in size in sections moving caudally towards CA, appears at its largest immediately ventral to CA, and quickly dissappears in sections more posterior. POMn volume was derived from these area measurements. No significant sex differences in POMn volume were observed at either developmental age Our results indicate that the sexual dimorphism of POMn volume observed in adult birds is not a simple function of embryonic hormone exposure, but instead likely involves a dependence upon the pubertal increases in testosterone that begin around 3 weeks of age (Ottinger & Brinkley, 1979). Currently, identical measurements are being taken from birds 4,5,6,7 and 8 weeks of age, and sample sizes are being increased to n=6 per sex for all developmental ages, including those reported above.

DEVELOPMENT OF SEX DIFFERENCES AMONG HVC NEURONS BORN DURING ZEBRA FINCH SONG LEARNING. E.J. Nordeen, M.J. Burek, and K.W. Nordeen. Dept. Psych., and Neuroscience Program, U. Rochester, Rochester, N.Y. 14627.

The higher vocal center (HVC), a region necessary for song production in zebra finches, contains more neurons in adult males (who sing) than in females (who do not sing). This dimorphism is regulated by early estrogen exposure and arises because new HVC neurons are added in greater numbers in juvenile males than in females. It is not known when these late-generated HVC neurons first become sexually dimorphic and thus, whether estrogen promotes their production or survival. We gave males and females 3H-thymidine on days 15 and 16 after hatching to label HVC neurons born on these days. Labeled neurons within HVC were then counted at 2, 13, and 39 days after the 3H-Thy regime. Neuronal labeling was not seen in HVC 2 days after 3H-Thy, implying that longer is needed for migration and/or neuronal differentiation. But, by 13 days after their birth new HVC neurons were already sexually dimorphic; the number of labeled HVC neurons being 4-5X higher in males than in females. This sex difference enlarged only slightly between 13 and 39 days after cell birth because a larger proportion of labeled HVC neurons was lost in females than in males during this time. However, this neuronal loss was not significant in either sex. Currently, we are counting labeled HVC neurons at other timepoints to determine if sex differences in their number emerge before these cells incorporate into HVC and interact with sexually dimorphic afferent or efferent targets.

HORMONES AND DEVELOPMENT: MOTOR NEURONS

529.1

DEVELOPMENT OF NEURONAL NUMBER IN PRIMARY AFFERENTS OF A SEXUALLY DIMORPHIC NEUROMUSCULAR SYSTEM IS ANDROGEN-DEPENDENT. A. Mills and D.R. Sengelaub. Program in Neural Science, Indiana University, Bloomington, IN 47405.

The spinal nucleus of the bulbocavernosus (SNB) in the rat contains many more motoneurons in males than in females. Androgens produce this sex difference by influencing normally occurring motoneuron death, but the site of androgenic action is unclear. Primary afferents have been previously demonstrated to be important in the normal development of spinal motor nuclei (Davis et al., 1983; Okado and Oppenheim, 1984). To investigate the potential role of afferents in the regulation of SNB motoneuron numbers, we studied the development and androgen dependence of the dorsal root ganglia (DRGs) which innervate SNB target musculature.

Male rats injected with WGA-HRP or Fluorogold into an SNB target, the bulbocavernosus muscle, showed extensive labeling of the L6 and S1 DRGs. Neuronal counts were therefore restricted to these DRGs, and made in normal males (M) and females (F) from embryonic day (E)18 through postnatal day (P)10, the period during which SNB motoneuron number is established. Counts were also made in females treated with testosterone propionate (TP) on E16-E22, P1, P3, and P5, a regimen which results in complete masculinization of SNB motoneuron number. Counts of DRG neurons declined from E18 through P10, by which time males had more DRG neurons than females [L6/S1 total: M (N=3), mean=8650 ± 220; F (N=3), mean=7030 ± 310]. Androgen treatment of females masculinized DRG neuron number at P10 (N=2; mean=8000 ± 470). These results suggest that the DRG can be masculinized by TP, a finding consistent with the hypothesis that primary afferents may be important in establishing the androgen-dependent sex differences in SNB motoneuron number.

529.2

HORMONAL CONTROL OF DENDRITIC DEVELOPMENT IN SEXUALLY DIMORPHIC RAT SPINAL NUCLEI. L.A. Goldstein and D.R. Sengelaub. Program in Neural Science, Dept. of Psychology, Indiana University, Bloomington, IN 47405.

Dendritic development of motoneurons in the spinal nucleus of the bulbocavernosus (SNB) is biphasic and androgen dependent. During normal postnatal development, SNB dendrites grow exuberantly and then retract to mature lengths. In adult males castrated at one week of age, SNB dendrites fail to grow beyond pre-castration lengths, but grow exuberantly in castrates treated with testosterone (T). To determine if dendritic growth involves the conversion of T to dihydrotestosterone (DHT) or estrogen (E), male rats were castrated on postnatal day (P) 7 and given daily injections of either DHT or E. Dendritic length and soma size of all SNB motoneurons retrogradely labeled with HRP were measured at P28 or P49. Results show that DHT, but *not* E, is as effective as T in supporting dendritic growth of SNB motoneurons, lending further support for the role of androgens but not estrogen in the masculinization of sexually dimorphic spinal motor nuclei.

The dendritic development and androgen regulation of motoneurons in the dorsolateral nucleus (DLN) were also examined. Using HRP, dendritic length and soma size of DLN motoneurons in normal males and in castrates treated with either T or oil vehicle were measured at P7, P28, P49 and P70. Like the SNB, dendritic development in the DLN is androgen dependent. Unlike the SNB, dendritic growth in the DLN is monotonic; the dendritic length of motoneurons increases more than 500% between P7 and P70. These results suggest that in addition to androgens, other factors may play a part in regulating dendritic development. Given that SNB and DLN motoneurons occupy different spinal locations and have different dendritic geometries, one factor may be the differential distribution of afferents to the two nuclei.

ROLE OF GONADAL STEROIDS IN THE DEVELOPMENT OF LAMINA X MOTONEURONS THAT INNERVATE PERINEAL MUSCLES IN MONGOLIAN GERBILS. T.B. Decker, C. Ulibarri, and T.R. Akesson. Dept of Veterinary and Comparative Anatomy, Physiology, and Pharmacology, College of Veterinary Medicine, Washington State University, Pullman, WA 99164-6520.

The bulbocavernosus (BC), levator ani, and anal sphincter muscles of gerbils are innervated by a sexually dimorphic, androgen-sensitive motoneuron pool located above the central canal in lamina X of lumbosacral spinal cord. This research investigated the role of postnatal gonadal steroids in the development of this unique motor system.

On the day of birth (P1) male gerbils were castrated or given sham surgeries. Female gerbils were injected with 100 μg dihydrotestosterone propionate and 20 μg diethylstilbestrol in 0.05 ml safflower oil or vehicle. As adults (P60) gerbils were castrated as necessary and implanted with Silastic capsules of testosterone propionate (10 mm). Four weeks later gerbils received injections of 1 μl of cholera toxin-HRP (0.2% CT-HRP) in each side of the BC. After one week gerbils were perfused and alternate sections were processed for visualization of CT-HRP (Mesulum, *J Histochem Cytochem 26*:106) or stained for Nissl substance.

Neonatally castrated males, steroid-treated females and vehicle-treated males had clearly visible BC muscles. Vehicle-treated females did not. Virtually all of the CT-HRP labelled motoneurons were located in lamina X above the central canal (213/214). Neonatally castrated males had fewer motoneurons than did vehicle-treated males (171 ± 5 vs 190 ± 9, respectively). Steroid-treated females had fewer motoneurons than did males (104 ± 4.9), but many more than vehicle-treated females (30 ± 2). These data suggest that the BC-spinal cord system develops under the control of gonadal steroids. Additionally, exposure to steroids either prenatally, or as a single low dose postnatally is sufficient to masculinize the BC and its innervating motoneurons. Supported by HD 22869 (TRA).

529.4

MOTONEURONS IN LAMINA X INNERVATE PERINEAL MUSCLES IN MONGOLIAN GERBILS. C. Ulibarri, P. Popper, and P.E Micevych. Dept of Veterinary & Comparative Anatomy, Physiology, and Pharmacology, College of Vet Med, Wash State Univ, Pullman, WA 99164 & Dept of Anatomy & Cell Biol, Lab of Neuroendocrinol, Brain Res Institute, UCLA Sch Med, LA, CA 90024.

The spinal nucleus of the bulbocavernosus innervates the bulbocavernosus (BC), levator ani, and anal sphincter (AS) muscles in several rodent species. Onuf's nucleus innervates these same muscles as well as the ischiocavernosus muscle and bladder sphincters in primates and carnivores. The purpose of this research was to define the location of the spinal motoneuron pool innervating the perineal muscles of gerbils and to determine if these motoneurons are sexually dimorphic and/or sensitive to adult castration effects.

Fluorogold (4%) or cholera toxin-HRP (0.2%) was injected into the BC, AS or IC in male and female gerbils. After IC injections labelled motoneurons were present in the dorsolateral nucleus of ventral horn in lumbar 5 and 6, as described in rats. The motoneurons labelled after BC or AS injections were found in lamina X above the central canal in lumbar 5 and 6 of spinal cord. We believe that this is the first report of motoneurons in lamina X of the spinal cord.

The motoneuron pool in lamina X was sexually dimorphic. Male gerbils had six times as many motoneurons as female gerbils, and motoneurons of males were significantly larger. Intact males had 192 ± 12 motoneurons (cell surface area 642.2 ± 10.5 μm^2) in the lamina X motoneuron pool while intact females had 31.9 ± 3 motoneurons (cell surface area 437.2 ± 19.3 μm^2).

Adult castration decreased the size of these motoneurons, but had no effect on the number. Castrated males had significantly smaller motoneurons (540.1 ± 15.1 μm^2) than intact males or males implanted with Silastic capsules of testosterone propionate at castration (658.8 ± 16.4 μm^2). Supported by NS 21220 to PEM.

PRENATAL FLUTAMIDE ALTERS SEXUALLY DIMORPHIC SPINAL NUCLEI. **W.Grisham, J.M.Casto, M.L.Kashon, I.L.Ward, and O.B.Ward. Department of Psychology, Villanova University, Villanova, PA 19085**

The dorsolateral nucleus (DLN) and spinal nucleus bulbocavernosus (SNB) of the lumbar spinal cord are sexually dimorphic. Males have more neurons than females in both nuclei and males have larger neurons in the SNB. The spinal cords of 16 male and 9 female offspring of rats which received 5 mg of the anti-androgen, flutamide, on days 11 through 21 of gestation and 16 male and 16 female controls were examined.

Flutamide males had fewer DLN neurons ($\bar{X}$=301) than did control males ($\bar{X}$=488), but flutamide females ($\bar{X}$=258) were not different from control females ($\bar{X}$=280). Flutamide males also had significantly fewer and smaller SNB neurons than did control males. Flutamide did not significantly alter the SNB of females. These results support the hypothesis that the sexually dimorphic characteristics of the DLN and SNB are androgen dependent.

529.6

DELAYED EXPRESSION OF CALCITONIN GENE RELATED PEPTIDE (CGRP) IN SNB MOTONEURONS. Nancy G. Forger, Lynn Hodges and S. Marc Breedlove, Dept. Psychology, Univ. California, Berkeley, CA 94720.

Motoneurons of the spinal nucleus of the bulbocavernosus (SNB) innervate sexually dimorphic perineal muscles. The development of this neuromuscular system is androgen dependent and differs temporally from that in other motoneuronal pools: 1) the normal period of motoneuron death is later in the SNB, with significant loss occurring postnatally and 2) neuromuscular synapse elimination occurs later in SNB cells. CGRP expression has been correlated with the period of motoneuron death in chicks and has recently been shown to be androgen regulated in rat SNB motoneurons in adulthood (Popper & Micevych, '89). We therefore examined CGRP-like immunoreactivity (CGRP-LI) in motoneurons of the lumbar cord of rats from postnatal day 3 to adulthood. In accord with previous findings, many lateral horn motoneurons were clearly positive for CGRP-LI on day 3 and all subsequent ages examined. In contrast, no CGRP-LI was detected in SNB cells on day 3 and only faint staining was observed on days 9-10. By day 16 occasional heavily labeled cells were found in the SNB and the adult pattern of CGRP expression was present by day 33. CGRP expression therefore appears to be significantly delayed in SNB motoneurons, suggesting an association with the events of cell death and/or synapse elimination.

529.7

ANDROGEN REGULATES GAP JUNCTION mRNA EXPRESSION IN THE MOTONEURONS OF LUMBAR SPINAL CORDS IN ADULT MALE RATS. A. Matsumoto (1), Y. Arai* (1), A. Urano (2) and S. Hyodo* (3). (1) Dept. Anat., Juntendo Univ. Sch. Med., Hongo, (2) Ocean Res. Inst., Univ. Tokyo, Nakano, (3) Fac. Art & Sci., Univ. Tokyo, Meguro, Tokyo, Japan.

Gap junctions are considered to play an important role in metabolic and electrical coupling between neurons. We studied androgenic influence on the expression of the mRNA for gap junction protein in the androgen-sensitive motoneurons in the spinal nucleus of the bulbocavernosus (SNB) by using in situ hybridization. Adult male rats (Wistar) were castrated and implanted with silastic tubes containing testosterone (T) or nothing. Animals were sacrificed 4 weeks later. A complementary DNA specific for the mRNA for rat liver gap junction protein (connexin 32)(a gift from Dr. D.A. Goodenough) was applied to in situ hybridization on cryostat sections of the lumbar spinal cords. Autoradiographic signals for connexin 32 mRNA were found to be localized on the somata and proximal dendrites of SNB motoneurons. The number of signals per motoneuron in castrates was significantly smaller than that in controls. The value in castrates given T was not significantly different from that in controls. These evidence suggests that androgen may regulate the expression of gap junction gene in SNB motoneurons. (Supported by grant from the Ministry of Education, Culture and Science of Japan).

ANDROGENIC MODULATION OF THE EXCITABILITY OF LUMBAR NEURONS IN THE RAT BULBOCAVERNOSUS REFLEX. J. Tanaka & A.P. Arnold. Dept. Psychology, and Brain Research Institute, UCLA, Los Angeles CA 90024-1563.

Since motoneurons in the spinal nucleus of the bulbocavernosus (SNB) are sensitive to androgens, we compared the bulbocavernosus (BC) reflex, recorded in BC motor nerve in response to electrical stimulation of the contralateral pudendal afferents, in intact (n=16), castrated (n=14) and testosterone-treated (n=12) male rats under urethane anesthesia. No group differences in reflex latency, sensory or motor conduction velocity, or central delay were observed. We also examined the effects of stimulation of the contralateral pudendal sensory or BC motor nerves on extracellular antidromic responses of SNB motoneurons evoked by stimulation of the BC motor nerve. Stimulation of the contralateral pudendal afferents 7-35 msec prior to stimulation of the BC motor nerve reduced the amplitude of averaged antidromic potentials recorded in the SNB nucleus, whereas contralateral BC motor nerve stimulation had no effect. The magnitude of this suppression was much greater in intact and testosterone-treated castrated males than in castrates, indicating that androgen modulates the excitability of SNB motoneurons or other neurons involved in the BC reflex. Supported by NIH grant HD15021.

529.9

ANDROGENS DIFFERENTIALLY AFFECT SYNAPTIC EFFICACY WITHIN MOTOR UNITS OF A SEXUALLY DIMORPHIC MUSCLE. N. Nagaya-Stevens and A. A. Herrera, Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089.

The flexor carpi radialis (FCR) is a sexually dimorphic forelimb muscle used by male frogs during mating. Preliminary data indicate that motor units (MUs) in the shoulder and elbow regions of the FCR are innervated by motor neurons in spinal segments 2 and 3, respectively. Studies comparing castrated males (C) with castrates given testosterone (CT) have shown that FCRs from CT males contract more slowly and have larger fiber cross sectional areas (CSAs). The effects of testosterone on CSA and contraction time are more pronounced in shoulder MUs. Using intracellular recording, we found that many shoulder fibers in CT muscles are innervated by subthreshold junctions. Only 63 % of shoulder junctions in CT muscles triggered fiber action potentials with a single nerve stimulus compared to 97 % of shoulder junctions in C muscles. Elbow junctions were found to be mainly suprathreshold in both CT and C muscles (80 and 98 %). These results suggest that testosterone may preferentially affect the synaptic efficacy of neuromuscular junctions within motor units in the shoulder region. The larger CSAs of shoulder fibers from CT muscles suggest that lowered synaptic efficacy may result from a decrease in input impedance (R_o). Mean R_o of shoulder fibers in CT muscles was significantly less than in C muscles (0.29 vs. 0.44 MΩ; $p < 0.0002$). We are currently investigating whether changes in neurotransmitter release may also contribute to altered synaptic efficacy.

CELLULAR SPECIFICITY OF STEROID INFLUENCES ON PROCESS OUTGROWTH OF IDENTIFIED MOTONEURONS IN CULTURE. J.L. Witten and R.B. Levine, ARL, Division of Neurobiology, U. Arizona, Tucson, AZ 85721.

Dramatic remodeling of the central nervous system (CNS) occurs during insect metamorphosis to accompany the changing lifestyle of the animal. In the moth, Manduca sexta, identified motoneurons exhibit cell-specific changes in morphological and biochemical properties during this transition and these changes are mediated by the steroid hormones, the ecdysteroids. To determine whether these changes result from the direct action of the steroid hormone on the neurons and to explore mechanisms underlying the cellular specificity of these effects, we have developed methods to culture identified motoneurons. We compared the effects of ecdysteroid on neurite outgrowth in two sets of identified motoneurons that have different developmental fates. Leg motoneurons display extensive growth of their central arborizations during adult development in vivo (Kent and Levine, '88) and have been shown previously to exhibit enhanced neurite outgrowth in the presence of ecdysteroids in vitro (Griffin and Levine, '89). In contrast to the leg motoneurons, the motoneurons that innervate the abdominal intersegmental muscles (ISM) do not exhibit significant dendritic growth during adult development in vivo, although they do alter the expression of a neuropeptide (Witten and Truman, '90). Accordingly, the ISM motoneurons do not show a steroid-mediated enhancement of neurite outgrowth in culture. Thus, these experiments confirm the specificity of steroid hormone action on process outgrowth.

LARYNGEAL NERVE AXON NUMBER IN PRE-METAMORPHIC *XENOPUS LAEVIS* IS ANDROGEN SENSITIVE. J. C. Robertson, J. T. Watson and D. B. Kelley, Dept. of Biol. Sci., Columbia Univ., New York, NY 10027.

Sexual dimorphism in the number of axons in the laryngeal nerve of the clawed frog (*Xenopus laevis*) originates before metamorphosis. At stage 56, males and females have equal numbers of laryngeal nerve axons; at later stages through adulthood, males have more axons. To investigate possible influence of androgen on laryngeal nerve axon number, tadpoles were maintained from stage 54 to 62 in water treated with dihydrotestosterone (DHT, Sigma), the anti-androgen flutamide (Schering Corp.) or ethanol (vehicle). Axons were counted on transmission electron micrographs of laryngeal nerves. Treatment with DHT (0.001 mg/L) increased axon number in both sexes (males=860, females=865) as compared with controls (male=675, female=460). At a concentration of 0.2 mg/L, axon number of flutamide treated males (578) was lower than that of control males, but not as low as control females. Number of axons in females from this flutamide group (498) was not significantly different from control females. With a flutamide dosage of 1.0 mg/L, male (588) and female (498) axon numbers did not significantly differ from the lower flutamide treatment. Hypermasculinization of axon number with DHT treatment may involve recruitment of additional vocal motor neurons or axon sprouting. The similar effect on male axon number of two flutamide concentrations could indicate that androgen sensitivity of this system begins prior to stage 54, that conversion of flutamide to an active form may be incomplete, or that other androgens may be involved.

HORMONES AND DEVELOPMENT: THYROID HORMONE

530.1

ROLE OF THYROID HORMONES ON OLFACTORY NEUROGENESIS IN THE POSTNATAL RAT: A QUANTITATIVE 3H-THYMIDINE STUDY. M. Paternostro and E. Meisami Physiol. Dept., Univ. of Illinois, Urbana, IL 61801

We have previously shown that the marked increase in surface area and total neuronal number occurring in the olfactory epithelium(OE) of growing rats is severely reduced in rats made hypothyroid (HT) from birth, while rats allowed to recover from hypothyroidism at 25d showed complete recovery in these parameters by 90d. To better understand these effects, a quantitative 3H-thymidine study was undertaken. Normal(N) and HT rats were injected with 3H-thymidine(5uCi/gbw) at 25d and 75d, while recovery rats were injected at 75d. Rats were sacrificed 1, 5 or 15d post injection(pi). Autoradiographs from septal OE were studied by measuring the density of labeled cells in both the basal cell zone(bcz) and the receptor zone(rz). Results from the 25d injection group revealed at 1d pi, a 25% reduction in the density of labeled cells in the bcz of HT rats(p=0.003). In both groups at 5d and 15d pi, the density of labeled cells was markedly decreased in the bcz and proportionally increased in the rz. The density of labeled cells in the rz at 15d pi was not significantly different between the two groups. Thus early thyroid deficiency reduces the rate of basal cell proliferation, but does not seem to significantly affect the survival and migration of the developing neurons. Work is currently being carried out on the 75d injection group.

530.2

THYROID HORMONE DEFICIENCY DISRUPTS DEVELOPMENT OF β-ADRENERGIC SIGNAL TRANSDUCTION IN THE NEONATAL RAT HEART. J. B. Pracyk and T.A. Slotkin, Dept. Pharmacol., Duke Univ. Med. Ctr., Durham, NC. 27705. (EPA CR-813769, USPHS HD-09713, CIIT fellowship)

In mature animals, thyroid hormone regulates cardiac β-adrenergic receptor numbers and the efficiency of receptor transduction. Exposure to excess thyroid hormone during early neonatal periods promotes the development of post-receptor transduction components independently from alterations in receptors; the current study determined whether normal development of β-adrenergic transduction requires endogenous thyroid hormone. To achieve neonatal hypothyroidism, pregnant rats were given propylthiouracil 20 mg/kg s.c. beginning on gestational day 17 through postnatal day 5 and their offspring were given the same dose on postnatal days 1 through 5. We evaluated receptor binding capabilities and adenylate cyclase activity in membrane preparations. Hypothyroidism produced an initial inhibition of [^{125}I]pindolol binding to cardiac membranes, followed by a return to control levels after discontinuing treatment. During the first two weeks, isoproterenol-stimulated adenylate cyclase activity displayed subsensitivity, corresponding to the deficits in β-receptor binding. Basal and forskolin-stimulated cyclase activities were initially unaffected, implicating a specific role for thyroid hormone in early stages of coupling of enzymatic responses to β-receptors. Thyroid induced deficiencies in basal and forskolin-stimulated adenylate cyclase activity eventually emerged, suggesting that, at later stages, normal development of adenylate cyclase requires prior establishment of a euthyroid state.

530.3

DISTINCT INDUCTION PATTERNS OF c-fos AND OTHER EARLY RESPONSE GENES BY INSULIN, HYDROCORTISONE, AND THYROID HORMONE IN GLIAL CELLS.

J. Cheng*, A. T. Arenander and J. de Vellis. Mental Retardation Research Center, Department of Anatomy and Cell Biology, Department of Physiology, and the Brain Research Institute, UCLA, Los Angeles, CA. 90024.

Recent evidence suggest various extracellular stimuli, such as growth factors and hormones, induce the cellular immediate early, or early response genes (ERGs) in neural cells. As such, ERGs may participate in the signal transduction processes that coordinate CNS development. However, whether the ERG products can confer the intracellular specificities of the extracellular signals is not clear.

In this study, we examined the induction of ERG mRNAs by insulin, hydrocortisone, and thyroid hormone in glial cells. We asked whether ERG expression could confer intracellular specificity by examining the patterns of ERG induction by these ligands individually or in combination. RNAs from treated astrocytes or C6 glioma cells were examined by northern analysis using ^{32}P-labeled cDNAs encoding for c-fos, c-jun, junB, egr1, NGF1B, or TIS11. Results showed that insulin, hydrocortisone, and thyroid hormone induced ERGs. The amounts and kinetics of ERG induction, however, differed in each treatment. Differences in the levels and time courses of mRNA expression were also observed when cells were treated with combinations of the ligands. Analysis of the ERG induction kinetics by various treatments showed that a specific pattern of ERG expression exists for a specific extracellular stimulus. These results suggest specific phenotypic responses to insulin, hydrocortisone, and thyroid hormone could be conferred by differential patterns of ERG expression. (Supported by NIH grant HD-06576 and DOE)

530.4

PERINATAL HYPOTHYROIDISM ELEVATES HIPPOCAMPAL MU–OPIOID RECEPTOR BINDING SITE DENSITY IN 31–DAY–OLD SPRAGUE–DAWLEY RATS. C.F. Sanchez,* K.A. Ortiz,* L.L. Paxton* and D.D. Savage. Department of Pharmacology, Univ. of New Mexico School of Medicine, Albuquerque, NM , 87131.

We have reported long–lasting reductions in kainate receptors and mossy fiber zinc in the hippocampal CA_3 region of rats made hypothyroid during the perinatal period using propylthiouracil (PTU). Perinatal hypothyroidism has been reported to elevate mu–opioid receptor binding in whole hippocampal homogenate preparations. To determine more precisely the anatomical location of the perinatal hypothyroidism–induced elevation in hippocampal mu–opioid receptors, we measured ^{3}H–Tyr–D–Ala–Gly–N–Methyl–Phe–Gly–ol (DAMGO) binding site density in 31–day–old PTU–treated rats using *in vitro* autoradiography techniques.

Timed pregnant Sprague–Dawley rat dams were given water containing either 0.002% or 0.02% PTU or untreated water from Gestational Day 18 until their litters were weaned at 31 days of age. Beginning on Postnatal Day 2, half of the offspring in each group received daily thyroxine (T_4) injections (1 microgram / 100 g body wt., sc) and the other half received saline. Offspring were sacrificed at 31 days of age. Serum T_4, T_3, body and brain weight data indicated that both groups of saline–injected PTU–treated rats were hypothyroid, whereas the T_4 supplemented PTU–treated rats were not different from euthyroid control rats.

Compared to untreated controls, specific ^{3}H–DAMGO binding site density was elevated significantly in both dorsal and ventral hippocampal formation of both 0.002% and 0.02% PTU–treated rats. In the dentate granule and hippocampal pyramidal cell body layers of PTU–treated rats, ^{3}H–DAMGO binding was increased 129% to 157% of control. In the apical dendritic field regions, binding was increased 212% to 263% of control. ^{3}H–DAMGO binding was increased also in the posterior neocortex of PTU–treated rats compared to controls. In contrast, ^{3}H–DAMGO binding was reduced to 20% of control in the deep cell region of the presubiculum. PTU treatment did not affect ^{3}H–DAMGO binding in the amygdala, entorhinal cortex, lateral or medial geniculate nuclei or dorsal lateral thalamic nucleus. T_4 supplementation reversed all of the PTU–induced mu–opioid binding site alterations noted above. (Supported by AA06548, RR08139 and GM08222)

530.5

NEONATAL HYPERTHYROIDISM SELECTIVELY DELAYS THE DEVELOPMENT OF RELATIONAL CUE USE AND INDUCES A SEXUALLY DIMORPHIC IMPAIRMENT OF RATS' SPATIAL NAVIGATION.

N.L. Dallal[1], M.E. Kleiderman[2], W.H. Meck[1], and C.L. Williams[3]. Departments of Psychology, Columbia University[1], New York, NY 10027, Brown University[2], Providence, RI 02912, and Barnard College[3], New York, NY 10027.

Both the short- and long-term behavioral consequences of early postnatal treatment of male and female Sprague-Dawley rats with 3,3', 5-triiodothyronine (T3 -- 0.5 µg/g body wt.) were examined by using water maze and radial arm maze tests of navigational ability at different stages of development. Because the hippocampus is one of several brain structures which selectively takes up T3, the deiodinated form of thyroxine, it was expected that behavioral tasks requiring hippocampal processing might be modified by this manipulation. A comparison of water maze performance at three time-frames spanning postnatal days (PD) 18-28 demonstrated that while all rats could learn the location of the escape platform using a single proximal cue as early as PD 18, the development of navigation using relational cues appeared on PD 24 for control rats but not until PD 28 for T3-treated rats. There were no effects of sex in either cue condition. Some of the cognitive effects of neonatal hyperthyroidism persist well into adulthood. When these same rats were trained as adults on a 12-arm radial maze with 8 baited and 4 unbaited arms, T3-treated rats required more choices to complete the task than did controls. This behavioral deficit was particularly pronounced in the T3-treated females suggesting a difference in the timing of developmental effects of T3 exposure in males and females.

530.6

SEX DIFFERENCES IN THE EFFECT OF NEONATAL HYPERTHYROIDISM ON HIPPOCAMPAL CELL MORPHOLOGY AND INTERVAL TIMING PROCESSES IN ADULT RATS.

M.E. Kleiderman, W.H. Meck, and C.L. Williams. Departments of Psychology, Brown University, Providence, RI 02912, Columbia University, New York, NY 10027, and Barnard College, New York, NY 10027.

The long-term behavioral consequences of neonatal treatment with 3,3',5-triiodothyronine (T3 -- 0.5 µg/g body wt.) administered on postnatal days 1, 2, and 4 were examined by training adult male and female Sprague-Dawley rats on a discrete-trials peak-interval timing procedure to discriminate between visual signals paired with 20-sec and 40-sec intervals. Signals were presented in a double-alternation pattern and response rate functions were analyzed separately for each of the four trial types. Analysis of the discrimination index for peak functions showed that T3-treated males were impaired in their ability to discriminate both within and between signal conditions relative to untreated males. In contrast, T3-treated females were improved in their ability to discriminate both within and between signal conditions relative to untreated females. No sex differences were apparent in control subjects. These results can be related to the sexual dimorphisms in basal forebrain and hippocampal cell morphology and the timing of T3 sensitivity of CA1 and CA3 pyramidal cells. Sexual dimorphisms and T3-induced cellular alterations are quantified using metrical and topological analyses (e.g., Sholl's method of concentric spheres) of 3D tracings of individual neurons obtained from Golgi-stained sections.

SYNAPTIC STRUCTURE AND FUNCTION II

531.1

A FAST ALGORITHM FOR SYNAPTIC CONNECTIVITY ESTIMATION.

X. Yang*(1), S.A. Shamma*(2), and M.J. Bak(3). (1) Multichannel Concepts, Inc., 13904 Grey Colt Dr., Gaithersburg, MD 20878; (2) Electrical Engineering Dept., Univ. of Maryland, College Park, MD 20742; (3) Lab. Neural Control, NIH-NINCDS, Bethesda, MD 20892.

The conventional method for the synaptic connectivity estimation is to use correlation histograms. Such a histogram estimate needs sufficient observation data to assure its accuracy. Often, a stable recording session is too short to collect enough neural spikes. To tackle this difficulty, we discuss a minimum mean square error (MMSE) estimation of the synaptic connectivity in biological neural networks. The recursive algorithm is developed using a Kalman filter and a general neuron model. The mean square error can be made arbitrarily small as long as sufficient spikes are collected. We also show that this method estimates what cross-interval histograms estimate with the advantage that it converges at a faster rate, and hence it requires less data to reach the same accuracy. It is illustrated to estimate the synaptic connection strength and integration time of networks of both inhibitory and excitatory neurons. In contrast to the conventional correlation histogram in which minutes of data are required for the estimation, the MMSE estimation in these simulations needs only 10 sec. of data with an acceptable accuracy.

531.2

NETWORK ACTIVITATION LEVEL INFLUENCES SINGLE-CELL PROPERTIES

Öjvind Bernander[1], Rodney Douglas[2], Kevan Martin[3], Christof Koch[1], Ernst Niebur[1], (1) Caltech, 216-76, Pasadena, CA, 91125, (2) Dept. Physiology, U. of Cape Town Medical School, Cape Town, SU, (3) MRC, Dept. Pharmacology, Oxford QX1 3QT, UK.

The standard one-dimensional Rall cable model of nerve cells assumes that their electrotonic structure do not change in response to synaptic input. This model is used in a great number of both theoretical and anatomical-physiological structure-function studies. In particular, the membrane time constant τ_m and the somatic input resistance R_{in} are used to characterize single cells. However, these studies do not take into account that neurons are embedded in a network of spontaneously active neurons. These synapses will make up a large part of the membrane conductance, especially if recent evidence of very high specific membrane conductance, $R_m = 100\ k\Omega cm^2$, is taken into account. We numerically simulated the electrical behavior of a morphologically identified layer V cortical pyramidal cell receiving input from 4000 excitatory and 1000 inhibitory cells firing spontaneously at 0–2 Hz. We found that over this range of neuronal background activity τ_m and R_{in} can change by more than a factor 10 (7–80 ms, 18–153 $M\Omega$) and the electrotonic length of the cell by a factor 3. Thus the global activity of the network controls how individual cells perform spatial and temporal integration. This provides possible mechanisms for gain control, coincidence detection, and dynamic control of tuning curves.

531.3

EFFECTS OF MICROENVIRONMENT COMPOSITION ON CIRCUIT FUNCTION USING PUSH-PULL PERFUSION WITH MICROELECTRODE RECORDING IN THE CAT CUNEATE NUCLEUS. V.R. Roettger and M.D. Goldfinger, Dept. of Physiology & Biophysics, Wright State University, Dayton, OH 45435.

In Nembutal-anesthetized adult cats, cisternal CSF (cCSF) was withdrawn (4-6 ml/6 hr) with no change in arterial blood pressure (1). The Push-Pull Cannula (PPC) [previously described - (1)] was placed onto the surface of the medial Cuneate Nucleus and was not moved; perfusion rate was 20 µl/min. Pulled perfusate was collected in continuous 5-min periods and stored (-70°C) for subsequent amino acid analysis (2). During perfusion with cCSF, pulled glutamate (Glu) concentration was consistently higher than in cCSF, suggesting a cCSF/interstitial concentration difference. To assess circuit function during perfusion, 20 evoked potentials were elicited every 5-min by constant amplitude 0.1 ms pulses @ 1/sec to the ipsilateral forepaw skin. During control cCSF perfusion (30-60 min), P1, N1, and P2 component amplitudes and latencies remained constant.

I. Perfusion with artificial CSF (aCSF): Following perfusate switch to aCSF, P1 amplitude increased and N1 amplitude decreased during the 60 min perfusion period; latencies and P2 amplitude remained unchanged. These data may indicate that aCSF perfusion causes hyperpolarization of 1° afferent terminals and reduced EPSP amplitude in cuneothalamic relay neurons.

II. Perfusion with high Glu: Following perfusate switch to high-Glu cCSF (10-100x), all component amplitudes and latencies remained unchanged during the 60 min perfusion period.

Ref: (1)V.R.Roettger & M.D.Goldfinger. Soc. Neurosci. Abst. 16 (1990): 224. (2)V.R. Roettger et al. Soc. Neurosci. Abst. 15 (1989):857.

531.4

CALCIUM INFLUX AT THE PROXIMAL REGION OF A MOTONEURON INFLUENCES TRANSMITTER RELEASE FROM DISTANT MOTOR TERMINALS. S.J. Hong and G.A. Lnenicka. Dept. of Biol. Sci., State Univ. of New York, Albany, NY 12222.

Tonic *in vivo* stimulation of a crustacean phasic motoneuron alters the transmitter releasing properties of the motor terminals so that they become more similar to those of a tonic motoneuron (J. Neurosci. **5**:459-467, 1985). The activity-dependent synaptic changes include a long-term reduction in initial transmitter release. We have recently demonstrated that local depolarization of the proximal region of a crayfish phasic motoneuron (abdominal motoneuron, F-3) *in vitro* is sufficient to produce this reduction in initial transmitter release from motor terminals (Soc. Neurosci. Abstr. **16**:1162, 1990). In order to examine the role of Ca^{++} influx in the induction of this synaptic change, the proximal region of F3 was depolarized in Ca^{++}-free saline containing the Ca^{++} channel blocker Mn^{++} (6 mM). While conditioning in normal saline resulted in a significant 30% decrease in initial EPSP amplitude ($p<.01$, t-test; $n=12$), blocking Ca^{++} influx during conditioning prevented this reduction in EPSP amplitude ($p>.10$, $n=10$). These results demonstrate that Ca^{++} influx at the proximal region of a motoneuron can influence transmitter release from distant terminals.

To examine the role of protein synthesis, the protein synthesis inhibitor, cycloheximide (CHX), was bath applied during conditioning. CHX (0.6 mM) applied 2 hr prior to conditioning prevented the reduction in EPSP amplitude. However, CHX application at the onset of stimulation did not block the effect as the conditioned axon showed a significant 25% decrease in initial EPSP amplitude ($p<.05$, $n=5$). These results are consistent with previous *in vivo* findings which suggest that a pool of preexisting proteins is essential for the induction of this activity-dependent change in initial transmitter release (J. Neurosci. **10**:1099-1109, 1990). (Supported by NSF grant BNS-8720135.)

ENZYMATICALLY DISSOCIATED NMJs FUNCTION ALMOST NORMALLY AFTER MANUAL REATTACHMENT OF TERMINAL TO ENDPLATE. R.S. Wilkinson and S.D. Lunin*. Department of Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO 63110.

NMJs are precisely organized at the submicron level, e.g., the close proximity of pre- and postsynaptic elements and the alignment of active zones opposite postsynaptic gutters. The functional importance of these features has been assumed but not directly tested. To address this we 'reconstructed' NMJs by manually positioning enzymatically-detached nerve terminals over vacant endplates in the snake transversus abdominis muscle. Reconstructed NMJs functioned immediately (<0.1 s). Mepps were of normal amplitude, slightly greater duration and lower frequency than controls. PSPs evoked in low Ca^{++} solution comprised fewer quanta than controls, but were of sufficient amplitude to elicit muscle action potentials (normal solution). Lifting the terminal ~0.1 µm above the endplate abolished mepps and PSPs. In contrast, deliberate lateral misalignment of terminal and endplate had no effect on mepp amplitude, but diminished mepp frequency and PSP amplitude in proportion to synaptic area lost. We conclude that basic synaptic function requires close contact between terminal boutons and endplate, and that area of overlap (number of boutons contacting the endplate) determines PSP amplitude. Precise alignment of active zones and gutters is evidently not required for basic function, or, alternatively, such alignment occurs spontaneously when terminal and endplate are placed in contact. Supported by NIH grant NS24752 and the MDA.

531.6

A POSSIBLE MECHANISM FOR BLOCKAGE OF SYNAPTIC TRANSMISSION BY Mg^{++}. J.H. Koenig and K. Ikeda. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

The relationship between synaptic vesicles and the presynaptic dense body at the neuromuscular junction of *Drosophila* was studied under various conditions of activity, rest, or exposure to substances known to affect synaptic transmission. The synapses of the coxal muscle were exposed to a particular condition, then instantly fixed and prepared for observation by electron microscopy. It was observed that under conditions of inactivity with the nerve cut, moderate activity by stimulation, or more severe activity using veratridine, the vast majority of the active zones showed no sign of exocytosis. Furthermore, the synaptic vesicles were located above the dense body plate, at least 50 nm from the presynaptic membrane. In a few cases, synaptic vesicles were observed lying under the dense body plate, next to the plasma membrane. These appeared attached to the presynaptic membrane by 2 or 3 thin filament-like structures. In synapses exposed to 35 mM Mg^{++}, 1 mM Ca^{++} saline for 20 min prior to fixation, the relationship between the synaptic vesicles and the dense body was dramatically different. Now, a build-up of vesicles was observed under almost all of the dense body plates. Furthermore, the presynaptic membrane showed numerous exo/endo-like pits. Many of these appeared as if they could have been exocytosing vesicles, but others were much larger than a vesicle, or were attached to the presynaptic membrane by a long thin neck. Since transmitter release is blocked by high Mg^{++}, it is not possible that these images represent exocytosis at the moment of fixation. It is possible, however, that Mg^{++} blocks the removal of membrane after exocytosis, so that no further release may take place.

MUSCARINIC SYNAPTIC TRANSMISSION IN CANINE INTRACARDIAC GANGLIA. X. Xi, W.C. Randall*, and R.D. Wurster. Physiology Department., Loyola Univ. Med. Ctr., Maywood, Il 60153.

The role of muscarinic mechanisms in mediating slow excitatory and slow inhibitory postsynaptic potentials (s-EPSP & s-IPSP) was investigated in the canine intracardiac ganglion with intact synaptic connections. The right atrial fat pad containing these ganglia which provided vagal innervation to the SA node, were removed from anesthetized dogs. Following dissection in a superfused tissue bath, ganglion cells were recorded using conventional intracellular microelectrode recordings techniques (JANS 32:177-182, 1991). Repetitive orthodromic synaptic activation was accomplished using a suction electrode applied to interganglionic nerves (0.1 ms, < 1s, <40Hz) in order to evoke s-EPSPs and s-IPSPs. Of 85 cells studied, 35 cells exhibited only s-EPSPs (3-4 mV amplitude) accompanied by an increased input resistance. Of 16 cells with s-IPSPs, 8 cells had only a s-IPSP while the other 8 cells had a s-IPSP followed by a s-EPSP. The remaining 34 cells had no slow potentials. All slow potentials were blocked by the nonspecific muscarinic blockers atropine (10^{-7} M, N=25) or by a synaptic blocking solution containing low Ca^{2+}/ high Mg^{2+} (N=5). Physostigmine (10^{-7} M) enhanced all slow potentials (N=38). The reversal potentials for the s-EPSP and for the muscarinic agonist bethanechol induced depolarization was -90 to -100 mv, suggesting the involvement of potassium conductance changes. The M_1 receptor antagonist pirenzepine (10^{-8} M, N=6), but not the M_2 receptor antagonist 4-DAMP ($5x10^{-7}$ M, N=5), blocked the s-EPSPs and the bethanechol evoked depolarizations but not the s-IPSPs (N=3). In conclusion, canine intracardiac ganglion cells exhibit s-EPSPs which involve M_1 receptor and s-IPSPs which are mediated by a distinct muscarinic receptor.

SINGLE CHANNEL PROPERTIES OF ACETYLCHOLINE RECEPTORS COEXPRESSED WITH THE 43K PROTEIN IN OOCYTES AND COS-7 CELLS. L.P. Henderson, C. Brennan*, P. Scotland, S.C. Froehner. Depts. of Physiology and Biochemistry, Dartmouth Medical School, Hanover, NH 03756

The nicotinic acetylcholine receptor (AChR) is a pentameric protein comprised of four subunits in the stoichiometry of $\alpha2\beta\delta\gamma$ or $\alpha2\beta\delta\varepsilon$ which mediates synaptic transmission at the skeletal neuromuscular junction. Clustering of these receptors at a high density in the postsynaptic membrane has been attributed to their association with a peripheral membrane protein of M_r 43,000 (43K protein) (Froehner, 1991). We have addressed whether the association of the 43K protein with the receptor can affect channel function, and thus neuromuscular transmission, by expressing AChR ($\alpha2\beta\delta\gamma$) with and without the 43K protein in *Xenopus* oocytes and COS-7 cells. Analysis of recordings made in the cell-attached configuration demonstrated a primary class of ACh-induced events with a conductance of ~60pS and a biexponential distribution of open durations with a fast component, τ_1 =~0.5 ms, and a slower component, τ_2 =~ 7.0 ms for the apparent mean open time and ~11.0 ms for bursts (i_{avg}=6.0pA). Coexpression of the 43K protein did not produce significant differences in either the conductance or the open state kinetics of the AChR. This was true in oocytes and also in COS cells where it was possible to identify 43K-induced receptor clusters under fluorescence optics and to record directly from clustered receptors. These experiments support previous studies in intact muscle cells which have demonstrated that the single channel properties of clustered synaptic receptors associated with the 43K protein and diffuse nonsynaptic receptors are not significantly different (2,3).

MINIATURE END-PLATE POTENTIALS FROM FROG SARTORIUS MUSCLE EXPOSED TO PEREZONE. E. Gijón, X. Garcia, and G. Alcántara*. Dept. of Physiol. and Dept. of Pharmacol. Sch. of Med. Universidad Nacional Autónoma de México. Ap. P. 70-250, México, D.F. 04510. MEXICO.

Perezone has an anticholinergic action in rat intestinal smooth muscle. It interrupts spontaneous activity, it blocks acetylcholine response, and it causes relaxation of an induced acetylcholine contraction. Perezone action in neuromuscular preparations shows that it also blocks neuromuscular transmission. The anticholinergic action of perezone is probably due to an interaction with acetylcholine receptors. To test perezone action we recorded intracellularly spontaneous miniature end-plate potentials from frog sartorius muscle. Perezone added to the bath induces a decrease in number and amplitude of the miniature end-plate potentials, and a depolarization of the superficial muscle fibers while the resting potential of less superficial fibers shows higher values, and miniature end-plate potentials of higher amplitude and frecuency. These results support that perezone interacts with acetylcholine receptors and probably decreases spontaneous acetylcholine release.

FLUCTUATION ANALYSIS OF SINGLE FIBER EPSPS IN THE SPINAL CORD OF THE BULLFROG. Ch. Stricker and H.-R. Lüscher, Dept. of Physiol., Univ. of Bern, Switzerland.

Synaptic transmission from muscle afferents to motoneurons in the frog spinal cord is both electrical and chemical. By comparing the fluctuations of the electrically and chemically evoked components, it should be possible to determine whether fluctuations are a result of failure to release transmitter or of uncertainty of potential propagation in afferent branches. We have shown that the method of variance analysis is not sufficiently sensitive to detect an expected variance of the electrotonic component because of contaminating noise. Therefore, we used a different approach. For comparison of the two components we have measured single fiber EPSPs in motoneurons elicited by tapping the fore limb triceps muscle (5 Hz). The animals were anesthetized with ice and the spinal cord and muscle rapidly dissected. The spinal cords were hemisected along the mid line and the preparation superfused with oxygenated Ringer (14°C). Motoneurons of the triceps muscle were impaled with bevelled microelectrodes (2 n K-citr., 30-70MΩ) and identified by antidromic stimulation. EPSP and noise measurements of only those cells were included in the analysis if the membrane potential during recording was <-55 mV and did not vary more than 5 mV. Afferent action potentials of the triceps nerve were used for spike triggered averaging of the EPSPs and noise records. The components of the EPSP were identified by shape and latency. The average and variance time courses of the EPSP were calculated and the latter corrected for noise variance. Amplitudes of the EPSPs were then grouped into two classes differing by at least two standard deviations of the noise. EPSPs belonging to the same amplitude class were averaged again and the results analyzed for shape and latency. The electrotonic component of the EPSP in the small amplitude group is often smaller in size than in the large amplitude group and that the quotient of electrotonic to chemical amplitude is always greater in the smaller group. The results suggest that the probability of transmitter release at this synapse is determined by two factors: impulse propagation and release process.

531.11

CALCIUM REGULATION IN RAT POSTERIOR PITUITARY NERVE TERMINALS. A.O. Johnson* & S.A. DeRiemer. Dept. of Biological Sciences, Columbia Univ., NY NY 10027.

The posterior lobe of the pituitary gland is composed primarily of neurosecretory axons and their terminals. This makes the gland a unique preparation for the study of synaptic mechanisms, specifically calcium regulatory mechanisms. We have used intact posterior pituitary glands or vibratome slices (60-80 μm) incubated with the membrane permeant calcium indicator dye, fluo-3/AM, in order to characterize the calcium regulatory mechanisms in these terminals. Data from standard fluorescent microscopy in similarly stained tissue is complicated by signals from surrounding structures. By using a confocal microscope we have been able to circumvent this problem. The initial phase in this project involved dealing with three technical problems. The first was to determine a range of laser intensities which gave reproducible signals without significant bleaching during experiments that lasted over forty minutes. Second, the application of secretogogues during intitial experiments caused tissue movements which interferred with data collection. We overcame this problem in the intact preparation by tacking the tissue down with minuten pins. The third was the calibration of changes in fluo-3 fluorescence with changes in intracellular calcium concentrations. This included the determination of whether the dye was primarily cytosolic and whether the concentration changed significantly over time. We have used the non-fluorescent calcium ionophore, 4-bromo-A23187, to determine the range of fluorescent responses to changes in the concentration of extracellular calcium and the accessibility of the dye. Data from endocrine cells and neuronal soma suggest that there are two major sources of calcium; extracellular calcium entering through ion channels and intracellular calcium released from stores. Posterior pituitary nerve terminals possess voltage gated calcium channels, however the presence of releaseable intracellular stores remains open. We are currently examining this question as well as the effects of neurotransmitters on calcium regulation in these nerve terminals. Supported by a Klingenstein Fellowship.

531.12

THREE DIMENSIONAL STRUCTURE OF NEUROSECRETORY AXONS ACCOMPANYING THE PERIPHERAL MOTOR AXONS IN MANDUCA LARVAE. M.B. Rheuben and D.M. Autio*. Dept. of Anatomy, Michigan State University, E. Lansing, MI 48824.

Insects have elaborate neurosecretory systems whose products are involved in development, ecdysis and modulation of muscle function. Nerve branches innervating skeletal muscles in Manduca include small axons of a neurosecretory (ns) type, but whose function is unknown. We have examined the ultrastructure of these ns axons in the vicinity of the neuromuscular junctions using serial sections. One ns axon accompanies a single motor axon to each muscle fiber. The ns axon is loosely wrapped in the outermost glial processes investing the motor axon, may at times be directly exposed to the hemolymph, and forms varicosities ranging from 0.24-1.1um in diameter and 0.6-6.7um in length, and with inter-varicosity distances averaging 5.5um. Within varicosities, dense- and clear-cored vesicles cluster around an electron dense presynaptic "specialization", many of which are in direct apposition to an ensheathing glial cell process. The ns axon itself, though close, does not appear to come into direct contact with the muscle fiber nor to enter into the neuromuscular junction. The results suggest that the ns axon could have a "distant" neuromodulatory influence on the neuromuscular junction or the muscle fiber, but also that it might interact in some direct way with the glial sheath.

SYNAPTIC ULTRASTRUCTURE OF TRIGEMINAL MOTOR NEURONS IN CATS. N. Capra, V. Hubbard*, and J. Bernanke*. Dept of Physiol., Univ. of MD, Baltimore, MD 21201; Dept. of Anatomy Univ. of MS, Jackson, MS 39216.

This study compares the synaptic ultrastructure along the soma and proximal dendrites of masseter and digastric motor neurons in cats. Horseradish peroxidase (HRP) injections were made into the digastric muscle in 2 cats and in the masseter muscle in 2 cats. Vibratome sections were reacted with diaminobenzidine to identify cells containing retrogradely transported HRP. Labeled neurons were trimmed from the sections, osmicated, processed into plastic, and prepared for ultrastructural study. Ten masseter and 10 digastric neurons, sectioned through the nucleolus, were studied. Terminal boutons in both cell populations contained either small clear spherical vesicles, a mixture of clear vesicles and large dense-core vesicles (LDCV), or small-flattened vesicles. Terminals containing flattened vesicles were more numerous along digastric neurons while spherical vesicles were more common in terminals on masseter neurons. Synaptic density along digastric somata was greater than along masseter somata (38% vs. 28%). In both populations, the largest terminals were associated with extensive subsynaptic cisterns and postsynaptic accumulations of granular endoplasmic reticulum. Other terminals contained typical symmetric or asymmetric contacts. Occasionally, boutons along the soma and proximal dendrites of masseter neurons were associated with prominent subsynaptic bars. In spinal cord motor neurons, these structures have been shown to be of dorsal root origin. Since this type of specialization is not seen on digastric neurons, it is possible that boutons with subsynaptic bars represent sites of monosynaptic input from the trigeminal mesencephalic nucleus. Supported by NIH, DE06027.

G_2-ACETYLCHOLINESTERASE IS LOCATED ON PRESYNAPTIC TERMINALS OF TORPEDO ELECTRIC ORGAN. L. Anglister, J. Eichler*, I. Silman* and M.K. Gentry*. Anatomy Dept., Hebrew Univ. Med. Sch., Jerusalem, Neurobiology Dept., Weizmann Inst., Rehovot, ISRAEL and Walter Reed Army Inst. Res., Washington, DC 20307

In Torpedo electric organ much of the acetylcholinesterase (AChE) is a globular dimer (G_2), anchored to the plasma membrane via covalently attached phosphatidylinositol and solubilized by a bacterial phosphatidylinositol-specific phospholipase C (PIPLC). While the structure of G_2-AChE is well-established, the localization of this form of the enzyme remains unclear. We have previously used selective solubilization by PIPLC combined with immunocytochemistry at the light microscope level, and shown an accumulation of G_2-AChE at synaptic sites. In order to define more precisely the subcellular location of G_2-AChE in Torpedo electric organ, a similar strategy was applied at the electron microscope level. Thin sections of electric organ were labelled with various antibodies to Torpedo AChE followed by gold-conjugated second antibodies, before or after exposure to the phospholipase. To test the resolution of the technique, antibodies against Torpedo acetylcholine receptors were employed. As expected, they bound to the postsynaptic face of electric organ synapses. Immunolabelling of AChE was detected in the synaptic clefts concentrated on both pre- and postsynaptic faces. Prior exposure to PIPLC significantly diminished labelling of the presynaptic nerve terminals. The results support our previous assignment, based on biochemical evidence and immunofluorescence, for a neuronal synaptic localization of G_2-AChE in Torpedo electric organ. (Supported by grants from BSF and Bruno Goldberg Foundation to L.A., Minerva Foundation to I.S. and Israel Acad. Sci. to L.A. and I.S.).

QUANTAL ANALYSIS OF ENDOGENOUS EXCITATORY POST-SYNAPTIC CURRENTS (EPSCS). Guosong Liu & J.L. Feldman. System Neurobiology Laboratory, Dept. Kinesiology, UCLA, Los Angeles, CA 90024-1527.

Quantal analysis can reveal important aspects of synaptic transmission. However, it is difficult to do quantal analysis in CNS neurons due to poor signal/noise ratio and lack of understanding of quantal variance. To solve these problems, we obtained whole cell patch clamp recordings in spinal cord motoneurons in the *in vitro* brainstem-spinal cord of neonatal rat (Liu & Feldman, Neurosci. Abs. 16:1184 '90), which allowed very low noise recording of EPSCs. This noise was further reduced by a novel filtering technique which allowed the removal of almost all background noise. In order to insure a complete space clamp of the EPSCs, only those recordings in which EPSCs had a very fast rise time (~0.5 ms) were selected for analysis. Under these conditions, we observed a quantal amplitude distribution of EPSCs consistent with an underlying quantal release process. The amplitude, location and variance of quantal peaks were determined by maximum likehood estimate procedure. The interval between the peaks in the amplitude distribution was ~10 pA. The mean EPSC amplitude ranged from 25 to 100 pA.

In order to analyze the origin of quantal current variations, synaptic currents were simulated based on channel kinetics associated with excitatory amino acid receptors. The experimentally observed quantal amplitude variations appear largely due to statistical properties of the channels. Therefore, we applied non-stationary noise analysis to each group of quantal currents to determine single channel conductance, number of channels, and probability of channel opening under endogenous EPSCs associated with synaptic drive to phrenic motoneurons. We found the smallest quantal synaptic current was due to activation of ~20 channels with single channel conductance ~30 pS. In summary, our results represent a novel approach for quantal analysis in CNS neurons and new insights into quantal release mechanisms *in situ*. Supported by NIH Grant NS 24742.

532.2

THREE POTASSIUM CHANNELS IN RAT NERVE ENDINGS. K. Bielefeldt, J.L. Rotter, M.B. Jackson. Dept. of Physiology, University of Wisconsin, Madison, WI 53706.

Voltage-dependent K channels determine the shape and duration of action potentials. Presynaptically, they influence transmitter release by limiting depolarization and, thereby, Ca influx through voltage-sensitive Ca channels. We used single channel techniques to study the K channels in cell-attached patches of nerve endings from rat posterior pituitary slices. In nominally symmetrical potassium, 3 K channels could be distinguished on the basis of channel conductance and kinetics. The most frequently observed K channel had a conductance of 21 pS, and inactivated rapidly (tau: 18 ms). A second K channel had a larger conductance of 110 pS, and inactivated more slowly (tau: 82 ms). A third K channel with a slope conductance of 16 pS activated slowly and did not inactivate during a 300 ms depolarization. An excellent correspondence was exhibited between the properties of these three K channels and the various components of macroscopic K current recorded in tight-seal whole-terminal experiments. Thus, the biphasic inactivation kinetics and complex voltage dependence of activation in macroscopic current can be explained in terms of the underlying behavior of three different K channels. The importance of voltage dependent K current inactivation in action potential broadening and frequency dependent facilitation suggests a physiological role for these K channels in synaptic plasticity.

532.3

CALCIUM CURRENTS RECORDED FROM PRESYNAPTIC TERMINALS IN THE CHICK CILIARY GANGLION. H. Yawo and A. Momiyama*. Department of Physiology, Kyoto University Faculty of Medicine, Kyoto 606, Japan.

The properties of calcium currents of vertebrate presynaptic nerve terminals were studied under whole-cell voltage clamp. Large calyciform presynaptic terminals of the chick ciliary ganglion were identified by fluorescence, dextran-tetramethylrhodamine applied to the cut end of the presynaptic oculomotor nerve 5 hrs prior to the experiment. When whole-cell recordings were made simultaneously from both the presynaptic terminal and postsynaptic ganglion cell, an EPSP (or EPSC) could be elicited by activation of presynaptic calcium currents. There was no evidence for the existence of low-threshold calcium currents in the presynaptic terminal. The high-threshold calcium current was potentiated by a dihydropyridine agonist, Bay K 8644. The potentiated calcium current as well as the control calcium current was irreversively suppressed by ω-conotoxin GVIA (ω-CgTX). However, 20-50 % of the control calcium current were resistant to 10 μM ω-CgTX. The ω-CgTX-resistant component was not sensitive to Bay K 8644.

These results suggest that in the chick ciliary calyx, there are at least 2 components of high-threshold calcium currents: the one component is sensitive to both Bay K 8644 and ω-CgTX, and the other is insensitive to both.

ALTERATION IN MICROFILAMENT ORGANIZATION OF BOVINE ADRENAL CHROMAFFIN CELLS DURING MASTOPARAN-EVOKED EXOCYTOSIS. K.Kumakura[1], T.Sakurai[2*], M.-O.Imaizumi[1*] and Y.Nonomura[2*]. [1]Life Science Inst., Sophia Univ. and [2]Dept. Pharmacol., Univ. of Tokyo, Japan

Mastoparan, a tetradecapeptide from wasp venom, is known as a nonspecific secretagogue for a variety of cells. Using a real-time monitoring technique, we found that pulsatile stimulation of bovine adrenal chromaffin cells with mastoparan evoked the transient secretory response with a biphasic dose-response curve. By persistent stimulation with 3-7 μM mastoparan, continuous release of catecholamines with a constant magnitude was evoked till withdrawal of mastoparan. These secretagogue action of mastoparan was completely independent of Ca^{2+}. By use of FITC-phalloidin and immunofruorescence method, we observed that subplasmalemmal microfilamental network was disrupted during mastoparan-evoked exocytosis either in the presence or absence of Ca^{2+}. Such disassembly of microfilamental network was also observed during nicotine-evoked exocytosis. These results suggest that mastoparan is a useful tool to study cellular mechanism for exocytosis.

532.5

INCREASE OF EXTRACELLULAR K^+ TO 10-12 mM ABOLISHES EXCITATORY SYNAPTIC TRANSMISSION BETWEEN CEREBELLAR NEURONS IN TISSUE CULTURE. W. Raabe. Neurology, VA Med. Ctr., Depts. Neurology, Physiology and Neuroscience Graduate Program, University of Minnesota, Minneapolis, MN 55417.

Increased extracellular K^+ (K_o^+) has been reported to affect axonal conduction and possibly synaptic transmission. To investigate the effects of increased K_o^+ in further detail, whole cell patch voltage clamp recordings were obtained from large (>20 μm φ) cerebellar neurons, presumably Purkinje cells, grown in primary dissociated tissue culture. An unpolished patch pipette was used to stimulate small nearby cells (<10 μm φ), presumably granule cells, to evoke monosynaptic EPSCs.

Normal extracellular solution contained 5 mM K^+. Increases of K_o^+ to 10 mM reversibly abolished the evoked EPSCs in most cells. In those cells, in which 10 mM K_o^+ did not abolish the EPSC, 12 mM K_o^+ abolished the EPSC. When increased K_o^+ abolished the evoked EPSC, neurons were still able to generate action currents and to produce spontaneous TTX-independent miniature EPSCs. The abolition of the evoked EPSC was always preceded by a transient increase in spontaneous synaptic activity.

The abolition of excitatory synaptic transmission between cerebellar neurons by K_o^+ 10-12 mM is consistent with a depolarizing conduction block for action potential invasion into presynaptic terminals. This suggests that for the study of transmitter release from neurons it may be best to increase K_o^+ to 8-9 mM to obtain increased spontaneous synaptic activity without blocking transmitter release from presynaptic terminals. In addition, it can be suggested that in those seizures which increase K_o^+ to 10-12 mM, increased K_o^+ may abolish neuronal excitatory synaptic transmission and may contribute to seizure termination.

532.6

INCREASE OF EXTRACELLULAR K^+ ENHANCES AMMONIUM TOXICITY. J. Mortimer and W. Raabe. Neurology, VA Med. Ctr., Depts. Neurology, Physiology and Neuroscience Graduate Program, Univ. of Minnesota, Minneapolis, MN 55417.

NH_4^+ (5 mM) produces a conduction block in presynaptic terminals and interrupts synaptic transmission (J. Neurophysiol. 62:1461, 1989; Soc. Neurosci. Abstr. 16:1015, 1990). This study examines the synergistic action of NH_4^+ and K^+ on synaptic transmission. Whole cell patch voltage clamp recordings were obtained from large (>20 μm φ) cerebellar neurons, presumably Purkinje cells, grown in primary dissociated tissue culture. An unpolished patch pipette was used to stimulated small nearby cells (<10 μm φ), presumably granule cells, to evoke monosynaptic EPSCs.

NH_4^+ 5-6 mM or K_o^+ 10-12 mM abolished evoked EPSCs. Mixtures of NH_4^+ plus K_o^+ abolished evoked EPSCs when the sum of $NH_4^+ + K_o^+$ exceeded 10-12 mM. NH_4^+, K_o^+ and $NH_4^+ + K_o^+$ abolished EPSCs without affecting action currents or TTX-independent spontaneous EPSCs. Before affecting EPSCs, NH_4^+, K_o^+ and $NH_4^+ + K_o^+$ always increased spontaneous synaptic activity.

Because NH_4^+ acts synergistically with the depolarizing effect of increased K_o^+ to abolish evoked EPSCs, it can be inferred that NH_4^+ has in cerebellar neurons (like in spinal neurons) the same effect as K^+ and produces a depolarization block for action potentials in presynaptic terminals. The synergistic action of NH_4^+ and K_o^+ on evoked EPSCs also indicates that increases of K_o^+ can make subthreshold concentrations of NH_4^+, e.g., 3.5 mM, toxic to neurons. Thus, increases of K_o^+ enhance the toxicity of NH_4^+ on the CNS.

532.7

FREQUENCY-MODULATION OF SYNAPTIC EFFICACY IN EMBRYONIC RAT SPINAL CORD SLICE CULTURE. Chr.Lüscher, J.Streit, H.P.Clamann and H.R.Lüscher, Department of Physiology, University of Berne, Switzerland

Frequency-dependent alterations of synaptic efficacy are believed to functionally determine neural networks during embryonic development. We looked for evidence for such a mechanism during the development of synaptic connections between DRG-cells and motoneurons in an organotypic co-culture of spinal cord, DRG and muscle. EPSPs and IPSPs were recorded from motoneurons during stimulation at different frequencies of DRG-cells, using conventional intracellular electrodes. A depression in amplitude by up to 100% of EPSPs and IPSPs and an increase in latency by roughly 1ms was found, when the frequency was increased by the factor 10 (range 0.1-10Hz). The decrease in amplitude showed the same quantal steps as were seen with amplitude fluctuations at constant frequency of stimulation. In addition, steps of multiple quanta were consistently found, suggesting a propagation failure at a higher order in the arborisation, leading to quantal events switched off in groups. Reducing extracellular Ca^{++} from 5mM to 1mM shifted the frequency-dependence of these effects towards higher frequencies. When action potentials invading DRG somata after stimulation of their central axons were investigated using the same frequency protocols, an increase in latency (17-35%) and its variance as well as the appearance of partial and complete failures were observed. These effects were again less pronounced with a reduced Ca^{++}-content of the perfusion-solution. From these findings it is concluded that synaptic depression is of presynaptic origin, and that there is strong evidence for a conduction failure in axonal arborisation as a underlying mechanism.

532.8

EFFECTS OF PYRETHROID INSECTICIDES ON SYNAPTIC FUNCTION J.T. Eells, J.M. Propp* and P.A. Holman* Dept. of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226.

The neuroexcitatory actions of two toxicologically distinct classes of pyrethroid insecticides were characterized in rat brain synaptosomes using ^{3}H-tetraphenylphosphonium to measure membrane potential and measuring the release of ^{3}H-acetylcholine (^{3}H-ACh). The type II pyrethroids, deltamethrin (E_{max} 25 mV depol.; EC_{50} 10^{-8} M), cypermethrin (E_{max} 24 mV depol.; EC_{50} 10^{-7} M) and fenvalerate (E_{max} 17 mV depol.; EC_{50} 10^{-6} M) elicited concentration-dependent, tetrodotoxin (TTX)-sensitive plasma membrane depolarizations which were specific for the neurotoxic pyrethroid isomer. These pyrethroids also elicited TTX-sensitive release of ^{3}H-ACh. These data support a stereoselective interaction of type II pyrethroids with the voltage-sensitive sodium channel producing sodium influx, synaptic membrane depolarization and neurotransmitter release. In contrast, the type I pyrethroids, allethrin and tetramethrin, produced profound synaptosomal depolarizations (>100 mV) that were not blocked by TTX and were apparent when the plasma membrane was depolarized (135 mM K^+). These type I pyrethroids also evoked TTX-insensitive increases in ^{3}H-ACh release. These findings suggest that the neuroexcitatory actions of type I pyrethroids are not mediated by an action on the voltage-sensitive sodium channel and may involve a disruption of calcium homeostasis and mitochondrial depolarizaton. GABA VIA PRESYNAPTIC $GABA_B$ RECEPTORS INHIBITS EXCITATORY POSTSYNAPTIC POTENTIALS IN NEONATE RAT SYMPATHETIC PREGANGLIONIC NEURONS. S. Y. Wu*, S. L. Dun*, C. Ren*, N. J. Dun and A. G. Karczmar. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699 and Hines VA Hospital, Hines, IL 60153.

Nerve fibers and a few small diameter cells immunoreactive to GABA antisera were observed near the lateral horn of the rat spinal cord. The effects of GABA and baclofen on the synaptic activity of sympathetic preganglionic neurons (SPNs) in neonate rat thoracic spinal cord slices were evaluated with intracellular recording techniques. Superfusion of GABA (25-100 μM) and (-) baclofen (1-10 μM) consistently depressed the excitatory post-synaptic potentials (EPSPs) evoked by dorsal root stimulation, without causing a significant change of membrane potential or input resistance of the SPNs nor the depolarizations induced by pressure applications of glutamate. GABA and baclofen also eliminated spontaneously occurring EPSPs. The synaptic depressant effects of GABA and baclofen were antagonized by the $GABA_B$ receptor antagonist 2-OH-saclofen (20 μM) but not by the $GABA_A$ receptor antagonist bicuculline (10-50 μM). These results suggest that GABA may be involved in the regulation of transmitter release by acting on presynaptic $GABA_B$ receptors in the lateral horn. (Supported by NS18710)

THE FUSION PORE OPENS BEFORE MEMBRANE LIPIDS MIX WHEN A VIRAL FUSION PROTEIN MEDIATES CELL FUSION F.W. Tse, A. Iwata & W. Almers. Dept. Physiol. & Biophys., U. Washington, Seattle, WA 98195.

We patch-clamped 3T3 fibroblasts expressing HA (the fusion protein of the influenza virus envelope) while they fused to single human red blood cells (RBC). The electrical conductance of the cell-cell connection (fusion pore) was estimated from the membrane capacitance (C) measured with a lock-in amplifier under whole-cell clamp (30°C). The RBC membrane was loaded with dipalmitoyl-phosphatidylethanolamine tagged with Texas Red, so that the diffusion of lipid into the fibroblast could be observed with an image intensifier and later analyzed digitally. When HA was activated by acidification of the external medium, an abrupt increase in C was seen 40 - 350 s later, indicating the opening of the fusion pore. Over the next 40 - 120 s, the pore conductance increased from <1nS to >5nS. Only then could we see fluorescent lipid move into the fibroblast, with lipid flux continuing for >20 min. In one fusion where the pore conductance remained 1 - 3 nS for >2.5 min, <3% of the fluorescent lipid passed into the fibroblast within 6 min. Assuming that only the outer leaflet of the RBC was labeled, this represents a lipid flux of <10,000 phospholipid molecules/s. Clearly the fusion pore must open and dilate before significant lipid mixing can occur. This fits with the idea that fusion begins with the opening of a narrow pore that, initially proteinaceous, only later dilates by the incorporation of lipids (Almers & Tse, Neuron 4, p. 813). Supported by GM-39520.

A NOVEL EFFECT OF OPIOIDS ON SYNAPTIC INHIBITION. V.A. Doze, G.A. Cohen and D.V. Madison, *Department of Molecular & Cellular Physiology, Stanford University School of Medicine, Stanford, California 94305.*

Opioid receptor agonists, such as the stable enkephalin analog, D-Ala^2-Met^5-enkephalinamide (DALA), potently reduce synaptic inhibition of pyramidal neurons in the rat hippocampus as evidenced by a decrease in the evoked inhibitory postsynaptic potential (IPSP). Although DALA has been shown to directly hyperpolarize and to reduce the action potential discharge of interneurons, it is not known whether these are the mechanisms for its disinhibitory action.

Experiments were performed on 500 μm hippocampal slices from male, 150-250 g Sprague-Dawley rats. Using intracellular and whole-cell patch-clamp recordings and various pharmacological probes, we examined the effect of DALA on: 1) polysynaptic evoked IPSPs, 2) monosynaptic evoked IPSPs (recorded in the presence of the glutamate antagonists CNQX and APV to ensure monosynaptic isolation), 3) monosynaptic spontaneous IPSPs (recorded with KCl and QX-314 in the recording electrode, and CNQX/APV in the extracellular ACSF), and 4) miniature spontaneous IPSCs (recorded with KCl and QX-314 in the recording electrode, and CNQX/AFV and TTX in the ACSF to block action potential-dependent release) to study the synaptic location for the opioid disinhibition.

DALA (10 μM) potently reduced the amplitude of both the polysynaptic and monosynaptic evoked IPSPs by greater than 50%. DALA also reduced the frequency of monosynaptic spontaneous IPSPs by about 50%. However, most interestingly, DALA potently and reversibly blocked the frequency of miniature spontaneous IPSCs by more than 50% without causing any change in the shape of their amplitude distribution. These results show that opioids block the action potential-independent release of GABA from inhibitory interneurons. Thus, the locus of opioid disinhibition may reside in the presynaptic interneuron terminal.

THE ROLE OF CA^{2+} AND NA^+ IN POSTTETANIC POTENTIATION AT THE CRAYFISH NEUROMUSCULAR JUNCTION. R. M. Mulkey and R. S. Zucker, Dept. of Mol. & Cell Biology, Univ. of Calif., Berkeley, CA 94720.

Published evidence suggests posttetanic potentiation (PTP) in invertebrates may be due to intracellular sodium accumulation that occurs during tetanic stimulation. It has been proposed that elevation of intracellular sodium concentration ($[Na^+]_i$) raises intracellular calcium ($[Ca^{2+}]_i$) by release of calcium from internal stores or by calcium entry through Na/Ca exchange. We have elevated $[Na^+]_i$ in presynaptic boutons of crayfish opener muscle using pharmacological and physiological methods while monitoring $[Ca^{2+}]_i$ with the indicator fura-2. Elevation of $[Na^+]_i$ using ouabain (0.5 mM), veratridine (0.5-1.0 μM) or sodium injection through microelectrodes increased $[Ca^{2+}]_i$ at rest by 136 ± 4 nM (N=14), 396 ± 127 nM (N=7), and 430 ± 223 nM (N=7), respectively. This increase in $[Ca^{2+}]_i$ occurred by calcium influx through Na/Ca exchange, as $[Ca^{2+}]_i$ elevation was dependent on external calcium. Loading presynaptic terminals with Na^+ and Ca^{2+} using high K^+ solutions slowed the extrusion of elevated $[Ca^{2+}]_i$ as the decay time for $[Ca^{2+}]_i$ was 12.3 ± 5 min with Na^+ loading and 4.0 ± 1 min without Na^+ loading, as measured in 7 preparations. In 5 preparations elevation of $[Na^+]_i$ during a tetanus, by blocking the Na/K pump with ouabain, increased the posttetanic time constant for decay of transmitter release from 4.4 ± 2 min in normal to 17.3 ± 8.5 min in ouabain and prolonged the decay of $[Ca^{2+}]_i$ from 5.8 ± 8.8 min to 35 ± 18 min. Blocking the Na/Ca exchange with lithium following a tetanic train also prolonged the time constant for $[Ca^{2+}]_i$ decay from 6.5 ± 5.2 min in normal to 15.7 ± 14 min in lithium (N=7). These results suggest PTP is influenced by intraterminal sodium accumulation which slows the rate of calcium removal via Na/Ca exchange. Supported by grant NS-15114.

KINETICS OF Na/Ca EXCHANGE IN RAT BRAIN PRESYNAPTIC TERMINALS. G. Fontana* & M.P. Blaustein. Dept. of Physiol., Univ. of Maryland Med. Sch., Baltimore, MD 21201

^{45}Ca fluxes were measured in rat forebrain synaptosomes in the presence and absence of external Na^+, Na_o. To determine "initial rates" and some kinetic parameters of Na/Ca exchange, 1 to 3 sec incubations were used; uptake was linear for 3 s at $[Ca^{2+}]_o$ = 0.2 mM, but declined after 1 sec at $[Ca^{2+}]_o \geq 0.5$ mM. Virtually all the ^{45}Ca uptake activated by removal of Na_o ($\Delta J_{Ca/Na}$) was internal Na^+- (Na_i-) dependent. $\Delta J_{Ca/Na}$ was measured as a function of $[Ca^{2+}]_o$ at 1 sec, at 37°C: apparent K_{Ca} = 0.25-0.7 mM; $J_{Na/Ca(max)}$ ≈1200-1400 pmol/mg protein x sec (p/mgs); Hill coefficient (n_H) ~1. The Na_i-dependent ^{45}Ca uptake ($[Ca^{2+}]_o$ = 0.2 mM) was inhibited by Na_o with an apparent K_{Na} = 50 mM and n_H ~ -2.6 (1 sec uptake, 37°C). The Na_i-dependent ^{45}Ca uptake was observed in the apparent absence of external and internal K^+; however, raising $[K^+]_o$ from nominal "0" to 5 mM increased the Na_i-dependent uptake in a concentration-dependent manner. After ^{45}Ca loading (≈ 6 nmol total Ca/mg protein, almost all the ^{45}Ca efflux was Na_o-dependent (Na/Ca exchange): ~1100 p/mgs without FCCP; ~1600 p/mgs with FCCP (to release Ca^{2+} from mitochondria and raise $[Ca^{2+}]_i$). Thus, maximal exchanger-mediated Ca^{2+} flux rates in both directions were about 1200-1400 p/mgs at 37°C. With this very large capacity ($J_{Na/Ca(max)}$), the exchanger in nerve endings may play a major role in regulating $[Ca^{2+}]_i$, and may even participate in the termination of transmitter release by rapidly extruding Ca^{2+}.

532.14

LOCALIZATION OF Na/Ca EXCHANGERS IN NEUROMUSCULAR PREPARATIONS BY IMMUNOFLUORESCENCE MICROSCOPY. P.W. Luther*, R.K. Yip, R.J. Bloch, A. Ambesi†, G.E. Lindenmayer†† and M.P. Blaustein. Physiol. Dept., U. MD Med. Sch., Baltimore, MD 21201 & †Pharmacol. Dept., Med. U. SC, Charleston, SC 29425.

Ion flux measurements reveal a large-capacity (high maximal flux) Na/Ca exchanger in vertebrate nerve terminals. We used polyclonal antibodies raised against dog heart sarcolemmal Na/Ca exchanger to localize the exchanger in neuromuscular preparations by immunofluorescence microscopy. This antibody recognizes the major polypeptide of the Na/Ca exchanger (MW ≈ 160 kD) in immunoblots of dog heart and rat skeletal muscle and brain. In frozen sections through the neuromuscular junction (nmj) of rat skeletal muscle, the antibody, but not preimmune serum, labelled junctional regions more intensely than nearby extrajunctional areas. In fixed and detergent-permeabilized Xenopus nerve and muscle co-cultures, the antibody labelled the nerves in a punctate fashion, suggesting that the exchanger is distributed heterogeneously. Labelling was observed where the nerve traversed the muscle as well as in nearby regions of axons not in contact with muscle. At nmj's where the nerve had been torn away from the muscle, the labelling remained associated with the neuron. The nmj was not labelled with preimmune serum. Specific labelling of muscle could not be detected. We conclude that the Na/Ca exchanger is present at high concentrations in presynaptic regions of the nmj, where it likely contributes to Ca homeostasis.

REDUCTION OF SLOW CHOLINERGIC EPSPs IN THE HIPPOCAMPUS OF AGED RATS. L. Taylor and W.H. Griffith. Dept. Med. Pharmacol. & Toxicol., College of Medicine, Texas A&M University, College Station, TX 77843.

Central cholinergic transmission has been proposed to decline as a function of age. We have tested this directly using cholinergic synaptic transmission in the *in vitro* rat hippocampus. Intracellular recordings were made from CA1 pyramidal cells using electrodes containing 2 M K-methyl sulfate. Slow excitatory postsynaptic potentials (slow-EPSPs) were evoked by repetitive stimulation (20 Hz, 500 ms duration) of the stratum oriens in the presence of physostigmine (1μM). Reproducibility was defined as 4-6 identical trains yielding consistent slow-EPSPs. In order to enhance reproducibility, the slow-EPSPs were evoked at membrane potentials of -52 mV to -55 mV. Slow-EPSPs were cholinergic in nature since they were blocked by atropine (0.5 μM). Slices were obtained from male rats (Sprague-Dawley and Fisher 344) from 3 age groups (1-2 months, 8-10 mo, 18-23 mo). The amplitude of the slow EPSPs was reduced in 18-23 mo rats as compared to the other two groups ($p < 0.02$, ANOVA followed by Scheffe's post-hoc test). In 1-2 mo rats, the amplitude was 8.2 ± 1.3 mV, 6.8 ± 1.1 mV for 8-10 mo and 3.5 ± 0.6 mV for 18-23 mo (n=11 for each group). These results suggest a decline in hippocampal cholinergic synaptic transmission with age.

PHARMACOLOGICAL PROFILE OF THE SELECTIVE D_2 DOPAMINE AGONIST, N-0923. D.J. Friedman, D.N. Krause and S.P. Duckles. Dept. of Pharmacology, College of Medicine, Univ. of California, Irvine, CA 92715.

We have previously shown in the rat tail artery that N-0923 activates prejunctional D_2 receptors to inhibit norepinephrine release. However, concentration response curves were complex, such that at concentrations of 10^{-7} M N-0923 no longer inhibited norepinephrine release. When α_2 adrenoceptors were blocked with yohimbine (10^{-6} M), concentration-response curves for N-0923 became monophasic up to a concentration of 10^{-7} M. N-0923 (10^{-7} M) inhibited contractile responses with an EC_{50} of 5.2 x 10^{-9} M and a maximum inhibition of 68 ± 2% and inhibited [^{3}H] efflux with an EC_{50} of 8.6 x 10^{-9} M and a maximum inhibition of 72 ± 3%. Inhibition of both contractile responses and [^{3}H]norepinephrine efflux was blocked by sulpiride confirming a D_2 receptor site of action. At a concentration of 10^{-6} M N-0923 increased baseline contractions as well as [^{3}H] efflux in tissues prelabeled with [^{3}H]norepinephrine, effects which were unchanged in the presence of yohimbine or sulpiride. N-0924, an enantiomer with less potency at D_2 receptors, was equipotent at increasing baseline [^{3}H] efflux indicating a lack of stereoselectivity. These findings suggest that N-0923, at concentrations of 10^{-7} M or higher, blocks α_2 adrenoceptors causing an increase in adrenergic transmitter release. Given the lipophilic nature of these compounds, the increase in baseline [^{3}H] efflux produced by 10^{-6} M N-0923 or N-0924 may reflect a tyramine-like action. *Supported by NIH fellowship MH09902.*

SENSITIVITY OF PREJUNCTIONAL α_2 ADRENOCEPTORS TO THE AGONIST UK14304 DECLINES WITH AGE IN THE RAT TAIL ARTERY. J. Buchholz and S.P. Duckles. Dept. of Pharmacology, College of Medicine, Univ. of California, Irvine, CA. 92717.

Our previous studies have shown that fractional norepinephrine release from adrenergic nerves in the F-344 rat tail artery significantly increases with age. Furthermore, the sensitivity of prejunctional α_2 adrenergic receptors to the antagonists yohimbine or idazoxan also declines with age. We have complemented these studies with the use of the selective α_2 agonist UK14304. This agonist inhibits fractional norepinephrine release as measured by HPLC and electrochemical detection. Our data (table 1) show that there is a significant age related difference in the inhibitory effect of UK14304 on fractional norepinephrine release at each concentration. These findings suggest that the function of inhibitory prejunctional α_2 adrenergic receptors is significantly altered with age in the rat tail artery. This may be one important variable in explaining the age-related increase in stimulation evoked norepinephrine release previously reported.

	% Inhibition of Fractional NE Release by UK14304		
Age in Months	UK 10^{-8} M	UK 10^{-6} M	UK 10^{-4} M
6	38.4 ± 5.5 *	50.6 ± 5.3 *	60.5 ± 3.5 *
20	7.2 ± 3.2	19.5 ± 5.9	33.6 ± 3.6

* = Significantly different from 20 months, P<0.01.

MULTIPLE TARGETS OF ARACHADONIC ACID IN THE MODULATION OF SYNAPTIC TRANSMISSION. J. E. Richmond, F. Bahls, W. L. Smith* and P. G. Haydon. Dept of Zoology and Genetics, Iowa State University, Ames, IA, 50011.

FMRFamide causes a presynaptic inhibition of synaptic transmission by neuron B5 of *Helisoma trivolvis*. This modulation is due to a coordinate reduction in the calcium current and in the response of the secretory machinery to internal calcium. By voltage-clamping acutely dissociated spherical neurons of B5, we now show that FMRFamide (threshold concentration $3x10^{-8}$M) also increases an outward current. This current reverses around -85 to -90 mV, shows little rectification and shifts by 40-50 mV with a 10x increase in external K^+, consistent with it being a voltage-independent K^+ current.

We have investigated the role of the arachadonic acid (AA) cascade in mediating some of these modulatory actions. Bath application of AA (50μM) increases an outward current that has properties similar to the FMRFamide evoked K^+ current. Furthermore, addition of the phospholipase-A_2 inhibitor BPB (10μM) or the lipoxygenase and cycloxygenase blocker NDGA (10μM) reduces FMRFamides activation of the outward current.

Somata of neurons B5 and B19 form a giant chemical synapse under appropriate culture conditions. We have developed a technique for producing long-lasting asynchronous release of miniature inhibitory postsynaptic currents (MIPSCs) at this synapse by elevating calcium levels through the micro-injection of the calcium cage DM-nitrophen. Under these conditions both FMRFamide and AA (10 and 50μM) cause a reduction in the frequency of MIPSCs in the postsynaptic neuron B19. Addition of AA (but not FMRFamide) also reduces the magnitude of MIPSCs. The effects of BPB and NDGA on the inhibition of secretion by FMRFamide are currently in progress. Taken together these data suggest that the AA cascade mediates some elements of synaptic inhibition produced by FMRFamide.

532.19

SYNAPTIC TRANSMISSION IS ALTERED IN ADULT SHR RATS.
J.C. Magee and G.G. Schofield. Dept. Physiology, Tulane Medical School. New Orleans, LA 70112.

Exaggerated sympathetic nervous activity, due to an increased neuronal excitability, has been implicated in both the development and maintenance of hypertension in the spontaneously hypertensive rat (SHR). However, transmission of high frequency stimuli through the superior cervical ganglion (SCG) of adult SHR is diminished. This suggests that synaptic transmission has been altered during the development of hypertension in SHR. In order to test this various parameters of synaptic transmission were assessed using *in vitro* isolated SCG from SHR, WKY and Wistar rats. Preganglionic stimulation was achieved using a suction electrode on the cervical trunk and fast EPSPs were recorded using standard intracellular techniques. Use of the variance method determined that quantal content was increased, but quantal size was the same in SHR neurons when compared to those from WKY. Short term facilitation, determined from paired stimuli with interpulse intervals of 25-1000 ms, was found to be smaller in magnitude and shorter in duration in SHR neurons compared to WKY neurons. Trains of EPSPs were observed to facilitate less and depress more in SHR neurons when compared to WKY neurons. In low Ca/ high Mg solution these differences were reduced, but not removed. The small amount of depression observed in SHR neurons during paired stimulation in normal solution was eliminated by the low Ca/ high Mg solution. In addition, under these conditions trains of presynaptic stimuli gave rise to EPSPs in SHR and WKY neurons which increased in size throughout. These observations will be discussed in terms of the relationship of sympathetic nerve activity and hypertension. Supported by PHS grant HL 43656.

COMPARISON OF THE ACTIONS OF BACLOFEN AND ADENOSINE AT PRESYNAPTIC RECEPTORS IN HIPPOCAMPAL SLICE CULTURES.
Scott M. Thompson, Helmut Haas, and Beat H. Gähwiler.
Brain Research Institute, Univ. of Zurich, 8029 Zurich Switzerland

We have used intracellular recordings from CA3 cells to characterize the mechanism by which baclofen (BAC) and adenosine (ADO) block synaptic transmission in the hippocampus. BAC, but not ADO, reduced the amplitude of monosynaptic IPSPs (mIPSPs) elicited in the presence of CNQX and D-APV, suggesting that inhibitory terminals do not possess ADO receptors. Both substances reduced the amplitude of isolated EPSPs elicited with mossy fiber stimulation. BAC and ADO produced no postsynaptic hyperpolarization in pertussis toxin-treated cultures, but both substances could still block EPSPs. However, BAC had no effect on mIPSPs. Stimulation of protein kinase C with phorbol ester reduced all presynaptic actions of both BAC and ADO. The postsynaptic hyperpolarization elicited by BAC was also reduced, but the hyperpolarization elicited by ADO was not. Barium (1 mM) blocked the postsynaptic hyperpolarizations elicited by both substances, as well as the action of BAC on mIPSPs. However, both ADO and BAC were able to depress EPSPs in the presence of barium. These results suggest that the presynaptic action of baclofen at inhibitory synapses is the same as the postsynaptic action: an increase in a G-protein mediated, barium-sensitive K^+ conductance, which prevents GABA release by hyperpolarizing the terminals. The actions of baclofen and adenosine at excitatory axon endings must be mediated by some other mechanism.

INTRACELLULAR Ca^{2+} MEASUREMENTS WITH FURA-2 IN PRESYNAPTIC TERMINALS IN BULLFROG SYMPATHETIC GANGLIA.
Y.-Y. Peng and R. S. Zucker. Dept. of Molecular and Cell Biology, Univ. of California. Berkeley, CA 94720.

To investigate the Ca^{2+} dependence of neurotransmitter release in bullfrog sympathetic ganglia neurons, where the preganglionic C fibers release both ACh and LHRH, a method was developed to fill the presynaptic terminal boutons with Fura-2. Fura-2 appears to be transported to the terminal boutons via a fast axonal anterograde transport system, because: 1) the fura-2 signal moved at about 2 mm/hr.; 2) it can be stopped by cooling to 4°C. The filled boutons have diameters of 1-3 μm. The organization of the presynaptic axon and terminal boutons with respect to the ganglionic neurons is similar to that studied by HRP methods. Typically, at least 30 surface cells possessed filled boutons. For a given neuron, up to 50 individual boutons were observed. Fura-2 concentration in boutons was 100-500 μM. Ca^{2+} elevation in synaptic boutons due to a single stimulus to the presynaptic fiber can be detected by a photomultiplier.

Most boutons had a resting Ca^{2+} concentration of ~30 nM. Only when the resting Ca^{2+} was >70 nM, was there spontaneous release of ACh, which was measured as m.e.p.s.p.s. Exogenous LHRH (salmon, 10 μm) caused a decrease of the resting Ca^{2+} in these boutons. For boutons on C neurons, the LHRH receptor antagonist ((D-pGlu[1], D-Phe[2], D-Trp[3,6])-LH-RH, 20 μM) decreased the Ca^{2+} elevation evoked by stimulation to the preganglionic fibers. Supported by NIH grant 15114 to R.S.Z..

RELATION OF PRETERMINAL NODES AND TERMINAL MORPHOLOGY TO DEPOLARIZATION OF THE MAMMALIAN MOTOR NERVE TERMINAL.
S. Shankar[1] and N. Robbins[2]. Departments of [1]Biomedical Engineering and [2]Neurosciences, Case Western Reserve Univ., Cleveland, OH 44106.

The mammalian motor nerve terminal (NT) is thought to be passively depolarized by inward Na^+ current from preterminal nodes of Ranvier. The spacing of nodes, morphology of the NT arbor, and distribution of ion channels in the nerve membrane may affect the depolarization of the terminal, and thus its function. Aged animals, in particular, frequently exhibit NT constrictions that might decrease the current to distal branches. Since direct measurement of the NT V_M is not currently feasible, these issues were approached by morphologic and computer-modelling studies. The shapes of mouse motor NT's and their preterminal axons were determined with vital fluorescent stains. Discrete cable models of these terminals were constructed from the morphologic data and from published work on ion channel density, distribution, and kinetics. Membrane voltages and currents were computed during simulations over a range of electrotonic parameters. The close (30-60 μm) spacing of the preterminal nodes resulted in a high safety factor for conduction, so that NT action potentials (AP's) occurred even after block of Na^+ channels in two preterminal nodes. Decreasing the internodal spacing did not significantly increase the current flow to the terminal, and the measured internodal distances were not correlated with the size or input impedance of the NT. Conduction through the NT was modelled as purely passive. Even for small values of leak resistance (10 Ω-cm²), small NT's were electrotonically compact. However, in large NT's, especially those with constrictions, AP amplitudes declined towards the distal ends. We conclude that preterminal internodal spacing provides safety of transmission, but is not fine tuned to match NT impedance. Also, in the passive case there are inhomogeneities in the depolarization of some NT's. Supported by NIA AG00105-07 and NIA AG08886.

CALCIUM-ACTIVATED POTASSIUM CHANNELS REGULATE SYNAPTIC TRANSMSSION AT THE FROG NEUROMUSCULAR JUNCTION.
R. Robitaille and M.P. Charlton, MRC Group, Physiol. Dept., Univ. of Toronto, Toronto, Canada M5S 1A8.

Transmitter release is steeply related to Ca^{++} concentration. The size of the Ca^{++} transient is modulated by the duration of the presynaptic action potential (AP). We tested the role of Ca^{++}-activated K^+ channels (IKca), in the regulation of transmitter release at the frog neuromuscular junction (NMJ). The motor nerve was stimulated and transmitter release was monitored using intracellular postsynaptic recordings and specific IKca channel blockers. Charybdotoxin (CTX, 2 nM), but not apamin (50 nM), increased release (163.6% ± 58.7%) without affecting MEPP frequency and amplitude. Similar results were obtained in low and normal Ca^{++} concentrations. CTX (2 nM) had no effect on release after a membrane permeant Ca^{++} buffer (DMBAPTA-AM) was loaded in the nerve terminal. This indicates that the toxin acts primarily on Ca^{++}-activated channels. Paradoxically, the intracellular Ca^{++} buffer first induced a transient increase of transmitter release (26.8% ± 6.3%) before the decrease occurred. This increase did not occur when the loading was performed in presence of IKca blockers (CTX 2 nM, Ba^{++} 2 mM) indicating that opening of IKca channels is reduced due to the attenuation of the Ca^{++} transient by the buffer . The early increase of transmitter release did not occur when EGTA-AM, a Ca^{++} buffer with similar affinity as BAPTA but slower forward rate constant, was used. We conclude that IKca channels are an important regulator of synaptic transmission at the frog NMJ, where they cause spike narrowing, and are probably clustered close to the Ca^{++} channels at release sites. Supported by MRC Canada.

NEOCORTICAL EPSP QUANTAL SIZE AND NUMBER ARE INFLUENCED BY POSTSYNAPTIC MEMBRANE POTENTIAL AND PRESYNAPTIC FIRING PATTERN
A.M. Thomson, S. Radpour* and D.C. West*,
Dept. Physiology, Royal Free Hospital School of Medicine, London NW3 2PF, UK.

In slices of adult rat neocortex, single axon epsps due to the firing of one pyramidal cell were recorded from one other, averaged and fluctuations in epsp amplitudes analyzed. These partially NMDA receptor mediated epsps increase in amplitude with postsynaptic membrane depolarization. Standard deviation time course matched average epsp shape at negative membrane potentials (-80mV), but exhibited an additional late component that increased further with depolarization from potentials less negative than -70mV. Altering postsynaptic membrane potential caused no significant change in the number of apparent failures but altered the position of peaks within the epsp amplitude distribution. In contrast, increasing presynaptic firing rate (1-5 spikes/s) greatly increased the proportion of apparent failures. These data support the view that fluctuation analysis of neocortical epsps can indicate whether a change in epsp amplitude is due to pre- or post-synaptic effects.

533.1

SIMULTANEOUS PATCH-CLAMP RECORDING AND CONFOCAL IMAGING OF CA^{2+} INFLUX INTO CA1 NEURONES OF THE RAT HIPPOCAMPAL SLICE. S. Alford,* B.G. Frenguelli* and G.L. Collingridge.* Dept. of Pharmacology, The Medical School, Birmingham University, Birmingham U.K. (Spon: European Neuroscience Association)

Long-term potentiation (LTP) is a long lasting increase in synaptic efficacy induced by tetanic stimulation. In CA1 pyramidal cells of the hippocampus, the induction of LTP is initiated by the activation of NMDA receptors and a postsynaptic Ca^{2+} influx (Collingridge et al 1983; J. Physiol 334, 33-46: Lynch et al 1983; Nature 305, 719-721). Ca^{2+} entry as a consequence of tetanic stimulation has been imaged using FURA-2 but the relative contributions of voltage-operated and ligand-gated Ca^{2+} entry has not been separated (Regehr and Tank 1990; Nature 345, 807-810). By combining whole-cell patch-clamp techniques in slices with confocal laser scanning microscopy of a Ca^{2+} fluorescent dye FLUO-3, introduced into cells through the patch pipette, we have attempted to differentiate, in various subcellular locations, between activation of voltage-operated and ligand-gated Ca^{2+} channels during the tetanus.Tetanic stimulation increases the fluorescence in voltage-clamped dendrites.This effect is blocked by the NMDA receptor antagonist AP5 and shows anomalous voltage-dependence consistent with NMDA receptor activation in the presence of extracellular Mg^{2+}. These data indicate tetanus-induced Ca^{2+} entry into dendrites directly through NMDA receptor channels. In contrast, Ca^{2+} enters the soma during the tetanus under current- but not voltage-clamp, indicating that the Ca^{2+} entry into the soma is through voltage-operated Ca^{2+} channels. In support of this, depolarising voltage steps from -70 to -10 mV caused a marked increase in somatic but not dendritic $[Ca^{2+}]$. The analysis of small areas of dendrite (approx 4 μm long) shows the decay in intracellular $[Ca^{2+}]$ is heterogeneous and oscillates as it returns to baseline levels. This may be due to Ca^{2+}-induced Ca^{2+} release.

Confocal Imaging of Calcium Transients and Whole-Cell Recording from Pyramidal Cells in Area CA1 of Rat Hippocampal Slices. R.J.Adams and T.J.Sejnowski. Computational Neurobiology Laboratory, The Salk Institute, La Jolla, Ca 92037.

Calcium transients are considered to be important mediators of synaptic plasticity in the hippocampus and elsewhere in the nervous system. We are using confocal microscopy to image changes in intracellular calcium ion concentration in pyramidal cells in area CA1 of 400μm thick slices of rat hippocampus. Cells about 100μm below the surface of the slice are recorded from using whole-cell techniques using electrodes of about 5MΩ resistance. The recording electrode filling solution includes fluo-3 as a fluorescent indicator of calcium ion concentration. Low noise electrical recording with simultaneous high temporal- and spatial-resolution imagining can be achieved with this technique.

Synaptic stimulation from axons of the Schaffer collateral/ commissural pathway produces calcium transients in the dendrites and soma of these cells. Changes in intracellular calcium in response to a single excitatory postsynaptic potential, causing the firing of a single action potential, can be detected in the proximal dendrites and soma.

CONFOCAL IMAGING OF CHANGES IN SYNAPTIC STRUCTURE IN LIVING HIPPOCAMPAL SLICES. A. Fine, T. Hosakawa* and T.V.P. Bliss. Dept. Physiol. & Biophys., Dalhousie Univ., Halifax, N.S., Canada B3H 4H7 and Div. Neurophysiol. & Neuropharm., NIMR, Mill Hill, London UK.

Laser-scanning confocal microscopy can be used to obtain submicron-resolution images of synaptic morphology in living hippocampal slices. We have investigated whether such morphologic changes occur in association with changes in physiological function. Synaptic structures are labelled by microinjection of a concentrated oil solution of DiI into the superfused slice; dye droplets are removed after 30 min. Anterograde diffusion of dye permits rapid, and often intense, labelling of dendritic spines and axon terminals. Viability of labelled neurons is assessed by ethidium bromide exclusion. Field potentials from labelled regions are normal, and LTP can be induced by electrical or chemical stimulation. Brief exposure to high concentrations of kainic acid can induce large changes in dendritic shaft and spine morphology; smaller and inconsistent changes can be seen in control slices and after induction of LTP by elevated extracellular calcium.

533.4

ANALYSIS OF THE VARIABILITY OF EVOKED SYNAPTIC CURRENTS DURING LONG-TERM POTENTIATION (LTP) IN HIPPOCAMPAL SLICES P. Renner*, T. Manabe*, D.M. Kullmann*, R.A. Zalutsky & R.A. Nicoll Depts. Pharmacol. and Physiol., UCSF, San Francisco CA 94143.

Quantal analysis of synaptic transmission was originally restricted to a small number of different synapses where the quantal amplitude could be easily resolved. The development of high resolution whole-cell recording techniques raises the possibility of extending this analysis to CNS synapses with small quantal size. These techniques have recently been used to analyze changes in the variability of evoked excitatory postsynaptic currents during LTP (Malinow and Tsien, Nature 346:177, 1990; Bekkers and Stevens, Nature 346:724, 1990). This analysis revealed a decrease in the coefficient of variation (CV), which was interpreted as an increase in transmitter release. We have repeated this analysis using different conditioning paradigms to elicit LTP. We first checked whether the CV analysis could detect some well known pre- and postsynaptic changes in transmission. Manipulations which affect the presynaptic site (applying baclofen, changing the Ca/Mg ratio, paired pulse facilitation), showed the expected change in CV, and the postsynaptically acting glutamate receptor antagonist CNQX had no effect. LTP was induced using low frequency stimulation (0.2 Hz) paired with postsynaptic depolarization (pairing). In 14 cells showing an average two-fold potentiation we saw no change in CV, whereas paired pulse facilitation, which was monitored in the same experiments gave the expected decrease in CV. When a tetanus was used instead of pairing to induce LTP, the results were more variable and, on average, a decrease in CV was observed (15 cells). Since the CV was unchanged, our results favor the hypothesis that LTP induced by low frequency pairing is expressed postsynaptically. This interpretation however depends on several assumptions which may well not apply for synapses onto CA1 pyramidal cells (Korn et al., Nature 350: 282).

533.5

THE EFFECT OF LONG-TERM POTENTIATION ON MINIATURE SYNAPTIC CURRENTS IN HIPPOCAMPAL SLICES. T.Manabe*, P.Renner*, D.Dixon and R.A.Nicoll. Depts. Pharmacol. and Physiol., UCSF, CA 94143.

Brief repetitive activation of excitatory synapses in the CA1 region results in long-term potentiation (LTP) of synaptic transmission in pyramidal cells. While there is general agreement that the induction of LTP occurs in the postsynaptic cell, the site of LTP expression remains controversial. We have used whole-cell recording from guinea pig slices to analyze spontaneous excitatory postsynaptic currents (sEPSCs) before and after LTP. Cells were voltage-clamped at -80 mV and EPSCs were evoked with electrical stimulation of afferent fibers at 0.2 Hz. LTP was induced by pairing 0.2 Hz stimulation with depolarization of the postsynaptic cell to 0 mV for 2.5 min. Presynaptic stimulation alone caused the frequency of sEPSCs to nearly double with little change in size. Following LTP induction, however, a significant increase in the size of sEPSCs was detected in 6 of 7 cells. In a second set of experiments we used a glass pipette, filled with 0.5 M sucrose in normal Ringer, to evoke miniature EPSCs (mEPSCs). This pipette was also used for focal electrical stimulation of afferents. Control mEPSCs and EPSCs were recorded in the absence of tetrodotoxin (TTX). Following LTP induction TTX was added to abolish spontaneous presynaptic action potentials and mEPSCs were again recorded. A significant increase in the size of mEPSCs was observed in 6 of 7 cells. Although we cannot exclude an increase in the amount of transmitter per quantum, a change in mEPSC size is usually interpreted as reflecting a change in postsynaptic sensitivity to the transmitter.

CHANGES IN NEURONAL EXCITABILITY DURING LONG-TERM POTENTIATION. W.D.A. Garner & R.F. Thompson. Neurosciences Program, University of Southern California, Los Angeles, CA 90089-2520.

High-frequency stimulation of the Schaffer axons, often inducing long-term potentiation, decreased the afterhyperpolarization (aAHP and mAHP) associated with the A current and M current. Intracellular recordings from CA1 neurons (Vm = -77 + 2 mV SD; n = 102 cells) showed that the decrease in the aAHP lasted about 30 s and was enhanced by application of 4-aminopyridine and 3,4-diaminopyridine, and by depolarization of the postsynaptic cell immediately prior to high-frequency stimulation. Conversely, when the postsynaptic cell was hyperpolarized immediately prior to stimulation, the aAHP increased in magnitude and the AP duration decreased slightly relative to controls. The decrease in the mAHP lasted significantly longer (at least 75 min). We postulate that suppression of the A current transiently increases $[Ca^{2+}]_{in}$ which, in turn, enhances activation of Ca^{2+}-activated K channels. Overall, CA1 cell excitability decreases during and immediately following high-frequency stimulation of Schaffer axons. Suppression of the M current can increase cell excitability by a mechanism yet to be determined.

AVP-INDUCED POTENTIATION AND DEPRESSION OF EVOKED POTENTIALS IN THE DENTATE GYRUS IS REGULATED BY CALCIUM. C.Chen, R.E.Brinton, T.J.Shors and R.F.Thompson. Neurosci.Prog.,USC,Los Angeles,CA 90089-2520.

Vasopressin (AVP) has been shown to modulate memory process (de Wied, 1984) and the level of NE-induced cAMP formation in rat hippocampus in a Ca-dependent fashion (Brinton & McEwen, 1989). Rat hippocampal slices, maintained at the interface of perfusion solution and a humidified oxygen mixture, were used to assess the effect of AVP on synaptic transmission. Field potentials were evoked by a bipolar electrode in the perforant path and were recorded by an extracellular microelectrode in the granule cell layer of the dentate gyrus. AVP (500 nM) applied in the perfusion solution has been found to have dual effects on response of cells in the dentate depending on the external Ca. In 1.5 mM Ca, AVP potentiated the evoked response as measured by the change of population EPSP slope by 31.4±8.1% (t_7=5.72, p≤0.001). In 2.5 mM Ca, AVP depressed the evoked response by 20±5.2% (t_7=-3.76, p≤0.007). Both the potentiation and the depression occured within 5 min and lasted for more than 30 min after AVP application. Moreover, the changes in EPSP persisted following wash out of AVP. Thus, AVP-induced changes in hippocampal synaptic efficacy are long-lasting and are regulated by external calcium.

INDUCTION OF HIPPOCAMPAL LONG-TERM POTENTIATION (LTP) BY PAIRING WEAK INPUT STIMULATION WITH IONTOPHORETIC K^+ APPLICATION. B.A. Ballyk and J.W. Goh. Department of Pharmacology & Toxicology, Queen's University, Kingston, Canada K7L 3N6.

While postsynaptic depolarization is required for LTP induction in the hippocampal CA1 region, the expression of LTP is at least partly presynaptic. Thus, a retrograde messenger must be involved, and our work suggests a role for K^+. We previously reported that elevating bath K^+ (10mM) during a weak tetanus facilitates the induction of LTP (IBRO abstracts, 1991). It was observed, however, that elevating K^+ in this manner potentiates the response during the K^+ application, raising the possibility that increasing bath K^+ acts at the stimulation site to recruit more fibres, thus converting a "weak" input to a "strong" input. This led to the present studies, in which we increased K^+ by iontophoresis at the synaptic zone, which does not potentiate responses during the exposure period, suggesting a synaptic mechanism for the co-operativity. Population EPSPs were recorded in CA1 region of guinea pig hippocampal slices by stimulation of stratum radiatum. Weak EPSPs (<300μV) failed to exhibit LTP following a 100Hz, 1s tetanus (98±9 % control, 30min post tetanus, n=6). K^+, iontophoretically applied at the site of recording for 10s, did not potentiate EPSPs (104±7 % control, 30min post K^+, n=6). However, delivery of weak tetanus with simultaneous iontophoretic (200nA) application of K^+ resulted in significant potentiation of EPSPs (168±5 % control, 30min post K^+ & tetanus, n=6). Preliminary experiments conducted in voltage clamped CA1 neurons (n=2) suggest that K^+ elevation at the synaptic zone in the absence of postsynaptic depolarization can facilitate LTP induction. We propose that the K^+ efflux from CA1 neurons critical for the induction of LTP is localized to the synaptic zone, possibly resulting from activation of NMDA receptors.

MODERATE CONCENTRATIONS OF POTASSIUM CHANNEL BLOCKERS INTERFERE WITH HIPPOCAMPAL LONG-TERM POTENTIATION. T. Bonhoeffer[1] and C.M. Müller. Max-Planck-Institut für Entwicklungsbiologie and Max-Planck-Institut für biologische Kybernetik, Tübingen, FRG. [1]current address: Max-Planck-Institut für Hirnforschung, Frankfurt/M, FRG.

Several experiments suggest that maintenance of long-term potentiation (LTP) includes mechanisms located remote from the postsynaptic induction site. One possibility to convey signals over some distance is by means of ionic concentration changes. In order to test the hypothesis that shifts in potassium concentrations may be a crucial factor we investigated the effect of the potassium channel blockers teraethylammonium (TEA) and barium (Ba^{2+}) on the induction of LTP in the CA1 region of rat hippocampal slices. We observed that moderate concentrations of TEA (5-10mM) or Ba^{2+} (0.5-1mM) reliably and reversibly prevented the induction of long-term synaptic enhancement following tetanic stimulation. As bath application of these drugs acts on, both, neurons and glial cells, we intracellularly recorded responses of both cell types to afferent stimulation. We observed increased depolarization in pyramidal cells, which should indeed facilitate the induction of LTP. In contrast, the responses of identified astroglial cells were clearly diminished in the presence of TEA or Ba^{2+}. These data accord with the hypothesis that activation of glial cells is an intermediate step in long-term plasticity.

BASAL- VS APICAL-DENDRITIC LTP IN HIPPOCAMPAL CA1 FOLLOWING COMMISSURAL STIMULATION IN THE ANESTHETIZED RAT. **T.Kaibara and L.S.Leung. Depts.of Physiol.and Clin. Neurol. Sci, Univ. of West. Ont., London, Canada.**

In urethane-anesthetized rats, basal- vs apical-dendritic long-term potentiation (LTP) in CA1 was studied following stimulation of the contralateral CA3 and different layers of contralateral CA1 (str.oriens, pyramidale or radiatum/moleculare). Average evoked potentials were recorded at 50 μm depth intervals and analyzed by a one-dimensional current-source-density (CSD) before and at 30-100 min. following a tetanus. Single test pulses evoked excitation(sinks) at both the basal- and apical-dendrites of CA1. Primed burst tetanization(1 pulse followed 190ms later by 10 pulses @ 100Hz) of the contralateral CA1 str. oriens yielded strong basal- (154.6% of baseline ±9.8,n=8) but little apical-dendritic sink LTP (106.9±6.4, n=8) while str. radiatum tetanization gave an unchanged basal-dendritic sink (103.2 ±19.6,n=6) and a depression of the apical-dendritic sink (83.3±7.5, n=6). Tetanization of str. pyramidale yielded a strong LTP of both basal (149.7±18.2, n=7) and apical-dendritic (143.1±15.8, n=7) sinks. Tetanization of CA3 showed a strong basal-dendritic (130.0±14.4) and weak apical-dendritic sink increase (109.0±10.3, n=11). Test responses evoked by CA1 str.radiatum stimulation after the CA3 tetanus revealed heterosynaptic depression of both basal- (75.9±10.5, n=7) and apical-dendritic (72.3±9.9,n=8) sinks. The CSDs indicated that both basal and apical dendrites are activated by hippocampal commissural stimulation, in some cases with more apical- than basal-dendritic excitation. However, the basal dendritic synapse seems to possess a greater propensity for LTP than the apical dendritic synapse, as in the behaving rat(Leung,Neursc.Abs.16:652).Support by Upjohn, NSERC.

HOMOSYNAPTIC LONG-TERM DEPRESSION IN CA1 OF RAT HIPPOCAMPUS *IN VITRO*. M.F. Bear, S.M. Dudek and J.T. Gold*. Center for Neural Science, Brown University, Providence, RI 02912.

A prominent form of synaptic plasticity in cerebral cortex, especially during development, is the weakening of ineffective synaptic inputs. For example, there is evidence in visual cortex that input activity which fails to correlate with postsynaptic depolarization beyond some threshold level leads to the down-regulation of the effectiveness of the active input. We have hypothesized that this "modification threshold" (θm) relates to the levels of postsynaptic response at which a significant NMDA receptor conductance is recruited during synaptic transmission. Further, we have proposed that the value of θm is not fixed, but rather is a function of the history of average postsynaptic activity.

The aim of the present study was to assess whether long-term synaptic depression (LTD) would result from persistent synaptic activation under conditions that are not favorable for recruiting NMDA receptors. The Schaffer collateral → CA1 pathway was investigated using conventional extracellular recording methods in transverse hippocampal slices prepared from adult rats. In attempts to induce LTD, low frequency stimulation (LFS; 0.5 Hz) was applied to the Schaffer collaterals for 15-30 minutes.

In naive slices, LFS produced a significant depression (as assessed using an F-test) in only 2 of 13 attempts. Even so, 9 of the 11 remaining cases showed a reduced response after LFS. The mean change (±SEM) after LFS for the group is -14 ±2%, which is significantly different from pre-LFS baseline values using a t-test. The depression of the CA1 response lasted at least 60 minutes and appeared to be stable. In striking contrast to the naive slices, LFS applied 60 minutes after the induction of LTP produced a significant depression in 6/6 attempts. The mean change in this group is -25 ±4%, this LTD is significantly greater than that observed in the naive slices. These findings suggest that this preparation can be used a model to study the mechanisms of use-dependent synaptic weakening in the cerebral cortex. LONG TERM POTENTIATION INDUCED BY PRIMED BURST STIMULATION IS REDUCED IN HIPPOCAMPAL AREA CA1 OF AGED, LEARNING IMPAIRED RATS. C.I. Moore*, G.M. Rose and M.D. Browning, Dept. of Pharmacology, UCHSC, and Medical Research, VAMC, Denver, CO 80262.

Long-term potentiation (LTP) is a form of synaptic plasticity that is widely thought to underlie certain forms of learning. Aged animals have been shown to exhibit marked deficits in a variety of learning tasks, and such animals also show reduced LTP in the hippocampal dentate gyrus (Barnes, JCPP, 93:74, 1979). In the present study we have focussed on area CA1 of the hippocampus. Specifically we have compared LTP induced by Primed Burst (PB) potentiation (a priming pulse followed 170 ms later by a 4-pulse burst at 200 Hz) in 3 and 24 month old male Fischer 344 rats which had been behaviorally tested in the Morris water maze. PB stimulation closely mimics endogenous patterns of hippocampal activity known to occur in behaving animals. All of the 3 month old animals rapidly learned the location of the hidden platform in the water maze. By contrast, none of the 24 month old rats learned over the 5 day training period. Following behavioral testing, field potentials were recorded from the CA1 pyramidal cell layer in *in vitro* hippocampal slices. Young and aged animals showed similar baseline response amplitudes at similar stimulus intensities. However, the potentiation observed in response to PB stimulation was significantly reduced in the 24 month old group. Subsequent analysis revealed that magnitude of both short-(1 minute post train) and long-(20 minutes post train) term potentiation were less in the old animals. Interestingly, there was no difference between age groups in LTP generated by conventional high frequency stimulation (a 1.0 sec/200 Hz train) delivered 20 minutes after PB stimulation. TIME-COURSE AND PLASTICITY OF RAT HIPPOCAMPAL CA3 PYRAMIDAL CELL RESPONSES TO INPUT FROM RECURRENT COLLATERALS EXAMINED BY WHOLE-CELL RECORDINGS. R. B. Langdon, J. Johnson, and G. Barrionuevo. Departments of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pgh., PA.

Pyramidal cells in the CA3 field of hippocampus make direct excitatory synapses onto each other. We have studied these (1) as a mechanism whereby neuronal activity is synchronized, and (2) because studies of LTP of responses in CA3 depend on discrimination between EPSCs evoked via collaterals and via mossy fibers; the latencies and rise-times of the former have not been well-studied and may provide criteria for such discriminations. To evoke EPSCs via collaterals in CA3b pyamidal cells we applied stimuli to the alveus of region CA3c, with, interposed near the CA3b/CA3c border, a cut extending 125 to 200 μm radially from the alveus. In 5 out of 11 cells, the rising phase (10 to 90%) of the EPSC lasted between 1.4 to 3.0 msec. EPSCs with longer rising phases often exhibited multiple inflections, suggesting temporal dispersion of inputs. The mean latency to EPSC onset was 2.7 msec (S.D. = 0.4, range = 1.9 to 3.2) for CA3b cells which were between 570 and 780 μm from the stimulus site (n = 10). By comparison, direct conduction over this same distance by mossy fibers should require 1.4 to 2.0 msec (at 33° C), based upon the latencies of antidromic responses in *s. granulosum*, evoked by stimulation of the *s. lucidum*. To induce LTP, we applied 100 Hz stimulus trains at least 30 min after break-in, with cells clamped at -70 mV; presumably these conditions resulted only in LTP expressed polysynaptically and not on inputs to the cell recorded. Although late phases of the EPSC exhibited the greatest potentiation, nevertheless, the initial 3 msec of the EPSC was enhanced appreciably. In conclusion, the time-course of responses of CA3b pyramidal cells to inputs from collaterals can be rapid, and activity-induced potentiation of the collateral connections can affect early phases of the EPSC to collaterals. ISOLATED MOSSY-FIBER SYNAPTIC CURRENTS IN CA3 PYRAMIDAL NEURONS. Z. Xiang, A.C. Nobre, and T.H. Brown. Dept. of Psychology, Yale University, New Haven, CT 06520.

The mossy-fiber synapse is particularly suitable for neurophysiological and optical experimentation of plasticity due to its large size and electrotonic proximity to the soma. Because there are many synaptic systems present in the CA3 region of the hippocampus, it is difficult to excite the mossy-fiber synapse selectively when using extracellular microstimulation. For example, if the stimulating electrode is placed either in the stratum granulosum or in the stratum lucidum, it is possible to activate not only mossy fibers, but also fibers of the perforant path, commisural fibers, CA3 recurrent collaterals, and local inhibitory circuits.

We have used previous characterizations of mossy-fiber synapses (Brown & Johnston, 1983; Williams & Johnston, 1991) and our own observations to devise a set of minimal criteria for identifying isolated mossy-fiber excitatory postsynaptic currents (epscs). These include: fast rise time (under 3 ms), voltage independence of the decay time constant, small variability of the epsc latency, and ability to follow high-frequency stimulation. These criteria are not easy to satisfy. Slower currents of unkown origin as well as polysynaptic contamination are much more frequently observed. Using whole-cell recording methods, which has improved our signal-to-noise ratio by a decade, it is possible to dissect more components of evoked epscs. We have noted that small slow currents, which would be below the noise level using intracellular methods, are often evoked in conjunction with currents satisfying the mossy-fiber criteria. Criteria for isolating mossy-fiber epscs should be employed regularly, since failure to obtain pure mossy-fiber epscs may lead to significant interpretational errors. (Supported by ONR and NIH.)

ASSOCIATIVE LONG-TERM POTENTIATION IN THE HIPPOCAMPUS USING ANTIDROMIC STIMULATION AS THE CONDITIONING TETANUS. J. M. Jester and T. J. Sejnowski, Computational Neurobiology Laboratory, Salk Institute, La Jolla, CA 92037.

Associative long-term potentiation (LTP) is a long-lasting increase in synaptic response produced when a stimulus insufficient to cause LTP is paired with a conditioning tetanus. In area CA1 of the hippocampus, associative LTP is mediated by depolarization of the post-synaptic membrane which relieves the Mg^{++} block of the N-methyl-D-aspartate (NMDA) type of glutamate receptor. Can antidromically-elicited action potentials in the soma of CA1 pyramidal neurons depolarize the post-synaptic membrane in dendrites enough to prime the NMDA receptor?

Extracellular field potentials were recorded from 400 µm thick slices of rat hippocampus. The orthodromic test stimulus site (TEST) was in stratum radiatum of CA1 and the antidromic stimuls site (ANTI) was in the alveus. The ANTI site received a train of 50 bursts of 5 pulses at 100 hz with an inter-burst interval of 200 msec. The TEST site received 50 shocks at 5 Hz so that the shocks arrived simultaneous with the bursts to ANTI.

The conditioning stimulation to ANTI when given alone did not produce a change in either population spike or EPSP of the test site (0.0 ± 3.9%, n=6 PS, -5.4 ± 9.6%, n=5 EPSP), nor did the 5 hz stimulation to TEST (-2.5 ± 6.3%, n=11, PS and 0.6 ± 2.7%, n=11, EPSP); however, when the ortho- and antidromic stimulations were paired an increase in the population spike was observed (+24.0 ± 9.4%, n=5) which lasted at least 30 minutes. Application of 2-amino-5-phosphonovalerate (AP5) reversibly blocked this associative LTP. Thus, antidromically stimulated action potentials may invade the apical dendrites of CA1 hippocampal pyramidal cells and provide the depolarization necessary for associative LTP.

CURRENT-SOURCE DENSITY ANALYSIS OF LTP INDUCTION IN HIPPOCAMPAL SLICES. G. Capocchi and M. Zampolini
Clinical Neurology, Univ. Sch. of Med. Perugia. Italy

In a previous study we showed that the Long Term Potentiation (LTP) in the CA1 area of hippocampus was more easily obtained in the proximal portion of Apical Dendrites (pAD) compared to the Distal Portion (dAD). The slope increase was greater in pAD than in dAD. In order to investigate the origin of these differences we performed a current-source density (CSD) analysis before and after LTP induction. The experiments were carried out on rat hippocampal slices maintained in vitro. The stimulating electrode was placed in dAD. The recordings were obtained with two electrodes: one placed in CA1 somatic layer to test the constancy of spike population and the other used to explore, with 50 µm steps, the dendritic tree. The data were stored in the computer and one-dimensional CSD was calculated. The LTP was induced with short burst (4 pulses at 100 Hz), repeated 10 times with 200 ms of interval. In some experiments a 5 sec. of interburst interval was used. The input-output curves were also computed before and after LTP.

The results showed that in some experiments an early sink (ES) in pAD after induction of LTP appeared. Stimulation at 5 sec of interburst interval showed LTP and ES in pAD whereas no modification was observed in dAD. The modification in pAd was not influenced by DL-APV (50 µM) perfusion following LTP induction.

The data suggest that the patterned stimulation inducing LTP modifies the properties of pAD increasing depolarizing currents and support the hypotesis of a second (dendritic) component in the expression of LTP. This modification is not mantained by NMDA receptor.

LONG-TERM POTENTIATION CANNOT BE INDUCED IN THE CA1-FIELD OF THE HIPPOCAMPUS OF MICROENCEPHALIC RATS. Ramakers,G.M.J.[1*], Urban, I.J.A.[1], De Graan, P.N.E.[1], Cattabeni, F.[2], DiLuca, M.[2], and Gispen, W.H.[1]
[1] Rudolf Magnus Institute, University of Utrecht, The Netherlands. [2] Institute of Pharmacological Sciences, Faculty of Pharmacy, University of Milan, Italy.

Injection of methylazoxy methanol (MAM) to pregnant rats produces in offspring a.o. microencephaly, hypoplasia in the cerebral cortex and CA1 field of the hippocampus, disturbances in cognitive behavior and a reduction in the phosphorylation state of the B50/GAP43 protein (a specific substrate for proteinkinase C (PKC)) in the hypoplastic brain areas. Since long-term potentiation in the hippocampus involves a PKC-dependent phosphorylation we decided to examine the hippocampal LTP in slices from the rats with MAM-induced microencephaly (25 mg/kg of MAM injected on day 15 of gestation (G15)) and from control (saline on G15) rats. Field potentials (FPs) were evoked in the pyramidal and radiate layers of the CA1 field or in the granular layer of the dentate gyrus (DG) by stimulating (at 0.1 Hz and 1/2 maximum intensity) either Schaffer collaterals or the perforant path. Glass-electrodes (2 MOhm; filled with perfusing medium) were used for the recording. After 20 min of base-line FPs, a tetanic stimulation (1 sec, 100 Hz) of the same intensity was given. The recording of FPs was continued for the 60 min following the tetanus. The magnitude of the population spike (PS) and the slope of the EPSPs of averaged FPs (every 5 min; n=30) were computed. None of the MAM-treated slices (n=7) exhibited LTP in the CA1 field, whereas control slices (n=7) exhibited after the tetanus a LTP-like increase in FPs (increase of PS by >50% and the slope of EPSPs by 45-50%). In the DG slices from MAM-treated and control rats (n=7) showed a long-lasting (45-50%) increase in the slope of EPSPs. Wether the inability of tetanic stimulation to induce LTP in the CA1 field of the microencephalic rats is due to the profound neuronal disorganisation found in this field of the MAM-treated rats or to abnormal intrinsic properties of the CA1 neurons is currently investigated.

533.18

HETEROSYNAPTIC LONG-TERM POTENTIATION IN THE LATERAL ENTORHINAL CORTEX; AND EXTRA AND INTRACELLULAR STUDY ON THE ISOLATED IN VITRO BRAIN PREPARATION. Marco de Curtis(*) and Rodolfo R. Llinas, Dept. of Physiology and Biophysics, New York University, New York and (*) Dept. Neurophysiology, Ist. Neurologico, Milano, Italy.

A study of the properties of LTP in the entorhinal cortex (EC) (Alonso, de Curtis and Llinas; PNAS; 87, 9280-84, 1990) demonstrated that a non-Hebbian potentiation can be evoked in the layer II neurons by direct manipulating the postsynaptic membrane potential. This potentiation does not require simultaneous activation of the presynaptic fibers, suggesting that postsynaptic mechanisms are operant in this form of LTP. The ability to induce heterosynaptic LTP to a non-tetanized input following a high frequency stimulation of a separate input converging on the same cell population has been described (Bradler and Barrionuevo; Synapse, 4, 132, 1989). Utilizing the isolated brain preparation maintained *in vitro* by arterial perfusion (Llinas, Muhlethaler and Walton; J. Physiol. 414, 16, 1989), we tested both extra and intracellularly the possibility of heterosynaptic LTP induction in the spiny stellate and pyramidal neurons of layer II in the lateral EC. Two separate inputs converging on the apical dendrites of these cells were studied. The EPSPs evoked by both stimulations were characterized pharmacologically. LTP was induced either by a theta-frequency tetanic stimulation of the one input or by intracellular postsynaptic manipulations. In both cases heterosynaptic and non-Hebbian potentiation of the responses evoked by both stimuli were obtained. In contrast, short-term post-tetanic potentiation (or depression) was observed only in the response to the tetanized input. Supported by N.I.H. grant NS13742.

LONG-TERM POTENTIATION AND DEPRESSION OF THE EXCITABILITY OF THE CORTICOSTRIATAL TERMINAL FIELD. M. Garcia-Munoz, S.J. Young and P.M Groves
Department of Psychiatry, University California San Diego, La Jolla, CA 92093-0603.
We have found that long-lasting changes in the excitability of glutamatergic corticostriatal terminals can be induced by tetanic stimulation . Antidromic responses, recorded from medial-prefrontal cortex, were elicited by stimulation of the contralateral corticostriatal terminal field in urethane anesthetized rats. Excitability was assessed by determining the threshold current for antidromic activation of the terminal field before and after tetanization. Tetanizing stimuli (100Hz/250ms, every 6 sec, 5 times) were applied either through the striatal stimulating electrode or near the cortical recording site with a current sufficient to consistently elicit action potentials. Cortical tetanic stimulation typically produced a long-lasting (62 ± 13 min) decrease in excitability (-22 ± 7 %, 6/7 cells). In most cases, the excitability change persisted as long as the recording could be maintained. In contrast, long-term increases in excitability were induced in animals in which dopamine and GABAergic transmission were both disrupted either by 1) pretreatment with alpha-methyl-paratyrosine (AMPT, 250 mg/Kg, i.p) and bicuculline (BIC, 0.5 mg/Kg, i.v.) (26 ± 4%, 56 ± 16 min, n=7), or 2) kainic acid (KA) lesions combined with haloperidol (HAL, 0.1mg/Kg, i.v.) pretreatment (11 ± 2 %, 88 ± 38 min, n=4) or 3) AMPT combined with KA (11 ± 1%, 69 ± 22 min, n= 5). However administration of HAL with BIC or disruption of either neurotransmitter system alone produced variable effects. These results suggest that long-term decreases in excitability occur with marked activation of cortical glutamatergic afferents when GABA and dopamine transmission are intact. If both inhibitory inputs are reduced, long-term increases in excitability may be induced presynaptically. Interestingly, direct application of tetanizing pulses to the striatal terminals typically increased excitability (5/7 cells, 12 ± 2%, 48 ± 6 min) in untreated rats. Striatal administration of AP-7 (10μM) blocked this effect (3/4 cells) suggesting the involvement of NMDA receptors. Similar to other systems, corticostriatal afferents appear to express long-term decreases and increases in excitability. The relative levels of activity in inhibitory and excitatory striatal afferents and postsynaptic elements may determine the occurrence and direction of the long-lasting excitability change. This work was partially supported by grants from NIDA and the Office of Naval Research.

LONG-LASTING MODIFICATION IN SYNAPTIC EFFICACY AT PRIMARY AFFERENT SYNAPSES WITH NEURONS IN RAT SUPERFICIAL SPINAL DORSAL HORN. R. Cerne, M.C. Jiang* and M. Randic. Dept. of Vet. Physiology and Pharmacology, Iowa State University, Ames, IA 50011.

Although a great deal is known about long-term potentiation (LTP) in the brain, the existence of a similar synaptic plasticity at primary afferent synapses has not been demonstrated, as yet. We have investigated the excitatory synapse between small primary afferent fibers (Aδ and C) and neurons in the superficial laminae (LI-III) of spinal dorsal horn (DH) using intracellular recording from dorsal horn neurons in a transverse slice preparation of rat (25-39-days-old) spinal cord. Single electrical stimuli applied to the dorsal root evoked monosynaptic and/or polysynaptic excitatory postsynaptic potentials (EPSPs) in all DH neurons. Both types of EPSPs were blocked (n=13) by a new non-NMDA receptor antagonist 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo (F) quinoxaline (NBQX, 0.5-1.0μM for 2-4 min) indicating that a non-NMDA subtype of glutamate receptor mediates most of the fast EPSPs. However, the participation of a slower NMDA receptor-mediated component has also been shown. The depolarizations evoked by L-glutamate and L-aspartate were depressed by only 15-60% in the presence of NBQX (1-10μM). Brief, high frequency electrical stimulation of primary afferent fibers (100 Hz, 1s) produced a long-lasting potentiation of primary afferent-evoked EPSPs that appeared to be monosynaptic. In addition, in several cells a long-term depression of monosynaptic excitatory transmission was elicited. The results demonstrate that distinct and long-lasting changes in synaptic efficacy can be induced by high-frequency stimulation of primary afferents and that these may be physiologically relevant for transmission and integration of sensory information, including pain. IDENTIFICATION OF A REGION WITHIN GLUTAMATE RECEPTOR SUBUNITS THAT CONTROLS CALCIUM PERMEABILITY. R. Dingledine, R.I Hume and S.F. Heinemann. Molecular Neurobiology Lab., The Salk Institute, La Jolla, CA 92037.

The glutamate receptor clones, GluR1 and GluR3, when transcribed and expressed individually or together in Xenopus oocytes, assemble into receptors that exhibit marked inward rectification and calcium permeability in response to kainate. Co-assembly of either subunit with GluR2, however, results in a receptor with a linear kainate i-v curve and greatly reduced calcium permeation (Hollmann et al., Science 1991). We have constructed subunit chimeras and point mutations to locate sites controlling the permeation characteristics of these glutamate receptors. A key residue was identified, R607 in GluR2 and its equivalent, Q612, in GluR3 (numbered from the initiator Met). Interconversion of amino acids at this position in GluR2 and GluR3 switched their phenotypes. Thus, GluR2(R607Q) expressed alone was active in contrast to the parent GluR2, which showed little activity, and GluR2(R607Q) behaved functionally like GluR3 in that its i-v curve displayed marked inward rectification in normal (high Na) solutions. In solutions containing low Na and high Ca or Ba, this construct responded to kainate with an inwardly rectifying current. Conversely, GluR3(Q612R) had a GluR2 phenotype since it was inactive when expressed alone but when co-expressed with GluR1 or GluR3 assembled into a receptor with linear i-v curve in normal solutions and outward Goldman rectification in low Na, high Ba solutions. Other mutants of GluR3 around position 612 produced similar but not identical effects. These findings suggest that the region identified is in or near the ion permeation path, and is an important determinant of ion permeability through non-NMDA receptor channels.

GLUTAMATE RECEPTOR CHANNEL KINETICS IN EMBRYONIC *DROSOPHILA* MYOTUBES
H. Chang* and Y. Kidokoro Jerry Lewis Center, UCLA School of Medicine, L.A., CA 90024

Glutamate receptor channel kinetics were studied in embryonic *Drosophila* myotubes formed in culture. There were many brief events together with prolonged events. Long openings were interrupted by brief closures, thus showing bursting behavior. The burst histogram was fitted with three exponentials, the brief, intermediate and long component. The mean duration of long bursts increased with the glutamate concentration. The closed time histograms within and between long bursts were fitted with two exponentials at low concentrations and three at high concentrations.

The concentration dependent change in the burst duration, the mean duration and the relative amplitude of the long closed time component were fitted with a set of rate constants in the four state cooperative model in which two glutamate molecules bind to the receptor and open the channel. Generally, the scheme well predicted these changes but there were systematic deviations from the basic scheme.

THE DIVERSITY OF NON-NMDA CHANNELS REFLECTS THE DIVERSITY OF DIFFERING SUBSETS OF HIPPOCAMPAL NEURONS. C-M. Tang and Q-Y. Shi*. Dept. of Neurology, Univ. of Penn., Phila. PA.

Electrophysiological recordings from single non-NMDA channels suggest that there is a diverse group of channels. The diversity is exemplified by the widely varying single channel conductances, open times, Kd, and desensitization kinetics. In an attempt to categorize these channels into distinct subsets we have also found that cell morphology to be one more useful parameter. Channels obtained repeatedly from a single neuron show characteristics that are strongly conserved when compared to channels obtained from a neighboring but morphologically dissimilar neuron. This association is less rigid but still present when channels from different but morphologically similar neurons are compared. The diversity of non-NMDA channels and their association with specific subsets of neurons may reflect different roles that these neurons serve within the hippocampus.

534.4

THREE CLASSES OF KAINATE ACTIVATED CHANNELS ARE PRESENT ON CULTURED MOUSE FOREBRAIN NEURONS.
C. Poulopoulou and L.M. Nowak. Department of Pharmacology, Cornell University, Ithaca, NY 14853.

Excitatory amino acid (EAA) receptors are broadly classified as NMDA and nonNMDA types. Functional separation of the numerous nonNMDA receptors coupled to ion channels has proved difficult because of poor pharmacolological tools. Recent molecular biology studies indicate a large diversity nonNMDA EAA receptor channels which is likely to underly the diversity seen in electrophysiology. Thus, we are continuing our efforts to characterize nonNMDA receptor-channels by measuring biophysical properties of kainate (5-200 μM) activated channels in outside-out patches excised from mouse forebrain neurons grown in dissociated cell culture for 10-35 days. Recording solutions contained (in mM): 150 NaCl, 2.5 KCl, 1.0 $CaCl_2$, 10 Hepes - Na (pH 7.2) and 300 nM tetrodotoxin. Pipettes (3-5 MΩ) contained (in mM): 145 CsCl, 4 ATP-Mg, 10 EGTA/1$CaCl_2$ and 10 Hepes-K(pH 7.2). Three different channels populations were identified. Most patches contained more than one channel type, but some patches, showing mainly one class were obtained for all 3 populations. The brief ($\tau \sim 0.8$ ms) 30-40 pS channel appeared to desensitize rapidly. The 12-14 pS channel openings were interrupted by brief closures (τ_1 = 20-30 ms; τ_2 = 0.5 - 0.8 ms from noise). The 1 pS conductance (estimated from noise variance) had a main τ of 20-40 ms (90% to 98% of the power density). 1 pS and 12-14 pS channels were activated by kainate, domoic acid, and Br-willardiine. The 12-14pS channel was more sensitive to inhibition by CNQX than the 1pS channel. Supported by NS 24467 to LMN.

534.5

NON-STATIONARY CURRENT-VARIANCE ANALYSIS OF GLUTAMATE RECEPTOR-MEDIATED EPSCs AT THE MOSSY FIBER-GRANULE CELL SYNAPSE. S.F.Traynelis, R.A.Silver*, and S.G.Cull-Candy*. Department of Pharmacology, University College London, Gower Street London WC1E 6BT.

We have exploited the excellent temporal resolution of electrical recordings from cerebellar granule cells to examine the mean unitary conductance underlying both non-NMDA and NMDA receptor-mediated components of EPSCs recorded in response to stimulation of presumed mossy fiber axons. A classically slow decaying (τ = 57ms) NMDA component could be recorded in 10μM bicuculline/3μM glycine/0mM Mg^{++}; rapidly decaying non-NMDA EPSCs (τ = 1.4ms) were studied in isolation using 10μM bicuculline/15μM APV/10μM 7-Cl-kynurenate. An exponential function with τ constrained to that of the average EPSC timecourse was fitted to each individual EPSC, and the fitted decay subtracted. The resulting record was divided into sections, the variance for each section summed over all EPSCs within a given cell, and baseline variance subtracted. The unitary current (i) and number of channels (N) were calculated by fitting the current-variance (I,σ^2) relationship with $\sigma^2 = iI - I^2/N$. Mean unitary conductances of 11.4 ± 1.3 pS (n = 4 cells) and 41.8 ± 6.0 pS (n = 5) were found for non-NMDA and NMDA receptor-mediated EPSCs (respectively), which represent the weighted means for all channels participating. Confidence intervals for measurements of unitary conductance underlying fast EPSCs were estimated from unfiltered EPSCs simulated by summing simultaneous conductance steps of random, exponentially distributed durations. Analysis of the current-variance plots from these simulated currents for different numbers of summed channels (10-150), numbers of EPSCs (30-150), and decay times (τ = 0.25-2.0ms) resulted in 95% confidence intervals ranging between ± 5.6 and ± 10.5%.

NMDA-MEDIATED SINGLE CHANNEL CURRENTS FROM MAMMALIAN BRAIN RECONSTITUTED IN ARTIFICIAL LIPID BILAYERS. F. Wirtz-Brugger*, S. Auerbach, L. Wheeler* and C. Wilmot. Dept. Biol. Sci. Rutgers Univ. Piscataway, NJ 08855 and Hoechst-Roussel Pharm. Inc., Somerville, NJ 08876.

Ligand-gated single channel activity was recorded from rat brain membranes reconstituted into phospholipid bilayers formed on the tips of patch electrodes. Using cesium as the charge carrying ion, the reconstituted receptor exhibited properties of the NMDA receptor complex. Addition of NMDA (20 μM to 100 μM) to the pipette solution produced channel openings. With glycine (10 μM to 100 μM) and strychnine (1 μM) present along with NMDA, channel conductance was 55 pS. The gating of this channel was independent of voltage in the absence of Mg^{++}. Addition of 100 μM Mg^{++} resulted in increased channel bursting and voltage dependency of opening. Addition of the NMDA antagonist MK801 (100 μM) completely blocked channel opening. This method provides an opportunity to study the effects of the NMDA receptor-channel complex under tightly controlled experimental conditions. (Supported by PHS RR 007085-23).

LOCAL ANESTHETIC AND PROTON BLOCK OF ACH-EVOKED CURRENTS IN RAT PARASYMPATHETIC NEURONS. T.J.Nutter*, J.Cuevas* and D.J. Adams, Dept. of Pharmacol., Univ. of Miami Sch. Med., Miami, FL 33101

The dose- and voltage-dependence of local anesthetic (procaine, QX222) and proton (H^+) block of ACh-evoked currents was investigated in cultured parasympathetic neurons dissociated from rat intracardiac ganglia. Whole-cell currents evoked by 100 ms pulses of ACh applied from a pressure ejection pipette were recorded with a patch pipette containing (mM): 140 NaCl or CsCl, 2 MgATP, 2 Na_4BAPTA, 10 HEPES-NaOH, pH 7.2. The external pH was varied in some experiments using histidine buffer. Bath application of procaine or QX222 reduced ACh-evoked current amplitude in a voltage-dependent and reversible manner. An e-fold reduction in current amplitude occurred with ~120 mV hyperpolarization in the presence of 100 μM QX222. The effect of the local anesthetics on the time course of ACh-evoked currents was most apparent as a prolongation (~50%) of the decay phase at -80 mV. The dose-reponse relationships obtained for procaine and QX222 at -80 mV gave K_d's of 1 μM and 30 μM, respectively. The K_d's obtained for local anesthetic block of the neuronal ACh receptor-channel are an order of magnitude lower than found at the frog motor endplate (J. Physiol. **268**,291; **277**,153). Changes in external pH alter both ACh-evoked current amplitude and time course of decay. Both the current amplitude and half-time of decay were maximal at pH 8.0 and declined at acid and basic pH. The reduction in ACh-evoked current amplitude at acid pH suggests a titratable ionic group with a pKa of ~6.7. At pH 6.5, a 30% increase in the rate of decay of ACh-evoked currents was observed independent of membrane potential. Changes in external pH did not alter the reversal potential for ACh-evoked currents, indicating no measurable proton permeability. Taken together, the higher affinity of local anesthetics and H^+ for neuronal ACh-activated channels may be related to differences in the primary structure between the neuronal and muscle nicotinic receptor-channels.

534.8

METHYLLYCACONITINE (MLA) IS A POTENT ANTAGONIST OF NICOTINIC ACETYLCHOLINE RECEPTORS (nAChR) ON RAT HIPPOCAMPAL NEURONS: WHOLE-CELL PATCH-CLAMP STUDIES. M. Alkondon[1], S. Wonnacott[2] and E.X. Albuquerque[1]. [1]Dept. Pharmacol. & Exp. Ther., Univ. of Maryland School of Medicine, Baltimore, MD 21201; [2]Dept. Biochem., Univ. Bath, Bath, England.

MLA, an alkaloid isolated from the seeds of *Delphinium brownii* has been shown to antagonize the nAChR of insect, nematode and mammalian tissues. Recent studies showed that MLA is able to inhibit the binding of [^{125}I]α-BGT from the rat brain membranes with high affinity (*FEBS Lett.*, **270**: 45, 1990). We have earlier demonstrated nicotinic responses in tissue cultured neurons of embryonic rat hippocampus (*FEBS Lett.*, **222**:63, 1987), which were sensitive to α-cobratoxin (*Eur. J. Pharmacol.*, **191**: 505, 1990). In the present study using the whole-cell patch-clamp technique, we tested the ability of MLA to inhibit nAChR responses of fetal rat (17-18 day gestation) hippocampal neurons grown in culture for 2-5 weeks. MLA (50-1000 pM) elicited a concentration-dependent inhibition of currents evoked by either ACh or (+)anatoxin-a with an IC_{50} of ~150 pM. However, NMDA-evoked currents were unaffected by MLA up to 100 nM. The block of nicotinic currents was observed within 2-10 min of perfusion of the neurons with MLA, and was completely reversed by washing within 10-20 min. Current-voltage plots indicated a voltage-independent effect of MLA from -100 mV to +80 mV. The ability of MLA to antagonize the nicotinic currents in hippocampal neurons and the ability of the same to inhibit α-BGT-binding in several preparations are in accordance with the concept of the existence of an α-BGT-sensitive nAChR in these neurons. POINT PROCESS ANALYSIS OF FROG ENDPLATE SINGLE CHANNEL CURRENTS. N.G. Castro*, E.F. Nobre*, and Y. Aracava, Lab. Mol. Pharmacol. II, IBCCF, UFRJ, RJ, Brazil 21941; Dept. Pharmacol. Exp. Ther., Sch. of Medicine, Baltimore, MD 21201.

Methods based on the theory of stochastic point processes were applied to the study of the temporal pattern of activation of endplate channels. Single channel currents activated by acetylcholine (ACh, 0.4-2.0 μM) were recorded from enzymatically dissociated muscle fibers with cell-attached patch clamping. Recordings started within 2 min of the initial exposure of the patch to ACh, allowing us to observed the relaxation to steady-state of slow desensitization. The digitized records were searched for opening transitions, which were taken for point events in time. The series of inter-openings intervals (IOIs) were statistically analyzed in order to characterize the structure of the underlying point process. This analytical approach depicted two main features of the receptor-channel desensitization process: i) a decreasing trend in the frequency of openings, the rate of which increased with ACh concentration, and ii) a tendency for openings to occur in clusters of bursts, also directly concentration-dependent. When several channels contributed to the currents, the trend could be fit by maximum likelihood, assuming a non-homogeneous Poisson model. In addition, expectation density function estimates showed evidences of tong term ($\approx$1 min) dependency between openings suggestive of a coupled regulatory process. Support: FINEP/UMAB Mol. Pharmacol. Training Program, CAPES & CNPq; U.S. Army Med. Res. & Devel. Comm. Contr. DAMD17-88-C-8119.

ION CHANNEL BLOCKADE BY OXIMES AND RECOVERY OF SOMAN-POISONED DIAPHRAGM MUSCLE IN VITRO. J.E.H. Tattersall. Biology Division, Chemical Defence Establishment, Porton Down, Salisbury, Wilts. SP4 OJQ, UK.

Oximes, which reactivate inhibited acetylcholinesterase (AChE), are used to treat poisoning by organophosphorus anticholinesterases. Some oximes, however, can produce neuromuscular recovery even when the inhibited AChE has aged and is no longer available for reactivation. I have tested the possibility that this "direct" recovery may be due to ion channel blockade.

The recovery produced by oximes and non-oxime analogues was measured in soman-poisoned guinea pig diaphragms in vitro. This was compared with their blocking activities on nicotinic receptor ion channels at the endplates of dissociated mouse muscle fibres.

There was a strong correlation between several parameters of ion channel blockade and the degree of direct recovery in diaphragms over the range of 12 compounds tested. Those which caused the greatest recovery produced a very rapid, flickering type of open channel blockade. Furthermore, the threshold concentrations for direct recovery and channel blockade were very similar.

The results are consistent with oxime-induced neuromuscular recovery from soman poisoning in vitro being due to ion channel blockade.

MAPPING OF THE LIGAND BINDING SITE OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS USING CHIMERIC SUBUNITS.

C. W. Luetje, M. Piattoni and J. W. Patrick. Division of Neuroscience, Baylor College of Medicine, Houston TX 77030.

A family of genes has been identified which encodes subunits of neuronal nicotinic acetylcholine receptors (nAChR). The α2, α3 and α4 subunits can each form functional nAChR when expressed in *Xenopus* oocytes in pairwise combination with either the β2 or β4 subunits. Each αβ subunit combination has unique pharmacological properties. α2β2 is insensitive to blockade by neuronal bungarotoxin (NBT) (IC50>1μM), and is more sensitive to nicotine than to acetylcholine. In contrast, α3β2 is highly sensitive to NBT blockade (IC50<10nM), and is less sensitive to nicotine than to acetylcholine. Amino acid residues involved in NBT and nicotine sensitivity were mapped by generating a series of chimeric subunits composed of portions of α2 and α3, and co-expressing them with β2 for analysis. NBT sensitivity was localized to a region of α3 between lys84 and ile215. Both chimeric subunits constructed at glu195 of α3 (α2-glu195-α3 and α3-glu195-α2) formed receptors insensitive to NBT, suggesting that amino acid residues involved in NBT sensitivity flank glu195. Chimeric subunit α2-ile215-α3 formed a receptor more sensitive to nicotine than to acetylcholine while chimeric subunit α3-ile215-α2 formed a receptor less sensitive to nicotine than to acetylcholine. Neither chimeric subunit constructed at glu195 (α2-glu195-α3 and α3-glu195-α2) formed a receptor more sensitive to nicotine than to acetylcholine. These results demonstrate that amino acid residues involved in nicotine sensitivity are located between the amino-terminus and ile215, and may flank glu195.

534.12

THE EXTRACELLULAR DOMAIN OF THE NEURONAL NICOTINIC SUBUNIT β4 DETERMINES THE PHARMACOLOGY OF RECEPTORS FORMED WITH α3 Roger L. Papke, Robert Duvoisin*, & Stephen F. Heinemann Molecular Neurobiology Laboratory, Salk Institute, La Jolla CA. 92037

The neuronal nicotinic acetylcholine receptor alpha subunit, α3, forms functional receptors when co-expressed in *Xenopus* oocytes with either β2 or β4 subunits. While the alpha subunits of nicotinic acetylcholine receptors are believed to contain the principle agonist binding sites for activation, in the case of neuronal nicotinic receptors beta subunits also influence receptor pharmacology, as well as the kinetics of agonist binding and channel activation. For example, it has been shown that α3β4 receptors are resistant to neuronal bungarotoxin (n-btx), while α3β2 receptors are blocked by this toxin (Duvoisin *etal.*, 1989). Also, α3β4 receptors are effectively activated by cytisine, while α3β2 receptors have been reported to be 100 fold less sensitive to cytisine than to ACh (Luetje & Patrick, 1991). In order to identify that portion of the beta subunits which may influence agonist and antagonist effects, we have created chimeric beta subunits which contain reciprocal exchanges between the β4 and β2 subunits in the first transmembrane domain. The chimeric subunits were constructed using PCRs to create half subunit pieces that shared a common terminal sequence. A final PCR then used the region of overlap to prime the synthesis of full length chimeric subunits. When β4/2 (β4 extracellular sequence and the remainder β2 sequence) is co-expressed with α3, receptors are formed which are resistant to neuronal-bungarotoxin and are activated equally well by cytisine and ACh. The macroscopic concentration-response relationships of receptors formed with β4/2 also show the higher Hill slope that is typical for β4-containing receptors. Conversely, α3β2/4 receptors are blocked by n-btx, are relatively insensitive to cytisine, and have a lower Hill slope.

DIFFERENTIAL MODULATIONS OF GABA RECEPTOR CHANNEL BY POLYVALENT CATIONS. M.Yan and T.Narahashi. Dept.of Pharmacol.,Northwestern Univ.Med.Sch.,Chicago,IL 60611.

$GABA_A$ receptor channel complex is a multimeric receptor protein with an integral chloride ion channel. We report here that polyvalent cations modulate the GABA-induced chloride current in a differential manner. The currents were recorded from the rat dorsal root ganglion neurons in primary culture by the whole cell patch clamp technique. The mechanisms underlying the modulations were also studied. Among all the cations tested at a concentration of 1 mM, Cu^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+} and Pb^{2+} suppressed the GABA-induced chloride current to different degrees whereas Mn^{2+} and Al^{3+} had no effect. Zn^{2+} and Cu^{2+} were most potent and abolished the GABA response almost completely. La^{3+}, however, increased the response 2-3 fold. The modulations by polyvalent cations were reversible after washing with normal solutions. Suppression by Cu^{2+} and Zn^{2+} and augmentation by La^{3+} occurred in a dose-dependent manner at a holding potential of -60 mV. La^{3+}, Cu^{2+} and Zn^{2+} all exerted their effects in a voltage-independent manner at holding potentials ranging from -80 mV to +60 mV. Competition studies showed that Cu^{2+} and Zn^{2+} did not compete with GABA for a binding site. These data suggest the existence of a cationic regulatory site distinct from the GABA site at or near the external orifice of the chloride channel.

INHIBITORY NEUROTRANSMITTER RECEPTORS PRESENT IN CULTURED RAT MEDULLARY NEURONS. C. A. Lewis and D. Faber, Neurobiology, SUNY at Buffalo, Buffalo, NY 14214.

Whole-cell current responses to bath application of glycine, ß-alanine, taurine, and GABA were studied in medullary neurons cultured from embryonic rats. Two-component responses were evoked by bath application of agonist, one component which desensitized and another which did not. The two current components have different dose-response characteristics with the nondesensitizing component being activated more effectively at lower concentrations than the desensitizing one and also reaching its peak at lower concentrations. For all agonists, the two current components have different strychnine sensitivities, with the desensitizing component being more sensitive. The complete occlusion between the responses to glycine and ß-alanine or glycine and taurine suggest that these agonists activate the same receptors. Taurine and ß-alanine are less potent agonists than glycine with relative potencies of 1: 0.4 :0.1 for glycine: ß-alanine: taurine. On the other hand, there was incomplete occlusion between the responses to glycine and GABA, suggesting that these agonists activate both similar and different populations of receptors. In confirmation, the receptor population activated by either glycine or GABA was blocked by both strychnine and picrotoxin. In conclusion, there appear to be at least 3 populations of inhibitory neurotransmitter receptors--GlyR, GABAR, and Gly/GABAR.

SINGLE-CHANNEL PROPERTIES OF NEWBORN RAT SPINAL CORD GLYCINE RECEPTORS EXPRESSED IN XENOPUS OOCYTES

Quoc Thang NGUYEN*, Andres MORALES* and Ricardo MILEDI, Laboratory of Cellular and Molecular Neurobiology, Dpt. of Psychobiology, University of California, Irvine CA92715 USA

Using the noise-analysis technique, we measured the single-channel characteristics of glycine receptors (expressed in Xenopus oocytes) by heavy (H) and light (L) mRNA isolated from the newborn rat spinal cord (cf.ref.1 & 2). Oocytes were injected with H or L fractions and recorded four to six days after injection. Cells were clamped at -60mV and perfused with 1-2x10-4M glycine in Ringer. Power spectra of newborn L receptors were well fitted by a Lorentzian. The unitary current at -60mV was -0.94+/-0.46pA (mean+/-S.D, n=17), the mean open time tau being 50.9+/-6.3ms, a near three-fold increase over the value found in the adult (ref.2). In oocytes injected with H fractions, some spectra could be fitted by one Lorentzian; in those cases the unitary current was -1.23 +/-0.45ms and tau was 7.7+/-2.4ms (n=9), values identical to the adult.

MOLECULAR CLONING AND FUNCTIONAL EXPRESSION OF A SEROTONIN-GATED ION CHANNEL. A.V. Maricq*, A.S. Peterson*, A.J. Brake*, L. Tecott, R.M. Myers*, and D. Julius*. Depts. of Pharmacology and Physiology, University of California, San Francisco, CA 94143-0450.

Serotonin is a ubiquitous neurotransmitter whose diverse functions are mediated by activation of pharmacologically distinct receptor subtypes. Although most serotonin receptors appear to transduce extracellular signals by interacting with G-proteins, the 5HT3 subtype of serotonin receptor (5HT3R) was recently shown to incorporate a ligand-gated cation-selective ion conductance. We have isolated a functional clone encoding a 5HT3 receptor (5HT3R-A) by screening a neuroblastoma cDNA expression library for serotonin-gated currents in *Xenopus* oocytes. The isolated clone encodes a single protein that has many of the predicted secondary structural features shared by other ligand-gated ion channels (e.g. the nicotinic acetylcholine, GABA-A, and glycine receptors). When the cloned receptor is expressed in oocytes, the pharmacological and electrophysiological characteristics of the serotonin-gated current are largely consistent with the known properties of the 5HT3R. Potent and selective 5HT3R antagonists such as ICS 205-930 block the serotonin-gated current at nanomolar concentrations. In agreement with previous reports, the current passes through a non-specific cation conductance that is modulated by the external concentration of divalent cations. However, we also find that I-V plots of the serotonin-gated current display a region of negative slope conductance that is sensitive to the external divalent cation concentration and that resembles the voltage and divalent cation mediated conductance changes observed in the NMDA subtype of excitatory glutamate receptor.

NORADRENERGIC α_1 RECEPTOR-MEDIATED DEPOLARIZATION OF NEURONS OF THE MEDIAL PONTINE RETICULAR FORMATION OF THE RAT, *IN VITRO*. D.R. Stevens, R.W. McCarley, and R.W. Greene. Neuroscience Lab., Dept of Psychiatry, Harvard Med. School and VAMC, Brockton, MA 02401

The medial pontine reticular formation (mPRF) plays an important role in REM sleep and in the startle reflex in waking. Neurons of the locus coeruleus display firing activity inversely correlated to the expression of REM sleep. Noradrenergic neurotransmission is important in behavioral state control and influences the appearence of REM sleep. The action of norepinephrine (NE) on neurons of the mPRF was examined in rat brain slices *in vitro* using intracellular electrophysiological methods.

Application of NE to mPRF neurons results in a depolarization of 74% of the neurons tested (n=28). NE is mimicked by the α_1 agonist phenylephrine (PE, n=19). NE and PE inward currents were accompanied by a decrease in membrane conductance. The reversal potential of the inward current elicited by PE corresponded to that of K^+ and was sensitive to alterations of K^+_o in a Nernstian manner. The current-voltage relation recorded during voltage ramp commands indicates a strong voltage-dependence of the PE sensitive current. The conductance change elicited by PE is greater at depolarized membrane potentials. The mechanism of the PE induced conductance change is under study.

These results support the conclusion that NE acting at α_1 receptors causes a decrease in potassium conductance. The potassium conductance(s) involved in the action of NE has not yet been identified.

REGULATION OF Ca^{2+} RESPONSES TO ENDOTHELIN-1 BY VOLTAGE- AND RECEPTOR-GATED Ca^{2+} CHANNEL ANTAGONISTS AND DRUGS ACTING ON PHOSPHOLIPASE C AND PROTEIN KINASE C. J. Chan and D.A. Greenberg. Department of Neurology, University of California, San Francisco, CA 94110.

Endothelin-1 (ET-1, 5 nM) produced biphasic (transient peak and sustained plateau) elevations of free intracellular Ca^{2+} (Ca^{2+}_i) detected by fura-2 fluorescence in NG108-15 neuroblastoma x glioma cells. Both peak and plateau responses were attenuated by depletion of extracellular Ca^{2+}. Peak responses were also reduced by the putative receptor-gated Ca^{2+} channel antagonist SK&F 96365 (30 μM), while plateau responses were abolished by 100 nM nimodipine. The phospholipase C (PLC) inhibitor U-73122 (1 μM) and the protein kinase C (PKC) activator phorbol 12-myristate 13-acetate (PMA, 1 μM) reduced peak responses by 80% and 35%, respectively, compared to responses in the presence of the inactive analogs U-73343 and 4α-PMA. In Ca^{2+}-depleted buffer, both U-73122 and PMA abolished peak Ca^{2+}_i responses, while the PKC inhibitor staurosporine (100 nM) increased peak responses by 250%. These findings suggest that peak Ca^{2+}_i responses to ET-1 result from influx of Ca^{2+} through receptor-gated channels and PLC-activated mobilization of intracellular Ca^{2+}, and are inhibited by PKC, while plateau responses involve influx of extracellular Ca^{2+} through dihydropyridine-sensitive, voltage-gated channels.

DOMAIN STRUCTURE OF THE INOSITOL-1,4,5-TRISPHOSPHATE RECEPTOR. G. A. Mignery*, C. L. Newton* and T.C. Südhof Howard Hughes Medical Institute, Department of Molecular Genetics, UT Southwestern Medical Center, 5323 Harry Hines Blvd., Dallas, TX 75235

The inositol-1,4,5-trisphosphate ($InsP_3$) receptor is composed of a homotetramer of highly conserved 313Kd subunits which contain eight membrane spanning regions in the COO-terminal fourth of the protein. The structural features of the receptor were examined by mutagenesis and transient expression in COS cells. Deletion of the eight transmembrane regions resulted in the expression of a soluble, monomeric protein which binds $InsP_3$ with an affinity and specificity similar to the wild type receptor. This data indicates that the membrane spanning regions are essential for subunit tetramerization but do not contribute to the ligand binding site and that each receptor subunit contains an independent ligand binding domain. To identify the sequences composing the ligand binding site COO-terminal deletion mutants were constructed. $InsP_3$ binding analysis on the truncated receptor proteins showed that the ligand binding region resides in the NH_2-terminal fourth of the receptor subunit which is separated from the putative Ca^{2+}-channel by over 1400 amino acids. Gel filtration experiments demonstrate a large conformational change of the receptor as a function of ligand binding suggesting a mechanism by which ligand binding might cause channel opening. Taken together, these results allow each receptor subunit to be divided into a NH_2-terminal ligand binding domain, a central coupling/regulatory domain and a COO-terminal cluster of membrane spanning regions which interact to form the receptor homotetramer and the Ca^{2+}-channel.

ION CHANNELS: CELL FUNCTION

535.1

EXPRESSION OF CONNEXIN26 GAP JUNCTION CHANNELS IN CELLS WITH NEURONAL PHENOTYPE. B. Eghbali*, J.A. Kessler, M. Dougherty*, H. Hsu*, M. Chanson*, and D.C. Spray. Einstein Coll. Med., Bronx, NY 10461

Connexin26 (Cx26) is an abundant gap junction protein in the developing nervous sytem; in the adult brain it is confined to specific cell types (e.g., pinealocytes and leptomeningeal cells) and is usually coexpressed with other connexins. To define the properties of Cx26 we stably transfected pc12 cells (a well-characterized, communication-deficient neuronal system) with Cx26 cDNA, using a plasmid containing a dexamethasone (dex)-inducible promoter and the selectable marker *neo*. G418-resistant colonies were injected with Lucifer Yellow and four dye coupled colonies were separated for further analysis. Whereas mRNA encoding connexins 32, 43 and 26 were not detectable in the parental cell line using Northern blot analysis, two bands (presumably elongated transcripts including portions of the vector) were found to hybridize to the Cx26 probe in the transfected colonies. Immunofluorescence using connexin-specific antibodies failed to reveal connexins 26, 32 or 43 in the parental line, but in the single transfected clone thus far analyzed, punctate Cx26 immunoreactivity was prominent. Junctional conductance was barely detectable in the parental line (0.03±0.03 pS; n=19) but was moderate in dex-treated transfectants (4.0±0.8 nS; n=41). Two populations of unitary junctional events were detected in Cx26 transfectants after dex treatment, <100 and >175 pS; because the latter event was seen in an untransfected dex-treated pc12 cell pair and in a pair of untreated pc12 transfectants, we attribute the smaller event to channels formed by the introduced Cx26. The stable expression of Cx26 in a well-coupled cell line in which neuronal phenotype can be induced should allow biophysical analysis of Cx26 and illuminate the role of gap junctions in neuronal differentiation and function.

EFFECTS OF METABOLIC INHIBITORS ON INSECT MUSCLE: A COMPARATIVE STUDY OF DIPTERA AND LEPIDOPTERA. E.M. Fitzgerald and M.B.A. Djamgoz.* Dept. Biol., Imperial College, London, SW7 2BB, U.K.

Work on insect muscle has shown that Diptera have a ouabain-sensitive Na^+/K^+-ATPase, whilst Lepidoptera have a ouabain-insensitive K^+-pump. Using K^+-selective microelectrodes, we have quantified the effects of various metabolic inhibitors on membrane potential (E_m) and intracellular K^+ activity (aK_i) in skeletal muscle of Phormia terranovae (Diptera) and Spodoptera exigua (Lepidoptera). The following inhibitors were used: dinitrophenol, cyanide, azide, rotenone, dicyclohexylcarbodiimide, salicylhydroxamic acid, ouabain, ethacrynic acid, vanadate, amiloride. Each inhibitor (conc. 1mM) was applied for 60 mins. at R.T. (20°C) and E_m and aK_i recorded continuously from different cells (20-50 cells; 5-7 insects).

Most inhibitors caused significant reduction of aK_i ($p < 0.001$) apart from ouabain and amiloride, which were ineffective in Spodoptera and Phormia, respectively. Strong inhibition by vanadate was common to both insects, suggesting that both have P-type ATPases. However, differences in ouabain and amiloride sensitivities suggest the molecular structures of the two pumps are different. All inhibitors except ouabain, caused significant depolarisation of E_m ($p < 0.001$). For a given species, the inhibitor profiles of aK_i and E_m were largely similar, implying that changes in E_m and aK_i are closely linked.

THE PERINEURAL WAVEFORMS AFFECTED BY DINOFLAGELLATE *PTYCHODISCUS BREVIS* TOXIN. M.C.Tsai, M.L.Chen*. Department of Pharmacology, College of Medicine, National Taiwan University, Taipei, Taiwan, R.O.C.

The dinoflagellate *Ptychodiscus brevis* induced numerous fish kills and human toxicity. The toxins in the dinoflagellate initially facilitated the transmitter releasing process followed by complete block of the neuromuscular transmission. Brevetoxin-B was one of the toxic component in the dinoflagellate. It increased the MEPP frequency and quantal content of EPP of mouse diaphragm. The effect of the toxin on the ionic currents of the nerve terminal was studied by the perineural waveform recordings of adult I.C.R. mouse (*Mus musculus* from Institute of Cancer Research). Waveforms were evoked by stimulating the motor nerve bia a suction electrode every 2-30 s with supramaximal pulses of 0.05 ms duration. At lower concentration (0.11 μM), brevetoxin-B increased the sodium and potassium currents of nerve terminal while it decreased the calcium activated potassium current and slow calcium currents of the nerve terminal. At this concentration, the toxin had no effect on the fast calcium current and slow potassium currents. At higher concentration (1.11 μM), the toxin decreased all of the perineural waveforms on the nerve terminal. The effect may contribute to the human toxicity of the dinoflagellate. (Supported by a grant, NSC080-0412-B002-13Z, NSC, ROC).

REGIONAL DISTRIBUTION OF ION CHANNELS IN A CULTURED CRUSTACEAN PEPTIDERGIC NEURON. D. E. R. Meyers and I. M. Cooke. Békésy Lab. of Neurobiology and Dept. of Zoology, University of Hawaii, Honolulu, HI 96822.

A subpopulation of neurons isolated from the X-organ of the tropical land crab (*Cardisoma carnifex*) and grown in primary culture in defined medium are reactive against crustacean hyperglycemic hormone (CHH) antisera. When plated with a neurite, a large lamellipodium forms (PNAS 86:402, 1989). Regular firing and bursts of action potentials can be recorded. Under whole-cell voltage clamp, Ca, Na and two types of K current can be isolated (Graf & Meyers, Meyers & Graf, FASEB J. 4:1200; 1201, 1990). The conductances resident in isolated somata and lamellipodia after 24 h in culture have now been examined. Conventional "whole-cell" patch-clamp recordings were made from somata and lamellipodia which had been separated by severing the neurite (internal and external solutions as previously).

Somatic and lamellipodial I_{Ca} were similar. From a V_h of -40 mV, the I(V) curve is without notches and shifting V_h from -40 to -80 mV has little effect on maximal I_{Ca}. Decay was slow and incomplete. In paired-pulse experiments in somata, the relation between test-pulse current amplitude and prepulse potential was U shaped. In contrast, lamellipodial test current did not recover with large depolarizing prepulses. I_{Na} was best developed in lamellipodia. Comparison of I_{Na} in somata with their lamellipodia showed that peak somatic I_{Na} was less than 30% of lamellipodial I_{Na} (at 0 mV, V_h = -40 mV). K current similar to I_A and I_K was observed in both regions. I_A was half-inactivated at -46 mV and inactivation was removed with a τ of 30 ms. The I(V) relations for I_K, and V_R measured in either region were similar. I_A was sensitive to 4-AP (6 mM) and I_K to TEA-Br (100 mM). As in intact cells, 4-AP was sometimes associated with an increase in I_K (FASEB J. 4:1200). The data suggest that voltage-dependent K channels with similar properties are distributed throughout the CHH neuron. Ca channels are also similar except that lamellipodial I_{Ca} is not enhanced by large prepulses. Na channels appear to be preferentially located in the distal neurite and/or lamellipodium. Supported by grants from the Whitehall Foundation, NSF BNS89-10432 and NIH G12RR03061.

GRADED AND REGENERATIVE POTENTIALS IN NORMALLY NONSPIKING STRETCH RECEPTOR NEURONS IN A SAND CRAB. D.H.Paul and J.Bruner. Biology Department, University of Victoria, Victoria BC V8W 2Y2

Electrical responses in the four dendrites forming the telson-uropod stretch receptor of *Emerita analoga* were triggered by stretch of the elastic receptor strand or by intracellular current injection. Investigations of three types of isolated receptor-ganglion preparation [intact neuron, isolated distal segment (DS), similar segment isolated from the receptor strand (DSWS)], using conventional two-microelectrode current clamp, revealed that the four neurons are not identical in all of their electrical properties. 1) Active responses to stretch do not normally occur, but in saline with 50mM TEACl (substituted for NACl) stretch triggers a regenerative potential out-lasting the stimulus; this potential is abolished in Cd^{2+} (1mM) and is not observed in DS. 2) Both DS and DSWS of all four dendrites show linear I/V relations between -120 and -30 mV (MP = -60 to -65 mV) and delayed rectification (abolished by 50 mM TEA^+) above -30 mV. 3) In dendrites III and IV depolarization triggers a fast, graded, TTX-sensitive potential which is not made regenerative by potassium channel blockers (50 mM TEA, 5 mM 4-AP). This transient is very small or absent from dendrites I and II. 4) In dendrite III, but apparantly not in the other dendrites, the transient is followed by a slowly increasing depolarization which develops over several hundreds of milliseconds.

MEMBRANE PROPERTIES AND GABA RESPONSES OF THE CULTURED TRIGEMINAL GANGLION CELLS OF THE MARINE CATFISH, PLOTOSUS. T. OGURA AND S. OBARA*, Dept. Physiol., Teikyo Univ. Sch. of Med., Tokyo 173, Japan

The trigeminal ganglion cells, isolated and cultured for 1-4 days, were examined with the whole-cell recording technique. The action potential showed a hump in the falling phase, with a half-duration of 1.8 ms. TEA enhanced the hump when the membrane potential had been shifted to more positive levels. Hence, the TEA-sensitive K current seemed to operate in repolarizing the spike. The spike duration was prolonged with CsCl-filled electrodes, which was reduced by Co2+, both suggesting an involvement of the Ca current. Two types of the Ca current, LVA and HVA, were confirmed. These currents seemed to govern the encoding pattern, with the maximum firing rate reaching only about 70 HZ. Perfusion with GABA of 0.1-1 mM induced inward, mostly Cl, current while glycine had no effect. In some cells, GABA also reduced the Ca current moderately. Thus, GABA might exert presynaptic inhibition directly by hyperpolarization, and also probably by modulation of an intracellular signal transduction, at the proximal endings of the trigeminal nerve.

INTRACELLULAR RECORDING AND STAINING OF TERMINAL NERVE-GNRH CELLS IN A FISH BRAIN IN VITRO. **Y.Oka. Zool. Inst., Fac. Sci., Univ. of Tokyo, Tokyo 113**

We have previously shown in the dwarf gourami that terminal nerve (TN) cells are a major component of the GnRH system and that the TN-GnRH system is structurally independent from the preoptic/hypophysial-GnRH system which facilitates gonadotropin release from the pituitary. Thus, we have hypothesized that GnRH may function as an important neuromodulator (Oka and Ichikawa, '90). A whole-brain in vitro preparation has been developed to facilitate studies on the ionic and biochemical mechanisms of the TN-GnRH neuromodulatory system. In the present study, I examined the spontaneous electrical activity of TN cells using both extra- and intracellular recording techniques and determined the morphology of individual cells by intracellular injections of either Lucifer Yellow or biocytin. TN cells showed endogenous activities of either slow regular beating (1-6 Hz) or bursting patterns according to the physiological conditions (e.g., sexual maturity) of the fish. Anatomical observation of intracellularly-labeled cells revealed multiple axonal branches that projected to those areas where we had previously demonstrated dense GnRH-immunoreactive fibers. The electrophysiological and morphological characteristics of TN-GnRH cells seem to be advantageous for their possible role as a neuromodulator; the intrinsic membrane properties of modulator neurons change according to the animal's physiological conditions, and these modulator neurons in turn modulate neural activities in a wide variety of brain regions simultaneously via multiple axon branches.

THALAMIC FIRING PATTERNS ARE HIGHLY SENSITIVE TO VARIATION IN LOW THRESHOLD CALCIUM CHANNEL: COMPUTER SIMULATIONS OF VOLTAGE AND CURRENT CLAMP EXPERIMENTS. W.W. Lytton and T.J. Sejnowski, Salk Institute, La Jolla, CA, 92037

The low-threshold calcium channel (T channel) is believed to be critical in producing the anode break behavior characteristic of thalamic relay cells. We used computer simulations of Hodgkin-Huxley like models to explore the influence of different models of this channel on responses to simulated current clamp. We first reproduced characteristic current/voltage curves under simulated voltage-clamp using a model of the high threshold calcium channel (L channel) combined with a model of the T channel obtained from either of two sources (Coulter et al., *J Physiol* 1989, 414:587-604; Crunelli et al., *J Physiol* 1989, 413:543-561).

Thalamic cells show a complex variety of responses under current clamp. Characteristic firing patterns include: 1) a single spike on a plateau in response to depolarization from rest 2) repetitive spiking in response to increased depolarization from a depolarized potential 3) a brief burst of spikes as an anode break response following hyperpolarization (Jahnsen and Llinas, *J Physiol* 1984, 349: 227-247). We were able to reproduce these 3 firing patterns using a model that included 8 channels found in this cell type. Firing behavior was highly dependent on the details of the T channel model used and varied widely between the two sets of parameters from the two different voltage clamp studies. These differences may reflect artifactual variation due to the different voltage-clamp techniques or actual differences due to species and developmental stage. Relatively minor channel variations could be exploited in control mechanisms that alter the firing pattern of the cell.

535.9

ESTIMATION OF PASSIVE ELECTROTONIC PARAMETERS USING THE INVERSE FOURIER TRANSFORM TECHNIQUE TO STUDY ETHANOL EFFECTS ON GRANULE CELLS. M. Patil, D. Durand, G.L. Yuen and R. Chintalacharuvu*, Applied Neural Control Lab., Dept. of Biomedical Engineering, Case Western Reserve University, Cleveland, OH-44106.

Accurate estimation of the passive electrotonic parameters of a neuron is essential for understanding the neuronal integration and information processing. The shunt cable model (Durand et al., 1982), which allows for different somatic and dendritic time constants was used to model the dentate granule cells and was modified to include an electrode artifact. The input impedance of the model and its voltage response to a current stimulus were calculated in the frequency domain, converted to the time domain using the inverse Fourier transform, and the parameters were estimated by nonlinear, least-square fitting of the model output to the voltage response to a current stimulus. Optimization of the objective function was obtained using the gradient method (NL2SOL) algorithm. In order to quantify the consequences of acute ethanol treatment on the neurons, parameters such as the input resistance, dendritic and somatic time constants, resistances, and capacitances were obtained before and after exposure to low doses (50 mM) of ethanol and compared.

Intracellular responses to short hyperpolarizing current stimuli (0.5 msec, 2.5/5/7.5 nA) were recorded in 12 cells from hippocampal slices prepared from adult rats. The membrane time constant (τ_m) was found to decrease in ethanol by 24 %, while the somatic time constant (τ_s) increased by 27 %. The electrotonic length also increased in ethanol from (mean ± SD) $L_c = 1.026 \pm .12$ to $L_e = 1.202 \pm .17$, ($p<.05$). Although the mechanism(s) for these changes is unclear at this time, they may influence the neuronal integration in ethanol.

CHOLINERGIC MODULATION OF ENTORHINAL CORTEX LAYER II NEURONS' INTRINSIC EXCITABILITY. A. Alonso and R. Klink. M.N.I., McGill University, Canada. H3A-2B4.

The entorhinal cortex (EC) layer II is the major source of afferents to the hippocampus via the perforant path and receives inputs from the entire cortical mantle. It is also innervated by multiple subcortical structures including notably the cholinergic neurons of the basal forebrain (Alonso and Kohler, J. Comp. Neurol., 1984). By using intracellular recordings in "in vitro" rat brain slices, we have investigated the effects of bath application of the muscarinic cholinergic agonist carbachol (15-50uM) on the two previously described groups of EC layer II neurons: the stellate cells (SCs) and the pyramidal-like cells (PLs) (Alonso and Llinas, Soc. Neurosc., 1990). On the SCs, carbachol induced a modest depolarization, decreased the fast afterhyperpolarization and suppressed cell firing accommodation. It also reduced a subthreshold Na-dependant component of the rebound potential at the break of hyperpolarizing current pulses suggesting a cholinergic modulation of a subthreshold Na-conductance. The Na-dependant subthreshold oscillatory activity characteristic of the SCs also showed a small reduction in frequency and rhythmicity with carbachol. On the PLs, among other effects, carbachol drastically affected the cells firing behavior by inducing a slow rhythmic bursting pattern which was associated with a substitution of the post-train afterhyperpolarizations by long-lasting plateau depolarizations. The results demonstrate a potentially strong influence of basal forebrain cholinergic inputs to the modulation of EC layer neurons' intrinsic excitability by which the processing of incoming neocortical information to the hippocampus will be strongly affected. (Supported by Canadian MRC).

535.11

INWARD AND OUTWARD RECTIFICATION AND SUBTHRESHOLD OSCILLATIONS IN ENTORHINAL CORTEX LAYER II STELLATE CELLS. R. Klink and A. Alonso. MNI, McGill University, Canada H3A 2B4.

The stellate cells from entorhinal cortex layer II display Na-dependent (not Ca) rhythmic subthreshold oscillatory activity that probably underlies the generation of the theta rhythm in this cortical area (Alonso and Llinas, Nature, 1990). By using intracellular recordings in "in vitro" rat brain slices, we have investigated some of the non-linear membrane properties that may contribute to generation of the oscillatory behavior. Following blockage of Na conductances with TTX, analysis of the current-voltage relationships revealed a robust time-dependent inward rectification as well as a fast (non-transient) outward rectification which developed strongly at the oscillatory voltage level. Time-dependent inward rectification could be abolished by bath application of 1-2mM Cs which had little effect on the outward rectification but had no effect on the time-dependent inward rectification. Carbachol (30-60μM), 4-AP (2mM) and Ca-channel blockers Co or CD, had no effect on the non-linearity of the membrane in the oscillatory voltage level. In control ringer solution both Cs and Ba ions almost completely abolished the subthreshold oscillatory activity. The results suggest that in addition to a persistent inward Na-current and a Q-like current, a voltage-dependent K outward current plays a major role in the generation of the rhythmic subthreshold oscillatory activity in entorhinal cortex layer II stellate cells. (Supported by MRC Canada).

535.12

SEROTONIN DEPOLARIZATION OF MOUSE PITUITARY CORTICOTROPE CELLS (AtT-20/D16V). L. M. Konopka, K.M. Braas, J.F. Fiekers and V. May. Dept. Anatomy & Neurobiology., Univ. Vermont College of Medicine, Burlington, VT 05405.

Serotonin (5-HT) is localized to a subset of gonadotrophs in the mammalian anterior pituitary gland (Payette et al., 1985) and elicits ACTH release from dissociated anterior pituitary cells (Spinedi and Negro-Vilar, 1983). In the present experiments the effects of 5-HT were examined on a homogeneous cell line of corticotrophs (AtT-20/D16V cells). 5-HT was applied by pressure ejection onto single AtT-20 cells plated on glass coverslips and maintained in HEPES-buffered solution. 5-HT activated these cells by producing a transient depolarization which could be superimposed upon spontaneous membrane oscillations. The amplitude and duration of the response to 5-HT depended on the pulse duration and did not desensitize. The depolarization was attributed to an increased conductance and exhibited a complex voltage dependence. These results demonstrate a direct excitant effect of 5-HT on AtT-20 cells which may initiate or regulate the release of ACTH. (Supported by NIH grants NS25973, NSF9010044)

535.13

SEROTONIN PRODUCES TRANSIENT AND SUSTAINED ELEVATIONS OF CYTOSOLIC CALCIUM IN FURA-2 LOADED CULTURES OF MOUSE PITUITARY CORTICOTROPE CELLS (AtT-20/D16v) J. F. Fiekers, L. M. Konopka and V. May. Dept. Anatomy & Neurobiol., University of Vermont College of Medicine, Burl., VT 05405.

The actions of serotonin (5-HT) were examined on AtT-20 mouse corticotrope cells. Individual cells were loaded with fura-2/AM and examined for changes in intracellular calcium concentration using ratio fluorescence of fura-2. 5-HT produced a concentration-dependent increase in $\{Ca\}_i$ in more than 80% of the cells studied. The response was repeatable, lasted for minutes, and was characterized by a transient elevation either with or without a plateau. At the peak of the transient calcium elevation, some cells exhibited additional, rapid, repetitive calcium transient responses which were also observed in the absence of extracellular calcium. Twenty percent of the cells in culture exhibited rhythmic spontaneous oscillations of $\{Ca\}_i$ and exposure to 5-HT induced rythmic oscillations of $\{Ca\}_i$ in quiescent cells. 5-HT responses could be superimposed on these oscillations. These results demonstrate that 5-HT increases $\{Ca\}_i$ and may modulate the release of ACTH from corticotropes. (supported by NIH grants NS27319 and NS25973)

535.14

VISCERAL C-FIBER NEURONS ARE HETEROGENEOUS WITH RESPECT TO THE K+ CONDUCTANCES CONTRIBUTING TO ACTION POTENTIAL REPOLARIZATION . E.P. Christian and K.E. Naper. Department of Pharmacology, ICI Americas, Inc., Wilmington, DE 19878.

Visceral C-fiber neurons in the nodose ganglion synthesize and release several tachykinin peptides that may be involved in hyperreactive conditions, such as asthma. Because action potential repolarization is an important locus for the control of transmitter release and repetitive firing, we examined the contribution of different K^+ currents to the action potential. Single microelectrode current- and voltage-clamp techniques were applied to study C-fiber neurons in intact guinea pig nodose ganglia maintained *in vitro*. C-fiber neurons that could not be otherwise distinguished by standard electrophysiological parameters differed with regard to the K^+ conductances contributing to action potential repolarization. Three components were identified: 1) in ~50% of the neurons charybdotoxin prolonged action potential duration to a maximal 160% of control in a concentration-dependent, and Ca^{2+}-sensitive manner (EC_{50} = 22.0 nM; n=10); 2) in ~70% of the neurons a Ca^{2+}-insensitive "A-like" current shortened the duration of the action potential by up to 25%, when it was de-inactivated by hyperpolarizing prepulses negative to -55 mV; and 3) in *all* neurons studied, tetraethylammonium (5-30 mM) increased the action potential duration (50-500%), independent of the presence of Ca^{2+}, or prepulse potential. Thus a Ca^{2+}-dependent, and at least two other voltage-sensitive K^+ conductances appear to be differentially available for action potential repolarization in subpopulations of C-fiber neurons.

LIMITED CORRELATION BETWEEN SYMPATHETIC NEURONE SUBTYPE AND PEPTIDE CONTENT IN GUINEA PIG PREVERTEBRAL GANGLIA. E.M. McLachlan, J.R. Keast and R.L. Meckler, Department of Physiology and Pharmacology, University of Queensland, Qld 4072, AUSTRALIA.

Guinea pig sympathetic neurones can be classified as phasic, tonic or long afterhyperpolarizing (LAH), by their discharge pattern following a depolarizing current step. These patterns result from the expression of different populations of voltage- and calcium-dependent K+ channels. Each neurone type receives a characteristic pattern of synaptic input. The proportions of each type in prevertebral ganglia of young guinea pigs varied rostrocaudally from the coeliac (CG) to the distal inferior mesenteric ganglion (IMG), with tonic cells increasing in the caudal direction (from 15 to 80%) and LAH cells being virtually absent in the IMG. The proportion of phasic neurones was 5-20% in all ganglia.

Colchicine-treated ganglia were stained immunohisto-chemically using antibodies to somatostatin (SOM) and neuropeptide Y (NPY). The proportions of NPY+ (20-40%) and SOM-/NPY- (30-40%) cells varied little between ganglia, although the proportion of SOM+ cells increased caudally (from 20% [CG] to 45% [IMG]). Physiologically-characterized neurones were filled with biocytin and subsequently immunostained. All SOM+ cells in CG were tonic (n=5). However SOM- cells were tonic (n=4), phasic (n=3) or LAH (n=4). There was no correlation between peptide content and neuron type in the IMG (n=14).

535.16

INTRACELLULAR ANALYSIS OF BIOPHYSICAL MEMBRANE PROPERTIES THAT MAY INFLUENCE TRANSMISSION IN THE CALYX-TYPE SYNAPSE OF THE CHICK CILIARY GANGLION. G.H. Fletcher *and V.A. Chiappinelli, Dept. of Pharmacological and Physiological Science, Saint Louis University Medical Center, St. Louis, MO 63104.

In order to determine those ion channels which contribute to the normal functioning of synaptic mechanisms in the chick ciliary ganglion, intracellular recordings were obtained from presynaptic calyx nerve terminals (n=69) and postsynaptic ciliary neurons (n=48). Under current-clamp conditions, depolarizing pulses (0.6-2.0 nA, 65 ms duration) applied to presynaptic calyces more usually elicited a single action potential (amplitude=84.9±1.2 mV, duration = 1.00±0.03 ms), whilst ciliary neurons fired either single or multiple spikes (amplitude=89.0±3.1 mV, duration=1.32±0.06 ms) in response to current steps of lower intensity (0.2-0.8 nA). 1μM TTX totally abolished spike generation in calyces and ciliary cells, suggesting that a fast inward Na^+ current is responsible for the upstroke of the action potential. Bath application of Ba^{2+} (5mM), TEA (10mM) and 4-AP (1mM), which are known to block M-current, the delayed rectifier potassium current and A-current respectively, prolonged spike generation and increased neuronal excitability by decreasing the threshold for action potential generation, when compared to similar current pulses delivered to these cells in normal recording medium. The results are a first step towards identifying those ion channels which are involved in transmission in this parasympathetic ganglion. Supported by NIH grant EY06564 to VAC.

EFFECTS OF AXOTOMY OR TARGET TISSUE ATROPHY ON THE ELECTRICAL PROPERTIES OF SYMPATHETIC NEURONS M. Sánchez-Vives and R. Gallego*. Instituto de Neurociencias, Universidad de Alicante, Spain.

We have studied the electrical properties of rat sympathetic neurons after axotomy or atrophy of their target tissue in an in vitro preparation of the superior cervical ganglion. Cells innervating the submandibular gland were identified by antidromic stimulation in preparations from control animals and from animals in which the gland was atrophied by ligature of the salivary duct three months before. The effects of axotomy were studied 7-10 days after sectioning the postganglionic branches.

The action potential was smaller in axotomized cells (75±1.3 mV, mean±s.e., n=61) and in cells from the atrophy group (76±1.3 mV, n=46) than in control cells (82±0.8 mV, n=157). Axotomy also produced a marked decrease in afterhyperpolarization duration, 89±8 ms against 208±6 ms for the controls. These changes are difficult to interpret because passive properties were also affected: axotomized cells showed a decreased membrane potential and input resistance, whereas this latter property was increased in the atrophy group. (Supported by DGICYT grant PM-89/0021, Spain)

MODELING THE PROPAGATION POTENTIAL, AN EXTRACELLULAR VOLTAGE PLATEAU PRODUCED BY ACTION POTENTIALS. S.E.Fox and A.P.Rudell. Dept. Physiol., SUNY Health Sci. Ctr., Brooklyn, NY 11203.

A propagation potential is recorded between two widely-spaced points outside an axon when an action potential is propagating in it. Between the peak recorded as the action potential passes the first point and the trough as it passes the second, the voltage does not return to zero, but maintains a constant value of the same sign as the initial peak and about one-third its magnitude. This propagation potential may be a general property of axons, since it is recorded from both frog sciatic nerves and earthworm giant axons.

The propagation potential cannot be explained on the basis of K^+ accumulation because TEA causes an increase, not a decrease, in its magnitude. The afterpotentials of earthworm giant axons are too steeply sloped to account for the flat plateau. It is not clear how such a flat plateau could be produced by volume conductor effects, especially since it could be recorded from nerves in air. Simple core-conductor models of axons do not generate the propagation potential. Even with the inclusion of the filtering properties of axon sheaths they do not produce flat plateaus.

Addition of longitudinal resistance gradients *does* produce flat plateaus. Integrated local circuit currents, equal and opposite on the rising and falling phases of the action potential, produce different extracellular voltage drops through the asymmetric longitudinal resistances. If the gradients are fixed in space, the sign of the plateau is reversed relative to the first peak when direction of propagation is reversed. This is not the case in real axons. The only way we have reproduced a propagation potential with a core-conductor model is by incorporating a transient change in longitudinal resistance associated with the passage of the action potential. Such longitudinal resistance changes might be caused by transient changes in the composition or size of the extracellular environment of the axon associated with the passage of the action potential. SUB-TYPES OF SODIUM-DEPENDENT HIGH AFFINITY (SDHA) GLUTAMATE TRANSPORT: I. LOCALIZATION. L.A. Dowd, J.D. Sinor, and M.B. Robinson, Children's Seashore House; Depts. Ped. and Pharm., U. of PA; Philadelphia, PA, 19104.

Evidence for a neuronal localization of SDHA glutamate (Glu) transport includes enrichment in "synaptosomal membrane fractions" and the decreases in uptake observed after neuronal lesions. Autoradiographic studies in primary cultures support a glial localization. Two subtypes of SDHA L-[^{3}H]-Glu transport can be differentiated by the selective inhibitors L-α-aminoadipate (AAD) and dihydrokainate (DHK). Uptake in cerebellum is inhibited by AAD and insensitive to DHK. The opposite pattern is observed in forebrain regions (Brain Res., 544(1991)196). In these studies, the localization of the subtypes of transporters was investigated. Subcellular fractionation of these tissues using discontinuous sucrose density gradients demonstrated that both subtypes were at least 4-fold enriched in the synaptosomal membranes fraction. Little or no transport activity was observed in myelin or mitochondrial fractions. Previous studies have demonstrated that both crude synaptosomal membranes (P2) and synaptosomes can contain significant amounts of glial protein (Brain Res. 101(1976)341). As ß-alanine is a more potent inhibitor of GABA uptake into glia than of GABA uptake into neurons (Biochem. Pharmacol. 24(1975)933), the inhibition of [^{3}H]-GABA uptake by ß-alanine was examined. In P2 preparations and fractionated synaptosomal membranes made from both brain regions, the inhibition of GABA uptake by ß-alanine was consistent with high and low affinity components (30-40% high affinity $p< 0.005$ 2-site fit). These data suggest that the uptake of Glu measured in "synaptosomal membrane fractions" may be glial and/or neuronal.

536.2

SUB-TYPES OF SODIUM-DEPENDENT HIGH AFFINITY (SDHA) GLUTAMATE TRANSPORT: II. ION-DEPENDENCE, PHARMACOLOGY AND REGULATION. J.D. Sinor, L.A. Dowd, and M.B. Robinson, Children's Seashore House; Depts. Ped. and Pharm., U. of PA; Philadelphia. PA, 19104.

Two subtypes of SDHA glutamate (Glu) transport can be differentiated by competitive inhibitors including dihydrokainate (DHK) (see accompanying abs. by Dowd et al.). These subtypes of L-[^{3}H]-Glu transport were characterized. The K_ms for sodium, measured at 50 and 100 μM L-[^{3}H]-Glu, were 5.3 mM in cerebellum and 12 mM in cortex. Of the over fifty EAA analogues tested, only 22 inhibited transport more than 65% at 1 mM. These compounds included EAA analogs that were not previously thought to interact with transport including (numbers in parentheses are IC_{50}'s in μM for cortex then cerebellum) kainate (160; 243), N-methyl-D-aspartate (428; 345), quisqualate (662; 95), D-glutamate (236; 57), and trans (dicarboxyl)-2,4-methanoglutamate (25; 5). Compounds that inhibited less than 65% at 1 mM included: ibotenate, quinolinate and AMPA. Cerebellar and hippocampal slices were transiently depolarized with 30 mM K^+. Following depolarization, the uptake of L-[^{3}H]-Glu was measured in crude synaptosomal membranes. Compared to control (incubation in normal K^+), the V_{max} for uptake was increased 2.1-fold by depolarization in cerebellar slices (DHK-insensitive). There was no change in hippocampus (DHK-sensitive). These data add further support for the differentiation of subtypes of SDHA Glu transport and suggest that these subtypes may be independently regulated. The effect of K^+ may have implications for the vulnerability of different brain regions to excitotoxicity during ischemic insults.

INHIBITORS OF EXCITATORY AMINO ACID (EAA) RECEPTORS COUPLED TO PHOSPHATIDYLINOSITOL (PI) TURNOVER INHIBIT L-[^{3}H]-GLUTAMATE (GLU) UPTAKE. L. Littman, J.D. Sinor, and M.B. Robinson. Children's Seashore House; Depts. Ped. and Pharm., U. of PA; Phila., PA 19104.

EAA receptors are coupled to increased PI turnover. The elucidation of the functional and developmental roles for these receptors is hindered by the lack of high-affinity antagonists. In the current studies, a possible relationship between inhibitors of these receptors and inhibitors of sodium-dependent high affinity Glu transport was investigated. Rat hippocampal slices prepared from neonatal animals were used to measure PI hydrolysis induced by agonists. The uptake inhibitor L-aspartate-ß-hydroxamate (AßHA) was a weak partial agonist with stimulation at 300 µM to 16 ± 4 % (n=5) of the maximal quisqualate response. PI hydrolysis stimulated by 100 µM quisqualate was inhibited up to 64 ± 4 % (n=3) by AßHA with an IC_{50} of 25 ± 6 µM. S-2-Amino-3-phosphonopropionic acid (S-AP3), previously identified as a non-competitive antagonist, has an IC_{50} of 370 µM (Mol. Pharm 38:222-228). Four phosphonocyclohexyl and cyclopentyl analogs of Glu did not inhibit PI hydrolysis (< 25 % at 1 mM). The transport of L-[^{3}H]-Glu was measured in crude synaptosomal membranes prepared from the cortex of adult animals. AßHA and S-AP3 inhibited transport with IC_{50}'s of 11 µM and 110 µM, respectively. As observed for inhibition of PI hydrolysis, the R-isomer was much less active (> 30-fold difference in potency). The cyclic analogs of Glu did not inhibit transport (less than 5 % at 1 mM). These studies support a correlation between potency for inhibition of PI hydrolysis and potency for inhibition of transport.

PHARMACOLOGICAL CHARACTERIZATION OF TYPE I AND TYPE II SODIUM-DEPENDENT EXCITATORY AMINO ACID TRANSPORT SITES. K.J. Anderson and T.W. Vickroy. Departments of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610.

Sodium-dependent transport of excitatory amino acids (EAA) represents the primary means by which these neurotransmitters are inactivated, and may play a role in the prevention of excitotoxicity. D-[^{3}H]Aspartate has been used extensively as a tool to characterize this transport process due to its specificity and high affinity. We have recently described two separate sodium-dependent transporter binding sites based on different sensitivities to L- or D-threo-β-hydroxyaspartate. These two sites are anatomically distinct, being found primarily in the forebrain (Type I) or in the cerebellar molecular layer (Type II). In an attempt to further pharmacologically characterize these two binding sites, we have screened a series of compounds that are thought to interact with EAA systems. Briefly, assays were conducted using 6µm-thick, horizontal sections of rat brain. D-[^{3}H]Aspartate binding (100 nM in 50 mM Tris-acetate with 300 mM NaCl, pH 7.4) was carried out in delipidated sections at 0-2°C. Following rinsing in ice-cold buffer, sections were air dried and either exposed to [^{3}H]-sensitive film or cerebellum and forebrain were individually scraped from the slides and total radioactivity was determined by liquid scintillation counting. Drugs that showed at least 10-fold higher affinity for Type I sites included D-threo-β-hydroxyaspartate, D-aspartate-α-benzyl ester and L-2,4-*trans*-pyrrolidine dicarboxylate (supplied by R. Bridges, Univ. Calif., Irvine). At present no compounds have been identified that show more that 5-fold higher affinity for Type II sites. The discovery of specific drugs which interact at these transporters may provide a valuable means to affect specific EAA-using pathways. Supported by AG-08843 (KJA) and NS-28268 (TWV).

NMDA ANTAGONISTS BLOCK C-FOS EXPRESSION DURING OPIOID WITHDRAWAL. C.E. Inturrisi, M. Brodsky* and K. Rasmussen, Dept. of Pharmacology, Cornell U. Med. College, New York, NY and Lilly Research Labs, Indianapolis, IN.

Naltrexone (NTX)-precipitated withdrawal in morphine dependent rats results in the induction of the proto-oncogene, c-fos (Hayward et al., Brain Res. 525, 256, 1990) and NMDA antagonists (MK-801 (MK) and LY-274614 (LY)) block the behavioral signs of withdrawal (Rasmussen et al., Eur. J. Pharmacol., in press). In morphine dependent rats c-fos mRNA levels, as measured by a quantitative solution hybridization assay, are increased 2-4 fold at 1 hour after NTX administration in locus coeruleus (LC), amygdala (AD), nucleus accumbens (NA), frontal cortex (FC) and hippocampus (HC) (but not in striatum or spinal cord). Pretreatment of dependent rats with MK (1 mg/kg sc) or LY (100 mg/kg ip) prior to NTX reduced by 60 to 90% the NTX withdrawal-induced increase in c-fos mRNA in AD, NA, HC and LC but not in FC. Differential drug-CNS region effects were noted: LY was a more effective blocker of c-fos induction in NA, while MK was more effective in LC and HC. These results demonstrate that competitive (LY) and noncompetitive (MK) NMDA antagonists can block both the behavioral manifestations of withdrawal and c-fos induction in those brain regions associated with opioid effects and withdrawal. Supported in part by NIDA Grant DA-01457 (CEI).

536.6

THE ACTIONS OF GLUTAMATE RECEPTOR AGONISTS AND ANTAGONISTS ON THE ACTIVITY OF PHOSPHATE-ACTIVATED GLUTAMINASE (PAG). R. Dawson, Jr. and D.R. Wallace. Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, FL 32610.

The conversion of glutamine (GLN) to glutamate (GLU) is catalyzed by PAG. PAG is under physiological regulation by end product inhibition due to GLU and ammonia and is activated by both phosphate and calcium. The pharmacological specificity of the binding site on PAG for GLU-induced allosteric inhibition of PAG activity was probed. In addition, the noncompetitive N-methyl-D-aspartate (NMDA) receptor blocker (+)MK-801 was also examined.

PAG activity was measured in crude synaptosomal (P_2) preparations by determining GLU formation after a 15 minute incubation in the presence of GLN. The assay buffer contained (in mM) sodium phosphate 10, Na_2EDTA 0.2, HEPES 20 and GLN 0.5. The GLU formed was measured by HPLC. PAG activity was measured in the cortex from 6 month old F344 rats (n=8) and 100 day old Sprague-Dawley (SD) rats (n=5).

PAG activity (expressed as percent of control) was significantly inhibited by 5mM of the following drugs: kainic acid (44±2%), NMDA (60±3%), quinolinic acid (44±2%), kynurenic acid (58±4%), AP4 (55±2%) and cis-piperdine dicarboxylic acid (79±3%). Interestingly, (+)MK-801 (5mM) stimulated PAG activity (209±10%) in F344 rats. (+)MK-801 (5mM) was tested in SD rats and was also found to stimulate PAG activity (183±4%). Ketamine (5mM) stimulated PAG activity (137±1%) whereas (-)MK-801 (5mM) had no effect on PAG activity. (+)MK-801 (5mM) was additive with the stimulating effects of calcium (1mM) on PAG activity and synergistically potentiated the effects of phosphate and substrate (GLN) on GLU synthesis by PAG. The results show that GLU analogs can inhibit PAG activity and demonstrate that high concentrations of (+)MK-801 can activate PAG activity in a stereoselective manner.

PRE-RELEASED ADENOSINE MODULATES NMDA-EVOKED NORADRENALINE (NA) RELEASE IN THE CORTEX. C.G. Craig and T.D. White. Dept. of Pharmacology, Dalhousie University, Halifax, N.S., Canada, B3H 4H7.

Adenosine, an important inhibitory neuromodulator, is released during NMDA receptor activation in the cortex. Maximal adenosine release occurs at levels of NMDA receptor activation which release minimal NA. We examined the potential modulatory role of adenosine released during NMDA receptor activation on NA release from slices of rat parietal cortex. The P_1 agonist R-PIA (10µM) decreased 100µM NMDA-evoked [^{3}H]NA release by 27%. Although the P_1 antagonist 8-phenyltheophylline (10µM, 8-PT) reversed R-PIA's inhibition of NMDA-evoked [^{3}H]NA release, alone it had no effect on 100µM NMDA-evoked [^{3}H]NA release. This suggests that adenosine released during NMDA receptor activation does not modulate [^{3}H]NA release. Indeed, adenosine release evoked by 100µM NMDA occurs later than [^{3}H]NA release, so that the released adenosine might not be temporally available to modulate [^{3}H]NA release. Pretreatment with an NMDA concentration (10µM) which releases substantial endogenous adenosine but very little [^{3}H]NA decreased subsequent 100µM NMDA-evoked [^{3}H]NA release by 63%. 8-PT partially reversed this inhibition, indicating that pre-released adenosine, acting at P_1-purinoceptors, modulated subsequent NMDA-evoked [^{3}H]NA release. These results suggest that adenosine released during submaximal NMDA receptor activation could provide an inhibitory threshold which must be overcome in order for other NMDA-mediated processes to proceed maximally. (Supported by the MRC of Canada).

DIVERSITY OF K^+ CHANNEL MODULATION BY SIGMA LIGANDS IN CULTURED CEREBELLAR NEURONS. P.G. Lysko, M.M. Gleason*, C.L. Webb*, K.A. Lysko*, and G. Feuerstein. Dept. of Pharmacology, SmithKline Beecham, King of Prussia, PA 19406.

Sigma ligands have been suggested to be modulators of K^+ channel activity, as determined by ^{86}Rubidium (Rb) efflux from preloaded rat cortical synaptosomes, where KCl-induced Rb efflux was reportedly blocked by σ-ligands but not by the NMDA antagonist MK-801. Here we studied Rb efflux from primary cultures of 7-9 da old rat cerebellar granule cells preloaded in buffer for 2 hr with ^{86}RbCl (2µCi/ml/35 mm dish). Rates of Rb efflux were measured at 37C by sequential removal, replacement, and counting of buffer solution every 2 min. Basal efflux was determined for 10 min, and stimulated efflux for an additional 12 min, at which time cells were solubilized with SDS and counted. Inhibitors were added 10 min prior to stimulation and included throughout. The basal rate constant of 0.133±0.005 min^{-1} (n=18) was increased 227% by 80 mM KCl and resolved by 10 min in spite of the continual presence of KCl. KCl-stimulated Rb efflux was differentially inhibited up to 60% by 100µM MK-801, DTG, SKF 10,047, and haloperidol, but not by (+)-3-PPP. When cells were incubated in the absence of glucose (in vitro ischemia),the basal rate constant increased to 0.153±0.005 min^{-1} (n=18); 100µM glutamate (excitotoxic) increased Rb efflux by 40%. This Rb efflux was inhibited up to 40% by MK-801, DTG, and SKF 10,047, but not by haloperidol or (+)-3-PPP. Kainate (100µM, excitotoxic) stimulated Rb efflux to the same extent as KCl, was not inhibited by any of the above compounds, but was inhibited by 100µM of the quinoxalinediones NBQX, DCQX, and MNQX. Data suggest selective inhibition of K^+ channels by σ-ligands, which may be neuroprotective by blocking NMDA channels.

CHANGES IN CONCENTRATIONS OF DOPAMINE, SEROTONIN AND THEIR METABOLITES INDUCED BY CARBON MONOXIDE (CO) IN THE RAT STRIATUM AS DETERMINED BY IN VIVO MICRODIALYSIS. M. Hiramatsu[1], S. Yokoyama[1]*, T. Nabeshima[2] and T. Kameyama[1]. [1]Dept. of Chem. Pharmacol., Meijo Univ., Nagoya 468, Japan and [2]Dept. of Hospital Pharmacy, Nagoya Univ. Sch. of Med., Nagoya 466, Japan.

Ischemic conditions can induce massive increases of neurotransmitters in the extracellular fluid of the brain. The increase in extracellular neurotransmitter concentrations has been implicated in the pathogenesis of hypoxic cell damage. In this study, striatal microdialysis was performed in rats subjected to hypoxia produced by CO-exposure. Extracellular changes of dopamine, serotonin and their metabolites were monitored before and after the CO-exposure at 15-min intervals by HPLC-EC analysis. Immediately after CO-exposure, extracellular dopamine increased, whereas 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) decreased. Dopamine was cleared from the extracellular fluid within 45 min and reached a baseline level after CO-exposure. Extracellular 5-hydroxyindoleacetic acid (5-HIAA) did not change after CO-exposure. The non-competitive N-methyl-D-aspartate (NMDA) antagonist, MK-801 (1 mg/kg, s.c.) tended to antagonize the increment of dopamine and the decrement of DOPAC. This protective effect might be due to the blockade of NMDA receptors since hypoxia induces glutamate release and glutaminergic system regulates the striatal dopaminergic system.

DEVELOPMENTAL PATTERNS OF GLUTAMATE-INDUCED INTRANEURONAL CALCIUM ACCUMULATION. E.F. May*, M.A. DeCoster and F.C. Tortella. Neuropharm. Branch, Walter Reed Army Inst. Res., Washington, DC 20307-5100.

The Adherent Cell Analysis and Sorting System (ACAS) has been used to measure glutamate (Glu)-induced intracellular calcium (Ca_i) changes in primary rat cortical neurons. (DeCoster et al., Trans. Am. Soc. Neurochem., 22: 1991). In this study, neurons of varying ages (7-29d) were treated with Glu (5-80 μM) and Ca_i measured using the ACAS. In neurons of all ages, 40-80 μM Glu caused an immediate sustained rise (ISR) in Ca_i. The amplitude of this response was greatest in 22d neurons. At 20 and 10 μM Glu, 14d neurons showed a greater amplitude of Ca_i increases than 7d neurons; however, the patterns of responses were heterogeneous, and included biphasic and ISR types. The responses to 5 μM Glu were also heterogeneous at different ages, but the ISR response was most often observed in older neurons, with the highest amplitude at 19-21d. In summary, ISRs were more frequent and greater in amplitude in older neurons. The heterogeneity of responses to lower doses of Glu at different neuronal ages may reflect the development of multiple Glu receptor types.

L-α-AMINOADIPIC ACID REDUCES KYNURENIC ACID PRODUCTION IN THE RAT HIPPOCAMPUS: A MICRODIALYSIS STUDY IN FREELY MOVING RATS. R. Schwarcz and H.-Q. Wu. Maryland Psychiatric Research Center, Baltimore, MD 21228.

Kynurenic acid (KYNA) is a broad-spectrum antagonist of excitatory amino acid (EAA) receptors in mammalian brain. Neuronal activity can influence KYNA synthesis in vitro and in vivo, and certain EAAs have been shown to regulate KYNA function in brain slices (Soc. Neurosci. Abstr. 15: 328.10, 1989). The effect of the most potent endogenous EAA in vitro, L-α-aminoadipic acid (αAA), was now studied by microdialysis in the rat hippocampus in vivo. αAA, administered through the dialysis probe, dose-dependently decreased extracellular KYNA concentration in the presence of kynurenine (500 μM), reaching 50% of control levels with 500 μM αAA. KYNA levels returned to basal level within 2 h after discontinuation of the αAA perfusion. 500 μM αAA also lowered endogenous extracellular KYNA levels by ~30%. Neuronal depletion by quinolinic acid lesions did not interfere with the αAA effect. Co-perfusion of 50 μM veratridine (which by itself potently decreases extracellular KYNA) with 500 μM αAA did not result in an additive KYNA reduction. Moreover, the αAA-induced effect was not blocked by tetrodotoxin (5 μM). These data suggest that αAA exerts its inhibitory effect through direct interaction with KYNA-producing glial cells. αAA may be an endogenous modulator of KYNA synthesis in the brain and may thus play a role in the function or dysfunction of cerebral EAA receptors. Supported by USPHS grant NS 16102.

536.12

MODULATION OF D-[^{3}H]ASPARTATE RELEASE BY KAINIC ACID IS NOT MEDIATED BY AUTORECEPTOR ACTIVATION. A.M. Palmer and C.T. Reiter. *Departments of Psychiatry and Pharmacology, University of Pittsburgh Medical Center, 3811 O'Hara Street, Pittsburgh, PA 15213.*

This study addresses the hypothesis that kainic acid receptors are present on excitatory amino acid (EAA) nerve terminals. Slices of rat cerebral cortex were preincubated in physiological media containing D-[^{3}H]aspartate, superfused (1.6 ml/min) and collection of twelve 0.5 min fractions begun at t = 30 min. Kainic acid (KA, 0.01 - 1 mM at t = 15-36 min) increased baseline counts in a dose-dependant fashion in both the presence and absence of Ca^{2+} (190 and 170% of control, respectively for a 1mM dose) but had no effect in media with Na^+ concentration reduced (with equimolar substitution of choline chloride) to 10mM. This suggests that the observed elevation is not mediated via interaction with the process of release but instead by inhibition of EAA uptake; D,L-threo-ß-hydroxy aspartate (100μM) increased baseline counts to 355% of control. In parallel studies, the Na^+-dependant binding of D-[^{3}H]aspartate was inhibited by both D,L-threo-ß-hydroxyaspartate and KA (IC_{50} = 0.5 and 78.3μM, respectively; n = 4-5). Elevated concentrations of K^+ (25-75 mM) at t = 31.5-32.5 min evoked a dose-dependent increase in the release D-[^{3}H]aspartate. Compared to baseline, 50mM K^+ evoked an elevation of 30.1 ± 3.3 (mean fold increase ± SEM, n = 6) that was higher than that occurring in the absence of Ca^{2+} (5.3 ± 0.2). KA inhibited this release (to 54 ± 5% of control for a 1mM dose) in a dose-dependant fashion and was insensitive to blockade of voltage-sensitive Na^+-channels (1μM tetrodotoxin at t = 15-36 min), application of an antagonist (30μM DNQX at t = 15-36min) and removal of Ca^{2+} ions; an alternative agonist (100μM domoic acid at t = 25-36 min) had no effect on release. These data are not consistent with the notion that KA receptors are present on EAA nerve terminals, but instead suggest that the effect of KA on EAA release are mediated via EAA uptake.

536.13

CHARACTERIZATION OF GLUTAMATE AND NMDA-EVOKED CALCIUM CHANGES IN SINGLE CULTURED CORTICAL NEURONS FROM FETAL RAT BRAIN. E.N. Fluhler[1], K.G. Fernandes*[1], S.L. Yates*[2], P.M. Lippiello[1]. [1]RJR-NABISCO, Winston-Salem, NC 27102 and [2]Duke University Medical Center, Integrated Toxicology Program, Durham, NC 27710

Excitatory amino acid (EAA) receptors, which are thought to play a role in learning and memory, have been shown to be significantly altered in the pathology associated with dementia of the Alzheimer's type (DAT). While a large amount of work has been done to characterize the functional properties of EAA receptors in the hippocampus and striatum, considerably less is known about EAA receptors found on mammalian cerebral cortical neurons. Our laboratory has previously developed a culture method for cortical neurons. These cultures have been shown to be essentially glia-free, and are ideally suited for functional studies based on fluorescence microscopic imaging techniques. Here we describe the results of experiments aimed at elucidating the pharmacological and functional properties of EAA receptors found on single cultured cortical neurons. The ion-selective fluorescent probe fura-2 was used to measure EAA-evoked changes in neuronal calcium under a variety of conditions. Application of the agonists glutamate (GLU) and N-methyl-D-aspartate (NMDA) caused increases in neuronal intracellular calcium in a dose dependent manner (ED_{50} ca. 0.4 and 8.4 μM respectively). The time course for GLU and NMDA-evoked responses were similar and approached a maximum within approximately 90 seconds. Magnesium (2.0 mM), MK-801 (1uM), and 2-amino-5-phosphonovaleric acid (AP5) all blocked NMDA-evoked responses. Interestingly, glycine did not significantly modulate NMDA-evoked calcium changes. These results indicate that cultured fetal rat cortical neurons possess EAA receptors which respond similarly, but not identically, to those found on cultured hippocampal and striatal neurons.

536.14

DOPAMINE RELEASE EVOKED BY SUCCESSIVE APPLICATIONS OF NMDA AND KAINATE: EVIDENCE FOR DESENSITIZATION OF NMDA RECEPTORS IN VIVO. D.P. Carrozza, T.N. Ferraro, G.T. Golden, P.F. Reyes, T.A. Hare. Thomas Jefferson University, Philadelphia, PA 19107 and DVAMC, Coatesville, PA 19320.

Intrastriatal (i.s.) application of NMDA or kainate (KA) via microdialysis causes dose-dependent release of striatal dopamine (DA). To further characterize the role of striatal excitatory amino acid (EAA) receptors in DA release, the effect of successive applications of NMDA and KA were compared. Male Sprague-Dawley rats underwent surgery for placement of guide cannulae at coordinates chosen to allow striatal microperfusion. After a 48 h recovery period, microdialysis probes were inserted in freely-moving, unanesthetized rats. Microdialysis was carried out at a rate of 3.0 μl/min with sample collection at 15 min intervals. Levels of DA, DOPAC, and HVA were measured using HPLC with coulometric detection. About 1 hour following probe insertion, a 5 min i.s. application of NMDA or KA (each 12.5 mM in Ringer's solution) was given followed by a 45 min perfusion with normal Ringer's and then a second 5 min application of NMDA or KA. Results showed that DA release evoked by the first and second applications of KA was similar (110.2 ± 39.9% of the first application, n=6). However, a second application of NMDA resulted in a significant reduction in DA release compared to the first (29.3 ± 11.5%, $p<0.004$, n=9). When aminophosphonovalerate (APV, 0.36 mM, 5 min, i.s.) was administered prior to the second NMDA treatment, the reduction of DA release associated with the second NMDA application was significantly inhibited (49.9 ± 9.1% of the first treatment, $p<0.015$ vs non-APV treated, n=7). Administration of dextromethorphan (DXT, 1.0 mM, 5 min, i.s.) also partially prevented the reduction in DA release associated with the second NMDA treatment (48.2 ± 11.6%, $p<0.03$ vs non-DXT treated, n=5). Results suggest that striatal EAA receptors which mediate NMDA-induced DA release in vivo are desensitized following successive applications of NMDA. This desensitization is attenuated by competitive and non-competitive antagonists. KA-induced DA release is mediated by EAA receptors which are not similarly desensitized.

536.15

COMPARISON OF CARBACHOL- AND GLUTAMATE-STIMULATED PHOSPHORYLATION OF RAT HIPPOCAMPAL MEMBRANE PROTEINS. L.M. Shaffer, M.A.N. Edgar* and L.A. Dokas*. Departments of Neurology*, and Biochemistry and Molecular Biology, Medical College of Ohio, Toledo, OH 43699.

Both cholinergic and glutaminergic agonists stimulate the hydrolysis of phosphatidylinositol 4,5 bisphosphate. These effects are differentially inhibited by active phorbol esters. Since phorbol esters stimulate the activity of protein kinase C, it was of interest to examine changes in the phosphorylation of membrane proteins correlated with manipulation of the cholinergic and glutaminergic systems in the rat hippocampus. Following incubation of adult rat hippocampal slices with 2.0 mM carbachol, no differences in the [γ-^{32}P]-ATP phosphorylation of membrane proteins were observed. However, incubation with glutamate, ibotenic acid and NMDA (10^{-3}M) resulted in altered phosphorylation of membrane proteins. The most prominent of these phosphoproteins has been identified by immunoblot analysis to be B-50/GAP-43. In contrast, increased phosphorylation in response to carbachol, glutamate and ibotenic acid was observed in hippocampal slices from 4 day old pups. Supported by grants from the Ohio Department of Aging and NIH (NS 23598).

THE MODULATION BY SIGMA LIGANDS OF NMDA-EVOKED [^{3}H]NORADRENALINE RELEASE INVOLVES $G_{i/o}$ PROTEINS. F.P. Monnet, P. Blier, G. Debonnel and C. de Montigny. Neurobiological Psychiatry Unit, McGill University, Montreal, and Institut de Recherche Jouveinal, Fresnes, France.

We have previously documented, using *in vivo* extracellular unitary recordings, a selective potentiation of NMDA-induced activation of CA_3 dorsal hippocampus pyramidal neurons by DTG, (+)pentazocine and JO-1784 and the suppression of this effect by haloperidol and (+)3-PPP, which all share a high affinity for sigma (σ) binding sites (*Soc. Neurosci. Abstr.*, 16: 396.11, 1990). High affinity σ binding sites have been proposed to be linked to G proteins (*Eur. J. Pharmacol.*, 149: 399, 1988; *J. Neurochem.*, 53: 779, 1989). The present studies were undertaken to investigate the effect of σ ligands on NMDA-evoked [^{3}H]NE release in preloaded hippocampus slices of Sprague-Dawley rats and to verify the possible involvement of $G_{i/o}$ proteins in mediating this effect of σ ligands. To this end, $G_{i/o}$ proteins were inactivated with pertussis toxin (PTX, 1 µg, *in situ* 4 to 11 days prior the experiments) or *in vitro* preincubation with *N*-ethylmaleimide (NEM, 30 µmol/l, 30 min prior the experiments). The slices were incubated with 0.1 µM [^{3}H]NE for 30 min and then superfused with Mg^{++} free Krebs' containing DTG, JO-1784 or (+)3-PPP and, 40 min later, the calcium-dependant tritium overflow was evoked by 100 µM NMDA. JO-1784 (0.01-0.3 µM) (+)3-PPP (0.1-0.3 µM) increased, whereas DTG (0.03-3 µM) decreased, in a concentration-dependent manner, [^{3}H]NE release evoked by NMDA. Haloperidol (1 µM), which did not modify the NMDA-evoked [^{3}H]NE release, prevented the effects of JO-1784 and DTG. The PTX and NEM pretreatments abolished the effects of JO-1784 and (+)3-PPP, but only shifted to the right the concentration-effect curve of DTG. The present results indicate that σ sites can modulate the NMDA-evoked [^{3}H]NE release and that these are coupled to $G_{i/o}$ proteins.

GABAERGIC MEDIATION OF PHENCYCLIDINE-INDUCED CHANGES IN STRIATAL NEUROPEPTIDE Y LEVELS IN THE RAT BRAIN. L.P. Midgley, L.G. Bush*, J.W. Gibb and Glen R. Hanson. Dept. of Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84112.

Alterations in neuropeptide Y (NPY) tissue content in CNS or extracellular fluid have been found in several psychiatric disturbances and neurodegenerative diseases. Phencyclidine-HCL (PCP), a psychotropic drug of abuse, interacts with a number of neurotransmitter systems and has been identified as an antagonist at the NMDA receptor. We previously reported that administration of PCP or the non-competitive NMDA antagonist, MK-801, significantly reduces (by 30-50%) striatal NPY levels in the rat brain. In the present study, we observed that administration of the GABA-T inhibitors, amino-oxyacetic acid (AOAA) and MDL 71,754 (gamma-vinyl-GABA, GVG), had no effect on striatal NPY levels. Conversely, the GABA antagonist, bicuculline, significantly reduced striatal NPY levels by approximately 20%. Pretreatment of rats with AOAA or MDL 71,754 completely blocked the effects of PCP and MK-801 on striatal NPY levels. These data suggest that GABAergic receptors mediate PCP- and MK-801-induced changes in striatal NPY systems and contribute to interactions between NMDA and NPY systems. (MDL 71,754 was (graciously) provided by Marion Merrill Dow Inc., and the research was supported by USPHS grants DA 00869 and DA 04222).

EXTRACELLULAR FLUID GLUTAMATE CONCENTRATION IN THE PARAVENTRICULAR NUCLEUS: THE EFFECT OF POTASSIUM CHLORIDE DEPOLARIZATION AND GABAERGIC STIMULATION. M. Tristan-Morales*, W.W. Morgan and J.R. Haywood. Departments of Pharmacology and Cellular and Structural Biology, University of Texas Health Science Center, San Antonio, TX 78284.

The goal of these studies was to measure neuronal glutamate concentrations in the paraventricular nucleus (PVN) as an estimate of glutamate release using microdialysis. In chloral hydrate anesthetized rats, a 0.5 mm concentric design dialysis probe was inserted in the PVN through a previously placed guide cannula. Artificial cerebrospinal fluid was infused at a rate of 0.5 µl/min, and samples were taken at 30 min intervals. Glutamate was measured in the effluent using HPLC with electrochemical detection. Recovery of glutamate was determined at 3.8%. Potassium chloride depolarization increased extracelluiar glutamate concentration from 26.3±6.3 pg/µl to 92±20.9 pg/µl during the first collection period and 131.9±15.4 pg/µl during the second period. Administration of the GABA uptake inhibitor, nipecotic acid (100µM), reduced glutamate concentration by 44% (31.6±4.2 pg/µl to 17.6±2.4 pg/µl). These findings suggest that glutamate is neuronally released in the PVN. Further, the release of glutamate can be inhibited by increases in extracellular concentrations of GABA. (Supported by HL 36080 and HL 32977)

NEUROPROTECTIVE PHARMACOLOGY AND ONTOGENY OF QUINOLINATE INDUCED INJURY IN DEVELOPING BRAIN. W.H. Trescher, J.W. McDonald, and M.V. Johnston, The Kennedy Research Institute, Johns Hopkins University School of Medicine, Department of Neurology, Baltimore, MD 21205.

We evaluated the pharmacology and ontogeny of quinolinate induced injury in the immature rat brain. The dose response of quinolinate mediated injury was determined in the PND 7 rat pup by unilateral microinjection (0.5 µl) of 4 doses of quinolinate (50-400 nmol, n = 6-7/dose) directed into the anterior striatum. The severity of brain injury was quantified on PND 12 by comparison of the wet weights of the hemisphere ipsilateral (I) and contralateral (C) to the injection, and expressed as % Damage = 100*(C-I)/C. The extent of damage produced by quinolinate, which was maximal with 400 nmol, 28.9 ± 2.9%, was linearly related to the dose injected (r^2 = 0.99). The pharmacology was tested against injury produced by intrastriatal injection of 150 nmol of quinolinate. 15 min. after injection of quinolinate, animals received an intraperitoneal injection of PBS (control), dextromethorphan (DM, 20 mg/kg), dextrorphan (DX, 20 mg/kg), MK-801 (1 mg/kg), and CGS 19755 (10 mg/kg); n = 9-10/treatment. CNQX (20 nmol, n = 9) and 7-Cl-kynurenate (40 nmol, n = 5) were coinjected with quinolinate. Partial protection against injury was afforded by DX, DM ($p < 0.05$) and CNQX (n.s). Complete protection was provided by MK-801, CGS 19755 ($p < 0.001$) and 7-Cl-kynurenate ($p < 0.005$). To evaluate the ontogeny of quinolinate induced injury, we injected 150 nmol/0.5 µl into the anterior striatum at PND 7, 14, 21, and 90. The severity of injury was evaluated 5 days later by comparing the regional cross-sectional areas of the striatum on Nissl stained sections. Reduction in the cross-sectional area of the striatum was maximal at PND 7 (74.4 ± 6.4%) and minimal at PND 90 (38.2 ± 14.5%). The data demonstrate an attenuation of quinolinate neurotoxicity by NMDA receptor antagonists in the immature rat brain and suggest an enhancement of that toxicity in the developing brain. EFFECT OF IBOTENIC ACID LESIONS ON NMDA-, DOPAMINE D1- AND D2-MEDIATED CHANGES IN STRIATAL NEUROTENSIN SYSTEMS. N. Singh, L. Midgley, J Wagstaff*, L. Bush*, J. Gibb and G. Hanson. Dept. Pharmacol. and Toxicol., Univ. of Utah, Salt Lake City, UT 84112.

N-methyl-D-aspartate (NMDA) receptors mediate dopamine D1-, but not D2-induced changes in striatal neurotensin (NT) systems. To elucidate further the role of NMDA receptors in regulating NT systems, rats were lesioned with the NMDA selective toxin, ibotenic acid (IBO) and NT levels were assessed by RIA after treatment with NMDA, SKF38393 (D1 agonist) and sulpiride (D2 antagonist). Substance P (SP) levels were used to determine the extent of the lesions. 6-8 days after rats were lesioned in the striatum with IBO (15 ug/2ul at 2 sites), they were treated with 3 doses of NMDA (100 mg/kg/dose), SKF38393 (20 mg/kg/dose) and sulpiride (80 mg/kg/dose) 6 h apart and sacrificed 18 h later. In animals with > 60 % striatal SP depletion, NT levels were unaltered by IBO lesions on the ipsilateral side, but were increased on the contralateral side when compared to unoperated rats. Ipsilateral IBO lesions blocked NMDA-induced increases in striatal NT but did not block sulpiride-induced increases in striatal NT when compared to unoperated controls. In preliminary studies, IBO lesions also appeared to block SFK38393-induced increases in NT. In contrast, basal increases in contralateral NT content after IBO lesions were additive with sulpiride- and SKF38393-induced NT changes but not with NMDA-induced changes when compared to unoperated controls. These findings confirm a role for NMDA receptors in controlling NT responses to D1 receptors and suggest that a compensatory NT change occurs in the contralateral side in response to IBO lesions. (Supported by USPHS Grants DA 00869 and 04222.)

STUDIES ON THE MECHANISM OF INTERACTION OF THE VOLATILE ANESTHETIC HALOTHANE WITH GABA-A RECEPTORS. B. Longoni and R.W. Olsen. Dept. of Pharmacology, School of Medicine, University of California, Los Angeles, CA 90024.

Volatile anesthetics enhance GABA-A receptor-chloride channel function in some neurons. The effects of halothane on GABA-A receptor-regulated chloride flux were evaluated in brain slices. Rat cortical slices were prepared according to the method of Yang and Olsen (1987). $^{36}Cl^-$ efflux was measured every minute for 24 consecutive minutes. GABA agonists such as muscimol (10 μM) added at the 14th minute of the assay significantly increased $^{36}Cl^-$ efflux via GABA-A receptor chloride channels. Simultaneous addition of halothane at clinically relevant concentrations of 0.8-1.7 mM (1-4 MAC) augmented and prolonged the muscimol-dependent $^{36}Cl^-$ efflux without affecting the basal flux. [^{3}H]Muscimol binding was augmented by halothane at similar concentrations. Halothane enhancement of muscimol-stimulated $^{36}Cl^-$ efflux appears to be dependent upon physiological concentrations of extracellular Ca^{2+}. In fact, in a Ca^{2+} free Ringer's solution, no halothane effect could be observed, while barbiturate enhancement of muscimol function was not impaired. GABA-mediated inhibition by halothane may be more complicated than direct modulation of GABA-A receptors by other CNS depressant drugs, and may contribute to our understanding of the role of GABA neurotransmission in general anesthesia.

PREFERENTIAL ANTAGONISM OF PENTYLENETETRAZOLE (PTZ)-INDUCED SEIZURES DIFFERENTIATES BENZODIAZEPINE (BZD) LIGANDS ACTING AS PARTIAL ALLOSTERIC MODULATORS AT $GABA_A$ RECEPTORS.

P. Giusti*, A. Guidotti and E. Costa.
F.G.I.N., Washington, DC 20007 and *Dept. of Pharmacology, University of Ancona, Italy.

PTZ and bicuculline (BIC) were infused i.v. at a constant rate into rats in order to progressively down regulate GABA action on $GABA_A$ receptors until seizures were elicited. The anti-PTZ and anti-BIC ED_{50} of several BZD and congeners were determined. Abecarnil (anti-PTZ EC_{50} = 1 μmol/kg iv) alprazolam (1.5), diazepam (3), chlordiazepoxide (20), behaved as full positive modulators of GABA action and have a PTZ/BIC antiseizure ratio close to 1, whereas the nonsedative BDZs (clonazepam, EC_{50} .6 and bretazenil EC_{50} .06) behaved as partial positive modulators (approximately half the maximal efficacy of diazepam) and had a PTZ/BIC antiseizure ratio 5 to 10 fold higher. Moreover when bretazenil was injected together with diazepam before BIC infusion, only the partial modulation of bretazenil was observed. These data suggest that bretazenil acts as partial positive modulator of $GABA_A$ receptors by blocking the full positive modulatory activity of diazepam. This indicates that BZD receptors can be occupied by compounds that have partial modulatory activity and prevent the action of the full positive modulators.

537.3

2-ARYL-3-INDOLEACETAMIDES (AIAM): A NEW CLASS OF POTENT AND SPECIFIC LIGANDS FOR THE MITOCHONDRIAL BENZODIAZEPINE RECEPTOR (MBR). E. Romeo, A.P. Kozikowski*, D. Ma*, V. Papadopoulos, J. Auta, A. Guidotti and E. Costa. F.G.I.N., Washington, D.C. 20007 and *Mayo Clinic, Jacksonville, FL 32224.

We have synthesized a series of AIAM that displace competitively ($n_H \approx 1$) and with high affinity (Ki 2-20 nM) [^{3}H] 4'Cl-diazepam and [^{3}H] PK11195 bound to rat MBRs prepared from cultured cerebellar astrocytes, brain homogenates and adrenal cortical cells. AIAM failed to displace the binding of [^{3}H] 4'Cl-diazepam to rat cerebellar granular neurons in primary culture or the binding of [^{3}H] flumazenil, [^{3}H] spiroperidol, [^{3}H] MK-801, [^{3}H] ketanserin, [^{3}H] AMPA, [^{3}H] 3-PPP, [^{3}H] glycine, and [^{3}H] naloxone to crude rat brain synaptic membranes. In C6-2B glioma cells the affinity of AIAM for the MBRs parallels their ability to increase mitochondrial pregnenolone synthesis. It is known that glial cells synthesize steroids that can modulate positively and negatively $GABA_A$ receptor function. Rats receiving small i.v. doses of AIAM show an increased behavioral output when placed on the elevated X-maze. When AIAMs are injected in doses twenty to fifty fold larger they produce sedation, ataxia, and respiratory depression. These effects are blocked by a pretreatment with subconvulsant doses of pentylenetetrazole but not of strychnine. A possible role of glia cell steroidogenesis in the pharmacological actions of AIAMs will be discussed.

PICROTOXIN BLOCK OF GABA CURRENT BY TWO DIFFERENT MECHANISMS. Kong-Woo Yoon, D. F. Covey, and Steven M. Rothman. Department of Anatomy and Neurobiology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

We examined the effect of the picrotoxin (PTXN) receptor antagonist, α-isopropyl-methyl-γ-butyrolactone (αIMGBL) and PTXN on GABA induced chloride currents in dissociated rat hippocampal neurons. When applied by U-tube, PTXN (40 uM) decreased the peak GABA (10 uM) current by 36.6 ± 3.9%. The amount of PTXN block increased to 73.6 ± 2.8% with continued application with a time constant of 2.1 ± 0.2 sec. The amount of early and late depression by picrotoxin was not dependent on GABA concentration in the range of 1 to 30 uM but it was dependent on picrotoxin concentration (10, 40uM). The time constant for the delayed block decreased with increasing GABA concentration (20 sec at 1 uM, 1 sec at 30 uM) suggesting further that this PTXN effect is use dependent. In a separate set of neurons the picrotoxin receptor antagonist αIMGBL (5mM) almost completely abolished the delayed block (74.4 ± 4.2% to 38.5 ± 10.1%, n=7) while it had no effect on the early current depression. With brief application of 1 uM GABA, we saw no use dependent PTXN block and no reduction of block by αIMGBL. Our observations suggests that the PTXN block of GABA currents is mediated at two different sites producing a fast and slow (use dependent) block. αIMGBL appear to selectively antagonize the use dependent block.
Supported by NS 14834.

THE MUSCLE RELAXANT EFFECT OF FLUPIRTINE - INDICATIONS FROM ELECTROPHYSIOLOGICAL STUDIES. M. Wienrich and I. Szelenyi*. Dept. Neurobiology, Battelle Europe and ASTA-Pharma AG*, D-6000 Frankfurt am Main, Germany

Flupirtine (F) is a centrally acting, non-opioid analgesic. Analgesia caused by F is accompanied by a muscle relaxant activity. In order to elucidate the mechanism of this effect, we studied the interaction of F with GABA. We used primary dissociated cultures derived from whole embryonic rat brain and performed whole-cell recordings in the current-clamp mode. Due to our recording conditions, GABA induced reversible, concentration-dependent membrane depolarizations (EC_{50} $1.5x10^{-6}$M) which were antagonized by bicuculline, indicating the presence of a $GABA_A$ receptor. F also induced reversible, concentration-dependent membrane depolarizations (EC_{50} $1.5x10^{-4}$M) which were also antagonized by bicuculline. At $1x10^{-5}$M GABA induced a maximal effect. At the same concentration F, however, had no effect. Moreover, F at a threshold concentration of $3x10^{-5}$M potentiated the GABA effect, causing the concentration response curve for GABA to shift to the left (EC_{50} $5x10^{-7}$M). This indicates a possible over-additive interaction between the two compounds. We conclude that F has $GABA_A$-agonistic properties.

537.6

EXPRESSION OF POLYPEPTIDE DIAZEPAM BINDING INHIBITOR (DBI) AND PERIPHERAL BENZODIAZEPINE RECEPTORS (PBR) IN CULTURED PRIMARY ASTROCYTES. H. Alho[1], V. Varga[1*] and K. Krueger[2]. [1]Dept. of Biomed. Sci., Univ. of Tampere, BOX 607, 33101 Tampere, Finland; [2]Fidia-Georgetown Institute for the Neurosci., Washington DC 20007, USA.

The polypeptide diazepam binding inhibitor (DBI) modulates the $GABA_A$ receptor ionophore complex. It inhibits benzodiazepine (BZ) ligand binding to both central and peripheral benzodiazepine receptor sites (CBR, PBR). It has been suggested that the PBR is involved in neurosteroid synthesis in oligodendrocytes and glioblastoma cell lines. However, the exact role and localization of DBI and PBR in neuronal tissues is not completely understood. Therefore we studied the expression and distribution of DBI and PBR, and measured steroid hormone synthesis in rat primary astrocyte cultures.

Most of the astrocytes exhibited DBI-LI and DBI mRNA. DBI-LI was localized throughout the cytoplasm of glial cells. However, PBR-LI was found only in some of the astrocytes. These cultures produced measurable amounts of steroids. This steroid production was affected by the PBR ligands PK 11195 and Ro5-4864. These results demonstrate a wide distribution of DBI and co-localization with PBR in the cultured astrocytes. It was concluded that DBI may modulate central neuronal activity by acting indirectly via neurosteroids beside its direct interaction with CBR.

537.7

ABECARNIL: A β-CARBOLINE ANXIOLYTIC SHOWING A SELECTIVE ACTION AT CENTRAL BENZODIAZEPINE RECEPTORS.

D.N. Stephens, H.H. Schneider, L. Turski, M. Hillmann*, R. Huba*, J.D. Turner* Schering AG, Berlin, Federal Republic of Germany.

The β-carboline abecarnil shows anxiolytic and anticonvulsant effects in animal models at lower levels of benzodiazepine receptor occupation than diazepam, but does not exert muscle relaxant or ataxic effects. (Stephens et al, JPET 253: 334, 1990; Turski et al, JPET 253: 344, 1990). These observations suggest some form of selective activity at subpopulations of benzodiazepine receptors. Consistent with this hypothesis, abecarnil in vitro showed a 15 fold lower affinity for ^{3}H-lormetazepam binding sites in spinal cord than in cortex (IC_{50} 250 vs 15 nM), whereas diazepam showed a similar affinity for the two sites (250 vs 80 nM). In cerebellum, abecarnil was able to displace binding of ^{3}H-Ro 15-4513 from both its binding sites (IC_{50} 2 and 560 nM), whereas diazepam and other benzodiazepines displaced maximally 60 % of Ro 15-4513 binding (IC_{50} 20 and >10000 nM). Electrophysiological studies in frog oocytes expressing defined combinations of benzodiazepine receptor subunits confirmed a differentiation between abecarnil and benzodiazepines. These findings are consistent with abecarnil interacting with an overlapping but different subpopulation of receptors from benzodiazepines.

537.8

DISULFIRAM AND DIETHYLDITHIOCARBAMATE ARE COMPETITIVE INHIBITORS AT THE PERIPHERAL BENZODIAZEPINE RECEPTOR.

M. Gavish, Y. Katz* and R. Weizman*. Dept. of Pharmacology, Fac. of Med. and Rappaport Inst., Technion; Dept. of Anesthesiology, Rambam Medical Center, Haifa; Hasharon Hosp. and Sackler Fac. of Med., Tel-Aviv Univ., Tel Aviv, Israel.

In the present study, in vitro interactions of disulfiram (an agent used to induce ethanol intolerance in alcoholics), its metabolite diethyldithiocarbamate (DDC), and metronidazole (a disulfiram congener), with central benzodiazepine (BZ) receptors (CBR) and peripheral BZ receptors (PBR) were investigated in rat tissues. Disulfiram displaced specific binding of [^{3}H]PK 11195 from PBR in the cerebral cortex with IC_{50} value of 5 x 10^{-7} M. The binding of [^{3}H]PK 11195 and [^{3}H]Ro 5-4864 to PBR in the kidney was displaced by disulfiram with IC_{50} values of 7 x 10^{-7} M and 2 x 10^{-7} M, respectively. DDC displaced [^{3}H]PK 11195 binding to kidney membranes with IC_{50} value of 5 x 10^{-5} M. Binding of [^{3}H]flunitrazepam (FNZ) to CBR in the cerebral cortex was not affected by either disulfiram or DDC. Metronidazole (up to 10^{-4} M) did not affect [^{3}H]FNZ and [^{3}H]PK 11195 binding to CBR and PBR, respectively. Scatchard analysis of [^{3}H]PK 11195 saturation curve to kidney membranes, performed in the absence or presence of 7 x 10^{-7} M disulfiram revealed a decrease in ligand affinity without influencing the maximal number of binding sites, suggesting a competitive inhibition.

537.9

QUANTITATIVE AUTORADIOGRAPHIC CHARACTERIZATION OF THE BINDING OF ^{3}H-NO 328 (TIAGABINE) TO THE GABA UPTAKE CARRIER.

P.D. Suzdak and K.E. Andersen. Novo Nordisk A/S, CNS Division, DK-2860 Soeborg, Denmark.

Gaba (Gamma aminobutyric acid) is a major inhibitory neurotransmitter in the CNS. A decrease in Gaba-ergic neurotransmission is believed to be involved in a number of neurological conditions, including epilepsy. NO 328 (Tiagabine) is a potent and selective inhibitor of both Gaba uptake in vitro (IC_{50} = 67 nM) and DMCM and PTZ-induced convulsions in mice and rats. The present report examines the autoradiographic localization of the Gaba uptake carrier in rat brain using ^{3}H-NO 328. ^{3}H-NO 328 binding was regionally distributed in the rat brain, with the highest level of binding present in the prefrontal cortex, somatosensory cortex, superior colleculus, substantia nigra pars compacta, dorsal raphe, amygdaloid nucleus, CA$_3$ and CA$_4$ of the hippocampus, and molecular layer of the cerebellum. Scatchard analysis serial sections were linear with dissociation constant values ranging from 10 nM (frontoparietal cortex, motor area) to 165 nM (globus pallidus) and Bmax ranging from 456 Fmol/mg protein (substantia nigra pars riticulta) to 28 Fmol/mg protein (corpus collosum).

537.10

BENZODIAZEPINE INHIBITION OF TRIIODOTHYRONINE UPTAKE INTO HUMAN LIVER CELL LINE HAS A UNIQUE STRUCTURE ACTIVITY RELATIONSHIP

L KRAGIE & D DOYLE* Depts. of Medicine & Biological Sciences, State University of New York at Buffalo, Buffalo, NY 14260

We have reported that high affinity temperature-dependent cellular uptake of triiodothyronine (T_3) into HepG2 cells is inhibited by uM diazepam and peripheral ligand RO5 4864 (Soc for NS 1990, abstr #36.19). This inhibition is is not due to toxicity and is reversible with washing . We assayed the dose response of 25 benzodiazepines (BZ's) and determined apparent IC_{50}'s to illustrate structure for inhibition. ASSAY Confluent HepG2 cells in multiwell plates were incubated 3 hr prior to assay with serum-free media. Wells +/- drug and 40 pM ^{125}I-T_3 incubated x 1 hr at 22 or 4 C, then cells were washed on ice. The NaOH hydrolysate was gamma counted. T_3 uptake at 22 C - 4 C uptake = ~80% of total 22 C uptake. RESULTS At R_2', Cl> F> Br; at R_7, Cl> NO_2; at R_4', Cl > H; at R_3, OH> H; at R_1, alkyl groups > H; on imidazole of 1,2 annelated BZ's, CH_3 > H; the nonfused phenyl ring and the carboxyl at R_2 in the 1,4 BZ's are essential for potency. Most potent drugs were lormetazepam, triazolam, and prazepam and least were flumazenil and RO5 3663. Lormetazepam and triazolam showed no effect on T_3 binding to isolated rat liver nuclei, indicating that the interaction is not at the nuclear receptor. T_3 did not affect RO5 4864 binding to rat liver homogenate, indicating that it does not share binding sites with this peripheral BZ ligand. Study supported by NIH grant K11 DK 01456 to Dr. Kragie. P. Sorter of Hoffman LaRoche generously supplied benzodiazepines.

537.11

EFFECTS OF SEDATIVES ON GABA-MEDIATED CHLORIDE FLUX MEASURED IN THE MILLISECOND TIME SCALE.

S.J. Mihic*, P.H. Wu*, G.A. Cottrell and H. Kalant*. Dept. of Pharmacology, University of Toronto, and Addiction Research Foundation, Toronto, CANADA M5S 1A8.

GABA-mediated chloride influx into rat cerebral cortical microsacs, and its potentiation by pentobarbital (PB), diazepam (DZ) and ethanol (EtOH), was studied in incubations lasting from 24 to 3000 msec. The 3000 msec assays were carried out manually, while all other assays were performed in a quench flow machine. The EC_{50} and Hill coefficient of each GABA concentration-response curve were found to depend on the incubation time; both were lower at longer incubation times. Pentobarbital enhanced the effect of GABA (at EC_{30} concentration) with greater efficacy in the 3000 msec than in the 50 msec incubations; the threshold PB concentration required for potentiation was also lower in the longer assay. Preincubation of microsacs with PB (40 - 80 μM) for 1 or 5 sec before a 50 msec incubation with GABA, did not increase the effect of PB beyond that obtained by adding PB only into the incubation. However, a 1 sec preincubation with DZ (1 μM) was necessary for showing its effect in the 50 msec assay. EtOH (50 mM) had no effect, whether or not it was added in the preincubation. When microsacs were preincubated with 32 μM GABA for 1 sec, far greater potentiation of the GABA effect was seen when PB was also present during the preincubation (1.47 ± 0.18 nmol Cl/mg protein) than when it was only added in the incubation (0.6 ± 0.12 nmol Cl/mg protein). This suggests that only PB binding which occurs after GABA binding potentiates the effect of GABA. Preincubation with both DZ and GABA produced greater influx (0.49 ± 0.12 nmol Cl/mg protein) than preincubation with GABA alone, but merely adding DZ into the incubation, after the preincubation with GABA had no effect (-0.16 ± 0.13 nmol Cl/mg protein). Ethanol also had no effect when added either during or after the 1 sec preincubation with GABA. The different effects of these sedatives on GABA-mediated chloride flux suggests that they do not have a common site of action.

Supported by NIAAA grant #1 R01-AA08212-02.

DEHYDROEPIANDROSTERONE SULFATE: A NEUROSTEROID THAT BLOCKS THE $GABA_A$ RECEPTOR NONCOMPETITIVELY.

C.E. Spivak. Laboratory of Molecular Neurobiology, NIDA/ARC, P.O. Box 5180, Baltimore, MD 21224.

Dehydroepiandrosterone sulfate (DHEAS) was tested at $GABA_A$ receptors on neurons cultured from the ventral mesencephalon of fetal rats. The currents were measured under whole cell voltage clamp. DHEAS blocked peak currents induced by GABA noncompetitively with a dissociation constant of 4.5 μM and a stoichiometry of 1:1. In addition, DHEAS caused a pronounced, double exponential decay in the conductance. Analysis showed that this decay was not due to any of the following: (1) accelerated desensitization of the receptor, which showed single exponential decay, (2) voltage dependent occlusion of the ion channel by DHEAS, or (3) binding of DHEAS to the activated state of the receptor.

DHEAS also decreased the time constant for the decay of large, but not small, inhibitory postsynaptic currents. This observation is attributed to either diminished release of GABA or accelerated reuptake.

THDOC DECREASES PLASMA CORTICOSTERONE CONCENTRATIONS VIA A NON-GLUCOCORTICOID MECHANISM. M.J. Owens, J.C. Ritchie and C.B. Nemeroff. Depts. of Psychiatry and Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Certain naturally occuring steroids that exist as trace metabolites of steroid hormones have been found to enhance GABAergic receptor function and binding. One of the most potent of these in *in vitro* studies is tetrahydrodeoxycorticosterone (THDOC; 5α-pregnane-3α,21-diol-20-one). THDOC, presumably acting via GABAergic mechanisms, possesses anxiolytic activity in the Vogel conflict test in the rat. Because enhanced CNS GABAergic activity appears to inhibit HPA activity and because the benzodiazepine, alprazolam, alters corticotropin-releasing factor (CRF) neurons in the locus ceruleus, we have examined the acute effects of THDOC on CRF neurons in several brain regions and on plasma corticosterone concentrations. In addition, we concomitantly examined the actions of the synthetic glucocorticoid, dexamethasone, and its purportedly active metabolite, 6β-OH-dexamethasone, on these same measures of CRF activity.

Following a single acute s.c injection, THDOC (2.5 mg/kg) and alprazolam (1 mg/kg) attenuated mild stress-induced increases in plasma corticosterone concentrations. In contrast, stress-induced corticosterone increases were completely abolished by dexamethasone and 6β-OH-dexamethasone. Attenuation of plasma corticosterone responses by THDOC were not due to any inherent glucocorticoid activity as THDOC had little affinity for the cytosolic glucocorticoid receptor. Unlike alprazolam, THDOC failed to decrease CRF concentrations in the locus ceruleus. While THDOC may plausibly act endogenously to reduce stress-induced endocrine and behavioral responses that are likely mediated in part by CRF neurons, these preliminary findings suggest that THDOC does not identically mimic the actions of alprazolam, another drug which potentiates GABAergic activity.

EFFECTS OF CHRONIC ANABOLIC/ANDROGENIC STEROID EXPOSURE ON INDICES OF FUNCTION OF THE GABA/BENZODIAZEPINE RECEPTOR COMPLEX. Daniel Bitran, Robert J. Hilvers*, and Carol K. Kellogg. University of Rochester, Department of Psychology, River Campus, Rochester, NY 14627.

The growing use of anabolic/androgenic steroids by athletes is of great concern to the medical and scientific communities. Although much research has addressed the mechanisms underlying steroid-mediated anabolic effects, little is known about the neural mechanisms that mediate the adverse effects of steroids on mental health. In addition to the classic genomic mechanism of steroid action, the modulation of neural excitability by 3α-hydroxylated pregnane steroids via effects on GABA/BDZ receptors has been demonstrated. Reduced metabolites of testosterone potentiate GABA-mediated function in a manner similar to that observed for reduced pregnane steroids. Since anabolic-androgenic steroid metabolites are potent agonists at the GABA/BDZ receptor complex, it was hypothesized that behavioral and neurochemical indices of the GABA/BDZ receptor system would be affected by chronic treatment, and subsequent withdrawal from testosterone-proprionate (TP) exposure.

In one experiment, 4 weeks following the implantation of a TP-filled silastic capsule (30 mm), male rats displayed increased anxiety as shown by an increase in the duration of burying behavior in the defensive burying paradigm. The androgenic efficacy of the steroid treatment was evidenced in a doubling of the weight of the ventral prostate gland in TP-treated males. The effector response of the GABA/BDZ receptor system was investigated using $^{36}Cl^-$ uptake in cortical synaptoneurosomes. Whereas TP treatment did not affect the maximal response to GABA, a significant decrease in the EC_{50} for GABA-stimulated Cl^- influx was observed. This pattern of results has been previously demonstrated following discontinuation from chronic treatment with BDZs, and is consistent with an upregulation in the function of the GABA/BDZ receptor complex. In our studies, silastic capsules were found empty upon sacrifice, suggesting that the rats were in a withdrawal phase. Current experiments will more precisely characterize changes in behavior and neural function during TP exposure and following steroid withdrawal.

ANXIOLYTIC ACTIVITY OF THE PROGESTERONE METABOLITE 5α-PREGNAN-3α-OL-20-ONE. S. Wieland, N.C. Lan, S. Mirasedeghi* and K.W. Gee. Dept. of Molecular Pharmacology and Toxicology, Sch. of Pharmacy, Univ. of Southern California, Los Angeles, CA 90033

3α-hydroxylated pregnane steroids have been shown to possess anesthetic, hypnotic, anticonvulsant and anxiolytic properties. In this study, metabolites of progesterone and deoxycorticosterone, 5α-pregnan-3α-ol-20-one (3α-OH-DHP) and 5α-pregnan-3α,21-diol-20-one (5α-THDOC), respectively, were tested for anxiolytic effects in N.I.H. Swiss-Webster mice using the light/dark transition, open-field and lick-suppression tests. Similar to the benzodiazepine (BZ) diazepam, 3α-OH-DHP (5-40 mg/kg) and 5α-THDOC (5-40 mg/kg) significantly increased the number of light/dark transitions. 3α-OH-DHP's effects were stereospecific as its diasteriomer, 3ß-OH-DHP was devoid of activity. The benzodiazepine antagonist CGS-8216 (10 mg/kg) blocked diazepam's (1.0 mg/kg) anxiolytic effects, but did not have any effect against 3α-OH-DHP (20 mg/kg). The data indicate that the pregnane steroids produce their anxiolytic effects through a separate mechanism than the BZs. 3α-OH-DHP (20 mg/kg), 5α-THDOC (20 mg/kg) and diazepam (1.0 mg/kg) increased activity in an open-field test. 3ß-OH-DHP had no effect in the open-field test. Furthermore, 3α-OH-DHP produced a 235% increase in punished responding in a lick-suppression test. These results demonstrate that the endogenous pregnane steroids possess anxiolytic effects that may be clinically relevant. (Supported by grants from CoCensys, Inc. and NS 24645 and NS 25986).

537.16

REGIONAL DISTRIBUTION OF A NEURONAL STEROID BINDING SITE IN RAT BRAIN D. Belelli* S. Wieland, N. C. Lan, R.E. Brinton and K.W. Gee. Dept. of Molecular Pharmacology and Toxicology, Sch. of Pharmacy, Univ. of Southern California, Los Angeles, CA 90033

The anatomical localization of the putative steroid recognition site associated with the $GABA_A$ receptor chloride ionophore was evaluated in rat brain by allosteric modulation of ^{35}S-t-butylbicyclophosphorothionate (TBPS) and ^3H-flunitrazepam (FLU) autoradiography.

All regions showing detectable specific ^{35}S-TBPS binding were affected by the most potent steroid 5α-pregnan-3α-ol-20-one (3α-OH-DHP). Detailed analysis of specific brain regions revealed regional variations in the potency of 3α-OH-DHP. For example, 3α-OH-DHP displaced ^{35}S-TBPS binding with nanomolar potency in the hippocampus but micromolar potency in the brainstem.

In addition, steroid coupling to the central benzodiazepine receptor was investigated by evaluating the ability of neuroactive steroids to enhance ^3H-FLU binding. A regionally dependent effect of 3α-OH-DHP on ^3H-FLU binding was observed since a lack of coupling between the steroid and the benzodiazepine sites was apparent in several brain regions.

Collectively these results provide initial evidence for a differential distribution of the benzodiazepine and steroid binding sites and suggest a unique regional distribution of a putative neurosteroid recognition site in rat brain. (Supported by a grant from CoCensys, Inc.)

TEMPERATURE DEPENDENCE AND STEROID MODULATION OF [^{3}H]FLUNITRAZEPAM BINDING TO RAT BRAIN MEMBRANES. R.J.Prince* and M.A.Simmonds. School of Pharmacy, University of London, London WC1N 1AX

The state of fluidity of lipid bilayers is dependent upon both the steroids present, notably cholesterol, and temperature. We have examined the effect of temperature upon [^{3}H]flunitrazepam (FNZ) binding to the $GABA_A$-benzodiazepine receptor and also upon the modulation of this receptor by the pregnane steroid alphaxalone.

The affinity of FNZ was measured at temperatures in the range 0-47°C using a displacement assay terminated by rapid filtration in the absence and presence of 100μM alphaxalone. Increasing temperature resulted in a decrease in affinity. A plot of reciprocal absolute-temperature against -log(Ki) showed a linear relationship in both cases. This is predicted by the van't Hoff equation ($\ln Keq = -\Delta H^\circ/RT + \Delta S^\circ/R$) and indicates that affinity changes may be due to thermodynamic considerations only. Linear regression yields values of -30.23 and -34.04 $kJ.mol^{-1}$ for ΔH° and 53.51 and 47.88 $J.K^{-1}mol^{-1}$ for ΔS° in the absence and presence of steroid respectively. The derived values for ΔH° are not significantly different at a confidence level of 95% indicating that steroid potentiation may be a temperature independent phenomenon.

537.18

PROPOFOL (PR), A NOVEL GENERAL ANESTHETIC, HAS SPECIFIC RECOGNITION SITES IN THE RAT BRAIN A. Concas, M.P. Mascia*, G. Santoro*, M. Serra*, E. Sanna and G. Biggio Dept of Experimental Biology, Chair of Pharmacology, Univ. of Cagliari, 09123 Cagliari, Italy

Recently, we have shown that PR, a novel general anesthetic enhances the function of $GABA_A$ receptor complex in the rat brain. In fact, like alphaxalone, barbiturates and benzodiazepines, PR increased ^{3}H-GABA binding and muscimol-stimulated $^{36}Cl^-$ uptake and reduced ^{35}S-TBPS binding. However, the additive effect produced by the concomitant addition of PR and the above drugs suggests different sites of action. To identify putative binding sites for PR we examined the binding of the radiolabelled PR (^{3}H-PR) in the rat brain. ^{3}H-PR binding to a crude synaptosomal preparation was specific (80-90% of specific binding), increased linearly with proteins concentration, reached equilibrium within 7 hr at 37 °C. In the rat cerebral cortex ^{3}H-PR binds to two population of binding sites (high affinity K_D 112 ± 8 nM; Bmax 7.8 ± 2 pmol/mg protein; low affinity K_D 6.4 μM; Bmax 55 ± 12 pmol/mg protein). Regional distribution studies showed that ^{3}H-PR binding was higher in the cerebellum, cerebral cortex and hippocampus and lower in the striatum and spinal cord. Finally, the finding that ^{3}H-PR binding is completely inhibited by pretreatment of membrane with proteinase K suggests the possible specific interaction of PR with some protein rather than other component of membrane.

537.19

BIOCHEMICAL EVIDENCE THAT "IN VIVO" ADMINISTRATION OF ABECARNIL ENHANCES GABAERGIC TRANSMISSION IN THE RAT CEREBRAL CORTEX. M. Serra*, M.C. Foddi*, C.A. Ghiani*, A. Concas, E. Sanna and G. Biggio Dept. of Experimental Biology, Chair of Pharmacol., Univ. of Cagliari, Cagliari 09123, Italy

The effect of abecarnil (AB), a new β-carboline possessing anxiolytic and anticonvulsant properties, was evaluated "in vivo" on the function of $GABA_A$ receptor complex. The intraperitoneal injection of AB produced in 30 min a dose dependent (0.25-20 mg/kg) decrease of [^{35}S]TBPS binding measured "ex vivo" in the rat cerebral cortex; this effect was abolished by the administration of the benzodiazepine receptor antagonist flumazenil (Ro 15-1788). AB, up to the maximal dose used (20 mg/kg), failed to induce ataxia and loss of righting reflex. Moreover, acute administration of AB (1 mg/kg) completely antagonized the convulsant activity and the increase of [^{35}S]TBPS binding induced by 350 mg/kg of isoniazid as well as the increase of [^{35}S]TBPS binding induced by foot-shock stress. Consistent with the above results the "in vitro" addition of AB, mimicking the action of benzodiazepines, increased [^{3}H]GABA binding, enhanced muscimol-stimulated $^{36}Cl^-$ uptake, reduced [^{35}S]TBPS binding and inhibited the binding of [^{3}H]Flunitrazepam. The results suggest that the enhancement induced by AB on GABAergic transmission can be detected biochemically in the membrane preparation "ex vivo".

OPIOIDS: BEHAVIOR I

ALFENTANIL DOSE-EFFECT RELATIONSHIPS FOR FOUR OPIATE EFFECTS IN THE RAT. M. B. Weinger, P. K. Yang*, S. S. Negus. Department of Anesthesiology, UCSD and VA Medical Centers, San Diego, CA 92161; Department of Neuropharmacology, Scripps Clinics, La Jolla, CA 92093.

Besides antinociception [AN] and sedation, opiates also cause catalepsy [CT] and muscle rigidity [MR]. However, MR dose-effect relationships have not been directly compared to AN or loss of righting reflex [RR]. To elucidate the mechanisms and sites of action of opiate anesthesia, the endpoints of opiate effect must first be described. We, therefore, studied four relevant opiate endpoints (AN, CT, MR, and RR) using the μ-agonist alfentanil [ALF] in the spontaneously ventilating rat.

Rats were randomized to receive a dose of ALF (0-500 μg/kg s.c.). For MR, 59 rats had EMG activity measured with percutaneous hindlimb electrodes. After ALF, data were recorded for 60 min. For AN and CT, 49 rats were studied for 120 min after ALF. CT was measured from the time the rat's forelimbs were placed on a 10-cm-high bar until either limb was removed. The nociceptive stimulus was tail immersion in 55°C water. AN latency was measured from tail immersion until purposeful tail movement (10-sec cutoff). For RR, 40 rats were studied for 120 min. RR was absent when a rat could not right itself in 15 sec. For each effect, data were converted to quantal responses by assigning any value >4 times baseline as a positive response. Data were converted to probit-log dose response curves, and slopes and ED50's were analyzed.

Slopes between the four dose-effect curves were not significantly different. The ED50 for RR differed significantly from AN and MR, and the ED50 for CT differed significantly from AN. The slopes and ED50's for MR and CT were similar, suggesting a common site of action. Catalepsy may be a useful model for spontaneous movement during opiate anesthesia. These techniques and data will help elucidate the pharmacology of opiate effects and their underlying receptor mechanisms.

538.2

SOCIAL DEFEAT IN FEMALE RATS: SENSITIVITY TO OPIATE SUPPRESSION OF TAILFLICK REFLEX AND ULTRASOUNDS. M. Haney, K.A. Miczek. Dept. Psychology, Tufts Univ., Medford MA 02155.

Female rodents are less sensitive to environmental stress-induced analgesia than males. We investigated the behavioral characteristics and pharmacological consequences of social defeat in female rats: (1) Do female rats emit ultrasounds during an aggressive encounter with a lactating opponent? (2) Do defeated females show a pattern of potentiation and cross-tolerance to morphine-induced analgesia? (3) Does gonadal hormone status modulate morphine sensitivity during or 1 week after a defeat experience? Morphine (1-10 mg/kg sc) or saline was administered to estrous and diestrous, Long-Evans rats exposed to 3 attack and threat encounters (ca. 1 min) over a 75 min period. The remainder of the 75 min, rats were threatened but protected from attack by wire mesh. Females emit ultrasonic calls during the physical and protected encounter. Morphine (6-10 mg/kg sc) selectively attenuated the high frequency (32-60 kHz) ultrasonic components without altering low frequency (22-32 kHz) or audible calls. Rats were analgesic within a similar dose-range; estrous state did not significantly modulate morphine's effects. Unlike males, (1) females actively escaped attack and rarely displayed submissive postures (crouch, supine) (2) morphine's analgesic properties were not potentiated during the defeat encounter. Rats treated with saline during the defeat were tolerant to morphine-induced analgesia one week later (1.5 fold rightward shift). The relatively attenuated opiate potentiation in defeated female rats may reflect the active rather than immobile response to attack.

538.3

OPIATE REGULATION OF AFFILIATIVE VOCALIZATIONS AND BEHAVIORS IN INFANT RHESUS MONKEYS. N.H. Kalin, S.E. Shelton* and C.T. Snowdon*. Dept. of Psychiatry and Psychology and VA Hospital, Univ. of Wisconsin, Madison, WI 53705.

We assessed the role of opiate systems in regulating affiliative behaviors and vocalizations. During maternal separation, infants emit coos. When separated and tested in proximity to conspecific adults with whom they cannot achieve physical contact, infants increase their cooing and also emit soft, low-frequency nasal whimpers (girns). Coos and girns differ on several acoustical parameters: duration (p <.001), frequency (p <.01), and number of harmonics, (p <.01). Behavioral and vocal responses are also modulated when infants are physically united with conspecifics after brief maternal separation. When united with an unfamiliar adult male, infants attempt to affiliate but are rejected. As attempts to achieve physical comfort fail, they express fear-related behavior, increase cooing (p <.01), and decrease girning. When reunited with their mothers, the mothers cradle them, and the infants girn more (p <.02) and cease cooing. These data suggest that both coos and girns are affiliative vocalizations but have different communicative functions. Pharmacological experiments reveal that opiate systems regulate coos and girns depending on environmental parameters. During reunion, endogenous opiate systems also appear to regulate infants' attachment behaviors.

538.4

SENSITIZATION OF OPIATE EFFECTS: PROGRESSIVE INCREASES IN FEEDING WITH REPEATED CENTRAL INJECTIONS OF DAGO BUT NOT DPDPE. R.A. WISE, and M.B. NOEL Center for Studies in Behavioral Neurobiology, Dept. Psychol., Concordia University, Montreal, Quebec, Canada. H3G 1M8

Ventral tegmental area (VTA) injections of morphine cause locomotion and potentiate feeding; the locomotor effects increase (sensitize) with repeated testing. In order to determine whether mu or delta receptors are involved in the feeding effects and whether sensitization occurs in relation to the feeding as well as the locomotor effects, we examined the effects of repeated administration of the selective mu agonist DAGO ([D-Ala^2,N-Me-Phe^4-Gly^5-Ol]-Enkephalin) and the selective delta agonist DPDPE ([D-Pen^2,D-Pen^5]-Enkephalin) in food deprived rats. Rats were implanted with stainless steel cannulae aimed at the VTA. Feeding behavior was quantified daily after 18 hours of food deprivation; food was presented in 18 meal segments consisting of five 45 mg food pellets per segment. VTA injections of DAGO and DPDPE caused dose-dependent acceleration of feeding; DAGO was 10 times more effective than DPDPE. While repeated injections of a low dose (0.05 nm) of DAGO resulted in progressively greater accelerations of feeding, repeated DPDPE (0.5 nm) injections did not. These data implicate mu opiate receptors in the facilitation of feeding and indicate that the potentiation of feeding, like the locomotor effects of mu opioids, is sensitized by repeated opioid treatment.

538.5

DIET AND OPIATE-INDUCED ANALGESIA IN RATS. R. B. Kanarek, E. S. White* and R. Marks-Kaufman*. Dept. of Psychology and School of Nutrition, Tufts Univ., Medford, MA 02155.

This series of experiments examined the effects of palatable foods on opiate-induced analgesia using a tail-flick apparatus in 42 adult male Sprague-Dawley rats. Rats were given ad lib access to Purina Chow (N=14), or given a choice of Purina Chow and either a 32% sucrose solution (N=14), or hydrogenated vegetable fat (N=14). Analgesic testing was conducted immediately preceding and at 30, 60, and 90 minutes following intraperitoneal injections of morphine sulfate (0.0, 5.0 and 10 mg/kg) or subcutaneous injections of ethylketocyclazocine (EKC) (0.0, 0.1, 0.3 and 0.6 mg/kg). No differences in analgesic responsiveness were observed as a function of diet preceding drug injections. However, dietary variables did alter opiate-induced analgesia. Sixty minutes following the injections of 10 mg/kg morphine, animals fed sucrose or fat had significantly longer mean tail flick latencies than rats fed only Purina Chow (Purina Chow = 1.5 sec; Purina + sucrose = 4.9 sec; Purina + fat = 3.3 sec). Similarly, at 30 minutes following injections of 0.3 mg/kg EKC, rats fed sucrose or fat had significantly longer mean tail flick latencies than their Purina Chow fed counterparts (Purina Chow = 0.7 sec; Purina + sucrose = 3.3 sec; Purina + fat = 2.7 sec). These data suggest that dietary variables interact directly with endogenous opioid systems to influence pain sensitivity.

538.6

THE RAPID DEVELOPMENT OF TOLERANCE TO MORPHINE IN GENETICALLY OBESE RATS. C.B. Goodman* and K.F.A. Soliman, College of Pharmacy, Florida A&M University, Tallahassee, FL 32307.

Endogenous opioids have been implicated in obesity in the genetically obese Zucker rat (fa/fa). The present study was designed to determine if tolerance would develop in the obese Zucker rat after two days treatment of morphine. Obese rats and their lean littermates were treated with morphine (10 mg/kg) for two days, while their corresponding controls received equivalent volumes of saline. Tolerance was assess by measuring pain sensitivity and plasma glucose level before and 30, 60, 120 minutes after morphine administration. The results show no tolerance was exhibited in the tail flick for both groups. The obese animals were shown to be more sensitive to morphine's antinociceptive effects. Moreover, in the hot plate test, both groups developed tolerance and the duration of analgesia was significantly prolonged ($p<0.05$) for 120 min in the obese rats when compared to their lean littermates. While no significant changes were observed in the plasma glucose levels of the obese animals, the lean group experienced a significant increase ($p<0.01$) in their plasma glucose levels for 60 mins. after the second day of morphine treatment. These results suggest that the acute development of tolerance may be mediated through a supraspinal mechanism. (Supported by NIH grants RR 0811, RR 03020 and NASA grant NAG 2-411).

538.7

ENHANCED DRINKING AFTER INJECTION OF THE *MU*-OPIOID AGONIST DAMGO INTO THE RAT VTA: SENSITIZATION AFTER CHRONIC AMPHETAMINE TREATMENT. A. Badiani, D. Rodaros and J. Stewart. Center for Studies in Behavioral Neurobiology, Dept. of Psychology, Concordia University, Montreal, QC, Canada, H3G 1M8.

Chronic pretreatment with amphetamine (AMPH) has been shown to enhance the effects of intra-ventral tegmental area (VTA) microinjections of morphine on locomotion (Stewart & Vezina, 1987) and food-intake measured over 2-5 h (Nencini & Stewart, 1990). In this experiment, highly selective μ- and *k*-opioid agonists, DAMGO and U-50,488H (U50), were compared for their effects on ingestive behaviors in 20 rats prepared with bilateral cannulae aimed at the VTAs. Two groups received daily i.p. injections of either saline (SAL) or 3 mk/kg of d-amphetamine (AMPH) in their home cages. After 10 days of chronic treatment, the rats were challenged, in a counterbalanced order, with U50 (1.0 nmol per side), DAGO (0.1 nmol per side) or saline (0.5 µl per side). 15 min after the microinjections, the rats were placed in test cages and feeding, drinking and other activities were recorded over 1 h. Tests occurred twice a week. DAMGO increased drinking by 64% in SAL-pretreated rats and by 185 % in AMPH-pretreated rats. Water-intake after microinjection of saline was the same in the two chronic treatment groups. DAMGO did not increase food-intake, measured over 1 h, in either group. U50 failed to affect both feeding and drinking. These results suggest that μ-opioid and dopaminergic pathways interact at the level of VTA to modulate drinking as well as other appetitive behaviors.

538.8

KAPPA OPIOID RECEPTOR MEDIATES FETAL RESPONSIVENESS TO MILK. W. P. Smotherman, R. R. Sheaffer*, S. Musselwhite* and S. R. Robinson*. Center for Developmental Psychobiology, SUNY-Binghamton, Binghamton, NY 13902-6000.

Fetal rats reliably express a facial wiping response to punctate tactile stimulation of the perioral area on days 20-21 of gestation (birth = 21.5 days). The wiping response is eliminated 60-s after intraoral infusion of milk. Pretreatment of fetuses with naloxone blocks the milk effect and restores the wiping response, indicating that milk activates a functional opioid system in the fetus. The κ opioid antagonist, nor-binaltorphimine HCl, also is effective in reversing the behavioral effects of milk, but the µ antagonist, β-funaltrexamine HCl, is not. These findings suggest that milk infusion triggers the release of endogenous opioids which bind to the κ receptor to alter fetal responsiveness to stimulation and effect global changes in fetal behavioral organization.

POMC SYSTEM AND ALCOHOL PREFERENCE. J.C. Froehlich*, G. Wand*, S. Ochs and T.-K. Li*. Dept. of Med., Indiana Univ. Sch. of Med., Indianapolis, IN 46202; Dept. of Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

We have previously reported that differences in activity within the central enkephalinergic system are associated with genetic differences in oral ethanol preference. We now report that rats that have been genetically selected for high or low alcohol drinking (alcohol-preferring or P, and alcohol nonpreferring or NP lines, respectively) differ in activity within the proopiomelanocortin (POMC) system. Ethanol-naive P and NP rats were sacrificed and the anterior pituitary (AP), neurointermediate lobe of the pituitary (NIL), and hypothalamus (H) were dissected out. Total RNA was extracted and northern analyses were performed using a POMC cDNA probe. POMC mRNA for each sample was normalized to the amount of 18S RNA present. Plasma content of β-endorphin and corticosterone were analyzed by RIA. Densitometric analyses showed that POMC mRNA was approximately 2-fold higher in the AP and NIL of P rats compared with NP rats. Plasma levels of β-endorphin and corticosterone were also higher in rats of the P line than in the NP line. The results suggest that a genetic predisposition towards alcohol drinking may be associated with increased activity or "tone" of the POMC system (AA07611; AA08312; AA08553; AA01298).

EFFECTS OF SELECTIVE SIGMA AGENTS ON LICKING AND OPEN-FIELD BEHAVIORS R.B. Murphy, L.H. Schneider, R. Bock*, and J.D. Davis, Cornell Univ. Medical College, Dept. of Psychiatry, Bourne Lab, White Plains, NY 10605 and Dept. of Chemistry and Ctr. Neural Sci., New York Univ., NY, NY 10003 and Univ. Illinois, Dept. Psychol, Chicago IL 60680

We previously reported that peripherally-administered sigma agents do not modulate sucrose sham feeding in the rat in a manner commensurate with their putative involvement with the ascending dopamine (DA) systems (Soc. Neurosci. Abstr.16:1028,1990). However, peripherally administered sigma agents do produce a significant shift in the mean of the interlick interval distribution toward longer time which is not observed when selective DA agents are administered centrally or peripherally. We report here the effects of intraventricular and bilateral intranigral administration of the selective sigma agents (+)-SKF 10,047 (SKF) and di-o-tolylguanidine (DTG) on the microstructure of ingestion of 50% sweetened milk, as well as on various open field behaviors. Male, 18-h deprived S/D rats received DTG (4 ug/rat) or SKF (10 ug/rat) intraventricularly; no significant effects on amount consumed or microstructure were found, other than a significant lengthening of the duration of feeding in DTG rats. In a separate group in which DTG (700 ng/rat) was infused bilaterally into the substantia nigra, a small but significant reduction in amount ingested was observed as compared with CSF. Rats which received DTG (700 ng/rat) or SKF (4 ug/rat) intranigrally were also examined in the open field. The only parameter effected was numbers of squares crossed, which were significantly increased in DTG but not in SKF or CSF rats. In summary, central administration of selective sigma agents failed to produce the shift in interlick interval distribution, in contrast to their peripheral administration. The central results further support the lack of involvement of DA systems in sigma-mediated behaviors. We hypothesize that the major effect of the sigma agents is on hindbrain sigma sites accessible to peripheral circulation which control lick rate. **[SUPPORTED BY: NIDA DA 05728 (RBM), NINDS NS24781 (LHS), and NIH DK 41563 (JDD)]**

Eigenmannia virescens: A NEW OPIATE ASSAY? R.D. Olson, B.B. Rowland*, S.M. Samuel*, A.M. Vasquez*, G.A. Olson, and A.J. Kastin. Department of Psychology, University of New Orleans, New Orleans, LA 70148.

Several species of African and South American fish are able to produce an electric organ discharge (EOD) rate that is both highly stable and individually unique. In Experiment 1, 75 fish (*E. virescens*) were injected IP (5 ul) with either diluent, naloxone (2 mg/kg), morphine (10 mg/kg), a single injection containing naloxone and morphine, or naloxone followed 10 seconds later by morphine. Testing consisted of a 10 minute pre-injection baseline period and a 30 minute post-injection test period. Morphine was found to significantly decrease ($p<.05$) EOD rate relative to diluent and naloxone, which did not differ. A single injection of naloxone and morphine produced results similar to separate injections of naloxone and morphine; in both cases, naloxone antagonized the effects of morphine, suggesting that separate injections are not necessary. Experiment 2 evaluated doses of morphine (0, 5, 10, 20, and 40 mg/kg IP), with results indicating that 40 mg/kg significantly reduced ($p<.05$) the EOD rate relative to all other groups and even terminated the EOD rate completely in some subjects; 20 mg/kg significantly decreased ($p<.05$) the EOD rate relative to the remaining doses, which did not differ from one another. The results suggest that *E. virescens* might serve as a new opiate assay.

538.12

NALOXONE ENHANCES ACQUISITION OF A SPATIAL TASK IN NON-BREEDING MEADOW VOLES IN A SEXUALLY DIMORPHIC MANNER. L.A.M. Galea, L. Saksida*, M. Kavaliers, and K.- P. Ossenkopp. Departments of Psychology and Oral Biology, Univ. Of Western Ontario, London, Ontario, Canada, N6A 5C2.

Endogenous opioid systems have been implicated in spatial task learning. Polygynous meadow voles, *Microtus pennsylvanicus*, display pronounced sex differences in the ability to learn spatial tasks. In the present study, we examined the effects of the opiate antagonist, naloxone (1mg/kg), in spatial task learning (Morris water maze) of non-reproductive adult male and female meadow voles. Females treated with naloxone acquired the task faster than any other group, although all groups learned the task in five acquisition days. Contrary to previous studies with adult reproductive voles, no sex differences favoring males were detected in acquisition of the spatial task. Results from this study suggest that there may be miminal sex differences in water maze learning in sexually immature voles. These findings also suggest that spatial learning may be differentially modulated by the endogenous opioid systems in male and female voles.

EFFECTS OF ß-FUNALTREXAMINE AND NALOXONAZINE ON ALFENTANIL-INDUCED MUSCLE RIGIDITY AND ANTINOCICEPTION IN THE RAT. S.S. Negus and M.B. Weinger, Dept. of Anesthesiology, UCSD and VA Medical Centers, San Diego, CA 92161

Alfentanil is a potent and short-acting opioid agonist that is selective for mu opioid receptors. As with other mu agonists, alfentanil produces such clinically useful effects as antinociception, while also producing such unwanted side effects as muscle rigidity. The purpose of the present study was to compare the pharmacological nature of alfentanil-induced muscle rigidity and antinociception by evaluating the susceptibility of these effects to antagonism by ß-funaltrexamine (ß-FNA) and naloxonazine (NXZ). ß-FNA has been characterized as a selective and irreversible mu antagonist, whereas NXZ has been characterized as a selective and long-acting antagonist of the mu-1 subtype of the mu receptor. Rats were pretreated with either ß-FNA (vehicle, 10.0 mg/kg , 20 mg/kg) or NXZ (vehicle, 7.5 mg/kg, 15.0 mg/kg) approximately 20 hours before evaluating the effects of alfentanil. Muscle rigidity was measured by recording the electromyographic activity from the gastrocnemius muscle, whereas antinociception was measured using the warm-water tail dip procedure. Alfentanil dose-effect curves were generated for each pretreatment using a between-subjects design. Both ß-FNA and naloxonazine antagonized alfentanil-induced muscle rigidity and alfentanil-induced antinociception. These results indicate that mu receptors in general, and mu-1 receptors in particular, are capable of mediating both the antinociception and the muscle rigidity produced by alfentanil in the rat.

THE INFLUENCE OF CONTINUOUS INFUSION OF NALOXONE AND ITS WITHDRAWAL UPON SPONTANEOUS AND AMPHETAMINE -STIMULATED LOCOMOTOR ACTIVITY. D.N.C. Jones* and S.G. Holtzman. Dept. of Pharmacology, Emory Univ. School of Medicine, Atlanta, GA 30322.

Several reports in the literature demonstrate an opioid receptor mediated modulation of dopaminergic function. Therefore, the present study was designed to investigate the influence of both the continuous infusion of the opioid antagonist, naloxone (NX) and its subsequent withdrawal upon spontaneous locomotor activity and amphetamine (AMPH) -induced hyperactivity in rats. NX filled (1 mg/kg/hr) or sham osmotic pumps were implanted s.c. in rats (male, 280-290g at start of experiment) under light anesthesia and similarly removed following a 7-day infusion period. Spontaneous locomotor activity (fine and gross movements) was assessed on days 0 (pre-infusion), 3,6,8 and 14. A cumulative-dose-response curve to AMPH (0.1-6.4mg/kg s.c.) was constructed either on day 6 or day 8 (24hr following the removal of the pumps). During the infusion of NX, rats exhibited a lower level of both gross and fine locomotor activity than did sham animals, although this reached statistical significance for the latter measure only ($F=4.86$, $P<0.05$). There were no differences between the treatment groups 24hr and 7 days after pump removal. Cumulative administration of AMPH on either day 6 or 8 produced dose dependent increases in both fine and gross locomotor movements. On day 6, however, the response of NX-infused rats to AMPH was significantly attenuated ($F=6.15$, $P<0.05$, gross counts only) compared with that of sham-infused animals, with no apparent differences between the groups following saline administration. 24hr following pump removal, there were no longer any significant differences betwwen the response of the two groups of rats to amphetamine. The finding that NX attenuates AMPH-induced hyperactivity agrees with those of others and is possibly explained by an attenuation of the AMPH-induced release of dopamine (Hooks et al.,this meeting). This study extends the range of conditions investigating NX/AMPH interactions to include continuous NX treatment and reveals that the influence of NX was not shown to persist beyond cessation of the infusion. THE EFFECT OF ALFENTANIL ON DIAPHRAGMATIC ELECTROMYOGRAPHIC RECORDINGS IN THE RAT. C. M. Campbell*, M. B. Weinger, M. Quinn*, S. S. Negus, R. L. Lieber (sponsor). VA Medical Center, San Diego, CA 92161.

Muscle rigidity and respiratory depression are two undesirable side effects of opiate anesthesia. Opiate-induced increases in thoracic muscle tone contribute to impaired ventilation. However, the effect of high-dose opiates on diaphragmatic muscle tone and function has not been described. We therefore studied the effects of alfentanil (ALF) on diaphragmatic electromyographic (EMG) activity in the spontaneously ventilating rat.

5 - 7 days before the experiment, a differential electrode was surgically implanted in the diaphragm. A 100-Hz - 3-kHz band-pass filter was employed to remove electrocardiographic and low-frequency respiratory artifact. Baseline EMG activity was recorded for at least 15 min. Rats were then injected with ALF (0.5 mg/kg s.c.), and the EMG was observed for the next 30 min. Data were analyzed by computer to determine the effects of ALF on inspiratory and expiratory diaphragm activity.

Before ALF, diaphragm EMG activity increased during inspiration and decreased during expiration. ALF disrupted this phasic activity by augmenting the expiratory phase EMG. Thus, after ALF, the diaphragmatic EMG activity level stayed relatively constant and high for the entire 30-min experiment. Further study will clarify the mechanism of the effect and the role of diaphragmatic "rigidity" in opiate-induced respiratory depression.

538.16

EFFECTS OF ACUTE NALTREXONE ON LOCOMOTOR ACTIVITY IN AUTISTIC CHILDREN. G.S. Asleson,* B.H. Herman, I.F. Borghese*, R.P. Allen* & A. Arthur-Smith Brain Res. Cen., Children's Natl. Med. Cen. & Depts. Psychiat. and Peds, George Washington USM, Washington DC, USA 20010 & Dept. Psychiat., JHUSM, Baltimore, MD 21214

We have estimated that about 90% of autistic children are hyperactive as measured by the Conner's Parent Teacher Rating Scale (CPTRS). Here we demonstrate that three methods for measuring activity all indicate that acutely administered naltrexone significantly decreases the hyperactivity of autistic children. Placebo (P1,P2) or naltrexone (Nal) (0.5, 1.0, 1.5, and 2.0 mg/kg) was administered once per week to autistic children (3-12 y.o.), and Ss were tested on the day of drug. Activity was measured in the BRC Social Proximity Test (BRCSPT) by determining the number of squares S crossed in a playroom and by recording activity by an ambulatory activity monitor (AAM). Parents rated 24h activity of their child on the CPTRS. The BRCSPT consists of three 10 min sessions, two in the presence of a familiar volunteer-one without toys and one with toys and a third with the mother. In the BRCSPT, Nal significantly decreased AAM scores in comparison with P1($N=3$, $p<.005$; M± SEM, P1=330 ± 45,1.0 =169 ± 54, 1.5=151 ± 34, 2.0= 186 ± 45). Similarly, Nal significantly decreased number of squares entered in the BRCSPT ($N=7$, $p < .05$; M ± SEM, P1 = 31 ± 2, 0.5 = 25 ± 1,1.0 = 23 ± 1,1.5= 24 ± 2, 2.0= 26 ± 2, P2= 28 ± 2. In the CPTRS, Nal significantly reduced parents' ratings of hyperactivity ($N=8$, $p<.05$; M ± SEM, P1=13 ± 3, 0.5 = 9 ± 2, 1.0 = 8 ± 2; 1.5 = 7 ± 2, 2.0 = 7 ± 1, P2 = 12 ± 2. Supported by FDA, NICHD, Du Pont (to BHH).

HIGH-AFFINITY SELECTIVE LIGANDS FOR MAPPING CNS D-1 DOPAMINE RECEPTORS. M.P. Kung, J. Billings, S. Chumpradit, C.D. Unsworth, P.B. Molinoff, H. Kung. Depts. of Radiology, Psychiatry & Pharmacology, Univ. of Pennsylvania, Phila., PA 19104

Selective D1 ligands with high affinity and high specific activity for mapping CNS dopamine D1 receptors were developed. Substitution with iodine at the 3' or 4' position of 5-phenyl ring of SCH23390 gave two compounds, R-TISCH and R-FISCH, respectively. Both R-[^{125}I]TISCH and R-[^{125}I]FISCH displayed high affinity and selectivity for CNS D1 dopamine receptors in rat striatal membranes (Kd = 0.20 nM for R-TISCH and 0.75 nM for R-FISCH). The binding of both ligands also showed a stereoselective preference for the R(+) over the S(-) isomer. Kinetic studies indicate that the dissociation rate of R-FISCH (k_{-1} = 0.353 min^{-1}) is faster than that of R-TISCH (k_{-1} = 0.082 min^{-1}).The high binding affinity in conjunction with the slower off-rate suggest that R-TISCH may be responsible for better target-to-nontarget ratio (striatum/cerebellum) than R-FISCH observed *in vivo*. R-TISCH also displayed high affinity for 5-HT$_2$ receptors (Kd = 0.28 nM); whereas R-FISCH appeared to have a low affinity for 5-HT$_2$ receptors. Regional distribution of R-TISCH and R-FISCH in rat brain, as measured by *ex vivo* autoradiography, displayed highest binding in regions known to have a high concentration of D-1 receptors. Initial *in vivo* imaging study of [^{123}I]TISCH in humans displayed a high concentration of this ligand in the basal ganglia. These results indicate that R-TISCH and R-FISCH are both suitable for mapping CNS D-1 receptors and are potentially useful for *in vitro* and *in vivo* pharmacological studies. (Supported by NIH grants NS-24538 and NS-18591.)

LAMINAR DISTRIBUTION OF DOPAMINE RECEPTOR SUBTYPE mRNAS IN THE MACAQUE ANTERIOR CINGULATE CORTEX. S.C. Sealfon, W.G. Janssen*, L.A. Snyder, G.W. Huntley, Y. Shiffman*, P.R. Hof, A. Prikhozhan*, J.H. Morrison. Fishberg Res. Cntr. for Neurobiology, Dept. of Neurology, and Dept. of Geriatrics. Mount Sinai Medical School. New York, NY 10029

The anterior cingulate cortex is a key cortical component of the circuits implicated in emotion, reward and affective responses to pain. In the primate, the anterior cingulate cortex receives a dense mesocortical dopaminergic projection that terminates in both superficial and deep layers. With the molecular cloning of the genes for multiple dopamine receptors, it has now become feasible to investigate, using subtype-specific probes, the laminar distribution of the dopamine receptor-expressing neurons in the anterior cingulate cortex.

cDNAs for the primate D_1 and D_3 receptors were isolated via PCR and subcloned into Bluescript plasmid. ^{35}S-labeled cRNA was synthesized for *in situ* hybridization, which was done in 20 μM thick sections of anterior cingulate and prefrontal cortex from paraformaldehyde perfused macaque brain. Both probes labeled neurons in lamina that receive dopaminergic imput and the precise laminar pattern and density of labelling was distinct for the D_1 and D_3 receptor. Preliminary data suggest that D_1 mRNA was most abundant in layer V, intermediate in layer III and detectable in layer VI. D_3 mRNA was greatest in layer III and was also relatively high in layers II and V. We are now cloning cDNAs for the primate D_2, D_4 and D_5 receptors. Quantitative analysis of the anterior cingulate laminar distribution of these subtypes will be presented. Supported by NIH grants K11 DK01854, MH 45212 and AG06647.

TIME COURSE OF ENHANCED D1 AGONIST-INDUCED METABOLIC RESPONSES FOLLOWING ACUTE DOPAMINE DEPLETION. J.M. Trugman and C.L. James*. Dept. of Neurology, Univ. of Virginia, Charlottesville, VA 22908

One key aspect of dopaminergic denervation supersensitivity is the enhanced efficacy of D1 agonists to stimulate movement; the increased ability of D1 agonists to stimulate regional cerebral glucose utilization (RCGU) in the substantia nigra pars reticulata (SNr) in rats with chronic dopamine depletion provides a metabolic correlate to the heightened motor response. The present study examined the time course of D1 agonist-induced metabolic responses following acute dopamine depletion with reserpine (5.0 mg/kg ip). RCGU effects were assessed with [14C]-2-deoxyglucose autoradiography. The D1 agonist SKF 38393 (30 mg/kg) increased SNr RCGU by 18 % in naive rats. In comparison, SKF 38393 increased SNr RCGU by 38%, 68% and 60% at 6, 12 and 24 hours post-reserpine ($p<.05$); the response returned to control values at 5 days. D1 and D2 receptor number in the striatum and SNr, as measured by antagonist ligand binding, were unchanged 24 hours post-reserpine. We conclude that the metabolic effects of D1 stimulation are clearly enhanced within 12 hours of reserpine injection and that the enhanced effects are not mediated by an increase in D1 receptor number. The data suggest that supersensitive responses to D1 stimulation correlate temporally with striatal dopamine depletion.

539.4

DIFFERENCES OF D_1 AND D_2 DOPAMINE RECEPTOR DENSITY BETWEEN THE NEUROLEPTIC NON RESPONSIVE (NNR) AND NEUROLEPTIC RESPONSIVE (NR) LINES OF MICE - A QUANTITATIVE RECEPTOR AUTORADIOGRAPHIC (QRA) STUDY. **Y. Qian, B. Hitzemann* and R. Hitzemann. Departments of Psychiatry and Neurobiology, SUNY @ Stony Brook, NY 11794 and Psychiatry Service, VA Medical Center, Northport, NY 11768.**

QRA was used to examine D_1 and D_2 receptor density in the NR and NNR lines of mice, which have differed by an order of magnitude in their sensitivity (ED_{50}) to catalepsy induced by neuroleptics with a high D_2/D_1 receptor activity profile. D_1 receptor density (^{3}H-SCH23390 binding) was not different in any aspect of the caudate-putamen (CPu), the nucleus accumbens (NA) and substantia nigra zona reticulata (SNr). D_2 receptor density (^{3}H-Spiroperidol binding) was not different in the dorsomedial CPu or NA but was 20 to 30% lower in the NNR line in the caudal aspect of the lateral CPu. The NNR line also showed a 20 to 50% elevation of D_2 receptor density across all the midbrain DA cell groups (A8,A9 and A10). Overall, the data show that selection of mice for response and non-response to neuroleptic-induced catalepsy is associated with changes in D_2 but not D_1 receptor density.

539.5

DENSITY OF DOPAMINE (DA) CELLS IN THE NEUROLEPTIC RESPONSIVE (NR) AND NEUROLEPTIC NON-RESPONSIVE (NNR) LINES OF MICE: RELATIONSHIP TO D_2 AUTO-RECEPTOR DENSITY. **B. Hitzemann*, Y. Qian and R. Hitzemann. Departments of Psychiatry and Neurobiology, SUNY @ Stony Brook, Stony Brook NY 11794 and Psychiatry Service, VAMC, Northport NY 11768.**

The NR and NNR lines of mice have been selectively bred for 14 generations to yield animals more and less responsive to neuroleptic-induced catalepsy. A principal correlated response to selection, appears to be an increase of D_2 somatic autoreceptor density in the NNR (see Qian et al. 1991, this meeting). This response was first noted in S_4 and has persisted through S_{11}. The trivial explanation for these data is that DA cell density is increased in the NNR line. We now report that DA cell density in actually decreased in the NNR line. The decrease is most marked (30 to 50%) in the cell sparse zone of the rostral substantia nigra zona compacta (SNc) and the ventral tegmental area. A 15 to 25% decrease is seen in the densocellular zone of the SNc and in the retrorubal field. These data suggest that the specific activity of D_2 somatic autoreceptors is markedly enhanced in the NNR line.

539.6

NEUROLEPTIC INDUCED CATALEPSY AMONG EIGHT INBRED STRAINS OF MICE. **S.J. Kanes, B. Hitzemann* and R. Hitzemann. Departments of Psychiatry and Pharmacology, SUNY at Stony Brook, Stony Brook, NY 11794-8101 and Psychiatry Service, VAMC, Northport NY 11768.**

Our laboratory has used selective breeding to investigate the genetic factors associated with response and non-response to neuroleptic induced catalepsy (see e.g. Qian et al., 1991) The study of multiple inbred strains provides a different strategy to understand such genetic factors. Eight inbred strains have been tested: LP, CBA, C57BL, C3H, A, AKR, BALB/C, DBA/2. The ED_{50} values (mg/kg) among the eight strains for haloperidol-induced catalepsy are: LP 9.5, CBA 4.5, C57BL 3.8, C3H 1.9, A 2.3, AKR 0.82, BALB/C 0.45, DBA/2 0.48. ED_{50} values for the specific D_1 antagonist, SCH 23390 are: LP 0.33, CBA 0.20, C57/BL 0.16, C3H 0.28, A 0.70, AKR 0.36, BALB/C 0.20, DBA/2J 0.32. There was no correlation between haloperidol and SCH-23390 induced catalepsy (r^2=.28,p >0.05). Studies are in progress to determine pre and post-synaptic D_2 receptor density among lines, focusing on those regions shown to be different between the neuroleptic responsive(NR) and non-responsive(NNR) lines.

539.7

D1 AND D2 DOPAMINE (DA) RECEPTORS IN MICE WITH GENETICALLY DIFFERENT MESOTELENCEPHALIC DA SYSTEMS. I. Laszlovszky[1] and C. Vadasz[1,2].
[1]Nathan Kline Institute, Orangeburg, NY 10962 and [2]New York University Medical Center, 550 First Ave., New York, NY 10016.

The aim of this work was to test the hypothesis that in the mesotelencephalic DA system densities of striatal D1 and D2 receptors are correlated with strain-dependent variations in mesencephalic tyrosine hydroxylase activity (TH/MES). In order to provide reliable estimates for D1 and D2 receptor properties by controlling the intra- and inter-assay variability, a homogeneous pool of reference striatal membrane was prepared, which was subjected to Scatchard analysis in each batch of assays. K_d and B_{max} data for striatal samples of BALB/c, C57BL/6 and CXBI mouse strains were corrected by factors derived from the references. Statistical analysis indicated that each strain significantly differed in TH/MES. However, no significant strain differences were found for striatal D1 and D2 receptor binding with ^{3}H-Spiperone and ^{3}H-SCH 23390, respectively. Our results demonstrate that genetic factors determine a highly significant variation of TH/MES that is not correlated with significant genetic changes in D1 or D2 receptor affinities or with densities in the striatal projection area.

539.8

THE PHARMACOLOGICAL PROFILE OF U-86170F, A DOPAMINE AUTORECEPTOR AGONIST. D.L. Evans, R.A.Lahti, and L.M.Figur*. CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001

Schizophrenia is believed to be due to an overactive dopaminergic system in the brain. Since dopamine (DA) autoreceptors regulate the synthesis, release, and firing rate of these neurons, DA autoreceptor agonists may be useful in treating schizophrenic symptoms.

U-86170F, a 3-amino-tetrahydroquinolinone-derived compound, binds to the high affinity agonist state of the D2 receptor (Ki=7.5 nM). In addition, it is a potent DA autoreceptor agonist in several *in vivo* models. This compound reversed the effects of γ-butyrolactone (GBL) on striatal DA levels (ED_{50} = 0.3 mg/kg) and exhibited autoreceptor agonist-like activity in the α-methyl-p-tyrosine/prolactin model (ED_{50} = 0.1 mg/kg IP and 0.4 mg/kg PO). In reserpinized mice, U-86170F caused an increase in locomotor activity, but unlike apomorphine, it had a ceiling effect. When administered IV once every hour for 2 weeks, U-86170F reversed the effects of GBL on striatal DA levels and plasma prolactin, as well as suppressed striatal homovanillic acid levels.

The pharmacological profile of U-86170F suggests that it is a potent DA autoreceptor agonist with limited postsynaptic activity. This unique autoreceptor agonist may be useful in the treatment of schizophrenic symptoms.

539.9

DOPAMINE (D2) AGONIST RECEPTOR BINDING PROPERTIES OF [^{3}H]U-86170. L.M.Figur*, D.L.Evans, and R.A.Lahti. CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001

Use of [^{3}H]U-86170 as an agonist (Ag) ligand in conjunction with [^{3}H]raclopride, an antagonist (Ant) ligand, has introduced a novel approach to predicting the intrinsic activities (IA) of dopaminergic compounds.

Saturation studies using [^{3}H]U-86170 in rat striata and cloned $D2_i$ cells (C.Chio *et al.*, Nature, 343:266, 1990) revealed Kd's of 1.72 and 0.99 nM, respectively. The Bmax in $D2_i$ clones was 60-70% of that obtained with [^{3}H]raclopride, and [^{3}H]U-86170 binding was inhibited by GTP, indicating that it binds to the high affinity Ag state of the D2 receptor.

Evaluations of several dopaminergic agents in [^{3}H]raclopride + GTP binding (low affinity Ag state) and [^{3}H]U-86170 binding (high affinity Ag state) were made. Ratios of the Ki values (LowAg/HiAg) correlated well with electrophysiologically derived IA values (M.Piercey *et al.*, Society for Neuroscience, Abs 109.11, 1990). The ratio of the Ki values of an agent for these two receptor states provides a useful measure of IA for dopamine Ag's and partial Ag's. In addition, a correlation exists between a compound's effect on rat striatal homovanillic acid levels and its IA.

Using an Ag and an Ant ligand in cloned D2 receptor membrane preparations provides a simple and effective means of identifying dopamine Ag, partial Ag, and Ant activity.

539.10

U-86170F, A POTENT DOPAMINERGIC AGONIST THAT DOES NOT INDUCE TOLERANCE WITH CHRONIC ADMINISTRATION. M.F.Piercey, M.W.Moon*, R.A.Lahti, W.E.Hoffmann, and J.T.Lum. CNS Research, The Upjohn Co., Kalamazoo, MI, 49001.

U-86170F(4H-Imidazo[4,5-i,j]quinolin-2[1H]-one,5-[dipropylamino]-5,6-dihydro-,[-], monohydrobromide, hemihydrate) is a novel potent dopamine (DA) agonist that binds to both DA and serotonin (5-HT) receptors. We have examined its effects on firing rates of DA neurons in substantia nigra (SNPC, Bunney *et al.*, JPET 155:560, 1973) and 5-HT cells in dorsal raphe (DR, Aghajanian *et al.*, JPET 137:178, 1970). U-86170 dose-dependently depressed DA neurons with an ED_{50} of 8 μg/kg i.v., by a haloperidol-sensitive mechanism. Higher doses depressed 5-HT neurons (ED_{50}=107 μg/kg i.v.). The (+)-enantiomer was inactive. Animals treated for 10 days with U-86170F (1.8 mg/kg/day) had potencies (ED_{50}=4.0 +/- 1.8 μg/kg) similar to those chronically treated with vehicle (ED_{50}= 3.0 +/- 1.0 μg/kg i.v.). In contrast, animals chronically treated with apomorphine were less sensitive to APO (68 +/- 35 μg/kg) than were vehicle-treated controls (27 +/- 12 μg/kg). It is concluded that U-86170 is a potent DA agonist which could be useful in the long-term treatment of Parkinson's Disease.

539.11

SCH 39166, A D-1 ANTAGONIST WITHOUT SEROTONERGIC ACTIVITY. R.D. McQuade, C.E. Tedford, R.A. Duffy *, L.A. Taylor, M.A. Hunt **, J.K. Wamsley + and A. Barnett, Schering-Plough Research, Bloomfield, NJ 07003 and Neuropsychiatric Research Center, Fargo, ND 58103 +

Previous data have clearly indicated that the benzonaphthazepine, SCH 39166, is a potent and selective D-1 antagonist. This drug is currently undergoing clinical trials as a potential antipsychotic agent. SCH 23390, the predecessor of SCH 39166, also was a selective D-1 antagonist, which in addition, exhibited moderate affinity for serotonin (5HT) receptors, especially the 5HT-2 and 5HT-1_c subtypes. Thus, the in vitro binding of SCH 39166 to the 5HT-2 and 5HT-1_c receptors was determined by its ability to inhibit the binding of ^{3}H-ketanserin to membranes from rat frontal cortex and ^{3}H-mesulergine to membranes from porcine choroid plexus, respectively. SCH 39166 inhibited the binding of ^{3}H-ketanserin with a K_i of 167.0 nM, while it inhibited the binding of ^{3}H-mesulergine with a K_i of 1328.0 nM. In contrast, SCH 23390 inhibited the binding to 5HT-2 and 5HT-1_c receptors with K_i's of 20.0 and 30.7 nM, respectively. The less active stereoisomer of SCH 39166, SCH 39165, exhibited a K_i of 381.0 nM at 5HT-2 and 566.0 nM at 5HT-1_c receptors. These data indicate that SCH 39166 does not exhibit the stereoselectivity at 5HT receptors which it does at D-1 sites.

The interaction of SCH 39166 with D-1 and 5HT receptors was also studied using in vivo autoradiography. In these studies, the animals are injected with ^{3}H-SCH 39166 and localization of the radioligand to brain tissue is measured via autoradiography. These studies indicate that ^{3}H-SCH 39166 binds to the striatal-nigral pathway, with a specificity indicative of a D-1 interaction. There is little or no apparent binding to frontal cortex or choroid plexus, demonstrating an absence of activity at 5HT-2 and 5HT-1_c receptors. These data confirm our earlier in vitro autoradiographic findings and together with the binding data strongly argue that SCH 39166 does not interact with 5HT receptors.

539.12

EFFECT OF THE D-1 DOPAMINE RECEPTOR ANTAGONIST SCH 39166 ON SEIZURES INDUCED BY LITHIUM+PILOCARPINE. P. Barone, G. Cicarelli*, M. Trampus, E. Ongini and G. Campanella*. Dept. of Neurology-2nd Sch. of Med., Univ. of Naples and Research Labs of Schering-Plough, Comazzo MI, Italy.

Recent evidence indicates that the two dopamine receptor subtypes, D-1 and D-2, exert opposing roles in the control of epilepsy propagation. Blockade of D-1 receptor elevates, while D-2 receptor blockade reduces the threshold for pilocarpine-induced seizures. Pretreatment with lithium chloride (LiCl) is known to potentiate the seizure activity induced by cholinomimetics. The present study investigates the effect of a novel D-1 receptor antagonist, SCH 39166, on seizures induced by lithium+pilocarpine. Male Sprague Dawley rats were treated with LiCl (4 mEq/kg ip) 24 hr prior to the intraperitoneal injection of either saline or SCH 39166 (0.01-0.3 mg/kg) or the D-2 antagonist raclopride (1-10 mg/kg). After 15 min rats were given either 10 or 15 mg/kg ip of pilocarpine, the ED50 and ED100 for convulsions, respectively. SCH 39166 prevented, while raclopride potentiated convulsive activity, as revealed by behavioural and electroencephalographic alterations and severe brain damage. These results suggest that the use of D-1 selective neuroleptics might reduce the risk of convulsions in patients under treatment with the combination of lithium and neuroleptics.

539.13

DIZOCILPINE (MK 801), BUT NOT NBQX, ALTERS DOPAMINE (DA)-MEDIATED CHANGES IN STRIATOPALLIDAL NEURONAL ACTIVITY AND BEHAVIOR. M.D. Kelland, R.C. Boldry, K.-X. Huang, T.N. Chase and J.R. Walters. ETB, NINDS, NIH, Bethesda, MD 20892, USA.

Altering basal ganglia glutamate (GLU) transmission may have potential for treating Parkinson's disease. Using single-unit recording techniques, and a stereotypy rating scale, we are examining the role of GLU in regard to apomorphine (APO)-induced electrophysiological and behavioral responses.

APO (0.3 mg/kg, i.v.) significantly reduced the firing rate of 9/10 Type I caudate neurons. Following MK 801 (NMDA antagonist; 0.1 mg/kg, i.v.), APO inhibited fewer cells (3/10), while remaining cells were excited or unaffected, resulting in no net change in rate. Globus pallidus (GP) neuronal waveforms can be identified as Type I (-/+) or Type II (+/-). APO excited Type II GP cells (10/11), and inhibited Type I GP neurons (10/12). MK 801 caused a net blockade of APO effects on Type II cells (4/10 excited, 3/10 inhibited), but had equivocal effects on Type I GP neurons. MK 801 increased locomotion, but completely inhibited the stereotyped sniffing and licking induced by i.v. APO.

NBQX (AMPA antagonist; 10 mg/kg, i.v.) reduced the firing rate of 4/5 Type II GP neurons, but did not alter their responsiveness to APO.

Ketamine-anesthesia (150 mg/kg, i.p.), did not share APO-blocking properties with MK 801 (only neuronal activity tested). Conversely, MK 801 (18.4 mg/kg, i.p.) did not induce anesthesia in rats.

These data suggest that normal glutamate transmission is necessary to observe DA-mediated electrophysiological effects and stereotypy. The ability of MK 801 to block APO stereotypy may be due to the observed alterations in striatal/GP output patterns and/or other sites of action of MK 801. While the locomotor stimulant effects of MK 801 indicate potential for treating Parkinson's disease, reduction of the DA-mediated effects addressed here suggests otherwise.

D1 AGONIST HAS OPPOSITE EFFECTS ON NEURONAL TRANSMISSION IN THE BASAL GANGLIA OF TWO ANIMAL MODELS OF PARKINSON'S DISEASE: EFFECTS BLOCKED BY NMDA ANTAGONIST. K.-X. Huang and J.R. Walters. NINDS, Bethesda, MD 20892.

Unilateral 6-OHDA-induced lesion of the substantia nigra dopamine neurons and subchronic treatment with reserpine are two strategies used for producing animal models of Parkinson's disease (PD). We have compared the responses of substantia nigra pars reticulata (SNpr) neurons to the D1 agonist SKF-38393 in these animal models using extracellular recording techniques in locally anesthetized, gallamine paralyzed rats. Effects of MK-801 were also examined since NMDA antagonists are of interest in PD. In rats treated with reserpine (1 mg/kg/day, sc) for 6 days, SKF-38393 (10 mg/kg, iv) significantly increased the firing of SNpr neurons (ave. increase: 88 ± 21%) compared with control (18 ± 8%, n=7). This effect was reversed by the D1 antagonist SCH-23390, and was persistent: SKF-38393 induced a similar change in rats treated with reserpine for 6 days then allowed a five-day washout period. As shown previously, in 6-OHDA-lesioned rats studied 9-26 weeks after lesion, SKF-38393 inhibited SNpr firing rates (ave. decrease: 75 ± 10% below baseline, n=5). Time course differences do not account for these opposite effects: seven days after 6-OHDA lesion SKF-38393 did not induce effects similar to those seen after reserpine. MK-801 (0.15 mg/kg, iv), 5 min before SKF-38393, blocked both the stimulatory and the inhibitory effects of SKF-38393 in reserpinized and lesioned rats, respectively. Results suggest that monoamine depletion and dopamine cell degeneration both affect D1 neuronal transmission, but in opposite ways, and raise questions about which model is more relevant to PD. They also support a role for tonic NMDA transmission and point to considerable plasticity in D1 mechanisms regulating striatal output.

539.15

AN EEDQ RESISTANT SUBPOPULATION OF D1 DOPAMINE RECEPTORS MAY BE INVOLVED IN THE MEDIATION OF REPETITIVE JAW MOVEMENTS (RJM) IN RATS.
H.Rosengarten,J.W.Schweitzer and A.J.Friedhoff
Millhauser Laboratories,NYU School of Medicine
New York,N.Y.10016
We have,in 1983,shown that an oral behavior in rats manifested by RJM and tongue protrusion,can be induced in a dose dependent manner by the D1 agonist SKF 38393 and abolished by specific D1 antagonist SCH 23390. Inactivation of D1 receptors with EEDQ reduces 80-85% of D1 dopamine receptor binding but has no significant effect on the rate of D1 agonist induced RJM. Scatchard analysis of caudate D1 receptor binding in control and EEDQ treated rats has revealed changes in density but not in affinity(Bmax 101.7+7.5 pmol/gm wet weight, Kd 1.16+0.21nM;and Bmax 16.5+2.7 Kd 0.90+0.13, respectively).We also wish to report that following a single injection of EEDQ,80-85% of D1 receptors is also lost in mpFc,olfactory tuberculum and substantia nigra. In the caudate the remaining population of D1 receptors is resistant to subsequent EEDQ challenge. In radioligand binding studies dopamine displacement of 3H-SCH 23390 binding to caudate homogenates resulted in 4 fold shift to the right(Allfit analysis)in the presence of 5.0 μMGpp(NH)p in control but not in EEDQ treated rats. It thus appears that RJM in rats may be mediated by a subpopulation of Gpp(NH)p-independent as well as EEDQ resistant D1 receptors in rats.

539.16

FUNCTIONAL COUPLING OF SOMATO-DENDRITIC AUTORECEPTORS IN THE RAT MESO-LIMBIC DOPAMINERGIC PROJECTION. S. Ahlenius. Department of Neuropharmacology, Astra Research Centre, S-151 85 Södertälje, Sweden.

Adult male rats were injected with the enantiomers of sulpiride (SULP)(0.2-5.0 μg) or 3-PPP (1.25-80 μg) into the nucleus accumbens or into the ventral tegmental area (VTA). These compounds present a range of intrinsic activities from a full DA agonist [(+)3-PPP], a partial agonist [(-)3-PPP] to an antagonist [(-)SULP]. In the accumbens region, SULP enantiomers and (-)3-PPP produced a suppression of locomotor activity (LMA), whereas (+)3-PPP appeared inactive. In the VTA, 3-PPP enantiomers and (+)SULP produced a suppression, whereas (-)SULP produced an increase, of LMA. These findings demonstrate that stimulation of somato-dendritic autoreceptors is of greater importance than stimulation of autoreceptors on nerve terminals for the suppression of LMA produced by systemically administered DA receptor agonists, and that a partial agonist like (-)3-PPP acts by a combination of post-synaptic receptor blockade and autoreceptor stimulation. Finally, a blockade of somato-dendritic autoreceptors by (-)SULP produced a stimulation of LMA, which may explain the behavioral activation that can be found after systemic administration of this or other DA receptor blocking agents, whereas the unexpected suppression of LMA produced by (+)SULP administration onto cell body autoreceptors suggests the possibility of weak intrinsic activity of this compound.

DO PRESYNAPTIC DOPAMINE AUTORECEPTORS INHIBIT DOPAMINE RELEASE VIA ACTIVATION OF POTASSIUM CHANNELS? Takahiko Tanaka*, Steven R.Vincent, George G. Nomikos and Hans C. Fibiger. Div. of Neurological Sciences, Dept. of Psych. Univ. of British Columbia, 2255 Wesbrook Mall, Vancouver, B.C., Canada, V6T 1Z3

Somatodendritic dopamine (DA) autoreceptors inhibit DA cell firing by activation of potassium (K^+) channels via a G protein mediated mechanism. However, the signal transduction mechanisms by which presynaptic DA autoreceptors in the striatum inhibit DA release are not known. The purpose of this study was to examine the role of K^+ channels in DA autoreceptor function in the striatum using in vivo microdialysis. Local application of the DA agonists quinpirole (QPR, 10 μM) and BHT-920 (1 μM) reduced extracellular DA in the striatum. This was blocked by the DA antagonist (-)-sulpiride (SLP, 10 μM), which itself increased extracellular DA. Local infusion of the K^+ channel blocker quinine (QIN, 1mM) caused a large increase in DA release which stabilized after 90 min. QIN completely blocked the SLP-induced DA increase but did not block the effect of QPR. SLP blocked the effect of QPR in both the presence and absence of QIN.

These results confirm that autoreceptors in the striatum regulate DA release. In addition, blockade of K^+ channels increases DA release. The findings suggest that endogenous DA inhibits DA release via a presynaptic receptor coupled to a K^+ channel. However, the results also indicate that DA receptor agonists act via additional mechanisms that are independent of K^+ channel activation to inhibit release.

539.18

BIOCHEMICAL EFFECTS OF (-)-STEPHOLIDINE ON THE PRESYNAPTIC DOPAMINE RECEPTORS. G.Z. Jin, L.J. Chen*, B.C. Sun*, X. Guo*, G. Hu* and H.Y. Huang*. Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai 200031, China.

(-)-Stepholidine (SPD), is a novel DA receptor antagonist on postsynaptic DA receptors, but it possesses agonistic action on rotational behaviour in the 6-OHDA-lesioned rats. This work attempts to investigate whether SPD exhibits antagonistic or agonistic action on presynaptic DA receptors in the striatum. It has been shown that SPD profoundly augumented the activity of TH in rat with an elevation of DOPA accumulation measured by HPLC. SPD could not reverse the inhibition on DOPA-accumulation against the enhancement of GBL. SPD, however, could potentiate the effect of GBL. SPD increased the DA release and DOPAC level in rat measured by in vivo voltammetry. SPD enhanced the [^{3}H]-DA release from rabbit slice by electric stimulation. Quinpirole inhibited the [^{3}H]-DA release. The inhibition of AC activity by NO437 and the stimulation on high affinity GTPase activity by NO437 on rat synaptosome were antagonized by SPD. These results clearly denote that SPD possesses antagonistic effect on presynaptic receptors (D-2).

539.19

CHRONIC SCH 23390 ACCELERATES THE RECOVERY OF D1 DOPAMINE (DA) RECEPTORS IN THE RAT STRIATUM (ST) AND S. NIGRA (SN) AFTER IRREVERSIBLE BLOCKADE. O.Giorgi,M.G. Pibiri,M.R. Murgia and M.G.Corda. Department of Experimental Biology, Section of Neuroscience, University of Cagliari, Italy.

The present study was designed to investigate the repopulation of 3H-SCH 23390 binding sites in the ST and SN after the irreversible inactivation induced by N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ, 10 mg/kg, SC) in rats chronically treated with SCH 23390 (0.05 mg/kg, SC, three times a day for three weeks). The process of D1 receptor repopulation could be adequately described by a model that assumes a constant rate of receptor production (zero order) and a first order receptor degradation rate. As expected, the repeated administration of SCH 23390 significantly enhanced the steady state density of D1 DA receptors in the ST (+30%) and in the SN (+24%). Chronic treatment with SCH 23390 also increased the production rates of D1 receptors in the ST (control: 6.6 fmoles/mg prot/h, treated: 7.8 fmoles/mg prot/h) and in the SN (control: 1.2 fmoles/mg prot/h, treated: 1.8 fmoles/mg prot/h). By contrast, the receptor degradation rate constants were unchanged: ST control, 0.0073 ± 0.0007/h, ST treated, 0.0066 ± 0.0005/h; SN control, 0.0047 ± 0.0004/h, SN treated, 0.0056 ± 0.0005/h. These data are consistent with the view that an increase in the receptor production rate is at the basis of the upregulation of D1 receptors in the ST and in the SN induced by chronic SCH 23390. The acceleration in the receptor production rate may be due to an increased expression of the genes that control the production of D1 DA receptors.

539.20

DEVELOPMENTAL DIFFERENCES IN D_1 AND D_2 DOPAMINE RECEPTOR DEPLETION AND TURNOVER IN RATS AFTER IRREVERSIBLE ANTAGONIST TREATMENT. C.A. Crawford, J.K. Rowlett, S.A. McDougall*, N. Elkins* & M.T. Bardo. Department of Psychology & Center of Membrane Sciences, University of Kentucky, Lexington, KY 40506.

Previously, our lab reported developmental differences in the behavioral responses to treatment with the irreversible dopamine (DA) blocker, N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ). We found that preweanling rat pups did not show the adult-typical attenuation of dopamine mediated behaviors after EEDQ treatment. In the present study, we investigated potential age-dependent differences in DA receptor subtype depletion and subsequent receptor recovery after treatment with EEDQ. Rats received a single injection of EEDQ (7.5 mg/kg) or vehicle when 10, 16 or 39 days old. Rats were sacrificed and their striata removed for assay 24, 48, 96 or 192 hrs after EEDQ treatment. Saturation experiments were done using [^{3}H]SCH 23390 (for D_1 binding) and [^{3}H]spiperone (for D_2 binding) in tissue homogenates. Results showed that EEDQ produced an initial depletion of D_1 and D_2 receptors in all age groups. This effect tended to be less profound in both 10- and 16-day old rats when compared to the 39-day old rats. For all ages, evidence for receptor recovery was obtained.

539.21

STRIATAL DOPAMINE RECEPTOR AND DOPAMINE LEVEL DEPLETION IN NEONATAL AND ADULT RATS FOLLOWING IRREVERSIBLE RECEPTOR MODIFICATION J.K. Rowlett, C.A. Crawford, S.A. McDougall* & M.T. Bardo Department of Psychology, University of Kentucky, Lexington, KY 40506.

The present study assessed the effects of the receptor alkylating compound N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) on D_1 and D_2 dopamine receptors, dihydroxyphenylacetic acid (DOPAC) and dopamine (DA) levels in 16 day old and adult rat striatum. Dopamine receptor binding was assessed in homogenates using [^{3}H]SCH 23390 (for D_1 binding) and [^{3}H]spiperone (for D_2 binding). DOPAC and DA levels were measured using high-performance liquid chromatography. Results revealed that for both dopamine receptor subtypes, EEDQ induced a dose-dependent depletion that was of lesser magnitude in 16 day olds than in adults. DOPAC values for 16 day old rat pups showed no effect of EEDQ, while DOPAC levels were increased for adult rats. DA values also were not altered by EEDQ treatment in 16 day old rat pups. However, adult rats showed a significant decrease in DA levels at all doses tested (7.5, 15, 25 mg/kg). The EEDQ-induced decrease in DA levels in adults was also evident in animals pretreated with selective D_1 and D_2 antagonists. These results suggest that EEDQ may produce receptor-independent neurotoxicity, and that neonatal rats are less sensitive than adults to both the receptor inactivating and DA depleting effects of EEDQ.

539.22

LEAD (Pb) AFFECTS DOPAMINE D1 AND D2 RECEPTOR DEVELOPMENT IN A BIPHASIC AND REGIONALLY DIFFERENT MANNER IN STRIATUM AND NUCLEUS ACCUMBENS. **D.V. Widzowski, and D.A. Cory-Slechta. Environ. Health Sci. Center, School of Med. and Dent., Univ. of Rochester, Rochester, N.Y. 14642.**

Alterations in dopaminergic (DA) systems have been suggested as one neurochemical mechanism for Pb-induced behavioral deficits. Previous work has shown DA receptor number (Bmax) to be elevated in the striatum (ST), but decreased in the nucleus accumbens (NA) after postnatal Pb exposure, suggesting regional differences in response to lead. Work in this laboratory has demonstrated alterations in DA (D1 and D2) Bmax after either postnatal (birth to day 21) or postweaning (day 21 onward) Pb exposure with an apparent biphasic dose-effect function; postnatal Pb exposures produced inverse U-shaped functions, while postweaning Pb exposure produced U-shaped curves. The present studies were undertaken to further characterize the biphasic and regional effects of Pb on DA receptors. For postnatal (PN) exposure, lactating dams received 0, 100, 350, 1000 or 2000 ppm Pb lead acetate in drinking water; postweaning (PW) Pb exposures were 0, 50 or 250 ppm Pb acetate. Rats were sacrificed on 7,14,21 or 60 days of age for PN exposure, and on days 28 or 60 for PW exposure. Results confirmed biphasic effects of lead following both postnatal and postweaning Pb exposure. For Pn-exposed rats on day 7, both ST and NA exhibited inverse-U shaped dose-response functions for both D1 and D2 receptors, with ST curves somewhat left-shifted relative to NA, suggesting a more pronounced effect of Pb on striatum. At neither day 21 or 60 was there evidence of differential Pb accumulation in ST vs NA, suggesting that in PN-exposed rats, differential Pb levels were not the mechanism of the differential sensitivity. By 60 days of age in PN-exposed rats, U-shaped rather than inverse U-shaped Bmax curves were apparent, including a significant increase in D1 receptors at the highest exposure level. Pb was still present in a dose-related manner at day 60 in both ST and NA, suggesting Pb might still be actively affecting the tissue. **This work was supported by NIH grant ES05017.**

CATECHOLAMINES: DOPAMINE II

540.1

DOPAMINE ACTIONS ON MEMBRANE CONDUCTANCES IN RAT VENTRAL TEGMENTAL AREA (VTA) NEURONS. Z.G. Jiang and R.A. North. Vollum Institute, Oregon Health Sciences University, Portland, OR 97201

Whole cell recordings were obtained from 120 VTA neurons in rat midbrain slices. Pipets contained potassium as the main cation, and ATP and GTP. First, dopamine (DA 30 μM, EC_{50} = 22 μM) caused an outward current at -50 mV in 56% of the cells; this was typically about 50 pA. The current reversed to inward at -105 mV, close to E_K. The current was associated with an increase in instantaneous conductance at -60 mV of 2 nS (27% of control, n = 14). Second, a voltage-dependent sustained outward current that was sensitive to TEA (10 mM) and barium (100 μM) was increased by dopamine (by 18% at 0 mV). Third, dopamine reduced a hyperpolarization-activated cation current (I_h) (by 22% at -120 mV), with no obvious shift of its voltage-dependence. Dopamine had no effect on a transient outward current (I_A). Thus, dopamine inhibits VTA principal neurons both by increasing two potassium conductances and reducing I_h.

540.2

VOLTAGE-CLAMP ANALYSIS OF CALCIUM-DEPENDENT INWARD CURRENTS IN CULTURED MESENCEPHALIC DOPAMINE NEURONS. L.-X. Liu, G. Kapatos, and L.A. Chiodo. Cellular & Clinical Neurobiology Prgm., Dept. Psychiatry, Wayne State Univ. Sch. Med., Detroit, MI 48235.

DA neurons were identified by preloading with 5,7-DHT (15-50 μM for 1 hr) and visualization under UV fluorescence. This resulted in a blue-violet fluorescence within the soma and dendrites. To study only calcium (Ca^{2+})-dependent inward currents, the extracellular solution contained 140 mM tetraethylammonium Cl, 10 mM $CaCl_2$, 1 mM $MgCl_2$, and 10 mM glucose (pH 7.4). The patch pipette solution contained 10 mM EGTA, 135 mM CsCl, 1 mM $MgCl_2$, 1 mM GTP, 2 mM ATP, 14 mM creatine phosphate, 50 U/ml creatine phosphokinase. Both solutions were buffered to pH 7.4 with 10 mM HEPES.

Depolarizing voltage steps from a holding potential of -90 mV resulted in inward currents which were observed at membrane potentials between -40 and 20 mV. These currents were not observed when Ca^{2+} was removed from the external solution. The whole-cell current displayed an initial peak outward component which rapidly inactivated to a sustained current of lower amplitude which lasted for the duration of the voltage step (500 msec). This current response suggests the presence of at least two Ca^{2+} currents in cultured DA neurons, one which is transient and a second which is sustained. Studies designed to isolate and characterize these inward currents are in progress. It was noted that the presence of inward currents was correlated with the age of the cultures. Cultures were studied between 8 and 19 days, however, inward Ca^{2+} currents were only present in culture which were at least 13 days old. (Supported by MH41557 and NS26081).

540.3

EFFECTS OF PRENATAL ALCOHOL EXPOSURE ON SUBSTANTIA NIGRA DOPAMINE NEURONS. R. Shen, A.S. Freeman and L.A. Chiodo. Cellular & Clinical Neurobiology Prgm., Dept. Psychiatry, Wayne State Univ. Sch. Med., Detroit, MI 48235.

Fetal Alcohol Syndrome is a disorder which is often associated with altered spontaneous motor activity and increased behavioral impulsivity. Some of the effects detailed in the literature are reminiscent of behaviors thought to be mediated, in part, by dopaminergic (DA) neuronal systems within the brain. In an attempt to better understand the neurobiological underpinnings of this syndrome, we have begun to study the effects of *in utero* exposure of rats to ethanol on the subsequent physiology and pharmacology of mesencephalic DA neurons in adulthood. Pregnant rats received a liquid diet containing 0%, 17.5%, and 35% ethanol-derived calories from day 8 of pregnancy until delivery. Total caloric intake was the same for all groups. At birth, pups were transferred to foster dams.

Single-unit extracellular recordings were made from identified DA neurons located within the substantia nigra, two to three months after weaning. DA neurons in rats treated with 17.5% and 35% ethanol exhibited slightly higher spontaneous firing rates and burst-related action potentials compared to controls. DA neurons in these rats also were dramatically less sensitive to the inhibitory effect of intravenous administration of the mixed D1/D2 receptor agonist apomorphine. This was observed as both a significant increase in the ED_{50} (144 µg/kg for the combined 17.5% and 35% ethanol groups *vs.* 16 µg/kg in controls) as well as a dramatic reduction in efficacy, suggesting a functional down-regulation of DA receptors. Thus, prenatal exposure of rats to ethanol affects the physiology and pharmacology of nigral DA neurons ultimately observed in the adult animals. (MH41557 and P50 AA07606).

540.4

EFFECTS OF SIGMA LIGANDS ON THE POPULATION ACTIVITY OF MIDBRAIN DA NEURONS. J. Zhang[1], L.A. Chiodo[1], J.G. Wettstein[2] and A.S. Freeman[1]. [1]Department of Psychiatry, Wayne State University School of Medicine, Detroit, MI 48201 and [2]Institut de Recherche Jouveinal, 94265 Fresnes, France.

Sigma receptors have been hypothesized to play a role in the etiology of psychosis and in the therapeutic effectiveness of antipsychotic drugs. Several sigma ligands also produce psychotomimetic effects although the receptor specificity of these responses are in question. Midbrain A9 and A10 dopaminergic (DA) systems are believed to mediate the side effects and therapeutic effects, respectively, of antipsychotic drugs. In the present study, we evaluated the effects of three sigma ligands, (+)-pentazocine (PZ), DTG and JO 1784, on the numbers of spontaneously active A9 and A10 DA neurons encountered per electrode track in anesthetized rats.

Acute injections were given 1 hr prior to electrophysiological recordings. Chronic treatment consisted of 21 daily injections with a 20 hr withdrawal. Each treatment group contained 10 rats. Acute i.p. PZ (10 mg/kg), DTG (2 mg/kg) and s.c. JO 1784 (1 and 10 mg/kg) did not alter the numbers of spontaneously active DA neurons per electrode track. Chronic treatment with PZ (1 and 10 mg/kg) or DTG (0.2 and 2 mg/kg) increased the numbers of A10 DA cells per track. At 1 mg/kg, chronic JO 1784 had no effect on the number of DA cells per track. At 10 mg/kg, chronic JO 1784 moderately decreased the number of active A9 DA cells per track and increased the firing rate of A10 DA cells. Thus, repeated but not acute treatment with these sigma ligands altered the population profile of active DA neurons. These effects differ from those of typical and atypical antipsychotic drugs which inactivate A10 DA neurons upon chronic administration. (Supported by MH42136.)

540.5

RELEASE OF CHOLECYSTOKININ FROM RAT MIDBRAIN SLICES. A.S. Freeman, L.A. Chiodo, S.I. Lentz, K. Wade and M.J. Bannon. Department of Psychiatry, Wayne State University School of Medicine, Detroit, MI 48201.

Cholecystokinin octapeptide (CCK-8) is present within a majority of rat midbrain dopamine (DA)-containing neurons. Exogenous CCK-8 can modulate DA neuronal electrophysiology, in part, by direct actions on the somatodendritic region of these cells. Thus, if CCK-8 is released somatodendritically from DA neurons, it may influence DA cell function as has been shown for DA itself. In the present study, RIA (sensitivity, 1 fmole/tube) was used to measure the *in vitro* release of CCK-8 from midbrain slices (400 µm). The slices obtained from a 2 mm coronal slab of trimmed rat midbrain were used in each assay tube. All CCK immunoreactivity was established by HPLC to be authentic CCK-8.

Low levels of CCK-8 were detected in the basal incubation medium. Thirty mM potassium caused about a 3-fold increase in the release of CCK-8. This stimulated release was abolished in calcium-free medium. The D2 DA receptor agonist quinpirole (1-100 µM), but not the D1 agonist SKF 38393 (10-100 µM), attenuated the potassium-stimulated release of CCK-8 without altering basal release. The quinpirole effect was prevented by the D2 antagonist l-sulpiride (10 µM) and was not affected by concurrent incubation with SKF 38393 (10 µM). These results show that CCK-8, like DA, can be released from midbrain slices, presumably from DA/CCK-8-containing neurons. This finding is in accordance with the possibility that CCK-8 plays a role in the regulation of DA neuronal function at the level of the cell body, where it might influence DA cell excitability. (Supported by MH41557, MH42136 and MH43026.)

DOPAMINE NEURON ONTOGENY: MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL CHARACTERISTICS. D.K. Pitts[1,2], J. Rubin[2], A.S. Freeman[2] and L.A. Chiodo[2]. [1]Dept. of Pharm. Sci., Coll. Pharmacy & A.H.P. and the [2]Cell. & Clin. Neurobiol. Prgm., Sch. Med., Wayne State Univ., Detroit, MI 48202.

Antidromically (AD) identified rat nigrostriatal dopamine (DA) neurons undergo significant physiological and pharmacological changes during postnatal (PN) development (Pitts et al. Synapse 6:309, 1990; Tepper et al. Dev. Brain Res. 54:21, 1990). The distribution of tyrosine hydroxylase-immunopositive (TH+) neurons and the electrophysiological characteristics of AD identified mesoaccumbens DA (MADA) neurons during PN development were examined in the present study. As previously described (Tepper et al. Neurosci. Abstr. 431:11, 1990), on PN day (PND) 1 TH+ neurons and fibers were found scattered throughout the substantia nigra with a subsequent reduction in TH+ somata/fibers ventrally by PND 14 resulting in the appearance of a more adult-like non-DAergic pars reticulata. In addition, at PND 1 separate posterior-lateral and anterior-medial groups of TH+ neurons were observed which may ultimately contribute to the adult mesencephalic DA neuron population. Preliminary studies of AD identified MADA neurons at PND 14-16 suggest that there are fewer cells with a bursting discharge pattern and that the burst duration is shorter relative to adullts. (Supported by MH47857 [DKP], MH42136 [ASF], MH41557 [LAC].)

540.7

EFFECTS OF 8-HYDROXY-2-(DI-N-PROPYLAMINO)TETRALIN (8-OH-DPAT) ON THE ELECTRICAL ACTIVITY OF DOPAMINE NEURONS IN THE RAT VENTRAL TEGMENTAL AREA. E. Esposito, M. Pessia* and S. Prisco*. Istituto di Ricerche Farmacologiche "Mario Negri", Consorzio "Mario Negri" Sud, S. Maria Imbaro (CH), Italy.

A number of studies have shown that serotonin (5-HT) containing neurons in the raphe nuclei exert an inhibitory influence upon dopamine (DA) neurons in the substantia nigra, pars compacta (SNc). The selective 5-HT1A receptor agonist 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) has been shown to increase the firing rate of DA neurons in the SNc, probably as a consequence of its inhibitory action on 5-HT containing neurons in the dorsal raphe nucleus. Neuroanatomical data indicate that DA neurons in the ventral tegmental area (VTA) receive a serotoninergic input from the raphe nuclei, however the functional role of serotonin in the control of the activity of mesolimbic DA system is still unclear.

In the present study, extracellular single unit recordings were performed in vivo on male Sprague Dawley rats, anesthetized with chloral hydrate. Dopamine neurons in the VTA were recorded using single barrel micropipettes and were identified by their location, waveform, firing rate and pattern. Intravenous injection of 8-OH-DPAT (10-160 µg/Kg; cumulative dose) caused excitation in about 40% of the neurons studied; in 20% of the cells recorded a slight inhibition was observed; the remaining cells were unaffected by 8-OH-DPAT. These findings indicate that the activity of a subpopulation of DA neurons in the VTA is under the control of the serotoninergic system. Experiments are under way to establish whether the effect of 8-OH-DPAT on VTA DA neurons is mediated by an inhibitory action on 5-HT-containing neurons in the nucleus raphe dorsalis (DR) and/or medianus (MR).

GAMMA-HYDROXYBUTYRATE INCREASES THE FIRING RATE OF A9 DOPAMINE NEURONS IN UNANESTHETIZED RATS.
M. Diana, A. Mura, A.L. Muntoni, M. Pistis, S. Aramo & G.L. Gessa.
Dept. of Neurosci. "B.B. Brodie", Univ. of Cagliari, ITALY.

Gamma-hydroxybutyrate (GHB) is a normal metabolite of the mammalian brain and is found in discrete cerebral regions such as the substantia nigra (SN). However GHB receptors are virtually absent from the SN while they are found in the striatum and hyppocampus. For these and other reasons GHB is a molecule of great interest especially in light of recently reported evidence which ascribes to GHB a role in the treatment of alcohol abuse (Gallimberti et al 1990 Lancet). Since electrophysiological effect of GHB have always been explored in anesthetized rats and anesthesia alters many drug-induced effects we studied the effect of GHB in unanesthetized rats. Male Sprague-Dawley (200-350 gr) rats were temporarily anesthetized with alothane then incannulated with a tracheal catheter for artificial respiration and in the femoral vein for intravenous administration of drugs. D-tubocurarine (4mg/kg iv) was administered and once muscular paralysis was obtained the rats were placed on a stereotaxic frame (Kopf) Low doses of GHB (50-400 mg/kg) dose dependently increased the firing rate of A9 dopaminergic neurons from about 10 to about 50% above baseline. When GHB was administered intraperitoneally in higher doses (750 mg/kg) only a mild reduction of firing rate was observed. In contrast, in chloral hydrate anesthetized rats, 200 mg/kg of iv GHB failed to modify neuronal activity while 400 mg/kg iv completely suppressed firing rate. The results indicate: 1) anesthesia alters the electrophysiological effects of GHB. 2) GHB mimics the effects of ethanol upon dopaminergic neurons in both unanesthetized and anesthetized rats.

Effects of Coadministration of SCH 23390 and SKF 38393 with Haloperidol on the Number of Spontaneously Active Dopamine Neurons in the SNC and VTA. D.E. Bregna*, S.E. Degelmann*, M.R. Szewczak. Dept. of Biological Research, Hoechst-Roussel Pharmaceuticals Inc., Somerville, N.J. 08876.

Extracellular single unit recordings were used to determine the effect of acute or chronic coadministration of either the D1 antagonist, SCH 23390, or the D1 agonist, SKF 38393, with the D2 antagonist, haloperidol on cell populations of the SNC and VTA areas in anesthetized rats. Acute administration of haloperidol caused a significant increase in active DA cells in both SNC and VTA; chronic 21 day administration resulted in a significant decrease in both areas. Acute and chronic treatment with SCH 23390 or SKF 38393 had no effect on the number of active DA neurons in either SNC or VTA. Acute coadministration of either SCH 23390 or SKF 38393 with haloperidol resulted in increases in both SNC and VTA similar to results seen with haloperidol alone. Chronic coadministration of SCH 23390 at 5 mg/kg or SKF 38393 at 3 mg/kg with haloperidol at 0.5 mg/kg resulted in a significant decrease in the number of active DA cells in both SNC and VTA similar to the effect of haloperidol alone. However, chronic coadministration of SKF 38393 at 10 mg/kg with haloperidol at 0.5 mg/kg resulted in a selective decrease in the number of spontaneously active DA neurons in the VTA and not the SNC. Thus, it appears that chronic stimulation of D1 receptors with SKF 38393 prevents haloperidol induced depolarization blockade of DA neurons in the SNC. These results substantiate the idea that stimulation of D1 receptors play a significant role in modulating expression of the D2 receptor.

DOPAMINE ACTIONS ON NUCLEUS ACCUMBENS NEURONS: WHOLE CELL RECORDING IN CULTURE. W.-X. Shi and S. Rayport. Dept. Psychiatry and Ctr. Neurobiol. & Behav., Columbia Univ.; Dept. Neuropathology, NYS Psychiatric Institute, NY 10032.

To examine the possible actions of dopamine (DA) at mesolimbic synapses, we made perforated-patch or whole cell tight seal recordings from cultured nucleus accumbens neurons. We used an intracellular solution containing 140 mM KGluconate, 0.1 $CaCl_2$, 2 $MgCl_2$, 1 EGTA, 2 ATP, 0.1 GTP, and 10 HEPES, pH 7.25. Neurons were dissociated from neonatal rats and maintained *in vitro* for up to 3.5 months. DA (50-100 μM) was applied by local perfusion to 74 cells; 31 cells responded to DA. Of these cells, 26% were hyperpolarized or showed an outward current under voltage clamp that reversed at more hyperpolarized levels and was due to an increase in membrane conductance. In the other 74% of DA-responding cells, DA produced either depolarization or an inward current that was diminished at hyperpolarized levels but could not be reversed.

In the same cells, we also examined the modulatory effect of DA on synaptic interactions between nucleus accumbens cells; 47 of the 74 cells received synaptic input from other neurons. Of these cells, 40% showed spontaneous EPSPs, 21% showed IPSPs, and the remainder showed both. In 20% of those cells which received PSPs, DA (100 μM) enhanced synaptic input by increasing PSP frequency, while in 12% of the cells, DA reduced PSP frequency or PSP size. These results reinforce the notion that DA has a wide range of actions in the nucleus accumbens, likely reflecting the activation of different DA receptors.

BLOCKADE OF SOMATODENDRITIC AUTORECEPTORS ON NIGRAL DOPAMINE NEURONS CONTRIBUTES TO THE FIRING RATE-INCREASING EFFECTS OF DOPAMINE ANTAGONISTS. M.L. Pucak and A.A. Grace. Depts. of Behavioral Neuroscience and Psychiatry, Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Systemic administration of the dopamine (DA) antagonist haloperidol (HAL) increases the firing rate of nigral DA neurons. This excitation has been suggested to result from the blockade of DA receptors located on striatal neurons projecting to the substantia nigra. HAL also may exert local effects within the nigra by blocking somatodendritic autoreceptors which are located on the DA neurons themselves, thus removing a tonic inhibition mediated by dendritically released DA; however, the importance of this mechanism is controversial. We have examined the relative significance of these two mechanisms by comparing the response of nigral DA neurons to intravenously administered HAL in anesthetized intact rats with the response observed in rats with hemisections of the striatonigral projection. In control rats, HAL (cumulative dose=4-6.4 mg/kg) caused >20% increases in firing rate in 4/5 DA neurons (average increase=24.8±6.1%). After hemisections, such increases were observed in 3/3 DA neurons (average increase=42.2±14.6%). Thus, the striatonigral projection does not entirely mediate the HAL-induced excitation of DA neurons, suggesting that HAL acts at least partially via blockade of DA receptors within the substantia nigra. In order to assess whether the local effects of HAL were mediated via blockade of D_2 DA cell autoreceptors or via blockade of D_1 receptors located on the terminals of the striatonigral projection, the D_2-specific DA antagonist sulpiride was administered. Sulpiride at a dose of 32 mg/kg was less effective than HAL at increasing DA neuron firing rate in intact rats; 2/5 DA neurons recorded from control rats showed >20% increases in firing rate upon administration of sulpiride (average increase=11.6±4.9%). However, 2/2 DA neurons recorded from rats with hemisections of the striatonigral projection showed >20% increases in firing rate (average increase=37.4±14.9%). Thus, blockade of somatodendritic autoreceptors appears to make a significant contribution to the increased firing rate of DA neurons in reponse to systemic administration of DA antagonists, suggesting that at least some DA neurons are tonically inhibited by dendritically released DA. ON THE EFFECTS OF THE DOPAMINE D3-RECEPTOR PREFERRING AUTORECEPTOR ANTAGONISTS (+)-AJ76 AND (+)-UH232 ON DOPAMINE RELEASE AND METABOLISM. Nicholas Waters, Montford Piercey# and Arvid Carlsson*.Dept. of Pharmacology, Univ of Göteborg P.O box 33031, S-400 33 Gothenburg, Sweden, # CNS research, The Upjohn Company, Kalamazoo, MI 49001, U.S.A

Recently, the existence of a third dopamine (D3) receptor (Sokoloff et. al. 1990) was revealed. The DA autoreceptor antagonists (+)-AJ76 and (+)-UH232 were shown to possess the highest preference for the D3 site of all DA antagonists screened. (+)-AJ76 and (+)-UH232 induce weak locomotor stimulation. Like classical dopamine receptor antagonists (+)-AJ76 and (+)-UH232 blocks the stimulatory effects of apomorphine and d-amphetamine. In biochemical experiments (+)-AJ76 and (+)-UH232, increase the synthesis and metabolism of dopamine in the striatal and limbic brain regions. However, neither (+)-AJ76 nor (+)-UH232 produces hypomotility or catalepsy. In this study we compare the effects of these two compounds on DA release and metabolism in the nucleus accumbens and in the caudate nucleus with raclopride and haloperidol, in the microdialysis model. We show that (+)-AJ76 is more effective on DA release than raclopride(max increase ≈200% of ctrl.) and haloperidol(max increase ≈200% of ctrl.). We found that (+)-AJ76 has a limbic preference, maximal DA release in n.accumbens is ≈500% but in the n.caudate ≈300%. The limbic preference is confirmed in electrophysiological studies, ED50 in VTA is 148 μg/kg i.v. and in the SNPC 316 μg/kg. (+)-UH232 releases dopamine in a fasion more like classical dopamine antagonists (maximal DA incerease ≈200% of controls) and we show no limbic preference for this compound.

THE DOPAMINE (D3 - PREFERRING) AUTORECEPTOR ANTAGONISTS (+)-AJ76 AND (+)-UH232 PRODUCE CONDITIONED PLACE-PREFERENCE IN THE RAT. Kjell Svensson , Marianne Thorngren *, Lena Wollter ,* and Arvid Carlsson * Department of Pharmacology, Univ. of Göteborg, P.O. Box 33031, S-400 33 Göteborg, Sweden

The preferential dopamine (DA) autoreceptor antagonists (+)-AJ76 and (+)-UH232 increase the synthesis and turnover of DA in brain limbic and striatal regions (Svensson et al., Arch. Pharmacol., 334:234, 1986). Sokoloff et al.(Nature, 347: 146, 1990) have recently shown that they possess a high preference for the DA D3 receptors. In contrast to classical DA receptor blockers, (+)-A J76 and (+)-UH232 produce a mild behavioral arousal over a wide dose range in habituated rats. Interestingly , in animals displaying a high baseline activity (e.g. d-amphetamine or cocaine-pretreatment), (+)-UH232 did not produce an excessive stimulation but blocked the hyperactivity. Various behavioral models were used in order to investigate the possible positive reinforcing properties . Both compounds were shown to be inhibitory in the intracranial self-stimulation paradigm (Kling-Petersen et al., this meeting) and (+)-AJ76 but not (+)-UH232 partially generalized to the to the cocaine cue (Hoffmann et al., this meeting). In the present study, we investigated the effects of (+)-AJ76 and (+)-UH232 in a three compartment conditioned place preference (CPP) paradigm. A clearcut dose-dependent (12.5-52 μmol/kg, sc) place preference was observed for both (+)-AJ76, (+)-UH232 and d-amphetamine (0.25-4 mg/kg, sc). Caffeine produced a weak preference at 5 mg/kg, sc but was inactive at 20 mg/kg , sc . We are at present studying the effects of other weak stimulants (such as DA reuptake inhibitors) and also the interactions of the preferential D3 receptor antagonists with raclopride, d-amphetamine and cocaine in the CPP paradigm. (Supported by The Upjohn Company, Kalamazoo, MI).

EFFECTS OF THE DOPAMINE (D3- PREFERRING) AUTORECEPTOR ANTAGONIST (+)-AJ76 AND OTHER WEAK CENTRAL STIMULANTS IN THE INTRACRANIAL SELF-STIMULATION MODEL. Torben Kling-Petersen and Kjell Svensson, Dept of Pharmacology, Univ of Göteborg, POB 330 31, 400 33 Göteborg, SWEDEN

The preferential dopamine autoreceptor antagonist (+)-AJ76, exerts a weak stimulatory effect when tested in locomotor activity experiments using habituated animals. However, (+)-AJ76 also blocks d-amphetamine induced hyperactivity. Thus, the behavioral effects of (+)-AJ76 is highly dependent on the baseline activity of the animal. Interestingly, Sokoloff et al. (Nature, 347, pp:146-151 (1990)) recently showed that (+)-AJ76 possesses a high preference for the newly cloned dopamine D3 receptor.

Various behavioral models have been utilized in order to investigate possible positive reinforcing properties of (+)-AJ76. In the intracranial self-stimulation (ICSS) paradigm in the rat, bipolar electrodes aimed at the median forebrain bundle delivers mono-phasic, cathodal current of varying intensities. When testing (+)-AJ76 in the ICSS paradigm, the results depend on the ICSS method employed: In a response rate independent threshold determination method, (+)-AJ76 (0.9-52.0 μmol/kg, s.c.) shifts the response curve to the right, ie acts inhibitory. The subthreshold method is designed to pick up weak stimulatory effects. It presents the animal to a non-rewarding current intensity, but can produce increased lever pressing when combined with a stimulant. In this model (+)-AJ76 exhibits weak stimulatory properties in 50% of the animals tested.While being mainly inhibitory in the ICSS model, (+)-AJ76 was shown to partially generalize to the cocaine cue (Hoffman et al, this meeting) and to produced conditioned place preference in the rat (Svensson et al, this meeting). We are presently investigating the interactions of (+)-AJ76 with cocaine, d-amphetamine and the effects of the DA reuptake inhibitors nomifensine and GBR-12909 in the ICSS paradigm. ANTAGONISM OF SYNTHESIS MODULATING DOPAMINE AUTORECEPTORS IN VITRO BY (+)-AJ76, (+)-UH232 AND PD-128483. M.P. Galloway, E.A.Novak*, B.N.Mathews* Cellular & Clinical Neurobiology Program, Lafayette Clinic and Dept. Psychiatry, Wayne State Univ Sch Med, Detroit MI

Dopamine (DA) synthesis can be regulated in situ by stimulation of nerve terminal DA autoreceptors (AR). Using striatal brain slices, we have examined the ability of different classes of DA antagonists to affect the inhibition of DA synthesis induced by DA agonists in vitro. Stimulation of DA ARs was measured as the inhibition of K^+ stimulated DOPA accumulation by a fixed dose of either quinpirole or 7-OHDPAT. The rank order for reversal of 1 μM QUIN was (+)-UH232 > (+)-AJ76 = clozapine > (-)sulpiride. Although (+)-AJ76 was equipotent with CLOZ against QUIN, (+)-AJ76 was more efficacious than CLOZ when tested against 7-OHDPAT (1 μM). PD 128483 (10 μM) partially reversed the effect of QUIN under these conditions. Under basal conditions (K^+ = 5 mM) to assess agonist characteristics, only (-)-UH242 and PD 128483 and (-)-3PPP, but not (+)-AJ76, (+)-UH232, or (+)-UH242, exhibited AR agonist properties. Under depolarizing conditions (K^+ = 30mM), neither PD 128483 nor (-)-3PPP inhibited DOPA accumulation. Compounds do not interact with the DA transporter since neither PD 128483 nor the aminotetralins alone increased extracellular DA and none of the aminotetralins (3 μM) blocked the amphetamine (3 μM) induced release of DA. The effects of PD 128483 at DA autoreceptors appear to mimic those of the partial agonist (-)-3PPP. Furthermore, our results confirm that (+)-AJ76 and (+)-UH232, putative D-3 receptor antagonists, are antagonists at synthesis modulating DA AR's. DECREASED SENSITIVITY OF APOMORPHINE (APO) FOR STRIATAL DOPAMINE (DA) AUTORECEPTORS IN TRANSGENIC HPRT⁻ MICE. D. Tang*, K. Harada*, K.Y. Lee, M. Goldstein and M.R. Kuehn*. Neurochem. Res. Lab., New York Univ. Med. Ctr, N.Y., N.Y. 10016 and Dept. for Genetics, Univ. Ill. Coll. Med., Chicago, Ill. 60612

To determine whether decreased striatal DA levels and increased DA turnover in transgenic HPRT⁻ mice is associated with sensitivity changes of DA agonists for DA autoreceptors, we have analyzed the effects of Apo on the γ-butyrolactone (GBL)-elicited enhanced synthesis of striatal Dopa. Basal striatal Dopa synthesis following inhibition of aromatic L-amino acid decarboxylase by NSD 1015 is not altered in HPRT⁻ mice as compared with HPRT⁺ controls. The cessation of dopaminergic impulse flow by administration of GBL increases the striatal Dopa synthesis to the same extent in HPRT⁻ and in control mice. Administration of the DA agonist Apo (0.1 mg/kg) reverses the GBL-elicited enhanced synthesis of striatal Dopa, but the % reversal is significantly lower in the transgenic HPRT⁻ mice than in controls. These results suggest that DA autoreceptors which regulate synthesis and release of DA are desensitized in HPRT⁻ mice. It is postulated that desensitization of DA autoreceptors might be responsible for the increased turnover of striatal DA in HPRT⁻ mice and may play a role in the pathophysiology of Lesch-Nyhan disease. Supported by NIMH 02717 and NINCDS 06801.

1-(SPIRO-1'-ALKYLPHENYL)BENZAZEPINES, NOVEL DOPAMINE D1 RECEPTOR SELECTIVE ANTAGONISTS. Paul P. Ehrlich*, James R. Campbell*, Robert Schoenleber*, Donald R. Britton, Robert MacKenzie and John W. Kebabian. Neuroscience Research D47U, Pharmaceutical Discovery, Abbott Laboratories, Abbott Park, Il 60064

Various 7-substituted-8-hydroxy-3-methyl-1-(spiro-1'-indan) and (spiro-1'-1',2',3',4'-tetrahydronaphthalene)-2,3,4,5-tetrahydro-1H-3-benzazepines were synthesized and evaluated as D1 antagonists.

The *in vitro* D1 and D2 binding assays and D1 functional activity were assessed according to previously established protocol.

The *in vivo* ED50 values were obtained by use of a behavioral assay which was based on the 6-hydroxydopamine unilaterally lesioned rat rotational model.(U. Ungerstedt and G.W. Arbuthnott, *Brain Research*, **1970**, *24 :* 485). Antagonist activity was measured by the ability of the test compound to block rotation induced by stimulation by A68930, a selective D1 agonist, (M.P. DeNinno et. al. *J. Med. Chem.* **1990**, *33* : 2948), by simultaneous subcutaneous injection of test drug.

Of the compounds generated four of the most promising candidates were shown to be the 7-bromo-spiro-1'-indan, 7-bromo-spiro-1'-naphthalene, and the corresponding 7-methoxy derivatives. These showed excellent *in vitro* activity, however, only the spiro-1'-indans showed good *in vivo* activity.

THE D1 DOPAMINE RECEPTOR ANTAGONIST SCH 23390 EXERTS AGONIST-LIKE EFFECTS ON RAT NUCLEUS ACCUMBENS NEURONS. S.R. Wachtel and F.J. White. Wayne State Univ. Sch. Med., Dept. Psychiatry, Cellular and Clinical Neurobiology Program, Neuropsychopharmacology Laboratory, Lafayette Clinic, Detroit, MI 48207

Previous behavioral and electrophysiological studies have demonstrated that acute dopamine (DA) depletion abolishes many effects of D2 DA receptor agonists unless D1 agonists are also administered. This enabling role of D1 DA receptor stimulation has also been indicated by the ability of D1 antagonists to prevent the unconditioned behavioral effects of D2 agonists. The present experiments investigated the ability of the selective D1 DA receptor antagonist SCH 23390 to alter the inhibitory effects produced by iontophoretic administration of the selective D2 DA receptor agonist quinpirole on rat nucleus accumbens (NAc) neurons. In contrast to its effects on D2 agonist-elicited behaviors, systemic administration of SCH 23390 (0.5 mg/kg, i.v.) failed to block subsequent inhibition of NAc neurons produced by iontophoretic administration of quinpirole (10 mM, 8-32 nA). Similarly, iontophoretic administration of SCH 23390 (50 mM, 5-40 nA) failed to block the inhibition of NAc neurons by iontophoretic quinpirole. In fact, SCH 23390 further inhibited the firing of NAc neurons. When administered alone, iontophoretic SCH 23390 produced a current-dependent inhibition of NAc activity similar to that observed with the D1 agonist SKF 38393. Furthermore, like D1 agonists, low iontophoretic currents of SCH 23390 (4 nA) "enabled" the inhibitory effects of quinpirole in rats acutely depleted of DA by pretreatment with the tyrosine hydroxylase inhibitor α-methyltyrosine. These finding are similar to previous behavioral reports indicating that low doses of SCH 23390 elicit D1 agonist-like grooming behavior in rodents. (Supported by MH-40832 and DA-04093)

540.19

ELIMINATION OF D1 AND D2 DOPAMINE (DA) RECEPTOR INTERACTIONS IN THE RAT STRIATUM BY CHRONIC BLOCKADE OF EITHER D1 OR D2 RECEPTORS X.-T. Hu and F.J. White. CCN Program, Dept. Psychiat., Wayne St. Univ. Sch. of Med., Lafayette Clinic, Detroit, MI 48207

Electrophysiological and behavioral studies were conducted to determine whether coincident supersensitivity of D1 and D2 receptors is necessary for elimination of the D1 and D2 receptor synergistic interactions within the dorsal (caudate-putamen, CPu) and the ventral (nucleus accumbens, NAc) striatum of rats. Selective supersensitivity of D1 or D2 receptors was induced by daily repeated administration (s.c.) of the selective D1 antagonist SCH 23390 (SCH) or the selective D2 antagonist eticlopride (0.5 mg/kg each) for 3 weeks with 1 week drug withdrawal. Single cell recordings indicated that the inhibitory responses of CPu and NAc neurons to iontophoresis of the selective D1 agonist SKF-38393 (SKF) (but not the selective D2 agonist quinpirole) were significantly enhanced in SCH (but not saline or eticlopride)-pretreated rats. In contrast, the inhibitory effects of quinpirole (but not SKF) were significantly enhanced in eticlopride (but not saline or SCH)-pretreated rats. In addition, while SKF usually potentiates the quinpirole-induced inhibition on CPu and NAc activity in rats with normosensitive DA receptors, such synergistic action was eliminated in either D1 or D2 sensitized rats. Also, the necessity of D1 receptor activation for D2 receptor-mediated neuronal inhibition, which is typically observed in rats acutely depleted of DA, was abolished following D2 receptor supersensitivity. Behavioral experiments indicated that the stereotyped responses to acute administration of quinpirole were significantly enhanced following chronic blockade of D2 receptors. Although acute DA depletion significantly reduced quinpirole (2 mg/kg, s.c.)-elicited stereotypies in saline-pretreated controls, supersensitive stereotyped responses to this D2 agonist remained in eticlopride-pretreated AMPT rats. These findings indicate that either D1 or D2 receptor supersensitivity affects the synergistic interactions of adjacent D1 and D2 receptors located on rat striatal neurons (Supported by USPHS Grants DA-04093 and MH-40832 to FJW).

EVIDENCE FOR DOPAMINE D2 AUTORECEPTORS IN NEONATAL AND INFANT RAT PUPS. C.A. Moody, H. Rabine*, L.P. Spear, Dept. of Psychology and Center for Developmental Psychobiology, SUNY, Binghamton, NY 13902-6000.

The presence of functional dopamine (DA) D2 autoreceptors was assessed in neonatal (postnatal day 3-P3) and infant (P10) rat pups. 35 min prior to sacrifice pups received a 750mg/kg s.c. injection of gamma-butyrolactone (GBL) to block impulse flow in DA neurons. 30 min prior to sacrifice all pups received a 100mg/kg i.p. injection of the dopa decarboxylase inhibitor 3-hydroxybenzylhydrazine, with pups in the quinpirole group receiving a s.c. injection of 0.5mg/kg quinpirole immediately thereafter. Following decapitation, forebrain and striatal regions were dissected on ice from P3 and P10 brains, respectively, and frozen for later assessment of DOPA concentrations via HPLC/ec. At both ages GBL treatment increased DOPA levels, with this increase being blocked by quinpirole. This agonist induced reduction in DOPA levels provides evidence that D2 presynaptic autoreceptors are functional in terms of inhibiting DA synthesis in young animals. In addition, preliminary findings suggest that the D1 agonist SKF-38393 may also inhibit DA synthesis early in life. Further investigations are being conducted to determine if this is indeed an apparent D1 autoreceptor effect or is merely a function of direct endproduct inhibition by this catechol compound.

BHT 920 SELECTIVELY STIMULATES A SUBTYPE OF D-2 RECEPTORS COUPLED WITH VOLTAGE-DEPENDENT K^+CHANNELS.
A. Valerio*, M. Pizzi, M.O. Carruba*, S. Espositi*, M. Benarese*, M. Memo, P.F. Spano. Dept. Biom. Sci. & Biotech. , Section Pharmacol. Exper. Ther. School of Medicine, Univ. Brescia, I-25124.

Radioactive rubidium efflux was used to measure potassium (K^+) permeability in a study designed to assess both the presence and the sensitivity to ions and drugs of the K^+ channels located in the presynaptic nerve terminals of rat striatum.Our data provide evidence for the existence of at least two different K^+ channels which participate differently in the regulation of K^+ fluxes under both resting and stimulated conditions. The two different components of K^+ fluxes were found on the basis of their kinetic properties and sensitivity to calcium ions. We also found that both the K^+ channels present in the isolated nerve terminals are sensitive to dopamine and various, but not all, D-2 dopaminergic drugs. In particular, the azepine derivative BHT 920 discriminates between the two channels behaving as selective opener of the voltage -dependent, calcium-insensitive K^+ channels. Our results support the conclusion that presynaptic nerve terminals of rat striatum possess two distinct categories of K^+ channels: a voltage-dependent and a calcium-activated K^+ channel. The two different K^+ channels serve as effectors of two distinct subtypes of dopamine D-2 receptors.

NEUROCHEMICAL EFFECTS AND SELECTIVE DISTRIBUTION OF AMISULPRIDE IN THE MESOLIMBIC DOPAMINERGIC SYSTEM AFTER CHRONIC TREATMENT.
M.C Maubrey*, A.M. Gardier, J.H. Trouvin, J. Margarit* and C. Jacquot, Fac Pharmacie, SDI 6313, 92296 Chatenay-Malabry, *Lab Delagrange, 91380 Chilly-Mazarin, France

We have previously shown that low-dose (2mg/Kg, i.p.) amisulpride (Ami), an atypical neuroleptic and D2 receptor antagonist, increases the concentration of 3MT (an index of dopamine release) in the nucleus accumbens (NAc) without modifying DOPAC or HVA concentrations. No effect was observed in the striatum (St).(Maubrey et al., 1988, Ann. Psychiatr, 3; 284-297). In this study, we determined whether the 3MT increase persisted after 14 days of treatment and whether the localized effect of Ami in the NAc was associated with a preferential distribution of the neuroleptic in this structure.
Wistar rats treated with Ami for 14 days (2mg/kg/day, i.p.) were sacrificed 60 min, after the last injection. DA, DOPAC, HVA and 3MT concentrations in the NAc and the St were determined by means of HPLC coupled with electrochemical detection. Trough Ami concentration was determined simultaneously in the NAc and the St, following chloroform extraction, by HPLC coupled with fluorimetric detection, 24 hours after the last administration.
Chronic treatment with Ami increased 3MT concentration in the NAc (+18%, $p < 0,05$), but not in the St. This DA releasing effect localized to the NAc was associated with a higher concentration of Ami in the NAc than in the St (218,3ng/g versus 99,7ng/g, respectively). These results support a selective involvements of the NAc in the effect of low-dose Ami and suggest that Ami may have a high affinity for a sub-type of DA receptors located preferentially in the NAc and involved in the release of DA.

DOPAMINE LEVELS IN CULTURED RAT MESENCEPHALIC NEURONS.
S.Schinelli,M.Paolillo*,M.Quartieri* and G.L.Corona*, Institute of Pharmacology, University of Pavia, 27100 Pavia, ITALY.

Dopaminergic neurons account for only a few per cent of the cells dissociated from embryonic midbrain and therefore the measurement of endogenous dopamine (DA) and its metabolites requires a very sensitive assay. We have developed an HPLC method coupled to coulometric detection to measure the levels of DOPAC and DA in rat mesencephalic cultures. Papain dissociated mesencephalic cells from 14-15 days old rat embryos were seeded in 24 multiwell plates at a density of 300000 cells/well, grown in 15% horse serum and then incubated up to 2 weeks in vitro. Cellular content of DA and DOPAC was monitored at 3,6,9 and 12 days in vitro (DIV); DA and DOPAC levels increased linearly with time of incubation ranging respectively from 2.5 pmoles/well and 0.12 pmoles/well at 3 DIV to 38.1 pmoles/well and 2.3 pmoles/well at 12 DIV. The DA/DOPAC ratio remained constant during the time of development in vitro. The levels of DA were significantly increased when mesencephalic neurons were cocultured with target striatal cells and furthermore cellular DA content in cocultures was directly correlated to the number of target striatal cells.

Anatomical Heterogeneity of Locomotor Responses to D1/D2 Agonists and Amphetamine in the Nucleus Accumbens.
W. D. Essman, P. McGonigle and I. Lucki, Depts. of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA, 19104.

The nucleus accumbens (N.Acbs) plays an important role in the locomotor effects of dopaminergic agonists. The present studies provide evidence for an anterior/posterior regional heterogeneity for induction of locomotion by coinjections of the D1 agonist SKF 38393 (S) and the D2 agonist quinpirole (Q), or the dopamine releaser d-amphetamine (A), into the N.Acbs. Two groups of male Sprague-Dawley rats were implanted with guide cannulae (ML: ±1.5; DV: -5.8) aimed at different sections of the N.Acbs (AP: +2.0; +2.5). Following assessment of the locomotor stimulating effects of coadministration of various doses of S/Q or 32 ug/side A, animals were sacrificed and cannulae placements histologically determined. Subjects were divided into anterior (ANT; AP:>+2.3) and central (CEN; AP:<+2.3) placements based on the atlas of Paxinos and Watson (1986).

All groups were acclimated to the activity chambers prior to examining drug effects (saline control values: range = 25.1 - 69.4 counts/hour (c/h)). Rats in the CEN group (N=19) showed a consistent and robust locomotor response to maximally-effective S/Q combinations (Mean = 1,320.5 ± 165.9 c/h). Fifteen rats showed a high locomotor response (>500 c/h) to S/Q, whereas only 3 rats showed a moderate response (100-500 c/h) and one rat failed to respond to the S/Q combinations (<100 c/h). In contrast, twenty rats with ANT placements displayed inconsistent locomotor effects to S/Q combinations (Mean = 507.8 ± 130.0 c/h). Ten rats failed to show increases in locomotor activity; two rats showed moderate increases in locomotion; and eight rats displayed high locomotor activity. The pattern of enhanced locomotor response in animals with central versus anterior accumbens placement was also evident in the response to A (CEN: 642.6 ± 80.7 c/h; ANT: 387.2 ± 45.6 c/h). These data suggest that the receptors mediating the locomotor responses to dopamine agonists in the N.Acbs are located in the central to posterior portion of this nucleus. Supported by USPHS grant GM 34781.

A COMBINED GOLGI-STAINING AND IMMUNO-CYTOCHEMICAL STUDY OF NEURONS CONTAINING DARPP-32, A DOPAMINE-REGULATED PHOSPHOPROTEIN, IN ANTERIOR CINGULATE CORTEX.
C. C. Ouimet, Psychology Department, Florida State University, Tallahassee, FL 32306.

Many neurons in layer VI of the rat cerebral cortex contain DARPP-32, a dopamine and cyclic AMP-regulated phosphoprotein enriched in cells containing the D_1 dopamine receptor. The present study was undertaken to determine whether DARPP-32-containing neurons in anterior cingulate cortex are of a single morphological type. Male Sprague-Dawley rats (150-250 g) were anesthetized with sodium pentobarbital (60 mg/kg) and perfused with fixative. Brain sections were immunolabeled for DARPP-32 and then Golgi-stained. After the neurons were drawn, the silver stain was removed with sodium thiosulfate. At least 5 morphological cell types, including modified pyramids, an aspiny neuron, an inverted pyramid, a bipolar cell and a horizontally oriented cell were then classified as immuno-reactive. These results indicate that DARPP-32 is present in many cell types in layer VI and suggests that dopamine and cAMP modulate layer VI cells that have different functions.

BIOCHEMICAL AND PHARMACOLOGICAL MODULATION OF THE DOPAMINE SENSITIVE ADENYLATE CYCLASE IN HOMOGENATES OF BOVINE RETINA.
M. Schorderet, S. De Raad* and S. Ofori, Dept. of Pharmacology, CMU, CH 1211 Geneva 4 and School of Pharmacy, B.E.P., CH 1005 Dorigny-Lausanne.

The effects of various biochemical factors or pharmacological agents on the dopamine (DA)-induced accumulation of cAMP mediated by the stimulation of DA D-1 receptors were investigated. The procedure of Markstein et al. (J. Neural Transm. 69, 179, 1987) was modified as follows in order to optimize the response to DA: 1)100 µl of retinal homogenate were added to 350 µl of the buffer (48.8 mM Tris-HCl, 2 mM $MgCl_2$, 0.45 mM EGTA, 0.1 mM IBMX, pH 7.4) containing DA-agonists or -antagonists or forskolin, except in the controls. The mixture was kept at ice-temperature during 13.5 min before a rapid conditioning of 1 min at 30°C. The final 3 min incubation was then started with 50 µl of a solution of 5 mM ATP/ 0.1 mM GppNHp. After centrifugation (3400 rpm), proteins and cAMP (Brown et al., Biochem. J., 121,561, 1971) were measured in the pellets and in the supernatants, respectively. Under these optimal conditions, reproducible dose-response curves to DA or forskolin were obtained. In addition, the system was successfully tested to study the DA D-1-agonist properties of a new ergoline (CY 208-243) and to reassess the D-1 antagonist properties of clozapine. These results would confirm the usefulness of bovine retinal homogenates for 1)the study of DA-sensitive adenylate cyclase; 2)the screening of DA D-1 agonists or antagonists.

A DOPAMINE MICROCULTURE SYSTEM FOR IN VITRO DRUG TOXICITY TESTING. J. van Lange, H.M. Akbari, X.P. Hou, and E.C. Azmitia.
Dept. of Biology, New York Univ., Washington Sq. East, NY, NY 10003.

Primary neuronal cultures have become an increasingly popular experimental method in examining the inhibitory or stimulatory effects of neuroactive agents. We have already established the validity and usefulness of a primary fetal serotonin (5-HT) microculture system for drug toxicity studies in our laboratory. In this study, we establish a similar culture system with dopamine (DA) neurons to compare the effects of various drugs on these two neurochemical systems. A mesencephalic tegmental slice containing the majority of DA neurons was dissected from gestational day 14 fetal rat brains (age established by crown-rump measurement) in Minimal Essential Medium(MEM) with antibiotics. Slices were mechanically dissociated and plated onto poly-d-Lysine coated 96-well microculture plates (NUNC). The optimal initial cell plating density was found to be 0.8-1.0 x 10^6 cells/cm^2. Cell viability and fiber outgrowth were assessed using ^{3}H-DA(50nM) uptake after 5 days culture. Nonspecific accumulation was determined by the addition of 5x10^{-5}M nomifensine, a specific dopamine uptake blocker.

We assessed the specificity of our culture system by examining the effects of both DA and 5-HT specific drugs on DA fiber outgrowth inhibition or enhancement. Drugs were added on day (D) 2 of culture and ^{3}H-DA uptake done on D5. Cocaine, MDMA, nomifensine and fenfluramine were tested. DA uptake development was most affected by nomifensine which reduced ^{3}H-DA uptake to 50% of control after a single application at 1x10^{-6}M concentration. Fenfluramine, a serotonergic releaser, did not inhibit uptake development unless added concentrations exceeded 10^{-5}M. Interestingly, cocaine is not as potent as nomifensine in inhibiting DA fiber outgrowth, indicating that the release properties of cocaine distinguish it from the reuptake blocker. We are currently investigating other drugs' effects on cultured dopamine neurons. Supported by NIDA contract # 271-A7-A144.

TRANSMITTERS IN INVERTEBRATES: MOLLUSCS II

541.1

IDENTIFICATION OF A NETWORK OF NEURONS IN THE ABDOMINAL GANGLION OF *APLYSIA* THAT ARE IMMUNOREACTIVE FOR THE R15α PEPTIDES. J. Koester
Center for Neurobiology and Behavior, Columbia University, N. Y., NY 10032

The endogenously bursting, peptidergic neuron R15 expresses the R15 gene, which encodes 3 neuropeptides: R15α1, R15β, and R15γ. The mRNA precursor transcribed from the R15 gene is alternatively spliced in other neurons, resulting in an mRNA that encodes a partially overlapping set of peptides: R15α2, R15β, and R15γ (Buck et al., 1987). The R15α1 peptide has been shown to cause water retention (Weiss et al., 1989) and both the R15α1 and R15α2 peptides have cardioexcitatory effects. We have previously found that in the abdominal ganglion only 5 cells are strongly immunoreactive (IR) for the R15α1 and R15α2 peptides. Two have previously been identified: R15 (which contains the R15α1peptide) and the cardioexcitatory neuron RB_{HE} (which contains the R15α2 peptide). The purpose of this study was to identify the other 3 IR neurons, all of which stain selectively for the R15α2 peptide.

The 3 remaining R15α2 – IR neurons have been identified. They are named L40, $L9_A$, and $L9_B$. The 2 L9 cells both project out the siphon nerve, and preliminary evidence suggests that they are the L9 gill motoneurons. The L40 cell is a newly characterized interneuron that projects to the head ganglia. It excites the other 4 IR cells by strongly exciting Int XIII, which directly excites R15, RB_{HE}, and the 2 L9 cells. Moreover, L40 is excited by L10, which also excites the other 4 cells that are IR for the R15α peptides.

Thus, all 5 of the neurons in the abdominal ganglion that are strongly IR for the R15α peptides appear to belong to the same functional network. Previous work has implicated R15, L10 and RB_{HE} in the control of water balance and kidney function. We are attempting to test this hypothesis and to determine the roles of the L40 and L9 cells in this context.

541.2

INNERVATION OF THE HEART OF *APLYSIA* BY SEROTONIN- AND R15α2 PEPTIDE- IMMUNOREACTIVE TERMINALS, AND BY NEURON L2. M.E. Skelton and J. Koester, Center for Neurobiology and Behavior, Columbia University, N.Y., NY 10032

Neuron L10 has been postulated to increase renal excretion by (1) opening the renal pore and inhibiting the LUQ cells that cause pore closure, and (2) exciting cardioexcitatory neuron RB_{HE}. The latter presumably increases filtration which takes place across the wall of the heart and/or the cristae aorta. The RB_{HE} cell has been shown to contain serotonin and R15α2 peptide. The purpose of this study was to (1) study the innervation of the heart by RB_{HE}; (2) to look for inputs to the heart that might counteract the L10-RB_{HE} effect, analogous to the way that the LUQ cells antagonize L10's effect at the renal pore.

Histofluoresence studies suggest that *Aplysia* heart is rich in serotonergic nerve endings (Taxi and Gautron, 1969). We have confirmed the serotonergic nature of these endings using fluorescent-labeled antibodies. However, double-label experiments revealed that R15α2 peptide immunoreactivity (IR) and serotonin-IR overlap only partially. Serotonin-IR is found in nerve terminals throughout the heart, while R15α2-IR is coextensive only with the serotonin-IR endings in the auricle and in the AV valves. This result indicates that either RB_{HE} segregates the R15α2 peptide to selected parts of its terminal field, or that the heart receives serotonergic input from neurons other than RB_{HE}.

We also found, based on extracellular recording and dye filling, that one of the LUQ cells (L2) has extensive nerve terminals in the auricle. Firing L2 has no effect on heart beat or on its modulation by other neural inputs. Our working hypothesis is that L2 activity modulates the filtration characteristics of the heart wall. Because L2 is inhibited by L10, we hypothesize that its actions in the heart oppose the actions of L10 that are mediated by RB_{HE}.

Current work is directed towards identifying more precisely the sources of the serotonin-IR and the R15α2-IR in the heart and further characterizing the role of cardioactive neurons in *Aplysia*.

541.3

PEDAL PEPTIDE MODULATES A SODIUM CURRENT IN NEURONS L2-L6 OF *APLYSIA*. W. L. Pearson & P. E. Lloyd, Comm. on Neurobiol. & Dept. of Pharmacol. & Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

Application of pedal peptide (Pep) has been shown to depolarize the left upper quadrant (LUQ) neurons (L2-L6) of *Aplysia*. Several Pep-induced ionic currents contribute to this depolarization. Using voltage clamp and ion substitution techniques, we have isolated and characterized one of the Pep-induced currents as a Na^+ current ($I_{Na(Pep)}$).

Pep (2.5 μM-15 μM) was bath applied to axotomized LUQ cells bathed in "Ca^{++}-free" saline. Voltage-jump experiments showed that Pep induced a large inward current that reversed near 20 mV. At negative potentials the current displayed pronounced rectification, so that the I-V curve was unsloped below -30 mV. Substituting tetramethylammonium for Na^+ in the saline reduced the current and shifted the reversal potential to lower potentials, indicating that the current is carried primarily by Na^+. Addition of divalent cations to the saline blocked $I_{Na(Pep)}$. For example, 2.5 mM Mn^{++} reduced $I_{Na(Pep)}$ by 50%. Ca^{++} and Co^{++} produced a similar reduction of $I_{Na(Pep)}$. At physiological Ca^{++} concentrations, $I_{Na(Pep)}$ is largely blocked.

The biophysical properties of $I_{Na(Pep)}$ are very similar to the properties of cyclic nucleotide-gated currents characterized in a wide variety of cells, including other *Aplysia* neurons. Ionophoretic injection of cyclic nucleotides evoked a current resembling $I_{Na(Pep)}$. Treating LUQ cells with IBMX, a phosphodiesterase inhibitor, enhanced $I_{Na(Pep)}$, indicating that a cyclic nucleotide may be involved in modulating the activity of this current. Supported by NS 23569.

541.4

ABSENCE OF ACETYLCHOLINESTERASE (AChE) ACTIVITY AT CHOLINERGIC NEUROMUSCULAR SYNAPSES IN *APLYSIA*. P.E. Lloyd Dept. Pharm. Physiol.Sci., Comm.Neurobiol. Univ. Chicago, Chicago IL 60637.

Intrinsic buccal muscle 5 (I5, also the ARC) is innervated by 2 cholinergic neurons which have axons in buccal nerve 3 (N3). The metabolism of ^{3}H-choline (^{3}Ch)and ^{3}H-acetylcholine (^{3}ACh) in I5 was studied. I5 contains a high affinity uptake system for ^{3}Ch which is active into the nM range. N3 stimulation increases ^{3}Ch uptake, which is then found entirely as ^{3}ACh (presumably in cholinergic terminals). When I5 is loaded with ^{3}ACh in this manner, subsequent N3 stimulation depletes only ^{3}ACh. Thus stimulation of N3 (even with contractions blocked) selectively affects ^{3}ACh metabolism. Several lines of evidence suggest that these neuromuscular synapses have very low endogenous AChE activity. First, when N3 is stimulated and the bath surrounding I5 analysed, over half the label is recovered as ^{3}ACh in the absence of any AChE inhibitor. Second, stimulation-dependent increase of released label is not changed by the addition of cold choline (≤100μM) indicating that little hydrolysis of ^{3}ACh and subsequent uptake of ^{3}Ch occurs. Finally, ^{3}ACh is hydrolysed very slowly by I5, and eserine (100μM) slows this hydrolysis only slightly suggesting that it may not be due to a true AChE. Thus, unlike vertebrate neuromuscular junctions, I5 terminals have little endogenous AChE activity. However it is possible that AChE activity could be provided by blood. Supported by NS 23569.

IN-SITU HYBRIDIZATION WITH NON-RADIOACTIVE PROBES IN WHOLEMOUNTS OF APLYSIA GANGLIA. J.K. Ono & R.E. McCaman. Dept. of Biol. Sci., Calif. State Univ., Fullerton, CA 92634 and Div. of Neurosciences, Beckman Research Inst. of the City of Hope, Duarte, CA, 91010.

The large identifiable neurons in the CNS of Aplysia californica may be useful for determining the subunit composition of ion channels that have been cloned. We have developed in situ hybridization preparations of wholemounts of Aplysia ganglia to facilitate identification of specific neurons containing particular mRNA transcripts of interest. These neurons may later be used in live preparations to test for the presence of specific types of ion channels. cDNA probes to neuronal actin and FMRFamide, previously cloned from Aplysia, were labeled with digoxigenin.

Results with these probes for abundant mRNAs indicate that the staining with the digoxigenin-based method is similar in appearance to immunohistochemically treated wholemounts of ganglia. Additional studies are planned to determine whether this procedure has the sensitivity to detect rarer Aplysia mRNAs. (Supported by CSUF Mini-Grant and NIH AREA Grant to JKO and Beckman Research Funds to REM).

EFFECTS OF APLYSIA BAG CELL PEPTIDES ON cAMP METABOLISM DISTINGUISH MULTIPLE FUNCTIONAL CLASSES. R. Sanger Redman and R.W. Berry. Dept. Cell, Molecular and Structural Biology, Northwestern Univ., Chicago, IL 60611.

The secretion of egg-laying hormone (ELH) by the bag cell neurons of Aplysia is modulated via cAMP by peptides which are secreted with ELH. We have examined each of the secretory products of the proELH precursor and related peptides of the atrial gland for effects on bag cell cAMP metabolism. We find that neither ELH itself nor the acidic peptide alter bag cell cAMP metabolism. In contrast, each of the Bag Cell Peptides (BCP's) and the structurally-related atrial A and B peptides do. As previously reported, α-bag cell peptide reduces bag cell cAMP at 15°, but elevates cAMP at 20°. Since only inhibition by this peptide is observed in adenyl cyclase assays and its effect on whole cells at 20° is converted to inhibition in low Ca^{++}/high Mg^{++} media, we suggest that the peptide evokes release of an excitatory agent at the higher temperature. However, its actions are not altered by tetrodotoxin, suggesting that presynaptic excitation is not involved. The effects of γ-BCP are qualitatively identical to those of α-BCP, although its potency is lower, and the inhibition of adenyl cyclase by these peptides is additive. In contrast, β-BCP and the atrial peptides elevate bag cell cAMP in a temperature-independent fashion. The effect of β-BCP persists in low Ca^{++}/high Mg^{++} medium, suggesting a direct action on bag cells, whereas the atrial peptides elevate bag cell cAMP when secretion is blocked at 15°, but not at 20°. Thus these structurally similar peptides differ substantially in their functional characteristics: α- and γ-BCP mediate temperature-dependent direct inhibition/indirect excitation; β-BCP mediates temperature-independent direct stimulation; and the atrial peptides mediate temperature-dependent direct/indirect stimulation.

541.7

INPUT RESISTANCE AND MEMBRANE POTENTIAL SHIFTS FOLLOWING TONIC NEUROTRANSMITTER APPLICATIONS TO *APLYSIA* SILENT NEURONS. A. R. Sheppard and R. G. Villanueva*. J.L. Pettis VAMC and Loma Linda Univ., Loma Linda, CA 92357.

Many studies identify modulation of specific channels or synthesis pathways by neurotransmitters (NXs), but leave open the question of the integrated effects on membrane properties. To do so, we measured membrane potential (V_m) and input resistance (R_{in}) in cells L1, R1 and R2 of the *Aplysia* abdominal ganglion by current clamps at 30 sec intervals. Bath perfusions of NX were for 30 min at 21°C. In general, dopamine, gamma-aminobutyric acid, and glutamate depolarized the cells, while R_{in} increased, decreased, and decreased, respectively. Serotonin effects (5 to 50 μM) were not well characterized, despite some significant shifts (2–10 mV, 50% in R_{in}). Acetylcholine had the least consistent effects. We saw few reliable correlations between the changes in R_{in} and V_m, although sometimes we saw the strong correlations expected if changes in one channel type were predominant. Effects shortly after NX application were sometimes reversed by slower trends, suggesting competition between processes with different time courses. Our results illustrate the complexity of integrated cell responses to modulation by tonic chemical stimulation. (Supported by U.S. DOE, Office of Energy Management, DE-AI01-90CE35035.)

541.8

THE ACTIONS OF MOLLUSCAN CARDIOACTIVE PEPTIDES ON THE HEART OF THE NUDIBRANCH ARCHIDORIS MONTEREYENSIS. B.L. Wiens and P.H. Brownell. Oregon State University, Corvallis, OR. 97331

The heart of the nudibranch mollusc *Archidoris montereyensis* is regulated by at least five motor neurons; two of these neurons, one excitatory and the other inhibitory, are uniquely potent modulators of cardiac activity. We are currently trying to identify the transmitters that mediate the actions of the powerful heart excitor. Previously, we demonstrated that the molluscan cardioactive transmitters serotonin (5-HT), dopamine, small cardioactive peptide B (SCP_B), and FMRFamide excite an isolated preparation of the *Archidoris* heart. Immunocytochemical studies indicate that 5-HT, SCP_B, and FMRFamide-like substances are present in axonal processes innervating cardiac and vascular tissues, although these transmitters were not detected in the identified heart excitor motor neuron. In this study we have assayed the activity of 4 additional peptides, R15α1 and 2, myomodulin, and substance P, recently shown to act on or innervate regions of other molluscan cardiovascular systems. The R15α2 peptide, present in *Aplysia's* heart excitor neuron RB_{HE}, is the most potent excitatory transmitter active on the heart of *Archidoris*. At threshold concentrations (<5 nM) this peptide increases the amplitude of heart contractions, and at progressively higher concentrations it also affects the rate in a dose-dependent manner. Myomodulin, though less potent (thres.= <500 nM), also increases the rate and amplitude of contractions. R15α1 and substance P do not appear to affect the heart's activity (highest concentrations tested 10 and 100 uM, respectively). Immunocytochemical labelling should reveal whether R15α2 and myomodulin-like transmitters are contained within the heart excitor neuron of *Archidoris* and its terminals on the heart. Thus, *Archidoris* should continue to be a useful model for studying the functional relationship between a small set of motor neurons, a larger number of cardio-excitatory transmitters, and regulation of cardiovascular processes. (Supported by NIH pre-doctoral felloship #MH09818, and Sigma Xi).

541.9

THE ONTOGENY OF NEURONAL SYSTEMS EXPRESSING SCP-LIKE AND SEROTONIN-LIKE ANTIGENS IN *BERGHIA VERRUCICORNIS*. S.C. Kempf, A. Saini*, and A. Jones*. Dept. of Zoology and Wildlife Science. Auburn University, Auburn, AL 36849

At 6 d after ovaposition these embryonic neuronal systems are much simpler that those found in near competent larvae. In 6 d embryos, only 5 neuron perikarya are positively labeled for 5-HT and one for SCP. the 5-HT positive neurons appear to be positioned centrally over the cerebral commissure rather than in the cerebral ganglia. 5-HT positive axons are present in the velum and in commisssures and connectives associated with the cerebral and pedal ganglia. SCP positive axons are present in the cerebral commissure and ganglia and extend from the single labeled neuron toward a cerebral ganglion. 12 d after ovaposition, competent larvae possess bilaterally symmetric pairs of 5-HT positive neurons apparently located in both the cerebral and pedal ganglion pairs. Numerous axonal processes are present, associated with the cerebral and pedal ganglia and also in the velum, visceral mass and foot. The SCP positive neuronal system now consists of bilaterally symmetric pairs of neurons that appear to be located in the left and right pleural ganglia. Axons extend from these neurons to their respective cerebral ganglia as well as through the circum-esophageal loop. Many SCP and 5-HT positive axons are parallell and directly adjacent to each other. Within the cerebral and pedal neuropils, SCP positive axons mingle closely with 5-HT positive axons.

541.10

IMMUNOLOCALIZATION OF HISTAMINE, OCTOPAMINE AND GABA IN THE CENTRAL NERVOUS SYSTEM OF LYMNAEA

T. Karhunen and P. Panula
Department of Anatomy, University of Helsinki, Finland

The distribution of histamine, octopamine and GABA in the subesophageal ring ganglia of the gastropod mollusc Lymnaea palustris was studied immunocytochemically in carbodiimide-fixed cryostat sections.

Octopamine-like immunoreactivity was distributed in only few large neurons predominantly in the buccal, cerebral and pedal ganglia. A total of 8-10 large neurons and a cluster of smaller positive cell bodies were found. Histamine was also found in the buccal, cerebral and pedal ganglia and in the visceral and large parietal ganglia. The number of histamine-positive cells was distinctly larger especially in the distal parts of the cerebral ganglia and the fiber tracts were more widespred in the connectives and nerves than those immunoreactive for octopamine and GABA. No colocalization of these three substances were found.

541.11

MET-ENKEPHALIN-LIKE IMMUNOREACTIVITY IN THE CNS AND HEART OF *LYMNAEA STAGNALIS*. N.M. Ewadinger, N.I. Syed, R.L. Ridgway, A.G.M. Bulloch and K. Lukowiak. Dept. of Med. Physiology, Univ. of Calgary, Calgary, Alberta, Canada T2N 4N1.

Using indirect immunocytochemistry on whole-mount tissues, we constructed a neuronal map showing met-enkephalin-like immunoreactivity in the CNS of *Lymnaea*. A total of 31 neurons, distributed among all except the pleural ganglia and left pedal ganglion, were consistently stained. In control experiments, no specific staining was observed when either the primary or secondary antiserum was omitted, or when non-immune serum replaced the primary antiserum. Preabsorption of the primary antiserum with met-enkephalin peptide (60 mM) eliminated specific staining.

Among the immunoreactive neurons were two giant, well-characterized peptidergic neurons: VD1 and RPD2. Their identity was further confirmed in double-labelling experiments which combined Lucifer yellow fills with immunocytochemistry. These cells are strongly electrically coupled and are known to be involved in cardiorespiratory and whole-body withdrawal behaviours. Since these neurons innervate the heart, we examined this target organ for the presence of met-enkephalin-like immunoreactivity and found staining of neuronal processes, particularly in the auricle. These results suggest that a met-enkephalin-like peptide is present in *Lymnaea* which may have a functional role in cardiovascular control.

Supported by MRC (Canada).

THE MECHANISM OF GLUTAMATE ACTION IN THE BUCCAL CPG OF HELISOMA TRIVOLVIS E.M. Quinlan and A.D. Murphy Department of Biological Sciences, University of Illinois at Chicago, Chicago, Illinois 60607.

The buccal CPG of Helisoma is comprised of three subunits (S1, S2, S3). Glutamate and its agonists mimicked the effect of S2 on identified S2 postsynaptic neurons, suggesting that the S2 neurons are glutamatergic. It appears that inhibition from S2 plays a critical role in the temporal linkages among subunits. Neurons that receive inhibition from S2 are hyperpolarized by glutamate and quisqualate, but not ACPD. These hyperpolarizations and the S2 IPSPS were not blocked by antagonists for ionotropic (e.g. CNQX) or metabotropic (e.g. AP4) glutamate receptors. These data suggest either a novel ionotropic glutamate receptor or an ACPD/AP4 insensitive metabotropic receptor. S2 excitation appears to be mediated by a kainate-like receptor. AMPA, glutamate and kainate depolarized neurons that receive excitation from S2. S2-evoked EPSPs and depolarizations produced by glutamate, AMPA, and kainate were blocked by CNQX. Glutamate, kainate and AMPA also stimulated rhythmic S2 activity. If kainate was used to evoke rhythmic S2 activity, addition of CNQX inactivated S2. If S2 activity was evoked by other neuroactive substances, CNQX blocked the S2-evoked EPSPs but not the S2 IPSPS, demonstrating that rhythmic S2 activity can occur in the absence of kainate-like excitatory influences. (NIH R01 NS26145)

541.13

A PECK OF PICKLED PEPTIDES. W. Lesser and M.J. Greenberg. Whitney Lab, St. Augustine, FL 32086.

Two series of cDNA clones have been sequenced from the garden snail *Helix aspersa*: clone HF1 and clone HF4. Clone HF1 encodes only the two tetrapeptides FMRFamide and FLRFamide; clone HF4 has sequences for eight longer peptides but no tetrapeptides. The peptides can be identified and quantified in tissue extracts with HPLC and RIA, and their distributions within a particular tissue can be visualised with immunohistochemistry. The two tetrapeptides and seven of the longer peptides end -RFamide while the eighth peptide encoded in clone HF4 has the sequence pQDPFLRIamide. HPLC/RIA analyses of heart extracts suggest that only the tetrapeptides are present in the heart. However, the heart stains with antisera raised against EFLRIamide implying that pQDPFLRIamide and the other longer peptides are also present.

Are the tetrapeptides the only FMRFamide analogues present in the heart? If so, then why does the EFLRIamide antiserum stain the heart? If the longer FMRFamide analogues are present in the heart why are they not detected by HPLC/RIA?

Funded by NIH grants F32 HL08371 and HL28440.

CHARACTERIZATION OF SQUID (*LOLIGO*) FMRFAMIDE RECEPTORS. G.J. Chin and K. Payza. Laboratory of Developmental Neurobiology, NIH, Bethesda, MD 20892 and LBG, St. Elizabeth's Hospital, NIMH, Washington, DC 20032.

We have continued our studies (Neurosci. Abstr. 16:550) of the receptor for the invertebrate neuropeptide FMRFamide by using a radioligand to characterize the binding site and by using detergents to solubilize the receptor. ^{125}I-daYFnLRFa binds to optic lobe membranes with a K_d of 0.15 nM and a B_{max} of 0.25 pmol/mg membrane protein at the optimal pH of 6.5. Binding is displaced potently by FMRFa (IC_{50} = 1-10 nM) and weakly by FMRF-OH (10 μM). GTP, GTPγS and GDP reduce binding by up to 85 % with IC_{50} = 5-10 μM while 100 μM ATP and GMP have no effect. FMRFa and pb2 stimulate adenylate cyclase in optic lobe membranes while pb5 is a partial antagonist. Both non-ionic (Triton X-100, octyl glucoside) and ionic (CHAPS, Zwittergent 3-10) detergents selectively solubilize the receptor. FMRFa (100 μM) inhibits labeling of the solubilized receptor by pb2 and pb5 while FMRF-OH, serotonin, and leu-enkephalin (all at 100 μM) do not.

HYPOTHALAMIC-PITUITARY-ADRENAL REGULATION II

542.1

EFFECTS OF REPEATED RESTRAINT STRESS IN RATS ON NEUROENDOCRINE AND MOLECULAR MARKERS OF THE BRAIN'S RESPONSE Yoshifumi Watanabe, Jesus Angulo, G. Bing[1], D.Filer[1], E.A. Stone[1] and B.S. McEwen Lab. Neurendocrinol. Rockefeller University, New York, N.Y. 10021; and [1]Department of Psychiatry, NYU School of Medicine, New York 10016, N.Y.

We have investigated effects of daily restraint stress on acute and chronic measures of the brain's response. Acute restraint stress elevated serum corticosterone levels; the response duration was reduced by repetition of the stress 3h/d. The attenuation occurred within the first 7d, and continued out to 28d. By 28d, rats showed no significant reductions in body, thymus and spleen weights and no increase in adrenal weights. Nevertheless, tyrosine hydroxylase mRNA in locus ceruleus increased by 30-40% during 7-28d of 3h/day stress. Sustained increases also occurred in the mRNA for oxytocin in the paraventricular nucleus; measurements of vasopressin mRNA are in progress. There are also rapid and delayed responses to restraint stress in cerebral cortex; just 1h of restraint stress produced marked increases in mRNA for 4 immediate early genes (nur77, c-fos, zif-268 and tis-7); in the hippocampus, 1h of restraint stress led to an increase of zif-268 but not c-fos mRNA. Repeated restraint stress of 7-10d duration decreases the cyclic AMP response to noradrenaline in cerebral cortex by a glucocorticoid-dependent mechanism (Stone et.al., Eur J. Pharm. 1987). The multiple changes induced by stress imply that many neurochemical systems are involved, some of which may be linked through causal cascades while others may involve modulatory effects of circulating hormones. (MH41256 [BMc];AF05R 89-0208 and MH 45265 [EAS]).

542.2

ALTERED ADRENOCORTICOTROPIN, CORTICOSTERONE AND OXYTOCIN RESPONSE TO STRESS DURING CHRONIC SALT LOAD. H.S. Chowdrey*, D. S. Jessop*, H. Patel* and S. L. Lightman. Neuroendocrinology Unit, Charing Cross and Westminster Medical School, London W6, U.K.

A chronic osmotic stimulus (12 days drinking 2% saline) can influence the hypothalamo-pituitary axis by inhibiting the secretion of basal and adrenalectomy-elevated plasma adrenocorticotropin (ACTH) in rats (1). To determine whether the stress response is also impaired, we measured plasma levels of ACTH, corticosterone and oxytocin in saline-treated rats following a 5 minute restraint stress. Morning plasma ACTH levels were markedly decreased from 972 ± 165 pg/ml in the control animals to 349 ± 114 pg/ml in animals given 2% saline. The stress-induced release of ACTH seen in the control rats (from 972 ± 165 to 1439 ± 105 pg/ml, n=6) was completely abolished in rats treated with 2% saline for 12 days (unstressed 349 ± 114 pg/ml, stressed 205 ± 27 pg/ml). A stress-induced release of corticosterone was also observed in control rats (from 28.8 ± 7.9 to 99.5 ± 8ng/ml) but not in saline-treated rats (stressed 36.0 ± 8.2ng/ml). A normal ACTH response to stress was obtained in adrenalectomised rats on isotonic saline (from 2338 ± 436 to 4265 ± 195pg/ml, n=9)) while ACTH levels in both unstressed and stressed rats on 2% saline were reduced (1175 ± 213 and 2338 ± 369pg/ml respectively, n=9). In contrast to ACTH and corticosterone, the oxytocin response to stress was intact in animals on 2% saline. These results demonstrate that a chronic osmotic stimulus activates an inhibitory mechanism over the release of ACTH and has differential effects on the ACTH/corticosterone and oxytocin responses to stress.

CORTICOTROPIC-RELEASING HORMONE (CRH) IMMUNOREACTIVITY (IR) IN THE PARAVENTRICULAR NUCLEUS (PVN) IS INFLUENCED BY TESTOSTERONE. E.W. Rodriguez, D.J. Magnuson, T.S. Gray, R.J. Handa. Dept. of Cell Biology, Neurobiology and Anatomy. Loyola University, Chicago. Maywood, IL 60153.

The plasma corticosterone response to novelty stress is greater following long term gonadectomy of male rats. To further characterize the role of androgens in the regulation of the hypothalamo-pituitary-adrenal (HPA) axis we castrated (gx'd) male Sprague/Dawley rats and treated them with testosterone (T). Control animals were castrated and sham treated or left intact. After 3-4 weeks of treatment, animals were perfused through the ascending aorta with paraformaldehyde, and CRH- or vasopressin- (VP) IR was examined in 20 μm-thick frontal sections. The number of CRH-IR cells was significantly greater by 68% in the PVN in gx'd animals compared to intact controls. T replacement restored CRH-IR cell numbers to that of intact animals. No differences were seen in VP-IR cells in the PVN or in CRH-IR cells in the bed nucleus of the stria terminalis. These data suggest that androgens can influence the HPA axis at the level of the PVN.

INDIVIDUAL DIFFERENCES IN THE HYPOTHALAMIC-PITUITARY-ADRENAL RESPONSE TO STRESS: RELATIONSHIP TO TESTOSTERONE. V. VIAU & M.J.MEANEY. Douglas Hospital Research Ctr., Depts. of Psychiatry and Neurology/ Neurosurgery, McGill Univ., Montreal H4H 1R3, Canada.

Male rats typically show smaller ACTH and corticosterone (B) responses to stress compared to females. This sex difference has been attributed, in part, to inhibitory affects of testosterone (T) on HPA activity. Considering that variations in circulating levels of T exist between male rats, we examined the extent to which T levels could account for individual differences in HPA response to restraint stress. ACTH and B responses were determined following 10 min of restraint stress in intact and gonadectomized males. The intact males were grouped on the basis of high or low basal T levels; 4.0 ± 0.6 vs 1.2 ± 0.3 ng/ml, respectively. The peak ACTH and B responses following stress were significantly lower in the high T group compared to the low T and GDX animals: ACTH; 267.2 ± 74.3, 614.6 ± 31.3 and 497.2 ± 63.2 pg/ml, respectively. B; 31.9 ± 1.9, 66.6 ± 11.5 and 73.1 ± 16.0 μg/dL, respectively. In the high T group, ACTH and B levels returned to pre-stress values by 10 and 60 min, respectively, following the termination of stress. However, in the low T and GDX groups, both ACTH and B levels remained elevated up to 60 min post-stress. There was a negative correlation between the level of T and the integrated ACTH and B responses to stress (r = .85 and .76, respectively; $p < 0.5$). No significant differences in pre-stress levels of ACTH and B were observed as a function of T. Finally, animals either showed an acute increase or decrease in T levels following stress. Interestingly, elevated ACTH responses to stress were associated with rats that showed a positive T response. These findings suggest that T is a potent regulator of HPA activity during stress, as slight variations in T levels are associated with profound differences in the pattern of ACTH and B responses to stress. Thus, in the male rat, individual differences in HPA responses to stress are, at least partially, related to the gonadal status of the animal.

ABSENCE OF CORTISOL NEGATIVE FEEDBACK REGULATION OF PULSATILE ACTH IN THE OVINE FETUS NEAR TERM. E.M. Apostolakis, L.D. Longo, S.M. Yellon. Div. Perinatal Biology, Depts. Physiol, Pediat, Ob/Gyn, Loma Linda Univ, Sch of Med, Loma Linda, CA 92350

During late gestation, as a part of the endocrine cascade which triggers parturition, plasma cortisol increases in the fetal sheep to surge within 48h of birth. Plasma ACTH also increases, suggesting an absence of negative feedback near term. To investigate the cortisol negative feedback regulation of pulsatile ACTH secretion, we continuously infused cortisol (CI, 1 μg/h/kg est BW, i.v.) for 96 h in 6 chronically catheterized fetuses beginning on d 133 and again on d 142 of gestation. Fetal blood (2 ml) was obtained every 5 min for 2 h (0900-1100 h) before infusion and 24 h later. As determined by RIA, pulse characteristics using previously defined criteria (*Biol Repro 42 Suppl:178A,1990*) were:

Fetal Plasma ACTH (pg / ml; x ± SE)

CI	Days	FREQ	AMP	PEAK	NADIR	x ± SE
0	133	1.7 ± .03	49 ± 11	74 ± 13	38 ± 4	48 ± 4
+	134	1.3 ± .03	41 ± 6	106 ± 13*	65 ± 9*	68 ± 13
0	142	1.4 ± .04	49 ± 27	87 ± 29	38 ± 26	82 ± 26
+	143	2.4 ± 05**	32 ± 5	118 ± 13**	86 ± 10**	89 ± 22*

*p < 0.05 vs 133 d; **p < 0.05 vs 142 d, ANOVA with repeated measures

Increased cortisol was associated with enhanced ACTH pulse peak and nadir at 134 vs 133 d and 143 vs 142 d. The data indicate an absence of cortisol negative feedback regulation of basal pulsatile ACTH secretion in fetal sheep during late gestation. Moreover, the data imply either a positive feedforward mechanism or independent regulation of plasma ACTH and cortisol (NR06042, HD03817).

STRESS-INDUCED HYPERSECRETION OF ACTH IN ADRENALECTOMIZED RATS REPLACED WITH CONSTANT CORTICOSTERONE IS NORMALIZED BY AN ACUTE INCREASE IN CORTICOSTERONE. L. Jacobson and R.Sapolsky, Dept. of Biological Sciences, Stanford Univ., Stanford, CA 94305-5020.

Constant corticosterone (B) levels that normalize basal AM plasma ACTH in adrenalectomized (ADX) relative to sham-ADX (SHAM) rats do not normalize ACTH responses to stress [Akana et al. Endocrinology 122 (1988):1337]. To determine if this enhanced ACTH response to stress is due to lack of stress-induced B secretion, 300 g male rats with indwelling arterial & sc catheters were subjected to hypoxia stress (10% O_2) 5 d after sham-ADX or ADX & 35% B sc pellet replacement (B-PELLET). B-PELLET rats received B or DMSO vehicle sc 5 min before gas flow began; SHAMs received DMSO. Although hypoxia-induced PaO_2 was comparable in SHAM & B-PELLET rats (ca. 42 mm Hg), vehicle-treated B-PELLET rats secreted significantly more ACTH than did SHAMs. However, ACTH responses to hypoxia were similar between SHAM rats & B-PELLET rats given acute B doses that mimicked the plasma B increase in SHAMs. We conclude that stress-induced hypersecretion of ACTH in B-PELLET rats is due at least in part to the lack of fast feedback inhibition by stress-induced increases in B.

STRESS-INDUCED RELEASE OF CORTICOTROPIN-RELEASING FACTOR FROM THE MEDIAN EMINENCE OF THE RAT IN VIVO. E. Merlo Pich, M. Lorang, W. Vale[1], G.F. Koob and F. Weiss. [1]Salk Institute and Dept. of Neuropharmacology, Scripps Clinic and Research Foundation, 10666 N. Torrey Pines Rd, La Lolla, CA 92037.

Corticotropin-releasing factor (CRF)-like immunoreactivity was measured by radioimmunoassay in perfusate collected under halothane anesthesia from microdialysis probes implanted into the median eminence region of rats. Procedures optimizing recovery were developed in vitro prior to the start of in vivo experiment. Perfusate was collected every 20 min starting at two hours after implantation. Basal levels were estimated to be about 108±26 pg/ml (n=6). Increasing the potassium concentration in the perfusion medium to 60 mM resulted in a 3-fold increase of CRF. A significant increase of CRF was also observed after injection of 1.5 M hypertonic saline (1.8 ml/100 g bw ip) to the anesthetized rats. Post-mortem histological analysis revealed that probe implantation produced a relatively small lesion in the median eminence and an enlarged third ventricle, suggesting the cerebrospinal fluid was also sampled. No CRF levels was detected when the microdialysis probe was implanted in the posterior hypothalamus under both basal and stimulation conditions. These data are in agreement with previous evidence of in vitro release of CRF from hypothalamic tissue (Smith et al. 1986) and in vivo secretion into hypophysial portal blood in urethane-anesthetized rats (Plotsky & Vale 1984). These findings also suggest that CRF is released in response to depolarization of nerve terminals in the medio-basal hypothalamus and median eminence and that CRF is released after certain physiological stressors.

RAPID CO-PRODUCTION OF VASOPRESSIN (VP) AND CORTICOTROPIN RELEASING HORMONE (CRH) WITHIN SELECT PARAVENTRICULAR NEUROSECRETORY CELLS FOLLOWING BEHAVIORAL STRESS. J.A. Barrett, A.J.Silverman and D.D.Kelly, Depts. of Psychiatry and Anatomy & Cell Biology, Columbia University, & NYS Psychiatric Institute, NY, NY 10032

VP is a potent synergist of CRH in the release of ACTH by the anterior pituitary. These two peptides can be localized within the same parvocellular neurons in adrenalectomized rats and in intact rats exposed to behavioral stress for 3-10 days or have been isolated for 4wks. To evaluate whether the degree of stress exposure affects the proportion of PVN cells that exhibit the property of CRH/VP co-production, we used a double label protocol with antibodies against CRH and the glycopeptide portion of VP neurophysin (AG Robinson;AM16166). Fischer 344 male rats were assigned to 5 experimental groups (N=6). Four groups were exposed to varying durations of behavioral stress (Hou-Yu et al, NS Abstr. 12:783,'89) prior to sacrifice: 2, 12, 24 and 48hrs. In the PVN of no-stress controls many pale CRH-positive cells were detected, 3% of which stained for VP. Stress exposure significantly increased the proportion of CRH/VP co-staining cells in all groups to 10-11%, regardless of whether stress duration was 2 hrs or 2 days. (Planned weighted comparison: p=.007). Although it is clear that the proportion of CRF/VP co-producing cells was insensitive to stress duration, it is not clear whether the same subpopulation of co-producing cells were observed in all groups.NS23858

DEXAMETHASONE BLOCKADE DOES NOT ABOLISH ULTRADIAN RHYTHMS IN CORTICOSTERONE SECRETION BY THE RAT ADRENAL. M.S. Jasper and W.C. Engeland. Sect. of Neurobiology/ Dept. of Surg., Brown Univ./RI Hospital, Providence, RI 02903.

An ultradian rhythm in corticosterone (B) secretion has been demonstrated in the rat using intra-adrenal microdialysis (FASEB J. 4:A827,1990). To determine if rhythmic corticosterone secretion is dependent on physiological presentation of ACTH, intradrenal microdialysis was performed on dexamethasone (DEX) blocked rats, with and without replacement of ACTH by constant infusion. Under pentobarbital anesthesia, rats were prepared with two jugular vein catheters and an adrenal probe constructed from cellulose fibers (9 kD MW cutoff). Experiments conducted 2 days post-surgery consisted of continuous collection of dialysate at 10 min intervals from 1000 to 1800 hr. All rats were administered DEX (25 µg/100g s.c.) two hours before sampling. In one group of rats (n=4), ACTH was not replaced. In the other group (n=3), ACTH was infused i.v. at 75 pg/min/100g., from 1100 hr to 1800 hr, producing a submaximal B secretion rate. Dialysate B was measured by RIA. Peak detection was performed by manually drawing a baseline through troughs in the secretory profile, and using the PC-Pulsar criteria for significance. Peaks were detected in B secretory rate in all animals. The mean pulse amplitude was increased by the infusion of ACTH (2.0±0.4 vs. 29.9±5.4 pg/min, $p<0.001$). Interpulse interval was not affected by ACTH. To determine if periodic components in B secretion persisted after DEX blockade, power spectra were calculated, and the significance of peaks was assessed by the permutation rank test. Significant periodicities were detected in all animals. When individual spectra were averaged in each group, both groups showed peaks near 100 min. These data suggest that ultradian rhythmic variation in adrenal B secretion can occur in the absence of physiological variation in ACTH stimulation; however ACTH appears to modulate the amplitude of the B pulses. Supported in part by NIH grant DK38951.

ELECTRICAL STIMULATION IN THE SUPRACHIASMATIC NUCLEUS DEPRESSES THE ACTIVITY OF NEURONS IN THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS REGION. M.L.H.J. Hermes*, R.M. Buijs and L.P. Renaud. Neuroscience Unit, Ottawa Civic Hospital, Ottawa, Canada, K1Y 4E9.

There is extensive evidence that the suprachiasmatic nucleus (SCN) contains the circadian oscillator responsible for 24-hour rhythms in many behavioural, endocrine, and autonomic functions. The mechanism by which information from the SCN is transmitted to other brain regions regulating these functions is unknown. Recently, by means of infusion techniques, it was demonstrated that peptides present within projections of the SCN may be involved in the control of these daily rhythms, in particular that of plasma corticosterone levels. This rhythm is considered to involve parvocellular neurons in the hypothalamic paraventricular nucleus that secrete CRF into the median eminence (ME) portal pituitary circulation.

To further understand the way by which the SCN may impose rhythms on centrally controlled processes we undertook electrophysiological recordings from neurons situated in the region of the paraventricular hypothalamic nucleus in pentobarbital anesthetized male Long-Evans rats and examined their response to electrical stimulation of the SCN. Of a total of 31 spontaneously active neurons, 4 could be identified as projecting to the ME. Following SCN-stimulation, peristimulus histograms of the ME-projecting neurons displayed a distinct 40-80 msec reduction is excitability. Of the 27 neurons that were not projecting to the ME, 23 were likewise depressed, one was stimulated and 3 were not responsive. The data suggest that in this experimental situation, the SCN exerts a predominantly depressant influence on neurosecretory and other unidentified neurons in the area of the hypothalamic paraventricular nucleus. Supported by MRC and Heart and Stroke Foundation.

INHIBITION OF PLASMA CORTICOSTERONE LEVELS BY THE SUPRACHIASMATIC NUCLEUS. R.M. Buijs[12]*, T.P. van der Woude[1], A. Kalsbeek[1] and J.J. van Heerikhuize[1]. [1]Neuroscience Unit, Ottawa Civic Hospital, Ottawa, K1Y 4E9, [2]Netherlands Inst. for Brain Research, 1105 AZ Amsterdam.

The suprachiasmatic nucleus (SCN) is established as the (main) circadian parameter of the mammalian brain. As such it synchronizes a number of humoral and behavioral rhythms to the daily dark-light cycle, of which plasma corticosterone (B) for example, is shown to rise shortly before the onset of the dark period. A number of studies have shown that the SCN is involved in the regulation of this process. Recently we provided evidence that vasopressin from the SCN inhibited B release when infused in the paraventricular-dorsomedial hypothalamic nucleus. To investigate further the role of the SCN this nucleus was lesioned bilaterally whereafter the animals received an indwelling jugular vein catheter allowing unrestrained blood sampling. Plasma B levels of SCN-lesioned animals during the light period were not different from those obtained during the dark period but were 4 times higher than those obtained from intact animals during the light period. No difference was observed in plasma B levels between SCN lesioned animals and intact animals during the dark period.

After receiving a mild stress the plasma B excursion in lesioned animals was much greater than that of intact animals during the light period but was comparable to that obtained from intact animals during the dark period. These data show that the SCN serves a inhibitory role on plasma B release but only so during the light period.

AGING, STRESS AND STRAIN-DEPENDENT DIFFERENCES IN HYPOTHALAMIC CATECHOLAMINES, PITUITARY CRH RECEPTORS AND PLASMA ACTH, PROLACTIN AND CORTICOSTERONE. Y. Tizabi, G. Aguilera[1], R. Li[1,2], R.J. Wyatt[2], D. Kirch[2] and G.M. Gilad[2]. Dept. of Pharmacol., Coll. of Med., Howard Univ.; [1] DEB, NICHD, NIH; [2] NPB, NIMH Neurosci. Cent. at St. Elizabeths, Washington, DC 20059.

Neuroendocrine regulation is known to be impaired in aging and this impairment may be genetically determined. Neuroendocrine changes were, therefore, characterized in the shorter lived and hyper-reactive to stress Wistar Kyoto (WKY) strain and compared to the Brown Norway (BN) strain. We found: 1. catecholamines, similar in the young strains, were reduced (20%) and were less responsive to restraint stress in aged WKY; 2. CRH binding, similar in the strains, was reduced (26%) in aging; 3. ACTH levels, 67% higher in WKY, were not changed in aging and both strains were similarly responsive to stress; 4. corticosterone, similar in the strains, was reduced (50%) in aging, but the stress-induced increase was relatively higher and was maintained longer compared to young; 5. prolactin, two fold higher in young WKY, was reduced (60%) in aged BN, but the stress response remained similar in both strains. The data support the premise that during aging regulatory neuroendocrine mechanisms deteriorate and the rate is genetically determined.

542.13

CAPILLARY VOLUME AND FILLING IN THE NEUROHYPOPHYSIS AND HYPOTHALAMUS. R.B. PAGE, T. RUTHERFORD, AND R. M. BRYAN. Division of Neurosurgery, College of Medicine, Pennsylvania State University, Hershey,PA. 17033.

We tested the hypothesis that selective filling occurs in restricted microvascular regions supplied by capillary loops in the median eminence by measuring percent capillary volume and filling in the median eminence and selected hypothalamic nuclei. 0.5 ml of FITC dextran (150 mg/kg) was injected via a femoral venous catheter over 4 seconds into six restrained, awake, male Long-Evans rats. The animals were decapitated 10 seconds after injection. Six micron thick cryostat sections were taken through the median eminence, neural lobe, SON, PVN, and arcuate nucleus. Sections were examined and photographed by fluorescence microscopy, stained for alkaline phosphatase and rephotographed by light microscopy. Percent capillary volume and filling were calculated for each region. In the median eminence capillary volume averaged 28%. The internal plexus accounted for more than 50% of the total capillary volume. Volume percent filling averaged 96% in the median eminence and 93% in its internal plexus. In the SON, PVN, and ARC capillary volume percent averaged 15%, 7% and 4% respectively. Capillary percent filling averaged 75%, 75% and 86%. These results do not support the hypothesis that selective recruitment of capillary loops occurs in the internal zone of the median eminence, but do allow the possibility of capillary recruitment in the Paraventricular Nucleus.

543.1

LHRH IS MORE POTENT THAN ENDOTHELIN-1 (ET-1) IN STIMULATING CHANGES IN INTRACELLULAR CALCIUM AND LH SECRETION FROM SINGLE PROESTROUS RAT GONADOTROPES. S.R.Rawlings*, J.Flores*, G.Block & D.A.Leong. Dept. Medicine & NSF Centre for Biological Timing, University of Virginia, Charlottesville, VA 22908.

A recent study using a rapid perfusion system showed that ET-1 and luteinizing hormone (LH)-releasing hormone (LHRH) were equipotent in stimulating LH release from dissociated gonadotropes of castrate rats, a result that parallelled their effects on intracellular free Ca^{2+} ion concentration ($[Ca^{2+}]_i$) in single gonadotropes (Stojilković *et al.*, Science 248, 1990). This result, and the presence of ET-1-immunoreactivity in the hypothalamus, has suggested a potential role for ET-1 in reproductive function.

Dynamic fura-2 video-imaging was employed to investigate the effects of ET-1 and LHRH on $[Ca^{2+}]_i$ in acutely dissociated proestrous rat gonadotropes post-identified using an LH reverse hemolytic plaque assay (RHPA). The RHPA was also employed to measure the cumulative LH release from single gonadotropes over a 2 hour period. The Ca^{2+} responses to ET-1 and LHRH were highly variable from cell to cell, although they both showed response profiles typical of factors that stimulate an $Ins(1,4,5)P_3$ and DAG-generating system. LHRH was, however, more potent at stimulating Ca^{2+} responses as summarized below:

Ca^{2+} Response	[LHRH]	[ET-1]
No response	-	$\leq 10^{-10}$M
Low amplitude rise	$<10^{-11}$M	10^{-10}M - 10^{-9}M
Ca^{2+} oscillation	10^{-11}M - 10^{-9}M	10^{-8}M - 10^{-7}M
Spike & plateau	10^{-9}M - 10^{-8}M	$\geq 10^{-6}$M

In the RHPA the ED_{50} for LHRH and ET-1-stimulated plaque number (a measure of gonadotrope secretion responsiveness) was 10 pM and 3 μM respectively. In conclusion, the potency of ET-1 to stimulate proestrous gonadotropes is significantly lower than the known regulator of gonadotrope function LHRH, calling into question any role of ET-1 in the *in vivo* regulation of LH release during the estrous cycle.

543.2

TRANSFORMING GROWTH FACTOR-β1 SYNTHESIS IN THE ANTERIOR PITUITARY GLAND IS REDUCED DURING ESTROGEN-INDUCED INCREASE IN LACTOTROPIC GROWTH. D.K. Sarkar and K.H. Kim*, Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, and Department of Biochemistry/Genetics and Cell Biology, Washington State University, Pullman, WA 99164.

We have previously shown a marked growth inhibitory effect of transforming growth factor-β1 (TGF-β1) on pituitary lactotropes. To determine whether changes of lactotropic growth reflect variations in TGF-β1 synthesis in the anterior pituitary (AP), we determined the level of immunoreactive TGF-β1 and TGF-β1 mRNA in the AP. Animal models used are ovariectomized and estrogen-treated ovariectomized Fischer 344 female rats (Gottschall *et al.*, Proc Soc Exp Biol Med, 181:78, 1986). A significant population of cells was identified to be TGF-β1 producing in the AP by using both immunohistochemical procedures and *in situ* hybridization techniques for TGF-β1 mRNA. The AP concentration of TGF-β1 was also measured by a specific radioimmunoassay for the peptide growth factor and was found to be reduced 6-fold following 7 days of estrogen administration in ovariectomized rats. When the relative level of TGF-β1 mRNA in the AP was measured using the Northern blot hybridization procedure, the estrogen-treated rats showed a significantly lower level of TGF-β1 mRNA than the control ovariectomized rats. The estrogen-treated rats, as compared to the controls, also showed a 3-fold higher concentration of AP prolactin and a 2-fold increase in AP weight. These data suggest that TGF-β1 synthesis in the AP is reduced during estrogen-accelerated lactotropic growth, and that the peptide growth factor may be important in controlling lactotropic growth and function.

GnRH INDUCES OSCILLATORY $[Ca^{2+}]_i$ AND ELECTRICAL RESPONSE IN RAT PITUITARY GONADOTROPHS. M. Kukuljan*, S.S. Stojilković*, D.A. Doron, E. Rojas* and K.J. Catt*. ERRB/NICHHD and LCBG/NIDDK, NIH, Bethesda, MD 20892.

Pituitary gonadotrophs secrete LH and FSH in response to GnRH, which induces release of Ca^{2+} from intracellular stores and oscillations of $[Ca^{2+}]_i$. Both this process and the regulation of voltage-activated Ca^{2+} channels are thought to be involved in the control of GnRH-induced gonadotropin secretion. Basal and receptor-regulated changes in $[Ca^{2+}]_i$ and membrane potential were monitored by fluorescence analysis and the perforated patch technique in individual rat pituitary gonadotrophs. All measurements were conducted at 20 to 25° C. Most gonadotrophs exhibited episodes of spontaneous oscillations in basal $[Ca^{2+}]_i$ that were abolished by addition of EGTA or Ca^{2+} channel blockers. Under control conditions, gonadotrophs also displayed continuous electrical activity with firing of action potentials (AP) at a frequency of 0.6 to 1.6 Hz. These AP did not overshoot and were insensitive to 15 μM TTX. At high doses (100 nM) GnRH induced biphasic response in $[Ca^{2+}]_i$ with a spike phase, followed by a oscillatory phase. Addition of 100nM GnRH to the bath resulted in hyperpolarization from -35 mV to aprox. -70 mV and inhibition of AP, followed by a pattern of regular, slower oscillations (0.1-0.3 Hz) of Vm between -65 and -35 mV. AP were regularly fired on top of the slow waves. However, in some cells slow oscillations occurred without AP firing, suggesting that both phenomena are independently modulated. Slow oscillations were insensitive to 20 mM TEA and were broadened by 1 μM BK 8644. These observations suggest synchronization of $[Ca^{2+}]_i$ and electrical activity in pituitary cells. Modulation of a Ca^{2+}-activated current and plasma membrane Ca^{2+} channels may be involved in GnRH-evoked Vm oscillations.

543.4

COMPONENTS OF THE MULTIUNIT ACTIVITY (MUA) INCREMENTS ASSOCIATED WITH HYPOTHALAMIC GnRH PULSE GENERATOR ACTIVITY IN THE RHESUS MONKEY. H. Cardenas*, K. T. O'Byrne*, C. L. Williams* and E. Knobil. Lab for Neuroendocrinology, The University of Texas Medical School, Houston, TX 77225.

Secretory pulses of gonadotropic hormones occur synchronously with sharp increases in MUA (volleys) recorded from the mediobasal hypothalamus (Neuroendocrinology 39:256, 1984). Such recordings from 4 unanesthetized ovariectomized monkeys were digitized and analyzed for their component spikes using cluster analysis (Discovery Software - Brainwave System Corporation, Bloomfield, CO). The spikes were categorized by their various dimensions (principal components) and their firing frequencies compared to those of the MUA. Of the 22 individual spike clusters identified, 15 increased and 2 decreased their firing rates synchronously with the MUA volleys. The firing rate of the remainder was unchanged. No evidence of recruitment was found. It is concluded that the MUA volleys that reflect the activity of the GnRH pulse generator represent the synchronized increase in firing rate of single units in the mediobasal hypothalamus and the simultaneous decrease in the firing rate of a smaller population of others. (Supported by NIH grants HD 17438 and HD 08610 and by The Clayton Foundation for Research)

HYPOTHALAMIC ACTIONS OF C-TYPE NATRIURETIC PEPTIDE (CNP) TO ALTER PITUITARY HORMONE SECRETION. W.K. Samson and F.-L.S. Huang*. Anatomy&Neurobiology, Univ. MO Sch.of Med. Columbia, MO 65212.

C-type natriuretic peptide (CNP) shares a high degree of sequence homology with ANP and BNP. CNP is present in brain in higher levels than ANP or BNP and binds preferentially to the guanylyl cyclase-B (ANPR-B) receptor. We compared the effects of CNP and ANP on the hypothalamic control of LH and PRL secretion. Like ANP, CNP failed to significantly alter LH, PRL or GH release from cultured, dispersed anterior pituitary cells. Both CNP and ANP significantly inhibited LH secretion when administered centrally; however, the minimum effective dose of CNP was 0.1 nmole, while 1.0 nmole of ANP is required. The inhibitory effect of CNP and ANP was abolished by prior, central injection of the delta opioid antagonist naltrindole. While central injection of ANP inhibited PRL secretion, 1.0 nmole CNP stimulated ($p<0.001$) PRL secretion in conscious rats. Plasma GH levels were not significantly altered. The data suggest that CNP might be the preferential neuroactive natriuretic peptide in brain and that endogenous CNP might exert physiologic effects on pituitary function.

DOPAMINE CONTENT IN THE BRAIN AND PITUITARY OF TILAPIA *(Oreochromis mossambicus)*. S.Ishwar[1,2] and M.K.Sim*[3]. [1]Lab. of Neurobiology, Rockefeller University, New York, NY 10021 and [2]Dept. of Zoology and [3]Pharmacology, National University Singapore, Singapore.

Hypothalamic dopamine (DA) has been shown to participate in neuroendocrine regulation of gonadotropin release in fish (Peter et al., Rec Prog Horm Res 42:513, 1986), and DA turnover in hypothalamus is decreased by sex steroids. In the present study we used HPLC with electrochemical detection to examine the relationship between sex steroids and ex vivo brain and pituitary DA and DOPAC levels in Tilapia. Tissue was taken from intact, gonadectomized (14d) and gonadectomized (18d) with testosterone (T) or estradiol (E2) replacement on days 14 and 17 (n=4). In intact fish, DA and the DA/DOPAC ratio, tended to be highest in the pituitary and the tuberal area, and lowest in the optic tectum and thalamus. Although not statistically significant, there was a tendency for T to decrease, and E2 to increase, DA levels in all brain regions (telencephalon, tuberal area, lateral lobes, optic tectum and thalamus) and the pituitary.

In a subsequent experiment, electrolytic lesions were made stereotaxically (Ishwar and Munro, unpub.) in the hypothalamus of Tilapia (4 or 14d survival period) to understand the origin of DA projections to the pituitary. Relative to controls, animals with preoptic lesions (14d) had significantly higher DA levels in the pituitary. Lesions in other areas of the hypothalamus had no effect. Thus this experiment provides evidence for the existence of a preoptico-hypophysial neural system that inhibits pituitary dopamine in tilapia.

COMPLEX REGULATORY PATHWAY OF GnRH GENE TRANSCRIPTS BY FORSKOLIN, IONOMYCIN AND PHORBOL ESTERS IN THE GT1 CELL LINE. T.T.Yeo*,K.W.Dong*,M.Jakubowski*,M.Blum,J.L.Roberts. Fishberg Center for Neurobiology, Mt.Sinai School of Medicine, New York, NY10029.

The GT1 cell line is derived from a GnRH-expressing hypothalamic tumor made by genetically targeted expression of a 2kb rat GnRH promoter/SV40-T antigen DNA construct in transgenic mice. We have used this cell line as an *in vitro* model system for the endogenous mouse GnRH gene regulation. Using a sensitive solution hybridization/RNase protection assay we have reported that, in a static incubation system, prolonged (24hr) treatment of GT1 cells with the GnRH secretagous forskolin (10mM), ionomycin (1mM) or phorbol ester (100nM) produces a decrease in GnRH mRNA level while short term (1hr) treatment shows no significant change (Abs Endo Soc 91). Whether this result is due to cytotoxicity of prolonged treatment with these agents causing an overall decrease in RNA Pol II transcription remains to be elucidated. Using cytoplasmic cyclophilin mRNA levels as an internal reference, we now report that treatment with the above secretagougs decreases GnRH mRNA levels, rendering cyclophilin mRNA levels unchanged. We have also studied the hnRNA levels under the same conditions and find that short term incubation with ionomycin and phorbol ester decreases GnRH hnRNA levels while forskolin causes no significant change; prolonged incubation caused a significant decrease with all three pharmacological agents. Surprisingly, using a 2kb rat GnRH promoter/CAT reporter construct transfected GT1 cells, we see that forskolin causes a 4-6 fold stimulation in CAT activity, despite its inhibitory effects on the endogenous mouse gene. To further understand the effect of forskolin on GnRH gene expression, we have done a time course study using cyclophilin as an internal reference and find that GnRH mRNA levels show no significant change up to 3 hours of incubation and decrease afterwards in a time-dependent manner. The varying response of GnRH gene transcripts and promoter activity to different second messengers indicates a complicated regulatory pathway for this gene.

TREATMENT WITH 8-OH-DPAT (DPAT) ALTERS THE TIMING OF THE ESTRADIOL (E2)-INDUCED LH AND PROLACTIN (PRL) SURGE IN OVARIECTOMIZED (OVX) RATS. J.R. Cohen and M.R. Sterner. Lilly Research Laboratories, Eli Lilly & Co., Greenfield, IN 46140.

The induction of cyclic release of LH and PRL is dependent on an E2 stimulus. The timing of these surges, however, requires the integrity of one or more circadian oscillators. Serotonin (5HT) activity within the hypothalamus shows a diurnal rhythm which is altered by E2. In the present study, we examined the effects of a 5HT1a agonist, DPAT, on the timing of the E2-induced surges of LH and PRL.

Young adult Fischer 344 rats maintained on a 12L:12D photoperiod (lights on 0600h) were OVX (Day 0). All animals were implanted with a Silastic capsule containing E2 (250 µg/ml sesame oil) on Day 7 and the right atrium was cannulated on Day 8. On Day 9, rats were placed into one of 3 groups: control (saline, sc); DPAT (0.1mg, sc) at 1100h; DPAT (0.1mg, sc) at 1200h. Rats were bled at 1100 (prior to dosing), 1130, 1200 (prior to dosing), 1230 and hourly from 1300-2200h. LH and PRL were determined by RIA.

The onset of the E2-induced LH surge in control rats was clearly detectable by 1400h. Treatment with DPAT at 1100h delayed the onset of the LH surge by 2 hours with the first detectable rise in LH at 1600h. Delaying treatment with DPAT until 1200h produced a further shift in the onset of the LH surge, which was first detectable at 1700h. Delayed onsets were also seen in the timing of the PRL surge; The first detectable rise in PRL occurred at 1300h in controls, but was delayed until 1500h in both DPAT treatment groups.

These data suggest that 5HT, possibly acting via the 5HT1a receptor, may play a role in timing the onset of cyclic release of LH and PRL.

DUAL MECHANISMS INVOLVED IN THE INHIBITORY INFLUENCE OF SUCKLING ON LH RELEASE IN THE OVARIECTOMIZED RAT. T.J. Wu, N.H. McArthur and P.G. Harms. Departments of Animal Science and Veterinary Anatomy and Public Health, Texas A&M University, College Station, TX 77843.

A study was conducted to further understand the involvement of the endogenous opioid peptides (EOPs) in suckling-induced inhibition of LH release in the rat. The experiments utilized postpartum rats (day 7) that had been ovariectomized the day following parturition. The first experiment was designed to determine the effect of opioid antagonism by naloxone infusion (NAL; 1.0 mg/kg bw/h) on the increase in peripheral LH concentration after 18 h of pup removal and the decrease in LH concentration after 18 h of resuckling. NAL during 18 h of pup removal or during 18 h of pup removal followed by 18 h of resuckling neither accentuated nor attentuated ($p>0.10$) the LH concentration. The second experiment was designed to determine the effect of NAL on peripheral LH concentration in continuously suckled rats. Serum LH increased ($p<0.10$ and $p<0.005$, respectively) in response to 18- and 36-h of NAL. The third experiment was designed to determine the effect of pup removal during NAL on serum LH. Peripheral LH concentration was not different in the rats treated with 36 h of NAL whether they were suckled for the duration of the infusion or nonsuckled for the latter 18 h of infusion. These results suggest that suckling may inhibit LH release through two mechanisms. The first may be an opioid-independent or enhanced opioid tone, important for the initiation of the inhibitory effect of suckling, and the second, an opioid-dependent mechanism for the sustained inhibitory effect of suckling on LH release.

543.10

THE EFFECT OF AGING ON OPIATE RECEPTOR DENSITY IN THE MEDIAL PREOPTIC NUCLEUS OF OVARIECTOMIZED (OVX) AND ESTRADIOL (E2)-TREATED RATS. J.M. Lloyd, N.G. Weiland and P.M. Wise. Department of Physiology, University of Maryland, Baltimore, MD 21201

Endogenous opioid peptides (EOPs) are thought to modulate reproductive cyclicity in the female rat by exerting a tonic inhibitory effect on LH secretion. The LH secretory response depends on gonadal steroids. Previously, we have shown that in young animals the steroidal milieu influences opiate receptor densities in hypothalamic nuclei involved in reproductive function. The purpose of the present study was to determine whether age-related changes occur in the density or diurnal pattern of naloxone binding sites and to correlate these with steroid-induced LH surges. Young (3-4 mo) and middle-aged (9-11 mo) cycling and old (17-19 mo) repeatedly pseudopregnant (RPP) rats were OVX (day 0). Seven days later half of each group received Silastic capsules containing E2, and the animals were killed on day 8 at 2300 h or on day 9 at 0300, 1000, 1300, 1500, 1800 or 2300 h. Brain sections (20 µm) were incubated with 2.0 nM [^{3}H] naloxone ± 1 µm unlabelled ligand and slides were apposed to LKB Ultrofilm for 4 weeks. Receptor densities were assessed by quantitating the relative optical density within a fixed window placed over the medial preoptic nuclei. E2 decreased the densities of naloxone binding sites compared to OVX in all three age groups ($p<0.0001$). Naloxone binding was lower in old E2-treated compared to young and middle-aged rats ($p<0.01$), and the steroid-induced decline in receptor binding was least pronounced in middle-aged and most pronounced in old rats. Interestingly, the relative ability of E2 to influence the density of naloxone binding sites correlates with its ability to induce LH surges. Old rats exhibited a more robust E2-induced LH surge compared to middle-aged animals. We postulate that rats become less sensitive to estradiol during middle-age due to chronic elevated levels of estrogen and that responsiveness returns in older rats due to the prolonged diminished level of estrogen in these previously RPP animals.

543.11

NEURONAL HYPERTROPHY IN THE HYPOTHALAMI OF OLDER MEN. N.E. Rance and N.T. McMullen. Departments of Pathology and Anatomy, University of Arizona College of Medicine, Tucson, AZ 85724.

A striking neuronal hypertrophy occurs in the infundibular nucleus of postmenopausal women (Rance et al. J.Clin.Endo.Metab., 1990; Rance and Young, Endocrinology, 1991). To determine the gender specificity of this response, we measured neuronal cross-sectional areas in the infundibular nucleus of young (24,32 and 41 yrs of age) and older (60,61 and 68 yrs) men and compared them to data reported previously from the hypothalami of pre-(28,32 and 40 yrs) and postmenopausal women (58,62 and 74 yrs). Formalin fixed hypothalami were paraffin embedded, serially sectioned and Nissl-stained. Cross-sectional areas of 2427 neurons were traced using an image-combining computer microscope. The mean cross-sectional area (± SEM) of neurons in the infundibular nucleus of young men (147.0 ± 1.3) was identical to that of young women (147.0 ± 2.2). The mean area of infundibular neurons from postmenopausal women (190.4 ± 2.1) was 30% greater than those from young men and women. We were intrigued to find that infundibular neurons from older men (171.9 ± 1.7) were significantly larger than those from young men, but still smaller than infundibular neurons from postmenopausal women. We have previously provided evidence that postmenopausal neuronal hypertrophy is secondary to the loss of ovarian steroids (Rance et al, 1990, Rance and Young, 1991). The moderate hypertrophy of infundibular neurons in older men may be due to the reduced circulating testosterone levels which have been reported in this age group. (Arizona Disease Research Control Commission #0-029)

543.12

DIVERGENT EFFECTS OF SHORT-TERM GLUCOCORTICOID EXCESS ON THE GONADOTROPIC AND SOMATOTROPIC AXES IN NORMAL MEN. J.D. Veldhuis, G. Lizarralde and A. Iranmanesh, Dept. Internal Medicine, NSF Science Center in Biological Timing, Univ. Virginia Health Sciences Center, Charlottesville, VA 22908, and Salem Veterans Hospital, Salem, VA 24153.

To investigate the effects of short-term glucocorticoid on the neuroendocrine activity of the gonadotropic and somatotropic axes, 6 men underwent 10-min blood sampling for 24 h after placebo or 7 days of dexamethasone (DEX) administration (1.5 mg orally twice daily). Compared to placebo, DEX caused significant decreases in serum concentrations of estradiol, viz., from 144 ± 18 to 99 ± 18 pmol/L, free testosterone from 105 ± 10 to 87 ± 10 pmol/L, and DHEA-S from 6.0 ± 1.6 to 1.7 ± 0.3 umol/L ($P < 0.05$), but mean serum LH concentrations did not change: viz., 5.3 ± 1.2 IU/L (control) vs. 4.2 ± 0.61 IU/L (DEX). The mean plasma somatomedin C concentration rose from 0.74 ± 0.08 to 2.0 ± 0.35 U/mL ($P < 0.05$) and the mean serum GH concentration, from 1.2 ± 0.90 ug/L (basal) to 4.2 ± 1.5 ug/L (DEX) ($P < 0.01$). Deconvolution analysis revealed that the half-life of endogenous GH, the duration and the amplitude (maximal rate of secretion) of computer-resolved GH secretory bursts, and the mass of GH secreted per burst were not influenced significantly by DEX. On the other hand, DEX significantly increased GH secretory burst frequency from 12 ± 1.6 to 18 ± 1.6 episodes/24 h, decreased the GH interburst interval from 127 ± 23 to 79 ± 5 min, and increased the daily GH secretion rate (ug/L/day) from 41 ± 11 to 101 ± 11 ($P < 0.05$). No changes occurred in the half-life of LH, or LH secretory burst frequency, amplitude, mass, or duration, or the total daily LH production rate. We conclude that short-term glucocorticoid excess augments pulsatile GH secretion without influencing the episodic release of LH in normal men.

GLUCOCORTICOID AND ESTROGEN INHIBITION OF CRF INDUCTION OF POMC GENE EXPRESSION S. J. Dermer, D. Lorang, and J. L. Roberts
Fishberg Center for Neurobiology, Mount Sinai School of Medicine, New York, NY 10029

Glucocorticoids and estrogens inhibit expression of the POMC gene via steroid receptor-mediated events. In pituitary corticotrophs, glucocorticoids inhibit POMC transcription directly and by interfering with transcriptional induction by CRF. In the hypothalamus, estrogens have direct inhibitory effects on POMC transcription. We have focused on comparing the mechanisms by which the two steroid hormones and their respective receptors influence expression of the POMC gene. Using a variant (ER-1) of the AtT20 D16-16 mouse anterior pituitary tumor-derived cell line, which expresses estrogen receptor, we find that short term estrogen (E2) treatment (20 or 30 min) (100nM) inhibits the stimulatory effects of CRF treatment (10nM) on POMC primary transcript and hnRNA levels. This effect is found using pretreatment with either CRF or E2 followed by short term cotreatment, and when the two hormones are added simultaneously. In AtT20 cells, using a similar experimental paradigm for glucocorticoid and CRF treatment we find that pretreatment with DEX inhibits CRF induction of hnRNA levels, whereas pretreatment with CRF followed by cotreatment does not affect CRF induction. When we transiently transfect a POMC promoter/enhancer (-704 to +38)-CAT fusion reporter gene into ER-1 cells and treat with E2 (16 hr), we find that CRF induction of the POMC promoter is diminished versus cells which are treated with CRF alone. Similarly, DEX treatment (100nM) of ER-1 cells also leads to a reduction in CRF induction of the POMC-CAT reporter. These results, along with our previous findings that estrogens and glucocorticoids do not elicit the same response in POMC primary transcript for acute treatment times suggest that the two hormones may use different mechanisms of regulation of POMC gene expression initially, but their long term overall effects are inhibitory.

ENDOGENOUS OVARIAN STEROID(S) MAINTAIN IMMUNOCYTOCHEMICAL NUCLEAR LOCALIZATION OF GLUCOCORTICOID RECEPTOR IN ADRENALECTOMIZED FEMALE RAT BRAIN. W. C. McGimsey, J. A. Cidlowski*, W. E. Stumpf, M. Sar*. Departments of Cell Biology and Anatomy, and Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599.

We have shown with the anti-glucocorticoid receptor antibody GR-57 nuclear localization of glucocorticoid receptor immunoreactivity (GR-ir) in brains of intact male rats, and adrenalectomized (ADX) male rats treated with corticosterone, dexamethasone, or RU486, and cytoplasmic GR-ir in brains of adrenalectomized male rats (McGimsey et al., Endocrinology 126S:484 1990; FASEB J 5:2835 1991). Since progesterone is known to bind GR this study tests the hypothesis that endogenous ovarian steroid(s) cause nuclear localization of GR-ir in ADX adult female rats. Vibratome sections of paraformaldehyde fixed brains from intact, adrenalectomized (ADX), and adrenalectomized-ovariectomized (ADX-OVX) adult female rats were incubated in GR-57 (1:10,000) for immunocytochemistry. GR-ir was nuclear in intact and ADX female rats' brains, and cytoplasmic in ADX-OVX rats' brains. Supported by USPHS Grant NS-17479.

OXYTOCIN RELEASES NOREPINEPHRINE IN VENTRO-MEDIAL & PERIVENTRICULAR HYPOTHALAMUS OF FEMALE RATS. P.A. Vincent and A.M. Etgen. Depts. Psychiatry & Neuroscience, Albert Einstein Coll. Medicine, Bronx, NY 10461

Oxytocin (OT) and norepinephrine (NE) have been shown to enhance steroid-dependent reproductive behavior in female rats. We are employing intracranial microdialysis to determine whether OT regulates hypothalamic NE release. Preliminary data show that systemic administration of OT (1 I.U., sc) to ovariectomized rats treated with estrogen plus progesterone results in release of NE when microdialysis probes are placed within 0.3 mm of the lateral border of the ventromedial hypothalamic nucleus (VMN). This brain region is known to be important in hormonal facilitation of reproductive behavior. Interestingly, the most robust release of NE was seen when dialysis probes were placed near the lateral border of the periventricular nucleus (PVN). In contrast, animals in which microdialysis probes were placed anterior, lateral or dorsal (> 0.3 mm) to the VMN or PVN did not exhibit the same pattern of NE release as animals with probes placed at the border of the VMN or PVN. Animals given OT in the absence of hormone did not show a release of NE regards of probe placement. These results suggest that OT-induced NE release in the hypothalamus may be related to female sexual behavior in rats.

EXOGENOUS PROLACTIN DOES NOT REVERSE THE BROMOCRYPTINE-INDUCED BLOCKADE OF PUBERTY IN THE FEMALE FERRET. K.D.Ryan*, E.A.Volk* and O.M.Reinmuth. Depts Physiology, Ob/Gyn and Neurology, Magee-Womens Hospital and Univ. Pittsburgh School Medicine, Pittsburgh PA 15213

Sexual maturation of female ferrets can be accelerated by changing the ambient photoperiod from a short day (8L:16D) to a stimulatory, long day (16L:8D) after they are 15 wks of age. Previous work has shown that an important endocrine correlate of puberty in female ferrets is a marked decrease in the ability of estradiol to inhibit LH secretion. However, the pubertal rise in LH was shown to be accompanied by a coincident increase in plasma prolactin (PRL) levels and when the pubertal rise in PRL was prevented by treatment of females with the dopamine agonist, bromocryptine, sexual maturation in response to long days was also prevented. The purpose of this study was to examine whether administration of exogenous PRL to ferrets maturing in response to a long day stimulus could reverse the ability of bromocryptine to block puberty. Immature female ferrets housed in short days were ovariectomized and treated with implants designed to deliver very low levels of estradiol (<10 pg/ml). At 17 wks of age, some animals were moved to stimulatory long days while the rest remained in short days. Bromocryptine or vehicle injections were begun 3 wks after onset of long days; 2 wks thereafter, Alzet mini-pumps containing ovine PRL were implanted in both bromocryptine- and vehicle-treated females. Blood samples were obtained from jugular venous cannulae 3x weekly to monitor plasma LH levels. As expected, vehicle-treated females exhibited a rise in LH secretion about 3 wks after onset of long days which did not occur in females which were treated with the DA agonist. This bromocryptine-induced blockade of puberty was not prevented by infusion of oPRL. The failure of exogenous PRL to reverse the blocking effect of bromocryptine on puberty suggests the action of the drug to block PRL is secondary to the effect of elevated DA activity on the maturing hypothalamus (or brain). We conclude that a decrease in central (perhaps hypothalamic) DA may mediate the pubertal loss of responsiveness to the negative feedback of estradiol on LH secretion in the female ferret. Supported by HD14489 and Magee-Womens Hospital Research Fund.

SHORT-TERM FEED RESTRICTION DECREASES IN VIVO RELEASE OF BETA-ENDORPHIN (BUT NOT OF LHRH AND NPY) FROM MEDIAN EMINENCE AND INCREASES NPY RELEASE FROM PARAVENTRICULAR NUCLEUS IN EWES. B.M. Prasad*, C.D. Conover, D.K. Sarkar, J. Rabii and J.P. Advis. Department of Animal Sciences, Rutgers Univ, New Brunswick, NJ 08903, VCAPP, Washington State Univ, Pullman, WA 99164, and Department of Physiology, Rutgers Univ, New Brunswick, NJ 08903.

We have previously suggested that the median eminence (ME) is a control site for LHRH release in ewes. During the follicular phase ME infusion of β-endorphin (β-end) inhibits, and of neuropeptide Y (NPY) increases, in vivo ME-LHRH release. Infusion of NPY in paraventricular nucleus (PVN) increases feed intake. Long term feed restriction (FR) decreases serum LH in ovx-ewes. However, feeding a diet providing 30% of NRC requirements of energy and protein for two months, does not affect estrous cyclicity and ovulation. We assessed if in vivo release changes of these neuropeptides underlies compensatory events after 14 days of FR. In vivo release from ME and PVN was measured during the follicular phase (day 14), by push-pull cannula sampling (flow rate: 100 µl/10 min/4h), in full fed and feed restricted ewes. All ewes were maintained under short photoperiod conditions. ME in vivo LHRH and NPY release, and plasma LH, were similar in feed restricted and control ewes. This was associated with a decreased ME-β-end (59.0±3.8 vs 7.2±2.5 pg/ 100 µl PPC perfusate, control vs FR, n=6, P<.01) and increased PVN-NPY release (13.4±1.9 vs 31.2±2.7, n=8, P<.01). Thus, feed restriction might induce a decrease in β-end inhibitory tone on median eminence LHRH neuronal terminals, temporally compensating for unknown inhibitory components which might ultimately constrain tonic and phasic LH control. The specificity of such compensatory event is suggested by the differential paraventricular and median eminence NPY release, observed in feed restricted ewes (supported by NJES-Hatch 06108 and USDA 89-37240-4587 to JP Advis).

Dopaminergic Inhibition of LH (GnRH) Release in the Growth-restricted Hypogonadotropic Lamb. H. I'Anson*, J.M. Manning and D.L. Foster*, Reproductive Sciences Program & Depts. of Obstetrics & Gynecology & Biology, University of Michigan, Ann Arbor, MI 48109-0404.

Growth-retardation induced by dietary restriction results in hypogonadotropism in the lamb, even in the absence of the ovaries, and is the result of central nervous system inhibition of GnRH release (I'Anson *et al., Endocrinology*, 126 (Suppl.):1473, 1990). The present studies examined if inhibitory dopaminergic neurons are activated during growth restriction. Our approach was to investigate the effects of the dopamine antagonist, fluphenazine, on LH secretion in ovariectomized (ovx), growth-restricted lambs. In the first study, lambs (n=6), maintained at weaning weight (ca. 20 kg) for 42 weeks, were injected iv with fluphenazine (Flu, 0.5 mg/kg) after 4 h of an 8 h frequent sampling period. An increase in LH in response to Flu was observed in 2 of the lambs. The second study compared the response to Flu in ovx, *ad libitum*-fed lambs (n=8, *ad lib*) and growth-restricted lambs which were maintained at 28kg BW (n=8). These latter lambs exhibited an LH pulse frequency (0.9 ± 0.3 pulses/4 h) intermediate between that observed in 20 kg growth-restricted lambs (0.0 ± 0.0 pulses/4 h) and *ad lib* lambs (3.4 ± 0.2 pulses/4 h), suggesting that the degree of dietary-induced hypogonadotropism was less pronounced. When the lambs were 53 weeks old (during seasonal anestrus), Flu was injected iv after 4 h of an 8 h frequent sampling period. An LH response to Flu was observed in all but 1 of the *ad lib* lambs and in 4 of 8 growth-restricted lambs. LH pulse frequency increased in both the *ad lib* lambs (2.7 ± 0.6 to 4.1 ± 0.8 pulses/4 h) and the growth-restricted lambs (0.0 ± 0.0 to 1.3 ± 0.3 pulses/4 h). Mean LH also increased in both groups (18.0 ± 3.4 to 25.3 ± 3.5 ng/ml and 0.5 ± 0.0 to 4.4 ± 1.5 ng/ml, respectively). These data suggest that (a) dopaminergic neurons inhibit GnRH secretion in the normally developing lamb; and (b) additional inhibitory pathways may also be active in the growth-restricted lamb. LUTEINIZING HORMONE DURING THE ESTROUS CYCLE OF THE FOOD DEPRIVED HAMSTER. L.P. Morin, R.S. Donham and M.H. Stetson. Dept. Psychiatry, SUNY, Stony Brook, NY 11794.

Acute food deprivation during estrous cycle Days 1-2 will block hamster ovulation (Morin, AJP, 251:R663, 1986). This is precipitated by retarded follicular development, low preovulatory estradiol level, absent ovulatory LH surge and loss of ovulatory response to exogenous estradiol or LH. The present three studies further elucidate the endocrine deficits in the phasically starved hamster.

A) Starved animals were injected with 5 μg estradiol benzoate or oil 8 hr before lights off on cycle Day 3; fed animals received oil. Fed controls ovulated; starved controls did not. Starved animals given estradiol failed to ovulate, but had a normal LH surge. B) LH was measured at 6 hr intervals across the estrous cycle. Starved animals had low LH levels throughout the cycle, including Day 4 when the ovulatory LH surge seen in fed animals was absent. Variability in LH measured during Days 2 and 3 tended to be greater for starved animals. C) LH was measured for 2 hr periods at 8 min intervals during the afternoon of Days 1 and 2 or during the morning of Day 2. Pulsatile LH was not abolished in animals that failed to ovulate in response to acute starvation.

The results confirm the absence of an ovulatory LH surge in phasically starved hamsters and show that estradiol priming will reinstate the surge without restoring ovulation. This is probably explained by the retarded follicular development in the food deprived animals. The precipitating endocrine events preventing normal follicle growth remain obscure.

FOOD DEPRIVATION DECREASES *c-fos* EXPRESSION IN GONADOTROPIN-RELEASING HORMONE (GnRH) NEURONS IN SYRIAN HAMSTERS. S.J. Berriman and G.N. Wade. Neuroscience and Behavior Program and Dept. of Psychology, University of Massachusetts at Amherst, MA 01003.

The Syrian hamster estrous cycle is highly sensitive to the availability of metabolic fuels. Two days of food deprivation immediately following ovulation is sufficient to prevent the next estrus and ovulation. We tested the hypothesis that food deprivation early in the cycle affects the GnRH neuronal system. This would lead to a decrease in pulsatile luteinizing hormone (LH) secretion and disrupt events leading to follicular maturation, estradiol release, the preovulatory LH surge, and estrus. The proto-oncogene, *c-fos*, is a marker of activity in the GnRH neuronal system in rats, sheep, and hamsters. In hamsters, 60% of the GnRH neurons express Fos immediately following the preovulatory LH surge, a time when GnRH neurosecretory activity is increased. On days 1, 2, and 3 of the cycle, approximately 20% of the GnRH neurons express the Fos protein. Since GnRH cells express Fos early in the cycle, these cells may represent neurons responsible for pulsatile LH release. If pulsatile LH secretion is affected by metabolic signals, then GnRH neurons should express little or no Fos after hamsters have been food deprived. In this experiment, hamsters were food deprived or fed *ad libitum* on days 1 and 2 of the estrous cycle. On the evening of day 2, brains were fixed with 4% paraformaldehyde and double label immunocyto-chemistry was used to localized Fos and GnRH in 50 μ sections beginning at the diagonal band of Broca and extending to the mammilary bodies. Fos-expression in GnRH neurons was substantially reduced after 2 days of food deprivation. These data suggest that food deprivation affects LH secretion early in the cycle by acting via the GnRH neuronal system.

NALOXONE INFUSION DOES NOT REVERSE THE HYPOGLYCEMIA-INDUCED REDUCTION IN LUTEINIZING HORMONE LEVELS OBSERVED IN CHAIR RESTRAINED OVARIECTOMIZED RHESUS MONKEYS L.E. Heisler, R.L. Reid* and D.A. Van Vugt. Dept. of Physiology and Dept. of Obstetrics and Gynecology, Queen's University, Kingston, Ontario, Canada, K7L 3N6

Administration of corticotropin releasing hormone (CRH) to monkeys, rats and sheep inhibits luteinizing hormone (LH) release. This inhibition is prevented by naloxone suggesting that endogenous opioid peptides mediate the effects of CRH on LH. Since CRH activity and the activity of the pituitary-adrenal axis are increased by stressful stimuli, we examined the effect of insulin induced hypoglycemic stress on LH release in ovariectomized rhesus monkeys and the ability of naloxone to reverse the effects of this stress. Ovariectomized monkeys were restrained in primate chairs and administered insulin (1.5 U/kg) after a four hour control period followed by an infusion of saline or naloxone (2mg/hour) for an additional four hours. Naloxone infusions were also given in the absence of insulin administration. Blood was collected at 15 minute intervals and assayed for LH, cortisol and glucose. All LH measurements are expressed as a percentage of the baseline established in the first hour of the experiment. LH levels decreased significantly within 2 hours after insulin administration (70.3±2.81 %) but did not fall in the non-insulin treated group (94.4±2.98 %). Naloxone infusion failed to reverse the insulin-induced suppression of LH (66.2±3.46 %). As expected, glucose levels decreased within 1 hour after insulin injection (from 4.9±0.44 mmol/L to 1.8±0.21 mmol/L) and cortisol levels rose within 2 hours (from 38.0±4.58 μg/dL to 71.8±5.53 μg/dL). These results indicate that endogenous opioid peptides do not mediate the hypoglycemic stress-induced decrease in LH levels observed during these conditions in ovariectomized rhesus monkeys. DEFINITION OF METABOLIC STATES ASSOCIATED WITH THE SUPPRESSION AND RESTORATION OF LH SECRETION CAUSED BY FASTING AND REFEEDING IN RHESUS MONKEYS. D.L. Helmreich, D.B. Parfitt*, and J.L. Cameron, Depts of Behavioral Neuroscience, Psychiatry, Physiology and the Center for Neuroscience, University of Pittsburgh, Pittsburgh PA 15260.

We have previously demonstrated in adult male rhesus monkeys that one day of fasting can cause a slowing of pulsatile LH secretion within the first 4 h after the missed meal. Additionally, we have shown that this slowing can be rapidly reversed by refeeding, and the degree of restoration of LH secretion is correlated with the size of the refeed meal. To define the metabolic states associated with these changes in LH secretion, we measured levels of metabolic hormones and substrates during fasting and refeeding. To characterize changes during fasting, blood samples were collected at 2 h intervals from 1100 h on a day of normal feeding (daily meal at 1100 h) until 1800 h on the subsequent day during which animals were fasted (n=5). Plasma glucose concentrations were not different in the afternoon on the day of fasting (51.6±1.41 mg/dl) compared to a day of feeding (56.53±0.87 mg/dl), although insulin levels were significantly reduced on a day of fasting. There were also no significant differences in ß-hydroxybutyrate (ß-HBA) levels on the afternoon of fasting (0.29±0.4 mmol/L) compared to the day of feeding (0.41±0.8 mmol/L). To examine changes that occur with refeeding, monkeys were fasted for one day and the next day they were refed different amounts of food (0, 200, or 600 Kcal) at 1100 h; blood samples were taken at hourly intervals from 0800-2400 h (n=6). Monkeys refed 0 Kcal maintained low glucose (46.35±1.21 mg/dl), low insulin (12.35±0.76 μIU/ml), and high ß-HBA (0.62±0.03 mmol/L) throughout the refeed day. Monkeys refed 200 and 600 Kcal had a rapid increase in glucose and insulin levels and an immediate decrease in ß-HBA levels after refeeding. These levels remained constant in animals refed 600 Kcal. However, in animals refed 200 Kcal, glucose and insulin levels began to decline by midafternoon, while ß-HBA levels gradually increased. These data indicate that suppression of LH secretion begins to occur on a day of fasting while monkeys remain euglycemic and are not yet ketogenic, and that the degree of restoration of LH secretion correlates with the extent of the metabolic changes occurring during refeeding. It is hoped that the results of these studies will help to identify possible "metabolic signals" that modulate the neuronal systems governing LH secretion during periods of altered nutritional intake.

544.8

EFFECTS OF OVERFEEDING ON SUBSEQUENT FASTING-INDUCED SUPPRESSION OF PULSATILE LH SECRETION IN MALE RHESUS MONKEYS (*Macaca mulatta*). D.A. Schreihofer, D.B. Parfitt*, and J.L. Cameron. Depts. of Behavioral Neuroscience, Psychiatry, Physiology, and the Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

We have previously shown that one day of fasting significantly suppresses the frequency of pulsatile LH secretion in adult male rhesus monkeys, and that this suppression is evident within the first four hours following a missed meal. We have hypothesized that restricting food intake may suppress the central drive to the reproductive axis via "metabolic signals" occurring during the transition from an energy storing (fed) state to an energy mobilizing (fasted) state. To further examine this hypothesis, we overfed adult male rhesus monkeys with the anticipation that animals would remain in a fed state longer, and that the decrease in LH secretion normally seen with fasting would be delayed. For these studies, monkeys were maintained with chronic indwelling venous catheters on a jacket/tether/swivel system. On day 1 of the study, 5 monkeys were allowed to overeat (i.e. fed 100 pellets of Purina monkey chow vs. the standard meal of 25-35 pellets at 1100 h), and on day 2 monkeys were fasted. Animals ate 1672±180 Kcal on the day of overeating, compared to 620± 38 Kcal on a day of normal feeding. Blood samples were collected from 1200 h to 2400 h at 20 min intervals on the day of fasting and on a separate day of normal feeding for measurement of pulsatile LH secretion. In contrast to our previous findings, when a day of fasting was preceded by overfeeding there was no suppression of mean plasma LH concentrations (normal feeding: 15.01±1.37 ng/ml; fasting: 14.33±0.62 ng/ml) or LH pulse frequency (normal feeding: 1.2±0.37 pulses/4 h; fasting: 1.2±0.2 pulses/4 h) during the first 4 h following the missed meal. However, there was a significant suppression ($P<0.05$) of both mean LH and LH pulse frequency measured from 1600 h to 2400 h on the fasting day following overfeeding. These findings suggest that the delay in the suppression of LH secretion is of short duration even though animals overate significantly. To begin assessing the metabolic state of animals who have overeaten, insulin was measured in four animals. On a day of normal feeding, the postprandial rise in insulin levels following the meal returns to baseline levels (<20μIU/ml) by 2400 h. In contrast, after overfeeding insulin levels remain elevated (>50μIU/ml) into the afternoon of the day of fasting (1200 h), suggesting that these animals are still in an energy storing state during the time when LH suppression is delayed. These data lend further support to the hypothesis that the suppression of pulsatile LH secretion during short-term fasting occurs during the transition from an energy storing state to an energy mobilizing state.

STIMULATION OF LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) RELEASE FROM HYPOTHALAMIC EXPLANTS BY gamma-AMINOBUTYRIC ACID (GABA) IS BLOCKED BY beta-ENDORPHIN. Richard W. Clough, Dept. of Anatomy, Southern Illinois Univ. School of Medicine-Carbondale, Carbondale, IL. 62901

GABA has stimulatory and inhibitory effects on luteinizing hormone (LH) secretion in male and female animals, and, the direction of the effect presumably reflects a site specificity in the brain (Ondo, Science 186,1976). In vitro studies demonstrate that GABA stimulates LHRH release from arcuate nucleus-median eminence fragments (Masotto and Negro-Vilar, GABA and Endocrine Function, Raven Press, NY, 1986). We have confirmed that naloxone (NAL) stimulates LHRH release from preoptic area-mediobasal hypothalamic (POA-MBH) explants in perifusion tissue culture (Clough et al., Neuroendo. 51, 1990). The similarity between the effects of GABA and NAL led us to investigate whether the stimulatory GABA-effect may involve the opioid system. POA-MBH explants were removed and placed in culture as previously described (Clough, et al., Brain Res. 446,1988). Following equilibration, POA-MBH explants were exposed to culture media containing either: GABA ($2X10^{-4}M$); beta-endorphin ($1.4 \times 10^{-7}M$), or a combination of the two drugs. Subsequent to drug challenge, explants were exposed to KCl (57mM) for viability assessment. Fractions of effluent were collected every 15 minutes, frozen and subsequently assayed for LHRH by radioimmunoassay. Exposure of explants to GABA resulted in a significantly increased LHRH release. Beta endorphin had no effect on basal release. However, exposure of explants to combined GABA and beta-endorphin completely abolished the stimulatory effect of GABA on LHRH release. In all experiments, a final KCl challenge effectively stimulated LHRH release. This study suggests that the stimulatory effect of GABA on hypothalamic LHRH release, and presumably stimulation of pituitary gland LH, is mediated by inhibition of hypothalamic beta-endorphin neurons and subsequent release of tonic inhibition (as seen with NAL). OPIATE REGULATION OF LHRH NEURONAL RESPONSIVENESS TO NOREPINEPHRINE (NE). **J-J. He and C.A. Barraclough.** Dept. Physiology, Sch. Med. Univ. Maryland, Baltimore, MD 21201.

These studies examined the effects of naloxone (NX) or morphine (MOR) on LHRH neuronal responsiveness to ICV norepinephrine (NE, 45 ug) alone or following electrochemical stimulation (ECS) of the medial preoptic area (MPOA) in ovariectomized, estrogen-treated rats.. Pretreatment with NX (5 mg/kg at -15 min) neither suppressed nor enhanced the release of LH evoked by ICV NE (45 ug at 0 min) or combined MPOA-ECS + NE. Thus, the opiate synapses which exist on LHRH neurons, do not to seem modulate LHRH neuronal responsiveness to NE but opiates suppress the presynaptic release of NE. In contrast, when MOR (20 mg/kg sc) was injected 45 min prior to ICV NE, LH release more than doubled (200-450 ng/ml). When MOR (-15 min) was combined with MPOA-ECS (0 min) + NE (30 min) peak LH values increased from 200 (NE only) to 1600 ng/ml. MOR blocks spontaneous LH surges and hypothalamic NE turnover and markedly increases prolactin secretion, an observation confirmed in these studies. This latter effect has been attributed to increased serotonin (5-HT) secretion which, in turn, may suppress dopamine (DA) release. To test this possibility, in other rats, MOR (10 ug/0.7 ul) was infused into the dorsal raphe nucleus (DRN) (-15 min) and ICV NE was given at 30 min. Amplified LH responses were equivalent to those obtained after sc MOR. Neither DRN-MOR nor saline alone altered basal LH secretion. Combined DRN-MOR + MPOA-ECS + NE resulted in an 8 fold rise in plasma LH (peak surge values). Thus, the combined priming of LHRH neurons with 5-HT (or suppression of DA) coupled with the removal of inhibitory GABA influences (by MPOA-ECS) and stimulation by NE may be important endogenous events which lead to LH surges. None of these treatments alone can produce this heightened LHRH neuronal response. Supported by HD-02138.

NEUROPEPTIDE Y (NPY) POTENTIATION OF LHRH-INDUCED LH SECRETION IS STEROID-DEPENDENT. J.E. Levine and A.C. Bauer-Dantoin. Department of Neurobiology & Physiology, Northwestern University, Evanston, IL 60208.

We recently demonstrated that NPY potentiates the ability of pulsatile LHRH infusions to restore LH surges in pentobarbital(PB)-blocked, proestrous rats. The present study tested the hypothesis that facilitory actions of NPY occur only during ovarian steroid-induced LH surges and not in unprimed, ovariectomized (OVX) animals. At 0900h on day 6 after OVX, female rats received 30 μg estradiol benzoate (EB) or oil sc, and 2d later received 5 mg progesterone (P) or oil sc. Hourly blood samples were obtained between 1100-2100h on the day of P/oil injections. At 1330h, rats received injections of PB to block endogenous LHRH release, or saline. Every 30min from 1400-1800h, PB-treated rats received iv pulses of LHRH (15ng/pulse) or saline, along with concurrent pulses of NPY (1 or 5μg/ pulse) or saline. Pulsatile LHRH infusions restored LH surges in EB+P treated, PB-blocked rats. Concurrent administration of NPY (5μg/pulse) significantly ($p<.01$) potentiated LHRH-induced LH surges in EB+P treated rats. The same dose of NPY was only marginally effective in rats treated with EB alone and completely ineffective in altering LHRH-induced LH secretion in oil-treated rats. These results demonstrate that the potentiation of LHRH-induced LH secretion in vivo is steroid-dependent and provide further support for the idea that the pituitary actions of NPY are specifically important for the generation of LH surges. (NIH HD20677)

STEROID ACTIVATION OF C-FOS EXPRESSION IN GnRH NEURONS IS BLOCKED BY PHENOXYBENZAMINE. J.C. Pearson, L. Jennes, E. DuPré*, and J. Hester*. Dept. of Anatomy, Wright State Univ. Sch. of Med., Dayton, OH 45435.

Progesterone (P) enhances the activation of GnRH neurons during estradiol (E)-induced LH surge, and together with E stimulates the expression of the proto-oncogene product fos in the GnRH cells. Since GnRH neurons lack P receptors it is suggested that the steroids influence GnRH cells via neural intermediaries. The present study tests the hypothesis that the influence of P on GnRH neurons is mediated at least in part by noradrenergic receptor mechanisms. OVX rats were primed with E implants followed by sc injection of P on day 2. After four hours, rats received an injection of the α-adrenergic receptor blocker, phenoxybenzamine (POB, 2mg/kg, i.v.), and were perfusion-fixed 2 hours later. Treatment with POB resulted in significantly lower peak LH levels as measured with RIA and in a dramatic reduction in the number of GnRH cells which showed fos immunoreactivity when compared to control rats. These data indicate that the enhancement of GnRH neuron activity by P was blocked by POB, and suggest that α-adrenergic receptor mechanisms are involved in the LH surge. (Support: WSU BMS Res. Grant and NIH HD24697).

ALPHA-1 ADRENERGIC REGULATION OF ESTROGEN-INDUCED INCREASES IN LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) mRNA AND RELEASE. G.D. Weesner*, L.C. Krey* and D.W. Pfaff, Laboratory of Neurobiology and Behavior, The Rockefeller University, New York, NY 10021.

Prazosin, an α-1 adrenergic antagonist, was used to examine the relationship between adrenergic inputs and the stimulatory effects of estrogen on LHRH mRNA and release. Bilateral cannulae were implanted just dorsal to the preoptic area (POA). Estrous cycles were monitored daily by vaginal smears. On the morning of proestrous, each rat was ovariectomized and assigned to one of three treatment groups: Control - injected with sesame oil; Surge - injected with estradiol benzoate (EB, 10 μg) to produce an LH surge; or, Surge+Prazosin - injected with EB and a prazosin-filled inner cannula was put into the POA. Between 4-6 pm of the following day, rats were anesthetized, decapitated, trunk blood collected, and brains were stored in liquid nitrogen. *In situ* hybridization was performed using a ^{32}P end-labelled 59-mer complementary to LHRH mRNA. Reduced silver grains, proportional to LHRH mRNA content, were quantified. Treatment with estrogen alone resulted in a 50% increase ($P<.05$) in numbers of cells expressing LHRH. This estrogen-induced increase was completely blocked ($P<.01$) by prazosin. Prazosin also decreased ($P<.01$) the median number of grains per cell from 81 (Surge) to 65 grains per cell (Surge+Prazosin). When the number of grains in LHRH-expressing neurons were totalled, EB increased ($P<.05$) LHRH gene expression by 53%. Prazosin completely blocked ($P<.01$) the estrogen-induced increase. Finally, the estrogen-induced LH surge was blocked by the local administration of prazosin. Thus, coincident with the LH surge, estrogen increased the number of LHRH-expressing neurons as well as total potential LHRH synthetic capacity. Administration of prazosin into POA blocked the ability of estrogen to increase LHRH mRNA and LH release. Therefore, it appears that an endogenous α-1 ligand, probably norepinephrine, helps mediate the stimulatory effects of estrogen on LHRH biosynthesis and release.

INTESTINAL DISTENTION ACTIVATES A VAGO-VAGAL REFLEX TO ALTER WATER ABSORPTION BY RAT JEJUNUM IN VIVO. X. Zhang*, X. Chu*, W. Renehan, R. Fogel, Henry Ford Hospital, Detroit MI.

Little is known about the central pathways that transmit information about intestinal stimuli or how intestinal afferents regulate absorption. The aim of this study was to determine whether 1) stimulation of vagal mechanoreceptors by intestinal distention alters water absorption along the rat jejunum and 2) the role of the dorsal motor nucleus of the vagus (DMNV) in the mediation of this effect. Intestinal water absorption was measuured in two segments of intestine. One loop was distended, whereas the adjacent noncontiguous loop of jejunum served as control. Intestinal distention did not increase water absorption in the control group when sympathetic and parasympathetic nerves were intact. However, distention increased absorption in the control loop if the sympathetic nerves were cut. Truncal vagotomy or selective afferent vagotomy prevented the distention effect. Our data suggested that vagal afferents, terminating in the brainstem initiated a reflex involving vagal efferents. To further explore this phenomenon we used glass micropipettes filled with 3.0 M KCl to record the activity of DMNV neurons while distending a segment of the jejunum. We found that 37 of 44 DMNV neurons were inhibited by distention. These results indicate that intestinal distention decreases the activity of neurons in the DMNV, and the inhibition of DMNV activity is responsible for increased absorption in the small intestine.

FLUOXETINE (Fl) PRETREATMENT POTENTIATES INTRA-CISTERNAL (ic) TRH ANALOGUE-STIMULATED GASTRIC ACID SECRETION IN RATS. R.A.Shockley* and R.L.Stephens, Jr. Department of Physiology, The Ohio State Univ., Columbus, Ohio 43210.

Ic injection of the TRH analogue RX77368 (RX) has been demonstrated to produce a vagal-dependent stimulation in gastric acid secretion. Accumulating evidence exists regarding the interaction of serotonin (5HT) with TRH containing neuronal systems. This study was performed to assess the effect of 30 min pretreatment with the 5HT uptake inhibitor Fl (10mg/kg,iv; or 60μg,ic) on the TRH analogue-induced gastric acid response. Systemic Fl produced a 43 - 85% increase in ic RX (30-300ng)-induced gastric acid output in urethane-anesthetized, acute gastric fistula rats while not altering the response to ic RX (10ng). In addition, ic Fl produced a 71 % augmentation of the acid secretory response of ic RX (100ng). The results show that Fl pretreatment potentiates the effect of ic RX on acid secretion. The effect appears to be impulse dependent, and central sites appear to be involved, although peripheral sites of the interaction cannot be excluded. The data suggests an interaction of synaptic 5HT with a RX-elicited event (activation of TRH receptors and/or firing of the motor vagus), resulting in potentiation of the RX-induced gastric response. Supported by DK 42880.

IMMOBILIZATION-INDUCED HYPOCALCEMIA IS MEDIATED BY GASTRIC VAGAL ACTIVATION: THE STOMACH AS THE MAIN CALCIUM REGULATOR DURING STRESS CONDITION. S. Aou, J-Y. Ma*, H. Matsui* and T. Hori. Dept. of Physiology, Fac. of Med., Kyushu Univ., Fukuoka 812 Japan.

The mechanism of immobilization (IMB)-induced hypocalcemia was investigated in female Wistar and Wistar King A rats (120-160 g body weight). The rats were randomly divided into two groups: one was IMB group in which rats were tied their four limbs on the board bars in supine position for two hrs and the other was a control group which accepted the same treatment except IMB. Calcium ion levels were measured by the calcium ion meter (Ciba-Corning, type 634) using blood samples taken just after IBM by cardiac puncture under light ether anesthesia. The peripheral muscarinic antagonist, atropine methyl bromide, applied 20 min before the IMB suppressed IMB-induced hypocalcemia in a dose-dependent manner. The vagotomy of the cervical trunk, but not that of the thyroid/parathyroid branches, abolished the stress-induced hypocalcemia. In the subdiaphragma level, the vagotomy of the gastric branch as well as gastrectomy suppressed calcium reducing effect of IMB, while the vagotomy of the coeliac branch or partial resection of the intestine did not prevent stress-induced hypocalcemia. The inhibitors of gastrin release, secretin and galanin as well as the histamine H_2 blocker, cimetidine, were effective to suppress calcium lowering effect of IMB.

It is concluded that decreased calcium level caused by IMB is due to the activation of the vagus innervating to the stomach. Gastrin and histamine are also involved as the consequent factors through the activation of the gastric vagus.

MORPHOLOGY AND DISTRIBUTION OF VAGAL AFFERENT INNERVATION OF RAT GASTROINTESTINAL TRACT. H.-R. Berthoud, and T.L. Powley. Lab. of Regulatory Psychobiology, Purdue University, W. Lafayette, IN 47907.

In order to selectively label vagal afferents to the gastrointestinal tract, the fluorescent carbocyanine dye DiI (0.2-1.0 μL of 20% DiI-oil in methanol) was injected into the left nodose ganglion of rats that had undergone an ipsilateral supranodose vagotomy 12 days earlier. After survival times of 20-50 days the animals were perfused and specimens of mucosa, submucosa and muscularis externa layers from throughout the gut were either whole-mounted or sectioned in a cryostat and analyzed by conventional as well as laser scanning confocal epifluorescence microscopy.

DiI labeled afferent vagal fibers and terminals were found in all layers of the GI wall. For the first time vagal afferents in the circular and longitudinal smooth muscle layers of the stomach, presumably gastric stretch receptors, could be morphologically characterized. Projecting through the myenteric plexus, where they gave off collaterals, these mechanoreceptive fibers climbed to either layer, where they ran in close contact with the interstitial cells of Cajal, parallel to the muscle bundles for long distances and often giving off collaterals. In the myenteric plexus throughout the GI tract, profusely arborizing terminal trees were indicated by patches of fine DiI granules covering entire ganglia or individual ganglion cells and, together with the muscle collaterals, possibly providing the basis for local reflex activity. Numerous, putative chemoreceptive, vagal afferent fibers were found coursing through the submucous plexus and to richly innervate the mucosal villi.

With this technique it should be possible to characterize vagal afferents to the liver, pylorus and duodenum that serve important physiological mechanisms involved in energy metabolism and feeding. NIH grants DK-27627 and NS-26632.

FUNCTIONAL ZONATION OF RESPONSES TO ANTRAL MECHANORECEPTOR ACTIVATION IN THE DORSAL VAGAL COMPLEX (DVC) OF RATS. Monica J. McCann and Richard C. Rogers. Ohio State University, Dept. of Physiology, Columbus, OH 43210.

Activation of gastric vagal afferents (by antral distention or electrical stimulation of the vagus) either excites (ON) or inhibits (OFF) the firing rate of cells in the DVC. In our extracellular recordings, ON cells were located dorsal to the OFF cells. The average depth from the dorsal surface of the brainstem was 536μ ±15 and 628μ ±14 for ON and OFF cells, respectively ($p < 0.001$). This, together with histological evidence, suggested that ON and OFF cells have different functions, i.e., ON cells may be NTS neurons, whereas OFF cells could be DMN neurons.

We studied this hypothesis directly by using electrophysiological criteria to identify distention-related cells as NTS or DMN neurons. Our results support the hypothesis that ON and OFF cells can be functionally distinct populations of neurons. Almost all ON cells (94%) are NTS cells, whereas many OFF cells (64%) are DMN neurons. These studies provide insight into the central organization of gastric vago-vagal inhibitory reflexes. Supported by NS08690 (MJM) and NS24530 (RCR).

TOPOGRAPHY AND DENDROARCHITECTURE OF HEPATIC PREGANGLIONIC NEURONS WITHIN THE DORSAL MOTOR NUCLEUS OF THE VAGUS. F.B. Wang and T.L. Powley. Lab. of Regulatory Psychobiology, Purdue University, W. Lafayette, IN 47907.

The hepatic branch of the abdominal vagus, a branch implicated in the control of diverse physiological functions, contains roughly 200 efferent axons which originate from the dorsal motor nucleus of the vagus (dmnX). Our recent results with a digital atlas of the dmnX generated from a composite distribution of several animals (Neurosci. Abst. 15: 264, 1989) suggested that the hepatic preganglionics might be organized as two coherent cell groups. To further evaluate this organization and patterns revealed by the dendroarchitecture, the cells were identified and then filled with Lucifer Yellow: Sprague-Dawley rats received selective vagotomies sparing only the hepatic branch; the hepatic preganglionics were retrogradely labeled with Fast Blue; the animals were perfused; 200-300 μm horizontal sections of the brain stem were vibratomed; and the labeled cells were stained with intracellular iontophoresis of Lucifer Yellow.

The hepatic preganglionics were organized into two relatively compact ensembles. One group of cells lies just rostrolateral to the area postrema, within the medial gastric column. The second group lies somewhat more caudally and laterally, within the lateral column of the dmnX which gives rise to the accessory celiac branch. In each of the two aggregates, the dendrites of the neurons distribute predominantly horizontally and most remain within their respective ensemble. This dual compartmentation of the hepatic preganglionics suggests the hypothesis that the two ensembles might represent respectively the two major secondary branches which separate from the hepatic branch to innervate different visceral targets, namely one which projects to the liver or hepatic field and another to the small intestine and pancreas. NIH grants DK-27627 and NS-26632.

CHEMICAL CODING IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS FOR GASTROINTESTINAL FUNCTIONS ? N.R. Carlson, H.-R. Berthoud, and T.L. Powley. Lab. of Regulatory Psychobiology, Purdue University, W. Lafayette, IN 47907.

The variety of receptors in the dorsal motor nucleus of the vagus (dmnX) suggests the possibility that selective control of different patterns of visceral responses might be achieved at least in part by chemical coding or addressing. Two such identified receptors, those for thyrotropin-releasing hormone (TRH) and angiotensin II (ANG II) are among the binding sites found in high density in the dmnX and could be involved in such a chemical coding scheme. To test this hypothesis, multiple-barrelled pipettes were used to pressure inject, in random order, large injections (300nl, designed to encompass a large portion the dmnX) of TRH (1mM), ANG II (1mM), and saline into the dmnX of 16 rats (the same site/animal) while gastric acid secretion and motility throughout the GI tract were simultaneously monitored.

As has been previously observed by others, TRH significantly increased acid output and gastric and duodenal motility. Further, TRH increased jejunal--but neither cecal nor colonic--activity. In contrast, ANG II did not activate either gastric secretory or motility, while it did significantly increase duodenal and motility. Electrical stimulation of the cervical vagus elicited responses from all locations. The different patterns of GI activation produced by the peptides suggest but do not prove that, in the dmnX, different endogenously released peptides may generate different visceral response patterns. Additionally the peptide-specific patterns suggest that at least some of the TRH responses are mediated by the gastric subnuclei of the dmnX and their corresponding peripheral branches of the vagus, whereas, conversely, some if not all of the ANG II responses are mediated by the celiac subnuclei of the dmnX and their corresponding peripheral branches.
NIH grants DK-27627 and NS-26632.

PANCREATIC NEURONAL CIRCUITS DEFINED BY TRANSNEURONAL TRANSPORT OF PSEUDORABIES VIRUS. C. Sternini, R. De Giorgio, K. Anderson, L.W. Enquist*, J.P. Card and L. Rinaman. CURE and Dept. of Medicine, UCLA School of Medicine, Los Angeles, CA 90073, Medical College of Pennsylvania, Philadelphia, PA 19129 and DuPont Merck Pharmaceutical Co., Wilmington, DE 19880.

Transneuronal transport of pseudorabies virus (PRV) was used to define the organization of neuronal circuits influencing pancreatic functions. Injection of PRV into the duodenal or splenic region of the rat pancreas identified a neuronal circuit including spinal afferent neurons, autonomic motoneurons of the brainstem and other central neurons throughout the neuraxis. Specifically, injection of PRV into the pancreatic parenchyma 1) revealed that spinal afferent neurons innervating the pancreas contain calcitonin gene-related peptide, 2) visualized a synaptically linked circuit of central neurons within the neuraxis involved in visceral function regulation and 3) identified a population of sympathetic preganglionic neurons in the intermediolateral cell column of the thoracic cord that project to postganglionic neurons in abdominal ganglia innervating the pancreas. Simultaneous injection of PRV and the β subunit of cholera toxin confirmed the brainstem-pancreatic connections revealed by pseudorabies virus transport. These findings confirm the specific uptake and transneuronal passage of α-herpesvirus in the nervous system and define the neuronal circuits that contribute to the control of pancreatic functions.
Supported by NIH grant DK38752 and DuPont Merck Pharmaceutical Co.

SEROTONERGIC MODULATION OF REPETITIVE FIRING ACTIVITY IN DORSAL MOTOR NUCLEUS NEURONS STUDIED *IN VITRO*. C.L. McNair and M.S. Dekin, School of Biological Sciences, University of Kentucky, Lexington, KY 40506-0225.

A brainstem slice preparation from adult guinea pigs was used to study both the location of serotonin (5-HT) containing nerve terminals and 5-HT's mechanism of action on dorsal motor nucleus (DMX) neurons. DMX neurons were filled with Lucifer yellow and stained with 5-HT antibodies. Labeled DMX neurons had large, ovoid cell bodies (30-40 um) and possessed several primary dendrites. Numerous serotonergic varicosities were observed in close apposition to cell bodies, while few appeared in the dendritic fields. During depolarization, DMX neurons exhibited a high frequency burst of action potentials which rapidly adapted with time, i.e., spike frequency adaptation (SFA). A large after-hyperpolarization (AHP) was observed at the end of the depolarization. In the presence of bath applied 5-HT, SFA was reduced in a dose-dependent manner (maximum response at 50 uM). 5-HT had no significant effects on input resistance (70 to 80 megohm), resting membrane potential (-55 to -65 mV), or the AHP. Both SFA and the AHP were blocked by the addition of 1 mM Cd^{++} to the bath suggesting that a calcium-activated potassium conductance (I_{KC}) mediated these properties. Apamin (100 nM), a selective antagonist for low conductance (LK) type I_{KC} channels, completely blocked SFA and the majority of the AHP. Charybdotoxin (50 nM), a selective blocker for intermediate and large conductance type I_{KC} channels had no effect on either SFA or the AHP. In the presence of both apamin and 5-HT, DMX neurons exhibited voltage-dependent conditional bursting activity. These data suggest that (1) 5-HT modulated a voltage-dependent inward current localized to the soma of DMX neurons and (2) this inward current could effectively compete with the LK type I_{KC} channels which normally limit the repetitive firing activity of these neurons. (Supported by NIH grants HL40369, HL02314, and RR07114).

NUCLEUS RAPHE OBSCURUS IN CONTROL OF GASTROINTESTINAL FUNCTION: AFFERENT PATHWAYS. Z.K. Krowicki* and P.J. Hornby. Dept. of Pharmacology and Exper. Ther., Louisiana State University Medical School, New Orleans, LA .

The caudal nucleus raphe obscurus (NRO) has emerged as an important nucleus in control of gastrointestinal function. The purpose of the present study was to determine the afferent pathways to the region of the NRO controlling GI function by using WGA-apoHRP-Au in Sprague-Dawley rats. Double-barelled micropipettes were filled with WGA-apoHRP-Au (1% solution) and L-glutamate (500mM) and inserted into the NRO in anesthetized rats with strain gauges attached to the stomach. Results. In two rats, L-glutamate microinjection increased the Minute Motility Index (+2.0 and +6.5) prior to WGA-apoHRP-Au (10 and 20nl) microinjection. Four additional rats received 10 nl WGA-apoHRP-Au into the same region of the NRO. Numerous retrogradely labelled cells were located in the rostral medullary raphe nuclei, of which some were also serotonin-immunoreactive (ir) cells, and in the A1 noradrenergic group, of which some were also tyrosine hydroxylase-ir cells. Retrogradely labelled cells were located in the dorsal hypothalamic nucleus, the region above the ventral tegmental area, and the dorsal pons. Few retrogradely labelled cells were noted in the paraventricular nucleus of the hypothalamus, bed nucleus of the stria terminalis and central amygdala. Conclusions: Medullary projections to the NRO are similar to those projecting to the dorsal vagal complex, whereas supra-medullary projections to the NRO differ substantially from those known to project to the dorsal vagal complex. These latter are potentially new pathways mediating control of GI function in anesthetized rats. Supported by the PMAF and an Institutional BRSG.

C-FOS IS EXPRESSED IN ANATOMICALLY DISTINCT BRAIN NUCLEI FOLLOWING INHIBITION OR POTENTIATION OF FOOD INTAKE AND GASTRIC MOTILITY IN RATS. B.R. Olson, G.E. Hoffman, A. Sved, E.M. Stricker, J.G. Verbalis. Departments of Medicine, Physiology and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261

Most treatments that inhibit food intake (FI) and gastric motility (GM) in the rat result in activation of central oxytocinergic (OT) pathways, one of which projects to the dorsal motor nucleus of the vagus (DMN) and the nucleus tractus solitarius (NTS). These experiments mapped the sites of c-fos expression within the dorsal medulla, hypothalamic paraventricular nucleus (PVN), bed nucleus of the stria terminalis (BNST), and central amygdaloid nucleus (Ce) in male rats 1h after ip administration of chemical agents that either inhibit (CCK, 100 μg/kg) or stimulate (insulin, 5 U/rat) FI and GM. We also studied animals treated with 2-deoxy-D-glucose (2-DG, 500 mg/kg), which inhibits GM and stimulates OT release, but paradoxically increases food intake. The patterns of c-fos staining are summarized in table below:

	Medulla		PVN	BNST	Ce
Treatment	DMN	NTS	(OT)		lateral subdivision
CCK	-	+	+	-	+
INSULIN	+	-	-	+	-
2-DG	+	+	+	+	+

The c-fos expression following insulin-induced hypoglycemia and CCK suggests that functionally distinct neural pathways become activated with stimulation or inhibition of FI and GM. Activation of OT-neurons, the lateral subdivision of the Ce, and the NTS occurs with inhibition, but not with stimulation, of GM. However, OT-pathway activation is absent with insulin-stimulated FI but is present with 2-DG-stimulated FI, suggesting that glucoprivation-induced excitatory inputs to FI can override OT-related inhibitory ones under certain conditions in rats.

PARAVENTRICULAR NUCLEUS STIMULATION-INDUCED GASTRIC DAMAGE IN HYPOPHYSECTOMIZED RATS. L.E. Hierlihy, J.L. Wallace*[†] and A.V. Ferguson. Dept. of Physiology, Queen's University, Kingston, ONT K7L 3N6 and [†]Dept. of Medical Physiology, University of Calgary, Calgary, ALTA T2N 4N1.

Electrical stimulation in the paraventricular nucleus (PVN) of the hypothalamus has been shown to induce gastric mucosal lesions in the rat (Ferguson et al., 1988). Such damage is dependent upon descending projections to vagal motoneurons although vagal efferent stimulation in isolation does not induce any significant gastric damage. Considering the well established role of the PVN in the control of pituitary secretion, the present study was designed to determine whether pituitary hormones are required for the development of PVN-induced damage.

Hypophysectomized male Sprague Dawley rats were obtained from Charles River Inc. Fasted animals were anaesthetised with urethane and fitted with indwelling femoral arterial catheters and tracheal tubes. The animals were placed in a stereotaxic frame and a monopolar electrode advanced toward the region of PVN. Electrical stimulation was applied for 1 hour (200μA, 60Hz, 100μs). The stomach was then removed, examined macroscopically and assigned a damage score ranging from 0-3. The brain was perfused, removed and prepared for histological determination of stimulation sites.

PVN stimulation in hypophysectomized animals resulted in a gastric damage score of 2.0 (median) whereas electrical stimulation in anatomical regions immediately surrounding PVN did not induce significant damage (1.0). PVN-induced damage observed in hypophysectomized animals was not significantly different from that observed in animals with an intact pituitary (1.5). In conclusion, these studies indicate pituitary hormones do not play a major role in the formation of PVN-induced gastric damage.

CHARACTERIZATION OF THE VISCERAL NEURAXIS BY TRANSNEURONAL PASSAGE OF PSEUDORABIES VIRUS.

R.R. Miselis, B.H. Lee*, L.W.Enquist* and J.P. Card, University of Pennsylvania, Phila., PA 19104 and DuPont Merck Pharmaceutical Co. Wilmingington, DE 1988.

We have used transneuronal passage of an attenuated strain of pseudorabies virus (Bartha) to define the visceral neuraxis innervating the esophagus, stomach and cecum. From each viscus the forebrain-spinal cord extent of the central visceral neuraxis was labeled in a projection specific fashion. The labeling in the vagal complex at short survival times occurred in a motor viscerotopic pattern as seen with conventional tracers. At longer survival times the virus passed transneuronally to label putative 2nd order neurons in the 1)intermediolateral cell column, nucleus of solitary tract and area postrema 2)A_1, A_5 and caudal raphe neurons, 3)juxtacapsular area of hypothalamus, 4)paraventricular hypothalamic nucleus, 5)central nucleus of amygdala, 6)bed nucleus of stria terminalis, 7)insular cortex, 8)2nd or 3rd order passage to SFO, OVLT and nucleus medianus, preoptic area, anterior and lateral hypothalamus, septum 9)3rd order passage to parabrachial nucleus and locus coeruleus. The pattern of viral replication in these regions was also projection specific as seen with conventional tracers. This provides highly defined visceral neuraxis directly related to specific visceral organs and ties the circumventricular organs into it.

DIAPHORASE POSITIVE NEURONS IN THE RAT OESOPHAGUS. D. Vyas, D. Bieger and C.R. Triggle[1]. Fac. of Med., Memorial Univ. of Nfld., St. John's, Nfld. Canada A1B 3V6 and [1]Dept. of Pharmacol. and Ther., Univ. of Calgary, Calgary, Al. Canada T2N 4N1

Previous work in our laboratory has suggested the involvement of NO (nitric oxide) in non-adrenergic non-cholinergic inhibition at the level of the tunica muscularis mucosae (TMM) of the rat oesophagus. Since diaphorase reportedly is a marker for NO-synthase containing neurons in both the CNS and PNS, we have examined its occurrence and distribution in this organ. Oesophagi of Sprague-Dawley rats were stretched, dissected into two layers viz, TMM and tunica muscularis externa (TME) and fixed in paraformaldehyde prior to staining. Diaphorase was reacted with either NADH or NADPH as electron donor and nitro blue tetrazolium as an electron acceptor. In adult animals, stained nerve cells were found throughout the myenteric plexus (MP) as solitary neurons or in groups of up to 15 per ganglion. Stained fibers and terminals were present in both TME and TMM. Staining was identical with NADPH or NADH as substrate. In larger ganglia, the staining was of uneven intensity and barely detectable in some cells. In contrast, in 5d old animals enzyme activity of MP ganglia was of uniform intensity. No neurons were seen in the submucous plexus of either young or old animals. We conclude : 1. Use of NADPH as substrate does not reveal a unique neuron population in the oesophageal MP. 2. The histochemical activity observed is probably due to DT-diaphorase. 3. In oesophageal MP neurons this enzyme is probably colocalized with markers other than those implicated in CNS neurons. 4. An association of DT-diaphorase with NO-synthase containing neurons cannot be ruled out at present. (Supported by MRC, Canada.)

SOMATIC AND VISCERAL AFFERENTS: NOCICEPTION

546.1

TEMPOROMANDIBULAR JOINT NOCICEPTORS RESPONDING TO HORIZONTAL AND VERTICAL DISPLACEMENTS OF THE MANDIBLE OF THE GOAT. B. Loughner* and B. Cooper.
Depts. of Oral and Maxillofacial Surgery, Oral Biology and Neuroscience, University of Florida, Gainesville, FL., 32610.

Experiments were undertaken to characterize nociceptors of the temporomandibular joint (TMJ). TMJ afferents were isolated from the trigeminal ganglion with tungsten microelectrodes. Force-movement curves indicated that capsular nociceptors responded exclusively to intense forces that produced extreme displacements of the mandible. Thirty-four units with receptive fields on the TMJ capsule were activated by jaw movement. Nineteen afferents responded preferentially to movement in the vertical plane (VP or opening) and 15 responded best to movement in the horizontal plane (HP or lateral displacements). Once preferred movements were determined, tests of dynamic and static reactivity were conducted. Simple linear regression was used to construct power functions relating either instantaneous (inst.) dynamic force, inst. force velocity, inst. movement, static force, and inst. position to inst. interspike interval. Comparisons between best fitted curves suggested that both VP and HP reactivity was best characterized by dynamically applied stimuli (16/19 VP; 10/12 HP). Very few units transduced static force or position (4/19 VP and 3/15 HP), and 19 additional units (12 VP and 7 HP) could not be fit to functions. Conduction velocities were observed to be in the A delta and C fiber range, but due to inaccessibility of many of the receptive fields, could only be obtained in a portion of the population. THE ACTION OF NGF ON SENSORY NEURONS MATURING IN VIVO IS SPECIFIC FOR HIGH THRESHOLD MECHANORECEPTORS (HTMRs). A. M. Ritter and L. M. Mendell
SUNY at Stony Brook, NY 11790

Dorsal root ganglion (DRG) cells subserve a multitude of physiological functions, and some of this heterogeneity is reflected in somal spike shape. HTMRs, which convey information about noxious mechanical stimuli, have long duration, large amplitude spikes with an inflection or "hump" on the falling phase. Low threshold mechanoreceptors (LTMRs) which respond to innocuous stimulation of the skin, have smaller amplitude, shorter duration spikes lacking the hump. NGF is known to be transported by a subpopulation of DRG cells in the adult animal, and here we ask what effect chronic treatment has on somal spike shape. Rats were treated with NGF (1 μg/g s.c.) from birth to 5 weeks of age. Intracellular recordings were made under α-chloralose anaesthesia from physiologically identified DRG cells with conduction velocities above 2 m/s. The somal spikes of LTMRs were completely unaffected by this treatment. However, somal spikes of HTMRs were longer in duration than spikes of HTMRs from untreated control animals. No accompanying change was seen in spike amplitude, AHP duration, input resistance, or resting membrane potential. Thus, the effect of NGF treatment seems to be specific for HTMRs, and opposite in direction to the effects of anti-NGF (Ritter and Mendell, 1990, Soc. Neurosci. Abstr. Vol 16(1):477). It has been reported that NGF shortens AP duration in cultured embryonic DRG cells (Chalazonitis et al, 1987, PNAS 84:289). It appears that NGF acts differently on intact neurons than on ones which have been axotomized and cultured. Supported by MH 18018 and NS PO1 14899

546.3

REGULATION OF NOCICEPTOR FUNCTION BY NGF IN THE NEONATAL AND ADULT RAT. By G.R. Lewin, A.M. Ritter and L.M. Mendell Dept. Neurobiology & Behavior, SUNY at Stony Brook, NY11794.

Treatment of rats with anti-sera to NGF has consequences which are specific for nociceptive afferents in the sural nerve (SN) (Ritter et al., Nature 350: 500, 1991). We now ask what are the physiological consequences for these afferents if they are provided with excess NGF *in vivo*. To examine this question we treated rats with NGF (1-2 μg/g, s.c.) every day for the first week then every other day until the end of the treatment. Two treatment regimes were used, neonatal NGF (from birth to 2 weeks) and adult NGF (from 2-5 weeks). When these treatments ceased animals were left to recover for at least 3 weeks, they were then anaesthetized with urethane (1.25g/Kg) and recordings were made in dorsal root filaments from Aδ afferents (2-17 ms^{-1}) projecting through the SN. NGF treatment did not alter the make-up of the Aδ population (unlike anti-NGF); about 40% were High Threshold Mechanoreceptors (HTMRs). Seventy-six percent (28/37) of control HTMRs were slowly-adapting (SA) and 24% (9/37) were rapidly adapting (RA); the latter tended to have higher mechanical thresholds (Burgess & Perl, J Physiol (Lond) 190: 541, 1967). A mechanoreceptive field could not be found for five fibers, ie. silent fibers. Adult NGF treatment left the Aδ population unchanged; 61% (11/18) of HTMRs were SA, 39% (7/18) were RA and two silent fibers were found. The mechanical thresholds (Von Frey hairs) of control and adult NGF treated SA HTMRs were not significantly different, being 9.8 $\pm$ 4.8g and 4.2 $\pm$ 0.6g, respectively. In contrast, HTMRs in neonatally NGF treated animals were all of the SA type (33 units). Their mean mechanical thresholds were significantly lower than control SA HTMRs (mean 2.5 $\pm$ 0.2g), $p<0.05$. Furthermore, no silent fibres were encountered in these animals. These experiments show that excess NGF can have profound and long lasting effects on Aδ nociceptors, but only if given in the first 2 weeks of life. Supported by NIH-NS 14899, NS 16996, and NIMH 18018.

THE POST-NATAL DEPENDENCE OF MYELINATED NOCICEPTORS ON NGF IS NOT MEDIATED BY CELL DEATH. By L.M. Mendell, G.R. Lewin and A.M. Ritter Dept. Neurobiology & Behavior, SUNY at Stony Brook, NY11794.

By chronically treating animals with anti-sera to 2.5S NGF (anti-NGF treatment) it is possible to produce an almost total depletion of Aδ (2-13 ms^{-1}) high threshold mechanoreceptors (HTMRs) with a concurrent increase in D-hair afferents in the cutaneous sural nerve (SN) (Ritter et al. Nature 350: 500, 1991). Here we have asked if sensory neuron cell death induced by anti-NGF treatment is necessary for this loss of HTMRs to occur. Rats were treated with anti-NGF (5μl/g, s.c.) from post-natal day (PND) 0-14 and from PND 2-14. When these animals reached adulthood (5 weeks) they were anaesthetized with urethane (1.25g/kg) and recordings were made in dorsal root filaments from Aδ afferents projecting through the SN. After anti-NGF treatment from PND 0-14 and 2-14 HTMRs made up only 16% and 17% of the total Aδ afferents respectively, compared to 45% in control animals. In a parallel series of experiments sensory neurons in the L4 and L5 dorsal root ganglia of anti-NGF treated animals were counted using the method of Rose & Rohrlich (J Comp Neurol 263: 365, 1987). Anti-NGF treatment from PND 0-14 produced a significant ($p<0.05$) sensory cell loss averaging 20%. However, only small C cells with mean diameters of approximately 25 μm or less were susceptible to this effect; medium size Aδ cells (Harper & Lawson J Physiol (Lond) 359: 47, 1985) were probably not affected. Furthermore, anti-NGF treatment from PND 2-14 produced no significant cell loss despite producing the same depletion of HTMRs. Thus the loss of HTMRs observed physiologically after anti-NGF treatment can occur in the absence of sensory neuron death. This supports the idea that in the absence of NGF putative HTMRs take on the phenotype of D-hair afferents which increase in number after anti-NGF treatment. Supported by NIH-NS 14899, NS 16996, and NIMH 18018.

MUSCLE NOCICEPTORS IDENTIFIED IN HUMANS: INTRANEURAL RECORDINGS, MICROSTIMULATION AND PAIN. D.A. Simone, G. Caputi, P. Marchettini and J. Ochoa. Good Samaritan Hosp. and Med. Ctr., Portland, OR 97210, and Oregon Health Sciences University.

Although muscle pain is a common feature in athletics and in various diseases, little is known about underlying somatosensory mechanisms (Marchettini et al., Neurology, March 1991, page 164). We have used intraneural microstimulation and recording in human nerve fascicles supplying skeletal muscle to identify muscle nociceptors. During intraneural stimulation of common peroneal nerve fascicles, seven subjects identified and mapped a field of deep cramp-like pain projected to muscle. Through natural stimulation with mechanical pressure on projected fields, receptive fields of mechanoreceptor units with moderate to high threshold could be located within or adjacent to the areas of projected pain. Conduction velocities ranged 3.1-13.5 m/s for Group III (n=7) and 0.6-1.9 m/s for Group IV (n=6) fibers. None of the Group III or Group IV units were spontaneously active. Mean receptive field areas, mapped with a 3 mm^2 blunt probe, were 3.2 ±0.84 and 4.7 ±1.03 cm^2 for Group III and Group IV afferents, respectively. The initial area of projected pain experienced immediately upon intraneural stimulation at threshold for pain sensation ranged from 0.78-20.4 cm^2. Continuous intraneural stimulation at steady intensity resulted in gradual enlargement of the painful area.

Injection of 0.01% capsaicin into one receptive field caused broad cramp-like pain: the recorded Group III nociceptor became spontaneously active.

This constitutes the first electrophysiological characterization of both Group III and IV human muscle nociceptors, and a direct endorsement that their activity evokes cramp-like pain. Supported by NIH NS 24766 and 28747.

DISSOCIATION OF CAPSAICIN DESENSITIZATION AND INHIBITION OF PLASMA EXTRAVASATION EVOKED BY ANTIDROMIC C-FIBER STIMULATION. Richard B. Carter, Joan M. Meyer, Georgiana C. Salyers*, and Lisa M. Leming*, Miami Valley Laboratories, The Procter & Gamble Company, Cincinnati, OH 45239.

Capsaicin evokes an initial neurogenic response that decreases upon repeated administration. Plasma extravasation (PE) was used to measure neurogenic response and was determined by measuring the increase in Evans blue dye content of skin from the dorsal hindpaw evoked by topical capsaicin application or antidromic stimulation of the saphenous nerve. Capsaicin (0.125%-1.0%) was applied topically to the dorsal surface of one hindpaw and vehicle to the other. PE was determined 24 hrs later. Whereas a single application of capsaicin produced a marked reduction in capsaicin-evoked PE, it failed to affect antidromically-stimulated PE. To determine whether desensitization represents a specific loss of capsaicin sensitivity or a generalized loss of chemical responsivity, either xylene (100%) or mustard oil (1.6%) was used to evoke PE. A single application of capsaicin produced a marked reduction in both xylene- and mustard oil-evoked PE. The effect of frequency of capsaicin dosing on block of neurogenic inflammation was also examined. Capsaicin (0.125%-1.0%) was applied topically either 1 time/day for 1 day, 1 time/day for 4 days, or 3 times/day for 1 day. Whereas a single desensitizing application of capsaicin failed to inhibit antidromically-stimulated PE 24 hrs after dosing, capsaicin applied 3 times daily for 1 day did. These effects were dose-dependent. These data indicate that desensitization and block of neurogenic inflammation are distinct and separable actions of capsaicin. Desensitization to capsaicin is accompanied by a generalized loss of chemical sensitivity in unmyelinated sensory afferent fibers.

546.7

RUTHENIUM RED ANTAGONISM OF CAPSAICIN'S INHIBITORY EFFECT ON C-FIBERS IN THE ELECTRICALLY-INDUCED PLASMA EXTRAVASATION MODEL. M.M. Rolfes* and J.M. Meyer. Procter & Gamble Company, Cincinnati, OH 45239-8707

Ruthenium Red (RR) is an inorganic dye which has been used in studies to antagonize the actions of capsaicin on sensory neurons and their terminals. In these studies the effect of RR on capsaicin inhibition of electrically-induced cutaneous plasma extravasation (P.E.) was investigated. Ruthenium Red or vehicle was injected near the saphenous nerves of male, Sprague-Dawley rats, followed 15 minutes later by capsaicin or vehicle injection. Two hours later, Evans blue dye was injected in the jugular vein and the saphenous nerves were electrically stimulated to produce P.E.

RR control studies showed no significant difference in P.E. between RR- or saline-treated limbs. In capsaicin control studies, 0.327 mM capsaicin inhibited P.E. by 47.6%, while 3.27 and 16.35 mM capsaicin inhibited P.E. by 72% and 87.8%, respectively. In experimental studies, the inhibitory effect of 0.327 mM capsaicin was antagonized by all concentrations of RR tested, while 3.27 mM capsaicin was antagonized by 10 mM and 1.0 mM RR, but not by 0.1 mM RR, and 16.35 mM capsaicin was antagonized by 10 mM RR, but not by 0.1 or 1.0 mM. This dose-responsive effect of RR on capsaicin inhibition which shifts the capsaicin dose-response curve to the right and down suggests that RR may be a competitive antagonist of capsaicin.

546.8

CONDUCTION VELOCITY (CV) OF RAT PRIMARY AFFERENT NEURONES WITH PERIPHERIN-LIKE IMMUNOREACTIVITY (PER-LI) OR CARBONIC ANHYDRASE ACTIVITY (CA). E. Prabhakar* and S.N. Lawson*, (SPON: Brain Research Association.). Dept. of Physiology, Medical School, Bristol BS8 1TD.

PER-LI is in all neurofilament (NF) negative and a few NF positive rat dorsal root ganglion (DRG) neurones all with small somata (Ferri et al., Brain Res. 515:331 1990). Since NF negative rat DRG neurones have C-fibres, it seemed possible that PER-LI was in all C- and some or all Aδ-neurones. If, as previously suggested (Szabolcs et al., Brain Res. 492:129 1989), CA is restricted to type I and II proprioceptive afferents it should be expressed only in fast conducting A-neurones.

We have made intracellular recordings from L3, L4 and L5 DRGs *in vitro* at 36.5±1°C, taken from pentobarbitone anaesthetised 6-8 week female Wistar rats. The neurones were classified according to their peripheral nerve CV into Aα/ß- (>12m/sec); Aδ- (1.5-12m/sec) and C-neurones (<1.5m/sec). After recordings were complete, a fluorescent dye (ethidium bromide or Lucifer yellow) was injected into the soma. The DRGs were then fixed with Zamboni's fixative and frozen serial 7µm sections were cut. PER-LI was examined using a polyclonal antibody, and Hanssons' method (Hansson, Histochemie 11: 112-128, 1967) was used to detect CA in the dye-filled neurones.

Of the labelled cells tested, all A-fibre neurones with CVs>10m/sec were positive for CA, while the slower conducting C-neurones were negative. PER-LI was found in most C-neurones but only in 8% of A-neurones and these had the slower conducting Aδ fibres.

These data indicate that PER-LI is indeed only in C- or slowly conducting Aδ-neurones, while CA is only in neurones with faster conducting A-fibres.

AXON REFLEX VASODILATATION IN CAT TOOTH-PULP. B.Matthews and N.Vongsavan* Dept. of Physiology, University of Bristol, Bristol BS8 1TD, England.

In recent experiments we have shown that electrical stimulation of the peripheral cut end of the inferior alveolar nerve in cats causes both pulpal vasodilatation and an increase in the rate of outward fluid flow through exposed dentine in the lower canine tooth. These effects required the recruitment of small Aδ and C fibres; stimulating the Aβ fibres alone had no effect. In the present experiments we have investigated whether the vasodilatation is produced by stimulation of afferent fibres with receptors in the same tooth.

Young adult cats were anaesthetized with sodium pentobarbitone (42mg/kg i.p. then 3mg/kg i.v. as required). Observations were made on their lower canine teeth. Approximately 1mm was removed from the tip of each tooth with a diamond disc under Ringer's and the exposed dentine was etched for 30s with 30% orthophosphoric acid. The exposed dentine was enclosed by a cap filled with Ringer's. A laser Doppler flow meter (model MBF3D; Moor Instruments, Axminster, England) was used to monitor pulpal blood flow. Its probe was fixed to the tooth at right angles to the enamel surface and 2mm from the labial gingival margin. Both the ipsilateral cervical sympathetic trunk and inferior alveolar nerve (IAN) were cut to prevent reflex effects.

Stimulation of the exposed dentine for 30s by gentle mechanical probing, application of osmotic stimuli (sat. $CaCl_2$), drying, and sub-atmospheric pressures (-250 to -500 mmHg), which are known to excite intradental nerves, all caused an increase in pulpal blood flow. The increase was between 24.0 and 73.7% of the resting flow. The blood flow took 6-10 min. to return to resting levels, similar to that observed after IAN stimulation. The results provide strong evidence for a axon reflex vasodilatation in tooth-pulp. Similar evidence has been obtained by Olgart et al., (*Acta Physiol Scand* 1988, 133:399) but they did not exclude reflex effects.

MECHANOSENSITIVE AND CHEMOSENSITIVE UNITS OF THE LUMBAR SPINE: AN IN VITRO STUDY. J Cavanaugh, A Avramov*, AC Ozaktay. Bioengineering Center, Wayne State Univ., Detroit, MI 48202.

An in vitro model was developed to characterize the response of somatosensory units of the lumbar spine to mechanical loading and chemical mediators of nociception. **METHODS:** 24 male New Zealand White rabbits were anesthetized with Na pentobarbital, iv. The lumbar spine, perfused with Kreb's solution through the abdominal aorta, was excised with dorsal roots intact and spinal cord removed and clamped in a chamber filled with Kreb's solution. While recording from dorsal roots, the spine was loaded in tension and compression via a threaded rod attached to a 45 kg load cell. Units were also characterized by their response to local mechanical and electrical stimulation and by injection of algesic substances interarterially or locally. **RESULTS:** Low threshold mechanoreceptors, high threshold mechanoreceptors and phasic receptors were characterized in the lumbar facet joints and paravertebral muscles. Conduction velocities ranged from 0.4 to 22 m/s. Some units responded to spine loads less than 1 kg while others did not respond until loads exceeded 5 kg. Other units were activated by injection of bradykinin and serotonin into the intervertebral disc and adjacent tissue. **ACKNOWLEDGEMENTS:** Supported by NIH Grant NS-28994 and a Whitaker Foundation Grant.

FINE CUTANEOUS AFFERENT FIBERS IN THE RAT. J.W. Leem, K. Sheen, W.D. Willis and J.M. Chung. Marine Biomed. Inst., Depts. of Anat. & Neurosci. and of Physiol. & Biophys., Univ. Texas Med. Br., Galveston, TX, 77550.

The aim of this study was to make a systematic examination of the properties of fine afferent fibers in the sural nerve innervating the skin of the rat hind foot.

Single unit recordings were made from fine filaments dissected from the sural nerve in 41 anesthetized (sodium pentobarbital, 50 mg/kg) rats. The properties of units were examined using various mechanical and thermal stimuli applied to the cutaneous receptive fields with intensities ranging from innocuous to noxious.

Of a total of 95 fine afferent units identified, 29 were Aδ (3.28-29.41 m/s) and 66 C fibers (0.49-1.70 m/s). Aδ fiber samples included nociceptors (76%), cold receptors (7%), and D-hair receptors (17%). C fibers included nociceptors (47%), cold receptors (20%), and mechanoreceptors (33%). No warm receptors were identified. Basically, the properties of both Aδ and C fibers are similar to those described in other mammalian species. The proportions of units of each type, however, are different.

The results indicate that mechanoreceptors and cold receptors are common among the C fiber population in rat skin, whereas the predominant type of Aδ fibers is nociceptors. The proportion of different types of fine fibers in the sural nerve is more comparable to the cat than the primate. (Supported by NIH grants NS21266, NS11255 and NS09743 and a grant from Bristol-Myers Squibb Co.)

PAIN MODULATION: SPINAL AND TRIGEMINAL

547.1

NOXIOUS CHEMICAL STIMULATION OF THE NASAL MUCOSA WITH CO_2 PULSES: CORRELATION OF HUMAN PSYCHOPHYSICAL DATA WITH RESPONSES OF RAT MEDULLARY DORSAL HORN NEURONS. I. Euchner*, P. Peppel*, F. Anton* (SPON: ENA). Institute of Physiology I, University of Erlangen-Nürnberg, 8520 FRG.

For noxious stimulation of the nasal mucosa an olfactometer presenting precisely controlled CO_2 pulses was used. These stimuli were embedded in a constant flow of warm and humidified air (flow rate in rat: 6 ml/s; in human: 85 ml/s).

Twelve volunteer subjects rated their pain intensities with a VAS. Randomized CO_2 concentrations ranging from 50-85% (pulse duration 2s) were used to plot the respective stimulus-response functions (SRF). The effect of stimulus duration (CO_2 pulses ranging from 0.125 - 4s, constant concentration) was examined in addition. Electrophysiological experiments with comparable stimulation protocols were performed in halothane anesthetized rats. The interstimulus interval was 30s in all the tests.

In both psychophysical and electrophysiological experiments we found consistent and reliable linear SRFs to different concentrations of CO_2. In humans, pain intensity increased with stimulus durations lasting up to 1s and then reached a plateau level. This finding was paralleled in a subpopulation (11 of 20) of rat MDH neurons which displayed a phasic discharge behaviour to whatever stimulus duration being presented. The other neurons showed phasic and tonic responses.

Our results prove that the psychophysical response behavior to controlled CO_2 pulses and the respective discharges of MDH neurons are closely correlated. The method described here thus provides a precise tool for the quantitative physiological and pharmacological investigation of chemically induced pain. (supported by the DFG)

EFFECTS OF TWO PERIPHERAL NERVE MANIPULATIONS THAT AFFECT NOCICEPTION ON NERVE FIBER CALIBER AND ON GLUTAMATE AND SUBSTANCE P (SP) IMMUNOREACTIVITY IN THE DORSAL HORN OF THE RAT. W.M. Al-Ghoul and A. Rustioni. Dept. Cell Biol. and Anat., Univ. of North Carolina, Chapel Hill, NC 27599.

Two peripheral nerve manipulations that cause long term effects on nociception are (1) loose ligature (a manipulation that decreases nociceptive thresholds and is a possible chronic pain model) and (2) capsaicin (a C-fiber neurotoxin that increases nociceptive thresholds) administration. We examined the effects of these manipulations on nerve fiber caliber and on glutamate and SP (two neurochemicals implicated in mediation of nociception) immunoreactivity in the superficial laminae of the dorsal horn of adult rats 2-4 weeks after loosely ligating the left sciatic nerve or 2-3 months after applying capsaicin to the right saphenous nerve. Fiber caliber and density of immunoreactivity were quantified using video microscopy.

Ligature resulted in an 18 to 54% drop in mean cross sectional area of sciatic nerve myelinated fibers on the ligature side relative to the control side (previous studies have shown that capsaicin impairs unmyelinated fibers). Furthermore, ligature reduced SP immunoreactivity by 18 to 36% compared to the control side but it did not affect the density of glutamate immunoreactivity. Conversely, capsaicin application did not affect the density of SP immunoreactivity but it resulted in an increase of 10% in the density of glutamate immunoreactivity as compared to control. Thus, differences in the effects of loose ligature and capsaicin on behavior are paralleled by differences in their effects on nerve structure and on immunoreactivity in the dorsal horn. Additional work is underway to examine the effects of the two manipulations on NMDA receptors in the superficial dorsal horn.

NEURONAL RESPONSES TO STIMULATION OF THE CERVIX, UTERUS AND COLON IN THE SPINAL CORD OF FEMALE RATS. C.H. Hubscher, K.J. Berkley and P.D. Wall*. Dept. Psychology, Florida St. Univ., Tallahassee, FL 32306.

Afferents from the cervix arrive in the rat spinal cord in two distinct areas, S1 and L1. Sixty-three cells which responded to pressure on the cervix were examined in these two areas in 7 nulliparous rats in estrus. The rats were decerebrated and had a T10 transection under brief anesthesia. In addition to the cervix, mechanical stimuli were applied to the uterus, colon and skin. Only minimal stimuli were used to avoid long-term sensitization. In the S1 segment, 33 cervix-responding cells were found in all dorsal horn laminae. All these cells had extensive cutaneous receptive fields and 45% also responded to the colon (39% excited, 6% inhibited). In addition, 42% responded to the uterus (18% inhibited by one uterine horn and excited by the other, 18% inhibited by the contralateral or both horns, 6% excited by either horn). In the L1 segment, 30 cervix-responding cells were found in the deep dorsal horn. All had large cutaneous receptive fields, 57% were excited by the colon, while 76% were excited and 8% inhibited by uterine distension of either horn. Thus, in both areas, all cervix-responding cells had in addition cutaneous receptive fields but they were differentiated by their location and by the degree of convergence from other pelvic structures. (Supported by NIH grant RO1 NS11892.)

TONIC DESCENDING MODULATION OF SPINAL NEURONS WITH RENAL INPUT. A. Standish, M. A. Vizzard, and W. S. Ammons. Department of Physiology, Thomas Jefferson University, Philadelphia, Pennsylvania

Experiments were conducted to determine the effect of tonically active descending pathways on thoracolumbar spinal neurons that respond to renal nerve stimulation in anesthetized cats. The influences of tonic descending controls on seventy-two spinal neurons were assessed by examining changes in cell discharge rate associated with reversible block of spinal cord conduction by local cooling. We determined the effect of spinal cold block on spontaneous activity, neuronal responses evoked by renal afferent nerve stimulation and neuronal responses to somatic stimulation. The interruption of descending pathways by cold resulted in either enhanced (tonically inhibited neurons), reduced (tonically excited neurons), or unchanged neuronal responses. The spontaneous activity of 61% of the neurons increased from 7.4 ± 2.1 imp/s before cooling to 24.1 ± 5.0 imp/s during cooling. A decrease in activity was observed in 10% of the neurons and 29% of the neurons had no change in activity. Cooling increased 75% of cell responses to renal nerve stimulation. Approximately a two fold increase in the spikes/stim for both A-delta and C-fiber mediated responses were observed. In addition, four neurons had C-fiber input which was revealed by cold block. Decreased responses to A-delta and C-fiber input occurred in 13% of the neurons during cooling. Twelve percent of the cell responses to renal nerve stimulation were not affected by cold block. All but one of the unchanged responses were mediated by A-delta input. All neurons had somatic receptive fields and most exhibited increased responses to somatic stimulation during cooling. In addition, receptive field sizes of 23 neurons increased during cold block. These data show that the majority of spinal neurons with renal input had increased spontaneous activity, increased cell responses to renal afferent nerve stimulation, increased cell responses to somatic stimulation and therefore were predominantly modulated by tonic descending inhibitory influences. Supported by NIH Grant HL363678.

MATURATION OF APV- AND SPANTIDE-SENSITIVE SLOW VENTRAL ROOT POTENTIALS IN RAT SPINAL CORD. L. M. Gibbs, J. J. Kendig. Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305-5123

The neonatal (1-6 day old) rat spinal cord exhibits a slow ventral root potential (slow VRP) of very long duration (10-40 s). Dorsal root-evoked motor neuron responses in older animals are reported to be of much shorter duration (1-3 s). We have investigated the maturation of the slow VRP in isolated superfused (27-28°C) spinal cord preparations from rats of ages 1-21 days, intact, hemisected or prepared as thick transverse slices. In cords from animals 1-9 days old, a single stimulus to a lumbar dorsal root evoked a monosynaptic reflex followed by a 20-40 s slow VRP at the corresponding ipsilateral ventral root; maximum amplitude of the slow VRP was at 3-4 s. Both the substance P antagonist spantide (10 μM) and the NMDA receptor antagonist APV (20 μM) depressed the slow VRP. Cords from 12-21 day animals displayed a VRP of 3-4 s duration, with maximum amplitude <1 s after the stimulus. APV, but not spantide, depressed this response; low Mg++ increased the amplitude but not the decay time constant. These results suggest that a very slow substance P-mediated component of the VRP is selectively lost or inhibited at 10-11 days postnatal development in rat spinal cord.

TONIC DESCENDING INHIBITION OF SLOW VENTRAL ROOT POTENTIALS IN ISOLATED NEONATAL RAT BRAINSTEM-SPINAL CORD. A. Tarasiuk*, L. M. Gibbs and J. J. Kendig. Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305-5123

Descending inhibition from brainstem nuclei modulates responses to noxious stimuli; its presence in the neonatal rat is controversial. We examined the extent of tonic descending inhibition in brainstem-spinal cords isolated from 1-6 day old Sprague-Dawley rat pups. Brainstem and lumbar regions were superfused separately. Slow ventral root potentials (slow VRP's) (10-40 s), which are mediated by NMDA receptors and by substance P and are linked to nociception, were evoked by electrical stimulation of a lumbar dorsal root and recorded at the corresponding ipsilateral ventral root. Integrity of brainstem-spinal cord connections was verified by evoking a medullospinal reflex from the trigeminal nerve root to the lumbar ventral root. Three different manipulations were used to assess descending modulation: severing the brainstem from the cord, cooling the brainstem from 28 to 15°C, and perfusing the brainstem with the local anesthetic lidocaine (1-5 mM). In each case the amplitude of the lumbar slow VRP increased, by as much as 25%. The effects of cooling and of lidocaine were reversible. Descending projections from brainstem nuclei are anatomically present in the neonate; these results show that they functionally inhibit slow spinal reflexes.

HYBRIDIZATION HISTOCHEMICAL ANALYSIS OF SPINAL NEURONS THAT EXPRESS THE α_2 ADRENERGIC RECEPTOR IN A RAT MODEL OF PERIPHERAL MONONEUROPATHY Frank Williams, Angela Birnbaum, George Wilcox, and Alvin Beitz. Departments of Veterinary Biology and Pharmacology, University of Minnesota,St. Paul, 55108

Several recent reports have implicated brainstem noradrenergic projections to the spinal cord in the modulation of antinociception. The present studies sought to determine whether chronic pain is associated with a physiologic response to increased adrenergic activity in the spinal cord dorsal horn. Specifically, we sought to test whether the biosynthesis of α2 adrenergic receptor mRNA is altered. Unilateral sciatic ligatures were placed in male Sprague-Dawley rats according the the method of Bennett and Xie (Pain 33:87). Hyperalgesia on the ligatured side was confirmed by comparing the latency of paw withdrawal following the plantar application of radiant heat. Difference scores averaged -5.2 sec. Sixteen to 18 days following ligation, lumbar spinal cords were removed under Nembutal anesthesia, cryosectioned (15μm), and the sections prepared for hybridization histochemistry. The sequences of the oligo-DNA probes (48 mers) were complimentary to unique portions of the mRNA encoding the large cytoplasmic loop of the human α_2-C10 or the α_2-C4 subtypes. Control probes either matched the mRNA or had random sequences. The hybridization patterns in the dorsal horn on the ligatured side differed from the control side in two ways. First, in the lateral portion of lamina I, significant increases in the α_2 mRNA hybridization signal were noted on the ligatured side. Depending on the individual probe, calibrated gray levels from video micrographs were 111% to 129% of those on the unligatured side, while background gray levels lowered to an average of 64% of the unligatured side ($p < .05$, ANOVA & Fisher PLSD). Second, frequencies of α_2-mRNA hybridization-positive neurons in the medial half of laminae II & III was increased on the ligatured side. Combining frequency data for all of the antisense probes, the average was 125% of the control dorsal horn ($p < .05$, ANOVA & Fisher PLSD). Hybridization-positive neurons were largely found in lamina II. The data suggest that chronic pain is associated with increases in α_2 adrenergic receptor biosynthesis, and imply that dorsal horn adrenergic input is selectively activated as a result of the neuropathic lesions. DESCENDING FACILITATION AND INHIBITION OF SPINAL MECHANICAL TRANSMISSION. M. Zhuo and G.F. Gebhart. Dept. Pharmacology, Univ. Iowa, Iowa City, Iowa 52242.

The present work investigated descending modulation from nuclei reticularis gigantocellularis and gigantocellularis pars alpha (NGC/NGCα) on spinal mechanical (noxious pressure and non-noxious brush) transmission of class 2 (WDR) cells. Electrical stimulation at 26/46 sites in the NGC/NGCα produced biphasic, only facilitatory (n=5) or only inhibitory (n=15) effects on responses of spinal units to noxious mechanical pressure. Electrical stimulation produced biphasic (n=9), only facilitation (n=2) or only inhibition (n=5) of unit responses to non-noxious mechanical brush. Descending influences on noxious and non-noxious mechanical transmission of the same spinal units, however, was the same in only 3/9 cases. Glutamate microinjection into the NGC/NGCα facilitated at lesser and inhibited at greater concentrations unit responses to noxious mechanical pressure as well as non-noxious brush. Local anesthesia of the ventrolateral funiculi (VLF) selectively abolished descending facilitation while dorsolateral funiculi (DLF) transections selectively abolished inhibition. These results suggest that: (1) descending biphasic modulation from the NGC/NGCα is qualitatively the same on non-noxious and noxious mechanical responses; (2) descending facilitation and inhibition are conveyed in the VLFs and DLFs, respectively.

LIDOCAINE INHIBITION OF HYPERACTIVE DORSAL HORN NEURONS IS NOT MEDIATED BY SUPRASPINAL SYSTEMS. P Marchettini*, M Lacerenza*, ML Sotgiu*[1], S Smirne*, F Lacquaniti. Istituto Scientifico H San Raffaele Dept. of Neuroalgology and C.N.R.[1] Milano, Italy.

Previous studies have shown an inhibitory action of systemic lidocaine on deafferented dorsal horn neurons. To study further the mechanism of this action a model of neuropathic pain was prepared in 20 adult male Wistar rats. All animals received 4 ligatures of the sciatic nerve of one limb. Signs of pain behavior were checked daily. Acute experiments were performed in all animals under pentobarbital anesthesia, 30-45 days after surgery or immediately in the presence of autotomy. Dorsal horn neurons responding both to non-noxious and noxious mechanical stimuli were isolated and recorded at lumbar level on the side ipsilateral to the lesion (24 units) and on the contralateral side (22 units). Units mean spontaneous activity (21.2 +- 3.2 s/sec) of the ipsilateral side was significantly greater ($p < 0.001$ t test) than that of the contralateral side (4.3 +- 1.6 s/sec). Section of the spinal cord at thoracolumbar level, performed during recording, increased the spontaneous activity of both the ipsilateral and contralateral side neurons. Following iv injections of 3-4 mg/kg lidocaine 2% diluted, significant ($p < 0.001$ t test) selective reduction of ipsilateral neurons spontaneous activity was observed. The present findings indicate that lidocaine action on hyperactive dorsal horn neurons is not mediated by supraspinal systems.

ANALGESIA PRODUCED BY A SYNTHETIC PEPTIDE CONTAINING THE AMINO ACID SEQUENCE 11-22 OF VASOACTIVE INTESTINAL PEPTIDE (VIP). J. Steinman[1], L. Rosario[1], D. Askin[1]*, J. Rigaud[1]*, P. Cash[2]*, F. Jordan[2]* and B. Komisaruk[1], Inst. Animal Behavior[1] & Dept. Chemistry[2], Rutgers-The State Univ., Newark, NJ 07102

Evidence is presented that analgesia is produced in female rats (n's=7-10/group) by injection directly to the spinal cord (intrathecally, IT) of a 12 amino acid-containing fragment of VIP that consists of the sequence of amino acids that are normally found at positions 11-22 of the 28 amino acid-containing parent molecule. The peptide fragment was synthesized in this laboratory. Analgesia was indicated by a significant elevation in threshold to elicit vocalization in response to electrical shock of the tail (VOCT). A dosage of 52 μg of the peptide (30 nmoles) in 5 μl Ringer's Solution (RS) significantly elevated VOCT over RS control injections at 20, 30, 40, 60 and 90 min post-injection, reaching a peak elevation of 98% over baseline at 60 min, whereas the RS group was -5% of baseline at the same time. A smaller, but significant elevation also was observed at 60 min following IT administration of 26 μg of VIP_{11-22} (30% over baseline; $p < .03$). No significant effect was observed at a dose of 13 μg. A significant elevation of tail flick latency after IT injection of 52 μg was observed at 60 min post-injection, but not at other times.

Our previous studies have shown that VIP_{11-22} and VIP_{11-28} are produced when VIP_{1-28} is incubated with spinal cord homogenate. Significant analgesia occurs when each of these compounds is administered IT. Thus, VIP_{1-28} may be a pro-peptide for these smaller, analgesically active fragments. Electroacupuncture modifies the expression of c-*fos* in the spinal cord induced by noxious stimulation. J. H. Lee*, D. R. Brown and A. J. Beitz. Dept. of Vet. Biology, Univ. of Minnesota, St. Paul, MN 55108.

Acupuncture is thought to be mediated in part by descending pain modulation pathways that impinge on nociceptive neurons in the spinal cord dorsal horn. Many investigators have suggested that low frequency electroacupuncture (EA) is mediated by endogenous opioid mechanisms for its analgesic effect, whereas non-opioid systems have important roles for the analgesic effect of high frequency EA. The present study was designed to investigate the effect of EA on c-*fos* expression in the spinal cord induced by noxious stimulation and to evaluate the opiate sensitivity of 4 Hz versus 100 Hz EA applied bilaterally for 60 min duration to the point Zusanli (S36) located in the hindlimb. Mechanical NS (10 sec/min for 10 min) was applied to the right hindpaw following 30 minutes of EA treatment and the resulting c-*fos* expression in the spinal cord dorsal horn was compared to that obtained in rats only exposed to the noxious stimulation. The opiate sensitivity of the 4 Hz versus 100 Hz stimulation frequency was evaluated by giving naloxone (ip,5mg/kg) treatment 10 minutes before initiating EA. Both 4Hz and 100Hz EA reduced the number of c-*fos*-immunoreactive neurons in the dorsal horn induced by noxious stimulation by 58% and 50%, respectively. The suppression of c-*fos* expression induced by 4 Hz EA was completely reversed by prior treatment with naloxone. On the other hand, the suppression of c-*fos* induced by 100Hz EA was only partially blocked by this opiate antagonist. These data indicate that both high and low frequency EA inhibit the expression of c-*fos* in the dorsal horn induced by noxious stimulation and further suggest that low frequency (4Hz) EA is primarily mediated by endogenous opioid systems, while both opioid and non-opioid mechanisms appear to be involved in mediating the analgesic effect of 100Hz EA. Supported by NIH grants DA 06687, DE 06682 and DC 01086.

Evaluation of the Release of i-CGRP in Rat Dorsal Horn following Carrageenan induced Inflammation.

Mary G. Garry and Kenneth M. Hargreaves, Univ. of Minnesota, Dept. of Restorative Sciences, Minneapolis, MN.

The physiology of dorsal horn neuropeptides in inflammation is largely unknown. Several studies have examined peptide content in the dorsal horn using various models of inflammation, however, these studies leave the release profiles for neuropeptides undefined. The purpose of this study was to examine the release of calcitonin gene-related peptide (i-CGRP) in vitro from the dorsal horn of the spinal cord following carrageenan (CARRA) induced inflammation in the hindpaw. Male Sprague-Dawley rats received an intraplantar injection of CARRA (6mg) into the right hindpaw. Prior to sacrifice, contralateral (CL) and CARRA paws were tested for hyperalgesia (radiant heat), edema, and hyperthermia. Spinal cords were collected 6, 24, and 48 hrs. following the CARRA injection. The lumbar enlargement was divided into dorsal quadrants, chopped into 300μ cubes, and superfused with oxygenated Krebs (pH 7.4). Quadrants from the CL and CARRA sides were superfused with capsaicin (CAP; 10μM) to evoke the release of i-CGRP from primary afferent neurons. I-CGRP was assessed by RIA (antiserum kindly provided by M. Iadorola). After injection of CARRA (6hr), the inflamed paws exhibited a decreased withdrawal latency (2.9±0.4 sec vs. CL: 11.6±0.9 sec; $p<0.01$), edema (10.9±0.3 mm vs. CL: 5.3±0.1 mm; $p<0.01$), and hyperthermia (34.0±0.2°C vs. CL: 31.9±0.2°C; $p<0.01$). Preliminary results indicate that basal release of i-CGRP was 161 fmol/gm tissue (CL) and 389 fmol/gm tissue (CARRA). CAP evoked release was 1829 fmol/gm tissue (CL) and 4535 fmol/gm tissue (CARRA). This marked difference in the release of i-CGRP between the CARRA and CL side appeared to be resolved at 24 and 48 hrs. Similarly, the hyperalgesia in the inflamed paw was resolved at these later time points while edema and hyperthermia persisted. These data suggest that, during inflammation, there is a temporally related increase in the basal and evoked release of i-CGRP from superfused dorsal quadrants. These data also suggest that there is a correlation between i-CGRP release from primary afferent neurons and hyperalgesia.

547.13

Evaluation of the Release of Immunoreactive CGRP from Peripheral Tissue Using an *In Vitro* Superfusion Method.

Kenneth M. Hargreaves, Walter A. Bowles* and Mary G. Garry, Dept. Restorative Sci., U. Minn. Sch. of Dentistry, Minneapolis, MN

Superfusion of spinal cord slices is useful for evaluating the regulation of neuropeptide release from central terminals of primary afferent fibers. To date, however, there is little information on the regulation of release from terminals located in peripheral tissue. Bovine dental pulp was selected for these experiments since the tissue is readily available and has a relatively high concentration of immunoreactive CGRP.

Mandibular incisors were extracted at the slaughterhouse and transported on ice to the laboratory. Pulps were harvested, sliced and chopped (300 μ cubes) with a McIlwain tissue chopper. Tissue (200-250 mg) was superfused with Kreb's buffer (400 μL/min; 3 min fractions) for a 120 min baseline recovery period; samples were collected in 100 μL glacial acetic acid and lyophilized. Potassium (60 mM)-evoked release of immunoreactive CGRP was measured by a RIA (antiserum kindly provided by Dr. M. Iadarola).

Initial studies demonstrated that bovine iCGRP diluted in parallel to rat CGRP in the RIA and was present in dental pulp at a concentration of nearly 8 fmol/mg wet weight. Basal levels of release averaged 15.3 ± 1.7 fmol/G/9 min (n=4) over the observation period. Stimulation of dental pulp with 60 mM potassium increased superfusate levels ($p<0.01$) of iCGRP to 155 ± 21 fmol/G/9 min (n=7).

These studies indicate that superfusion of dental pulp permits evaluation of the regulation of neuropeptide release from peripheral tissue stores.

ADRENALECTOMY ENHANCES C-FOS-LIKE IMMUNOREACTIVITY IN TRIGEMINAL SUBNUCLEUS CAUDALIS IN RESPONSE TO NOXIOUS CORNEAL HEAT STIMULATION. J. Lu and D.A. Bereiter. Section of Neurobiology & Dept of Surgery, Brown Univ/RI Hospital, Providence, RI 02903

The role of glucocorticoids in somatic sensory function is not well defined, however, receptors for glucocorticoids are found in substantia gelatinosa of the spinal cord and certain forms of stress-induced analgesia may involve adrenal steroids. Expression of the proto-oncogene, *c-fos*, by noxious sensory stimuli induces fos-like immunoreactivity (FLI) in spinal laminae consistent with the location of nociceptor specific neurons. To assess the influence of glucocorticoids on FLI evoked by a well-defined noxious stimulus, the distribution of FLI-positive neurons within trigeminal subnucleus caudalis (Vc) was quantified in barbituate-anesthetized rats in response to thermal stimulation of the corneal surface. Noxious (52°C) or innocuous (42°C) thermal stimuli were applied in 20s pulses for 15min to adrenal intact, adrenalectomized (ADX), and adrenalectomized rats given corticosterone replacement (ADX+B). Rats were perfused and sections were processed for FLI at 2h after stimulation. In intact rats, noxious corneal heat evoked a reliable increase in FLI somatotopically localized to the ipsilateral superficial laminae of the caudal Vc (460±104 cells). In ADX rats, noxious corneal heat evoked a dramatic ($P<0.001$) increase in the number of FLI-positive neurons (2552±166 cells) in Vc, whereas in ADX+B rats the number of FLI-positive cells (827±75) was reduced compared to that of ADX rats. Sparse FLI was seen also in Vc at obex levels ipsilaterally, in the deep laminae of ipsilateral caudal Vc, and in contralateral caudal Vc in all groups. ADX alone or innocuous corneal heat had little effect on FLI in Vc. FLI was seen also in NTS and ventrolateral medulla bilaterally after noxious corneal heat and was increased in ADX compared to intact rats. The results are consistent with the hypothesis that glucocorticoids modify the function of superficial medullary dorsal horn neurons in response to noxious trigeminal input. Supported by NIH grant NS26137.

TIME COURSE OF AMINO ACID RELEASE INTO THE LUMBAR DORSAL HORN OF THE PRIMATE DURING DEVELOPMENT OF AN ACUTE ARTHRITIS. L.S. Sorkin, K.N. Westlund, K.A. Sluka, P.M. Dougherty and W.D. Willis. Marine Biomedical Institute, Univ. of Texas Med. Branch Galveston, Tx. 77550.

Extracellular levels of several amino acids were measured in the dorsal horn of anesthetized primates. Half hour continuous samples were obtained via a microdialysis probe before, during and for 4.5 hours after injection of kaolin/carrageenan into the articular capsule of one knee and assayed using HPLC with fluorescence detection.

Glutamate, aspartate, glycine and serine increased ipsilateral to the inflammation following injection of irritative agents; glutamine levels decreased. Within two and one half hours after the injection, these amino acid levels returned to near baseline. Movement of the knee after, but not before inflammation lead to release of these same amino acids.

In animals that later were found to have depletion of immunoreactive-substance P (SP) in the dorsal horn on the side of the inflammation, taurine (Tau) levels rose starting two to three hours after the injection. In animals with less than 10% SP depletion, Tau remained at baseline levels throughout the experiment.

Thus, during the first stages of joint inflammation, EAAs are released into the dorsal horn. This is followed by increased levels of IAAs, presumably representing activation of descending endogenous analgesia systems. This phase is followed by a semiacute response consisting in part of increased extracellular levels of SP as well as Tau. While SP is presumably part of a nociceptive transmission system, Tau via its ability to reduce Ca^{++} influx, could be part of a second analgesia mechanism aimed at semiacute and/or chronic pain. Supported by NS11255, NS09743 and Bristol Myers-Squibb.

CHANGE IN GLUTAMATE IMMUNOREACTIVITY IN THE MEDIAL ARTICULAR NERVE OF THE PRIMATE DURING ACUTE EXPERIMENTAL ARTHRITIS. K.N. Westlund, Y.C. Sun, K.A. Sluka, P.M. Dougherty, L.S. Sorkin and W.D. Willis. Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550.

Glutamate (GLU) and other excitatory amino acids have been shown to play a key role in nociception and the hyperalgesia associated with the acute inflammatory response. In an effort to more fully understand the role of GLU in this process, the percentage of axonal fibers immunoreactive for GLU was determined in the medial articular nerve, a source of preterminal afferent fibers innervating the knee joint of the monkey. After induction of the experimental knee joint inflammation with a kaolin/carrageenan mixture, comparison was made of the percentage of GLU positive axons from the control side versus the side of the inflammation. A doubling in the percentage of GLU axons was observed on the side of the experimental arthritis as compared to the medial articular nerve of the other side suggesting that GLU content is greatly increased in the preterminal afferents. These increases were observed only when injection of kaolin/carrageenan was combined with joint flexion and mechanical stimulation in the anesthetized preparation. GLU positive axons were of small diameter and unmyelinated or were included in the thinly myelinated group in the control nerve. Following induction of the inflammation, axonal diameter determination revealed an increase in the percentage of thinly myelinated GLU axons which would correspond to the A delta fiber type. An increase in GLU could explain the enhanced mechanosensitivity and increased resting discharges observed in afferents in this model of inflammation. These findings implicate increased GLU as a causal factor in the lacinating pain of movement and hyperalgesia experienced in the inflammatory state. (Supported by grant #NS11255, NS09743, NS08860, RCDA NS01445-02 and Bristol-Myers Squibb.)

SUBSTANCE P, CALCITONIN GENE-RELATED PEPTIDE AND GLUTAMATE ALTERATIONS IN THE SPINAL CORD OF THE PRIMATE DURING ACUTE ARTHRITIS. K.A. Sluka, P.M. Dougherty, L.S. Sorkin, W.D. Willis and K.N. Westlund. Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550.

The effects of an experimentally induced arthritis on immunoreactivity of putative primary afferent neurotransmitter/neuromodulators were examined. Immunoreactive staining for substance P (SP), calcitonin gene-related peptide (CGRP), and glutamate (GLU) in the monkey dorsal horn was examined following inflammation of one knee joint induced by injection of kaolin and carrageenan (5% and 5%). Spinal cords were examined at different time periods after induction of arthritis (2.5, 4, 6, and 8 hours). Side to side differences in the density of immunoreactive staining were determined by a computer-assisted quantitation system. A significant decrease in immunoreactivity of the ipsilateral dorsal horn was found for SP at 4, 6, and 8 hours. The decrease for SP was 68.3% at 4 hours, 54.7% at 6 hours, and 65.5% at 8 hours. Immunoreactivity for CGRP was significantly decreased 31.5% after 8 hours. Immunoreactivity for GLU, on the other hand, showed an increase ipsilaterally of 31.4% at 4 hours, 33.7% at 6 hours, 39.9% at 8 hours. The frequency of peripheral stimulation of the joint was shown to be important for changes in GLU and SP immunoreactivity. Without frequent joint stimulation in the early stages of the development of arthritis, increases in GLU immunoreactivity were not as prominent. In these same animals SP and CGRP showed no quantitative side to side differences without the joint stimulation. These studies suggest that GLU may be involved in arthritic pain at rest, whereas SP, CGRP and GLU may mediate pain induced by joint movement. (Supported by grants NS11255, NS09743, NS08860, RCDA NS01445 and Bristol-Myers Squibb.)

ENHANCEMENT OF RESPONSES OF MONKEY SPINOTHALAMIC CELLS TO EXCITATORY AMINO ACIDS ACCOMPANIES THE DEVELOPMENT OF ACUTE ARTHRITIS. P.M. Dougherty, K.A. Sluka, L.S. Sorkin, K.N. Westlund and W.D. Willis. Marine Biomedical Institute, 200 University Blvd, UTMB, Galveston, Texas 77550-2772.

The experiments described here show a potentiation of the responses of spinothalamic tract (STT) neurons to both chemical and mechanical stimuli in monkeys during the development of an acute arthritis. A total of 12 young adult monkeys (Macaca fascicularis) were anesthetized and a laminectomy was performed to expose the lumbar enlargement. STT neurons in the L4-L6 segments were recorded with carbon filament containing multibarrel electrodes. STT cells were isolated and identified by use of antidromic pulses passed through an electrode placed in the ventral posterior lateral nucleus of the thalamus. The responses of STT cells to mechanical stimulation of the receptive fields and to chemical stimulation by iontophoretically released glutamic, aspartic, quisqualic and *N*-methyl-D-aspartic acids were recorded before and following induction of arthritis. Arthritis was produced by injection of 0.5 ml of a 5% kaolin-5% carrageenan mixture into the knee joint capsule. The results of this study show an increase of the responses of 8 of 12 cells to non-noxious flexion of the knee joint following this injection. The responses of these cells to noxious pinch of the skin were also enhanced. The enhancement of both these responses followed a similar time course, with onset of changes one to two hours following injection of the knee joint. The results also demonstrate that the increase in responses of STT neurons to mechanical stimuli is accompanied by an increase in response to iontophoretically applied excitatory amino acids (EAA's), particularly those acting at non-*N*-methyl-D-aspartate (non-NMDA) receptors (e.g., glutamate, aspartate and quisqualate). (Supported by NS08860, NS09743 and NS11255.)

POTENTIATION OF RESPONSES OF MONKEY SPINOTHALAMIC (STT) CELLS TO EXCITATORY AMINO ACIDS ACCOMPANIES THE DEVELOPMENT OF CAPSAICIN-INDUCED HYPERALGESIA. W.D. Willis and P.M. Dougherty. Marine Biomedical Institute, 200 University Blvd, UTMB, Galveston, Tx. 77550-2772.

The present study addresses the role that excitatory amino acids (EAA's) may play in the sensitization of STT neurons by intradermal (i.d.) capsaicin (CAP). A total of 10 young adult monkeys (Macaca fascicularis) were anesthetized and a laminectomy was performed to expose the lumbar enlargement. STT neurons located in segments L4-L6 were recorded with carbon filament containing multibarrel electrodes. STT cells were isolated and identified by use of antidromic pulses passed through an electrode placed within the ventral posterior lateral nucleus of the thalamus. The responses of the STT cells to mechanical stimulation of the receptive fields and to chemical stimulation by iontophoretically released glutamic, aspartic, quisqualic and *N*-methyl-D-aspartic acids were recorded before and following injection of capsaicin. Capsaicin was injected at a concentration of 3% in 0.1 ml of a mixture of ethanol/tween 80 and saline into the center of the receptive field of each cell. Testing of responses to mechanical and chemical stimulation began at 30 minutes after injection and was continued for up to two hours afterward. Our results show that the responses of STT cells to *N*-methyl-D-aspartate, glutamate, aspartate, and quisqualate become increased in those cells which also show increased mechanical responses following i.d. CAP. Finally, in each of the cells showing an increase in response to mechanical stimulation the responses to at least one EAA (and often more than one EAA) became increased with a time course identical to that for the mechanical responses. (Supported by NS08860, NS09743 and NS11255.)

NEUROPLASTIC EFFECTS INDUCED BY LINGUAL INFLAMMATORY IRRITANT ON CUTANEOUS AND DEEP RECEPTIVE FIELD PROPERTIES OF NEURONS IN TRIGEMINAL (V) SUBNUCLEUS CAUDALIS.

X.-M. Yu, J.W. Hu and B.J. Sessle. Faculty of Dentistry, Univ. of Toronto, Ont. M5G 1G6 Canada.

We have documented that the inflammatory irritant mustard oil injected into the masseter muscle can change the cutaneous receptive field (RF) properties of caudalis nociceptive neurons. This study's aim was to characterize the properties of caudalis neurons receiving deep as well as cutaneous RF inputs and to test the effect on them of mustard oil. Of 196 single neurons recorded in V subnucleus caudalis in 15 anaesthetized rats, 74% received cutaneous input only, 14% deep input only and 12% were neurons (CD) receiving nociceptve cutaneous and deep inputs. Reversible effects of mustard oil (5μl) injected into the tongue on cutaneous and deep RFs were observed in 8 of 9 CD neurons tested . There was a significant increase of both cutaneous and deep RFs and, compared with the effect of vehicle injection, the expansion of deep RFs was significantly greater (45%, $p<0.01$) and longer in duration (10-15 min); also, deep RFs expanded more than cutaneous RFs ($p<0.05$). These results provide further support for injury-induced neuroplasticity in V nociceptive neurons and suggest that deep inputs may particulary manifest this effect. Supported by NIH grants DE04786 and DE09559.

PAIN MODULATION: PHARMACOLOGY II

548.1

CAPSAZEPINE: A COMPETITIVE ANTAGONIST OF THE SENSORY NEURON EXCITANTS, CAPSAICIN AND RESINIFERATOXIN. S. Bevan*, S. Hothi*, G.A. Hughes*, I.F.James, H.P. Rang*, K. Shah*, C.S.J. Walpole*and J.C. Yeats*,Sandoz Institute for Medical Research, 5 Gower Place, London WC1, UK.

Capsaicin depolarizes and excites a subset of primary afferent, sensory neurons by opening a membrane ion channel that is permeable to monovalent and divalent cations. This action is shared by resiniferatoxin (RTX), another plant product that is 100-1000 times more potent than capsaicin. Here we report the discovery of a compound, capsazepine, that acts as a specific, competitive antagonist of capsaicin and RTX. The competitive antagonism provides evidence that capsaicin and RTX act on a specific membrane receptor. Whole cell currents were recorded under voltage clamp from dorsal root ganglion (DRG) neurons isolated from neonatal rats. Capsazepine (0.5-1μM) reversibly reduced or abolished the response to 0.1-0.5μM capsaicin, but had no effect on the response to GABA. In ion flux studies, capsazepine antagonized the capsaicin induced uptake of $^{45}Ca^{2+}$ in neonatal rat cultured DRG neurons, with an IC50 of 0.5μM. Capsaicin dose-response curves for both $^{86}Rb^{+}$efflux from cultured DRG neurons and ^{14}[C]-guanidinium efflux from adult rat vagus nerves provided evidence that the antagonism was competitive. Parallel shifts in the log concentration-effect curves were seen with increasing concentrations of capsazepine. Schild plots of these data were linear with a slope very close to 1, and yielded K_d estimates of 100nM (DRG) and 690nM (vagus) . A similar competitive antagonism between capsazepine and RTX was noted in ^{86}Rb efflux and $^{45}Ca^{2+}$ uptake studies on DRG neurons.

SELECTIVE ANTAGONISM OF CAPSAICIN-INDUCED EXCITATION OF C-FIBERS BY CAPSAZEPINE, A NOVEL CAPSAICIN ANTAGONIST. L. Urban N. Seno' and A. Dray. Sandoz Institute for Med. Res., London, 5 Gower Pl., WC1E 6BN, U.K.;Sandoz Pharm. Ltd., Tokyo 106, Japan

There are several lines of evidence indicating that the selective excitatory action of capsaicin on primary sensory neurons is produced by activation of a specific receptor (Bevan & Szolcsanyi, 1990). This suggestion has been recently supported by using a competitive capsaicin antagonist, capsazepine (Bevan et al., 1991). We now show selective antagonism of the capsaicin-induced activation of sensory C-fibers by capsazepine, using two *in vitro* preparations: the mouse spinal cord - DRG, and the rat hindpaw skin - saphenus nerve.

Capsaicin (0.2-1.0 *u*M, 30 sec) applied to the receptive field of single primary afferent fibers selectively excited C- and A-delta mechano-heat receptors. Capsazepine (0.7 *u*M, 5 min) perfused to the receptive field prior to capsaicin significantly reduced the firing evoked in single fibers. In the spinal cord a majority of dorsal horn cells were depolarised when primary afferents were activated by capsaicin (0.4-0.7 *u*M) applied to the DRG. Superfusion of the DRG (but not the spinal cord) with capsazepine blocked the capsaicin-induced depolarization of dorsal horn cells. Depolarization evoked in the same cells by application of substance P (0.8 *u*M) to the cord was not affected by capsazepine. The antagonistic effects of capsazepine were reversible, and similar concentrations were ineffective when administered alone in both preparations.

These data show that capsazepine acts as a selective capsaicin antagonist and support the concept that capsaicin activates C-fibers via a specific receptor site.

CAPSAICIN ANTAGONISED BY CAPSAZEPINE; IN VIVO STUDIES. M.N.Perkins, A.Dray, and E.A.Campbell.* Sandoz Institute for Medical Research, London, WC1E 6BN, UK.

Capsazepine, has been shown to be a selective, competitive antagonist of capsaicin-induced activation of sensory neurones *in vitro* (Bevan et al 1991, Dray et al 1991). We now show that capsazepine antagonises both capsaicin-induced agonist responses and antinociceptive effects *in vivo*. The capsaicin- evoked reflex blood pressure fall in anaesthetised rats and the bronchoconstrictor responses in anaesthetised guinea pigs were both antagonised by capsazepine infused at 0.2-0.5 µmol/min for 5 min. In carrageenin- induced paw pressure hyperalgesia in rats the antinociceptive action of capsaicin (20µmol/kg sc) was reversed by 100µmol/kg sc capsazepine. In the tail -flick model in rats and mice capsazepine (100µmol/kg sc) prevented the antinociceptive action of capsaicin (20µmol/kg sc). Lower doses of capsazepine were generally ineffective. In a model of persistent hyperalgesia, produced by the injection of uric acid into a rat knee joint ,the antinociceptive action of capsaicin (20µmol/kg sc) was partially reversed by capsazepine at 100 µmol/kg and completely reversed at 200µmol/kg. In each of these models, systemic capsazepine alone was without effect. These data show that capsazepine acts as a capsaicin antagonist *in vivo* and supports the concept that both the agonistic and antinociceptive actions of capsaicin are mediated by the same specific membrane receptor.

548.4

CAPSAZEPINE; CAPSAICIN ANTAGONISM AND EVIDENCE FOR A SPINAL MECHANISM IN CAPSAICIN-INDUCED ANTINOCICEPTION. A. Dray and A. Dickenson* Sandoz Institute for Medical Research, and *Department of Pharmacology University College, London, England.

Systemic capsaicin produces antinociception by an action on spinal afferent nerve terminals (Dickenson et al 1990, Eur J. Pharmacol. 187,225). The effects of capsaicin are likely to be mediated by a specific receptor. This is supported by recent studies using the competitive antagonist capsazepine (Bevan et al 1991, Br J. Pharmacol, 1991, 102, 77P; this meeting). Presently we have used capsazepine to show antagonism of capsaicin-induced activation of nociceptors and that antinociception produced by systemic capsaicin is mediated via a capsaicin receptor. Spinal ventral root responses were recorded in vitro from the neonatal rat cord/tail preparation following brief application of capsaicin and other noxious stimuli. Responses evoked by capsaicin administered to the tail or spinal cord were selectively and reversibly reduced by capsazepine (IC50= 200nM). In anesthetized adult rats, C- but not Aβ-fiber evoked discharges of WDR dorsal horn neurones, were reversibly reduced by a low dose of capsaicin (20 µmol/kg s.c.). This was antagonised by capsazepine administered either s.c. (100µmol/kg) or directly to the spinal cord (5nmol in 50µl). Capsazepine alone did not affect neuronal responses to peripheral stimuli. Local injection of capsaicin into the peripheral receptive field first activated C-fibres and then reduced their electrical excitability. Co-injection of capsazepine reduced both these effects of capsaicin. *These results show that capsazapine antagonises a number of actions of capsaicin. Specifically the data support the hypothesis that antinociception, following systemic capsaicin, is due to an effect via capsaicin receptors on spinal afferent fibres .*

EFFECTS OF INTRATHECAL CAPSAICIN AND STRYCHNINE AND TOPICAL COLCHICINE ON THE THERMAL HYPERALGESIA FOLLOWING SCIATIC NERVE CONSTRICTION MODEL IN RATS. T. YAMAMOTO* and T.L. YAKSH. Depart. Anesth. UCSD, La Jolla, CA 92093.

A chronic sciatic nerve constriction injury produces ipsilateral hyperalgesia in rats and this hyperalgesia was proposed as an animal model of peripheral neuropathy. This syndrome is thought to reflect activation of small afferents and an altered processing of noxious input due to trans-synaptic change in the dorsal horn. To investigate possible mechanisms leading to the hyperalgesia, we examined the effects of intrathecal (IT) capsaicin (CAP; C-fiber neurotoxin), IT strychnine (STR; glycine antagonist) and topical (TOP) colchicine (COL; axon transport blocker) on the hyperalgesia following sciatic nerve constriction injury. Under halothane, both sciatic nerves were exposed. 4 ligatures were tied loosely around one (lesioned) but not the other (normal) nerve. For CAP treatment, 75µg of CAP or vehicle (VEH; 20% cyclodextrin) were injected IT 2 days after nerve lesion. For STR treatment, 15µg of STR or saline was injected IT at the surgery day and 1 day and 2 days after surgery under halothane anesthesia. For COL treatment, 5 mM and 50 mM of COL or saline were TOP applied adjacent to the lesioned nerve, proximal to the constriction. 7 days after nerve lesion, latency to withdrawal from a thermal stimulation was examined in the ipsilateral and contralateral hind paw of each rat. A difference score (DS) was calculated by subtracting the average latency of the control from the average of the lesioned side. CAP but not STR or COL treatment resulted in a significant increase in the latency of the normal paw.

	CAP	VEH	STR	saline	COL 5	COL50	saline
DS (sec)	-5.7	-3.7	-4.5	-2.8	-1.2	-0.1	-3.0
(±SEM)	±1.3	±0.4	±0.3	±0.5	±0.2	±0.3	±0.3

These results suggested that : 1) C fiber afferents did not play an important role in producing hyperalgesia; 2) glycine receptor activity inhibits developing hyperalgesia; 3) the hyperalgesic state depends upon axonal transport.

548.6

PROSTAGLANDINS STIMULATE THE RELEASE OF SUBSTANCE P FROM RAT SENSORY NEURONS GROWN IN CULTURE. K.J. Waite* and M.R. Vasko, Dept. Pharmacol. and Tox., Indiana U. Sch. Med., Indianapolis, IN 46202

When injected into peripheral tissues or directly onto the spinal cord, prostaglandins (PGs) lower the algesic threshold in animal models of nociception. One possible mechanism to explain this hyperalgesia is that PGs increase the release of neurotransmitters from nociceptive sensory neurons. To test this hypothesis, we studied the effects of PGs on the release of substance P (SP) from rat sensory neurons grown in culture.

Neurons were dissociated from dorsal root ganglia of 16-18 day old rat embryos and grown in culture for 14 days. Release studies were performed by exposing neuronal cultures to Krebs buffer containing 3.5mM KCl (basal release) or buffer containing 1uM capsaicin, 30mM KCl, and/or PGs (stimulated release). Buffer was then assayed for SP using RIA.

Exposure of neurons to 1uM capsaicin or 30mM KCl resulted in a 3-4 fold increase in SP release that was calcium dependent. Addition of 10uM PGE2 to the cells significantly increased SP release by 2 fold from 26.9 ± 1.5 pg/well/10 min to 48.9 ± 1.6 pg/well/10 min. In contrast, neither 10uM PGD2 nor 10uM PGF2α produced a significant increase in SP release. PGF2α did, however, enhance the potassium-stimulated release of SP. These results demonstrate that PGs can stimulate release of neurotransmitter from rat sensory neurons and suggest that this effect may contribute to PG-induced hyperalgesia. (Supported by the Arthritis Foundation and NS21697).

SYSTEMIC MORPHINE COMPLETELY BLOCKS ACUTE C-FIBER STIMULATION-INDUCED DEPLETION OF CGRP AND REDUCES DEPLETION OF GALANIN. C.M. Klein, C.M. Pover, R.E. Coggeshall, and L.S. Sorkin. The Marine Biomedical Institute, Dept. of Anatomy and Neuroscience and Dept. of Physiology & Biophysics., The University of Texas Medical Branch, Galveston, Texas 77550.

In past studies, we observed decreases in immunoreactive staining of calcitonin gene-related peptide (CGRP) and galanin (GAL) in the L4-L_5 dorsal horn following acute stimulation of the sciatic nerve at C- but not A-fiber strength. In the present study, we determined if depletion of these substances is blocked by morphine.

Adult Sprague-Dawley rats were anesthetized (50 mg/kg pentobarbital i.p.) and the sciatic and tibial nerves isolated. After being placed on a respirator, they were paralyzed with gallamine (15 mg, i.v.) and administered morphine (9 mg/kg i.v.). Fifteen mins after morphine administration, the sciatic nerve was stimulated. (1 Hz, 0.3 ms) for 20 mins, fiber volleys were monitored from the tibial nerve. Immediately after stimulation, rats were perfused with 4% paraformaldehyde, 0.1% picric acid in 0.1 M phosphate buffer. The L_4-L_5 spinal cord was removed and processed for immunocytochemistry by the PAP method. Systemic morphine administration blocked C-fiber induced depletion of CGRP and attenuated but did not eliminate the decreased staining for GAL.

These findings may indicate that 1) CGRP immunoreactive C-fibers are inhibited by opiates and 2) some galanin immunoreactive primary afferent fibers are unaffected by opiates or galanin immunoreactive cells in the dorsal horn are activated by opiate insensitive afferent input. SUBSTANCE P(1-7) SPINAL ANTINOCICEPTION AND INTERACTION WITH THE β-FNA-SENSITIVE OPIATE RECEPTOR SUBTYPE. V.M. Goettl and A.A. Larson. Dept. of Veterinary Biology and Program in Neuroscience, Univ. of Minnesota, St. Paul, MN 55108.

Substance P (SP), a putative neurotransmitter of pain, is cleaved by peptidases in the synaptic cleft resulting in several metabolites including the N-terminal peptide SP(1-7). SP(1-7) has been shown to have specific CNS membrane binding sites which interact with the mu-opiate ligand DAMGO as well as biological activity including antinociception when given intracerebroventricularly in mice. To investigate SP(1-7) antinociception at the spinal level, doses of 0.5, 5, 50 or 1000 pmoles were given intrathecally (i.t.) to male Swiss-Webster mice. Tail flick latency, hot plate paw lick latency or the number of abdominal stretches 5 min after an intraperitoneal injection of 0.3 ml of 1% acetic acid was determined 3, 5, 10 or 30 min after i.t. SP(1-7). SP(1-7) was not significantly antinociceptive ($p<0.05$) with the tail flick latency. A dose of 0.5 pmole of SP(1-7) significantly increased the hot plate rear paw lick latency ($p<0.05$) at 3 and 30 min. post i.t. injection. Doses of 5, 50 and 1000 pmole significantly decreased ($p<0.05$) the number of abdominal stretches 30 min post i.t. injection. To determine if opiate receptor subtypes were involved, mice were injected i.t. with 1µg of β-FNA, a mu_2 selective antagonist, or 0.5µg naloxonazine, a mu_1 selective antagonist, 24 hrs before the abdominal stretch assay; 1 µg naltrindole, a delta selective antagonist, was coadministered with the i.t. SP(1-7). Only the β-FNA blocked the antinociceptive effect of 50 pmoles SP(1-7) 30 min. post i.t. injection. These experiments demonstrate that SP(1-7) may attenuate pain transmission at the spinal level through the β-FNA-sensitive opiate receptor subtype. (NIDA 04090,04190,00124)

548.9

SPINAL MUSCARINIC TYPE 2 RECEPTORS MEDIATE THE ANTINOCICEPTION INDUCED BY N-METHYLCARBACHOL IN THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS (PPTg). E.T. Iwamoto, L. Marion*, and J.R. Holtman. Pharmacology Dept., Univ. of Kentucky Col. of Med., Lexington, KY 40536

N-methylcarbachol (NMC) microinjection into the PPTg produces antinociception as assessed by the hot-plate and tail-flick tests. Adult male Sprague-Dawley rats were implanted with both 25 ga guide cannulas aimed at the PPTg and intrathecal PE10 catheters terminating in the lumbar enlargement. One wk after surgery, animals received an intrathecal injection of 0.1 μmole of drug in 10 μl phosphate buffer 12.5 min before the injection of 40 nmole NMC in 0.5 μl buffer into the PPTg. NMC produced hot-plate and tail-flick antinociception for 15 to 25 min which was not accompanied by losses of corneal or righting reflexes, a placing reaction, or a negative geotaxic response. Intrathecal (-)-scopolamine or methoctramine antagonized the antinociception produced by NMC injection into the PPTg; mecamylamine or pirenzepine had little effect. Mecamylamine, (-)-scopolamine, pirenzepine, or methoctramine did not alter baseline nociception when administered alone intrathecally. The data indicate that either a local or a descending spinal muscarinic M2 system mediates the antinociception produced by nicotinic stimulation of the PPTg. (Supported by NS 28847 and the KTRB.)

548.10

IMPACT OF SCOPOLAMINE AND YOHIMBINE ON PAIN REACTIVITY AND SHOCK-INDUCED ANTINOCICEPTION IN SPINALIZED RATS. P.S. Chen*, P.A. Illich, M.W. Meagher, & J.W. Grau. Dept. of Psychology, Texas A&M Univ., College Station, TX 77843.

We have previously shown that exposure to three brief (2 sec) 3.0 mA tail-shocks elicits an opioid antinociception, and that longer (75 sec) tail-shocks elicit a nonopioid antinociception in spinalized rats. The present experiments evaluate whether cholinergic or noradrenergic systems play a role in the production of these antinociceptive effects. In both experiments, subjects were spinalized at T2 and tested 8-10 hr later. Fifteen min after subjects received the test drug, or its vehicle, 3 tail-flick tests were performed to establish baseline levels of nociception. Subjects then received either no shock, 3 brief (2-s), or 3 long (75-s) 3.0 mA tail-shocks, after which nociception was assessed 5 more times with the tail-flick test. We found that the cholinergic antagonist scopolamine (1 mg/kg) decreased baseline tail-flick latencies. A similar effect has been observed in intact subjects (e.g. Grau et al., Behav. Neurosci., 105, 62, 1991). Scopolamine did not, however, affect the magnitude of either brief or long-shock induced antinociception. In contrast, the alpha-2-noradrenergic antagonist yohimbine (10 mg/kg) attenuated the antinociception observed after both shock schedules without affecting baseline tail-flick latencies. We are currently assessing the impact of intrathecal application of these drugs and the role of other neurochemical systems.

548.11

STIMULATION OF THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS PRODUCES ANTINOCICEPTION THAT IS MEDIATED BY MUSCARINIC AND NICOTINIC RECEPTORS IN THE NUCLEUS RAPHE MAGNUS. L.F. Fitzgerald and H.K. Proudfit. Dept. of Pharmacology, Univ. of Illinois at Chicago, Chicago, IL 60680.

Previous studies have suggested that the pedunculopontine tegmental nucleus (PPTg) is involved in the descending control of nociception, probably through a connection to the nucleus raphe magnus (RMg). For example, electrical stimulation of the PPTg in the lightly-anesthesized rat produces antinociception in the tail flick test. The present experiments were designed to determine whether antinociception produced by stimulation of the PPTg is mediated by cholinergic receptors in the RMg. The results of these experiments demonstrate that microinjection of atropine, a muscarinic antagonist, or mecamylamine, a nicotinic antagonist, into the RMg blocked the antinociception produced by PPTg stimulation. In addition, injection of methacholine, a muscarinic agonist, or nicotine into the RMg produced antinociception. These results suggest that both muscarinic and nicotinic receptors within the RMg mediate the antinociception produced by PPTg stimulation.

548.12

NICOTINE INDUCED ANTINOCICEPTION IS MEDIATED BY SPECIFIC CHOLINERGIC AND OPIOID RECEPTORS. M.E.Wewers, A.K.Rattan and G. A. Tejwani*. Ohio State University College of Medicine & College of Nursing, Columbus, OH 43210.

The objectives of this study were to investigate the role of nicotinic, muscarinic and opioid receptors in nicotine induced antinociception in adult male Sprague Dawley rats. Antinociception was measured by tail-flick and hot plate 52° C tests after subcutaneous or lateral intracerebroventricular nicotine injections. Nicotine (10-1000 μg/kg,subcutaneous) or (50-200 μg/kg,intracerebroventricular) induced a dose dependent increase in antinociception in both tests. Antinociception produced by subcutaneous nicotine was antagonized by mecamylamine, a nicotine receptor antagonist but not by scopolamine hydrobromide, scopolamine methyl nitrate or hexamethonium. Opioid receptors antagonist naloxone blocked subcutaneous nicotine effects completely and μ receptor antagonist ß-Funaltrexamine blocked subcutaneous nicotine effect only in hot plate while κ receptor antagonist WIN 44,441-13 (WIN) blocked subcutaneous nicotine effects in both tests. Antinociception produced by intracerebroventricular nicotine was antagonized by mecamylamine, hexamethonium, scopolamine hydrobromide and scopolamine methyl nitrate as well as naloxone, ß-Funaltrexamine, WIN and δ-receptor antagonist naltrindole in both tests. Nicotine inhibited binding of opioid ligands to receptors in the cortex with $(IC)_{50}$ of 2.3 mM (^{3}H-naloxone), 2.6 mM (^{3}H-DAGO), 3.4 mM (^{3}H-DSTLE) and 12.9 mM (^{3}H-EKC). It is concluded that nicotine induced antinociception is mediated by μ, δ and κ receptors in addition to nicotinic and muscarinic receptors.(Supported by USPHS 5K08NR00018).

RETINA AND PHOTORECEPTORS: GANGLION CELLS AND CENTRIFUGAL CONTROL

549.1

MORPHOLOGICAL CLASSIFICATION OF RETINAL GANGLION CELLS PROJECTING TO THE OPTIC TECTUM IN TURTLE. D. Zhang, M.J. Endl* and W.D. Eldred. Department of Biology, Boston University, Boston, MA 02215.

There is little detailed information about particular types of retinal ganglion cells which project to specific central targets. In this study we have examined retinal ganglion cells which project to the optic tectum in turtle. Rhodamine crystals were applied to the optic tectum and retrograde transport carried the rhodamine back to the ganglion cell bodies. Intracellular injection of Lucifer yellow was used to label the rhodamine containing ganglion cells. Following photoconversion using diamino-benzidine, detailed camera lucida drawings were made. More than 20 morphologically-distinct classes of ganglion cells were identified based on their stratification within the inner plexiform layer (IPL), the complexity of their dendritic arborizations and the presence or absence of dendritic beads. Ganglion cells were seen with mono-, bi-, tri-stratified or diffuse dendritic arborizations. Different subclasses of mono-, bi-, or tri-stratified cells were distinguished using the location of their arborizations within the IPL. Several different classes of diffuse type ganglion cells were also distinguished by having concentrations of processes within certain strata of the IPL. Other classes of ganglion cells with the same stratification within the IPL, were distinguished by the presence or absence of dendritic beads. Many of the cells with asymmetric dendritic arborizations had dendritic trees which were parallel or sometimes orthogonal to the visual streak. Overall, the ganglion cells projecting to the optic tectum in the turtle displayed a great degree of morphological diversity, which may reflect a similar heterogeneity in their functions. 549.2

MORPHOLOGY OF HAMSTER RETINAL GANGLION CELLS. E. N. Yamasaki, C. R. Schätz and D. O. Frost. Dept. of Neurology, Massachusetts General Hospital, Charlestown, MA 02129.

Neonatal surgery in hamsters can produce novel, functional retinal projections to non-visual nuclei. The retinal ganglion cell (RGC) types that make these projections are unknown. Such data would reveal the relative plasticity of different RGC types and help interpret neurophysiological data on the novel pathways. To begin clarifying this issue, we have examined the morphology of RGCs in normal adult hamsters. In living retinae, RGCs previously labeled by injections of rhodamine labeled latex microspheres into the superior colliculus (to which virtually all RGCs project) were intracellularly injected with lucifer yellow (LY), revealing their soma/dendritic morphology. The retinae were then fixed and LY-filled RGCs were either photoconverted using DAB and drawn with a computer microscope (n=22) or drawn under epifluorescent illumination using a camera lucida (n=24).

RGC soma and dendritic field diameters and the number of dendritic branch points and dendritic spines were measured. RGCs were classified as types I, II or III following Perry's (1979) scheme for the rat. Type I RGCs have soma and dendritic field diameters of 21-28 and 233-391 µm, respectively. Type II RGCs have soma and dendritic field diameters of 14-24 and 173-272 µm, respectively. Type III RGCs have soma and dendritic field diameters of 17-22 and 192-270 µm, respectively. Dendritic field diameter increases with increasing eccentricity and decreasing RGC density. Type I and type III RGCs have few dendritic spines; type II RGCs have many spines. Type II RGC dendrites are highly branched, type III are sparsely branched and type I are intermediate. The dendritic fields of some RGCs of each type are stratified in the inner plexiform layer within presumptive ON or OFF sublaminae.

PARASOL RETINAL GANGLION CELLS IN MACAQUES CONNECT INTRACELLULARLY TO OTHER PARASOL CELLS, AND TO AMACRINE CELLS FOUND IN THE GANGLION CELL LAYER.

R. W. Rodieck and T. J. Haun*, Department of Ophthalmology, University of Washington, Seattle, WA 98195.

Dr. David Vaney (personal communication) has recently shown in cats and rabbits that intracellularly injected fixable biotin derivatives are able to pass into other retinal cells of the same type, and may also pass into certain other specific retinal cell types. We have applied the approach to cells in the ganglion cell layer of an *in vitro* wholemounted preparation of the macaque retina, using 3% Neurobiotin (Vector) in 0.1 M Tris, and a positive current of 1 to 3 nA for 1 to 3 min. After fixation the retina was placed in detergent to aid penetration, followed by avidin then biotinylated HRP, and reacted with DAB.

Around and outside the dendritic fields of parasol cells we observed a ring of 2 to 6 labeled somata having the same size as the injected cell (i.e. larger than all other common cell types in this layer). None of these large somata were found that overlapped or were within the dendritic field of the injected cell, suggesting that the other labeled parasol cells belong to the same type as the injected cell, and that the population of this type formed territorial domains. In addition, 2 to 7 cells with smaller somata (ca 7 µm diameter) were also labeled; these were found both within the dendritic field of the injected cell, and in the surrounding region. Some were sufficiently well labeled to trace their processes; they lacked an axon, had 2 to 3 main processes, and showed a sparse field of processes that seldom branched. They showed the morphology of certain amacrine cells; we could not determine the full extent of their dendritic fields, but they were considerably larger than that of the injected parasol cell.

IDENTIFICATION OF ALL CELLS IN A SMALL PATCH OF FOVEA OF MACAQUE RETINA

Karl Klug*, Stanley J. Schein, Patricia Masarachia*, Peter Sterling & Yoshihiko Tsukamoto*. Dept of Psychology, UCLA, Los Angeles, CA, Dept of Anatomy, University of Pennsylvania, Philadelphia, PA, & Hyogo Coll Med, Hyogo, Japan.

We identified, from serial ultrathin sections, all cells in a small patch of retina containing 50 contiguous cone pedicles at 1.5^0 eccentricity. The corresponding region of the inner nuclear layer contained 98 midget bipolar cells, 52 diffuse bipolar cells, 49 horizontal cells, 63 amacrine cells, and 59 Müller cells. A comparable region of the ganglion cell layer contained 122 cells.

Midget bipolars had a thick dendrite that almost invariably approached a single pedicle closely before breaking up into a fine arborization. Fifty midget bipolars had pale somata. We traced 40 to their terminals: all were in the outer third of the inner plexiform layer (IPL), within sublamina *a*. Forty-eight midget bipolars had dark somata. We traced 23 to their terminals: all were in the inner third of the IPL, within sublamina *b*. Thus, virtually every pedicle contacted 1 *a*- and 1 *b*-midget bipolar. The only exceptions were 2 pedicles that contacted no *b*-midget bipolars. Moreover, with just 1 exception, every midget bipolar was contacted by only 1 pedicle.

Diffuse bipolar dendrites branched immediately upon entering the outer plexiform layer, extending processes horizontally under several pedicles. We traced 28 to their terminals, 18 in sublamina *a* and 10 in sublamina *b*. These partially overlapped with the midget terminals but were located more centrally.

Thus, the numbers of *a*-midget and *b*-midget bipolars, diffuse bipolars, and horizontal cells are virtually identical to the number of cone pedicles. This simple rule may apply throughout central retina (Schein & Klug 1990, Martin & Grünert 1990). There are, however, fewer cells in the ganglion cell layer, 122, than the total number of cone bipolar cells, 150.

THE SPATIAL RESOLUTION OF COMBINED ON- AND OFF- GANGLION CELL ARRAYS IS NOT LIMITED BY POSITIONAL DISORDER AMONG THE SAMPLING ELEMENTS.

M.H. Rowe, Neurobiology Program, Ohio Univ., Athens, OH 45701.

The additional irregularity present in combined on- and off- ganglion cell arrays potentially results in a loss of spatial information, and this has been taken as evidence that the two subvarieties form independent sampling arrays. However, the hypothesis that the positional disorder of the combined arrays is sufficient to prevent any potential increase in spatial resolution from being realized has not been empirically tested. Positional disorder in the spacing of the ganglion cell array does not reduce resolution per se, but acts like a low pass spatial filter, and the degree of demodulation produced at any spatial frequency can be determined directly from the statistics of the nearest neighbor histogram (French, et al., 1977). The relative importance of this 'position' filter can be determined by comparing its spatial bandwidth to the Nyquist limit of the array and to the bandwidth of the receptive field centers which also act as low pass spatial filters. For both Alpha and Beta Cells in cat retinas, nearest neighbor histograms for on-, off- and combined arrays are accurately described by gaussian curves of approximately equal width. Fourier transform of these gaussian profiles indicates that the spatial bandwidth of these 'position' filters are 3-5 times higher than the Nyquist limit for combined on- and off- arrays, and 2-3 times higher than the bandwidth of the receptive field centers. When nearest neighbor histograms are convolved with receptive field center profiles, the effective bandwidth of the receptive field center is reduced by less than 10%, and is still significantly higher than the Nyquist limit of the combined array. Thus, the positional disorder within combined on- and off-center ganglion cell arrays is not sufficient to prevent them from cooperating to achieve higher spatial resolution.

GLUTAMATE AND SEROTONIN IMMUNOCYTOCHEMISTRY INDICATE CENTRIFUGAL FIBERS AND A VISUAL STREAK IN THE SKATE RETINA.

Etha Schlemermeyer* and Richard L. Chappell. Hunter College and City University of New York Graduate Center, New York, 10021

We have performed both glutamate and serotonin immunocytochemistry in the retina of the skate, *Raja erinacea*. The glutamate immunoreaction labelled ordinary ganglion cells as well as giant superficial ganglion cells. In the inner nuclear layer, a regular pattern of labelled cell bodies was observed in retinal wholemounts. In the nerve fiber layer, single smooth fibers exhibited unusually strong immunoreactivity. A characteristic feature of these fibers was their antidromic branching, hence we tentatively classify them as centrifugal axons.

Serotonin-like immunoreactivity (SLI) in wholemounts revealed not only the class of bipolar cell previously reported but also a network of intensely staining amacrine cells. The density distribution of SLI bipolar and amacrine cells provides convincing evidence for the existence of a visual streak in the skate retina. The strongest SLI was observed in a small number of varicose fibers radiating from the optic disc. These fibers extended over the whole retinal surface and appeared to make *en passant* contacts with the perikarya of SLI amacrine cells. We suggest that they may also represent a class of centrifugal fibers as demonstrated in other species.

SLI bipolar cells have a morphology typical of "OFF" bipolar cells, branching as they do in layers 1 and 4 of the inner plexiform layer. Presently, we are quantitatively analyzing the topographical distribution of SLI and PKC-immunoreactive bipolar cells. The latter have a morphology typical of the "ON" rod bipolar cells identified in many duplex retinas.

DECREASE IN THE NUMBER OF LARGE AND MEDIUM RETINAL GANGLION CELLS FOLLOWING TRANSECTION OF THE OPTIC NERVE IN ADULT FERRETS.

T.J. Drolsum* and E.H. Polley. Dept. of Anatomy & Cell Biology, Univ. of Ill., Chicago, Ill. 60612.

As a prelude to the study of retrograde transneuronal degeneration in the retina of the adult ferret (Mustela putorius furo), an assessment was made of retrograde degeneration in retinal ganglion cells (RGC) in 3 ferrets following intracranial transection of the optic nerve. Survival times ranged from 5-7 mos. 5 micron sections of flat mounted, plastic embedded retinae were stained with 0.1% Thionin. Corresponding regions of the retinae were localized and the cells were counted utilizing a Camera Lucida drawing tube and a Bioquant LED cursor which were tied directly to the Sigma Scan (2.5, Jandel Scientific) computer program. Data analysis showed that there was a significant decrease in both the Alpha and Beta RGC size ranges among all the experimental animals when compared to controls. Compared to the cat, our findings are consistent with those of Tobimatsu, et al., (Electroenceph. and Clin. Neurophy., 73: 341-353, 1989) but are at variance with those reported by Hollander, et al., (Exp. Brain Res., 59: 633-635, 1985). The latter group of investigators maintained that there was long term survival (15.5 mos.) of large and small RGCs after optic nerve section. Based on our findings, it appears that both large and medium RGCs in the ferret undergo retrograde degeneration within as brief a period as 5 mos.

WAVELENGTH-DEPENDENT INHIBITORY INPUT TO ON-OFF AND OFF GANGLION CELLS IN THE TIGER SALAMANDER RETINA.

S.H. Hensley* and S.M. Wu. Cullen Eye Institute, Baylor College of Medicine, Houston, TX 77030.

Response-intensity and spectral sensitivity functions for ON, OFF and ON-OFF ganglion cells were obtained from extracellular recordings from the dark-adapted, flat-mounted, isolated retina of the larval tiger salamander. Two different types of ON-OFF ganglion cells were identified based on the form of the response-intensity function measured with different stimulus wavelengths. In the first type, both the ON and OFF response-intensity functions at all wavelengths were sigmoid-shaped with a relatively narrow dynamic range. These cells were similar to those described previously in the mudpuppy retina. In the second type, the shape of the OFF response-intensity function varied with stimulus wavelength. Between 450 to 600 nm, the OFF response-intensity function was not sigmoidal but had two distinct peaks with a period of suppressed OFF activity over a range of about 1.5 log units interposed between them. Between 650 to 700 nm, the OFF response-intensity function became more sigmoidal in form, with only a single peak. The shape of the ON response-intensity function of these cells did not display this wavelength dependence and appeared similar to that of the first type of ON-OFF ganglion cells. In all, 74% of the ON-OFF ganglion cells recorded from were of the second type. The OFF response-intensity function of some sustained OFF ganglion cells also exhibited this wavelength-dependent inhibition, while the ON response-intensity function of sustained ON ganglion cells did not. The period of suppressed OFF responses observed with short wavelength, medium intensity light may indicate that a subpopulation of ON-OFF and OFF ganglion cells receive inhibitory, possibly rod-dominant input from an interneuron over an interval within their dynamic range. DO NMDA CHANNELS CONTRIBUTE TO THE RESTING CONDUCTANCE OF RETINAL GANGLION CELLS? J. Gottesman & R.F. Miller Dept. Physiology & Graduate Program in Neuroscience, Univ. of Minnesota, Mpls. MN 55455.

The voltage-dependent block of the *N*-methyl-D-aspartate (NMDA) receptor by magnesium ions is thought to prevent this glutamate receptor subtype from being active when cells are at their normal resting potential. Voltage-clamped retinal ganglion cells in a larval tiger salamander slice preparation display inward currents to applied NMDA under Mg^{2+}-free conditions (V_{hold} -70 mV). NMDA-evoked responses are reduced by increasing external Mg^{2+}, but even 1 mM Mg^{2+} does not abolish responses at -70 mV (1 mM Mg^{2+} 30% of Mg^{2+}-free response; n=40). These data demonstrate that NMDA currents are generated at the resting potential.

We used fluctuation analysis of the current noise in voltage-clamped cells to determine if the NMDA channel is active under steady-state resting conditions. Under control conditions (V_{hold} -70 mV 1 mM Mg^{2+}), power spectra in the presence of 25-250 μM NMDA were sometimes, but not always, well fit by a single Lorentzian function. These data are consistent with prior results indicating that NMDA can evoke inward currents under control conditions.

In all cells tested (n=14), application of the selective NMDA antagonist D-AP7 reduced resting current noise amplitude and yielded power spectra with a 1/f form. Depolarizing the cell or reducing extracellular Mg^{2+} increased the noise power. This increase could be reversed by application of D-AP7. It remains to determined if the power spectra in Mg^{2+}-free Ringers with no added agonist conform to a single Lorentzian function, characteristic of an NMDA channel. However, the voltage- and D-AP7-sensitivity of the resting current noise suggest that the NMDA channel is a component of the resting conductance of all ganglion cells. This study emphasizes the importance of precise knowledge of levels of extracellular Mg^{2+} to more accurately predict the influence of the NMDA receptors at rest and near threshold.

SYNAPTOLOGY OF A PHYSIOLOGICALLY IDENTIFIED Y-CELL AND W-CELL IN THE CAT RETINA. A.J. Weber and L.R. Stanford. Department of Comparative Biosciences and the Waisman Center, University of Wisconsin, Madison, WI 53706.

Following intracellular horseradish peroxidase injection in an in vivo preparation, the synaptology of a Y-cell and a W-cell in the cat retina are being studied by complete serial section reconstruction of their dendritic arbors. The Y-cell, injected at a retinal eccentricity of 2.1°, had an ON-center receptive field, nonlinear spatial summation, and responded phasically to a stimulus of standing contrast. This neuron has a soma diameter of 30μm and its dendritic tree has a mean diameter of 331μm. We have thus far identified 269 synaptic contacts onto the labeled dendrites of this Y-cell. Sixty five percent of this input is from amacrine cells and 35% originates from bipolar cells. The W-cell has a soma diameter of 9.5μm and was injected at a retinal eccentricity of 4.5°. This cell had an OFF-center receptive field, linear spatial summation, and responded tonically to a stimulus of standing contrast. The dendritic arbor of this neuron is extensive although very sparse. More than 50% of the dendritic tree has been reconstructed at this time, and we have found that the number of synaptic inputs received by its dendrites is extremely low. Only 25 bipolar cell inputs and 8 synapses from amacrine cells have been identified.

We have previously analyzed the pattern and distribution of synaptic input onto the dendritic arbors of two physiologically identified retinal X-cells. Similar data for the two cells currently being reconstructed will compare the distribution of bipolar and amacrine cell input among X-, Y-, and W-cells to determine whether the proportions of amacrine and bipolar cell input contribute to the functional differences among these retinal ganglion cell types. DIRECTIONAL SELECTIVITY AND SYNAPTIC POTENTIALS OF IDENTIFIED TURTLE RETINAL GANGLION CELLS. R. D. DeVoe, P. L. Carras*. Indiana University, School of Optometry, Bloomington, IN 47405.

Intracellular recordings and Lucifer Yellow stainings reveal that ganglion cell types G3, G4, G6, G7, G9, G13, G15, G19 and G20 of Kolb (1982) are directionally selective (DS). Impulse discharges of any cell type are more narrowly tuned in polar plots than are the underlying synaptic potentials, which lack null directions. Thresholding makes the synaptic potentials narrowly tuned like the impulse discharges.

The masked drifting gratings used elicited periodic synaptic potentials. For G3, G15 and G19 ON-OFF cells, the dominant harmonic was the supra-threshold stimulus fundamental in preferred directions but the sub-threshold second harmonic in anti-preferrred directions (the frequency doubling expected from ON-OFF cells). In most cells tested, the amplitudes of periodic responses in preferred and anti-preferred directions were nearly the same (nonDS) for small mask apertures, became maximally different (DS) at some optimal intermediate aperture, and became the same again at still larger apertures. These optimal mask apertures were either ≤ (G6, G15, G19, G20) or ≥ (G3, G7, G9) dendritic field diameters. The latter cells thus had DS centers larger than their dendritic fields. G7 and G20 cells also had dynamic, DS, inhibitory surrounds with preferred directions opposite to their centers. In contrast, optimal diameters of flashed spots were always ≤ dendritic field diameters. Only G19 cells lacked static inhibitory surrounds.

GABA AND FACILITATION IN TURTLE RETINAL DIRECTIONAL SELECTIVITY. Randall D. Smith*, Norberto M. Grzywacz, and Lyle J. Borg-Graham, Center for Biological Information Processing, MIT, E25-201, Cambridge, MA 02139 and the Smith-Kettlewell Institute.

Barlow and Levick (1965) proposed a model for retinal directional selectivity based on an asymmetric inhibitory process. Later experiments (Caldwell et al., 1975, Ariel and Adolph, 1985, Smith et al., 1991) indicated that GABA (an inhibitory neurotransmitter in the retina) is important in the production of directionality. The first question addressed in this work is: 1) Is GABA the output of an asymmetric process responsible for directional selectivity? Another mechanism that might contribute to the directionality is preferred-direction facilitation (Barlow and Levick, 1965; Grzywacz and Amthor, 1988). The second question we address is: Is there an asymmetric facilitatory process that contributes to directional selectivity?

We examined the effect of picrotoxin (a GABA_A antagonist) on directional selectivity for a range of contrasts and speeds. In 36% of the cells, we found a motion asymmetry despite saturating concentrations of picrotoxin. In 26% of the cells, the preferred and null directions were actually reversed. These results indicate that GABA is not the output of an asymmetric process, which mediates directional selectivity.

To answer the second question, we used apparent-motion protocols. The results show preferred-direction facilitation for the control condition and preferred- and null-direction facilitation for the picrotoxin condition. This strongly suggests that facilitation does not contribute to directional selectivity independently of GABA. We will present a model based on amacrine input/output asymmetry that accounts for these results.

549.13

DISTINGUISHING MODELS OF DIRECTIONAL SELECTIVITY WITH PATCH CLAMP RECORDINGS FROM AN ISOLATED RETINA PREPARATION OF TURTLE. Lyle Borg-Graham and Norberto M. Grzywacz, Center for Biological Information Processing, MIT, E25-201, Cambridge, MA 02139, and the Smith-Kettlewell Institute.

Several lines of evidence strongly suggest that an inhibitory process underlies retinal directional selectivity (Barlow and Levick, 1965; Wyatt and Daw, 1975; Ariel and Adolph, 1985). A model for this computation postulates that this inhibitory process works at the dendritic tree of the directionally selective (DS) ganglion cell (Torre and Poggio, 1978). Alternatively, a recent model postulates that this inhibitory process acts on the dendritic tree of an amacrine cell and hence, that the input onto the ganglion cell is already DS. In this model, the dendrites receive distributed excitatory and inhibitory inputs and output the ganglion cell via the dendritic endings. The dynamics of the inputs and the cable properties of the dendrites make the output of these dendrites DS.

To distinguish these alternatives, we recorded the responses of directionally selective ganglion cells of turtle to moving stimuli under conditions in which the inhibitory input onto these cells has been dramatically reduced. The recordings used a whole-cell patch clamp technique in an isolated retina preparation (Borg-Graham and Grzywacz, 1991). With this technique, we reduced the inhibitory input onto the ganglion cell in two ways: 1) by voltage clamping the cells to the reversal potential of the inhibitory currents and 2) by removing ATP-Mg++ from the patch electrode. Under dramatically reduced inhibition, directional selectivity was essentially unaffected. Therefore, we conclude that the input to the ganglion cell is DS.

ON AND OFF RESPONSES FROM OPTIC NERVE COMPOUND ACTION POTENTIAL RECORDINGS IN TWO TELEOST FISHES. C.W. Hawryshyn, L. Beaudet, and H.I. Browman, Dept. of Biology, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2.

We characterized the photopic spectral sensitivity (340 to 720 nm) of adult African cichlids (Haplochromis burtoni) (HB), and large (> 55 g) rainbow trout (Oncorhynchus mykiss) (OM), using optic nerve compound action potential recordings. The ON responses in both species exhibited sensitivity peaks corresponding to S, M, and L wavelength photoreceptor mechanisms. In HB, these peaks occurred at 450-460 nm, 540-550 nm, and 590-610 nm, whereas in OM, the peaks were recorded at approximately 440 nm, 540 nm, and 620 nm. The OFF response in both species was characterized by two broad peaks in the S and L wavelength parts of the spectrum. Under a M and L wavelength adapting background, the relative sensitivity of the OFF response (from 500-700 nm) in HB was consistently higher than that for the ON. However, under the same conditions, the relative sensitivity of the OFF response in OM was consistently lower than that for the ON. L.B. was supported by a NSERC Canada Postgraduate Scholarship, H.I.B. by a MRC Canada Postdoctoral Fellowship, and C.W.H. by a NSERC Canada URF and Operating Grant (# URF 0043984). We thank R.D. Fernald for supplying the cichlids.

CIRCADIAN RHYTHMS IN THE JAPANESE QUAIL RETINA

N.F. Buelow, M.E. Kelly, H. Uchiyama, R.B. Barlow, Jr.
Institute for Sensory Research, Syracuse University, Syracuse, New York

Retinal sensitivity of the Japanese quail exhibits a circadian rhythm. When the animal is held in constant darkness, retinal sensitivity as measured by the ERG b-wave, increases at night and decreases during the day (Uchiyama et al., Neurosci, Abstr., 16, 1333, 1990). Spectral sensitivity also shifts with time of day. Maximum spectral sensitivity is about 500 nm at night reflecting rod-dominance and about 600 nm during the day reflecting cone-dominance. thus the change in rod-cone dominance of the retina (Purkinje shift) is controlled in part by an endogenous circadian clock.

What is the origin of the circadian changes in the retina? To investigate this question we analyzed both the photoreceptor (a-wave) and postphotoreceptor (b-wave) components of the ERG and found that only the b-wave exhibits a circadian rhythm in amplitude and spectral sensitivity. The spectral sensitivity of the a-wave is broad and does not change with time of day. We tentatively conclude that the circadian clock does not modulate photoreceptor sensitivity directly but rather influences the pathways that carry those signals to the inner retina.

Retinal levels of melatonin and dopamine have been found by others to undergo circadian changes in galliform birds. We are currently investigation whether those neuromodulators have a role in the circadian rhythm of the quail retina.

549.16

CENTRIFUGAL INPUTS ENHANCE VISUAL RESPONSES OF RETINAL GANGLION CELLS WITHOUT CHANGING THEIR SPATIAL CODING PROPERTIES IN THE JAPANESE QUAIL.

H. Uchiyama[1,2] and R.B. Barlow, Jr.[1] [1]Institute for Sensory Research, Syracuse University, NY 13244-5290; [2]Department of Anatomy, Nippon Medical School, Tokyo 113, JAPAN

Stimulation of the centrifugal fibers enhances visual responses of the retinal ganglion cells (RGC) of birds. The effect has been attributed to disinhibition, that is reduction of the inhibitory surround of the receptive field of the RGC (Miles,'72). The inhibitory surround is thought to contribute significantly to the contrast sensitivity of the RGC, and thus disinhibition of the surround may decrease contrast sensitivity. However, a behavioral study showed that transection of the centrifugal fibers projecting to the retina does not cause any major change of visual acuity of the pigeon (Knipling,'78). To further investigate this problem, we studied the effects of the centrifugal inputs on the spatiotemporal properties of the RGC receptive fields of the Japanese quail. Urethane-anesthetized, curarized animals were used. Spatial frequency analysis showed that stimulation of the centrifugal fibers enhanced the responses of > 60% of single optic nerve fibers without changing the shape of their spatial frequency turning curve. Centrifugal inputs also changed the temporal response properties of some units. The present results do not support the conclusions of the previous studies, but suggest that the centrifugal inputs enhance visual responses of the RGC through the neural circuits that are independent of the center-surround organization of the receptive field.

UV Light Modulates the Retinal Sensitivity of *Limulus*.

E.D. Herzog and R.B. Barlow, Jr.
Institute for Sensory Res., Syracuse Univ., Syracuse, NY 13244

Ultraviolet light enhances the circadian rhythms in the sensitivity of the *Limulus* lateral eye (Westerman and Barlow, 1983). Ambient UV light is sensed by a pair of frontal eyes called median ocelli. At night, this UV information is transmitted by optic nerve activity to a circadian clock located in the brain. The ocellar input enhances the clock's neural output. Efferent optic nerve fibers feed the clock's output back to the ocelli and lateral eyes enhancing their sensitivity. As a result, retinal sensitivity is 0.5 log units higher at night under UV illumination than in complete darkness.

Nighttime UV illumination of the ocelli enhances retinal sensitivity; daytime illumination does not. Exposing the ocelli to environmental light at any time during the night increases sensitivity of the lateral eyes within minutes. Blocking UV illumination (<430nm) of the ocelli at night decreases lateral eye sensitivity while blocking visible wavelengths (>360nm) has no effect.

The ocellar influence on retinal sensitivity may have a role in the animals' nocturnal mating behavior which is known to involve vision. Both starlight and moonlight contain significant levels of UV light. At night, sufficient amounts of UV light can penetrate the water column to a depth of 10 meters to stimulate the median ocelli . Knowing all this, we still do not understand what role UV light may have in the animals' behavior.

SUBCORTICAL VISUAL PATHWAYS: CORTICAL INPUTS AND SUBCORTICAL RESPONSES

550.1

PROPERTIES OF CELLS IN AREA 17 PROJECTING TO THE CAT'S LATERAL POSTERIOR-PULVINAR COMPLEX.

C. Casanova. Dept. of Ophthalmology, Faculty of Medicine, University of Sherbrooke, Sherbrooke, Canada, J1H 5N4.

The main visual input of the lateral part of the lateralis posterior nucleus (LPl) comes from the striate cortex. When compared with cortical units, cells in LPl have properties similar to those of complex rather than simple cells. Anatomical studies have indicated that cortico-LPl cells are mainly located in layer V of areas 17 and 18 were most complex cells lie. We have investigated the properties of cortical units antidromically activated from the LPl and from the superior colliculus (SC).

Experiments were performed with anesthetized and paralyzed normal adult cats. Bipolar stimulating electrodes were placed in LPl and SC. A first set of electrodes was placed in the superficial layers of SC. Multi-unit responses were recorded from an electrode placed in successive latero-medial positions in the LGN. The location of LPl was derived from these recordings. Tungsten-in-glass microelectrode was used to record from cells in area 17. Receptive fields were stimulated with drifting gratings.
