EXPRESSION OF C-JUN PROTEIN IN SCHWANN CELLS DEPENDS ON THEIR ENVIRONMENT. **E.Vaudano*[1,3], C.de Felipe[2], S.W.Davies[3], A.R.Lieberman[3] and S.P.Hunt[2]. [1]Dip. Anatomia e Fisiologia Umana, Univ. di Torino, Italy, [2]Molecular Neurobiology Unit, Cambridge, UK, and [3]Dept. of Anatomy and Dev. Biology, University College London, London, UK**

The Schwann cell, in contrast to glia derived from the adult CNS, is considered a permissive substrate for axonal regeneration. CNS neurons can regenerate an axon inside a peripheral nerve graft implanted into the CNS, although such regeneration is very limited in comparison with regeneration in the PNS. We show that the expression of the transcription factor c-jun in Schwann cells of adult rats is differentially regulated according to whether the cells are exposed to a PNS or CNS environment. Jun protein was studied in Schwann cells of adult rats in vivo and in vitro using a polyclonal antibody. c-jun mRNA was localized and quantified using in situ hybridization with radiolabelled oligonucleotides. In the intact tibial nerve, Schwann cells were Jun negative. However one week after transection of the nerve all Schwann nuclei in the distal stump are Jun positive. In contrast, if a segment of tibial nerve was cut and immediately autografted with one end (proximal tip) in the thalamus or the cerebellum, and the other end (distal tip) left free subcutaneously, only the Schwann cells in the distal tip had Jun positive nuclei, while Schwann cells in the portion of nerve deep within the CNS remained Jun negative. When Schwann cells were grown in vitro from dissociated adult dorsal root ganglia and peripheral nerve, c-jun mRNA and Jun protein were expressed at high levels within 24h of plating. These levels could be substantially reduced by treatment of cultures with dibutyryl cyclic AMP or forskolin. Thus it appears that the CNS environment also contains factors which can inhibit the upregulation of c-jun. The genes regulated by c-jun in Schwann cells are not known but they might well be involved in the ability of these cells to potentiate axonal regrowth, explaining at least in part, the relatively poor regenerative response of CNS neurons inside peripheral nerve autografts.

THE DEVELOPMENTAL REGULATION OF GROWTH FACTOR RECEPTOR EXPRESSION IN THE RAT SCIATIC NERVE: CORRELATION WITH THE PERIOD OF SCHWANN CELL PROLIFERATION. J. B. Davis*, The Salk Institute, PO Box 85800, San Diego, CA 92186.

During the development and myelination of peripheral axons, Schwann cells go through consecutive periods of proliferation, growth arrest, and differentiation. Schwann cell proliferation declines rapidly after birth (P0), inversely correlated with the onset of myelin gene expression.

The control of Schwann cell proliferation during the developmental process might be achieved by : (a) levels of growth factor, (b) control of Schwann cell receptor expression, or (c) a dominant inhibitory signal. In order to test (a & b), we have studied the expression levels, in sciatic nerves, of PDGF and FGF, and their receptors, over the P0-P14 period, by means of northern analysis.

There is a rapid decline in FGF and PDGF-B receptor mRNA expression over P0-P3, which correlates with the rapid decrease in Schwann cell proliferation rate over the same period. In contrast, the expression of the mRNAs for the growth factors remains constant, PDGF-B chain mRNA is absent, whilst FGF expression is retained in the adult. These data are consistent with the theory that regulation of growth factor receptor expression might control Schwann cell proliferation during development.

DEVELOPMENT OF NEURONAL AND MESODERMAL COMPONENTS OF THE ELASMOBRANCH VIth NERVE AND LATERAL RECTUS MUSCLE. E. Gilland, R. Baker and R. Gould*. Marine Biological Laboratory, Woods Hole, MA 02543

Neuroepithelial and mesodermal components associated with the VIth nerve were studied by means of paraffin sections, SEM and the application of lipophilic fluorescent dyes in *Squalus acanthias* embryos. Motoneurons originated in rhombomere 6 and by Stage 23 axons exited into a mesenchymal matrix far caudal to the mesodermal precursors of the lateral rectus. Fiber outgrowth occurred later than any other cranial nerve except IV. By Stage 24 VIth nerve growth cones were observed to contact two separate epithelial-like rudiments of mesodermal origin. A distinct hyoid-derived component was located medial to the Vth ganglion and a mandibular component, Platt's muscle E, lay slightly more rostral. Each pre-migratory muscle rudiment received a separate VIth nerve branch. Confocal microscopy showed that some dye labelled abducens motoneurons in contact with the mesodermal targets retained ventricular attachment in the neuroepithelium. Between Stages 25-27 the two pre-muscle masses maintained their epithelial organization while extending forward onto the globe where, by Stage 29, they merged together. These observations demonstrate an autonomous development of two separate mesodermal derivatives that each receive a VIth nerve branch. Both moieties are displaced rostrally before fusing to form a common lateral rectus muscle. A caudally directed VIth nerve branch associated with the most caudal VIth nerve rootlet was present at Stages 26-29. Dye applied to the caudal branch labelled peripheral ganglion-like cells and showed entry of fibers into the neuroepithelium, but revealed no motoneurons. These data suggest that this nerve may originate from one of a series of ectopic neural crest-derived ganglia associated with the cranial nerves.

DEVELOPMENT OF NORADRENERGIC INNERVATION IN THE RAT HYPOGLOSSAL NUCLEUS. L.D. Aldes*. Dept. of Structural and Cellular Biology, Univ. S. Alabama, College of Medicine, Mobile, AL 36688

Although the functions of norepinephrine (NE) in the central nervous system remain speculative, recent studies have provided evidence that NE plays an important modulatory role in somatic motor reflexes. Studies from this laboratory have established a unique NE innervation pattern in the hypoglossal nucleus (XII) of the adult rat. Since tongue protrusor motoneurons are the principal targets of NE-nXII afferents, and this motoneuron group plays a crucial role in several oral behaviors, the sequence of NE pattern development in XII was investigated in the rat. This was accomplished immunocytochemically with antisera to tyrosine hydroxylase (TH). Experiments were conducted in Sprague-Dawley rats of both sexes. For prenatal studies, rat pups were removed surgically on gestational days (GD) 16-21 and euthanized by decapitation. Brains were fixed by immersion in aldehydes. For postnatal studies, pups ranging from 12 hrs to 40 days were perfused-fixed transcardially. Brainstem sections were cut serially through XII, incubated in anti-TH (1:20,000), biotinylated goat-anti-rabbit IgG (1:1,000), and steptavidin HRP (1:1,000) before reacting with DAB/H_2O_2. Results from this study include the following: 1) TH immuno-reactivity is initially found in XII on GD 16/17; 2) preferential targeting of protrusor motoneurons is first observed on GD 17/18, but is not consistently present until GD 19; and, 3) the density of NE innervation increases progressively from GD 19 to adulthood. These results establish the early prenatal presence of NE in XII of the rat, and suggest that the control of XII motoneurons and tongue reflexes by NE commences early in development. The temporal and spatial patterns of NE development in XII is interpreted as reflecting the importance of oral reflexes in both the newborn and adult.

MORPHOMETRIC CORRELATIONS BETWEEN MOTONEURONS AND MUSCLE FIBERS IN DEVELOPING RAT MUSCLES. W.Z. Zhan,* Y.S. Prakash and G.C. Sieck. Mayo Clinic and Foundation, Rochester, MN 55905.

It has been proposed that there is a relationship between motoneuronal size and the size of its peripheral field, i.e. motor unit (MU) size. In the rat, by postnatal day 21 (D21), synapse elimination and myogenesis is complete for the diaphragm (DIA) and medial gastrocnemius (MG) muscles. We hypothesize that subsequent growth of muscle fibers is paralleled by growth of phrenic and lumbar motoneurons (MNs). We obtained estimates of muscle fiber volume by measuring optimal fiber length and fiber cross-sectional area (CSA). Phrenic and lumbar MNs were retrogradely labelled with tetramethylrhodamine dextran via intramuscular injection. "Optical slices" of labelled MNs were obtained using a Bio-Rad Laser Confocal microscope. In both muscles at D21, type I and II muscle fibers were comparable in size, while type II fibers were larger in both adult muscles. Adult MG fibers were significantly larger than DIA fibers. Since innervation ratios are constant by D21, postnatal changes in fiber volume reflect MU growth. Phrenic MN somal volumes doubled between D21 and 10 weeks (adult), while lumbar MNs nearly tripled in size. At each age lumbar MNs were larger than phrenic MNs. This is consistent with the growth in MU size in the two muscles, although MU growth was not in direct proportion to changes in somal volume. A bi-modal distribution of somal volume was evident in adult MG MNs, but less so in the phrenic pool. We speculate that the bi-modal MN volume distributions reflect differences between slow and fast twitch MUs. Bi-modal distributions were less obvious at D21, which may reflect the absence of heterogeneity in fiber CSA between different muscle types at that age. Supported by NIH grants HL34817 and HL37680.

A motor neuron-specific epitope and the low-affinity nerve growth factor receptor display reciprocal patterns of expression during development, axotomy and regeneration. A.Y. Chiu,* E.W. Chen and S. Loera, Division of Neuroscience, City of Hope, Duarte, CA 91010.

Embryonic motor neurons express the low-affinity Nerve Growth Factor receptor (NGFr). However, in postnatal life, they lose NGFr-immunoreactivity, and acquire a motor neuron-specific epitope that is recognized by the monoclonal antibody, MO-1. We examined the effect of nerve injury on these two developmentally regulated markers in two populations of somatic motor neurons. Unilateral transection, ligation or crushing of the sciatic nerve resulted in loss of MO-1 binding and a concomitant rise in NGFr-immunoreactivity within motor neurons in lumbar levels of the spinal cord. Transection of the hypoglossal nerve, a pure motor nerve, resulted in a similar loss of MO-1 binding and a selective rise in NGFr immunoreactivity in neurons within the ipsilateral hypoglossal motor nucleus. These changes, detectable within 5 days following nerve injury, are reversed with reinnervation, but persist if reinnervation is prevented by chronic axotomy. Thus, regulation of the expression of NGFr and the MO-1 epitope appears to be dependent upon interactions between motor neurons and target muscles. These observations are also consistent with the idea that regenerating neurons may revert to a developmentally immature state; in the case of motor neurons, this state is characterized by the presence of NGFrs and the absence of the MO-1 epitope.

THE ROLE OF EXTRACELLULAR CALCIUM AND CALCIUM CHANNELS IN ACTIVITY DEPENDENT INTRACELLULAR CALCIUM CHANGES IN EMBRYONIC CHICK MOTONEURONS. Michael O'Donovan* and Stephen Ho. Lab. of Neural Control, NINDS, Bethesda, MD, 20982

Imaging studies have revealed that spinal neurons in the chick embryo accumulate intracellular calcium during spontaneous activity through an unknown mechanism. Here we examine the mechanisms responsible for activity dependent calcium accumulation in motoneurons retrogradely filled with fluorescent dextran-conjugated calcium sensitive dyes: fura-2 and calcium green. Fluorescent responses were monitored using real-time intensified video-microscopy during stimulation of spinal nerves or ventral roots. Fluorescent changes could be detected in motoneurons following a single stimulus and progressively increased in amplitude during stimulus trains (1-5 sec) at frequencies from 5-50Hz. The single stimulus transient peaked within 2-3 video frames after the stimulus, exhibited an approximately exponential decay with a 1/2 width of ~200 msec, which was briefer than transients recorded from dorsal root ganglion cells, but similar to transients in motoneurons loaded with fura-2AM. Fluorescent responses were almost abolished during perfusion with 0 Ca^{++}, and exhibited a dependence on the extracellular concentration of Ca^{++}. They were increased during perfusion with 4-aminopyridine (2.5 mM), and could be depressed by Ni^{++} (100-200 μM) and dihydropyridines (20-50 μM). A significant stimulus-induced fluorescent change remained in the presence of Ni^{++} and dihydropyridenes that could be blocked by Cd^{++}. These results suggest that the intracellular calcium changes accompanying action potentials in embryonic chick motoneurons are the result of calcium entry through low and high voltage activated calcium channels, although we cannot exclude a contribution from Ca-induced release from intracellular stores.

ONTOGENY OF MOTONEURONS, ACETYLCHOLINE AND MUSCLE FIBERS IN THE VOCAL MOTOR CIRCUIT OF A TELEOST FISH. M. Marchaterre*, M. Lindholm and A. Bass. Section of Neurobiology and Behavior, Cornell Univ., Ithaca, N.Y. 14853 and Bodega Marine Laboratory, Univ. California, Bodega Bay, CA. 94923.

Sexually mature males and females of the plainfin midshipman (*Porichthys notatus*) vocalize by the simultaneous contraction of sonic muscles attached to the lateral walls of the swimbladder (review: TINS 15:139). Previous studies have demonstrated that each muscle is innervated ipsilaterally by motoneurons located in caudal brainstem sonic motor nuclei. Biocytin was used as a retrograde tracer to identify paired, midline sonic motor nuclei in specimens ranging from 0.85-2.5 cm total length (~14-40 days post-fertilization). Following ipsilateral applications of biocytin to the sonic muscle, there is a Golgi-like filling of motoneurons; label is bilateral with increasing survival times. During these stages, myofibers differentiate and sonic motor axons form 'typical' neuromuscular junctions (cf. Brain Res. 251:312). Surprisingly, sonic motoneurons at these stages do not express choline acetyltransferase (ChAT), the rate limiting enzyme in the synthesis of acetylcholine. In contrast, other nearby motor nuclei are ChAT-positive, as are sonic motoneurons in sexually mature adults (AB8 monoclonal antibody; cf., J. Comp. Neurol. 275:87). The results suggest that: (1) acetylcholine synthesis is not requisite for early events in motoneuron and muscle fiber differentiation in this vocal pathway, and (2) there is late onset of ChAT expression, perhaps linked to sexual differentiation of the vocal motor phenotype. THE ONTOGENESIS OF PROPRIOSPINAL CONNECTIONS IN THE OPOSSUM, MONODELPHIS DOMESTICA. G. Cassidy* and T. Cabana. Sciences biologiques, Université de Montréal, C.P. 6128, Succ. "A", Montréal, QC, Canada, H3C 3J7.

The small Brazilian opossum *Monodelphis domestica* is born more immature than placental mammals. At birth, the hindlimbs (HL) are little more developed than embryonic buds that do not move independent of the trunk, and HL muscles are not all individualized (Astrow & Thompson, Soc. Neurosci. Abst. 153.5, 1989). It is possible to observe postnatally the development of HL motility and the coordination between them and the forelimbs (Cassidy *et al.*, Soc. Neurosc. Abst. 377.6, 1991). Furthermore, supraspinal centers have not reached the lumbosacral enlargement (LS) of the cord at birth (Wang *et al.*, Soc. Neurosci. Abst. 377.4, 1991). In view of such immaturity of the newborn opossum's HL, we sought to verify if the connections between the two enlargements of the spinal cord, which contribute greatly to interlimb coordination and are more precocious than most projections descending from the brain, are established at birth. We have used DiI and WGA-HRP as retrograde markers to study those connections. At day 1, projections to LS originate mainly from the ventral horn of the brachial enlargement, presumably from presumptive laminae VII-VIII, and, to a lesser extent, from presumptive laminae V-VI. Projections from these laminae increase after birth and those from the more dorsal lamimae (Cabana & Parent, Soc.Neurosc. Abst. 282.2, 1989) are added. A proportion of propriospinal connections is thus established well before any behavioral evidence for them. Supported by NSERC.

EVIDENCE FOR SELECTIVE REINNERVATION IN ADULT CAT TIBIALIS ANTERIOR MUSCLE. G. A. Unguez*, S.C Bodine-Fowler, R.R. Roy, D.J. Pierotti and V.R. Edgerton. Dept. Physiological Science and Brain Research Inst., UCLA, LA., CA 90024 and Dept. Orthopaedics, UCSD, SD, CA 92039.

It is often assumed that following axotomy, reinnervation of adult mammalian muscle is non-specific for fiber type and that the consequential heterogeneity that results from the random reinnervation eventually becomes homogeneous as a result of fiber type conversion (Karpati & Engel, *Neurol* 18:447, 1968). We examined the fiber type composition of motor units (MUs) 6 months after the nerve branches innervating the anterior compartment of the tibialis anterior (TA) were cut and resutured in adult female cats. MUs were isolated via ventral root teasing, physiologically characterized and glycogen depleted (Bodine et al *J Neurophysiol* 57:1730, 1987). Fibers were typed using monoclonal antibodies specific to myosin heavy chains (MHCs) (provided by Dr. S. Schiaffino, Padova, Italy).

Based on MHC composition, at least 2 fiber types were observed in each of the 9 MUs (S, n=1; FR, n=6; FI, n=2) analyzed. Each unit, however, was markedly biased towards one fiber type. In one unit, 3% of the fibers coexpressed slow and fast MHCs within the same fiber. Chi-square analyses showed significant differences ($p<0.05$) between the observed frequencies of each fiber type within a MU and the frequency of occurrence of each fiber type within the territory of the unit. This suggests that the reinnervation process was not random. The mean percentages of slow (10%) and fast (90%) fibers in reinnervated muscles were similar to that of control TA muscles. Further, after self-reinnervation, the distribution of unit fibers expressing different MHCs within a unit displayed a normal gradient of fiber types across the muscle compartment, i.e. the proportions of slow, high oxidative fibers decreased, and fast, low oxidative fibers increased along the deep-superficial axis of the muscle. In spite of a greater than normal incidence of MU fibers to be adjacent (Bodine-Fowler et al *Muscle & Nerve* In Press), fiber type grouping was not apparent in any self-reinnervated muscles. Together, these data are consistent with the interpretation that TA motoneurons selectively reinnervated fibers and that this process was highly correlated with MHC expression. (Supported by NIH Grant NS16333).

MORPHOLOGIC AND FUNCTIONAL EFFECTS OF PHENOL ON PERIPHERAL NERVE AND MUSCLE S.C. Bodine-Fowler*, F.L. Dulbecco, L.R. Kitabayashi and M.J. Botte Dept. Orthopaedics, UCSD School of Medicine and VA Medical Center, San Diego, CA 92161-9151

Intraneural or perineural phenol injection is an accepted procedure used to produce a temporary but long lasting peripheral motor nerve block in spastic muscle. The purpose of this study was to evaluate the morphologic and functional effects of phenol application on peripheral nerves and skeletal muscles and to establish the degree to which nerve and muscle recover after the nerve block. A 5% aqueous solution of phenol was applied to the sciatic nerve of the rat by intraneural injection using a 30-gauge hamilton syringe or by bathing the the entire nerve with the solution. Phenol was injected into the nerve or applied extraneurally until a complete motor block was produced, i.e., no detectable nerve conduction or contraction of lower limb muscles. At 2 days, 1 wk and 2 wks the sciatic nerve and soleus (SOL) and tibialis anterior (TA) muscles were removed. At each time period, muscle contraction could not be elicited with stimulation of the sciatic nerve proximal to the site of phenol application. Phenol produced extensive degeneration of the axons and demyelination of the nerve fibers resulting in denervation of the SOL and TA muscles. At 2 days there was no significant atrophy in the SOL or TA. At 1 wk, the weights of the SOL and TA were 66 and 82% of control values, respectively. At 2 wks, the weights of the SOL and TA were 51 and 50% of control values, respectively. In general, the slow fibers atrophied more rapidly than the fast fibers. Phenol appears to produce a motor block by causing axonal degeneration without damaging the endoneurial tube. The degree to which axons reinnervate the appropriate muscle remains to be determined.

MILK PROMOTES COUPLING OF BEHAVIORAL SETS IN THE FETAL RAT. S. R. Robinson* and W. P. Smotherman. Laboratory of Perinatal Neuroethology, Center for Developmental Psychobiology, SUNY-Binghamton, Binghamton, NY 13902-6000.

During the late prenatal period, fetal rats exhibit spontaneous motor activity that is characterized by synchrony of movement, sequential organization, and temporal patterning (bout structure and cyclicity). The prenatal emergence of motor organization also is evident in the expression of behavioral sets: discrete periods of time comprising patterns of behavior that are similar based on their spatial or temporal distribution. In the present study, fetal rats were directly observed on day 20 of gestation during 60-min sessions to characterize behavioral sets defined by spatial (part of the body) or temporal (intervals between successive movements) criteria . Motor activity comprising rostral elements (head, forelimbs) tended to alternate with periods predominated by caudal elements (rearlimbs). Simulation studies employing Monte Carlo techniques indicated that the duration of spatially-defined sets was longer than expected if rostral and caudal movements were randomly ordered. Sets defined by temporal criteria (variability of inter-movement intervals) also persisted longer than expected by chance. In the absence of explicit stimulation, periods of high or low rearlimb activity and periods of high or low interval variability were poorly associated. However, a single 20 µl infusion of milk (bovine light cream) into the mouth of the fetus increased the duration of rostral-caudal sets and promoted synchronization of spatial and temporal variables. The independence and stimulus-evoked coupling of these behavioral variables in altricial rat fetuses suggests that behavioral state organization may result from self-organization and not from the maturation of central regulatory mechanisms during the prenatal period.

ELECTRICAL ACTIVATION AND INHIBITION OF RESPIRATION IN VITRO. O. Hamada*, E. Garcia-Rill and R.D. Skinner, Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR

Previously we reported that the rib-attached brain stem spinal-cord preparation in vitro showed spontaneous rhythmic respiratory movements at a consistent rate around 0.1 Hz at a temperature of 25°C . Transection at the pontomedullary level caused an immediate increase in respiratory rate to 0.2 Hz, and exposure to high temperature (33°C) increased the rate as high as 0.3 Hz. We also were able to dictate the onset of respiratory activity with electrical stimulation of the cervical cord and drove it to 0.2 Hz (Hamada et al. 1991). Previous in vitro studies have shown that electrical stimulation of the caudal ventrolateral pons inhibited the respiratory rhythm generated by the medullary respiration generator (Hilaire et al, 1989).

The present study was undertaken to determine the effect of electrical stimulation delivered to the medulla, the pons and the combination of both so some of the functional interactions within the brain stem could be revealed. 25 S-D rats aged 0-2 days were used in this study. Stimulation required to activate respiration consisted of low frequency pulses (0.2-0.4 Hz) and the most effective area was the ventromedial medulla. In 15 of 19 cases, stimulation at 0.2-0.3 Hz activated respiration at the same frequency using low amplitude currents (23.3±13.5µA at 0.2 Hz, 24.7±13.6 µA at 0.3 Hz). In 7 out of these 15 cases, respiration followed 0.4 Hz stimulation. Stimulation of the pons at low (0.1-0.4 Hz) frequency did not activate respiration, whereas stimulation of the pons at high (3-10 Hz) frequency inhibited spontaneous respiration. The ventrolateral pons had a lower threshold for inhibition than the ventromedial pons (24.0±5.6 µA, 34.0±8.9 µA, respectively) and poststimulus inhibition was evident only when the ventrolateral pons was stimulated.

Our results suggest that the ventromedial medulla was most effective in driving, and the ventrolateral pons was more efffective than the ventromedial pons in inhibiting, respiratory activity. They also suggest that the upper limit of the respiratory rate generated in the medulla in this preparation is approximatley 0.4Hz.

CENTRAL PATTERN GENERATORS AS REGIMES OF OPTIMAL MOTOR CONTROL SYSTEM FUNCTIONING. K.V. Baev*, Yu.P. Shimansky, Dept. of Physiol. of the Spinal Cord, A.A.Bogomoletz Inst. of Physiol., 252024 Kiev, Ukraine.

It was shown in experiments on scratching and locomotor reflexes in decerebrate cats that the most important peculiarities of their afferent control are common to the corresponding central pattern generators (CPGs). A concept of universal spinal motor control system, which is capable of controlling movements of both postural and rhythmic types by using the same functional mechanism, is put forward. From the mathematical view-point, this system should be considered as an optimal control system possessing, for its optimality, the intrinsic model of the object it controls. Thus, the problem of afferent control of CPGs is, actually, the problem of the mechanism of interaction between peripheral afferent inflow and the internal flow originated from the controlled object model. The key role of presynaptic inhibition in this interaction is revealed.

These ideas allow to ascribe functional meanings to all the main ascending spinal cord pathways. Ascending tracts convey informational signals of three types: i. about the current phase state of the controlled object obtained during the above interaction; ii. information about peripheral events not covered by the internal model; iii. information on mismatch between real peripheral events and those predicted by the internal model. A concept of interaction between the spinal motor control system and higher brain motor control sub-systems during control of complex motor automatisms and learning is suggested.

INFLUENCE OF THALAMIC PROJECTION PATTERNS ON DENDRITIC MORPHOLOGIES OF CELLS IN LAYER 4 IN CAT VISUAL CORTEX. A.Kossel* and J.Bolz, Friedrich-Miescher Labor der Max-Planck Gesellschaft, 7400 Tübingen, Germany

Thalamocortical afferents in layer 4 of the primary visual cortex are segregated according to eye of origin into alternating patches that represent the system of ocular dominance (OD) columns. The activity-dependent formation of OD columns during development and its perturbation by visual deprivation during the critical period has been thoroughly studied at the level of the thalamic afferents. However, it is not known whether this reorganization of the presynaptic terminals is accompanied by a remodeling of their postsynaptic target cells in layer 4. In the present study we made *in vivo* injections of the fluorescent tracer DiI into layer A of cat LGN to label anterogradely thalamic afferents of one eye only. By intracellular injections of Lucifer Yellow in slice preparations we were able to visualize simultaneously the morphology of cells in layer 4 and the termination pattern of the thalamic afferents. A quantitative analysis of the dendritic branching revealed that spiny stellate cells with their somata in the middle of OD columns as well as in the middle of layer 4 had nearly radially symmetrical dendritic fields. Cells near the upper or the lower borders of the thalamic afferents showed strong asymmetries in their dendritic fields; their dendrites were for the most part confined to the afferent recipient zone. Finally, the dendrites of cells near the border between two OD columns showed a tendency to avoid crossing the OD borders. We also examined monocularly deprived animals and found that cells in deprived visual cortex also respected the upper and lower borders of the thalamic input zone. Likewise, cells in the columns of the open eye respected the OD borders. In contrast, cells in the deprived columns extended their dendrites into neighboring columns. These results indicate that the dendritic fields of cortical neurons are shaped by patterns of afferent inputs. Thus, the segregation of thalamic afferents into OD columns during normal development and its perturbation by visual deprivation plays a significant role in defining the structure of cortical neurons.

THE DEVELOPMENT OF GENICULOCORTICAL PROJECTIONS IN ORGANOTYPIC CULTURES. R.B.Lotto*, S.Rennie and D.J.Price. Dept. of Physiology, Univ. Med. Sch., Teviot Place, Edinburgh EH8 9AG, U.K.

Our aim is to investigate factors that influence the development of the projection from the lateral geniculate nucleus (LGN) to the visual cortex using an in vitro organotypic co-culture system. Explants of occipital cortex and LGN from prenatal and neonatal mice were cultured on collagen-treated filters suspended in a chemically defined serum-free medium. Axons growing from geniculate neurones were labelled with the carbocyanine dye, diI.

When the LGN from embryonic day 16 (E16) mice was cultured alone, large fiber tracts developed within it but appeared unable to emerge onto the collagen filter. However, the presence of the occipital cortex, or the use of medium conditioned by the occipital cortex, promoted the outgrowth of axons onto the filter.

These results suggest that the occipital cortex releases a diffusable factor that induces outgrowth from the LGN, although it is not necessary for growth within the nucleus. It is possible that this substance plays a role in directing geniculocortical axons towards the developing cortex in vivo.

551.3

EARLY DEVELOPMENT OF CORTICOCORTICAL CONNECTIONS IN THE CAT'S VISUAL CORTEX. D.Caric* and D.J.Price. Dept. of Physiology, Univ. Med. Sch., Edinburgh EH8 9AG, U.K.

Our aim was to investigate the early postnatal changes in the organization of the area 17-to-18 association projection.

We injected neuroanatomical tracers in the visual cortex of 1-30-day-old kittens. In some, the retrograde tracer diamidino yellow (DY) was injected in area 18 or the white matter below it, to label cell bodies in area 17. In others, the axons of association cells in area 17 were visualized with anterogradely transported carbocyanine dyes, DiI and DiA.

Our results with DiI and DiA reveal that axons from area 17 have reached area 18 at birth. The majority of these fibres project highly divergently and terminate in deep layers; a few penetrate the superficial layers at regions topographically related to the position of the injection. As the pathway develops, the topographic projection to the superficial layers becomes denser, while the exuberant projection to the deep layers is reduced. Results with DY confirm these observations: injections involving the deep layers of area 18 and the underlying white matter produce more widespread labelling of area 17 than those restricted to superficial layers.

TRANSITORY CORPUS CALLOSUM AXON TERMINALS IN RAT SHOW SYNAPSE FORMATION IN VISUAL CORTEX. A.J. Elberger*, M.M. Hester and S.-L. Ding. Dept. of Anatomy and Neurobiology, The University of Tennessee Memphis, Memphis TN 38163.

A previous study using DiI to label corpus callosum (CC) connections in rat revealed a substantial number of transitory CC axons extending throughout visual cortex that gradually disappear during the first postnatal month (Elberger, Soc. Neurosci. Abstr. 1991). These axons had large *en passant* and terminal swellings in all cortical layers; the swellings were hypothesized to be synapses. To evaluate this hypothesis in neonatal rats, biotinylated dextran amine was injected into the visual cortex of one hemisphere to anterogradely label CC axons. The rats were sacrificed during postnatal week 2 and coronal sections were histochemically processed (Veenman et al., J. Neurosci. Meth. 41:239, 1992). Slices were processed for electron microscopy and regions within area 17 were selected for further analysis.

Labeled CC axons were detected by their shape and homogeneous dark appearance. Some regions of enlarged axonal diameters appeared to form synapses because within the labeled axon there were numerous vesicles, many clustered near the axonal membrane. In addition, there was a second parallel membrane forming a cleft; in some cases, a densification was coincident with the second membrane. These features support the conclusion that transitory rat CC axons form synapses in neonatal cortex; these presumed synapses were located as superficially as layer I. The formation of synapses by the abundant transitory CC axons extending throughout visual cortex provides an extensive opportunity for the CC to influence the development of visual cortex. Supported by NIH grant EY08466 (AJE) and State of Tenn. Neuroscience Center of Excellence (SLD).

INTERHEMISPHERIC CONNECTIONS IN NEWBORN GALAGOS (*Galago crassicaudatus*) AND OWL MONKEYS (*Aotus trivirgatus*). P.D. Beck* and J.H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Interhemispheric connections of newborn primates were studied by injecting HRP and WGA-HRP at multiple sites in dorsolateral cortex of one cerebral hemisphere of three galagos and one owl monkey within the first postnatal week. Brains were cut in the coronal plane, or cortex was removed from the rest of the brain, flattened, and cut parallel to the surface to aid reconstructing surface-view patterns. In both primates, the total pattern of callosal connections was remarkably adult-like. In all regions of cortex, labeled neurons and processes were unevenly distributed, and there was no clear evidence of excessive exuberance. Callosal connections were concentrated along the 17/18 border in both primates, and they extended only a short distance into area 17 in owl monkeys. In galagos, area 17 was more extensively connected with the other hemisphere, and connections tended to overlap the CO blobs. In galagos, callosal connections were sparse in CO dense portions of S-I and dense in CO light portions. Such compartmentalization has not yet been reported in adult galagos, but it may be a common feature of S-I in mammals. (Supported by NEI EYO2686).

MORPHOLOGICAL DIFFERENTIATION OF LAYER 5 PROJECTION NEURONS FROM THE IMMATURE RAT VISUAL CORTEX STUDIED *IN VITRO*. Ekkehard M. Kasper* Joachim Lübke and Colin Blakemore. University Laboratory of Physiology and Dept.Human Anatomy, Oxford University, Parks Road, Oxford, U.K.

Recent studies have demonstrated that projection neurons in layer 5 (L5) of the adult rat visual cortex differ in their intrinsic morphological and physiological characteristics which are correlated with their respective axonal projection target (Kasper et al.,1991). Corticotectal neurons have a prominent apical dendrite extending into layer 1 where it forms an extensive arborisation. Interhemispherically projecting neurons possess a slender apical dendrite which tapers below layer 1 and does not arborize in form of an extensive terminal tuft.

To find out how early the two characteristic morphological types can be distinguished in cortical development, we have now studied L5 neurons in a fixed brain-slice preparation of late prenatal and early postnatal cortex (E17 - E19; P1 - P5). Brains were perfusion-fixed at various postnatal stages and coronal slices prepared. Individual cortical neurons were intracellularly injected with Lucifer Yellow, subsequently photoconverted, and drawn according to Buhl and Lübke (1989).

At E17 and E19, no morphological differences were observed between L5 neurons. However, at P5 corticotectal and interhemispherical neurons had aquired their distinct morphology.

LOCALIZATION OF NEURONS RETROGRADELY LABELED AFTER INJECTIONS OF ^{125}I-NGF INTO THE OCCIPITAL CORTEX OF RAT DURING POSTNATAL DEVELOPMENT.

L.Domenici*,[1]G.Fontanesi,[2]G.Traina,[2] P.Bagnoli,[3,4]A.Cattaneo and [5]L.Maffei. *Inst.of Neurophysiol.CNR, [1]Dept.of Physiol.and Biochem., [5]Scuola Normale Superiore,Pisa 56127; [2]Dept.of Environmental Science,Viterbo; [3]Inst.of Neurobiol.,CNR,Roma; [4]Sissa,Trieste,Italy.

We studied the distribution of neurons trasporting labeled NGF, injected in the rat occipital cortex at various postanatal ages. ^{125}I-labeled NGF (0.5-1 ul) has been injected into the posterior occipital cortex of rats at the postnatal age P14, P20, 3 months. NGF was iodinated by the chloramine T method (protein concentration=5 ng/ul; specific activity= $5x10^7$ cpm/ug). The animals were perfused (under chloral hydrate anaesthesia) 24 hours later. After an exposure time of 3 weeks, the autoradiograms were developed and the slices counterstained with Cresyl Violet. The results showed that NGF was taken up and retrogradely transported by forebrain neurons at all the postnatal ages investigated. After injection of NGF at P14 and P20 labeled cells were found within the visual cortex ipsilateral to the injection site. These cells were not found in adult rats (3 months). In conclusion, the present results confirm earlier findings in forebrain neurons projecting to the visual cortex (M.Seiler and M.Schwab,Brain Res.300:33-39,1984) and further suggest that in cortical cells, the expression of receptors for NGF or for related compounds could be modulated during postnatal development.

THE TOPOGRAPHIC ORGANIZATION OF PRIMARY VISUAL CORTEX (AREA 17) IN THE ALBINO FERRET M.P. Graham, E.V. Joynes and I.D. Thompson University Laboratory of Physiology, Parks Road, Oxford, OX1 3PT, U.K. (SPON: Brain Research Association)

Electrophysiological mapping of visual cortical receptive fields was performed on albino and pigmented adult ferrets (*Mustela furo*), which were anaesthetised (70:30 N_2O:O_2, Sagatal 1 mg/kg/hr) and paralysed (Flaxedil 35 mg/kg/hr). Electrophysiologically, the location of the 17/18 border was defined by a reversal in the progression of receptive field positions, and by qualitative changes in receptive field properties. The visuotopic mapping was subsequently related to cortical cytoarchitecture. In pigmented animals, area 17 contained a single visuotopic map of the contralateral hemifield, oriented as previously reported by Law et al. (1988). In the albino ferret, however, area 17 also included a representation of the ipsilateral hemifield, which was topographically continuous with that of the contralateral hemifield. The organization of the map is such that a given cortical site is associated with a single receptive field and the most ipsilateral fields are located adjacent to the 17/18 border. Such an organization is analogous to the "Boston" pattern reported for the Siamese cat (Hubel & Wiesel, 1971). The maximum extent of this ipsilateral representation ranged from 10° to 32° for different albino animals, compared with 2° to 4° for the pigmented animals. For a given animal, the extent of the ipsilateral representation increased with receptive field elevation; in one albino, for example, from just 9° ipsilateral at 13° below the horizontal meridian, to 20° ipsilateral at 10° above the horizontal meridian. (Receptive field positions are corrected for a standard optic disc projection of +30° azimuth and +11° elevation). We are now using anatomical techniques to investigate the development of the geniculocortical projections which presumably underlie these topographical arrangements.

DEVELOPMENT OF BINOCULAR VISUAL FUNCTIONS IN MONKEYS. Rick J. Brown, James R. Wilson, Yvette P. Veira, Jamie L. Goss and Ronald G. Boothe*. Depts. of Psychology, Ophthalmology, Anatomy & Cell Biology, and Yerkes Regional Primate Research Center, Emory University, Atlanta, GA 30322.

A number of characteristics of binocular vision are immature at birth and develop concurrently during postnatal development. These functions are often disrupted by visual deprivation rearing, but few norms are available regarding the exact sequence of emergence during normal development. Thus, it is impossible to differentiate deprivation effects that involve failure to develop from effects that involve deterioration. We are addressing this issue by using a combination of cross-sectional and longitudinal methods to track normal development of several binocular functions in infant rhesus (Macaca mulatta) monkeys. Our methodologies used for these assessments include visually evoked potentials (VEP), optokinetic nystagmus (OKN), preferential looking (PL), and corneal reflex photography. During the first few weeks after birth, ocular alignment changes from intermittent exotropia to predominantly orthotropic; stereoscopic sensitivity to horizontal disparity emerges, and there is a conversion of an immature motion response from a nasal directional bias to symmetry. Thus, visual deprivation has to begin shortly after birth in order to have the potential to disrupt emergence of these functions. Deprivation that begins later is more likely to involve deterioration than failure to develop. This situation contrasts with spatial resolution which continues to develop for several months, and thus remains susceptible for a longer period to both disruption of development and deterioration. DEVELOPMENT OF DISPARITY SENSITIVITY IN A CORRELATIONAL-BASED NETWORK MODEL OF THE VISUAL CORTEX REQUIRES TWO PHASES. GS Berns, P Dayan and TJ Sejnowski*, The Salk Institute, La Jolla, CA, 92037.

A correlational-based model of development of disparity sensitivity in the visual cortex was simulated. Two one-dimensional input layers, representing retinal and thalamic inputs from each eye, were fully connected to a single one-dimensional cortical layer with fixed intra-cortical connections. The weights were modified by a linear Hebb rule using correlations both within and between eyes and were subtractively normalized. Weights that reached zero were frozen. Three developmental paradigms were investigated: 1) retinal activity locally correlated within each eye but not between eyes, which might occur during prenatal development; 2) retinal activity locally correlated both within and between eyes, which might occur during postnatal development; and 3) two-phase development with the first phase corresponding to paradigm 1 and the second phase corresponding to paradigm 2, modelling both pre and postnatal development. The development of disparity and ocularity are intimately linked in our model. With no between-eye correlation, the cortex developed only monocular cells without any disparity sensitivity. Between-eye correlations throughout development led to a cortex of uniformly binocular cells with the receptive fields of both eyes aligned and thus tuned to zero disparity. The two-phase paradigm allowed the initial development of a monocular bias which was partially reversed by the addition of between-eye correlations. This resulted in a cortex populated by both monocular and binocular cells, the binocular cells tending to have zero disparity and the more monocular cells having nonzero disparity, thus matching the experimentally observed relationship of disparity and ocularity in the cat (LeVay & Voigt, *Vis. Neurosci.* 1988). (Supported by the Howard Hughes Medical Institute and SERC).

551.11

DEVELOPMENTAL ON/OFF COMPETITION CAN QUANTITATIVELY ACCOUNT FOR PREFERRED SPATIAL FREQUENCIES OF CORTICAL SIMPLE CELLS K.D. Miller*, Division of Biology, Caltech, Pasadena, CA 91125.

I have previously shown that a Hebbian or similar developmental competition between ON- and OFF-center inputs can lead to development of orientation-selective simple cells and their periodic organization into orientation columns (1989, 1990, this meeting; *NeuroReport* **3**:73-76 (1992)). The key assumption is the existence of a reversal in the correlation structure between ON- and OFF-center inputs, as follows: at small retinotopic separations, two inputs of the same center type (two ON-center inputs) are better correlated with one another than are two inputs of opposite center type (an ON- and an OFF-center input); but at larger retinotopic separations, where one input's receptive field (RF) center overlaps another's RF surround, two inputs of opposite type are best correlated.

Here I show that this hypothesis also can quantitatively account for the mean preferred spatial frequency (MPSF) of cortical simple cells. The model predicts that the MPSF of these cells is that which maximizes the Fourier transform of the correlation function $C^D(\alpha) \equiv C^{\mathrm{ON-ON}}(\alpha) - C^{\mathrm{ON-OFF}}(\alpha)$; this function tells the difference between like-type and opposite-type correlations, as a function of the retinotopic separation α. Precise comparison with experiment will require measurement of this function in the developing LGN. However, Mastronarde (1983) measured the separations at which like-type correlation and opposite-type anticorrelation falls to zero in adult cat retinal dark activity. Assuming that this corresponds to the distance at which reversal in ON/OFF correlations occurs in LGN, we obtain a prediction for MPSF in cat visual cortex that agrees well with measurements across eccentricities (Movshon, Thompson and Tolhurst, 1978).

552.1

SUPPRESSION OF THE RELEASE OF GABA BY NORADRENALINE INFUSION IN THE KITTEN VISUAL CORTEX. Shirokawa, T.* and Ogawa, T. Dept. of Physiology, Akita Univ., Sch. of Med., Akita 010, Japan.

Release of γ-aminobutyric acid (GABA) was measured by brain microdialysis and high-performance liquid chromatography in the visual cortex of anesthetized kitten. First, we confirmed that visual stimulation gave rise to a marked increase in GABA release which was completely suppressed by infusion of tetrodotoxin (TTX). However, GABA release induced by nipecotic acid, a GABA uptake inhibitor, was not affected by the TTX infusion. Next, we examined the effect of local infusion of noradrenaline (NA) on the release of GABA. Exogenous NA caused a complete suppression of visually-induced GABA release as well as basal release of GABA. These results suggest that cortical GABA release may play a role in the NA-induced ocular dominance plasticity that cortical infusion of NA caused an obvious shift of ocular dominance in favor of the eye exposed monocularly to moving visual stimuli in the kitten visual cortex (Imamura and Kasamatsu, Exp. Brain Res.,1991).

552.2

POSTNATAL DEVELOPMENT OF GABA IMMUNOREACTIVITY IN CAT VISUAL CORTEX. G.D. Mower*, J. Hoffpauir, I. Kaplan, N.G.F. Cooper. Department of Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, Ky. 40292.

Immunohistochemistry (anti-GABA) was used to describe postnatal changes in the laminar distribution of GABAergic neurons and puncta in cat visual cortex. Cats at postnatal ages .5,1,5,10,15,20 weeks and adult were studied.

At one week of age and younger, a dense population of immunoreactive cells is present in two distinct bands, one superficial (layer I, future layer II) and another deep (Layer VI, subplate and white matter). There is a marked reduction in immunoreactivity in the middle of the cortical plate at these ages. At 5 weeks, there is an marked reduction in immunoreactivity in all layers, with only a few palely stained neurons present. From 10 to 20 weeks there in a gradual increase in the density and staining intensity of GABA neurons. There is a laminar gradient in staining across these ages, with cells in deeper layers (IV-VI) being densest at earlier ages and superficial layers (I-III) filling in by 15-20 weeks. A steady increase in the density of GABAergic puncta was evident from 5 to 20 weeks. By 20 weeks, staining was indistinguishable from that in the adult.

These results suggest a two stage process in postnatal development of GABA immunoreactivity in cat visual cortex. At very young ages (up to 1 week), there is dense staining of cells which could be primordial cells of the marginal zone and subplate. The subsequent decrease in GABA immunoreactivity leads us to suggest that these cells largely disappear. After formation of the mature laminar pattern, GABA immunoreactivity steadily increases in a manner suggesting an inside to outside pattern of neurochemical differentiation.

552.3

THE POSTNATAL DEVELOPMENT OF EXCITATORY AMINO ACID BINDING SITES IN FERRET VISUAL CORTEX. A.L. Smith and I.D. Thompson (SPON: Brain Research Association). University Laboratory of Physiology, Oxford University, Parks Road, Oxford OX1 3PT, U.K.

We have used a combination of transneuronal tracing techniques and quantitative *in vitro* autoradiography to investigate how the distribution and levels of EAA binding sites in cortex correlate with the establishment of geniculocortical connectivity in ferrets. Intraocular injections of wheatgerm agglutinin horseradish peroxidase showed that geniculate afferents were present in subplate at birth, had started to enter the cortical plate by PD16 and exhibited an adult-like laminar distribution in cortex at PD40. Radioligand binding studies, performed on cryostat sections, showed marked differences in the expression of kainate, AMPA and NMDA binding sites. Kainate binding sites (labelled with [^{3}H]kainic acid) are highly localized throughout development and are found mainly deep in the cortical plate or in the subplate. AMPA binding sites (labelled with [^{3}H]AMPA), however, are widely distributed in the developing ferret brain and before eye-opening exhibit a much more homogeneous distribution in the cortical plate than kainate binding sites. A variety of radioligands (L-[^{3}H]glutamic acid, [^{3}H]CGP-39653 and [^{3}H]MK-801) were employed to localize NMDA binding sites and these gave rise to different distributions implying a heterogeneity in the binding sites for these radioligands. NMDA binding sites are only present at very low levels on the day of birth and throughout early development and they exhibit a more homogeneous distribution in cortex than non-NMDA binding sites. Shortly before eye-opening NMDA binding site levels increase dramatically. Taken together these findings suggest that the subtypes of EAA binding site play distinct roles in regulating thalamocortical connectivity during development.

AGE DEPENDENCE OF MK-801 BINDING SITES IN VISUAL CORTEX: TISSUE SPECIFICITY, BINDING SITE SPECIFICITY, AND CHANGE IN PROPERTIES. B. Gordon*, Y. Tseng, and K. Tovar. The number of MK-801 binding sites in cat visual cortex is maximal at about 42 days (d) of age. This fact, among others, suggests that these receptors may be involved in visual cortex plasticity. We asked whether this age dependence of MK-801 binding sites is specific both to visual cortex and to the MK-801 binding site. To examine tissue specificity we compared MK-801 binding in visual cortex, retina and hippocampus. We selected retina because it is never plastic and hippocampus because it is, presumably, plastic throughout life. Retinal binding was very low and did not vary consistently with age. Hippocampal binding increased significantly from 7d to 42d and decreased slightly, but not significantly, in adulthood. Thus, development of MK-801 binding parallels the critical period in both visual cortex and hippocampus, but statistically significant decreases with increasing age occur only in visual cortex. To examine binding site specificity we compared the development of MK-801 and AMPA binding in visual cortex. AMPA binding increased from 7 to 42d, but did not decrease significantly in adulthood. Therefore, the binding peak at 6 weeks may be specific to the NMDA receptor. To determine whether the properties of the MK-801 binding site varied with age, we examined the age dependence of the ability of glutamate, glycine, and spermidine to enhance MK-801 binding. Preliminary data suggest that addition of a second enhancer may be more effective in adults than in younger animals, suggesting that the properties of the binding sites vary with age.

PATCHY EXPRESSION OF *C-FOS* IN AREA 17 OF KITTENS C. Beaver, K.M. Murphy and D. E. Mitchell*. Dalhousie University, Halifax N.S. and McGill University, Montreal, CANADA.

Physiological and anatomical investigations of area 17 of cats have revealed a system of functional modules or columns based upon two salient visual response characteristics of cortical cells, namely ocular dominance and orientation preference. Both systems of columns exist in an immature state at birth, but develop rapidly afterwards in normal kittens to attain adult-like anatomical form by about 6 wks of age. The postnatal development of both systems of columns requires visual experience since their development is both arrested in kittens reared from birth in total darkness and their pattern is altered in animals that receive biased early visual experience. Recent results obtained from the use of other anatomical methods (such as cytochrome oxidase histochemistry) on cat visual cortex point to the possible existence of other principles of modular organization in addition to those uncovered earlier. In order to investigate whether any system of modular cortical organization arises by factors intrinsic to the cortex itself we have exploited the recent observation of rapid expression of the immediate-early gene, *c-fos*, in the visual cortex of dark-reared kittens following very brief exposure to light. We have examined the tangential distribution of *c-fos* in kittens reared from birth in total darkness until 30d and then allowed 1-2 hrs of either monocular or binocular visual exposure. The *c-fos* positive cells were labeled immunohistochemically and vizualized in tangential sections from unfolded and flattened visual cortex. Surprisingly, distinct patches of *c-fos* expression were evident in layers 2 and 3 of area 17 of binocularly, as well as monocularly exposed kittens. The arrangement of the patches of *c-fos* expression were compared to the modular structure revealed by other immunohistochemical methods. However, the fact that *c-fos* expression in these dark-reared kittens is so non-uniform suggests that at least some aspects of cortical modularity may be intrinsically determined.

552.6

DEVELOPMENT AND REGULATION OF ALPHA ADRENOCEPTORS IN KITTEN VISUAL CORTEX

Wei-Guo Jia*Yu Lin Liu and Max Cynader
Department of Ophthalmology, University of British Columbia
Vancouver, B.C. Canada V5Z 3N9

Alpha1 and alpha 2 adrenergic receptors were localized in developing cat visual cortex by using [^{3}H]prazosin, and [^{3}H]rauwolscine, respectively. Effects of neuronal activity on development of the two receptor subtypes were also studied in animals with lesions at various sites of central visual pathway. Binding densities for both ligands increased during the first few postnatal weeks and declined thereafter. For both receptor subtypes, the highest concentration of binding sites was found in the subplate zone of the neonatal cortex, then concentrated in cortical layer IV beginning at postnatal day 30 and finally in the superficial cortical layers in adulthood. However, the developmental redistribution of α1 receptors began earlier than that of the α2 sites. Quinolinic acid lesions within cortex, lesions of the lateral geniculate nucleus and of optic tract reduced binding of both [^{3}H]prazosin, [^{3}H]rauwolscine to various extents in the cortex. Our results suggest that the two α-adrenoceptor subtypes were mainly located on cortical cells and their lamination is age-dependent and the density of the receptors is regulated by neuronal activity.

552.7

Transient overexpression of IP3 receptors during the critical period for kitten visual cortex plasticity. Y.L. Liu* and M.S. Cynader. Department of Ophthalmology, University of British Columbia, Vancouver, B.C., Canada. V5Z 3N9

Inositol 1,4,5-trisphosphate (InsP-3), a second messenger generated via receptor-stimulated hydrolysis of phosphatidylinositol 4,5-bisphosphate, mediates calcium mobilization from intracellular stores. Previous studies in kitten visual cortex have shown that neurotransmitter/modulator receptors linked with PI turnover are transiently concentrated in cortical layer IV during the postnatal critical period for kitten visual cortex plasticity. In order to investigate the correlation of this second messenger molecule with the molecular basis of visual cortex plasticity, we used an antibody directed against a purified InsP-3 receptor glycoprotein of relative molecular mass 260,000 (Ross *et al*, Nature, 1989) to visualize InsP-3 receptors in kitten visual cortex. InsP-3 receptor immunoreactivity was found to be concentrated in the pyramidal cells of the deep cortical layers in the first two weeks after birth, and in pyramidal cells of layers III and V in the third and fourth weeks. Between postnatal days 40 to 60, InsP-3 receptor immunoreactivity was most highly expressed in the cortex. Immunoreactive cells were present in all cortical layers, and were most dense in layers VI, IVab and III. After postnatal day 90, the number and intensity of InsP-3 receptor immunoreactive cells decreased gradually until adulthood. In adult cat visual cortex, immunoreactive cells were most concentrated in the superficial and deep cortical layers. These results show that InsP-3 receptor immunoreactivity is transiently concentrated in different populations of cortical cells during postnatal development and that the overall expression peaks during the critical period. The relationship between the transient expression of the InsP-3 receptor and the developmental alteration in cell surface receptors that evoke PI turnover is under study.

552.8

DEVELOPMENTAL EXPRESSION OF bFGF IN THE CAT VISUAL CORTEX. I. Cokgor* and M.S. Cynader, Department of Ophthalmology, Univ. of British Columbia, Vancouver, B.C., Canada V5Z 3N9

bFGF is an important neurotrophic factor that modulates glial cell differentiation and function, neuronal maturation, survival and growth of neuritic processes. It affects glial cell motility and migration, regulates protein synthesis and is also a major trophic factor operating at all stages of embryogenesis. It is known that bFGF is widely distributed in CNS and PNS as well as other tissues.

In this study, we immunohistochemically localized bFGF in the cat visual cortex. We used rat anti-bFGF (1/1000 dilution) and examined its distribution in microtome sections of different age kitten cortices. We showed that bFGF was heavily concentrated in glial cells in the white matter, the subcortical plate and the deep cortical layers of the gray matter in young kittens. Overall immunoreactivity peaked in 10 days old kittens. In 0 and 10 day old kittens bFGF staining was also shown in growth cones and neural processes in the visual cortex. In 20 and 30 day old kittens bFGF was abundant in the white matter and layer 1 of the gray matter. Its concentration showed a dramatic decrease in older age animals in which it was homogenously distributed throughout the cortex.

We studied the cellular distribution of bFGF with double-labelling immunohistochemistry, using GFAP as an astrocyte marker. Although it showed co-localization with GFAP (proving that it is localized in the astrocytes), its distribution was not restricted solely to astrocytes. The binding of bFGF with microglia in this system is still under investigation.

These results show that bFGF is overexpressed in young kittens prior to the critical period, suggesting that it may modulate glial proliferation, cell migration and may help to set up the cortex for activity dependent plasticity.

SEQUENCE ANALYSIS OF cDNA CLONES SELECTIVELY EXPRESSED DURING THE CRITICAL PERIOD FOR VISUAL CORTEX DEVELOPMENT.

Shiv Prasad* and Max S. Cynader Department of Ophthalmology, University of British columbia, Vancouver, B.C., V5Z 3N9 CANADA.

During the first few months of a kitten's life, the structure and function of the cortex can be dramatically altered as a result of abnormal visual input. During this critical period, which peaks at about 30 days of age, studies at the protein level have documented transient elevation of several important molecules within cortical cell populations.

We have isolated cDNA clones of mRNAs whose levels are higher during the critical period of development in kittens than in adult cats. Among approximately 12000 cDNA clones from a 30 day old kitten visual cortex cDNA library, 200 were identified by screening with a subtractive probe. About 150 of these cDNA clones were found to be unique. We have now tested 50 of these single copy cDNA clones with northern blots and found that 49 of these represent mRNAs whose levels are much higher in the 30 day old kitten visual cortex than in adult visual cortex. Partial nucleotide sequences for about 100 of these cDNA clones have been determined in order to search the EMBL DNA database for identities of these clones. Twenty-two of these clones were identifiable. Their identities showed that these sequences are involved in cell-cell communication, cellular remodelling, neurotransmitter release and processing, neurofilament assembly, energy metabolism, and RNA and protein synthesis.

552.10

ISOLATION AND CHARACTERIZATION OF cDNA CLONES OF mRNAs SELECTIVELY EXPRESSED IN KITTEN LATERAL GENICULATE NUCLEUS.

J.S. Bhangav, S.S. Prasad, R.M. Douglas* and M.S. Cynader Dept. of Ophthalmology, University of British Columbia, Vancouver, B.C. Canada.

During the first few months of a kitten's postnatal development, monocular visual deprivation causes marked effects on the morphology, growth, and connectivity of cells in the lateral geniculate nucleus (LGN) connected to the deprived eye. The same manipulation performed in adult animals has no effect. To understand the molecular mechanisms underlying the age and use-dependent plasticity in this nucleus we have used the method of subtractive hybridization to isolate genes that are differentially expressed in the LGN of 30-day-old kittens and not in adult cats.

Subtractive hybridization is a powerful technique for isolating differentially expressed mRNAs. A potential limiting factor for proper subtraction, however, is the requirement of large amounts of driver mRNA. We have utilized a subtractive hybridization protocol with modifications designed to avoid this problem. This method relies on a) Directional cDNA cloning b) Large scale in vivo phagemid excision and c) Generation of biotinylated run-off transcripts.

Thus far we have isolated five cDNA clones from a 30-day-old kitten LGN cDNA library that appear unique to kitten LGN. Characterization of the clones by Northern and DNA sequence analysis is underway.

ENZYMES, IONS AND RECEPTORS DISTINGUISH NOVEL, COMPLEMENTARY COLUMNAR SYSTEMS IN DEVELOPING CAT VISUAL CORTEX. Richard Dyck* and Max Cynader. Dept. of Ophthalmology, University of British Columbia, Vancouver, British Columbia, Canada, V5Z 3N9.

Using *in vitro* autoradiographic methods we have established that serotonin (5-HT) 1C receptors, labelled with [^{3}H]-mesulergine, are transiently expressed in columns through layer 4 of area 17 between 30 and 90 days postnatally (Dyck & Cynader, J Cellular Biochem, 1990), and that the columnar expression of these receptors is input- and experience-dependent (Dyck et al, Soc Neurosci Abstr, 1991). These 5-HT1C-rich columns are on average 420 μm in diameter with a centre-to-centre spacing of ~900 μm. Here, we present evidence that other molecules associated with serotonergic, glutamatergic and cholinergic function, as well as several metabolic enzymes, exhibit a patchy distribution in kitten visual cortex and are differentially localized within or between 5-HT1C columns to form an interdigitated mosaic. In carefully aligned, transverse sections through the opened and flattened kitten visual cortex, zinc-containing, glutamatergic, terminals were preferentially distributed in layer 4 of area 17, in the same columns as 5-HT1C receptors while the distribution of acetylcholinesterase- (AChE), cytochrome oxidase- (CO), and succinate dehydrogenase- (SDH) positive patches were limited to the layer 3 / 4 border and avoided the Zn / 1C columns. The patchy distribution of a second 5-HT receptor, the 5-HT2 subtype labelled with [^{125}I]-DOI, was also limited to the layer 3 / 4 border in area 17, but these patches were vertically aligned with Zn / 1C columns. Unlike the Zn /1C columns, 5-HT2 receptors were also highly expressed in area 18 and lateral suprasylvian cortex. This distinct anatomical distribution of 5-HT receptors suggests that the 1C receptor subtype is associated with the geniculocortical X pathway while 5-HT2 receptors mark the Y pathway transiently in development. The role of these multiple markers in column formation within the cortex is under investigation.

SUBMICROMOLAR CONCENTRATIONS OF LEAD CAUSE ABERRENT GROWTH OF RETINAL AXONS IN THE OPTIC TECTUM OF RANA PIPIENS TADPOLES. H. T. Cline* and L. C. Chen. Dept of Physiology & Biophysics, Univ. of Iowa, Iowa City, IA. 52245.

The retinal projection to the optic tectum of the frog tadpole is a well characterized system for the study of factors regulating neuronal development. We examined the possible influence of low levels of lead on axon growth. Lead (10^{-6}M - 10^{-8}M) was applied to the optic tectum of Rana pipiens tadpoles using the slow release polymer Elvax. We estimate that concentrations of lead released by the Elvax were10^{-8}M - 10^{-10}M, respectively. Tadpoles were T&K stage V at the beginning of treatment and stages X - XIII when we assayed the arbors. We reconstructed a total of 13 lead-treated HRP-labeled RGC axon arbors at the following concentrations: 4 at 10^{-6}M; 3 at 10^{-7}M; 6 at 10^{-8}M. RGC axon arbors which were exposed to lead for 2 months are severely reduced in size to about 30% of stage-matched control arbors. Despite their small size, the treated arbors display as many branchtips as controls. Consequently, the arbors have a branch density (branchtips/μm^2) about 4 times the normal value. The treated arbors also appeared to have many more growth cones than untreated arbors. These data suggest that lead may increase the rate of branch initiation, but the branches are not stabilized as they are in controls. We have begun to examine the development of tectal cells to determine if similar treatments might influence the growth of both the pre and postsynaptic partners in the retinotectal system. Supported by the McKnight Foundation.

553.2

NMDA AND NON-NMDA MEDIATED SYNAPTIC TRANSMISSION IN THE OPTIC TECTUM IN VITRO: DIFFERENCES BETWEEN XENOPUS AND RANA. S.G. Brickley and S. Grant (SPON: Brain Research Association). Div. of Neurophysiology & Neuropharmacology, NIMR, London NW7 1AA, and Dept. of Anatomy, CXWMS, London W6 8RP, UK.

A vision-dependent plasticity of synaptic connections in a commissural pathway, which re-aligns binocular tectal maps after early eye rotation occurs in Xenopus but not in Rana. The NMDA-type glutamate receptor has recently been implicated in this plasticity. Here we investigate the role of both NMDA and non-NMDA receptors in synaptic transmission at the tectum of these species, using an in vitro preparation. Postsynaptic potentials recorded in the superficial neuropil following optic tract stimulation showed early and late components, corresponding to the U1 and U2 responses seen in vivo (Chung et al, 1974: Proc. R. Soc. Lond. B. **187**, 421-447). Bath application of 20μM CNQX reduced the peak amplitude of both components (by ~60%) in both species. Application of 50μM AP5 affected only the long-latency U2 component in Xenopus(~30% reduction in peak amplitude) and had no effect in Rana. The NMDA-receptor mediated component of the long-latency response may provide a substrate for the vision-dependent plasticity that is exhibited only in Xenopus.

NMDA RECEPTOR CONTRIBUTION TO EPSCs IN THE DEVELOPING FROG OPTIC TECTUM. S. Witte* and H. T. Cline, Dept. of Physiology and Biophysics, University of Iowa, Iowa City, IA 52242.

The NMDA receptor has been implicated in a variety of neural plasticity phenomena, including long term potentiation, spatial memory, and activity dependent sorting of sensory afferents. Refinement of retinotectal projections in the frog is blocked by chronic application of the NMDA receptor antagonist APV. However, the sorting of nasal from temporal retinotectal fibers, occurring earlier in development, has been shown to be activity independent. We hypothesize that NMDA receptor activation may contribute differentially to EPSCs recorded from optic tectum neurons of tadpoles at different developmental stages.

Whole cell patch clamp recordings were made from a region in the middle third of the optic tecta of isolated superfused brains from Rana pipiens tadpoles. The perfusate contained 1.5 mM Ca^{2+} and 2.5 mM Mg^{2+} to reduce polysynaptic activity. Recorded neurons were labelled with neurobiotin or biocytin for later examination of their morphologies to seek possible correlations with electrophysiological findings. Stimulation of the optic nerve was delivered through a suction electrode attatched to the nerve stump. Several neurons appeared to have only indirect retinotectal connections. The majority of neurons displayed monosynaptic responses to optic nerve stimulation. For these neurons, separate current voltage curves were constructed from the early and late components of recorded EPSCs. Preliminary data show that in younger animals (stages III and IV) the late, voltage dependent component was very small compared to that in older animals (stage VIII). It appears that NMDA receptors contribute increasingly to retinotectal responses as tadpole development procedes. (Supported by McKnight Fund for Neuroscience.)

POLYSIALYLATED NCAM AND PLASTICITY IN XENOPUS TECTUM. S.B. Udin*, G. Rougon, J. Bandarchi, L. Gannon-Murakami, K. Murakami, S. Chen. Depts. of Physiology and Biochemical Pharmacology, SUNY, Buffalo, NY 14214.

The polysialylated form of the neural cell adhesion molecule NCAM (PSA-NCAM) has been shown to reduce membrane-membrane adhesion and thus may be permissive for reorganization of axonal connections. We have therefore compared the amount of PSA-NCAM in the Xenopus optic tectum, as revealed by immunostaining, with the degree of capacity for reorganization of ipsilateral connections to the tectum. During normal development, the ipsilateral eye's map, relayed indirectly via the nucleus isthmi, comes into register with the contralateral eye's map, relayed directly via the optic nerve. Visual input is required for this process. Abnormal visual input resulting from surgical rotation of one eye induces a systematic reorganization of the ipsilateral map. This reorganization normally can occur only during the critical period of development, lasting until about three months after metamorphosis. Plasticity can be prolonged by dark-rearing and can be re-established by chronic treatments of adult tecta with NMDA.

Using a monoclonal antibody to PSA-NCAM, we have found that the amount of staining in the superficial layers of the tectum is low in normal adults, in which plasticity is low. In contrast, staining is high in normal tadpoles, dark-reared adults, and NMDA-treated adult tecta, all of which show high levels of plasticity. These results suggest that the activity-dependent mechanisms associated with plasticity may affect connectivity in part by altering expression of variants of NCAM.

CHARACTERIZATION OF PROTEIN KINASES IN THE DEVELOPING OPTIC TECTUM. A.J. Scheetz*, L.O. Doan and M. Constantine-Paton. Yale University, Department of Biology, New Haven, CT

In order to maintain retino-tectal topography the synapses between retinal ganglion cells and their tectal targets in the *Rana pipiens* tadpole are being broken and reformed continuously throughout tadpole life. The maintenance of this topography is dependent on N-methyl-D-aspartate (NMDA) receptor activation. Such synaptic flux makes the retino-tectal projection an excellent model system for examining molecular mechanisms associated with plasticity of synapse formation. Using an *in vitro* kinase assay we have examined properties of the cyclic AMP-dependent (cAMP), calcium and calmodulin-dependent (CAM-II) and calcium and phospholipid-dependent kinases (PKC) in this tissue. Tectal kinase activity was similar to values for the mammalian enzymes, indicating that the amphibian kinases are functionally related to their mammalian counterparts. Additionally, we have investigated the effects of glutamate receptor activation on protein phosphorylation in intact tectal tissue. Fifty μM glutamate stimulated the phosphorylation of 12 proteins that we could identify as specific kinase substrates from our *in vitro* assays. Five have molecular weights and isoelectric points similar to proteins identified as CAM-II substrates; 3 appear to be PKC substrates and 4 are cAMP kinase substrates. Phosphorylation of some of these 12 substrates is likely an indirect effect of increased metabolic rate due to continuous glutamate receptor activation. We are investigating currently the difference between these general effects and specific receptor mediated events by selectively activating or inhibiting glutamate receptor subtypes, ie. NMDA receptors, in the presence of low concentrations of glutamate. In addition, we are coupling this manipulation with chronic treatments which are known to alter the specificity of new synapse formation in order to add to our understanding of the correlation between synaptic plasticity and kinase second messenger systems in developing neuronal pathways. DEVELOPMENT OF SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE OPTIC TECTUM OF TADPOLES. E.A. Debski* School of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506.

In adult *Rana pipiens*, somatostatin-like immunoreactive (SOM-IR) tectal cells are found mainly in the caudal third of the optic tecta (Debski, Neurosci. Abstr. 17:1134, 1991). This non-uniform distribution implies that different regions of the tectum may be composed of functionally non-equivalent cells. To begin to understand what function(s) these SOM-IR cells may have, I investigated their distribution in tadpoles.

In stage XIX tadpoles, where caudal regions of the tectum are largely developed, the number and location of SOM-IR cells are about the same as in the adult. Neurites from some of the stained cells in layers 4 and 6 can be followed radially into layer 7 where they turn and extend horizontally. This morphology indicates that at least some of the SOM-IR cells may have efferent projections. In stage XIII tadpoles much of the caudal tectum is immature. Nevertheless, SOM-IR cells, present in much greater numbers than in the adult, are largely restricted to these regions. In caudal tectum that has a thickened but as yet unlaminated cellular layer, the cells are found in radially oriented clumps throughout the layer. Within the thin caudal regions of tecta that are the least mature, SOM-IR cells are seen above a thickened ventricular zone. Staining of neurites has not been observed at this stage. These data suggest that SOM-IR tectal cells are a late developing population of cells that may be specialized to adult function. Supported by BRSG SO7 RRO7114-22 and FFS GA91079.

THE EFFECTS OF RETINAL INNERVATION ON TECTAL DEVELOPMENT IN THE EMBRYONIC ZEBRAFISH. L.S. Ross and J.M. Zook*. Dept. of Biological Sciences, Ohio University, Athens, OH 45701.

Previous studies have suggested that retinal afferents regulate both the embryonic and regenerative development of the optic tectum in teleost fishes (Schmatolla, 1972; Raymond et al, 1983). We have examined the effect of eye removal on tectal development in the embryonic zebrafish to verify these effects and provide a foundation for future longitudinal studies.

One eye was removed from zebrafish embryos prior to the initiation of optic axon outgrowth, at 24 hours postfertilization. The development of the tectum was examined in sectioned material, with the opposite, innervated tectum serving as a control. In embryos as young as 72 hours, the non-innervated tectum was smaller than the innervated tectum. Volumes of the marginal and subventricular zones of the tectum were measured in 7 day old embyros. The mean volume of the marginal zone was reduced by 37.3%, and the subventricular zone was reduced by 28.0%. Examination of the tectal cytoarchitecture suggested that in the absence of innervation fewer cells migrated from the subventricular zone to populate the marginal zone. At 7 days, laminae of differentiated cells had formed in the innervated tectum; the non-innervated tectum lacked these laminae and contained 59.6% fewer cells. We are examining these proposed effects on tectal development with time-lapse video microscopy. Supported by NSF BNS91-11813 and OURC grant #861 to L.S.R

553.8

ABNORMAL RECOVERY OF RESPONSES TO VISUALLY PRESENTED PREY AND LOOMING STIMULI AFTER TRANSECTION OF THE OPTIC CHIASM IN *RANA PIPIENS*. R.F. Waldeck and E.R. Gruberg*. Temple Univ., Philadelphia, PA 19122

After complete transection of the optic chiasm frogs do not respond to visually presented prey and looming stimuli. Two months later there is recovery of function. However, unlike recovery after optic nerve transection, animals respond as if the stimulus were not at its actual position but at the symmetric position in the contralateral field. For instance, if a prey stimulus is located at an eccentricity of 40^0 left the animal will respond as if the stimulus were at 40^0 right. These animals typically respond to looming stimuli either by hitting the stimulus or jumping to the same side as the approaching stimulus. These behaviors persisted throughout the testing period, up to 13 months.

Electrophysiological recordings revealed visual activity in the optic tectum that is retinotopically organized but driven primarily by stimuli to the ipsilateral eye. Using HRP histochemistry, some retinal fibers were found to cross the midline of the chiasm. Thus, the midline is not impenetrable to crossing retinal fibers.

Abnormal behavioral recovery also occurs when 3/4 of the chiasm is cut. Initially, post-lesion animals responded to prey stimuli in 80% of the visual field. Responses were generally accurate. After two months these animals behaved similarly to the animals that recovered after complete transection. Physiological and histological results were also similar.

These results suggest there are important guidance cues at the chiasm for retinal axons. Supported by NIH grant EY04366.

VISUAL DEVELOPMENT: MAMMALIAN THALAMUS AND MIDBRAIN

554.1

DENDRITIC DEVELOPMENT OF LGN CELLS DURING LAMINAR AND SUBLAMINAR RETINOGENICULATE SEGREGATION IN THE FERRET. M. Rocha* and M. Sur, Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139; and Biophysical Institute, Federal University of Rio de Janeiro, 21941, Brazil.

The ferret LGN undergoes profound morphological changes during the first postnatal month. Retinogeniculate afferents first segregate into eye-specific laminae and then into on/off sublaminae during the first and third postnatal weeks, respectively. Here, we have examined how LGN cells acquire their mature dendritic form during this period. Ferrets between postnatal day 1 (P1) and 28 were used. Rhodamine-labeled latex microspheres were injected into primary visual cortex to backfill LGN relay cells. The detailed morphology of these cells was then revealed by intracellular injections of Lucifer Yellow in 300- μm, horizontal thalamic slices kept alive in a tissue-slice chamber. At P1, LGN cells were morphologically immature, with small dendritic arbors and few branches (mean (±s.d.) dendritic area: 2.2±1 $x10^3$ μm^2; 7±4 branch points/cell). By P7, dendritic arbor area increased several times (17.4±6.4 $x10^3$ μm^2). Dendrites were more branched (32±6 branch points/cell), distributed in a stellate or oriented pattern, and were covered with dendritic appendages (30 spines/cell). At P14, a more elaborate pattern of dendritic branching was observed (dendritic arbor area: 25.6±11.3 μm^2; 50±17 branch points/cell), and spine density had increased significantly (45 spines/cell). By P21, cells appeared adult-like in structure (dendritic arbor area: 33.6±18.9 $x10^3$ μm^2; 40±12 branch points/cell). Cells at P28 were similar in morphology, (dendritic arbor area: 29.8±5.0 $x10^3$ μm^2; 38±9 branch points/cell). We conclude that developing LGN cells undergo considerable dendritic remodelling to reach their mature morphology, attaining most of their adult features by P21. This indicates that dendritic development is correlated with the formation of appropriate retinogeniculate connections. Supported by EY07023 and CNPq.

RAPID INCREASE IN ASTROCYTIC GFAP IMMUNOREACTIVITY IN LGN OF ENUCLEATED RATS K. S. Canady*, J. F. Olavarria & E. W Rubel, Virginia Merrill Bloedel Hearing Research Center and Dept. of Psychology, Univ. of Wash., Seattle, WA 98195

We have previously found that the cessation of action potentials in the cochlear nerve (by deafferentation or TTX treatment) results in increased immunoreactivity for glial fibrillary acidic protein (GFAP-IR) in the chick cochlear nucleus within 1-3 hours (J. Neurosci. 12:1001, 1992; J. Comp. Neurol. 318:415, 1992). To determine whether this rapid astrocytic response to neuronal inactivity occurs in other systems, we examined GFAP-IR in the rat LGN at short times after unilateral enucleation. Anesthetized rats were perfused 3, 6 or 12 hours following eye removal. Paraffin sections containing the LGN were processed immunohistochemically using a polyclonal antiserum to GFAP. Area density of GFAP-IR in the deafferented LGN relative to the contralateral LGN was measured using a BioQuant microdensitometry system. Unoperated control rats showed no significant difference in GFAP-IR between the two LGNs. No reliable differences were found in the 3-hour enucleated rats either. At 6 and 12 hours following enucleation, a 30% increase in area density of GFAP-IR was found in the deafferented LGN relative to the contralateral LGN. For comparison, rats studied 3 weeks after enucleation show a 150% increase in GFAP-IR in the deafferented LGN, presumably in response to neural degeneration. Thus, our results suggest that the rapid (≤ 6 hours) astrocytic response to deafferentation is common across mammals and birds as well as across different sensory systems. Whether blockade of neuronal action potentials is sufficient to reproduce this effect remains to be determined.

DIFFERENTIAL EXPRESSION OF CALCIUM BINDING PROTEINS AND CYTOSKELETAL PROTEINS IN HUMAN FETAL THALAMUS. X.-B. Liu, S.A. Mednick, S. Hodgins and E.G. Jones, Dept. of Anatomy and Neurobiology, University of California, Irvine, University of Southern California and Institute Philippe Pinel de Montreal, Canada.

The localization of calcium binding proteins, growth associated proteins and cytoskeleton proteins was examined by immunocytochemisty in the thalamus of human fetal brains at 15-20 weeks gestation.

Calcium binding protein immunoreactivity is absent from pulvinar and lateral group nuclei and stains different subpopulations of neurons and fibers in others. Parvalbumin is localized in cells of the geniculate, ventral, intralaminar and reticular nuclei, while calbindin appears in ventral nuclei cells only. Parvalbumin immunostaining is also more prominent in the optic tract and medial lemniscus. GAP-43 immunostaining is homogeneous in the thalamus and adjacent fiber tracts. Fibers immunostained for neurofilament proteins, NF-160 and SMI-32, are distributed in certain parts of thalamus, mainly following the pattern of parvalbumin fiber staining.

These results indicate the early developmental pattern of calcium binding protein immunostaining which may correlate with differential expression of cytoskeleton proteins. Temporal changes in expression of those proteins are under investigation.

FACILITATION OF LGN UNIT ACTIVITY ASSOCIATED WITH THE NON-RETINAL PONTO-GENICULO-OCCIPITAL (PGO) WAVE LACKS LAMINA SPECIFICITY. J.P. Shaffery*, H.P. Roffwarg and G.A. Marks. Sleep Neurophysiology Unit, UT Southwestern Medical School. Dallas, Tx 75235.

Development of the visual system has been shown to be dependent upon a competitive mechanism utilizing information contained in the afference from each respective retina. PGO waves represent a non-retinal source of LGN activation during the sleep phase most represented in young developing animals: rapid eye-movement sleep (REMS). Both retinal and PGO-related activation may play a role in the maturation of the visual system. Inasmuch as the retinal input to LGN demonstrates eye specificity among laminae in the cat, we have investigated whether PGO activation is also lamina-specific.

We report here that phasic PGO waves are associated with a very similar facilitation of unit activity in the A and A1 laminae of LGN. Regular and frequent PGO-like (PGOro) waves in LGN are observed in acutely urethanized, RO4-1284 (a reserpine-like drug)-treated adult cats. A bipolar, stainless steel, macro-electrode was placed in the right LGN to record photically evoked and spontaneous PGOro field potentials. An etched tungsen micro-electrode recorded neurons extracellularly in the A- and A1-laminae identified by responses to monocularly-presented photic flash. Perievent histograms of unit activity, which was analyzed in relation to PGOro wave triggers, demonstrated in both laminae clear facilitation associated with occurrence of the wave. Unlike the activation of LGN derived from the eyes, PGOro-related activation lacks laminae-specificity. These results are consistent with our observation that elimination of PGO exaggerates alterations of interlaminar cell-size disparity in LGN due to monocular deprivation.

LOCALIZATION OF CALCIUM-BINDING PROTEIN IN THE DEVELOPING CAT PRETECTUM. **B.Hutchins* and A.N.Taylor. Dept. of Biomed. Sci., Baylor Coll. of Dentistry, Dallas, TX. 75246.**

Routine Immunocytochemical techniques were used to localize the calcium-binding protein, calbindin-D 28K (CaBP) within the developing cat pretectum. Brains fixed in Bouin's were embedded in paraffin and cut in one of three stereotaxic planes. Tissues were sampled from neonatates and postnatally at 7, 14, 28, and 56 days. CaBP positive cells appeared to be randomly distributed within the nucleus of the optic tract (NTO), posterior (NPP), and medial pretectal nuclei (NPM). Within the anterior pretectal nucleus (NPA), CaBP positive cells could not be easily separated into the two subdivisions, NPAc and NPAr, however, there was a distinct ring of CaBP stained tissue along the border of NPA. The percentage of cells staining for CaBP either remained level or generally increased postnatally for NTO, NPA, NPP, and NPM, with the maximum cellular immunoreactivity never exceeding 26 %. Of particular interest, however, was the pretectal olivary nucleus. Neurons staining positive for CaBP numbered approximately 50 % for the first two weeks of neonatal life, dropping to approximately 25 % after two months of development. These preliminary data would suggest that the olivary nucleus is under considerably different developmental influences than the other four pretectal nuclei. (Supported by NEI EYO6977)

PROGRESSIVE LOSS OF SEROTONINERGIC SYNAPSES FROM THE SUPERFICIAL LAYERS OF THE HAMSTER'S SUPERIOR COLLICULUS. R.S. Crissman*, D. Jiang, E.A. Arce, C.A. Bennett-Clarke and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699

A previous report from this laboratory (Arce, E.A., et al., Synapse, in press) demonstrated that only a few (4.4%) serotoninergic processes make conventional synaptic contacts in the superficial gray layer of the superior colliculus of adult hamsters. The present study used a combination of immunocytochemistry and electron microscopic techniques to describe the development of the serotoninergic projection to the colliculus and we now report a surprising loss of synapses during the development of this projection. Serotonin-immunoreactive (5-HTIR) profiles were examined from pups killed on P-0 (the day of birth), P-3, P-7, P-12, P-15, and P-20. Of the 256 profiles examined on P-0, 36.3% made synapses. On P-3 (N=311 profiles), 40.5% made synaptic contacts; on P-7 (N=310 profiles) 32.3% made synapses; on P-12 (N=335 profiles), 37.6% made synaptic contacts; on P-15 (N=306 profiles), 17.3% made synapses; and on P-20 (158 profiles), 9.5% made synaptic contacts. Virtually all of the serotoninergic synapses made at each of these ages were axodendritic. Thus, there is a gradual decline in the percentage of synaptic contacts made by 5-HTIR profiles during postnatal collicular development in the hamster. Importantly, this change occurs without any apparent reduction in the density of the serotoninergic input to the superficial collicular laminae as evaluated by either light or electron microscopy. At present, the function of these transient serotoninergic synapses remains unknown. EY 04170, EY 08015

DEVELOPMENTAL REGULATION OF NITRIC OXIDE SYNTHASE mRNA AND NEURONAL NADPH DIAPHORASE ACTIVITY IN THE RAT SUPERIOR COLLICULUS. G. Prusky*, M. Hofer and M. Constantine-Paton. Department of Biology, Yale University, New Haven, CT 06511.

In rats, there is a topographical refinement of the retinal projection to the superior colliculus (SC) during development which is dependent upon NMDA receptor activation (Prusky et al, 1991). Since NMDA receptor activation can lead to the production of nitric oxide (NO), a messenger molecule that has been proposed as a diffusible retrograde signal at Hebbian synapses (Galley et al, 1990), we are investigating a possible role for NO in retinocollicular plasticity. Using a cDNA probe that recognizes NO synthase (NOS) (Bredt et al, 1991), we have employed quantitative Northern blot analysis of the rat superficial SC during postnatal development. NOS mRNA levels were very low during the first postnatal week, and increased moderately by postnatal day (P)12. The highest NOS mRNA levels were observed at P19. By adulthood, NOS message was reduced by 50% from levels detected at P19. Since NOS appears to be identical with nicotinamide adenine dinucleotide phosphate (NADPH) diaphorase (Dawson et al, 1991), we have also used histochemistry of this enzyme as a marker of age-related alterations in NOS activity. There was no detectable NADPH diaphorase activity during the first postnatal week, but faint staining of neurons in the superficial SC could be detected by P12. By P19, NADPH diaphorase positive neurons were more abundant and were more intensely labelled. This trend continued and reached its peak by P27 when many neurons of different cell classes were labelled in the superficial SC. In the adult, the overall level of NADPH diaphorase reaction product in the superficial SC was lower than at P27. NOS markers have similar developmental profiles to NMDA message (Hofer et al, this meeting), and may indicate a relationship between NO production and NMDA receptor expression in the control of collicular synaptic plasticity. Supported by NEI EY06039 to MCP, and MRCC and EMBO fellowships to GP and MH respectively.

554.8

REGULATION OF NMDA RECEPTOR mRNA IN THE RAT SUPERIOR COLLICULUS. M. Hofer, G.T. Prusky and M. Constantine-Paton* Department of Biology, Yale University, New Haven, CT 06511.

Glutamate receptors have been implicated in several forms of central nervous system plasticity. Recently, it was demonstrated that the developmental refinement of the initially diffuse rat retinocollicular projection requires normal function of the N-methyl-D-aspartate (NMDA) glutamate receptor subtype (Prusky et al., 1991). Based on this observation, we are investigating the developmental expression of NMDA receptor mRNA and are testing whether it has any relation to the time course of the map formation in the superior colliculus (SC). *In situ* hybridization with a probe encoding the NMDA receptor subunit NMDAR1 (Moriyoshi et al. 1991) showed highest expression in the superficial layers of the SC at all ages examined. Northern blot analysis quantifying the 4.2 and 4.4 Kb transcripts in the superficial layers revealed low levels during the first postnatal week. A sharp increase was observed between postnatal day (P) 6 and P12 and maximal expression with tenfold higher amounts of NMDAR1 mRNA than at birth occurred at P19. In adults, NMDAR1 message was 30% lower than at P19. The ratio of the two NMDAR1 transcripts changed during this period with the 4.4 Kb band being more abundant than the 4.2 Kb band at early developmental ages and an opposite ratio at later stages. Chronic treatment with the NMDA receptor antagonist APV for 12 or 19 days led to a decrease in mRNA levels. The results show that the NMDA receptor is regulated at the mRNA level during collicular development. Furthermore, they suggest that treatment with receptor antagonists, which prevents normal retinocollicular map formation, modulates NMDA receptor expression. The sharp rise of NMDAR1 mRNA levels in the second postnatal week appears to parallel the refinement of the topographic map in the SC and supports a role for the NMDA receptor in collicular synaptic plasticity. Supported by NEI EY06039 to MCP and EMBO and MRCC fellowships to MH and GP respectively.

554.9

EARLY DEVELOPMENT OF THE RETINOCOLLICULAR PROJECTION IN THE OPOSSUM, *Monodelphis domestica*. T. W. Axlund, D. S. Sakaguchi, and C. D. Jacobson*. Dept. Zool and Genetics, Vet. Anatomy and Neurosci. Prog., Iowa State Univ., Ames, IA 50011.

The development of the retinocollicular projection in the Brazilian short-tailed opossum, *Monodelphis domestica* was examined from birth (PN1) until PN10. *Monodelphis* is a small, pouchless marsupial which breeds well under laboratory conditions and whose young are born in an extremely immature state. Retinal ganglion cell (RGC) axons were anterogradely labeled by placing crystals of the axon tracer DiI into the eyes of aldehyde-fixed specimens.

The eyes of PN1 opossums were relatively immature and immunocytochemical localization of neurofilament protein revealed axons of differentiated RGCs in only the central 1/3 of the developing eye. In PN1 opossums the contralateral projection has grown across the chiasm and proceeded a short distance up the optic tract. By PN3, RGC axons have grown approximately 2/3's the distance up the side of the midbrain towards the superior colliculus (SC). Ipsilaterally, a smaller number of optic axons were observed. RGC axons have reached the SC by PN6/7 and have begun elaborating axonal arborizations by PN8.

Examination of the optic tract region revealed numerous varicosities as well as side branches emanating from many of the RGC axons. Growth cones were identified in a number of specimens at various ages, displaying a variety of morphologies. Axons pioneering the retinal projection usually terminated in morphologically complex growth cones. We have also observed DiI labeled RGCs in the contralateral eye, suggesting the presence of inter-retinal projections at these early stages of development.

Since a great deal of the development of the visual projection occurs postnatally in *Monodelphis*, this species is likely to provide an excellent system for *in vivo* experimental manipulations and analysis.

554.10

ABNORMAL LAMINAR SELECTION AND SEGREGATION OF RETINOTECTAL PATHWAYS IN DEVELOPING RATS. C.A. Serfaty*[1,2] & R. Linden[1] [1]I. Biofisica da UFRJ, Rio de Janeiro & [2]Dept. Neurobiol. da UFF, Niteroi, Brazil.

The uncrossed retinotectal pathway in normal rodents terminates deeply within the upper grey layers and there is no binocular segregation in the tectum. We studied the retinotectal projections in rats using anterogradely transported horseradish peroxidase, after changing the balance between the pathways originating from both eyes as a consequence of either contralateral optic tract lesions (OTL) or small temporal retinal lesions (TRL) made at birth (P0). After left OTL an aberrant uncrossed projection develops at the surface of the right tectum at P3. At P10 this projection is fully developed and binocular segregation starts to appear. At P14 46% of the animals had gaps in the crossed pathway from the left eye. This figure increased to 55% at P42 and to 69% in adults. Neither bilateral nor unilateral (right) eyelid suture prevented segregation, but removal of the right eye at P14-P21 resulted in the absence of gaps in the crossed pathway from the left eye. Left TRL made at birth also produced an aberrant uncrossed projection in the right tectum, which was most prominent at the surface. Similar, though progressively smaller, rearrangements were obtained after TRL at P5-P21. We conclude that both laminar selection and segregation of the rat retinotectal pathways depend on a critical balance between the inputs from both eyes, which can be modified during a protracted period of development. *(CNPq, FINEP)*

554.11

EXPANSION AND ALTERED STRUCTURE OF RETINOTECTAL AXON ARBORS IN MONOCULARLY ENUCLEATED HAMSTERS. M. Xiong*, S.S. Lim, and B.L. Finlay, Dept. of Psych., Cornell Univ., Ithaca, NY 14853.

Neonatal removal of one eye in the hamster results in a massive loss of the contralateral input to the tectum and an expanded ipsilateral projection from the remaining eye (Finlay et al., 1976). The retinal terminal density, however, is still significantly reduced compared to normal. It is not known how the size and conformation of retinal axons are adjusted to the greater available tectal volume. In this study, we used an in vitro bulk fill technique, in which a bead of HRP was placed into the brachium of the superior colliculus to visualize individual axon arbors in tecta of both normal (N) and monoenucleated (E) hamsters. Tecta were processed with DAB histochemistry, retinal axons were drawn and the area, length and bouton number were quantified.

The retinal axon arbors of the monoenucleated hamsters had long, sparsely distributed branches with concentrated areas of boutons which covered a much larger area than those of normal animals (N=16,250±3170μm^2, n=15; E=147,200±51,070μm^2, n=6; t=4.169, p≤.001). They also had more boutons (N=161±16, n=15; E=273±76, n=6; t=2.125, p≤.05) and branches (N=39±5, n=15; E=72±20; t=2.283, p≤.05). This indicates that the increased tectal area for each retinal axon allowed them to make more contacts in the tectum than they do in the tecta of normal hamsters. However, the bouton density (N=.013±.002, n=15; E=.003±.001, n=6; t=3.82, p≤.005) and branch density (N=.003±.000493, n=15; E =.001±.000276, n=6; t=3.037, p≤.01) of the retinal axon arbors in the enucleated animals were lower, suggesting that there is an intrinsic limit to the number of boutons and branches that these axons can form.

Our previous study showed that retinal ganglion cells can reduce their arbor size by almost half to compensate for a decrease in available tectal area and remain viable. This study shows retinal ganglion cells can support greatly increased arbors, but with markedly altered clustering of terminal areas along their increased length. Supported by NIH R01 NS 19245.

REORGANIZATION OF RETINOCOLLICULAR TOPOGRAPHY FOLLOWING FETAL ENUCLEATION IN THE CAT. T.C. Steineke[2], Q.S. Fischer[1], P.D. Wilson[1], and M.A. Kirby[2*]. [1]Dept. of Psychology, U.C. Riverside, Riverside, CA 92521, and [2]Dept. of Pediatrics, Loma Linda University, Loma Linda, CA 92350.

We have examined disruption of binocular interactions during development of the retinocollicular projection in the fetal cat. Single and multi-unit recordings of light evoked responses in the superior colliculus (SC) were obtained using tungsten electrodes (1-10 megaohms) from eight adult cats, 4 that were monocularly enucleated on embryonic day 42 (gestation is 65 days). Fields were mapped on a tangent screen with reference to the optic disk and area centralis. Following the recordings, unilateral injections of horseradish peroxidase (HRP) were made into the SC. The animals were perfused 24-36 hours later and the retinas and brain sections were reacted for HRP.

In contrast to the control animals, the retinocollicular projection in the enucleates displayed several aberrant characteristics: (1) a disorganized progression of receptive field positions, (2) double response fields (simultaneous representation of extreme nasal and temporal fields at a single SC site), and (3) reversals in the caudal SC to the inappropriate hemiretina. Corresponding to the observed reversals in receptive fields, HRP labeled ganglion cells were found in the extreme nasal hemiretina. Morphologically, labeled cells resembled members of the major classes described in the normal adult retina.

Our data indicates the fetal enucleation in the cat results in a disruption of the normal topographic map combined with the production of nontopographic loci.

INNERVATION OF THE SUPERIOR COLLICULUS BY NASAL OR TEMPORAL RETINAL GANGLION CELL AXONS FROM ECTOPIC HEMIRETINAE K.T. Yee* and R.D. Lund Department of Neurobiology, Anatomy and Cell Science, School of Medicine, University of Pittsburgh, Pittsburgh, PA 15261 and Department of Anatomy, University of Cambridge, Cambridge, CB2 3BY, U.K.

Ectopic retinae introduced into postnatal hosts maintain intrinsic dorsal/ventral polarity, but afferents from these retinae show no such topographic ordering in their projection to the primary target, the host superior colliculus (SC) (Yee and Lund, '91), although synapses able to mediate behavior through the host animal are established (Lund, et al., '91). We have postulated that markers for establishing topography may no longer be present when ectopic retinal afferents arrive in the SC. Walter et al. ('87) have shown that temporal, but not nasal axons are repelled, *in vitro*, by posterior tectal membranes; this mechanism may be important for map formation in the tectum. We have examined whether a similar mechanism is operative, *in vivo*, following retinal transplantation.

Retinae transplanted to the midbrain were used to examine whether innervation patterns from nasal and temporal retinal ganglion cell axons differ. Nasal or temporal hemiretinae from embryonic day 12 mouse donors were transplanted over one SC of postnatal day 1 rat hosts. Animals were sacrificed at 3-5 weeks of age and midbrain sections were stained with a mouse specific antibody (anti-M4) to identify projections from the transplanted mouse retina.

Afferents from both nasal and temporal hemiretinae innervate the caudal aspect of the SC more heavily than the rostral portion, and show no differential patterns of innervation which reflect the region of retina transplanted.

While the hemiretinae show regional specificity of innervation, innervating only visual target nuclei of the host, mechanisms governing the establishment of normal retinotopy do not appear to be operative.

DEVELOPMENT OF CORTICOTECTAL ARBORS AND SYNAPSES IN CATS. L.L. Bruce* and T.J. Neary. Div. of Anatomy, Sch. of Med., Creighton Univ., Omaha, NE 68178.

Maturing corticotectal axons undergo morphological changes that parallel development of synapses in the superior colliculus. To correlate morphological changes with synaptic development, electron micrographs were used to serially reconstruct biocytin-labeled axons and their contacts. Biocytin was injected into the visual cortex of cats aged 0 to 35 days. The tissue was processed to visualize the biocytin.

At the earliest age the labeled corticotectal axons were thin and unbranched with periodic dilations. These dilations contacted multiple vesicle-filled profiles that were absent along the lengths of axons lacking dilations. Profiles contained either clear pleomorphic vesicles or both clear pleomorphic and dense-core vesicles. Maturing labeled axons developed short side branches with presynaptic vesicles and contacted vesicle-filled postsynaptic profiles with synaptic clefts. Later axons developed elaborate arborizations with greater numbers of presynaptic vesicles and synaptic clefts that contacted dendritic profiles with fewer postsynaptic vesicles. Thus, vesicle-filled dendrites appear to interact with axonal dilations prior to the initiation of synapse formation and may guide local axonal reorganizations, and synapse selection and formation.

MOLECULAR DIFFERENTIATION OF GANGLION CELLS IN NORMAL AND *OCULAR RETARDATION* MOUSE RETINA. M.H. Hankin*, E. Hoover§ and D. Goldman§. *Med. Coll. of Ohio, Toledo, OH, and §Univ. Michigan, Ann Arbor, MI.

We are interested in molecular mechanisms underlying retinal ganglion cell (RGC) differentiation in normal and *ocular retardation* (orJ) mice. Since orJ mice (which show arrested retinal development) do not form retinofugal projections, we used this animal to test whether gene induction in recently differentiated RGCs is correlated with RGC axon-target interactions, as suggested in goldfish (Hieber et al., 1992. *J Neurochem* 58:1009).

We have assayed the retina for genes which are induced during RGC differentiation: gene expression was detected by in situ hybridization with cRNAs for GAP-43, nAChR α-3 and β-3 subunit genes (markers of RGCs which have migrated to their final position); protein expression was detected immunohistochemically using antibodies against neuron-specific β-tubulin (TuJ1) and a neuronal cell adhesion molecule mediating interactions between RGC axons (L1), both of which are expressed in early differentiating RGCs. In mouse retina, embryonic day 11 (E11) is the first day at which RGCs become postmitotic. At E11 we detected expression of β-tubulin (in soma and axons) and L1 (on axons) in cells spanning from the central ventricular margin to the central vitreal surface. In contrast, β-tubulin was not detected in the orJ retina until E12, implying that RGC development may lag behind that in normal mouse retina. Nicotinic AChR and GAP-43 gene expression was induced in vitreal RGCs at E12 in normal retina; by E13 the boundaries of nAChR and GAP-43 gene expression had spread peripherally. In striking contrast, nAChR α-3 and β-3 subunit genes were not induced in orJ RGCs, while the GAP-43 gene was expressed in a manner consistent with the normal retina.

These results indicate that RGCs develop in the orJ mouse, as revealed by positive TuJ1, L1 and GAP-43 expression. The lack of nAChR gene expression in orJ ganglion cells is consistent with the hypothesis that an interaction between a RGC axon and a brain target is responsible for nAChR gene induction. In addition, these results suggest that the mechanisms regulating the expression of temporally correlated ganglion cell-specific genes proceeds along diverging pathways.

AXOTOMY-INDUCED EXPRESSION OF IMMEDIATE EARLY GENES IN RAT RETINAL GANGLION CELLS. G.A. Robinson* and A.R. Light. Department of Physiology, University of North Carolina, Chapel Hill, NC 27599.

To assess the effect of axotomy on retinal ganglion cell (RGC) expression of immediate early genes (IEGs), we retrogradely labelled RGCs with Flouro-Gold (FG) applied to their targets in the midbrain and diencephalon in adult female Long-Evans rats, transected the optic nerve <1 mm from the eye and immunocytochemically identified IEG proteins (FOS, JUN and KROX 24) using Texas Red-conjugated secondary antibodies in retinal whole-mounts at various time points after axotomy.

These double-labelling studies (FG/Texas Red) revealed that JUN-like and KROX 24-like immunoreactivity increased in a small percentage of RGCs beginning approximately 3 days after axotomy and lasting at least a week after injury compared to control retinae. Expression of both of these IEGs was largely limited to FG-containing RGCs. FOS-like immunoreactivity also increased in the retina after axotomy. It is known that after axotomy close to the eye, only a small number of RGCs will sucessfully regenerate an axon into an autologous peripheral nerve graft. One possibility is that the observed expression of JUN and KROX in only a small percentage of RGCs may be related to the ability of some RGCs to sustain a regenerative response. DENDRITIC STRATIFICATION OF DEVELOPING RETINAL GANGLION CELLS IS A GLUTAMATE-MEDIATED PHENOMENON. Stefan R. Bodnarenko*, Gayathri Jeyarasasingam and Leo M. Chalupa. Dept. of Psychology and the Center for Neurobiology, University of California, Davis, CA 95616

A fundamental attribute of vertebrate retinal ganglion cells (RGCs) is the stratification of their dendrites within distinct sublaminae of the inner plexiform layer (IPL). Whereas in adults dendrites of ON-center RGCs stratify nearer to the soma than dendrites of OFF-center cells, early in development RGCs are multistratified. The factors underlying the segregation of dendrites within the IPL are unknown.

We now report that repeated intraocular injections of 2-amino-4-phosphonobutyrate (APB), a glutamate agonist which in adults increases spontaneous activity of OFF-center RGCs and decreases spontaneous and light evoked activity in ON-center RGCs (Boltz et al. 1984), disrupts RGC dendritic stratification in neonatal cats. Animals received daily injections of APB into one eye beginning at age P2/P3. RGCs were labeled with DiI following application of the tracer into the fixed optic nerve. Examination of retinal cross-sections revealed a significant increase in the incidence of multistratified beta cells in the treated eye (survival age: normal vs. treated) P8: 21% vs. 39%; P10: 16% vs 29%; P13: 12% vs. 34%. The incidence of OFF as well as ON beta cells was decreased in the treated eye, suggesting that APB disrupted the normal stratification of both cell types. These results indicate that glutamate plays a role in the remodeling of RGC dendrites into sublaminae of the IPL, and imply that normal retinal activity is essential for the establishment of RGC mosaics. (Supported by EY03991 from the NEI).

555.4

DEVELOPMENT OF Na CURRENTS IN DISSOCIATED CAT RETINAL GANGLION CELLS. I. Skaliora*, L.M. Chalupa and R.P. Scobey. Depts of Psychology, Neurology and Neurobiology Graduate Group, University of California, Davis CA 95616.

We have previously shown that electrical excitability of retinal ganglion cells (RGCs) increases dramatically during the period of axonal pathfinding and initial synaptogenesis (embryonic days 30 - 38; gestation in the cat is 65 days). We now report quantitative changes in the properties of the voltage gated Na currents (I_{Na}) during the same period.

Whole-cell patch-clamp recordings are obtained from RGCs acutely dissociated from fetal and postnatal animals of known gestational ages. Ganglion cells are identified by retrograde labeling with rhodamine beads previously injected into the subcortical targets. Sodium currents were isolated by pharmacological channel blockers and ion substitution. The identity of I_{Na} was verified by its reversible block with TTX and by the influence of external [Na+] on current amplitude. The following ontogenetic modifications were observed (mean ± S.D.): (i) an increase in Na current densities, from a mean of 66.4 ± 32.4 pA/pF (n=25) at E30 to 142.4 ± 54.5 pA/pF (n=23) at postnatal ages. (ii) a significant ($p<0.05$) shift in the voltage dependence of both activation and steady-state inactivation toward the resting potential: the midpoint of the I_{Na} activation curve changes from -17.9 ± 2.4 mV (n=25) at E30 to -24.5 ± 4.1mV (n=23) postnatally; the midpoint of the inactivation curve shifts from -60.8 ± 3.7 mV (n=25) to -50.2 ± 3.4 mV (n=26) over the same developmental period. (iii) a decrease in decay time constants of the Na current, at membrane potentials negative to -15mV. These changes are largely occuring during the early part of the developmental period we studied (E30-38) and are consistent with the increase in excitability observed during the same period. (Supported by EYO 3991 from the NEI)

555.5

REGENERATING RETINAL GANGLION CELL AXONS BRIDGED BY PERIPHERAL NERVE GRAFTS CAN EXTEND INTO THE BRAIN STEM THROUGH THE TRIGEMINAL NERVE ENTRY ZONE. R. Pallini, E. Fernandez *, L. Lauretti, V. Bozzini and A. Spriccoli (#). Institutes of Neurosurgery and Neurology (#), Catholic University, Rome, Italy.

Axotomized retinal ganglion cells (RGC) of adult mammals can regenerate their cut axons over long distances into peripheral nerve (PN) grafts (Vidal-Sanz et al, J Neurosci 7:2894-2909, 1987). The regenerating RGC axons can be directed through the PN graft to selected central targets. However, most of the regenerating axons are blocked by the glial scar at the interface between the PN graft and the CNS. In the present study, we developed a new model aimed specifically at increasing the penetration of the regenerating RGC axons into the central environment.
The optic nerve (ON) of adult rats was cut intraorbitally and an autologous sciatic nerve graft (40 mm) was sutured to the ON stump. After a complete homolateral retrogasserian rhizotomy, the other end of the PN graft was apposed to the central stump of the trigeminal nerve (TN). Three-10 months after grafting, the regenerated RGC axons were labeled by anterogradely transported horseradish peroxidase (HRP) (WGA-HRP, Sigma, 8% solution) injected into the graft (0.05-0.2 µl) or vitreous body (1-2 µl).
We found that a substantial number of the RGC axons that had regenerated into the PN graft succeeded in growing through the TN entry zone and extended into the brain stem for distances of up to 1200-1300 um. Although many of these axons followed various different positional paths, a preferential growth into the spinal trigeminal tract was seen.

AN IMMUNOCYTOCHEMICAL MARKER FOR HAMSTER RETINAL GANGLION CELLS. P. G. Bhide*[1], W. C. West[1], K. R. Fry [2] and D. O. Frost[1]. [1]Dept. of Neurology, Massachusetts General Hospital, Charlestown, MA & [2] Center for Biotechnology, Baylor College of Medicine, Houston, TX.

About 50% of the neurons in the ganglion cell layer of the rodent retina are amacrine cells. Therefore, the presence of a soma in the ganglion cell layer *per se* does not identify that cell as a retinal ganglion cell (RGC). At present, hamster RGCs can be unequivocally distinguished only by retrograde labeling with neuroanatomical tracers injected into the brain.

To overcome this difficulty, we determined if AB5, a monoclonal antibody that selectively labels RGCs in rabbits, cats and monkeys (Fry *et al.*, Brain Res. 1985, 338: 360) selectively labels RGCs in developing and adult hamsters and if AB5 labels all RGCs. Retinae from postnatal day 0 (P0=first 24 hours following birth), P7, P10, P12, P14, P20 and adult (>P30) hamsters were immunostained as wholemounts or as 20-40 µm thick frozen sections using AB5 and biotinylated or FITC conjugated secondary antibodies. AB5 selectively labels perikarya in the ganglion cell layer, their proximal dendrites and their axons in the nerve fiber layer, in P12 and older hamsters. AB5 does not label somata or processes in other retinal layers or RGC axons in the optic nerve, chiasm or the brain. All RGCs that are retrogradely labeled by DiI or Evans blue injections into the optic tract of adult hamsters are AB5 positive. We are now investigating whether any AB5 reactivity remains when RGCs are ablated by neonatal optic nerve section. We could not detect AB5 immunoreactivity prior to P12. AB5 labeling is compatible with bromodeoxyuridine (BrdU) immunocytochemistry and therefore useful for studies of RGC generation.

MORPHOLOGY OF RETINAL GANGLION CELLS IN OPERATED HAMSTERS WITH NOVEL RETINAL PROJECTIONS. Edna N. Yamasaki* and Douglas O. Frost. Dept. Neurol., Mass. Gen. Hosp., Charlestown, MA.

Neonatal surgery in hamsters can produce novel, functional retinal projections to non-visual thalamic nuclei. The morphological types of retinal ganglion cells (RGCs) that survive the neonatal surgery are unknown. To address this issue, RGCs, identified by retrograde transport of fluorescent latex beads injected into the superior colliculus (normal hamsters) or stained with acridine orange (operated hamsters), were intracellularly filled with Lucifer yellow (LY) *in vitro* to reveal their soma-dendritic morphology. Retinae were then fixed and immunostained with an antibody against LY. RGCs in operated hamsters were identified by the presence of an axon. RGCs were drawn using a computer microscope.

The 3 RGC types previously described for rats could be recognized in both normal (32 RGCs) and operated (12 RGCs) hamsters. There were quantitative differences between RGCs in normal and operated hamsters. Mean dendritic field diameter was significantly larger in operated than in normal hamsters (378.8 µm vs 324.9 µm, respectively; p=0.038). Mean total dendritic length was also greater in operated vs normal hamsters (5560.9 µm vs 3945.3 µm, respectively; p=0.0037). The total number of dendritic spines was also significantly greater in operated than in normal hamsters (335.7 vs 176.7, respectively; p=.0001) but spine density was not significantly different (0.047 vs 0.066 μm^{-1} respectively; p>0.05). The mean number of dendritic branch points in operated and normal hamsters was not significantly different (66.7 vs 56.7, respectively; p>0.05). There was no significant difference (p>0.05) in mean soma diameter between normal (21.8 µm) and operated (19.1 µm) hamsters. These findings suggest that RGCs in the operated hamsters maintain their basic morphology but their dendritic tree dimensions increase in response to the reduced RGC density in operated hamsters (Irons, Métin & Frost, Neurosci Abs. 16: 336, 1991).

555.8

ESTABLISHMENT OF AXON DIAMETER CLASSES IN THE RAT OPTIC NERVE IS INFLUENCED BY OLIGODENDROCYTES. R.J. Colello[1], R.W. Guillery[2]* and M.E. Schwab[3]. [1,3] Brain Research Institute, Univ. of Zürich, August Forel-Str. 1, CH-8029 Zürich, Switzerland and [2] Dept. of Human Anatomy, Univ. of Oxford, South Parks Road, Oxford, England.

Axons within the rat optic nerve can be classified into distinct groups according to their conduction velocities (Fukuda, 1977) and axon diameters (Hildebrand and Waxman, 1984). In the rat, axon diameters are uniform in size at the time of birth (Colello and Guillery, 1992) and increase from P6 on. This maturation occurs simultaneously with myelination and is complete by the first postnatal month. What is not clear, however, is to what extent myelination helps to establish the adult fiber diameters.

In the present development study, we examine the possible role of oligodendrocytes in establishing the distinct axon diameter classes by, a: measuring the cross-sectional area of fibers within the optic nerve before (P4) and during (P8 and P15) myelination and, b: measuring axonal area in optic nerves where oligodendrocyte development was suppressed by neonatal X-irradiation.

At P4, before initial myelination, there is a unimodal distribution of axon areas with a mean axon area of .12-.14um^2 in both normal and X-irradiated optic nerves. At the time of initial myelination (P8), the mean axon area in both normal and X-irradiated nerves increases to .15-.18um^2, but distinct axon diameter classes cannot be detected yet. This, however, becomes evident in the normal nerve at P15, where a trimodal distrubution of axon areas is established: the smallest populations, represented by 42% of total fiber numbers are .5um^2 or less, whereas the medium-sized (30%) and largest fiber (28%) groups have axon areas of .5-.8um^2 and .8-2.7um^2 respectively. Interestingly, optic nerves free of oligodendrocytes at this age contain a majority of axons (85%) with axonal areas of .5um^2 or less; the remaining axon (15%) have axonal areas of .5-1.7um^2.

These results indicate that the formation of adult axon diameter classes in the optic nerve is a result of both intrinsic cues present in the ganglion cell and extrinsic cues presented by oligodendrocytes.

555.9

EFFECTS OF PRENATAL IONIZING IRRADIATION ON THE DEVELOPMENT OF MOUSE VISUAL PATHWAYS.

S.L. Schmidt* (1,2); R.W.F. Vitral (2) and R. Linden (1). Departamento de Neurobiologia, Instituto de Biofisica da UFRJ (1); Departamento de Ciências Fisiológicas, Instituto de Biologia da UERJ (2).

Prenatal ionizing irradiation of pregnant mice produces in the progeny extensive shrinkage of the posterior halves of the cerebral hemispheres and the dorsal lateral geniculate nuclei (dLGN). In this study we describe the retinal projections to subcortical nuclei in adult mice irradiated prenatally. Pregnant mice were exposed to a gamma source at 16 days of gestation receiving a total dose of 3Gy. Adult mice (n = 13, irradiated progeny; n = 13, nonirradiated controls) received an eye injection (5μl) of a 30% solution of horseradish peroxidase (Sigma type VI). Tha animals were allowed to survive for 2 days. Then the brains were reacted for peroxidase using tetramethyl-benzidine as a cromogen and adjacent sections were counterstained with neutral red. Analysis of the retinal projections indicated that the general pattern of connection of normal and irradiated animals was similar. Bilateral retinal projections were found in dLGN, ventral lateral geniculate nucleus, posterior pretectal nucleus, olivary pretectal nucleus and superior colliculus. Label was found in nucleus of the optic tract only on the side contralateral to the injected eye. In spite of the damage to the striate cortex and the reduction of the dLGN, no abnormal retinal projection fields were detected in irradiated animals. These data differ from those obtained by other authors after neonatal surgical removal of the rat striate cortex. In these cases, aberrant pathways were consistently found. Our data suggest that neonatal or prenatal cortical damage may lead to distinct consequences regarding the redistribution of the retinal axons.

VISUAL DEVELOPMENT: ABNORMAL DEVELOPMENT OF CORTEX

556.1

RESTRICTED CALLOSAL CELL DISTRIBUTION IN THE STRIATE CORTEX OF THE RABBIT FOLLOWING SYSTEMIC YOHIMBINE ADMINISTRATION DURING DEVELOPMENT.

Yuechu Wang,[1] A.M. Grigonis*[2] and E.H. Murphy.[1] [1]Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129, and [2]Department of Anatomy, Hahnemann University, Philadelphia, PA 19102-1192.

In the mature rabbit, the distribution of visual callosal cells which project to the contralateral visual cortex is limited to the 17/18 border. In the newborn rabbit callosal cells are distributed throughout most of the mediolateral extent of area 17. This developmental process of fine tuning in the visual cortex has been shown to be regulated in part by the level of noradrenaline (NA). In the present study we examined the effects of administration of an alpha-2 receptor antagonist, yohimbine, during the critical period, on the development of the visual callosal cell distribution. Yohimbine increases the release of NA by blocking presynaptic alpha-2 adrenergic receptors. Rabbits received intraperitoneal injections of yohimbine HCl (2.5 mg/kg) every day from postnatal day 5 through day 12 (N=4). Rabbits were raised until adult, at which time multiple injections of HRP (Boehringer, 20% in H_2O) were made (total volume injected: 8 μl) throughout one entire visual cortex. Animals were perfused 24 hours later and the brains were cut and reacted with TMB. Adult animals which received yohimbine injections had a significantly reduced tangential extent of the callosal cell distribution in area 17, and also had a significantly reduced callosal cell density in lamina II and III compared to normal animals. Yohimbine administration during the critical period enhanced the process of retraction of exuberant callosal projections. The results provide evidence that NA plays a role in the normal elimination of early exuberant projections during development.

556.2

NEONATAL ENUCLEATION INCREASES THE COMPLEXITY OF THE VISUAL CALLOSAL PATTERN IN THE HAMSTER.

B. J. O'Brien, J.F. Olavarria, J. W. Lewis, E.A. Brenowitz*. Psychology, and Physiology & Biophysics Depts. Univ. of Washington, Seattle, WA 98195.

Callosal cells are widely distributed at birth but become restricted to specific cortical zones during development. It has been suggested that disruption of visual input neonatally arrests this normal process of reorganization, leaving what have been described as abnormally broad patterns of callosal connections. However, enucleation in young rats produces entirely new callosal features which cannot be explained by this mechanism alone. For instance, the most prominent anomalous feature in monocularly enucleated rats is an extra callosal band that runs rostrocaudally through the center of area 17 ipsilateral to the remaining eye. Analysis of these extra features offer clues for identifying extracortical mechanisms capable of altering the callosal pattern, but similar anomalous features have not been described in other species studied to date.

We have, therefore, investigated whether neonatal enucleation induces extra callosal features in golden hamsters. The callosal pattern was revealed with the TMB-HRP technique in coronal and tangential sections of the flattened cortex after multiple injections of HRP contralaterally. Although features of the normal callosal pattern were recognizable at the lateral border of striate cortex and in lateral extrastriate cortex, the callosal pattern in both monocularly and binocularly enucleated hamsters presented distinct anomalies that were very similar to those reported in the rat. In monocular enucleates we observed an extra callosal band in roughly central portions of striate cortex that was beaded in appearance due to fluctuations in the labeling density. Binocular enucleation markedly increased the width of the lateral callosal band in striate cortex, produced discrete areas of reduced callosal labeling within this band and small finger-like extensions of this band into medial striate cortex. Since the distribution of visual callosal connections is closely tied to the underlying topography, the increased complexity of the callosal pattern suggests that disruption of visual input markedly changes the organization of visual cortex.

Development of Retinotopy in Rewired Ferret Auditory Cortex - A Model

B. Sheth *, M. Sur. Dept. of Brain and Cog. Sciences, M.I.T., Cambridge, MA 02139

A topographic map of visual space forms in primary auditory cortex of ferrets with retinal input directed to the auditory thalamus (Roe et al., Science 250: 818, 1990). Interestingly, the visual map in rewired auditory cortex shows retinotopic order despite rather convergent and divergent projections from the thalamus (Pallas et al., JCN 298:50, 1990). We have used a self-organizing model based on Hebbian plasticity of synaptic weights to investigate the possible mechanisms underlying map formation. As expected, auditory input, modelled as a column of thalamic cells activated synchronously, does not cause enhancement of topography in the isofrequency dimension within cortex. Visual input, consisting of local activation of adjacent input cells, guides the development of cortical retinotopy. Thus, the specific nature of input activity appears to play a crucial role in the development of different maps given the same underlying anatomy.

We investigated the relative importance of thalamocortical and intracortical connections in the development of retinotopy when the model is driven by visual input. Retinotopy does not develop when initial thalamocortical and intracortical weights are random. Short-range intracortical excitation leads to enhancement of retinotopy whatever the thalamocortical weights. A higher degree of retinotopy requires some initial topography in the thalamocortical weights; this is sharpened during development by the interplay between the thalamocortical and intracortical weights. Simultaneous changes in both sets of weights leads to the development of a greater degree of retinotopy than is possible by changing either set alone.

More generally, these results indicate that activity-dependent mechanisms can significantly improve the functional topography of widespread anatomical projections in developing pathways. Connections within the target layer (intracortical connections) play an important role in this process. [Supported by EY07719]

INTERFERENCE WITH GENERATION OF LAYER 4 PREVENTS THE FORMATION OF OCULAR DOMINANCE COLUMNS.

Peter Kind*, Frank Sengpiel, Jürgen Engelage and Colin Blakemore University Laboratory of Physiology, Oxford OX1 3PT, U.K.

In the cat, the LGN fibers arrive under the visual cortex and 'wait' before entering, while their principal targets, the cells of layer 4, migrate to their final position. At birth, the terminal fields of fibers from the two eyes overlap, but they gradually segregate into ocular dominance (OD) columns over the first few postnatal weeks.

To investigate the relationship between the generation of layer 4 and subsequent synaptogenesis and formation of OD columns, we used methylazoxymethanol acetate (MAM), a cytotoxin that destroys dividing cells, partially to disrupt the generation of layer 4. Time-mated pregnant cats were given a single injection of MAM (15mg/kg i.p.) on embryonic day 40.5 (the peak of layer 4 cell generation). The pattern of termination and extent of geniculocortical segregation were assessed in the adult offspring using transneuronal tracing with WGA-HRP.

Cortical thickness in the MAM-treated animals appeared virtually normal and lamination roughly equivalent to layers 4 and 2/3 was discernible; however, the density of cells in layer 4 was modestly reduced. Moreover, transneuronal tracing revealed an abnormal pattern of geniculate termination in some parts of areas 17 and 18 with dense termination extending up to the lower limit of layer 1. Even years after birth there was no hint of segregation into OD columns. There was also a marked down-regulation of the Cat-301 antigen in the upper and lower layers of areas 17 and 18. These data suggest that the cells of layer 4 play an important role in determining the laminar pattern of axon termination and in regulating the competition that underlies OD column formation. - Supported by the MRC.

RECEPTIVE FIELDS IN ASSOCIATION AND PRIMARY VISUAL AREAS OF MONOCULARLY DEPRIVED AND NORMAL CATS. U. Yinon*, G. Dobin and I. Volkon, **Physiol. Lab., Goldschleger Eye Res. Inst., Tel-Aviv Univ. Fac. Med., Sheba Med. CTR, Tel-Hashomer, 52621, Israel.**

Receptive fields (RF's) properties have been compared in each animal for two association suprasylvian (PMSA, AMSA) and for two primary (17; PMLS [Clare-Bishop]) visual cortical areas. Unit recording was extracellularly performed in early monocularly deprived (MD) and normal cats. Preliminary data (5 cats; 80 RF's) showed that the ocular dominance distribution of the cells is biased for all these areas in the MD cats and nearly symmetric in the control cats. In all areas both movement and stationary sensitive cells were found; however, the tendency was for more ambiguity in the association areas. RF's of the association areas had extended into the ipsilateral hemifield, albeit their geometric centres were found in the contralateral field. In the MD cats extremely large RF's were found for the association (average: 67.5 deg.^{2}) and PMLS (87.8 deg.^{2}) areas, in comparison to area 17 (2.3 deg.^{2}). In analogy, the RF sizes for normal cats were 258.7 deg.^{2} for the association and 286.9 deg.^{2} for the PMLS areas and 4.7 deg.^{2} for area 17. It has been further concluded that in all four areas studied RF's were remarkably smaller for the deprived cats.

CHOLINE ACETYLTRANSFERASE FIBERS IN THE STRIATE CORTEX OF VERTICAL AND HORIZONTAL STRIPE-REARED KITTENS PREFERENTIALLY DEVELOP ORTHOGONAL TO THE SELECTED VISUAL ORIENTATION. Nancy J. Woolf*, Laboratory of Chemical Neuroanatomy and Dept. Psychology, UCLA, Los Angeles, CA 90024-1563, U.S.A.

Limited visual experience in young, light-deprived kittens to vertical or horizontal stripes has been shown previously to produce morphological changes in the basilar dendrites of pyramidal cells in striate cortex (Tieman and Hirsch, *J Comp Neurol.*, 211: 353, 1982). The present study addressed the possibility of developmental plasticity in one of the presynaptic inputs to cortical pyramidal cells, namely the cholinergic afferent axons. Kittens were reared in the dark until 5 weeks of age, at which time they were 1) exposed to a vertical stripe pattern, 2) exposed to a horizontal stripe pattern, or 3) given no light exposure. After multiple exposures spaced over a 2-week period, kittens were euthanized. Striate cortex was sectioned horizontally and processed immunohistochemically for choline acetyltransferase (ChAT). The orientations of ChAT fibers in and around the basilar dendrites of layer 5 pyramidal cells were clearly distinguishable and in the vast majority of cases were oriented nearly parallel or orthogonal (± 15°) to the vertical median. In the dark reared-condition, total lengths of ChAT axonal segments oriented parallel or orthogonal to the vertical visual meridian were roughly equal, but in stripe-reared conditions, ChAT fibers running parallel were decreased 25 - 68% in length relative to those running orthogonal to the preferred visual orientation.

A GLIOTOXIN, FLUOROCITRATE, REDUCES EFFECTS OF MONOCULAR DEPRIVATION. K. Imamura*, N. Mataga, K. Muguruma, and Y. Watanabe. Dept. of Neurosci., Osaka Bioscience Institute, Suita, Osaka 565, Japan.

Acetate and citrate have been shown to be selectively taken up into the glial cell's compartment. The corresponding fluorinated analogues, fluoracetate and fluorocitrate competitively inhibit the enzyme aconitase, resulting in the reduction of energy supply in this compartment (Clarke et al., 1970). Using the fluorocitrate as a gliotoxin, we studied roles of immature astrocytes in the regulation of the ocular dominance plasticity. Around 20µl of 10µM fluorocitrate was infused diffusely by pressure application into the visual cortex (area 17, subcortical depth 0-5mm) of 7-9 week-old kittens. Following the infusion, the contralateral eye was closed monocularly for 3 days. Physiological recordings from the vicinity of the infusion site (~1 mm) revealed that an usual shift in ocular dominance toward the open eye was prevented. Whereas a normal shift was consistently observed in the region ~ 4 mm remote from the infusion site in the same hemishere. The proportion of binocular cells was significantly higher in the region affected by fluorocitrate (average binocularity; 0.42, control; 0.23, t-test; $p < 0.05$). These results suggest that some functions of astrocytes in the immature kitten visual cortex is a prerequisite for the full expression of the ocular dominance plasticity.

UP-REGULATION OF POLYSIALYLATED NCAM EXPRESSION BY ACTIVITY BLOCKADE IN KITTEN VISUAL CORTEX G.E. Baker*, E.S. Ruthazer, U. Rutishauser and M.P.Stryker Keck Center for Integrative Neuroscience & Neuroscience Program, Univ. of California, San Francisco, CA 94143; Dept. of Developmental Genetics, Case Western Reserve Univ, Cleveland, OH 44106

Polysialylated NCAM (psa-NCAM) on developing axons has been shown to be directly involved in chick limb bud innervation, and the degree of NCAM sialylation is regulated by the level of neural activity (Landmesser et al., *Neuron* 4:655, 1990). In mammals, the organization of retinogeniculate and geniculocortical axonal arbors is profoundly influenced by patterns of neural activity during development. We have therefore studied the expression of psa-NCAM in the visual pathways of cats.

In the normal visual cortex, psa-NCAM was immunohistochemically nearly undetectable at birth and remained low thereafter. Tetrodotoxin (TTX) was chronically infused at 0.5 ul/hr into one visual cortex of kittens beginning at postnatal day 24. One week later, blockade of neural activity in a region extending approximately 7mm rostral to the infusion site was confirmed using conventional extracellular microelectrode recording. The brains were subsequently fixed, sectioned, and processed for immunoreactivity to psa-NCAM and to total NCAMs. The expression of psa-NCAM was elevated manyfold above normal levels in the region of cortex in which activity was blocked. In the cortical plate, the region in which this elevation was found extended at least 5mm from the site of infusion of TTX in the lateral gyrus. The highest density of staining was found in cortical laminae IV and VI. In addition, staining in the white matter was greatly increased and extended laterally into the suprasylvian and ectosylvian gyri, and medially through the corpus callosum into the contralateral hemisphere.

The finding that TTX blockade of activity results in up-regulation of psa-NCAM on axonal connections of the kitten's visual cortex raises the possibility of a direct causal link between the expression of psa-NCAM and activity-dependent changes in organization of the geniculocortical projection.

CALCIUM INCREASE IN RAT VISUAL CORTEX NEURONS DURING TETANIC SYNAPTIC INPUTS.

M. P. Takahashi, M. Sugiyama, Y. Hata* and T. Tsumoto, Dept. of Neurophysiology, Biomedical Research Center, Osaka University Medical School, Suita, 565 Japan

An entry of Ca^{2+} into postsynaptic sites through NMDA receptor-linked channels is suggested to be a trigger for induction of long-term potentiation following tetanic synaptic inputs in the developing visual cortex. To test this hypothesis, we measured changes in $[Ca^{2+}]_i$ following tetanic stimulation of the white matter with fluorometry using a Ca^{2+}-sensitive indicator, rhod-2, in slice preparations of the visual cortex of rats aged from 15 to 30 days. Slices were loaded with 10 µM rhod-2/AM and fluorescence image of slices was recorded with a SIT camera. Simultaneously, field potentials to test stimulation of the white matter were recorded from layer II/III of the cortex. During tetanic stimulation (5 Hz, 1 min) of the white matter, the fluorescence increased in a columnar manner from the stimulation site to the pial surface and the increase was most marked in layer II/III. An application of D,L-2-amino-5-phosphonovaleric acid, an NMDA receptor antagonist (100 µM), reduced the tetanus-induced fluorescence increase in layer II/III to 75 ± 15 % of the control. Effects of a non-NMDA receptor antagonist, CNQX (20 µM), was tested in a Mg^{2+}-free medium and turned out to be ineffective. Nifedipine (10 µM), an L type Ca^{2+} channel blocker and Ni^{2+} (100 µM), a relatively selective blocker for T type Ca^{2+} channel, also exerted suppressive effects, but with less extent. Thus, tetanic synaptic inputs may lead to an influx of Ca^{2+} into cortical neurons at least partly through NMDA receptor-linked channels.

DARK-REARING POSTPONES RATHER THAN ABOLISHES THE CHANGE IN THE NMDA CONTRIBUTION TO THE VISUAL RESPONSE DURING THE DEVELOPMENT OF THE CAT VISUAL CORTEX. N.W. Daw*, D. Czepita and S. Reid. Dept. Anatomy and Neurobiology, Washington Univ. Med. Sch., St. Louis, MO 63110

The contribution of NMDA receptors to the visual response in layers IV, V and VI of the cat visual cortex drops from an average of 60% to an average of 10-15% between 3 and 6 weeks of age (Fox, Sato & Daw, J. Neurosci. 9: 2443-2454, 1989). This drop can be halted by rearing the cats in the dark to 6 weeks of age (Fox, Daw, Sato and Czepita, Nature 350: 342-344, 1991): it then proceeds when the cats are brought into the light. In the current experiments we tested whether this drop can be halted indefinitely by rearing in the dark. We reared three cats in the dark to 5 months of age, then assayed the NMDA contribution to the visual response by iontophoresing the NMDA antagonist APV near the cell being recorded. The average contribution of the NMDA receptors to the visual response was 27% in layer IV, and 16% in layers V and VI. Our conclusion is that rearing in the dark can delay the drop in NMDA contribution, but will not halt it indefinitely.

NERVE GROWTH FACTOR INDUCES NEURONAL PLASTICITY IN ADULT CAT VISUAL CORTEX. Q. Gu*, Y.L. Liu and M.S. Cynader. Department of Ophthalmology, University of British Columbia, Vancouver, British Columbia, Canada, V5Z 3N9.

Nerve growth factor (NGF) has been shown to be involved in neuronal survival, growth and differentiation. We have been examining whether NGF also plays an important role in neural plasticity in the visual cortex. During early postnatal development, neuronal connections in the visual cortex are highly susceptible to activity-dependent modification. For example, a few days of monocular deprivation renders most neurons in the visual cortex, which normally respond to stimulation of both eyes, unresponsive to stimulation of the deprived eye. However, this activity-dependent modification occurs only within a "critical period" in development and not thereafter. In adult visual cortex, neurons are no longer susceptible to monocular deprivation. To test the hypothesis that NGF may enhance neural plasticity in adult visual cortex, varied doses of NGF were continuously infused, by means of osmotic minipumps, into visual cortex of adult cats who had one eyelid sutured closed at the time of minipump implantation. After various times (minimum 2 weeks), the ocular dominance distributions of neurons in the visual cortex were assessed with single unit recording. We found that there was a dramatic change in ratio of binocularly activated neurons to monocular neurons in the adult visual cortex after monocular deprivation coincident with NGF-treatment. Our results demonstrate that intracortical infusion of NGF can recreate ocular dominance plasticity in adult cat visual cortex. The mechanisms by which NGF induces neural plasticity in adult visual cortex are now under investigation.

Anti NGF monoclonal antibodies affect the postnatal development of the rat geniculocortical system N. Berardi*, A. Cattaneo+,§, A. Cellerino§, L. Domenici, M. Fagiolini, L. Maffei§ and T. Pizzorusso§. Istituto di Neurofisiologia del CNR, I-56127 Pisa, § SNS, I-56125, Pisa, +SISSA, Trieste and §Ist. Neurobiologia del CNR, I-00156 Roma (Italy)

We have recently found that exogenous supply of NGF in rats monocularly deprived during the critical period of cortical plasticity prevents the effects of monocular deprivation, i.e., deprived eye amblyopia, shift in ocular dominance (OD) distribution of visual cortical neurons and shrinkage of cell bodies in the deprived Lateral Geniculate Nucleus (LGN) laminae. To test the role of endogenous NGF in the normal postnatal development of the geniculocortical system we have studied if and how it is affected by inhibiting the physiological activity of NGF. Hybridoma cells secreting an anti NGF antibody, aD11, known to inhibit NGF binding to the target cell (Cattaneo A. et al. 1988 J. Neurochem. 50(4), 1003) have been transplanted in the right lateral ventricle of 10 rats (age 15-18 postnatal days, P15-P18), to provide continuous supply of antibody. 2µl of Hanks solution containing 10^6cells/µl were injected. The presence of aD11 in the visual areas was readily detected by Western blot. Parental myeloma cells were transplanted in ten P15-P18 rats as control. At P45 cell soma size in cresyl violet stained sections of the LGN, OD of visual cortical cells and visual acuity (recordings from the left visual cortex) were evaluated for both groups and compared with those of normal rats of the same age. We found that cell soma size in the LGN of Hybridoma transplanted rats was 30% smaller than in normal rats, visual acuity was reduced by 40 % and the percentage of binocular cortical neurones was nearly halved. By contrast, these parameters were within the normal range in Myeloma transplanted rats. We conclude that inhibition of NGF activity affected both the LGN and the visual cortex, suggesting a physiological role for NGF in the development of these structures.

Transplant of Schwann cells in the lateral ventricle prevents the effects of monocular deprivation in the rat T. Pizzorusso§, M. Fagiolini&, M. Fabris#, G. Ferrari# and L. Maffei*§. §Scuola Normale Superiore, Pisa, & Istituto Neurofisiologia CNR, via S.Zeno,51 Pisa, # Fidia Research Laboratories Abano Terme (PD) (Italy).

Monocular deprivation (MD) during the critical period of mammalian visual cortex shifts the ocular dominance distribution of visual cortical neurons towards the non deprived eye. Recent results showed that an exogenous supply of NGF prevents the effects of MD in the rat visual cortex (Domenici et al., '90, PNAS 88, 8811-8815; Berardi et al. J. Physiol. '91, 434 14P). Since Schwann cells are known to produce NGF,BDNF and CNTF, we tested the possibility of using Schwann cells (SC) as biological pumps for neurotrophic factors in the CNS. 21 rats were used. 19 rats were monocularly deprived before eye opening (P14). 3 of them were transplanted with 10^6 SC, 7 MD rats with 6 10^5 SC, 2 MD rats with 3 10^5 SC, 3 MD rats with 10^5 SC and 4 MD rats were left untreated. SC were transplanted by intraventricular injection at P15. In 2 rats of each group SC were labeled prior to transplantation with Fluorogold. After one month, the impulse activity of single cortical cells was recorded from the primary visual cortex. We found that MD shifts the ocular dominance away from the deprived eye both in untreated and in 10^5 SC transplanted. Increasing amounts (3 10^5, 6 10^5) of SC gradually attenuate the shift in ocular dominance distribution and in 10^6 SC transplanted rats the ocular dominance distribution was similar to that observed in normal adults. The transplant did not affect the selectivity for the stimulus parameters of cortical cells. After the recording session, the rats transplanted with Fluorogold labeled SC were perfused and their brains sectioned. We found that SC were located on the white matter nearby the injection site and on the blood vessel walls of the whole telencephalon. We conclude that the transplant of SC in the CNS prevents the effect of MD, its effectiveness increases with the number of transplanted SC.

"MAGNO-WEIGHTED" STIMULI DISCLOSE BIASES OF VERTICAL AND HORIZONTAL MOTION PERCEPTION IN HUMAN INFANTILE STRABISMUS. A. Rastelli, S. Steinman+, L. Tychsen, and A.Burkhalter*. Dept Ophthalmology, Washington Univ Sch Medicine, and +School Optometry, Univ Missouri St Louis.

Humans who have onset of strabismus in infancy have maldeveloped visual motion processing when viewing monocularly (Tychsen and Lisberger, 1986). To determine if the motion anomaly could be elicited by a simpler stimulus optimally "tuned" for magnocellular neurons, we tested 5 subjects (2 controls, 1 motor nystagmus, 1 late-onset exotrope, and 1 infantile-onset esotrope) using stationary, low spatial frequency, high temporal frequency, reversing, black-and-white bar gratings.

Motion misperception was found only in the subject with infantile-onset strabismus. Vertical gratings were perceived to be moving nasally at a low velocity. Nasally-directed pursuit eye movement was induced when the misperception became robust. Horizontal gratings were perceived to be moving upward, and upward pursuit eye movement was induced. Optimal properties for inducing misperception were gratings with spatial frequencies < 1.6 cycles/deg and temporal frequencies > 6.7 cycles/sec. Absence of the misperception in the subjects with motor nystagmus and exotropia show that ocular motor abnormalities cannot account for misperceptions.

We conclude that a simple grating stimulus, designed to emphasize the spatio-temporal tuning properties of the magno-system, is a useful tool for detecting the motion pathway anomalies of infantile strabismus.

BEHAVIORAL FUNCTION OF NOVEL NEURAL CIRCUITS. L.A. Rothblat* and D.O. Frost. Dept. Psychol., George Washington Univ., Washington, DC and Dept. Neurol., Mass. Gen. Hosp., Charlestown, MA.

In hamsters, novel, retinal projections to the primary auditory (medial geniculate, MG), primary somatosensory (VB) or visual association (lateral posterior, LP) thalamic nuclei can form after neonatal surgery. We have previously demonstrated that the projections to the somatosensory system are functional at the neurophysiological level. We now offer preliminary data on the behavioral function of novel projections.

The discrimination of 3 horizontal rows vs 3 vertical rows of black squares on a white background normally depends upon the integrity of the retino-geniculo-striate system: 4 normal adult hamsters learned this task to a 90% correct criterion in 8, 17, 17 and 21 days (30 trials/day) respectively. After reaching criterion, 2 animals (which learned in 8 and 17 days) received lesions that included all of area 17 plus adjacent parts of areas 18a and 18b. These animals failed to relearn the task postoperatively within 40 days. 4 newborn hamsters received bilateral lesions of the superior colliculus, the brachium of the inferior colliculus and the occipital cortex (areas 17, 18a and 18b); the cortical lesions caused retrograde degeneration of the dorsal lateral geniculate (LGd), LP and lateral dorsal nuclei. In all 4 animals, as adults, the losses of area 17 and LGd were complete, but there were variable-sized remnanats of area 18a and LP; all 4 also had variable losses of MG and other thalamic nuclei. 3 of the 4 hamsters had novel retino-LP projections; 2 of these 3 had retino-MG projections. When tested behaviorally, the 3 hamsters with retinal projections to LP or MG learned the task in 14, 15 and 31 days; the 4th hamster still failed after 40 days. The 3 successful hamsters then received lesions of the remaining occipital and temporal cortices. All 3 failed to relearn the task after 40 days. Thus, it appears that the primary auditory- or an associative thalamocortical pathway can take over a visual function normally mediated by the geniculo-striate system. SYNAPTIC PLASTICITY FOLLOWING EARLY AND LATE DECOMPRESSION FOR INFANTILE HYDROCEPHALUS. J.P. McAllister II*, R.A. Morano, R.A. Ireland, D.V. Shroff, P.M. Hale and R.M. Kriebel. Depts. of Anatomy, Temple Univ. School of Medicine and Phila. Coll. Osteopathic Medicine, Philadelphia, PA 19140.

Controversy persists regarding the clinical decision of when to surgically decompress hydrocephalic children. To address this issue systematically, the present study continues our quantitative analysis of the neuropil of hydrocephalic animals before and after ventriculo-peritoneal (VP) shunting at two different time points. Obstructive hydrocephalus was induced in 10 day old kittens by intracisternal injection of kaolin; VP shunts were placed in hydrocephalic animals at early (6-8 days post-kaolin) and late (11-14 days) stages of ventriculomegaly. Normal animals served as age-matched controls. Hydrocephalic animals were sacrificed at times corresponding to immediate pre-shunt periods, and about 7 days after shunt placement. Tissue from primary visual cortex was processed for electron microscopy and the number of synapses per unit area determined for deep laminae. As shown below, early and late shunts restored synaptic density to within 32% ($p = 0.08$) and 35% ($p = 0.005$) of controls, respectively. These data modify our previous findings and suggest that only early decompression is effective in promoting synaptic recovery.

	Early Shunts			Late Shunts		
	Control	Hydro	Shunt	Control	Hydro	Shunt
Synapses/ 100 µm²	17.6 ±3.1	9.1 ±3.1	12.0 ±4.1	21.0 ±1.7	14.2 ±2.6	13.8 ±.14

LOCALIZATION AND CHARACTERIZATION OF SPECIALIZED MEMBRANE CONTACTS BETWEEN IMMATURE CONES IN THE PHOTORECEPTOR MOSAIC OF THE FETAL MONKEY RETINA Kenneth C. Wikler*and Pasko Rakic. Sect. of Neurobiol., Yale Univ. School of Medicine, New Haven CT 06510.

Developmental examination of the maturing photoreceptor mosaic in the fetal monkey retina has revealed a regular array of precocious cones that are transiently in apposition with their nascent cone neighbors (Wikler and Rakic, '91, Nature, 351: 397). Previous studies of dissociated cell cultures suggest that the development of photoreceptor phenotypes may be specified in part through early cell: cell interactions that may be mediated by either diffusable agents or through specialized membrane contacts (Watanabe and Raff, '90, Neuron, 2: 461). To examine the existence of potential contacts between neighboring cones in the primate retina we initiated an ultrastructural and immunocytochemical study of the photoreceptor mosaic at the onset of differentiation for the red/green- and blue- sensitive cone subtypes.

The perifoveal region of retinae from rhesus monkeys sacrificed at embryonic (E) days ranging between E60 and E110 were prepared for electron microscopy or immunocytochemistry. Examination of the retina at E60 or E70, prior to the development of outer segments, revealed the presence of punctate specialized membrane contacts between the inner segments of immature cones. At early fetal ages these contacts are unlikely to be gap junctions since neither our electron microscopic or immunocytochemical analysis using antibodies specific to the connexin- 32 fragment of the gap junction protein have revealed the presence of gap junctions between cones. These specialized intercone membrane contacts do resemble puncta adherentia having symmetrical filamentous thickenings facing the cytoplasmic compartments of the apposing segments and a wide intermembrane cleft. In some instances, vesicular profiles were found associated with these membrane junctions. In contrast, in the E100 or E110 cases, specialized membrane contacts between cones were not observed after the development of cone outer segments. The transient appearance of specialized membrane contacts between immature cone inner segments suggests a role for these junctions in the emergence of the photoreceptor mosaic. Supported by EY02593

DEVELOPMENT OF cGMP-PHOSPHODIESTERASE IN RETINAL PHOTORECEPTORS OF THE RAT. E. Strettoi*, and L. Colombaioni Istituto di Neurofisiologia CNR, 56127 Pisa, Italy

In retinal photoreceptors, the process leading from light absorption to cell membrane hyperpolarization involves the activation of a specific cGMP-phosphodiesterase (cGMP-PDE); this enzyme hydrolyses 3'-5' cyclic guanosine monophosphate that regulates the permeability of the light-sensitive channels.

We have investigated by immunofluorescence and electron microscopy immunocytochemistry the appearance of cGMP-PDE during the postnatal development of the rat retina. The distribution of cGMP-PDE during development has been compared with that of the adult retina. A monoclonal antibody, ROS1, specific for photoreceptor cGMP-PDE, has been employed. We show that a sudden increase in immunoreactivity takes place during postnatal day 5, when rod outer segments begin to form; immunoreactivity develops rapidly in the following days. Labelling is restricted to the developing photoreceptor outer segments, sparing other cellular districts and other retinal cells, as confirmed by electron microscopy. cGMP-PDE immunoreactivity mirrors the centre-to-periphery gradient of photoreceptor differentiation.

cGMP-PDE appears in photoreceptor outer segments concomitantly with photoactive rhodopsin and rhodopsin kinase, suggesting a coordination in the appearance of phototransduction proteins during development. If photoreceptor outer segments are assembled fully provided with their enzymatic machinery, it is conceivable that light dependent electrical events could take place in photoreceptors before the retinal circuitry has completely developed.

557.3

REGULATION OF INTEGRIN ALPHA AND BETA mRNA'S IN DEVELOPING CHICK RETINA. D. B. Gervin, G. M. Cann, A. D. Bradshaw, R. C. Cadwell, C. J. Cummings, A. W. Hunter, R. M. Lebel, E. S-H. Choi, and D. O. Clegg*. Neuroscience Research Institute and Division of Molecular and Cellular Biology, Department of Biological Sciences, University of California, Santa Barbara, CA 93106.

Interactions between developing retinal cells and the extracellular matrix may play roles in retinoblast migration or translocation, determination of cell fate, axonal pathfinding, and possibly synapse formation. Matrix proteins such as laminin, S-laminin, vitronectin, and thrombospondin have provocative distributions that in some cases correlate with developmental events. Receptors that mediate cell responses to matrix include those in the integrin family, but little is known about which receptors are used and how they are regulated.

To address these questions, we have attempted to identify integrin mRNA's that are expressed in the developing chick retina, and determine how they are regulated. We have employed a polymerase chain reaction (PCR) strategy using degenerate primers that recognize related integrin alpha or beta subunits. We have detected 5 alpha subunit mRNA's and 3 beta subunit mRNA's that are expressed in retinal tissue: Alpha's 2, 4, 6, 8, and v; and beta's 1, 3, and 5. PCR was also used to quantify changes in the relative amounts of these messages during development. We have found that alpha 6 and 8 mRNA levels decrease between embryonic day 6 to embryonic day 9, which correlates with changes in matrix responses that have been observed in cultured embryonic neurons. We speculate that changes in integrin expression may be important for retinal development, particularly during axonal pathfinding.

557.4

IMMUNOHISTOCHEMICAL LOCALIZATION OF CALPAINS AND CALPASTATIN IN THE EYE OF THE RABBIT. H. Persson* and J.-O. Karlsson. University of Göteborg, Dept of Anatomy and Institute of Neurobiology, Box 33031, S-400 33 Göteborg, Sweden.

The tissue distribution of m-calpain (calpain I) and μ-calpain (calpain II) in the eye of the rabbit was examined using polyclonal and monoclonal antibodies against the corresponding rabbit antigens. Purification of antigens was made as described previously (e.g. Nilsson, E. *et.al.*, Neurobiology of aging, 11 (1990) pp. 425-431) and purified antigens were injected into chickens to produce IgY antibodies recovered from the egg yolk. Monoclonal antibodies were a generous gift of Dr. S. Kawashima. Adult New Zealand White rabbits were perfusion fixed with 4 % paraformaldehyde and the eyes postfixed overnight after enucleation. 10 μm thick cryostat sections were cut, blocked with normal rabbit serum and incubated overnight with appropriately diluted primary antibodies. Bound antibodies were visualized with FITC-conjugated rabbit anti-chicken IgG fraction antibodies and sections mounted in DABCO before viewing in a Nikon Microphot FX epifluorescense microscope equipped with FITC optics. Distinct immunoreactivity against the two forms of calpains and calpastatin was observed in the epithelial cells on the external and internal surface of the cornea as well as in the epithelial cells covering the iris and ciliary body. The sclera and choroid layers showed a relatively weak immunoreactivity with anti-calpain antibody, while anti-calpastatin immunoreactivity was more distinct. By contrast, in the retina, the pigment epithelium, as well as the outer and inner plexiform layers, the inner and outer borders of the Müller cells and the retinal ganglion cells and the nerve fiber layer were distinctly labelled by the anti-calpain antibodies while anti-calpastatin immunoreactivity was less pronounced in these areas. The outer segments of many receptor cells showed a distinct immunoreactivity with both anti-calpain- and -calpastatin antibodies. Thus, labelling by antibodies against these antigens appears to be associated with areas expected to have a high degree of metabolic activity and/or membrane turnover, in line with the notion that calpains are protein degrading enzymes representing part of a non-lysosomal catabolic pathway. TRK PROTEIN IS DISTRIBUTED IN A DORSOVENTRAL GRADIENT IN THE EMBRYONIC RAT RETINA. R.H. Fryer,* D.R. Kaplan, and L.F. Kromer. Dept. of Anat. & Cell Biol., Georgetown University Medical Center, Washington, DC 20007 and the National Cancer Institute, Frederick, MD 21702

During embryonic development, retinal ganglion cells form specific topographic projections in the LGN and tectum. Although it is uncertain what governs this specificity, temporal and axial gradients of specific molecules on retinal neurons and axons are thought to be important for this process. Since retinal neurons respond to trophic molecules, such as NGF and BDNF, the objective of the present study was to determine whether receptors for these neurotrophins, which belong to the *trk* family of tyrosine kinase receptors, might also be associated with the appearance of gradients within the embryonic retina. For these experiments immunofluorescence techniques with a pan-*trk* antibody that recognizes a highly conserved intracellular domain present in *trk*A, *trk*B and *trk*C, were used to examine the timecourse of expression of these neurotrophin receptors. By embryonic day 14 (E14), all cells in the dorsal most retina and their associated axons in the initial optic nerve segment express *trk* proteins. At E15 and 16, *trk*+ cells are still restricted to the dorsal retina but *trk*+ axons are now observed in the optic chiasm (E15) and track (E16). By E18, *trk* staining is mainly localized to retinal ganglion cells present in both the dorsal and ventral retina. These results indicate that during a critical period in retinal development there is a gradient in the expression of *trk* receptors on retinal cells and their axons which might be involved in the formation of the retinotopic map.

DISTINCT PATTERNS OF SODIUM CHANNEL-LIKE IMMUNOREACTIVITY EXPRESSION DURING PRENATAL DEVELOPMENT OF THE CAT AND MONKEY RETINA. J.J. Miguel-Hidalgo*, K.J. Angelides+, L.M. Chalupa. Ctr. Neurobiology, Univ. California, Davis, CA 95616; +Physiol. & Molec. Biophysics Dept., Baylor Univ., Houston, TX 77030.

Polyclonal and monoclonal antibodies to the α subunit of the voltage-gated sodium channel (αVGNaC) were used to examine the distribution of sodium channel-like immunoreactivity during the prenatal development of the cat and monkey retina. At all prenatal ages studied, beginning embryonic day 29 (E29) in the cat and E45 in the monkey, both antibodies labeled optic axons. With the polyclonal antibodies the appearance of positive cells largely mirrored the onset of their morphological maturation. For instance, immunoreactivity appeared first in the somata of ganglion cells. A few weeks later horizontal cells displayed immunolabeling. This was followed by immunoreactive cones, with the bipolar cells labeled only postnatally. By contrast, with the monoclonal antibody some cells were found to be immunoreactive while their somata were still in the ventricular layer (E33 in cat and E52 in monkey). Many of these cells appeared to migrate to the outer portion of the prospective inner nuclear layer where they gradually acquired the morphological appearance of bipolar cells. These results indicate that different types of αVGNaC-like proteins are expressed in the mammalian retina at distinct developmental periods. They also suggest that these proteins could be playing developmental roles unrelated to their function at maturity. Supported by NIH and NMSS.

LIGHT-INDUCTED EXPRESSION OF IMMEDIATE EARLY GENES IN RAT RETINA

K.P. Gudehithlu[1]*; A.M. Duchemin[1]; N.H. Neff[1] and M. Hadjiconstantinou[1,2]. Depts. of Pharmacology[1] and of Psychiatry[2] and the Neuroscience Program, The Ohio State University College of Medicine, Columbus, OH 43210.

Induction of immediate-early genes expression occurs in response to a wide range of extracellular stimuli. We present evidence for the expression of *c-fos* and *NGFI-A* in rat retina after exposing them to room light. Male Sprague-Dawley rats were maintained in a 12-h light/dark cycle with lights on at 0800 h. Animals were decapitated either in the dark or after various time intervals in room light. Total RNA from retina was extracted and *c-fos*, *c-jun* and *NGFI-A* mRNA were assayed by Northern blot hybridization. A dramatic increase of *c-fos* expression was observed in retina of light exposed animals which reached a peak (682%) after 30 min. In contrast, *NGFI-A* reached a peak after 15 min (246%) of light. Both mRNAs returned to basal values after 2 h of continuous light. Under our lighting conditions, we were unable to observe enhanced expression of *c-jun* in the retina. Basal content of *c-fos*, *NGFI-A* and *c-jun* were assayed at 0700, 1 h before the onset of room lighting. Injection of MK-801 (NMDA receptor antagonist) or SCH 23390 (D1 dopamine receptor antagonist) 30 min before exposure to light did not prevent the induction of either *c-fos* or *NGFI-A* in retina. Our results show that light transiently induces the expression of some immediate early genes in rat retina and that the induction is probably not mediated by glutamate or dopamine receptors.

CLONES AND POLYCLONES IN THE RETINA OF ADULT INTRASPECIES MOUSE CHIMERAS: D.S. Rice*, R.W. Williams, and D. Goldowitz
University of Tennessee, College of Medicine, Memphis, TN 38163

We are interested in the clonal structure of the mammalian retina. *Mus musculus* intraspecies chimeras were generated by fusing embryos from ICR and globin transgenic (GT) strains. GT cells were labeled with DNA probes in 5-μm paraffin sections of retina or in wholemounts. GT cells contribute a variable percentage of cells to chimeric retinas (0.5% to 70%). Clones and polyclones of GT cells are aligned radially and uniformly across inner and outer nuclear layers. As in interspecies chimeras (Williams & Goldowitz, 1992, PNAS 89,1184), boundaries between regions of different genotypes are well defined in our intraspecies chimeras. We have not noted any marked differences in the organization of clones or polyclones between intra- and interspecies chimeras. However, the number of small cohorts (1-2 cell diameters) appears to be greater in intra- than interspecies chimeras.

To reveal the pattern of clones and polyclones across the entire retina, we developed a method to label GT cells in wholemounts using DNA *in situ* hybridization. This makes it feasible to directly examine the distribution of the two genotypes in the ganglion cell layer of chimeras, as well as, to determine the correspondence between genotypes in the ganglion cell layer and in the inner and outer nuclear layers. In many instances, GT ganglion cells are displaced horizontally by as much as 20 to 30 μm from GT-labeled regions in inner and outer nuclear layers. Conversely, unlabeled ganglion cells are often found directly beneath cohorts of GT cells in the nuclear layers. This demonstrates that ganglion cells are often separated from the other members of their clones and suggests that these laterally-displaced cells make functional contacts with cells that have different clonal origins, and even different genotypes. Supported by NEI R01-8868.

DYNAMICS OF MOUSE RETINOGENESIS: A POPULATION AND CLONAL ANALYSIS. Dan Goldowitz* and Robert W. Williams. University of Tennessee, College of Medicine, Memphis, TN 38163

We have studied the dynamics of the increase in total cell number and clone structure in mouse retina. Estimates of the total number of retinal neuroepithelial cells were made in *Mus musculus* mice (albino ICR strain) at embryonic days E11, E12, E13, E15, the day of birth, and in adults. The retina consists of about 10,000 neuroepithelial cells at E11. There are essentially no postmitotic cells in retina at this age. By E13 the total cell population is ~40,000. By E15, the total cell population has increased to ~100,000, and at maturity the retina contains 3 to 4 million cells. To examine how this 300-fold increase between E11 and maturity is reflected in the clonal and polyclonal architecture of the retina, intraspecies chimeras were made using the globin transgenic (GT) mouse strain and the ICR strain. Chimeric retinas were examined at embryonic and early postnatal stages using in situ hybridization with labeled DNA to mark GT cells.

Cohorts and clones in these chimeric embryos typically form small radial arrays even at the earliest stages of development. The pattern is qualitatively similar to that seen in adult chimeras (Williams and Goldowitz, 1992, PNAS 89, 1184), except that cohorts contain far fewer cells—often less than 4 cells. In one E11 chimera, the right eye contained less than 1% GT cells, whereas the left eye contained no GT cells whatsoever. In this case, GT cells in the right retina were widely, but unevenly distributed. It is possible that the rudiment of this animal's right eye included a single GT cell, whereas the rudiment of the left eye included no GT cells. Our analysis indicates that a relatively small pool of progenitors—possibly less than 100—contributes to the murine retina and that even a single progenitor can give rise to a widely dispersed family of clones.

DEVELOPMENTAL EXPRESSION OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) mRNA IN THE RAT RETINA. **G. Casini*, M. Molnar and N. Brecha, Depts. of Anatomy & Cell Biology and Medicine, BRI and CURE, UCLA and VAMC-West Los Angeles, Los Angeles, CA 90073.**

Using *in situ* hybridization histochemistry, we examined the developmental regulation of VIP mRNA in the rat retina. Retinas collected from birth to postnatal day (PND) 30 were hybridized with a rat VIP RNA probe (from Dr. Goodman) as whole mounts, and then cut either perpendicularly or parallel to the vitreal surface. In adult retinas, VIP mRNA is localized to somata positioned in the proximal inner nuclear layer (INL) and rarely in the inner plexiform or ganglion cell layer. These cells are amacrine and displaced amacrine cells. Neurons expressing VIP mRNA are sparsely distributed, with a non-random distribution and densities typical of wide-field amacrine cells. VIP mRNA is first detected in the retina during the first postnatal week. The hybridization signal is weak, suggesting low levels of VIP mRNA in these cells. As in the adult retina, labeled neurons are located in the proximal INL, suggesting that these cells express their transmitter phenotype when they are in their final laminar position in the INL. Stronger hybridization and more numerous VIP mRNA-containing neurons are present in the retina at PND 10, which is near eye opening. By PND 15 to 20, the maturation of this cell population is virtually complete. These results show that 1) VIP is expressed in a specific population of amacrine cells in the rat retina; and 2) the developmental expression of VIP is similar to that of other amacrine cell neurotransmitters.

IMMUNOCYTOCHEMICAL CHARACTERIZATION OF RPE-CELL TRANSPLANTED RETINAS OF RCS DYSTROPHIC RATS. M.J. Sheedlo[1], L. Li[1], C.J. Barnstable[2] and J.E. Turner[1]*, Department of Neurobiology and Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC[1] and Department of Ophthalmology and Visual Science, Yale University School of Medicine, New Haven, CT[2].

This study was undertaken to further characterize the photoreceptor cell (PRC) rescue effect of RPE-cell transplants in retinas of Royal College of Surgeons (RCS) dystrophic rats (Li and Turner, 1988). Retinas of control and RCS dystrophic rats were immunostained with the monoclonal antibodies RET-P1 (N-terminus of opsin), SVP-38 (synaptophysin) and HNK-1 (a carbohydrate of N-CAM) using a paraffin technique (Sheedlo et al., 1989). RET-P1 in neonatal normal retinas immunostained the neuroblast layer, while in adult retinas outer and inner segments and PRC bodies were immunostained. In retinas of RCS rats, beginning by day 30, in addition to PRC constituents, a subretinal debris zone stained. By one year in RCS retinas, RET-P1 immunostained debris material was sparse and confined to the periphery. SVP-38 densely stained the outer plexiform layer (OPL), with lighter staining found in the inner plexiform layer (IPL) of normal retinas. In RCS retinas, a similar pattern was observed up to 2 months; however, at about 4 months, only the IPL stained. The HNK-1 antibody densely immunostained the OPL, IPL, a few cell bodies in the inner nuclear layer (INL) and ganglion cell bodies and their axons in control retinas. In RCS retinas, this staining pattern persisted until 2 months. Most importantly, in retinas of 4 month-old RCS rats transplanted with normal RPE cells at 26 days, the pattern and density of immunostaining for each of the above monoclonal antibodies was identical to that observed in control adult, healthy retinas, especially directly beneath the transplant. This result suggests that RPE transplants not only promote PRC survival, but also maintain the structural and, possibly, the functional integrity of dystrophic retinas. Two monoclonal antibodies (RET-PE2 and RET-PE10) which are specific for RPE cells are also being studied in RPE-transplanted RCS retinas.

PRENATAL DEVELOPMENT OF HORIZONTAL CELLS IN THE RETINA OF THE RHESUS MONKEY. S.J. Kim and M.A. Kirby*, Department of Pediatrics, Loma Linda University, Loma Linda, CA 92350.

Recent studies have shown that the formation of the primate fovea is characterized by the lateral migration of cell classes. At present nothing is known of the effects of this movement on the morphological development of horizontal cells. Using retinal explants and horseradish peroxidase (HRP) we investigated the maturation of this cell class from embryonic day (E) 68 to E150 (term is 165 days). Animals were delivered by C-section, deeply anesthetized, and the retinas rapidly removed and placed into medium. HRP was inserted into the retina at different locations. After three hours, the retinas were fixed and processed for HRP.

At E68 horizontal cells at all locations had surprisingly complex arbors and could be classified as HI or HII cells described in the adult (Kolb et al., **JCN**, 1980, 189:31). Between E90 and E140 the soma and dendritic areas increased as a function of both age and eccentricity. The exception were cells in the central retina which were similar to cells observed in younger animals. At all ages and eccentricities the number of dendritic terminal clusters ranged between 6-12 per cell with the exception of peripheral HI cells in late term animals which had 14-19 per cell.

In summary, as early as E68 horizontal cells have surprisingly complex morphologies in both branching order and dendritic clusters. The mature appearance and lack of substantial growth in these cells during the majority of fetal development is surprising given the large migration of different cell classes to form the fovea.

DISPLACED RETINAL GANGLION CELL TOPOGRAPHY SUGGESTS A PROGRESSIVE DEGRADATION OF RETINAL HISTOGENESIS WITH CONTINUED RETINAL GROWTH. A. D. Springer*, Department of Cell Biology and Anatomy, New York Medical College, Valhalla, NY 10595.

Displaced retinal ganglion cells (dRGCs) in goldfish retina were backfilled by applying cobaltous-lysine to the severed optic nerve. dRGCs in flatmounts were defined as labeled cells that were not in focus with the orthotopic RGCs. In sectioned material, dRGCs were defined as cells touching the inner nuclear layer. The x-y coordinates of dRGCs were determined in retina having areas of 11mm² - 49mm².

dRGCs represented a nonhomogeneous RGC population since, in large retina, they varied in soma area from 20 - 300μm^2. However, the dendritic arbors of these cells were homogeneous in that they were consistently located in the outermost part of the inner plexiform layer. dRGCs represented 0.05% of the total RGCs in small retina and 0.2% of the total RGCs in large retina. This four-fold increase in the percentage of cells that were dRGCs was related to a progressive increase in dRGC **density** with retinal eccentricity and retinal area. dRGCs were not observed within a 250μm radius of the optic disc, and their density progressively increased to about 4 cells/mm² at a distance of 3.5 - 4mm from the optic disc. dRGC density did not differ as a function of retinal quadrant. Sectioned material showed a similar dRGC distribution. Furthermore, **doubly-displaced** RGCs were found near the **outer** plexiform layer in the retinal periphery.

The non uniform distribution of dRGCs suggests that repeated retinal germinal cell division at the retinal margin may be associated with a general, progressive degradation in retinal topography, as well as an increased incidence of ectopic retinal cells. Supported by grant EY-03552 from the NEI.

DISPROPORTIONATE INCREASE IN THE DENSITY OF LARGE DISPLACED CHOLINERGIC AMACRINE CELLS WITH RETINAL GROWTH IN GOLDFISH. E. Garcia-Valenzuela, A. D. Springer, A. B. Drakontides*, Department of Cell Biology and Anatomy, New York Medical College, Valhalla, NY 10595.

An antibody tc choline acetyltransferase (AB8) was applied to small (20mm²) and large (49mm²) flatmounted retinae. Two different sizes of cholinergic amacrine cells were found in the inner nuclear (INL) and ganglion cell layers (GCL). These cells had a mean soma area of 15μm^2 and 50μm^2 in the INL and 20μm^2 and 60μm^2 in the GCL.

Density of large displaced amacrine cells (dAC) decreased from 3.6/mm² in small, to 2.5/mm² in large retina. For small dACs, the density decreased from 1135.4/mm² in small, to 610.2/mm² in large retina. Similarly, small and large orthotopic cholinergic amacrine cell densities in the INL decreased as a function of retinal expansion. Cell density and retinal area were used to estimate the total number of cells per retina.

Concomitant with 2.5 fold increase in retinal area, the total number of orthotopic cholinergic amacrine cells and small dACs per retina increased by 25%. However, the number of large dACs increased by 71%. The nondisplaced cells in the INL, and the small dACs in the GCL were uniformly distributed across the retina. However, the density of large displaced amacrine cells progressively increased with eccentricity. This increased cell density was unrelated to that normally seen close to the germinal zone.

The paradoxical increase in the occurrence of large dACs as the retina grows may reflect a small degradation in histogenesis with continued production of new retinal cells. Furthermore, large dACs, because of their low incidence (0.3% of all cholinergic dACs), may be ectopic cells. Supported by grant EY-03552 from the NEI.

REGENERATION OF THE DOPAMINE-CELL MOSAIC IN THE RETINA OF THE GOLDFISH. P.F. Hitchcock* and J.T. VanDeRyt. Departments of Ophthalmology and Anatomy and Cell Biology, The University of Michigan, Ann Arbor, MI 48105.

A fundamental feature of the retina is the planar mosaic of each neuronal type. We have characterized the mosaic of regenerated dopaminergic interplexiform cells, and determined if the absence of the extant dopaminergic cells during regeneration modulated its density (see Reh and Tully, (1986) Dev. Biol., 114:463). Regeneration was induced locally by removing a 0.2-2.0mm^2 piece of retina, which was replaced during the subsequent 6-8wks. Two groups of eyes were studied: Group 1 (n=14) received surgical lesions only; Group 2 (n=18) received intraocular injections of 6-OHDA, to destroy all extant dopaminergic cells, 3 wks. prior to the surgical lesions. All retinas were immunostained with antibodies against tyrosine hydroxylase, and regenerated and normal cells were analyzed in wholemounts. The data from both groups were statistically identical: the somata of the regenerated TH-cells were more randomly arrayed than normal, and their planimetric density was significantly greater than control values. These data show that regeneration creates a less orderly inner retina than does *de novo* development, and suggest that, unlike retinal development, extant neurons do not modulate cell proliferation during retinal regeneration. Supported by NIH (NEI) grants EY07060 and EY07003 (CORE).

VISUAL FUNCTION IN REGENERATING TELEOST RETINA FOLLOWING RETINECTOMY AND CYTOTOXIC LESIONING. A. F. Mensinger* and M. K. Powers Vanderbilt Univ., Nashville, TN.

Components of the electroretinogram (ERG) were recorded in intact fish during regeneration of the neural retina. Portions of goldfish retina were removed by trans-scleral surgery or aspiration. Additional retinas were destroyed by intraocular injections of ouabain. Contralateral eyes served as controls.

Following trans-scleral removal of small retinal patches (10-25% retinal area, n=12), b-wave amplitude of experimental eyes increased from 70% (day 14) to 91% (day 75) of control eyes. Experimental eyes with large percentages (75-90%; n=8) of retina aspirated increased b-wave amplitude from 11% (day 14) to 30% (day 75). Complete aspiration (n=9) and ouabain injection (n=37) temporarily eliminated ERGs. Following complete aspiration, experimental eyes attained 3% of control b-wave amplitude by day 55. Ouabain treated eyes were 5-10% of controls at day 55 and increased steadily through day 210, when they were 50% of controls.

The experiments show that regenerating goldfish retina is responsive to photic stimulation. Partial retinectomy leads to swifter recovery presumably due to a larger population of undamaged retinal cells that can initiate repair. Histological examination of ouabain eyes revealed an occluded lens and a disorganized inner nuclear layer; this probably accounts for experimental eyes only attaining half of control values. Retinectomy circumvents optical side effects and enables a more precise evaluation of the visual sensitivity of the regenerating retina.

557.17

RETINAL RESISTANCE TO HYPERBARIC OXYGENATION (HBO) IN NEWBORN RATS. **H. WAFAPOOR, D. TORBATI* AND G.A. PEYMAN. LSU Eye Ctr. and Dept. Physiol. New Orleans, LA 70112.**

Retinopathy of prematurity (ROP) can be produced by exposure of newborn animals to normobaric hyperoxia (NH) of 60-80% oxygen for several days. The proposed mechanisms for ROP are either retinal damage by reactive oxygen species (ROS) or a maintained retinal vasoconstriction after NH exposure. We have demonstrated that, unlike adult rats, the newborn rats can survive up to 3 h at 5 atmospheres absolute (ATA) oxygen without mortality or visible morbidity. In the adult rat, however, HBO produces both vasoconstriction and ROS before the onset of CNS oxygen toxicity. Because of sensitivity of premature retina to NH, we hypothetized that exposure of newborn rats to acute HBO may accelerate the rate of production of ROS and/or create a severe retinal vasoconstriction, which later may result in the development of ROP. Four days postnatal litters (9-11 rats each) were subjected to a single exposure at 5 ATA oxygen for either 30, 60 or 90 min. Histopathological evaluation by light microscopy up to two weeks after HBO exposure showed no detectable retinal damage. These preliminary results indicate that contrary to ROP developed following exposure to NH, the retina of the newborn rat is resistant to HBO. Whether retinal resistance to HBO is due to existence of an efficient antioxidant mechanism or because of a reversible but protective retinal vasoconstriction, remains to be clarified. Supported by NEI grants No. EY07541 & EY02377.

PREDEGENERATED NERVE GRAFTS FOR PRIMARY AND DELAYED REPAIR. J.M. KERNS*, N. DANIELSEN, M. KANJE AND G. LUNDBORG. Dept. Anatomy, Rush Med. Coll., Chicago, IL. and Depts. Hand Surg. Malmö Gen. Hosp., Animal Physiol., Univ. Lund, Sweden.

The early progress of nerve regeneration was studied in rat sciatic nerve using fresh vs. predegenerated autografts in primary vs. delayed nerve repair. Results from the sensory pinch test on alternate postoperative days showed that 10 mm grafts predegenerated for one week by transection/ligation and placed in a fresh contralateral host site were superior to fresh nerve grafts. The initial delay period was reduced from 3.6 to 0.2 days, there were no "failures" (0/40 vs. 13/44), the regeneration rate was slightly increased (1.8 vs. 1.5 mm/day) and there was less individual variability. The presence of regenerating axons in the graft was confirmed by immunocytochemical staining for neurofilament protein. The response of the fresh graft was identical in either a primary or delayed nerve repair. Predegenerated grafts used in delayed repair were better than fresh grafts, but inferior to predegenerated grafts for primary repair. It is suggested that an increased number of Schwann cells is condusive to more immediate and improved nerve regeneration.

558.2

NERVE GRAFTS CAN BE IMPROVED BY PRIOR CRUSH. N. DANIELSEN*, J.M. KERNS, M. KANJE AND G. LUNDBORG. Depts. Hand Surg. Malmö Gen. Hosp., Animal Physiol., Univ. Lund, Sweden and Dept. Anatomy, Rush Med. Coll., Chicago, IL.

In our companion study of rat sciatic nerve grafts, predegeneration by transection/ligation for 7 days improved the regeneration compared to fresh nerve grafts. In the present study we determined whether predegeneration for longer periods and prepared by nerve crush had a similar effect. Results from the sensory pinch test at 2-10 days showed a nearly identical response for grafts predegenerated for 7 days prepared by either transection or crush; both regeneration rates were 1.8 mm/day. The presence of regenerating axons was confirmed by immunocytochemical staining for neurofilament protein. The regeneration distance at 8 dpo was not significantly affected by the duration of the predegeneration (7-28 days) or the type of injury. These data suggest that the presence of newly regenerated axons in the graft predegenerated by nerve crush do not interfere with the enhancement effect produced by activated Schwann cells. The predegeneration enhancement effect can be produced by both types of lesions and can last for at least 28 days.

PRELABELING OF NEURONAL POOLS TO STUDY ACCURACY OF MOTOR AND SENSORY AXONAL REGENERATION IN THE RAT FEMORAL NERVE. R.D. Madison*[1], S.J. Archibald[2], T.M. Brushart[3], and S.M. Meadows[2]. Depts. of Surgery (Neurosurgery)[1,2], Neurobiology[1], Duke University Medical Center, and Research Service[1], VA Hosp., Durham, NC 27710, and Depts. of Neurology and Orthopaedics[3], Johns Hopkins, and Curtis Hand Center, Baltimore, MD 21218.

Madison and colleagues have recently devised a method of double labeling neuron pools to determine the accuracy of axon regeneration at the single neuron level (J. Neurosci. Meth., 39, 123-129, 1991. The rat femoral nerve divides into a terminal sensory branch (saphenous nerve) and a terminal motor branch to the quadriceps muscle. Motor axons preferentially regenerate into the terminal motor branch following nerve transection and repair proximal to the terminal bifurcation (Brushart, J. Neurosci., 8, 1026-1031,1988). In the present study, adult rats received transection of the femoral nerve either 1 (low) or 4 (high) cm proximal to the terminal bifurcation (N=10 in each group) two weeks after prelabeling of the neuronal pools which contribute to the motor branch (see ref. above). Four weeks later we determined the number of neurons in the original pools which correctly regenerated an axon back into the motor branch by using a second fluorescent label and quantifying double-labeled neurons. Approximately 78% and 61% of the motor neurons were doubled labeled in the low and high transection groups respectively. Approximately 73% and 49% of the sensory neurons to the muscle spindles were doubled labeled in the low and high transection groups respectively. These data show that preferential motor reinnervation takes place regardless of the level of transection, but preferential sensory reinnervation only takes place with a low transection. NS22404-07 and VA Merit Review (RM).

558.4

DISTINCTIVE ABNORMALITIES IN REGENERATED RAT CUTANEOUS AND MUSCLE NERVES AFTER NERVE CRUSH INJURY. C.M. Bowe*[1], N.H. Evans[1] and C. Hildebrand[2], [1]Dept. of Clinical Neurosciences, Brown Univ., Providence, RI 02912 and [2]Dept. of Cell Biology, Univ. of Linköping, Linköping, Sweden.

Regenerated sciatic nerves chronically exhibit a pronounced sensitivity to potassium channel blockade with 4-aminopyridine (4-AP). This has been attributed to the "unmasking" of paranodal potassium channels by myelin sheath remodelling which occurs in regenerated axons. It is not known if these axonal abnormalities are present in all regenerated fibers or if they are restricted to a subpopulation of regenerated axons. The present study examined the morphological and physiological properties of regenerated, myelinated axons in a rat cutaneous and muscle nerve, following unilateral, sciatic nerve crush injury. *In vitro*, whole nerve recordings (CAPs) were performed in regenerated sural (R-SN) and lateral gastrocnemius (R-GN) nerves during superfusion with oxygenated Krebs' solution (NS) and during exposure to NS containing 1 mM 4-AP. Light and electron microscopy were used to determine the morphological characteristics of R-SN and R-GN.

During recording in NS, latencies to peak CAP amplitude in R-SN and R-LN were comparable to values for their respective control (C-) nerves. After 4-AP, a delayed depolarization was noted in R-GN, C-GN and C-SN. In contrast, a pronounced, second negativity with a "rippled" appearance was seen in R-SN exposed to 4-AP and recovery properties were significantly compromised. Decreased internodal distances and axonal diameters were observed in R-SN and R-GN but active myelin sheath remodelling was not prominent in either nerve.

SENSORY FIBER PATHWAYS IN EMBRYONIC AND REGENERATE CERCI OF THE INSECT, *ACHETA DOMESTICUS*. I.S. Edwards*, W.P. Chan, N.V. Sherbina, and M.R. Meyer. Dept. of Zoology, NJ-15, Univ. of Washington, Seattle, WA 98195.

Using neuronal and other markers, events of neurogenesis and axon outgrowth in the cricket cercus, a caudal sensory appendage, have been determined to investigate sensory pathway formation during both embryonic development and postembryonic regeneration. In the embryonic cercus, a cluster of neurons first appears near the base of the cercal lumen. These cells project axons to establish the first connection with the central nervous system (CNS). Subsequently, a second cluster of neurons appears more distally in the lumen and projects axons toward the basal cluster. Following formation of these distal cells, neurons arise within the cercal epidermis. The epidermal neurons project axons toward the cercal base either along the luminal wall or via pre-established pathways in the lumen.

Following cercal amputation at a postembryonic instar, new neurons and axons are observed in the regenerate cercus after the first postoperative molt. DiI labelling at later stages shows that axons of the regenerate sensory neurons can reestablish connections with the CNS by following either the nearest persistent sensory pathway or the extrinsic cercal motor nerve.

In embryonic cerci, basal lamina expression of glionexin (GX; antigen 5B12), a glia-related extracellular matrix glycoprotein, [Meyer et al., Dev. Biol. 130:374 ('88)], precedes appearance of neuronal structures. GX expression is correlated with the luminal neurons, their projections to the CNS, and other early axon pathways. Similarly, GX is transiently re-expressed on the basal lamina of regenerating cerci during axon outgrowth. These observations suggest elements of pathway formation are common to both the embryonic and regenerate cerci, while other mechanisms may be unique to either state. Supported by NS-07778.

558.6

PATTERN OF AXON REGENERATION FOLLOWING HYPOGLOSSAL NERVE TRANSECTION AND ENTUBULATION REPAIR. C. Timo-Iaria*[1], G. Chadi[2] and C.F. Da-Silva[3]. [1]Laboratories of Clinical Physiology and Experimental Neurology, [2]Dept. of Anatomy and [3]Dept. of Histology, University of São Paulo, São Paulo, Brazil.

The pattern of axon regeneration following unilateral hypoglossal nerve lesion was studied in adult rats. Transected nerves were repaired by entubulation technique with silicone tubes. Three months after the lesion, animals were processed for morphometric analysis. In one series of experiments, both the regenerated cable found within the tubes and the main medial and lateral branches of the hypoglossal nerve were processed for E.M. Quantitative parameters were determined with a computer system (Biographics Inc.) and compared with uninjured control animals. Regenerated animals showed a higher number of myelinated and unmyelinated axons in the distal nerve branches and regenerated cable of the hypoglossal nerve. Ultrastructural analysis demonstrated a decrease in the mean myelinated axon diameters and myelin thicknesses for the regenerated animals compared to the control group. In another series of experiments, HRP was applied to the cut end of 1) the regenerated hypoglossal nerve distal to the tube; 2) the main medial and 3) the main lateral branch of the hypoglossal nerve proximal to their ramifications. The number and distribution of HRP-labeled cell bodies in the hypoglossal nucleus after regeneration were compared with non-operated animals processed in the same fashion. The results demonstrated that, after nerve lesion and entubulation repair, no significant loss of motor neurons occurred, but hypoglossus nucleus somatotopy was not maintained. These findings indicate that after hypoglossal nerve transection and regeneration the normal pattern of axon innervation is only partially restored.

Supported by grants from FAPESP and CNPq.

SENSORY REINNERVATION OF THE RAT GLABROUS SKIN BY ORTHOTOPICALLY GRAFTED FETAL ALLOGENEIC AND XENOGENEIS DORSAL ROOT GANGLION CELLS. P. Dubovy, C.M. Rosario, T. Carlstedt* and H. Aldskogius . Departments of Anatomy, Medical Faculty, Brno, Czecho-Slovakia and Karolinska Institutet, S-104 01 Stockholm, Sweden.

Sensory reinnervation of the glabrous skin of the hindpaw in adult host rats was examined following orthotopic transplantation of fetal rat or mouse dorsal root ganglia (DRG). Sensory corpuscles were identified by the presence of non-specific cholinesterase (nChE) in their non-neuronal cells. Nerve fibers were identified with antibodies to neurofilament proteins (RT-97) or growth-associated protein, GAP-43. Eight months after allografting to the L4 and L5 DRG levels (L6 removed at the time of grafting, saphenous nerve cut seven days prior to sacrifice), RT-97+ nerve fibers were present, some of which terminated in sensory corpuscles. A few fibers displayed GAP-43 immunoreactivity. In xenografted animals, numerous GAP-43+ nerve fibers were present five weeks after grafting (cf. allograft procedure). Some of these fibers were associated with nChE+ cells of sensory corpuscles.

These findings demonstrate that orthotopically grafted fetal DRG neurons extend axons all the way to the hindpaw and differentiate into terminals of sensory corpuscles.

558.8

SPROUTING IN PARTIAL NIGROSTRIATAL LESIONED RATS FOLLOWING ADRENAL MEDULLA AND SCIATIC NERVE COGRAFTS. Z. Zhang,*[1] M. Bresjanac,[1] J.T. Greenamyre,[2] J.Olschowka[1] and D.M. Gash.[1] Depts. of Neurobiology & Anatomy[1] and Neurology,[2] University of Rochester, Rochester, NY 14642.

We report regenerative sprouting of dopaminergic fibers in the striatum following cografts of adrenal medulla and sciatic nerve in hemiparkinsonian rats. Adult Fischer 344 rats with unilateral 6-OHDA partial lesions were divided into three groups: nongrafted controls, sham-implanted controls and cografted hosts. After surgery, eight animals in each time point were sacrificed on 3, 7, 14, 28 days for immunohistochemical studies and 32 rats used for behavioral evaluation were sacrificed at 3 months and another nine animals sacrificed at 28 days were used for autoradiographic quantitation of high affinity dopamine uptake sites (HADAUS) and D2 receptors. The results of computer image analysis showed that there was a significant increase in the TH positive fibers seen at 3 days in both sham and cografted animals. However, TH fiber density in sham-grafted animals was significantly declined by 7 days and nearly reduced to background levels by 28 days post transplantation. In contrast, TH fiber density remained elevated in cografted animals with no significant differences seen between recipients in the 3, 7, 14 or 28 day test groups. Additionally, a positive correlation was found between the maintenance of TH positive fibers density and the viability of Schwann cells in cografted hosts. The results of amphetamine-induced ipsilateral rotation revealed a 30 to 45% decrease in the cografted group and a slightly increased number of rotations in sham-implanted controls over 3 months compared with the baseline. Finally, autoradiography showed an increase in HADAUS density as well as a decrease in D2 receptors in the cografted striata. All results suggest factors produced by the cografts influenced the dopaminergic regenerative response. Supported by NIH 2 P01 NS25778.

DEVELOPMENTAL PLASTICITY OF SELECTED BRAINSTEM-SPINAL PATHWAYS. G.F. Martin*, X.M. Wang and X.M. Xu. Department of Anatomy, The Ohio State Univ., Coll. of Med., Columbus, Ohio 43210

Rubral axons grow around a lesion of their spinal pathway at early stages of development in the North American opossum and it is possible that all brainstem axons do so. We have attempted to establish whether reticular and vestibular axons can circumvent a spinal lesion during development and, if so, to determine their critical period(s) for plasticity. We hemisected the thoracic cord and 30 days later made bilateral injections of Fast-Blue caudal to the lesion. At postnatal day (PD)20, rubral neurons were labeled contralateral to the lesion, as expected; but neurons in the medial pontine reticular formation and the dorsal part of the lateral vestibular nucleus were not labeled ipsilateral to it. Rubrospinal axons project contralaterally, whereas the reticular and vestibular axons in question project ipsilaterally. At EPD5, however, neurons were labeled in all of the above areas. We conclude that reticulospinal and vestibulospinal axons are capable of plasticity and that the critical period for their plasticity ends earlier than that for rubrospinal axons. Supported by NS-25095 and 10165.

AXONAL REGENERATION AND PATHWAY SELECTION BY BRAINSTEM NEURONS AND BEHAVIORAL RECOVERY IN SPINAL-TRANSECTED LAMPREY LARVAE. G.R. Davis* and A.D. McClellan Div. of Biological Sci., Univ. of Missouri, Columbia, MO 65211.

Larval lampreys recover swimming 3-6 wks after a complete spinal cord transection. Our goals are to identify the brainstem regions involved in the recovery of locomotion and to describe the specificity of tract selection in the spinal cord by regenerating axons from the brainstem.

Four months after a complete spinal cord transection at 10% of body length (BL), Petromyzon marinus larvae (n =27) swam with few or no deficits. These animals received additional cord lesions several segments both above and below the original transection. Behavioral tests and EMG's were done 5-7 days after the second lesions, and HRP was applied to the spinal cord at 25% BL. Nine to 14 days later, brains and spinal cords were processed with Hanker-Yates reagents. Labeled cells in wholemounts were classified into 1 diencephalic, 2 mesencephalic, 3 isthmic, 2 bulbar, 1 lateral, and 3 vagal cell groups.

Medial tract lesions typically altered posture and equilibrium but otherwise did not disrupt locomotion. Labeled cells were consistently found in large numbers within subdivisions of the isthmic, bulbar, and vagal groups. Cells were rarely labeled in diencephalic, mesencephalic, and lateral groups. Animals with bilateral lesions of the lateral tracts rarely swam spontaneously or in response to stimulation of the head. Very few labeled braintem cells were found in these animals suggesting that regenerating axons either prefer to grow into the lateral tracts and/or avoid the medial tracts. Most animals with hemisections on the left side had an altered posture and all swam only in small circles to the right. The pattern of cell labeling indicated that the axons of many neurons which normally project to one side of the cord had crossed to the opposite side. Labeled axons were observed crossing the midline only at the site of the healed transection. Most animals with lesions of the medial tracts above and both lateral tracts below the original transection could swim suggesting that some descending lateral tract axons which are important for initiation of locomotion in normal animals (McClellan, 1988) can regenerate into the medial tracts. (Support: NIH NS29043, APA MB1-9108.)

CHRONICALLY INJURED SUPRASPINAL NEURONS EXHIBIT AXONAL REGENERATION FOLLOWING SPINAL CORD INJURY. J.D. Houlé*, J.W. Wright and M.K. Ziegler. Dept. of Anatomy, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72205.

Intraspinal and dorsal root ganglion neurons will regenerate into peripheral nerve (PN) segments grafted 1-2 mos. after injury to the lumbar spinal cord. The lack of regeneration by supraspinal neurons following injury at this level suggested that some neurons may be unable to regrow under chronic injury conditions. To test this True Blue (TB) was injected into the cervical (C6) spinal cord of adult rats. A hemisection lesion cavity including the injection site was created after 7 days, followed 30 days later by apposition of an autologous PN graft to the lesioned surface. The distal tip of the PN graft was exposed to Nuclear Yellow (NY) after 30 days. Chronically injured neurons capable of regeneration contained both TB and NY and were found in several regions of the brainstem, including: the spinal trigeminal nucleus, medullary and pontine reticular formation, ventral raphe, the spinal and lateral vestibular nuclei, several hypothalamic nuclei and nucleus cuneatus. Regions lacking TB/NY labeled neurons included locus coeruleus, red nucleus and motor cortex, although numerous TB labeled neurons were present in all areas. In contrast, PN grafts placed immediately after injury contained regenerated axons from both the locus coeruleus and red nucleus. These results demonstrate differences in the regenerative response of neurons relative to the post trauma interval and level of spinal cord injury. Supported by NIH Grant NS-26380.

CO-EXISTENCE OF REGENERATING AND SEVERED AXONS IN THE OPTIC NERVE OF THE FROG *LITORIA (HYLA) MOOREI*. S.A. Dunlop* & W.M. Ross, Neurobiology Laboratory, Dept. of Psychology, University of Western Australia, Nedlands 6009.

After extracranial optic nerve crush in the frog *Litoria moorei*, regenerating axons penetrate the crush site, grow along the optic nerve and tract to re-innervate the optic tectum; normal vision is restored within 2-3 months. Using horseradish peroxidase labelling and light microscopy to examine the optic tracts and tecta, we have recently shown a co-exitsence of regenerating axons with the distal stumps of the severed axons that are destined to degenerate (Humphrey, Dunlop, Shimada and Beazley, Exp. Brain Res. *in press*). To investigate the spatial and temporal relationship between the regenerating and severed axons in the optic nerve, we examined animals between 3 and 28 days after optic nerve crush. Animals were perfused with 4% paraformaldehyde and regenerating axons labelled anterogradely with DiI from the optic disk; the distal stumps of the severed axons that are destined to degenerate were labelled retrogradely from the optic brachia with DiA. Nerves were examined as wholemounts and as longitudinal sections. At 3 days regeneration, DiI-labelled regenerating axons had retracted somewhat towards the eye; by 7 days, axons had penetrated the crush site although few had reached the other side. Between 10 and 14 days, a small number of pioneer axons had grown through the crush site to the chiasm; these axons were peripherally located and closely grouped. Between 17 and 28 days, more axons crossed the crush site and occupied both the core and the periphery of the nerve. The DiA-labelled severed axons persisted in the nerve at all stages examined. Severed axons were lost first from the core of the nerve and then the periphery; there was a progressive loss from the crush site towards the brain.

RESTORATION OF RETINOCOLLICULAR PATHWAY AFTER SCIATIC NERVE TRANSPLANTATION INTO THE SECTIONED BRACHIUM IN ADULT HAMSTERS. H.Sawai, Y.Fukuda and M.Watanabe*° Dept. Physiol. Osaka Univ. Med. Sch.,Suita 565, °Dept. Physiol., Aichi Pref. Colony, Kasugai 480-03, Japan.

After transection of the brachium of superior colliculus (BSC) we transplanted the autologous sciatic nerve to make a bridge to the deafferented colliculus in 28 anesthetized adult hamsters. Four to 15 weeks later, we examined photic responses (PR) to diffuse flash stimuli applied to the contralateral eye in operated animals. PR of moderate amplitude were obtained from both the graft and the superior colliculus (SC) in 8 grafted animals. The PR were further verified at single unit level in 3 of the 4 grafted animals examined. In the remaining 8 animals, however, the graft came out from the SC and no PR was obtained from the SC. None of the 5 control animals, in which the BSC had been transected without the graft, exhibited any visual response when tested at 5-20 weeks after surgery. With intraocular injection of WGA-HRP, we were able to trace regenerating retinal axons to pass through the graft and terminate in the superficial part of the SC in 4 grafted animals. In other 3 animals the graft was missing and yet some regenerting fibers were found to traverse the cleft of the sectioned BSC. From these results we conclude that the sciatic nerve graft is benificial for the functional and morphological restoration of the retinocollicular pathway after BSC section.

DEVELOPMENTAL CHANGES IN THE RESPONSE OF OPTIC TRACT AXONS TO TRANSECTION IN THE HAMSTER: SWITCHING FROM REGENERATION TO RETRACTION. L.I. Mortin* and G.E. Schneider. Department of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Following a complete transection of the brachium of the superior colliculus (SC) in Syrian hamsters, optic tract axons can regenerate if the lesion occurs prior to four days postnatal (P4); axons severed in P4 and older animals normally do not regenerate (So et al., Exp. Neurol. 72, 1981). What is the nature of regenerative growth or its failure, and how soon can we differentiate between them? We used the carbocyanine dye DiI to visualize the response of single optic tract axons to transection at P1 and P6, developmental stages permissive and restrictive, respectively, for regeneration. Retinofugal axons were labeled either *in vivo* by injecting a solution of DiI dissolved in N,N-dimethylformamide into the eye or in fixed tissue by placing a crystal of DiI in the optic chiasm. Anterograde labeling with HRP was used to determine the rate of growth or retraction of cut axons.

After transection on P1, optic tract axons grow rapidly across the lesion site, sometimes in large numbers; they can extend up to 800-1000μ in 24 hr. Axons crossing the region of gliosis and beyond are mostly unbranched, and have simple growth cones. Some growth cones remain in the gliotic region longer or grow along the axis of the lesion, perpendicular to their normal pathway. Caudally axon growth appears to slow significantly; nine days after the lesion the SC is still not completely reinnervated. By three weeks the processes of optic tract axons can cover the entire SC.

When the transection occurs on P6, retraction of severed axons can be seen within 12 hr. These axons display retraction bulbs or simple growth cones at their tips. Some axons can remain near the gliotic region of the lesion; some become thinner near the lesion site. Thus, within hours, the response of axons transected at P6 is different from those transected at P1.

FORMATION OF NEURAL LOBE-LIKE NEUROVASCULAR CONTACT ZONES IN TISSUES GRAFTED INTO THE HYPOTHALAMO-NEUROHYPOPHYSEAL TRACT IN RATS. J. Carithers* and H.-D. Dellmann. Dept. of Veterinary Anatomy Iowa State Univ., Ames, IA 50011.

Large neural lobe-like neurovascular contact regions developed within 6/7 neural lobe explants (after 30 days in vitro axonal fragments had disappeared, and explants consisted mainly of pituicytes) grafted into contact with neurosecretory axons transected in the lateral retrochiasmatic hypothalamic area. Much smaller contact regions were seen in 4/9 optic nerve grafts and 3/17 sciatic nerve grafts, and none developed in vascular grafts. In neural lobe explants the fine structure of contact regions resembled that of normal neural lobes; i.e., neurosecretory axon terminals associated with pituicytes formed palisades abutting perivascular spaces of capillaries, most of which were fenestrated. In grafts of optic and sciatic nerves, although neurosecretory axon terminals accompanied by astrocytes or neurolemmocytes incompletely invested capillaries, they did not form palisades, and capillaries were non-fenestrated. Moreover, it was not always possible to delineate neurovascular contact regions within optic and sciatic nerve grafts from contact regions that developed in the adjacent hypothalamic neuropil. These results are consonant with our hypothesis that non-neuronal components of neural lobes, most likely pituicytes, promote development of neurovascular contact regions. Supported in part by NSF grant BNS 8919729.

Fate of CNS neurons afferent to an excitotoxic lesion. S. Marty, N. Le Forestier, J.M. Weinitz and M. Peschanski*, INSERM CJF 91-02, Faculté de médecine, F - 94010 Créteil, France

Injection of an excitotoxic substance into the adult CNS induces a rapid neuronal death, while acutely sparing axons afferent to the lesion. Excitotoxins can thus be used as tools to investigate the dependance of neurons toward their targets. In a previous study we found that in these conditions dorsal column nuclei (DCN) axons formed terminal varicosities in a one month old kainic acid lesion of the adult rat thalamus. The persistance of some of these varicosities one year post-lesion indicated that afferents can survive for long periods of time after loss of their targets. Using wheat germ agglutinin conjugated to peroxidase (WGA-HRP) as an anterograde and retrograde tracer in light microscopy, or electron microscopy, we have now characterized this evolution over time between four days and eight months.

In one group of rats WGA-HRP was injected into the DCN at different times post-lesion, and allowed to be anterogradely transported to the thalamus. Peroxidase was revealed using TMB. In another group WGA-HRP injected into the thalamus at different times post-lesion was allowed to be retrogradely transported to the DCN. Peroxidase was revealed using nickel-enhanced DAB. The third group was directly perfused and brains were processed for electron microscopy.

Major changes occur during the first month. There is an important decrease in axonal density. Terminal enlargments appear as soon as four days and become prominent after two weeks, while presynaptic profiles disappear. During the same period there is an atrophy of DCN neurons and a conspicuous decrease of their retrograde HRP labeling when compared with controlateral controls. After one month the decrease in number of axons is slower so that there are always axons from the DCN in the eight months lesion. These axons always exhibit varicosities, and the retrograde labeling of their cell bodies remains altered.

The present results indicate that during the first month excitotoxicaly induced loss of their targets provokes modifications of adult CNS neurons : axons loose presynaptic specializations and form varicosities, retrograde WGA-HRP labeling is decreased, and cell bodies are atrophic. Some of these modified neurons can survive for months.

CHONDROITIN SULPHATE AND ASTROGLIAL DISTRIBUTION IN NEURAL TRANSPLANTS AND IMPLANTED GLIOMA. J. Rosenstein* and T. Moody. Depts. of Anatomy, Neurosurgery, Biochemistry Molecular Biology, George Washington University Medical Center, Washington, D.C. 20037.

The advent of an injury to the brain produces potential long term cellular and extracellular changes. To determine the presence of the glycosaminoglycan chondroitin sulphate (CS), a molecule involved in axonal growth by inhibitory mechanisms we examined the expression of the MAb CS-56 in neocortical grafts (2 weeks-18 mos) and C6 gliomas (3 day-3 weeks). Concommittant distribution of astrocytes was also examined by GFAP. Early grafts up to 4 weeks had CS staining only at the host interface after which time it almost entirely disappeared. Gliosis was found around the grafts for at least one year where it overlapped with extracellular glucose transporter immuno-staining. Stab wounds showed similar results. In gliomas, CS stained intensely particularly at the proliferating tumor-brain interface. In gray matter surprisingly little gliosis was observed whereas in white matter GFAP staining was intense. Ultrastructurally, tumor cells supplanted astrocytes at the interface and CS filled the extracellular space. In neural grafts there appears to be transient expression of CS whereas in tumors CS is intensely expressed and reactive astroglia have disparate distribution. (NS-17468) (BNS88-15133).

MIGRATION PATTERNS OF TRANSPLANTED LABELLED GLIAL CELLS. A. Espinosa*, A. Watabe, M.-S. Zhang and J. de Vellis. UCLA Mental Retardation Research Center, Los Angeles, CA. 90024-1759.

Glial cell plasticity has been investigated in vitro by numerous laboratories. Such plasticity persits when normal cultured glial cells are grafted into perinatal host brains. Fast Blue labeled O2A lineage cells can survive migrate and integrate within normal and abnormal host brains. In the present study we compared the migration patterns of unaffected rat O2A cells to those of C6 glioma cells grafted into normal rat hosts. Migration patterns of FB^+ C6 cells are extensive throughout the brain. These cells migrate continuously and form clusters (1 week post-grafting), and tumors later on. Cells derived from such tumors migrated out to form new tumors. FB label persists with variable intensity within grafts despite intense proliferation. This model is useful to investigate a) the differences in cell migration between normal and transformed cells; b) the early changes in host brain caused by tumoral cells, and graft/host interactions; c) the plasticity of grafted C6 cells vs cultured C6 cells. DIFFERENTIAL SEIZURE SUPPRESSANT EFFECTS OF SOLID NORADRENALINE-PRODUCING LOCUS COERULEUS AND SUPERIOR CERVICAL GANGLION GRAFTS IN KINDLING.

M. Kokaia[1], M.A. Cenci[2], Z. Kokaia*[1], J. Bengzon[1], O. Nilsson[2], A. Björklund[2] and O. Lindvall[1]. [1]Restorative Neurology Unit, Department of Neurology, University Hospital, S-221 85 Lund, Sweden. [2]Department of Medical Cell Research, University of Lund, S-223 62 Lund, Sweden.

The noradrenergic locus coeruleus (LC) system exerts a strong inhibitory influence on kindling development. We have previously shown that the facilitation of kindling caused by lesions of this system can be reversed by intrahippocampal LC cell suspension grafts. Similar to intrinsic LC neurons, grafted cells increase their release of noradrenaline (NA) in response to seizures. We investigated whether also solid LC and superior cervical ganglion (SCG) grafts can influence kindling. Rats were given 6-hydroxydopamine (6-OHDA) in the ventricle and were then subjected to a bilateral aspirative fimbria-fornix (FF) lesion and cervical sympathectomy. One week later, fetal LC and autologous SCG grafts were placed in the FF lesion cavity. Lesioned and intact animals served as control. After 10-12 weeks the animals were subjected to kindling, microdialysis and histological analysis. Solid LC grafts significantly retarded the development of kindling in previously 6-OHDA-lesioned animals, whereas SCG grafts had no effect. Both baseline and seizure-induced NA release was significantly higher in the LC grafted animals than in the SCG grafted group. No release of NA was detected in lesioned animals without grafts. Normal or supranormal fiber density was observed in the dorsal hippocampus of LC grafted rats, while the SCG graft derived reinnervation was restricted to certain subfields. These results indicate, that solid LC grafts can suppress seizure development and restore noradrenergic innervation as well as basal and seizure-induced NA release in the hippocampus of NA depleted rats. The lack of effects on the development of kindling in the SCG grafted animals can possibly be accounted for by more limited graft-derived fiber outgrowth and NA release. However, the present data may also suggest that the seizure suppressant action of NA is dependent on a synaptic release, which can be provided by the LC but not the SCG grafts.

559.4

INTEGRATION OF LABELED FETAL HIPPOCAMPAL GRAFTS INTO KAINIC ACID-LESIONED F344 RATS.

G.K. Pyapali*, D.A. Turner and R.D. Madison. Neurosurgery and Neurobiology, DUMC, and VAMC, Durham, NC 27710.

Survival of grafted neural tissue is improved if the graft is placed into a pre-lesioned area of the host. The overall time course and critical factors underlying enhanced survival and synaptic integration of grafts into lesioned hippocampus remains unclear. This study investigated the differential influence of the availability of neurotrophic factors and vacant synaptic sites on the survival and integration of fetal tissue grafts in a kainic acid lesion model.

Dissociated fetal hippocampal and cerebellar cell suspensions were labeled with rhodamine dextran amine and stereotaxically implanted into pre-lesioned hosts. Two-three months later hippocampal slices containing the grafts were assessed for graft survival, integration, migration and the development of individual cells using anatomical and physiological indices. Compared to normal hosts, grafts in lesioned hosts showed enhanced cellular survival, development, migration of cells from the needle track and synaptic interconnections with the host. Survival was significantly increased in early transplants (at 2-4 or 11-12 days) compared to controls, grafts at 6-7 days and late grafts at 14-16 and 28-33 days post lesion. Late grafts demonstrated equally good synaptic interconnection but only moderate survival and enhanced migration of cells away from the needle track. Grafted cells showed considerable development and the processes were mainly confined to the graft region; synaptic potentials could be elicited with host fiber stimulation.

The time course of graft survival and integration indicates that host recovery processes leading to enhanced survival may be separate from factors influencing migration and integration of graft cells within the host. This finding has important implications for the timing of grafts following a lesion and the evolution of lesion recovery mechanisms in the host. DENDRITIC OUTGROWTH OF TRANSPLANTED DENTATE GRANULE CELLS.

D.I. Legendre, B.P. Vietje and J. Wells*. Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

Allogeneic neonatal granule cells were injected into the infragranular cleavage plane of the rat dentate gyrus, simultaneously lesioning and replacing the host granule cells. The transplanted granule cells were intracellularly labeled with Lucifer Yellow in fixed sections. Normal granule cells were similar to those already described in the literature. At one week post-transplant, many of the dendrites that had not reached the hippocampal fissure had growth cones, and their dendritic spines were longer than those on adult granule cells. Virtually all of the dendrites reached the hippocampal fissure by two weeks post-transplantation and the spines looked normal. By eight weeks, the dendrites appeared thicker, more coiled, and more spiny than normal. Some of the dendrites bent back into the molecular layer upon reaching the hippocampal fissure. Between three and eight weeks a return of cytochrome oxidase staining indicated that the transplanted cells formed functional synapses. If transplanted granule cells were placed into the hippocampal fissure, the dendrites developed spines and grew preferentially into the molecular layer rather than CA1.

INTRACRANIAL TRANSPLANTATION OF HYPOTHALAMIC NEURONS.

Hanna Bergman*[1] George D Prell[2] and Ann-Charlotte Granholm[3]. [1]Dept Cell Biology, Univ. of Linköping, Sweden, [2]Dept Pharmacol., Mount Sinai School of Med, NY, NY 10029 and [3]Dept Basic Science, Univ. of Colorado, HSC, Denver, CO 80262.

Many histamine-containing tuberomammillary neurons of the hypothalamus project to the hippocampus through the fornix. Afferent denervation has been shown to significantly decrease hippocampal levels of histamine. In order to investigate survival and growth of intracranial grafts containing histaminergic neurons, fetal hypothalamic tissue from day E17 was grafted into lesion cavities two weeks after unilateral lesions of the fornix in adult Sprague-Dawley rats. Hippocampal levels of histamine and its metabolites were determined in lesion-free, lesioned and lesioned-grafted rats. Post-transplant immunohistochemical evaluation showed that all animals contained surviving transplants; furthermore, numerous immunoreactive fibers projected from transplanted tissue into host brain, including the hippocampus. In conclusion, we found that histaminergic neurons will survive intracranial grafting and innervate surrounding host brain. Sponsored by the Swedish MRC, Blanceflor Fnd and Magnus Bergvall Fnd and NINDS grant NS-28012 to GDP.

ADULT OLIVARY AXONS ENLARGE THEIR TERMINAL DOMAIN TO INNERVATE EMBRYONIC PURKINJE CELLS GRAFTED ON THE SURFACE OF THE ADULT RAT CEREBELLUM.

P. Strata, F. Rossi and T. Borsello, Dept. of Human Anatomy and Physiology, I-10125 Turin, Italy. SPON: European Neuroscience Association

It is commonly assumed that neuronal loss in the host brain is necessary for the integration of grafted embryonic neurones. We have studied the capability of transplanted cells to interact with host elements in an intact adult brain. To this aim solid pieces of cerebellar primordia taken from 14-days-old rat embryos, were placed in the fourth ventricle of adult hosts in close contact with the cerebellar surface, where they developed minicerebella. Embryonic Purkinje cells (PC) visualized by anti-D-28k calbindin antibodies were able to leave the graft and penetrate the host molecular layer, where they developed adult structural features. PHA-L tracing of host olivocerebellar axons, revealed that adult climbing fibres (CF) emit collateral sprouts, which elongated through the molecular layer and ended in terminal plexuses impinging upon grafted cells. Such a process was already active at early stages after transplantation, during the migratory phase of grafted PCs development and continued at longer survival times, ending with the formation of fully developed new CFs. In addition, CF sprouts were able to leave the host cerebellum and penetrate the transplant, where they innervated clusters of PCs. These results show that grafted PCs are able to migrate and develop in an adult unlesioned cerebellum and to interact with host elements by eliciting the growth of adult axons. On their part, adult olivary axons, which face an increased target population, are able to enlarge their terminal domain by retaining their adult targets and innervating a number of transplanted cells.

Effects of Amygdala Grafts from SHR and WKY Donors on Depletion-Induced Water and Saline Intake in Amygdala-Lesioned Wistar Rats.

C.A. Murphy, R. Canbeyli, & B.G. Yongue*. Columbia Univ. and N. Y. S. Psychiatric Inst. New York, NY 10032.

Damage of the amygdala including the central nucleus is known to reduce salt appetite and blood pressure (BP). We have previously shown that transplantation of hypothalamic or cortical tissue from spontaneously hypertensive rat (SHR) fetuses to normotensive Wistar and Wistar-Kyoto (WKY) rats induces elevated BP. This study investigated the effects of fetal amygdala grafts including the central n. in Wistar rats with damage to the central n.

Rats underwent bilateral lesion aimed at the central n. at 25 days of age; 8 were lesioned controls, others received bilateral grafts, in the lesioned area, of amygdala from SHR (n=6) or WKY donor (n=7) fetuses at day 17-18 of gestation. Sham operated controls (n=8) received volume-matched infusions of 0.9% saline. Tail-cuff BP was measured at 30,60,90 & 120 days of age. To assess need-free salt appetite, animals were presented at 60 & 120 days with 1.5% saline, H_2O and low-Na^+ diet for 4 days; depletion-induced consumption was then measured for 2-hours, 24 hours after a diuretic/natriuretic. Direct BP was measured via the tail artery at 180 days of age.

The 4 groups (lesion, sham, SHR- and WKY-amygdala graft) did not differ in BP or need-free saline intake. At 60 days, depletion-induced saline intake was reduced (ns.) in the lesion group (mean 9.2 ml) relative to the shams (16.5 ml). SHR grafts restored intake to levels (14.6 ml) comparable to shams. WKY grafted rats consumed significantly less saline (4.8 ml) than shams. Water intake for the 24-hours after diuretic injection was comparable in the sham and SHR-amygdala grafted groups, which were significantly higher than in the WKY-amygdala grafted group in the second depletion test. The results are interpreted in terms of the differential effects on fluid and mineral intake of amygdala grafts from SHR and WKY; donors with phenotypic differences in salt appetite and BP regulation. THE DYNAMIC CHARACTERISTICS OF INJECTED MYOBLASTS IN THE HOSTS. H. J. Li*, Q. Fang, M. Chen, T. Goodwin and P. K. Law. Cell Therapy Research Foundation, Memphis, TN 38117.

In animal experiments and clinical trials, various laboratories have demonstrated that injected normal myoblasts survive and fuse with host muscle fibers. However, there has been little description about myoblast distribution in the host muscle. We injected Fluoro-gold (FG) labelled myoblasts (C57BL/6J) into the quadriceps muscle of mice (C57BL/6J). These mice were sacrificed every seven days lasting up to 1.5 months after myoblast injection. Injected muscles were cut with cryostat at 10 μm. Muscle sections were examined under fluorescence microscope. The cell fusion rate was determined. We found that the distribution of injected myoblasts in the host muscle sections varies according to the different ways of injection. A good injection method allowed even distribution of donor myoblasts over the whole muscle cross-section and it increased the chance for the donor cells to fuse with host myofibers. Mosaic myofibers were observed within seven days after cell injection. The highest fusion rates ranged between 62.5%-72.2%. These results are used to improve the efficacy of myoblast transfer therapy. (Supported by PHS NS 26185 PKL)

IMMUNE REACTIONS FOLLOWING MYOBLAST TRANSPLANTATION IN DUCHENNE MUSCULAR DYSTROPHY PATIENTS. Tremblay, J.P.*, Huard, J., Roy, R., Bouchard, J.P., Malouin, F., Richards, C.L., Lemieux, B. and Langevin, P. Neurobiology Laboratory, Enfant-Jésus Hospital, 1401, 18e Street, Québec (Qc), G1J 1Z4

The discovery of the genetic defect resulting in a protein deletion responsible for Duchenne Muscular Dystrophy (DMD) has led to intense investigation aimed at achieving a therapy for this disorder. A possible therapy is the transplantation of normal myoblasts into DMD muscle. This would result in fusion of the donor myoblasts with host myoblasts to form hybrid muscle fibers which have the ability to produce dystrophin and incorporate it into the sarcolemma. Our research group has transplanted myoblasts obtained from an MHC compatible donor to nine Duchenne patients. Transplantations were done in the biceps, extensor carpi radialis longus and/or tibialis anterior muscles. No immunosuppressive treatment was used during the follow-up period (8-19 month). No clinical sign of rejection (i.e. fever, swelling or pain) was observed. Biopsies done 1 month after myoblast transplantation showed the presence of dystrophin in an higher percentage of muscle fibers in the myoblast injected muscle than in the contralateral muscle in 7 of the nine patients. Antibodies against the donor myoblasts and/or myotubes were observed in five patients. In some case these antibodies were capable of fixing the complement and lyzing the myotubes in vitro. Transient increase of maximum voluntary contraction were observed in only 3 patients. Although some aspect of these experiments are encouraging, they also indicate that myoblast transplantation cannot be done without some immunosuppression even when the donor is immunocompatible.

VIABILITY, MORPHOLOGY AND IMMUNOGENICITY OF COLD PRESERVED NERVE ALLOGRAFTS. P.J. Evans*, S.E. Mackinnon, J. Wade and R. Midha. Peripheral Nerve Lab., Univ. of Toronto, Toronto, Ontario, Canada, M5S 1A8.

PURPOSE: Nerve banks may provide ready access to tissue and ample time for donor tissue screening. Three week stored nerve allografts may be dead and subsequently non-immunogenic and serve as a connective tissue scaffold for proximal regenerating host axons.

METHODS: Three centimetre ACI rat nerve grafts were harvested and stored in 15 ml of Belzer/UWCSS solution at 5°C for 0-22 weeks. Nerves were prepared for standard light and electron microscopy and for laminin immunostaining. Graft cell viability was assessed by DNA or protein synthesis by incorporation over 24 or 96 hrs of 2 μCi/ml of ^{3}H-leucine or ^{3}H-thymidine respectively, and corrected for total protein by protein spectrophotometry. Immunogenicity was assessed by recipient sera screening utilizing the complement dependent cytotoxicity assay at 16 weeks post-engraftment.

RESULTS: Morphology and laminin staining in grafts stored for up to 22 weeks remained similar to fresh nerve grafts. DNA and protein synthesis was maximal in 3 day *in vivo* Wallerian degenerated nerves, lower in normal and 24 hr stored nerves, but still present in 3 week stored nerves. Nerve allografts stored for up to 5 weeks tested positve for antibody, but freeze-thawed nerve allografts were negative.

CONCLUSION: Stored nerve grafts appear to undergo early Wallerian degeneration, but leave behind an intact connective tissue scaffold rich in laminin. Some cells within the graft remain viable after 3 weeks of storage and grafts stored up to 5 weeks remained immunogenic.

UNBIASED QUANTITATIVE STEREOLOGICAL ASSESSMENT OF INTRACEREBRAL GRAFT SURVIVAL. D.A. Peterson[1], H. Takayama[1], D. Barba[2], G.R. Chalmers[1], M.H. Tuszynski[1], and F.H. Gage[1]* Departments of Neurosciences[1] and Surgery[2], UC San Diego, La Jolla, CA, 92093-0627

Histology of engrafted neural tissue has largely focussed on qualitative aspects of graft health, integration, morphology, and phenotype. To objectively assess the survival of cografted cells in a variety of paradigms, we found it necessary to perform quantitative assessment to permit statistical evaluation. We present here the application to the intracerebral grafting model of two unbiased stereological techniques: the optical disector estimator of cell numerical density (N_v) and Cavalieri reference volume (V_{ref}) estimator.

Stereology has been applied to estimate cell numbers in normal neuroanatomical structures, and recently to cultured tissue, but it has not been used with intracerebral grafts. The optical disector directly counts cells in a known volume using the formula $N_v=\Sigma Q^-/V_{dis}$ where Q^- is the number of cells counted within the sampling volume (V_{dis}) which is determined by multiplying the *x,y* area of the sampling frame by the sampled depth of focus (*z* axis) into the tissue (measured with an electronic microcator). All cells within the optical disector volume are sampled with equal probability with respect to cell size, shape, or distribution and sampling is therefore without bias and requires no correction factors. Using the Cavalieri estimator formula $V_{ref}=(\Sigma P)(A_p)(t)$, graft volume is quickly calculated from systematically sampled sections knowing only the sum of points (ΣP) from a point-counting grid overlying the graft profiles, the calibrated area associated with each point (A_p), and the section thickness (t). In addition to providing a useful parameter in itself, graft volume (V_{ref}) can be combined with N_v to estimate the total number of cells (N_{abs}) by the equation $N_{abs}=(N_v)(V_{ref})$. Our resulting estimations of absolute graft volume and unbiased total cell number provide a reliable, comparable basis upon which to assess biological significance.

PHOSPHORYLATION OF GAP JUNCTION PROTEIN IN C6 GLIOMA CELLS TRANSFECTED WITH CONNEXIN43 cDNA. M. Deakin, J.F. Bechberger and C.C.G. Naus*. Dept. of Anatomy, The University of Western Ontario, London, Canada N6A 5C1.

Gap Junctions are transmembrane channels which aid in intercellular communication permitting the transfer of ions and low MW molecules between cells. C6 glioma cells transfected with connexin43 (cx43) cDNA were used to examine the association of phosphorylation of cx43 on intracellular localization. The total, membrane and cytoplasmic fractions of these cells were isolated by differential centrifugation, and separated using PAGE and Western Blotting. In these cells, the phosphorylated state of cx43 was found principally in the membranous fractions while the non-phosphorylated state was found principally in the cytoplasmic fractions. Following treatment in culture with either 10 μM or 100 μM forskolin to increase cAMP production and protein phosphorylation, an increase in the amount of cx43 in C6 cells was evident by indirect immunofluorescence. Examination of cx43 mRNA levels revealed a 7 fold increase in mRNA production in C6 cells treated with forskolin, as well as a 5 fold increase in endogenous mRNA production in transfected cells. However, the expression of the transfected cx43 cDNA was not affected by forskolin. Forskolin treatment appears to increase the endogenous mRNA and protein levels of cx43 in the C6 cells. In transfected cells, forskolin induced an increase in the phosphorylation of cx43, suggesting an enhanced insertion of this protein into the membrane. Supported by a grant from the Medical Research Council of Canada.

TRANSFECTION OF C6 GLIOMA CELLS WITH CONNEXIN43 UNDER HUMAN METALLOTHIONEIN PROMOTER CONTROL: EXPRESSION, DYE COUPLING, AND GROWTH RATE FOLLOWING INDUCTION. J.F. Bechberger*, D. Zhu, G.M. Kidder and C.C.G. Naus. Depts. of Anatomy & Zoology, University of Western Ontario, London, Ontario, Canada, N6A 5C1.

C6 glioma cells express very low levels of the gap junction protein, connexin43 (cx43), but upon transfection with cx43 cDNA in a pLTR expression vector, the amount of cx43 protein is greatly increased with a resultant increase in dye coupling and reduced cell growth rate (Zhu et al., 1991). The pLTR expression vector contains a constitutive promoter, thus individual clones could demonstrate mutational or clonal differences not related to the presence of the exogenous cx43 protein. An expression vector containing a modified metallothionein promoter (pM 2.6) has been engineered which has a very low level of basal activity, but an extremely high inducible expression in the presence of Zn^{2+} (McNeall et al., 1989). The use of this vector enables the transfected clones to be analyzed prior to induction for cellular alterations due to the insertion of the vector and/or clonal selection. Cx43 cDNA was inserted into the pM 2.6 plasmid and stable transfectants were isolated. After 12 hours of Zn^{2+} treatment (100 μM), several clones demonstrated up to a 25 fold induction of cx43 mRNA, as well as an increase in cx43 protein. Dye coupling analysis of these clones demonstrated a significant increase in functional gap junctions. At present, we are determining if the induction of cx43 protein causes a reduction in growth rate. Supported by Medical Research Council of Canada.

PURIFICATION AND CHARACTERIZATION OF AN ENDOGENOUS PROTEOLYTICALLY-DERIVED SOLUBLE FRAGMENT OF N-CADHERIN WHICH RETAINS ADHESIVE FUNCTION. Nancy E. Paradies* and Gerald B. Grunwald, Dept. of Anatomy, Thomas Jefferson University, Philadelphia, PA.

The expression of N-cadherin is developmentally down-regulated in the neural retina of the chick embryo after day 9. We have previously shown that this is in part due to decreased mRNA levels. However, there is evidence that epigenetic mechanisms are also at work, in that a soluble 90kD fragment of N-cadherin is shed from the cell surface into conditioned medium during retina organ culture. We now provide biochemical evidence from pulse-chase studies that this fragment is indeed derived directly from N-cadherin. This activity is apparently due to a membrane-associated metalloprotease as turnover occurs in isolated membranes. Turnover of N-cadherin also occurs in vivo, as we have purified this fragment from freshly isolated embryonic vitreous humor. The purified protein retains adhesive activity, promoting attachment, spreading, and neurite outgrowth among cultured neural retina cells. Neurites growing on the 90kD fragment are shorter and more highly branched than those growing on laminin. We conclude that an intact transmembrane and cytoskeletal domain may not be essential for cadherin function, and that proteolysis may be an endogenous mechanism for regulating N-cadherin expression and function and generating novel functional forms of the protein. Supported by grants from NIH and NSF.

MUSCLE CADHERIN IS SPECIFICALLY EXPRESSED IN DEVELOPING SKELETAL MUSCLE OF THE MOUSE EMBRYO R.Moore, F.S.Walsh*, Dept. of Experimental Pathology, UMDS, Guy's Hospital, London SE1 9RT, UK.

We have examined, by *in situ* hybridization, the spatiotemporal pattern of expression of the muscle cadherin (M-cad) molecule (Donalies *et al.*, Proc.Natl.Acad.Sci. USA 88 8024, 1991) during mouse embryogenesis. We compared the M-cad staining with that obtained with neural cadherin (N-cad) and several muscle specific probes applied on serial tissue sections. The probes used were ^{35}S-labelled cRNA riboprobes. We found that at all embryonic ages examined M-cad was expressed in developing skeletal muscle and was absent from all other tissues. The M-cad transcript was found in the skeletal muscle myotome shortly after its formation. However high levels of myogenin transcripts were found in the myotome prior to M-cad at E8.5. The M-cad transcript was also found in muscles derived from the myotome such as those surrounding the vertebrae. Cells immigrating into the forelimb buds, from which the limb musculature develops, did not express M-cad until E11.5 when they did so coordinately with several other muscle specific genes. In contrast the N-cad transcript was found in both the neural tube and the early somite. At later embryonic stages the neural distribution of N-cad predominated as levels decreased in muscle. However transcription of both cadherins was down regulated shortly prior to birth such that at E17.5 neither transcript could be detected. We believe that the tissue specific distribution of M-cad, which has not been described for any other cadherin to date, suggests that it plays a role in cell sorting prior to myoblast fusion.

560.5

CHARACTERIZATION OF cDNAS ENCODING HUMAN CONTACTIN E.O. Berglund and B. Ranscht*, La Jolla Cancer Research Foundation, La Jolla, CA 92037.

We have recently reported the isolation and characterization of a membrane glycoprotein, Gp135, from human brain (Berglund et al., 1991). Amino acid sequence analysis of the amino terminus and of an internal peptide revealed a strong similarity of Gp135 to chicken contactin/F11 and mouse F3. These glycoproteins belong to the immunoglobulin superfamily of cell adhesion molecules in the nervous system.

We now report the isolation and characterization of cDNA clones encoding Gp135. The protein sequence predicts that Gp135 consists of six immunoglobulin-like domains and four fibronectin type III domains and thus shares structural similarity with chick contactin/F11 and mouse F3. At the amino acid level, the sequence identity with these proteins is 78 and 94 %, respectively. The sequence terminates with a hydrophobic region indicating that Gp135 is anchored to the membrane through a glycosylphosphatidylinositol moiety. Surprisingly, we isolated two types of cDNAs that indicate heterogeneity at the amino terminus of the Gp135 protein. The two cDNAs are identical except for the insertion of a 33 basepair stretch at the 5'-end. The cDNAs therefore encode proteins of different length with differences at their extreme amino termini. The amino terminus of the longer form is identical to the amino terminal sequence of purified Gp135 (Berglund et al., 1991) and thus matches the corresponding region of F3 with the exception of a few amino acids. In comparison, the shorter form of Gp135 lacks 11 residues at the amino terminus and is three amino acids shorter than contactin/F11. By Northern analysis, one mRNA species of approximately 6.6 kb is detected in normal human brain.

These data confirm that contactin/F11, F3 and Gp135 are species homologues.

Distribution of NCAM Isoforms and N-Cadherin on Developing Muscle Cell Surfaces BJ Fredette*, LT Landmesser, U Rutishauser Dept. Physiol. Neuro., U. Connecticut, Storrs, CT and Dept. Genetics, Case Western U., Cleveland, OH.

Myotubes develop in tightly adherent clusters of cells within which myoblasts fuse on the surfaces of primary myotubes to form secondary myotubes. These then separate from the clusters to become independently contracting myofibers. This study describes the temporal and spatial distribution of NCAM and N-cadherin on muscle cells during fusion and myotube separation in the chicken hindlimb. Both LM and EM immunocytochemistry reveal that N-cadherin, and the low and high sialylated forms of NCAM are differentially expressed. N-cadherin is preferentially localized on myoblasts and on newly formed myotubes attached to primary myotubes, but not on the surfaces between more mature myotubes. While NCAM is expressed on all cell surfaces, its polysialylated form is restricted to the free surfaces of muscle cells and is not expressed on surfaces apposed to other cells. Biochemical analysis shows that a major portion of polysialic acid is carried by the 130 kD, lipid-linked NCAM, and that a shift in the predominant expression of 145 kD NCAM during primary myogenesis to 130 kD NCAM during secondary myogenesis corresponds to a rapid and transient increase in immunostaining for polysialic acid. When muscles develop in the absence of nerve activity, myotubes fail to separate from clusters normally. This correlates with a delay in the down-regulation of N-cadherin, a failure of NCAM to be polysialylated, and with a failure in the shift from 145 kD to 130 kD NCAM to occur. Since in other systems NCAM promotes and polysialic acid reduces adhesion, the distributions of N-cadherin and polysialylated NCAM during normal development and the perturbations observed in activity blocked muscles implicate N-cadherin down-regulation and polysialylated NCAM up-regulation in the process of myotube separation from clusters, and indicate that this is a nerve activity dependent process. *Supported by NSF grant BNS 9109529.*

EFFECTS OF CYTOSKELETAL INHIBITORS ON N2A AND CHO CELL ADHESION TO N-CAM SUBSTRATES. S.D. Storms, D. Yaghmai, J.J. Jensen, and B.A. Murray*. Dept. of Dev. and Cell Biology and Dev. Biology Center, Univ. of CA, Irvine, CA 92717.

The role of the cytoskeleton in N-CAM mediated adhesion was studied using a quantitative centrifugal removal assay. In order to evaluate the effects of cytoskeletal perturbation on time dependent strengthening of adhesion, cells were treated for 30 minutes with 1μM colchicine to inhibit microtubule assembly or with 1μM cytochalasin D to inhibit microfilament formation. Following treatment, N2A and CHO cells were centrifuged onto immobilized N-CAM substrates and allowed to incubate at 37°C for 10-60 minutes prior to the removal assay. Strengthening of adhesion in both treatments was not statistically different from controls at $p<0.05$, although the range of strength of adhesion in both treated groups was more variable than the controls. Adhesion of N2A and CHO cells to laminin was not significantly different in the colchicine treatment but strengthening was significantly slowed by cytochalasin D treatment. This is expected as laminin is bound by receptors in the integrin family which are known to interact with the cytoskeleton through microfilaments. These results suggest that N-CAM binding is independent of the cytoskeleton but may be affected indirectly by cytoskeleton mediated effects on cellular events such as flattening on a substrate.

This project was supported by American Cancer Society grant CD-416.

A NOVEL IG-SUPERFAMILY CELL SURFACE PROTEIN DIFFERENTIALLY DISTRIBUTED BOTH ON OPTIC FIBERS AND IN THE CEREBELLUM

Jost Vielmetter*, Jon Faiz Kayyem, Janet Roman, Uli Schwarz, and William Dreyer, CalTech, Pasadena CA 91125.

The establishment of axonal projections in the nervous system is believed to be achieved in part by an address system of cell surface recognition molecules. Address molecules must by definition be distributed differentially in space and/or in time during embryogenesis. Of particular interest are those molecules that contain Ig-like domains which are common to many cell adhesion and recognition molecules and whose primary function is specific recognition of molecules. We developed a method that enabeled us to successfully generate monoclonal antibodies against a large number of cell surface proteins belonging to the Ig-superfamily. One interesting molecule was detected with the monoclonal antibody 10-22A8. In the chick retina at embryonic stages E7 to E10, it stains optic fibers of the nasal retina while staining temporal fibers little if at all. The staining on optic fibers disappears at later stages of development (E11-E22), while it persists in the inner and outer plexiform layers. In the cerebellum the external granular cell layer is stained heavily in the most posterior part, whereas staining of this layer is much less conspicious in other regions of the cerebellum. This staining pattern persists throughout embryonic stages E8-E18. Preliminary sequence information of cDNA clones coding for a portion of this protein reveals its homology to members of the Ig-superfamily. It contains at least 4 Ig-domains and 3 fibronectin typeIII repeats. Determination of the entire coding sequence of this complex, multifunctional protein will make it possible for us to design molecular level experiments to study the functions of the various intracellular, extracellular, and alternatively spliced domains.

HETEROPIHLIC Ng-CAM BINDING: EVIDENCE FOR INTERACTIONS WITH LAMININ. Martin Grumet* and Gerald M. Edelman, NYU Medical Center and Rockefeller University, New York, NY 10016.

Ng-CAM is a cell adhesion molecule mediating neuron-glia and neuron-neuron adhesion via different binding mechanisms. It can bind homophilically as demonstrated by the ability of Ng-CAM coated beads (Covaspheres) to self-aggregate. In the present study, we found that the rate and extent of Ng-CAM Covasphere aggregation were strongly diminished in the presence of approximately stoichiometric concentrations of laminin. Comparisons among different laminin preparations indicated that, in contrast, to aged preparations that inhibited aggregation of Ng-CAM-Covaspheres, non-aged preparations of laminin induced formation of very large aggregates of Ng-CAM-Covaspheres. To analyze whether the ability of laminin to cross-link Ng-CAM-Covaspheres was related to its ability to self-associate, the effects of the molecule were tested after gentle proteolysis with elastase which cleaves the globular A-chain domain that has been implicated in self-association of laminin. This treatment yielded prepartions that inhibited aggregation of Ng-CAM-Covaspheres and contained a major fragment of Mr 130,000 on SDS/PAGE. In addition, laminin-Covaspheres coaggregated with Ng-CAM-Covaspheres, and this binding was inhibited by anti-Ng-CAM and by anti-laminin Fab' fragments. To test whether Ng-CAM present on neurons is involved in binding to laminin, neuronal adhesion to various protein substrates was tested in the presence of specific antibodies. Anti-Ng-CAM Fab' fragments inhibited neuronal binding to laminin. The combined results suggest that Ng-CAM on the surface of neurons may be one of several molecules that bind to laminin.

560.10

CHARACTERIZATION OF FOUR CELL ATTACHMENT SITES IN CYTOTACTIN. A.L. Prieto, C., Andersson-Fisone, K.L. Crossin*. Dept. of Neurobiology, Scripps Res. Inst., La Jolla, CA. 92037

The multidomain structure of the extracellular matrix molecule cytotactin/tenascin, and its restricted distribution suggest that it plays diverse roles during morphogenesis. Cytotactin has domains homologous to epidermal growth factor (EGF), fibronectin type III repeats (FN type III) and fibrinogen (Fg). Previous studies indicate that these domains may represent independent functional units. To search for functions of the various domains, non-overlapping recombinant protein fragments were made that spanned almost the entire molecule. Cell attachment and morphology of fibroblasts, glia, and neurons were examined using several adhesion assays. In contrast to the previous identification of one cell attachment and one counter-adhesive site, at least four non-overlapping sites on the molecule were found to interact with the cell surface. Two sites mediated cell attachment and were located in the proximal FN type III repeats (I-VI in the chicken sequence) and in the Fg domain; two others were located in the EGF region and the distal FN type III repeats (VII-VIII), and were counteradhesive. The quantitation of attachment on these fragments, competition experiments, and differences in adhesion of the different cell types support the hypothesis that cell attachment to different sites on cytotactin is mediated by different cell receptors and may be responsible for differential cell adhesion to intact cytotactin.

REGULATION OF ASTROCYTIC TENASCIN BY BASIC FIBROBLAST GROWTH FACTOR (bFGF). Sally Meiners, Jennifer L. Rittenhouse, and Herbert M. Geller*, Department of Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854

Extracellular matrix (ECM) molecules have been implicated in the regulation of neurite adhesion and outgrowth both during development and after injury. We have previously shown that astrocytes are heterogenous in terms of expression of the extracellular matrix protein tenascin. High tenascin astrocytes have a reduced ability to support neurite outgrowth. In other experiments, bFGF was shown to cause a significant change in the morphology of cultured neonatal rat cerebral cortical astrocytes and also reduced neuronal adhesion to these astrocytes. In this series of experiments, we tested the hypothesis that bFGF could have increased expression of tenascin by the astrocytes. Cultures of purified protoplasmic astrocytes were established from the cerebral cortex of neonatal rats and subcultured into tissue culture flasks coated with polylysine. Basic FGF was added to test cultures at a concentration of 5 ng/ml, a concentration which was previously shown to cause a significant change in astrocyte morphology and neuronal adhesion. Tenascin levels were evaluated by Western blot analysis of both extracted cells and conditioned media. Tenascin levels began to increase after 24 h and continued to increase throughout 8 days of treatment. The bFGF treatment was discontinued, and the cells were maintained for an additional 8 days in culture. Tenascin levels returned to control values, demonstrating that the bFGF effect is transient. Neuronal adhesion was reduced on bFGF-treated cultures, suggesting that tenascin may be inhibitory to neuronal growth. It is our hypothesis that the action of growth factors during injury may evoke the induction of tenascin on astrocytes, thereby reducing regeneration in the central nervous system.

Isolation from human brain of large hyaluronate-binding proteoglycan (versican?). G. Perides*, and A. Bignami. Harvard Medical School and Brockton/West Roxbury VA Medical Center, Boston, MA. 02132.

A large proteoglycan (365 kDa), identified with monoclonal antibodies raised against chondroitin sulfate, was isolated from human brain. The isolation required cation and anion chromatography followed by gel filtration through a Sephacryl S-500 column. The proteoglycan bound specifically to [^{3}H]-hyaluronate (HA). The binding was not reduced by high salt concentrations (up to 4M) and was inhibited at low pH (< 4.0). The binding was inhibited specifically by the octamer and the decamer but not the hexamer oligosaccharide of HA. Limited proteolysis of the proteoglycan gave rise to a relatively stable polypeptide (80 kDa). The amino terminal sequence of the 80 kDa polypeptide was identical to the cDNA derived amino terminal sequence of versican, a large fibroblast proteoglycan (Zimmerman and Ruoslahti, EMBO J. 8:2975, 1989) and to previously reported sequences of the 60 kDa glial HA-binding protein (GHAP). The finding suggests that a large aggregating proteoglycan participates with hyaluronate and GHAP in the formation of brain ECM. Supported by NIH grant NS 13034 and by the Veterans Administration.

pgT1, A LARGE CHONDROITIN SULFATE PROTEOGLYCAN FROM ADULT RAT BRAIN, BINDS TO HYALURONIC ACID.
Mineo Iwata*, Thomas N. Wight^ and Steven S. Carlson, Dept of Physiology and Biophysics and ^Dept of Pathology, University of Washington, Seattle, WA.

We have identified a large chondroitin sulfate proteoglycan (pgT1) that has the characteristics of a general extracellular matrix component of rat brain (Iwata and Carlson, Abst. Soc. Neuro.,16:496,1990). This proteoglycan is identified with a mAb to a rare chondroitin sulfate epitope (T1). pgT1 is immunocytochemically localized throughout the brain in white and gray matter. Like extracellular matrix components from other tissues, pgT1 requires denaturing conditions to be solubilized from brain tissue. pgT1 is distinct from the 'space-filling' proteoglycans, smooth muscle cell versican, nasal cartilage aggrecan and rat brain versican-like proteoglycan. We propose that pgT1 is a general component of adult brain extracellular matrix (Iwata and Carlson, Abst. Soc. Neuro, 17, 575, 1991).

pgT1 has a high affinity for hyaluronic acid. We measured binding affinity of pgT1 to human hyaluronic acid (hHA) by the affinity coelectrophoresis developed by Lee and Lander (P.N.A.S., 88:2768-2772,1991). The Kd of pgT1 for hHA was determined to be 0.4nM. This is somewhat higher than that found for versican of 38nM. pgT1 was also shown to bind to endogenous HA of rat brain by gel filtration. When complexes of pgT1 and HA were visualized by electron microscopy, we observed "bottle brush" structures attached to a thin filamentous strand resembling hyaluronic acid.

We propose that pgT1 binds to hyaluronic acid and forms a part of extracellular matrix in brain.

PERINEURONAL AND WHITE MATTER LOCALIZATION OF HYALURONIC ACID IN POSTNATAL RAT CNS. H.J.L. Fryer*, G.M. Kelly, R.G. Kalb and S. Hockfield. Sect. of Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510

The CNS Cat-301/304 antigen is a high molecular weight chondroitin sulfate proteoglycan (CSPG) related to the cartilage CSPG, aggrecan [Fryer et al., JBC 267:9870]. Both CSPGs aggregate with hyaluronic acid (HA). Purified cow and cat CSPGs are recognized by antibodies Cat-301 and Cat-304. The Cat-301/304 CSPG is associated with the cell surface of neuron cell bodies and proximal dendrites of specific neuronal populations in the mammalian CNS. In this study we have used purified aggrecan to localize candidate receptors for CNS CSPGs. Sections of postnatal and adult rat spinal cord were incubated with bovine aggrecan then stained for bound CSPG using monoclonal antibody Cat-304, which recognizes bovine, but not rodent, CSPG.

At the light microsopic level purified aggrecan binds to neurons and axons in sections of adult spinal cord. In white matter aggrecan binds to spaces surrounding axons, and in grey matter it binds to elements of the neuropil and is also associated with the surface of cell bodies of neurons in the ventral horn. Binding of aggrecan is inhibited in spinal cord sections that are treated with hyaluronidase or chondroitinase ABC (both of which digest HA) prior to incubation of sections with aggrecan. This suggests that aggrecan binding is mediated through HA in tissue sections.

Perineuronal binding of aggrecan increases during postnatal development. At P5 diffuse staining is seen throughout the grey and white matter with no apparent association with neuronal cell surfaces. By P22 surface staining of neurons as well as axonal staining is present. The developmental time course of aggrecan binding to neuronal cell surfaces parallels the time course of expression of the Cat-301 CSPG on neuronal cell surfaces. These results suggest that HA is present on neuron cell surfaces and that the assembly of neuronal extracellular matrix occurs over the first postnatal month in the rodent spinal cord. Proteoglycan Distribution in Developing Retinal Neurons, Arnold G. Hyndman*, Sandra Echeverria, and Nelda Davis. Department of Biological Sciences, Rutgers University, Piscataway, NJ 08855

Proteoglycans are known to play an important role in the development of the nervous system. We examined the distribution of proteoglycans in the developing chick retina using an Alcian Blue staining procedure. Proteoglycan staining was observed at embryonic day 6 (E6) and was present throughout remainder of embryonic development. Photoreceptors, ganglion cells and the nerve fiber layer were most heavily stained. Moderate staining was seen in all other regions. To determine where neurons deposit newly synthesized proteoglycans, isolated retinal neurons were maintained in culture. The incorporation of [^{3}H]-glucosamine into proteoglycans was determined in three fractions. Results indicate that approximately 50% of the newly synthesized proteoglycans were secreted by neurons and 40% remained associated with the cell surface. A remnant of radioactivity was found "tightly" associated with either the intracellular or matrix compartments. In cultures from E8 retina, total proteoglycan synthesis is one-third less than in E11 cultures. Furthermore, transferrin increased the amount of proteoglycan secreted in E11 cultures, but not in E8 cultures.

560.16

GLYPICAN, A PROTEOGLYCAN, IS REGIONALLY EXPRESSED IN THE DEVELOPING RAT BRAIN. E.D. Litwack*, C.S. Stipp, and A.D. Lander, Dept. of Biology and Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139

Proteoglycans (PGs) bind and regulate the function of a variety of proteins, including growth factors (such as bFGF) and extracellular matrix molecules (such as fibronectin and laminin). A major heparan sulfate PG (HSPG) of the rat brain, designated M12 (Herndon and Lander, Neuron, 4:949, 1990), has a protein core with an apparent M_r of 65kD and is associated with cell membranes via a phosphatidylinositol linkage. Rat brain extracts made at E18, P0, and adult all contain this core. The biochemical properties of M12 are similar to those of a human lung fibroblast PG, glypican (GP) (David et al., J. Cell Biol., 111:3165, 1990), raising the possibility that GP is expressed in the rat brain, and is M12. To test this possibility, M12 was purified from neonatal rat brain. N-terminal sequences obtained from tryptic fragments of M12 were all highly similar to sequences in human GP, varying from 72% to 100% identical. To confirm that M12 is rat GP, a rat GP cDNA was obtained as follows: A human GP fragment was obtained by PCR from human foreskin fibroblast RNA. Northern analysis detected an RNA of about 3.7 kb from neonatal rat brain, rat fibroblasts and PC12 cells, a rat neuronal-like cell line which we find contains an M12-like major HSPG. One of the clones detected upon screening a PC12 cDNA library with the GP probe was an approximately 3.0 kb cDNA. Partial sequence indicates that it is 85% similar to human GP. One M12 peptide falls in the region of and is correctly predicted by the partial cDNA sequence. To determine the pattern of expression of GP in the adult rat brain, in situ hybridization was performed with a probe from the rat GP cDNA. Results indicate that GP is regionally expressed, with high levels present in areas such as the thalamus. Further studies will characterize the pattern of GP expression during rat brain development. (Supported by NIH grant NS26862)

THE 1D1 PROTEOGLYCAN OF BRAIN. U. Rauch, L. Karthikeyan, P. Maurel, R.U. Margolis, and R.K. Margolis* NYU Med. Center, NY, NY 10016, and State Univ. of NY Health Sci. Center, Brooklyn, NY 11203.

Two rat brain proteoglycans (PGs) with core glycoproteins of 150 and 245 kDa were isolated by immunoaffinity chromatography using the 1D1 mAb (Rauch et al., *J. Biol. Chem.*, 266:14785, 1991). Up to ~2 weeks postnatal the PG with the 245 kDa core glycoprotein is the main physiological product, whereas after three weeks the smaller PG becomes predominant and is essentially the only species present in adult brain. Peptide maps of both core proteins indicated that the 150 kDa core glycoprotein is a part of the 245 kDa PG, because all peptides generated from it could also be found in the larger species. The amino acid sequence of the cloned 150 kDa core protein revealed a high degree of homology with versican and aggrecan, based on the presence of two EGF-like domains, a lectin-like domain, and a complement regulatory-like domain in the C-terminal half of the PG. The larger PG has the ability to form aggregates with hyaluronic acid, and peptide and cDNA sequences from this PG revealed the presence of immunoglobulin folds and tandem repeats similar to those present in the hyaluronic acid binding regions of versican and aggrecan which, however, have much longer glycosaminoglycan attachment domains which cannot be accommodated in the 1D1 core glycoprotein. Northern blots demonstrated that only a single message of 7.5 kb was detected in either 4-day or adult brain, and no message was detectable in liver, kidney, muscle, or lung mRNA. Our results therefore indicate that the adult form of this PG is derived by *in vivo* proteolytic processing from the larger species present in early postnatal brain, and that the 1D1 PG is a new, and possibly central nervous tissue-specific, member of the versican/aggrecan PG family.

ROLE OF GLYCOSPHINGOLIPIDS IN SKELETAL MUSCLE DIFFERENTIATION *IN VITRO*. K.C. Leskawa*, S. Hickerson and L.D. Cambron. Dept. Anat. Sci. & Neurobiol., Sch. of Med., Univ. of Louisville, Louisville, KY 40292.

We have previously reported that when glycosphingolipid (GSL) synthesis is inhibited by PDMP, which blocks the formation of glucosylceramide, clonal muscle cells cease to fuse to form multinucleated myotubes. This inhibition of myogenesis was overcome by addition of exogenous lactosylceramide (LacCer) or ganglioside GM3, suggesting a role for these compounds in myoblast fusion. We have recently explored this phenomenon in greater detail. Myoblasts, either controls or PDMP-treated, were pulsed with radiolabeled LacCer or GM3 and the fate of these added GSLs examined at varying times thereafter. It was found that neither LacCer nor GM3 were converted to any other GSL structure, in either treated or untreated muscle cells, up to 96 hr following exposure.

Whether the reversal of fusion inhibition by LacCer or GM3 was specific, as opposed to a general membrane lipid perturbation effect, was examined by assessing the effects of various other GSLs on PDMP-treated myoblasts. It was found that neither GalCer, GbOse$_3$Cer, ganglioside GM2 nor GM1 were capable of reversing the myoblast fusion block caused by PDMP.

Skeletal muscle cells were also treated with exogenous neuraminidase and ceramide glycanase. Both treatments inhibited myoblast fusion. Myoblasts treated with neuraminidase assumed an entirely different, non-myoblast morphology and exhibited loss of contact inhibition. In contrast, cells treated with ceramide glycanase resembled PDMP-treated cells morphologically, in that they migrated and aligned in parallel arrays.

These studies further support our hypothesis that surface GSLs play an important role in skeletal muscle differentiation. In addition, these results specifically point to a necessary role for lactosylceramide and GM3.

NEUTRAL GLYCOSPHINGOLIPIDS OF NORMAL ADULT HUMAN BRAIN: MOLECULAR CHARACTERIZATION OF GgOse$_4$Cer. E.L. Hogan* and S. Dasgupta. Neurology, Med Univ SC, Charleston, SC 29425.

The nonpredominant neutral glycosphingolipids (Ngsls) of neuronal tissues of the globo-, ganglio- and lactoseries, accumulate in brain in some sphingolipidoses. Ngsls of normal fetal brain have been characterized as galactosyl/glucosylceramide (48%), lactosylceramide (17%), Gb$_3$Cer, Gg$_3$Cer (9%) and traces of Gb$_4$Cer and Gg$_4$Cer and two additional Ngsls as nLc$_4$Cer (13%) and III^{3}FucnLc$_4$Cer (10%) [Ishikawa et al, J Biochem (Tokyo), 101, 1369, 1987]. FucnLc$_4$Cer, a minor constituent of normal adult brain [Vanier et al, FEBS Lett, 112, 70, 1980], is considered a stage-specific fucolipid antigen. GgOse$_4$Cer (GA1 or asialo-GM1) identified in mouse myelin [Kusunoki et al, Brain Res, 334, 117, 1985], has recently been analytically and immunochemically characterized in bovine brain [Dasgupta et al, FEBS Lett, **in press**, 1992], adult human and rat brain and myelin. We have purified and characterized several Ngsls from human brain as GalCer, GlcCer, LacCer, Gb$_3$Cer, Gg$_3$Cer and possibly Gb$_4$Cer and nLc$_4$Cer. A homogeneous glycolipid band that comigrates with standard GA1 has been purified and characterized as GA1. PMAA-derivative of another partially purified Ngsl with Rf close to GA1 has the possible structure of GbOse$_5$Cer. Employing the DIG-immunostaining [Kniep and Muhlradt, Ann Biochem, 188, 5, 1990] and FACE [Jackson, Biochem J, 270, 705, 1990; Stack et al, Glycoconjugate J, 8, 249, 1991] we have identified several minor long chain (CHO- > 4-5) Ngsls bands in brain and myelin that have not been previously reported. The specific expression of these Ngsls during brain development and myelinogenesis remains to be explored.

GANGLIOSIDE BINDING MOLECULES OF RAT SKELETAL MUSCLE. R.E. Shapiro*[1] and R.L. Schnaar[2]. Depts. of [1]Neurology and [2]Pharmacology, Johns Hopkins School of Medicine, Baltimore, MD, 21205.

Gangliosides on motoneuron terminals have been proposed as binding sites for several neuropathogenic agents. We hypothesize that motoneuron gangliosides also act as specific receptors for molecules derived from surrounding endogenous tissues including skeletal muscle. We evaluated crude sarcosolic extracts from male rats in a soluble assay for binding activity to a ganglioside ligand (bovine trisialogangliosides (G_{T1b}) covalently and multivalently bound to radioiodinated bovine serum albumin). We found specific binding activity with a rapid on-rate (>75% of max. binding within 1 min.), and which was proportional to the quantity of extract protein in the assay. Binding activity is eliminated by prior boiling of the extract, and is inhibited by free gangliosides (G_{T1b} $IC_{50} \approx 0.5$ μM; $G_{M1}/G_{D1b}/G_{D1a}/G_{M2}/G_{M3}$ IC_{50}'s between 0.5 μM and 5 μM), by phosphatidylcholine ($IC_{50} \geq 50$ μM), or by increased ionic strength (NaCl $IC_{50} \approx 50$ mM), but not by the disaccharides cellobiose or lactose (up to [10 mM]). Binding at pH 7.4 is >90% dependent upon the presence of divalent cations (Ca^{++} or Mg^{++}). Binding activity increased at low pH (specific binding at pH 4.5 was >6 fold that at pH 7.4), but this increased binding activity was ≤50% Ca^{++}-dependent. Scatchard analysis indicated a single class of Ca^{++}- dependent ganglioside ligand binding sites ($K_D \approx 5.6$ nM) at pH 7.4. [NIH grants KO8 NS01518 and HD14010.]

560.21

DOPAMINE β-HYDROXYLASE AND CYTOCHROME B561 ARE PRESENT ON THE AXONAL RETICULUM IN BOVINE SYMPATHETIC NEURONS. J.R. Quatacker, W.G. Annaert, B.J. Miserez and W.P. De Potter. N. Goormaghtigh Inst. Univ. Hosp. Ghent and Lab of Neuropharmacol., Univ. Antwerp, B-9000, Belgium.

The axonal reticulum in sympathetic neurons is considered to be an extension of the secretory pole of the Golgi apparatus. If so it would likely contains the enzymes involved in catecholamine elaboration.

To test this hypothesis the distribution of DβH and cyt b561 was investigated in bovine splenic nerve and nerve terminals in the vas deferens with an immunogold procedure after glycolmethacrylate embedding. Counterstaining was with phosphotungstic acid at low pH.

With antibodies against both enzymes gold labeling was detected over the large dense-cored vesicles, the Golgi-associated axonal reticulum, the reticulum within axons and over the tubular complex at the nerve terminal.

From our results it can be concluded that in sympathetic neurons the axonal reticulum represents a tubular, neurosecretory transport system, spanning the neuronal cell from Golgi apparatus to nerve terminal.

THE LOCALIZATION OF A NOVEL CA^{2+}-BINDING PROTEIN (CBP-18) IN THE RAT BRAIN. D.P. Wolfer*, H.-P. Lipp, W. X. Qin and C.W. Heizmann. Institute of Anatomy, University of Zürich, CH-8057 Zürich, Switzerland.

The distribution of a novel calcium-binding protein (CBP-18) with a molecular weight of 18 KDa in the rat brain (Manalan & Klee, *J. Biol. Chemistry* **259**, 2047-2050, 1984) was studied by means of immunohistochemistry on cryostat-sectioned tissue and compared with staining patterns of parvalbumin on adjacent sections.

The polyclonal rabbit-derived antibody for CPB-18 showed selective affinity for periglomerular cells and dendrites in the olfactory bulb, and also distinctly stained some cells and dendrites in the anterior olfactory nuclei. Marked but diffuse pericaryal staining of neuropil and of cell bodies (including proximal dendrites) was observed in the retrosplenial cortex, hippocampal rudiment, the septum, area preoptica, hypothalamus, in the parabrachial nuclei and in the cerebellar neuropil of both the molecular and the granule cell layer. Less intense neuropil staining for CPB-18 was found in the neocortex, the remaining basal forebrain, parts of the colliculus superior, and in the entire brain stem. Neuropil staining was barely detectable or missing in the striatum, the hippocampus, the thalamus, the colliculus inferior, the cerebellar Purkinje cell layer, and in the cuneate nucleus. CPB-18 appeared to stain regularly cross-sectioned axons but rarely longitudinal fibers. Thus, CPB-18 shows an unique staining pattern in the CNS different from all other Ca^{2+}-binding proteins studied so far. Supported by Swiss National Science Foundation for Scientific Research (SNF 31-27737.89, 31-9470 and 31-30742).

PURIFICATION AND CHARACTERIZATION OF CMP-SIALIC ACID:LACCER SIALYLTRANSFERASE (ST-I) FROM RAT BRAIN. Preuss, U., Gu, X. and Yu, R.K.* Dept. of Biochem., Med. Coll. of Virginia, Richmond, VA 23298

Sialyltransferases (STs) are a family of glycosyltransferases which catalyze the transfer of sialic acid (NeuAc) to the non-reducing terminal sugar of glycoproteins and glycolipids. One of the key enzymes in the synthesis of gangliosides is CMP-sialic acid:LacCer sialyltransferase (ST-I) which catalyzes the transfer of sialic acid to lactosylceramide (CDH) to form GM3. In this report we describe the purification and characterization of ST-I from a Triton X-100 extract from rat brain. The enzyme was purified by affinity chromatography on CDP-Sepharose and resolved by NaCl gradient elution from the same adsorbent. Further purification of GM3 synthase was achieved by chromatography on a "CDH-acid"-Sepharose column eluted with CDH. The enzyme activity was highest at pH 6.5 and required Triton CF-54 or Triton X-100 (0.15%) for full activity. The apparent Km value for CMP-sialic acid was 170 μM. These data correpond with the results obtained for ST-I purified from rat liver (1), suggesting that both enzymes may share a common domain structure or may have significant sequence homology. (Supported by USPHS grant NS-11853 and A. von Humboldt Found. to U.P.)

An Estrogen Receptor-Like Antigen on Membranes of GH_3 Cells. T.C. Pappas[1]*, B. Gametchu[2] and C.S. Watson[1]. [1]Univ. of Texas, Med. Br. Galveston Tx 77550, [2]Med. College of Wisconsin, Milwaukee WI 53226.

The mechanisms of rapid actions of estrogen, such as the rapid release of prolactin from GH_3/B6 cells, have not been elucidated. We hypothesize that a membrane form of the estrogen receptor (ER), similar to the intracellular ER may mediate some these actions. A polyclonal antibody (anti-ER) was generated to a peptide corresponding to amino acids 270-284 of rat ER. The antisera recognizes both native (sucrose density gradient) and denatured ER from rat uterine cytosol, and peptide affinity purified antisera recognizes a single species of 67 KD on immunoblots. GH_3/B6 cells were separated by estrogen affinity chromatography using magnetic beads. When these enriched populations were incubated at 2°C with the affinity purified anti-ER, indirect immunocytochemistry revealed heterogeneous membrane labeling. Anti-Actin controls showed that cells were not permeablized by the live-labeling procedure. When cells were brought to 37°C after anti-ER incubation, labeling became "patchy" and decreased in amount, disappearing by 15 min. Nuclear and cytoplasmic labeling were also evident in cells permeabilized with detergent after fixation. Both membrane and intracellular labeling could be competed with the peptide used to generate the antibody.

DIFFERENTIAL EXPRESSION OF GLUCOSE TRANSPORTERS, GLUT3 AND GLUT1, IN CULTURED CEREBELLAR GRANULE NEURONS: EFFECTS OF POTASSIUM AND NMDA. Frances Maher* and Ian A. Simpson. NIDDK, NIH. Bethesda, MD 20892.

Cerebellar granule neurons in culture express two glucose transporter isoforms, GLUT3 and GLUT1. GLUT3 is the predominant isoform. We investigated the chronic effects of depolarizing stimuli, ie. high potassium concentration and NMDA, on glucose transporter expression in neurons cultured in defined medium. Compared to culture in standard high KCl (25mM; K25), neurons cultured in low KCl (K5 and K15) showed similar morphology but up to 20% decline in cell number. In K5 medium, 2-deoxyglucose transport activity was decreased by 50-60%. This corresponded to decreased glucose transporter expression as determined by immunoblotting with antisera to each isoform; GLUT3 levels decreased by 40-50% and GLUT1 by 20%. Addition of NMDA (100-200μM) to K5 and K15 medium stimulated GLUT3 expression to the levels in K25 but failed to fully restore GLUT1 levels. The effect of NMDA was blocked by APV. Potassium concentration, NMDA and other EAA had no acute effects on glucose transport or GLUT1 and GLUT3 levels. Expression of Na^+K^+ ATPase isoforms was not altered by these culture conditions. In conclusion, potassium depolarization and NMDA receptor activation result in optimal expression of neuronal glucose transporters, the GLUT3 isoform being more sensitive than GLUT1 to chronic regulation by these conditions.

CHOLINE METABOLISM AND THE CONFORMATIONAL EPITOPE OF *TOR 23*. M.B. Foreman*, S. Wright and P.D. Kushner. ALS Research Center, California Pacific Medical Center, San Francisco, CA 94115

Previously we reported that the epitope defined by the monoclonal antibody *Tor 23* is on a presynaptic form of *Torpedo* acetylcholinesterase (AChE), which associates with the membrane via a glycophosphatidylinositol (GPI) linkage. To confirm the conformational architecture of the epitope we have performed a series of Triton X-100 experiments. Although Triton does not inhibit AChE activity, even trace amounts (0.001%) interfered with the immunoprecipitation of AChE by *Tor 23*. To test whether the lack of precipitated AChE was due to a change in the AChE molecule such that the antibody failed to recognize it, Triton was added to immune precipitates and the pellet and supernatant assayed for AChE activity. Triton released AChE activity from the pellet into the supernatant. In contrast, AChE activity remained in the pellet in untreated samples. These experiments support other data suggesting that *Tor 23* identifies a conformational epitope of presynaptic *Torpedo* AChE.

Although we have no data that *Tor 23* recognizes AChE in mammals, the antibody inhibits high affinity hemicholinium-3 binding, high affinity choline uptake and acetylcholine synthesis in rat neocortex (Evans et al., submitted). Furthermore, our studies of neuroblastoma cell lines using mannosamine suggest that, as in the *Torpedo*, the *Tor 23* antigen has a GPI linkage in mammals. In sum, evidence supports the hypothesis that the *Tor 23* antigen, in both *Torpedo* and mammalian systems, is a GPI-linked molecule involved in cholinergic processing.

PURIFICATION AND IMMUNOCHEMICAL STUDIES OF HUMAN BRAIN NA,K-ATPASE ALPHA SUBUNIT PROTEINS AND THEIR POLYPEPTIDE FRAGMENTS. J.H.F. Peng*, Y.C. Zeng and J.C. Parker, Jr. Department of Pathology, Univ. of Missouri-Kansas City Sch. of Med., Kansas City, MO 64108.

In order to study the properties, structure and function of human Na,K-ATPase, the alpha (α) subunit proteins as well as their polypeptide fragments of the enzyme were purified. Polyclonal antibodies to these antigens were prepared. The enyme was purified from axolemma, which was isolated from brainstem, by selective SDS extraction and followed by sucrose density gradient centrifugation. Partially purified enzyme was resolved by SDS-PAGE, stained with zinc ions, and the stained band(s) corresponding to 100 kDa molecular weight (MW) were excised, with the proteins in the gel being eluted by electroelution. The purified proteins were treated with 88% formic acid, lyophilized, and incubated with the SDS sample buffer. The polypeptide fragments were separated by SDS-PAGE. Protein bands corresponding to 40, 50, and 60 kDa MW were cut out of the gel, and the proteins electroeluted as above. Rabbits were subcutaneously immunized and boosted with 100 µg of antigens, which were emulsified with complete and incomplete Freund's adjuvant, respectively. Seven days after the fourth booster injection, blood samples were collected. The antisera to α proteins, and 60 & 40 kDa polypeptides were obtained and characterized by Western blotting. Antiserum to α proteins cross-reacted with α bands as well as 40, 50, & 60 kDa bands. Antisera to 40 and 60 kDa cross-reacted, respectively, with 40 and 60 kDa band as well as α bands. These antibodies will be valuable reagents for immunoaffinity purification, for cDNA screening during cloning of α1, α2 & α3 isozymes, and for immunohistochemistry studies.

HETEROGENEITY IN mRNAs ENCODING THE Na/Ca EXCHANGER IN RAT BRAIN. M.Juhaszova[1], P.Kofuji[2], D.Schulze[3], W.J.Lederer[1], S.M.Wang[1], P.J.Yarowsky[2], M.P.Blaustein[1*]. Depts.[1]Physiol., [2]Pharm., [3]Microbiol. Immun., U. of MD Med. Sch., Baltimore, MD 21201.

Northern blot analysis of total RNA from rat brain revealed heterogeneity in mRNAs encoding the Na/Ca exchanger. The blots were probed with an 800 bp 3' end cDNA probe coding for the rat cardiac Na/Ca exchanger and with the full length cDNA probe coding for human heart Na/Ca exchanger (Kofuji et al., *Biophys. J.* **61**:A387, 1992). Blots were washed using medium stringency conditions (0.1% x SSC at 37°C). We identified three Na/Ca messages (~15 kbp, 7 kbp and 3.2 kbp) not only in whole adult rat brain total RNA, but also in the developing rat brain total RNA in late embryonic stage (day 18). Northern blot analysis of total RNA from cultured cortical astrocytes at 10 days in vitro, however, showed only a 7 kbp Na/Ca exchanger mRNA under the same conditions. Immunochemical Western blot analysis of the astrocytes, synaptic plasma membranes and heart sarcolemma proteins using polyclonal antibody raised against purified canine heart Na/Ca exchanger (Ambesi et al., *Biophys. J.* **59**:138a, 1991) revealed the same protein band pattern in all samples: 70, 120 and 140 kDa. These data suggest that the expressed Na/Ca exchanger in whole brain and in astrocytes may be the same protein, highly homologous to heart Na/Ca exchanger. The different-sized mRNAs probably vary from each other only in their untranslated regions.

560.29

AXONAL TRANSPORT OF FOUR SYNAPSINS IN RAT SCIATIC NERVE; DIFFERENT DEGREE OF VESICLE ASSOCIATION. *J.Y. Li*, A. Czernik† and A. Dahlström, Institute of Neurobiology, Medicinareg. 5, Univ. of Göteborg, S-413 90 Göteborg, Sweden, and Dept. of Cell. & Molecular Neurobiology†. The Rockefeller University, New York, 10021 NY, USA*

Previous immunofluorescence work has shown that synapsin I (SYN I) is transported with rapid axonal transport in sciatic nerve and ventral roots of mammals. SYN I-like immunoreactivity (LI) accumulates proximal to the site of a short term crush, but only very little accumulation is observed distally (10-20 % of proximally). Recent studies, using immunofluorescence and cytofluorimetric scanning (CFS), have concentrated on accumulation and transport of the SYN isoforms, SYN Ia, Ib; SYN IIa and IIb, using isoform-specific antisera on consecutive sections of rat crushed (1-8 h) sciatic nerves. The immunofluorescence proximal and distal to the crush region, after incubation with the various antisera, was quantitated, in relation to gelatine standards with purified SYN Ia,b. Also p38, the vesicle marker, was studied, and this protein accumulated bidirectionally, with 60-80% of anterograde amounts present in retrograde accumulations (recycling). Initially (1h) after crush, SYN Ib-LI showed small, distinct accumulations proximal to the crush. However, little or no SYN Ia-LI was seen near the crush. After 8h an increase in both SYN Ia-LI and SYN Ib-LI was evident, but proximal SYN Ib-LI was stronger than SYN Ia-LI ($p<0.001$). Proximal accumulations of SYN IIa-LI and SYN IIb-LI were observed 1h after crush, and at 8h. More SYN IIa-LI than SYN IIb-LI ($p< 0.001$) was seen proximal to the crush. The results suggest that the isoforms may have different affinities to organelles in fast anterograde transport.

TYROSINE PHOSPHORYLATION OF GP180 IN ADULT AND DEVELOPING BRAIN. **J.W. Gurd*, N. Bissoon, M. Khurgel and J. Soulliere. Scarborough Campus, University of Toronto, West Hill, Ontario, M1C 1A4.**

We have reported the presence of protein tyrosine kinase in isolated postsynaptic densities (PSDs) and demonstrated that the PSD glycoprotein, GP180, is phosphorylated on tyrosine residues (Gurd and Bissoon, J. Neurosci. Res. 25 336-344). We have now used Western blotting of rat brain homogenates with anti-phosphotyrosine antibodies to determine the distribution of ptyr-containing GP180 (PTGP180). GP180 was the only ptyr-containing Con A-binding glycoprotein in PSDs and was the major immunoreactive Con A* glycoprotein present in homogenates. PTGP180 was enriched approximately 20-fold in PSDs relative to homogenate consistent with a postsynaptic localization. Cerebellum and hippocampus contained low levels (less than 15% of forebrain) of PTGP180. PSDs from these regions contain GP180 suggesting regional variation in the activities of postsynaptic tyrosine kinases or ptyr-phosphatases or both. Forebrain homogenates from newborn rats contained less than 5% of the adult level of PTGP180. The amount of PTGP180 increased markedly during the third and fourth weeks of postnatal development before declining to adult values. Incubation of PSDs with ATP increased the tyrosine phosphorylation of GP180 12 to 15-fold, indicating that less than 10% of potential tyrosine phosphorylation sites are occupied in vivo. Supported by the N.S.E.R.C.

IMMUNOHISTOCHEMICAL STUDY OF C-*kit* RECEPTOR EXPRESSION IN ADULT PRIMATE AND MOUSE BRAINS. Q. Yan*, J. Sun, C. Matheson Neurobiology Program, Amgen, Inc., Amgen Center, Thousand Oaks, CA 91320

The tyrosine kinase receptor c-*kit* is coded by the *W* locus and its ligand, stem cell factor (SCF), is coded by the *Sl* locus in mice. c-*kit* and SCF play a critical role for the development of neural crest-derived melanoblasts, germ cells and hematopioetic stem cells. Using a mouse monoclonal anti-human c-*kit* antibody (SR-1) and a rat monoclonal anti-mouse c-*kit* antibody (ACK2), the expression of c-*kit* was studied in the brains of adult baboon and rhesus monkey with SR-1 and mouse brains with ACK2 by conventional immunohistochemistry. c-*kit* IR was observed in the hippocampus, dentate gyrus, fimbria-fornix and lateral septum. The staining appeared to be on fiber tracts and terminals but not on the hippocampal and dentate pyramidal cells. Distinct c-*kit* IR were observed in many areas including olfactory bulb, cerebral cortex, amygdala, caudate putamen, thalamus, interpeduncular nucleus, and inferior olive. In the brainstem and spinal cord c-*kit* IR seemed associated with the sensory pathways which included dorsal horn in the spinal cord, spinal trigeminal nucleus and tract, gracile and cuneate, vestibulocochlear nucleus and solitary tract and its nucleus. In the cerebellum, very intense staining was on Purkinje cell axon hillock and around Purkinje cell bodies. Staining was also seen in the molecular layer and upper granule layer. This study and recent reports on the expression of mRNAs for both c-*kit* and SCF in mouse brain (Motro et al., Development 113:1207-1221; Morii et al., Dev. Brain Res. 65:123-126) suggest potential functions of these proteins in the nervous system.

560.32

CAROTENOID REPLACEMENT IN *Drosophila*: FREEZE-FRACTURE. W.S.Stark*, G.Brown, D.Hombs, J.S.Christianson & R.White±. Div. Biol. Sci., Univ. of Missouri, Columbia, MO 65211 & ±Dept. of Biology, Univ. of Massachusetts, Boston, MA 02125.

Carotenoid deprivation in *Drosophila* reduces visual pigment, opsin, size of the rhabdomere and P-face particle density; replacement by feeding carrot juice rapidly restores visual pigment (Sapp et al., 1991, *Exp.Eye Res.* **53**:71). Our data indicate that this effect is mediated by retinoid-activated opsin gene transcription (Stark et al., 1992, *Invest. Ophthal. Vis. Sci.* **33**: 1398). Here we report that P-face particle density also increases in rhabdomeric microvilli in the early days of replacement therapy to 3000 particles/μm^2 by 1 day, reaching the control level of over 4000 by day 2. Our vistas reveal a continuity of the microvilli with the adjacent retinula cell plasmalemma between the adhering junction and the rhabdomere. This plasmalemma reflects the rhabdomeric P-face particle density. Freeze-fracture preparations of *Drosophila* photoreceptors also displayed autophagic coated pits budding from bases of microvilli and from plasmalemma as well as multivesicular bodies and Golgi apparatus. Recovery in *Drosophila* is considerably faster and more complete than recovery induced by 11-*cis* retinal in similarly deprived *Manduca* (Bennett & White, 1991, *Vis. Neurosci.* **6**: 473). Further, there are substantial differences in the endomembrane traffic in deprivation vs. replacement. Support: NSF BNS8811062 & NIH EY07192 (WSS) & NSF BNS91 10672 (RW).

EFFECTS OF ISCHEMIA ON BRAIN LIPID MONOLAYER SURFACE PRESSURE-AREA DIAGRAMS (SPAD). E.M. Nemoto*, M. Chavko, V.R. Hartwell. Department of Anesthesiology/CCM, Univ. of Pittsburgh, Pittsburgh, PA 15261

The rapid rise in brain free fatty acids during ischemia signals the breakdown of membrane lipids which could affect membrane biophysical characteristics and function. We evaluated the effect of ischemia on brain lipids and the impact on their surface-pressure area diagram (SPAD).

Wistar rats on 70% N_2O/30% O_2 were subjected to 0 or 30 min of complete global brain ischemia by neck cuff and arterial hypotension. The brains were frozen in situ and cerebrosides, sulfatides, phospholipids, cholesterol and sphingomyelin in the frontal cortex, hippocampus and basal ganglia were quantitated by HPTLC. SPAD were constructed using the Wilhelmy plate method on lipid monolayers at 25°C.

Thirty min ischemia without recirculation expanded the SPAD of brain lipids such that at a given area/molecule, SP was increased by 10 dynes/cm. SPAD of some lipids were more greatly affected than others. The magnitude of the changes in the SPAD indicate that membrane function should be markedly affected.

GENE STRUCTURE AND FUNCTION VII

CULTURED POSTMITOTIC NEURONS DO NOT UNDERGO VIRION-MEDIATED HOST CELL SHUTOFF OF PROTEIN SYNTHESIS AFTER INFECTION WITH HERPES SIMPLEX VIRUS-1; A UNIQUE RESPONSE IN NEURONS AND A PROMISING RESULT FOR HSV-1 VECTOR TECHNOLOGY. P. F. Nichol,* J. Y. Chang, L. S. Greenlund, P. Olivo, E. M. Johnson, Jr. Washington University School of Medicine, St. Louis, MO 63110

Herpes simplex virus (HSV)-derived vectors or recombinant HSV have been proposed and preliminarily characterized as vehicles for expression of foreign genes in neurons. A potential factor compromising the utility of such vehicles is the ability of HSV to produce virion-induced host-cell shutoff (VHS), a phenomenon mediated by a virion-associated protein (UL41). Upon infection, the UL41 gene product decreases protein synthesis (20-50% of controls) by disrupting translation, degrading cellular transcripts, and potentially preventing further cellular transcription. If such a shutdown were to occur in neurons, a significant alteration of the cellular physiology would be produced that might affect the ability of a neuron to express and respond to foreign genes. VHS has not been examined in neurons. We demonstrate that shutdown of global protein synthesis does not occur after infection of cultured rat sympathetic neurons with HSV-1 strains KOS and, the replication incompetent mutant, KOS d120. Also, no difference is seen in the rate of protein synthesis in neurons infected with d120 or KOS-derived *vhs*-ΔSma, a deletion mutant that lacks the UL41 gene. Undifferentiated or NGF-differentiated PC-12 cells and Vero cells experienced VHS upon infection with KOS-derived d120 (a decrease in protein synthesis to 40% of controls at an MOI of 20). The results suggest that neurons are resistant to VHS as mediated by the UL41 gene product. This apparent lack of VHS may be important in the ability of HSV to become latent in these neurons. The results indicate that VHS should not be a complicating factor in these, and perhaps all, postmitotic neurons. (Supported by the American Paralysis Association and by the Monsanto Corporation.)

TRANSCRIPTIONAL ELEMENTS OF THE HUMAN GENE FOR GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP). F. Besnard, K. Masood, Y. Su and M. Brenner*. Lab. of Molec. Biol., NINDS-NIH, Bethesda, MD 20892

To gain insights into how astrocyte functions are regulated, we are studying transcriptional control of the human gene for glial fibrillary acidic protein (GFAP), an intermediate filament protein found almost exclusively in astroctyes. We previously found that the 5'-flanking region of the gene contains three segments, A, B and D, that contribute to its cell-type specific expression in cultured cells; and that the most potent of these is the 124 bp B region, which resides about 1500 bp upstream of the RNA start site [J. Biol. Chem. 266, 18877-18883 (1991)]. We now report that site-directed mutagenesis of the B segment reveals it to contain several active subregions. One of these is a novel 12 bp sequence found also in the other two important regulatory segments, A and D. Another critical sequence matches precisely the consensus AP-1 binding site for the Fos and Jun families of transcription factors. Gel mobility shift assays indicate that both Fos and Jun family members are present in a GFAP-expressing astrocytoma cell line. Demonstration of a functional AP-1 binding site in the GFAP gene provides a focus for future studies of astrocyte regulation during development and reactive gliosis.

561.3

ALTERNATIVE EXONS AND PROMOTER ELEMENT OF THE $GABA_A$ RECEPTOR β3 SUBUNIT GENE.
E.F. Kirkness*, G.A. Hastings and C.M. Fraser. Section on Mol. Neurobiol., LN, NIAAA, Rockville, MD 20852.

The $GABA_A$ receptor β3 subunit is a relatively abundant component of several $GABA_A$ receptor subtypes. The gene encoding the human β3 subunit maps to a region of chromosome 15 that is associated with two imprinted, genetic disorders (Prader-Willi and Angelman syndromes). In order to examine how expression of this gene is regulated, the 5' regions of rat and human β3 subunit genes have been cloned and characterized.

RNase protection and RACE analyses indicate that transcription of the β3 gene starts from multiple sites, 100-200 bp upstream of the putative initiation ATG within exon 1. The RACE analysis of human brain RNA also uncovered the expression of an alternative exon 1 (exon 1a) that is located upstream of exon 1 on the human β3 gene. Exons 1 and 1a appear to encode distinct signal peptides of identical length. Cell lines were identified in which the β3 transcript is present (eg PC12, GT1-7) or absent (HeLa). These cell lines were transfected with CAT-constructs in order to identify regulatory elements within the 5' region of the human β3 gene. A strong promoter activity was detected within a 140 bp region, between exons 1a and 1. Incubation of this minimal promoter with nuclear extracts in a DNase 1-footprinting assay revealed a single protected element of 23 bp. Mobility-shift DNA binding assays indicate that this element binds both Sp1 and at least one additional factor. The activities and specificities of these binding factors have been assessed using transfected CAT-constructs, and by binding studies *in vitro*.

CHARACTERIZATION OF ISO- AND DIVERSITY-FORMS OF NCAM IN PRIMARY AND TRANSFECTED CELLS
D. Barthels*, U. Hartmann[1], A. Christoph[1], G. Vopper[1], M. Ramos Gomez[2], G. Ramirez[2], and W. Wille*. [1]Institut für Genetik, Universität zu Köln, FRG & [2]Centro de Biologia Molecular, Universidad Autonoma, Madrid, Spain

Alternative RNA splicing of primary transcripts coding for cell adhesion molecules is the main source for immense molecular diversity. A well analyzed example is the neural cell adhesion molecule (NCAM). This Ig-family gene codes for 192 NCAM amino acid sequences (Barthels *et al.* (1992) Eur. J. Neurosci. 4: 327-337). In addition to postranslational modifications, alternative splicing significantly contributes to the diverse population of NCAMs. it is of subtantial interest whether the differences of defined protein domains are important for the function of different NCAMs.

Transfection of NCAM-cDNA sequences into mammalian cells provide a usefull tool to investigate interactions of specific NCAM forms with primary neurons. For this analysis one needs a sensitive detection system for the influence of different NCAM iso- and diversity-forms on neuronal adhesion and fiber outgrowth. One of the *in vitro* systems discussed is the modified 'stripe assay' (after F. Bonhoeffer), in which axons of primary retinal explants are forced into numerous decisions between alternative substrates. In addition, specific antisera and monoclonal ABs against diversity epitopes have been developed in order to identify specific gene products and to interfere with defined functions. The second strategy of investigating the biological relevance of NCAM diversity forms is the analysis of their regulation in defined parts of the CNS. We choose the embryonic chicken retina for this study because of the limited number of neuronal cell types and the well defined developmental pattern.

DIFFERENT STRUCTURAL REQUIREMENTS FOR MAO A AND B CATALYTIC ACTIVITY. H.F. Wu*, K. Chen, and J.C. Shih , Dept. of Mol. Pharm. and Tox., Sch. of Pharmacy, Univ. of Southern California. Los Angeles, CA 90033.

There are seven conserved cysteines in the deduced amino acid sequences of human liver MAO A and MAO B. Site-directed mutagenesis of these cysteines to serines showed that the MAO catalytic activity was totally lost when FAD-linked cysteine was mutated (Cys 406 and Cys 397 for A & B respectively). Mutant Cys-156 and Cys-356 of MAO B also lost their activities, but the corresponding MAO A mutant Cys-165 remained active.

Chimeric MAO A/B enzyme were also constructed. When the N-terminal 30 amino acids were exchanged between A and B, the catalytic properties remained the same, suggesting that the N-terminus may not be important for enzyme specificities. When the C-terminal 125 amino acids were exchanged, MAO A with MAO B C-terminus has normal MAO A activity, suggesting the C-terminal of MAO A has no effect on the A activity. However MAO B with MAO A C-terminus has no activity for either A or B. This result suggested the C-terminus of MAO B is critical for MAO B activity. Taken together, these results suggest that the tertiary structure for MAO A and B may be different and the requirement for MAO B activity is more stringent. (Supported by NIMH grants R37 MH39085 (Merit Award), K05 MH00796 (Research Scientist Award), R01 MH37020 and Welin professorship).

DOPAMINE TRANSPORTER MUTANTS SUPPORT DIFFERENTIAL FUNCTIONS FOR TRANSMEMBRANE SEGMENTS 8-12. **J.B. Wang, D. Donovan*, and G. Uhl.** *Lab. Mol. Neurobiol., ARC/NIDA & Depts. Neurol.& Nsci., JHUSM, Box 5180, Baltimore, MD. 21224.*

The dopamine transporter's (DAT) 12 hydrophobic putative transmembrane domains contain polar amino acid residues that are candidates for involvement in recognizing cocaine analogs (eg. CFT), dopamine (DA) and the dopamine neurotoxin MPP^+ (see abstract by Kitayama et al). DAT cDNAs mutated by changing polar amino acids in domains 8-12 to alanine were examined in COS cells for their abilities to mediate DA and MPP^+ uptakes and CFT binding. Mutants in domains 9 and 12 ablate each function. Mutants in domains 8 and 10 and more selective mutations in domain 12 reduce DA and MPP^+ uptakes and CFT binding by 50-80%. Mutations in domain 11 increase DA and MPP^+ uptakes without changing CFT binding.

Differential effects of changes in different domains are consistent with differential contributions of each to DAT function in dopamine transport and cocaine recognition.

561.7

DOPAMINE TRANSPORTER RESIDUES IMPORTANT FOR SUBSTRATE TRANSPORT AND LIGAND RECOGNITION. S. Kitayama*, S. Shimada, D. Donovan & G. Uhl. *Lab. Mol. Neurobiol. ARC/NIDA & Depts. Neurol. & Nsci, JHUSM, Box 5180, Baltimore, MD. 21224.*

Polar amino acids lying within putative transmembrane (TM) regions 1, 7 and 8 of the dopamine transporter (DAT) are analogous to those important for ligand recognition by catecholamine receptors. Their possible functional significance was examined by testing binding and function in COS cells expressing mutant DAT cDNAs. Substitution of aspartate at position 79 in TM 1 with alanine, glycine or glutamate dramatically reduced uptake of [^{3}H] dopamine and [^{3}H] MPP^+ and the mutants' affinity for the cocaine analog [^{3}H] CFT without affecting B_{max}. Replacing serines at positions 356 and 359 in the outer portion of TM 7 by alanine or glycine reduced dopamine and MPP^+ uptake, while [^{3}H] CFT binding was less affected. Mutations in serine residues predicted to lie in the inner half of TM 7, 350 and 353, yield enhanced dopamine and MPP^+ uptake, with little change in [^{3}H] CFT binding B_{max}. Substitution of two serines in TM 8 results in wild-type values for dopamine and MPP^+ uptake and [^{3}H] CFT binding.

The TM1 aspartate residue is thus crucial for cocaine binding and dopamine uptake, while serine residues in TM 7 appear to play larger roles in substrate transport. These data define molecular features differentially important for cocaine binding and for dopamine uptake.

METHYLATION OF CpG SEQUENCES IN THE GLIAL FIBRILLARY ACIDIC PROTEIN GENE PROMOTER IN RAT ASTROCYTES. B.D. TETER*, H.H. OSTERBERG, C.E. FINCH, Neurogerontology Division, University of Southern California, Los Angeles, CA 90089-0191.

The astrocyte-specific gene encoding glial fibrillary acidic protein (GFAP), an intermediate neurofilament, increases in expression in the brain with age, as well as with hormone manipulations and deafferenting lesions. Analysis of sequence data (Miura *et al.*,1990,*J. Neuroch.*,55:1180) shows that the mouse GFAP gene promoter contains an island of eight CpG sequences (CpG dinucleotides are rare in eukaryotic genomes). Limited sequencing of the rat GFAP promoter shows additional CpG sites; the absence of these sites in the mouse promoter is consistent with their loss by mutation of methyl-cytosine to thymine. CpG sequences are sites of cytosine methylation which is correlated with promoter activity (in general,↑ CpG methylation = ↓ promoter activity). CpG methylation shows a generalized decrease in rat brain with age (Das and Das,1989,*Biochem. Arch.*,5:359), which suggests the hypothesis that demethylation of the GFAP promoter CpG island will correlate with the age-related increase in GFAP expression. We are investigating the pattern of CpG methylation in the GFAP promoter in GFAP-expressing tissues (hippocampus) and non-expressing tissues (liver) using ligation-mediated polymerase chain reaction (LMPCR). We are characterizing the pattern of CpG methylation in C6 glioma cells and any changes with corticosterone treatment (see abstract by C.J. Huang, *et al.*). Results will evaluate whether the pattern of GFAP promoter CpG methylation is corrlated with constitutive and induced GFAP expression and whether a change in the methylation pattern with age is dependent on GFAP expression. Extracellular ATP stimulates DNA synthesis in PC12 cells via P_2-purinergic receptor.

A. Takashima*, K. Noguchi, Y. Kudo, K. Inoue, Mitsubishi Kasasei Institute of Life Science, and National Institute of Hygenic Science, Tokyo, Japan.

ATP (0.1 mM) and [*methyl*-^{3}H]-thymidine(20 Ci/mmol) were added to the culture medium, and the incorporated ^{3}H-thymidine into DNA of PC12 cells were measured as an acid insoluble precipitation. We investigated the stimulant-evoked DNA synthesis. Only ATP showed the stimulation of the DNA synthesis in PC12 cells. Even if the ATP was washed out from medium after the stimulation of cells for 10 min, the DNA synthesis could be observed at after 2 hr incubation. The DNA synthesis of PC12 cells was stimulated by ATP, or ADP, but not by AMP, or adenosine. Moreover, suramine, a specific antagonist of P2 purinergic receptor, inhibited ATP-evoked DNA synthesis. These results suggested ATP-evoked DNA synthesis was stimulated through P_2 purinergic receptor. This DNA synthesis was insensitive to aphidicholine treatment(0.1 ng/ml), a DNA replication inhibitor, and the growth rate of ATP treated PC12 cells decreased to a half of control cells. Thus, the ATP was not recognized as a mitogenic stimulant for PC12 cells. The ATP-evoked DNA synthesis was insensitive to cycloheximide treatment, a protein synthesizes inhibitor, but was completely inhibited by actinomycine D treatment(0.1 ug/ml), which is an RNA synthesize inhibitor. These results suggested that the ATP-evoked DNA synthesis occurred through RNA dependent manner. This type of DNA synthesis was observed in the differentiated PC12 cells and in the primary culture of rat hippocampus.

***In Vitro* Pre-mRNA Splicing of the Amyloid Precursor Protein Gene** L.C. Kalef and G.A. Higgins. Molecular Neurobiology Section, NIA/NIH, Baltimore, MD 21224.

Alzheimer's disease (AD) and Down's syndrome (DS) are characterized by the extracellular deposition of amyloid in the form of senile plaques and cerebrovascular amyloid. The major component of these neuropathological markers is a 4 kDa protein called the ß/A4 protein, which is derived from a larger 110 to 135 kD precursor protein. The amyloid protein precursor (APP) gene consists of at least 18 exons, which undergo alternative RNA splicing to produce at least six different precursor protein products. APP-695 is the primary form found in the brain and lacks two exons (E) (E7 and E8), which are present in the predominant forms (APP-751 and APP-770) of APP found in most other tissues. Changes in the differential expression of the APP gene, through alternative splicing, may play a role in the deposition of the ß/A4 peptide found in the senile plaques and cerebrovasculature of AD and DS brains. We have developed a model to identify and characterize the splicing mechanism of the APP gene *in vitro*, using multiple minigene constructs of E6 through E9 (E6/7, E6/9, E7/8, E7/9, E8/9, E6/7/9, and E6/7/8/9). The hierarchy of splicing reaction intermediates and products of minigene constructs for E6/7, E6/9, and E8/9 have been directly analyzed in a HeLa cell *in vitro* splicing system. Branchpoints are being identified using primer extension analysis of lariat intermediates of the *in vitro* splicing reactions. A subcloned fragment of a full-length cDNA for APP-770 has been used in RNA protection analysis to quantify the relative levels of the wild-type APP transcripts normally produced by HeLa cells. Future studies involve development of a cellular model to study splicing of our mininigene constructs, and mutagenisis is being used to identify critical cis-acting elements required for correct splice site selection.

561.11

ALTERNATIVE SPLICING OF A HUMAN AMYLOID PRECUSOR PROTEIN MINI-GENE CONSTRUCT IN MOUSE N2A NEUROBLASTOMA CELLS. D. Willoughby*, S. A. Johnson, and C. E. Finch. Andrus Gerontology Center and Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089

In Alzheimer's disease, the amyloid precursor protein (APP) is cleaved abnormally to produce a 42-43 amino acid ß-amyloid peptide that accumulates extracellularly as a major component of senile plaques. Alternatively spliced APP-mRNAs encode 695, 751 and 770 amino acid polypeptides. This alteration in coding potential of APP-mRNAs is conferred by the variable inclusion of exon 7 and exon 8 of the APP gene. Exon 7 encodes a 57 amino acid Kunitz protease inhibitor domain, while exon 8 encodes a 19 amino acid motif with similarity to OX2, a neuron and thymocyte cell surface marker. Alterations in the relative abundance of alternatively spliced APP mRNAs were observed in neurons undergoing differentiation and as an in vivo neuronal response to neurotoxic lesions. We constructed a plasmid ($pRSV^{6-9}$), which contains in series the exons 6/7/8/9 of the human APP gene. Each exon is flanked by 0.1Kb to 1Kb of intron sequence except exon 6, which is fused at the 5' end to the Rous sarcoma virus LTR. Similarly exon 9 is fused directly to SV40 3' sequences.

$pRSV^{6-9}$ was transfected into N2A neuroblastoma cells. RNA transcripts derived from the transfected construct were assayed by reverse transcription-PCR. Processed mRNA containing exons 6/7/8/9, exons 6/7/9 and exons 6/9 were detected. A related plasmid $pRSV^{6-9\Delta 8}$, which lacks exon 8, gave rise to splice variants both containing and lacking exon 7. Alternatively spliced mRNAs derived from $pRSV^{6-9}$ were also detected in transfected rat C6 glioma cells. $pRSV^{6-9}$ in transfected neuroblastoma cells can be used to explore the mechaism(s) of APP RNA differential splicing during neuronal differentiation and in response to neuronal trauma. DW was supported by TG-AG00037-13; this work was supported by AG7909 to C. E. F.

SYNTHESIS OF cRNA PROBES FROM PCR-GENERATED MINIGENES. J. Logel*, D. Dill, C. Drebing, S. Leonard. Denver Veterans Administration Medical Center, Denver, CO 80220.

Many molecular biological techniques such as northern, RNase protection and *in situ* hybridization analyses are dependent on the use of radioactive probes. High specific activity cRNA probes offer greater sensitivity and more stable duplexes, but they require the availability of cloned cDNAs in vectors containing T7, T3 and SP6 RNA promoter sequences.

We report a method for *in vitro* transcription of cRNA probes using PCR generated DNA fragments or minigenes. Sense oligonucleotide primers, specific for mouse acidic fibroblast growth factor (aFGF), were synthesized with 5'-extensions containing sequences for the T7, T3 and SP6 polymerase promoters. A common antisense primer was used with each of the promoter/aFGF primers to prepare PCR-generated DNA fragments (minigenes). *In vitro* transcription efficiency for each of these constructs was evaluated by incorporation of radioactivity into the cRNA products. We find that both the T7 and T3 promoters can direct the synthesis of cRNA probes of high specific activity from a PCR-generated DNA fragment, but the SP6 promoter can not.

Antisense cRNA probes, transcribed from minigene constructs for aFGF were used for northern blot hybridization. *In vitro* transcription of minigene constructs for β-nerve growth factor (β-NGF) were used to synthesize antisense and sense cRNA probes for *in situ* hybridization of human hippocampal tissue sections.

GENE STRUCTURE AND FUNCTION VIII

562.1

REGULATION OF THE MAJOR NEURONAL GROWTH ASSOCIATED α-TUBULIN GENE, Tα1, BY NGF. J.G. Toma, Y. Ma*, and F.D. Miller, Dept. of Anat. & Cell Biol., University of Alberta, Edmonton, Canada T6G 2H7.

We have previously demonstrated that two members of the α-tubulin multigene family that encode virtually identical proteins are differentially regulated in mammalian neurons; expression of Tα1 mRNA is specifically correlated with process outgrowth, whereas expression of T26 mRNA is constitutive. Furthermore, expression of Tα1 mRNA is upregulated by NGF both *in vivo*, and in cultured sympathetic neurons, whereas T26 mRNA levels are not altered. In order to address the regulatory elements responsible for inducing Tα1 mRNA in response to NGF, we have isolated the promoter region from a rat genomic library. The 5' promoter region thus isolated has been fused to lacZ and CAT reporter genes. We have used PC12 cells to start to map the elements responsible for NGF-inducibility. The results obtained so far indicate that, in PC12 cells, endogenous Tα1 mRNA levels were increased within 2-6 hours following NGF addition, while levels of T26 mRNA were not altered. The observed increases in Tα1 mRNA occurred at the transcriptional level, as determined using nuclear run-offs. Transient transfection experiments indicate that 1.1 kb of the Tα1 promoter is sufficient to confer NGF-inducibility in PC12 cells. To determine whether this promoter fragment confers NGF-inducibility *in vivo*, we have introduced a similar construct into transgenic mice. Analysis of these mice is currently underway.

562.2

REVERSIBLE INTERRUPTION OF FAST AXONAL TRANSPORT IN VIVO LEADS TO ALTERATIONS IN GENE EXPRESSION IN BOTH NEURONS AND SCHWANN CELLS. W. Wu, T.C. Mathew, J.G. Toma, and F.D. Miller*, Dept. Anat. & Cell Biol., University of Alberta, Edmonton, Canada T6G 2H7.

Following nerve injury, axotomized neurons respond by inducing a number of genes associated with neuronal growth, and Schwann cells distal to the site of injury down-regulate genes associated with myelination. We hypothesized that at least some of these alterations were due to the loss of ongoing homeostatic signals that were transduced as a function of fast axonal transport. To directly address this hypothesis, we selectively blocked fast axonal transport in vivo by locally-cooling nerves to 3-8° C (a cold block). Immunocytochemistry for the antigens OX-42 or ED1 demonstrated that macrophages do not accumulate at the site of a cold block. Furthermore, neurons rapidly regained the ability to retrogradely transport tracers upon removal of the cold block. Thus, any effects of the cold block were not likely due to nerve injury. To determine whether blocking fast axonal transport was sufficient to induce a neuronal "axotomy" response, we examined expression of Tα1 α-tubulin and p75 NGF receptor mRNAs in facial motoneurons. In situ hybridization and image analysis revealed that both of these mRNAs were induced to a similar degree 36-60 hours following either a cold block or nerve transection. To determine whether blocking fast axonal transport also affected any nonneuronal cells distal to the cold block, we examined expression of Po and p75 NGF receptor, both of which are regulated as a function of Schwann cell:axon contact. Levels of p75 NGF receptor mRNA and protein were unaffected by the cold block. In contrast, levels of Po mRNA were decreased in the distal nerve in a fashion similar to that observed following axotomy. These data therefore suggest a) that neurons normally monitor the status of their axons and connections as a function of fast axonal transport, and b) that alterations in expression of Po and p75 NGF receptors result from two different aspects of Schwann cell:axon communication, one of which involves fast axonal transport.

562.3

THE Tα1 α-TUBULIN PROMOTER DIRECTS GENE EXPRESSION TO DEVELOPING NEURONS IN TRANSGENIC MICE. F.D. Miller, A. Speelman, and J.G. Toma*, Dept. Anat. & Cell Biol., University of Alberta, Edmonton, Canada T6G 2H7.

The Tα1 α-tubulin gene is one member of the α-tubulin multigene family that is regulated as a function of neuronal growth in both developing and mature mammalian neurons. During development, Tα1 mRNA is abundantly expressed in newly-differentiated neurons during the period of morphological growth, and is subsequently downregulated as a functional of target contact and neuronal maturation. We have isolated the Tα1 gene, and have fused 1100 nucleotides of the upstream putative promoter region to a nuclear β-galactosidase reporter gene. Transient transfection assays demonstrated that this upstream fragment was sufficient for basal expression of the marker gene in cultured PC12 cells. To determine whether this fragment was sufficient to direct appropriate expression *in vivo*, transgenic mice were generated. At embryonic days 14 and 16, a developmental period when expression of the endogenous gene is maximal, the transgene is expressed throughout the developing peripheral nervous system. The transgene is also expressed at high levels in some regions of the developing central nervous system, but is not globally expressed. By postnatal day 1 expression of the transgene is undetectable in the brain and in peripheral ganglia. At all timepoints the transgene appears to be specific to the nervous system. Thus, 1100 nucleotides of the Tα1 promoter is sufficient to developmentally regulated gene expression to at least some populations of central and peripheral neurons.

562.4

AMPHETAMINE INDUCED ROTATIONAL BEHAVIOR IN NON-LESIONED RATS: A ROLE FOR *C-FOS* EXPRESSION IN THE STRIATUM. B.J. Chiasson*, M.L. Hooper and H.A. Robertson. Dept. of Pharmacology, Dalhousie University, Halifax, N.S. Canada B3H 4H7.

Ungerstedt (1971a) reported that rats having had a unilateral lesion to the nigrostriatal pathway responded to a D-amphetamine (A) challenge by rotating toward the damaged side. More recently, it has been demonstrated that A can influence the expression of immediate-early genes (IEGs), such as *c-fos*, in normal animals (Graybiel, Moratalla & Robertson, 1990). Here we ask whether the expression of *c-fos* might be important in modulating the functional output of the striatal system in normal non-lesioned animals following an A challenge. To test this possibility we used oligodeoxynucleotide (ODN) technology to selectively inhibit mRNA translation of *c-fos*. Under stereotaxic guidance sense (S) and antisense (AS) ODN's were infused unilaterally into the striatum of normal rats. At varying times post-infusion, 10 and 22 h, animals were given 5mg/Kg A (i.p.) and their rotational behavior was monitored for two hours. Subsequently, animals were sacrificed and immunocytochemistry for Fos-like protein was performed on striatal sections.

Striatum infused with AS ODN at 10h prior to the injection of A showed a marked reduction in the number of Fos positive neurons when compared to the S infused side. These animals rotated 400-500 times in the direction of the AS over a 2h period. The animals that received AS infusions 22h prior to A demonstrated little or no difference in the number of Fos positive neurons in the striatum compared to the S infused side. Unlike the previous group these animals rotated only 30-50 times in the same 2 h period and showed no directional preference in their rotational behavior. Thus, it appears that striatal *c-fos* expression may regulate the sensitivity of the striatum to indirect acting dopamine agonists. Supported by MRC (Canada) & The Savoy Foundation.

DIFFERENTIAL *C-FOS* ACTIVATION BY PATTERNED STIMULATION H.Z.Sheng*, R.D.Fields, and P.G.Nelson. Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892

The pattern of electrical activation is important for such examples of neuronal plasticity as LTP or regulation of muscle contraction properties. To test whether immediate early gene expression is sensitive to the pattern of electrical stimulation, dissociated neurons of mouse dorsal root ganglion (DRG) were stimulated with electrical pulses organized in various patterns. The expression of c-*fos* mRNA by DRG neurons was monitored in a semi-quantitative PCR assay with optical density reading of ethidium bromide stained gel. A constant number of stimuli (180) were delivered in 3 different patterns for 30 min: 1) steady 0.1 Hz; 2) bursts of 6 stimuli at 10 Hz delivered every minute; 3) 12 stimuli at 10 Hz delivered every 2 minutes. The steady 0.1 Hz produced a small increase in c-*fos* expression over control, unstimulated values (69%, $p<0.02$; 22±5.8 vs. 13±2.8, mean O.D.±SD), while bursts of 6 pulses at 10 Hz produced a significantly larger increase (168%, $p<0.001$; 34.8±3.8). By contrast, the relatively infrequent 12 pulse bursts at 10 Hz produced no significant increase in c-*fos* expression (14.8±1.9). These results show that different patterns of stimulation can differentially regulate transcriptional events in neurons. Hence our data suggest that the cascade leading to c-*fos* activation could represent a mechanism by which the information in patterned electrical activity is decoded.

562.6

SPATIAL AND TEMPORAL DIFFERENCES IN THE DISTRIBUTION OF mRNA ENCODING HEAT SHOCK PROTEIN 70 IN THE RABBIT BRAIN IN RESPONSE TO HYPERTHERMIA. P. Manzerra and I.R. Brown* Dept of Zoology, Univ of Toronto, Scarborough Campus, West Hill, Ontario M1C 1A4, Canada.

Our previous studies have shown that hyperthermia induces the expression of a heat shock gene (hsp70) in the rabbit brain with striking regional differences (for review see J. Neurosci Res., 27, 247-255, 1990). In situ hybridization studies using riboprobes which can distinguish between constitutive and inducible members of the hsp70 gene family revealed the prominent induction of a 2.7 kb hyperthermia-inducible mRNA species at 1 hr in glial-enriched areas of the rabbit brain with little induction in neuronal enriched areas such as the hippocampus. Further studies have revealed that hsp70 gene expression is not only regulated in a spatial manner but temporal differences in expression are also observed. Several neuronal populations including hippocampal and cortical neurons show delayed induction of the hyperthermia-inducible hsp70 mRNA species at 5 hrs post-heat shock with decreases by 10 and 24 hrs. This temporal study has also been extended to the protein level using Western blot and immunocytochemical procedures. Hsps may play important roles in cellular repair and/or protective mechanisms in the nervous system. Supported by grants from MRC Canada.

562.7

EXPRESSION OF INSULIN-LIKE GROWTH FACTOR BINDING PROTEINS IN HUMAN RETINAL PIGMENT EPITHELIAL CELLS. A. Randolph*, D. Yee[1] and E. Feldman. Univ. of Michigan Med. Center, Ann Arbor, MI 48109, [1]Univ. of Texas Health Sci. Center, San Antonio, TX 78284.

Human retinal pigment epithelial (HRPE) cells provide a good *in vitro* model for studying the action of insulin-like growth factor I (IGF I), a polypeptide with growth-promoting and insulin-like activity. HRPE cells express both IGF I and the type I and II IGF receptors. In HRPE cells, IGF I action is modulated by a series of high affinity binding proteins, designated IGFBPs. IGFBPs regulate the tissue compartmentalization of IGF I and its binding to the type I IGF receptor. Glucose, insulin and IGF I alter hepatic IGFBP secretion. In this study we examined the regulation of IGFBP gene and protein expression in HRPE cells by glucose, IGF I, and serum. HRPE cells were grown in MEM in the presence of either 5 to 300 mM glucose, IGF I, IGF I plus the IGF I receptor antibody (αIR_3) or serum. After collecting conditioned media, total RNA was isolated from each condition. Human cDNA clones were obtained from Dr. S. Shimasaki, La Jolla, CA (IGFBP 2,3,5) and from Dr. D. Powell, Houston, TX (IGFBP 1,4). RNA was analyzed by Northern blotting and RNase protection. The IGFBPs present in conditioned media were characterized by ligand blotting. Under all conditions, IGFBP 3 mRNA constituted the major transcript in HRPE cells. Ligand blotting demonstrated the presence of glycosylated IGFBP 3 forms at 42-49 kDa. There was no effect on basal IGFBP 3 gene expression by 1) physiologic concentrations of glucose; 2) IGF I; or 3) αIR_3, added to cells to block potential effects of constitutive IGF I production by HRPE cells. In contrast, IGFBP 3 gene expression was up-regulated, in a dose dependent fashion, by calf serum. These findings suggest that IGF I alone cannot regulate the production of its binding protein(s) and implicate a role for other trophic factors in the IGF I-IGFBP axis. Supported by NIH grant NS01381 (EF) and R29CA52592 (DY).

EZRIN AND OSTEONECTIN, TWO PROTEINS WHICH INFLUENCE CELL SHAPE AND GROWTH, ARE ENRICHED IN THE LOCUS COERULEUS. C. Bergson*, H. Zhao, K. Saijoh, R. S. Duman and E. J. Nestler. Dept. of Psychiatry and Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06508.

In a first attempt to better characterize the noradrenergic neurons of the locus coeruleus (LC) at the molecular level, we screened a bovine LC cDNA library with a bovine LC minus cerebellum subtracted cDNA probe. Two of the cDNA's isolated show enrichment in LC compared to other regions tested on bovine brain regional northern blots. DNA sequence analysis and GenBank database searches indicate that the more LC-specific clone probably encodes the bovine homolog of ezrin, a phosphoprotein found in cytoskeleton of microvilli, and that the more ubiquitous clone encodes osteonectin, an extracellular Ca2+-binding glycoprotein. *In situ* hybridization studies in sections of rat brains at the level of the LC show that the mRNA's for these two genes are concentrated in LC noradrenergic neurons, but are also present in certain other cell bodies, including motor neurons of the trigeminal nerve. Ezrin-and osteonectin-like immunoreactivity are also enriched in LC noradrenergic neurons. It will be interesting to determine the functions subserved by ezrin and osteonectin in LC neurons.

562.9

INCREASED EXPRESSION OF RAT ADRENAL TYROSINE HYDROXYLASE GENE BY IMMOBILIZATION STRESS. E.L. Sabban*[1], R. Kvetnansky[2], A. McMahon[1], W.G. Frankle[1], B.B. Nankova[1], K.Fukuhara[2], E. Viskupic[2] and I.J. Kopin[2]. [1]Dept. Biochem. & Mol. Biol., New York Med. Coll. Valhalla, NY 10595 and [2]NINDS, Nat. Inst. of Health, Bethesda, MD 20892.

Repeated immobilization (IMO) stress has been shown to elevate circulating catecholamines and the activity, as well as mRNA levels, of their biosynthetic enzymes, especially tyrosine hydroxylase (TH). A single 2 hr IMO of Sprague Dawley rats greatly elevated adrenal TH mRNA levels, with maximal induction up to 12 hours after the IMO. Wistar-Kyoto, Lewis and Fisher rats also increased adrenal TH mRNA levels of 4-10-fold after a single 2 hr IMO. After a 30 min IMO, TH mRNA was not elevated immediately, however 90 min later TH mRNA was increased as much as with continuous 2 hr IMO.

The splanchnic nerve is known to be crucial for the biochemical responses of the adrenal to prolonged IMO. The neuronal output to the adrenal is cholinergic, although other neurotransmitters, such as VIP are co-released. We therefore, examined the effect of a nicotinic cholinergic antagonist, chlorisondamine and of a VIP antagonist. Chlorisondamine (10 mg/kg), prevented the IMO-induced rise in plasma norepinephrine and reduced plasma epinephrine. Surprisingly, chlorisondamine had little effect on the rise in adrenal TH mRNA levels, while the VIP antagonist partially inhibited the rise in the TH mRNA levels following a single IMO.

Actinomycin D prevented the rise in TH mRNA by 2 hr IMO, suggesting transcriptional activation. The IMO induced transcription factor interaction with upstream elements of the rat TH gene is being studied by gel shift assays using adrenal nuclear extracts from IMO rats.

SULFATED GLYCOPROTEIN-2 (SGP-2, CLUSTERIN) AND THE CENTRAL NERVOUS SYSTEM (CNS): DETECTION OF SGP-2 mRNA IN THE NEVROGLIA AND DISCRETE POPULATIONS OF NEURONS. J.-G. Chabot*, M. Danik, D. Hassan-Gonzalez and R. Quirion. Douglas Hospital Research Centre, Department of Psychiatry, McGill University, Verdun and Maisonneuve-Rosemont Hospital Research Centre, Department of Medicine, Montreal University, Montreal, Quebec, Canada.

We recently reported on the expression of SGP-2 mRNA in human gliomas, epileptic foci and rat brain tissues (Danik *et al.*, PNAS 88, 8577-81, 1991). We now extended these findings and report an extensive analysis of the cellular distribution of SGP-2/clusterin transcripts in the adult rat CNS. The overall pattern was one of widespread expression with several regions showing strong hybridization signals. Resolution at the cellular level revealed the differential labeling of distinct cell types. Among the non neuronal elements expressing SGP-2 mRNA, ependymal cells forming the walls of brain ventricles were strongly labeled. Although glial cells showed a diffuse labeling throughout the neuropil, scattered highly labeled cells were observed in the optic nerve, the corpus callosum and the hippocampal fissure. Specific mRNA labeling was also seen in neurons of the habenular complex, substantia nigra, cerebellum, several hypothalamic and brainstem nuclei, and the gray matter of the spinal cord. Strong labeling was especially concentrated in the motoneurons of the brainstem and the ventral horn of the spinal cord. It is thus clear that SGP-2 gene expression is not restricted to glial cells but is seen in specific populations of neurons. This suggests that SGP-2 (also known as clusterin) may be a multifunctional protein which may be implicated in events such as the packaging, processing and transport of neurotransmitters and neuropeptides, as well as in the lipid metabolism. Supported by MRC Canada.

REGIONAL DISTRIBUTION OF ALPHA 1 SUBUNIT ISOFORM OF (Na,K) - ATPase IN THE RAT SPINAL CORD. S. Sayers, R. Shahid, M. Dauzvardis, T. Khan*, L. Farber and G. Siegel. Rehab. R&D Center and Neurology Service, Hines VA Hospital, Hines, IL 60141 and Loyola University Medical School, Maywood, IL 60153

(Na,K)-ATPase is the membrane bound enzyme that produces active cation transport, and therefore is responsible for maintenance of the resting membrane potential. It is a heterogeneous oligomer of a catalytic (alpha subunit) and a glycoprotein (beta subunit). Three isoforms of the alpha subunit have been identified in the central nervous system. Both alpha 1 and alpha 3 mRNAs were found in neurons of the CNS but their proportions vary in different regions of the brain. Alpha 1 mRNA was found predominantly in cerebral cortex, dentate gyrus of the hippocampus, specific isolated brain stem nuclei such as the locus ceruleus and motor nuclei V and VII, and in discrete subsets of anterior horn cells in the lumbar spinal cord. In the present study, mRNA levels for the alpha 1 isoform of (Na,K)-ATPase were measured from five levels of the rat spinal cord.

The spinal cords of 5 anesthetized young adult rats were rapidly harvested and divided into five sections each; Section 1 (C1-C8), Section 2 (T1-T4), Section 3 (T5-T8), Section 4 (T9-T13), and Section 5 (L1-L5). Total RNA from each section was isolated using the method of Chomczynski and Sacchi, slot-blotted onto membranes, and hybridized with 32P-labeled riboprobe transcribed from the cDNA clone which codes for the alpha 1 isoform of (Na,K)-ATPase. The membranes were subjected to autoradiography, the autoradiographs were scanned, linear regression lines were plotted, and the slopes of the lines were compared.

The amount of total RNA/g of tissue varied in the five different spinal cord sections. After normalizing for the total µg of RNA, the alpha 1 mRNA levels were also found to vary. Assigning a value of 1 to the slope obtained from Section 1, Section 2 was 2.6 times higher, Section 3 was 4.5 times higher, Section 4 was 2.6 times higher, and Section 5 was 1.7 times higher. Our results show that alpha 1 mRNA levels are highest in the mid-thoracic level (T5-T8). *In situ* hybridization experiments are underway to further localize expression of alpha 1 mRNA in the rat spinal cord.

Supported by funds from Veterans Administration, Rehabilitation R&D Service.

INDUCTION OF CALBINDIN-D_{28k} mRNA IN MEDULLOBLASTOMA CELLS BY RETINOIC ACID AND IN HIPPOCAMPUS AFTER KAINIC ACID INDUCED SEIZURES IS PRECEDED BY THE INDUCTION OF ZIF/268 mRNA. Y. Wang, S. Lee, and S. Christakos*. Dept. of Biochemistry and Molecular Biology, UMDNJ-New Jersey Medical School, Newark, NJ 07103.

Previously, we reported that calbindin-D_{28k} can be induced by retinoic acid (RA) in B104 neuroblastoma cells (which do not contain calbindin endogenously) after transfection with a retinoic acid receptor α expression vector. We recently found that the human medulloblastoma cell line D283 contains calbindin endogenously and that calbindin protein and mRNA can be induced 8-10 fold in these cells by 10^{-8} M RA. These findings are the first evidence of the presence of calbindin, which can be regulated, in a neuronal cell line. Regulation by RA suggests a role for calbindin in neuronal differentiation. The time course of response indicated that the first significant increase in calbindin mRNA is at 3 hrs with a plateau of calbindin mRNA induction at 48 hours after RA treatment. Co-treatment of D283 cells with RA and either cycloheximide or actinomycin D completely blocked the increase in calbindin mRNA, suggesting that the induction of calbindin by RA requires both RNA and protein synthesis. Induction of calbindin mRNA by RA was preceded by the induction of the early response gene zif/268 (also known as EGR1 and NGFI-A) at 30 min. and 1 hr. after RA treatment. In addition, we have observed that the induction of rat hippocampal calbindin mRNA by kainic acid (12 mg/kg i.p.), which is maximal at 6 hours, is also preceded by the induction of zif/268 mRNA. These findings suggest that the early response gene zif/268 may be involved in calbindin-D_{28k} transcriptional regulation. (Supported by NIH NS-20270)

CORTICOSTERONE MODULATES THE EXPRESSION OF THE RAT GLIAL FIBRILLARY ACIDIC PROTEIN GENE AND ITS PROMOTER ACTIVITY IN THE C6 GLIOMA. C.J. Huang, N.J. Laping, Y. Su, D.G. Morgan*, C.E. Finch. Neurogerontology Division, Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089-0191.

The intermediate neurofilament, glial fibrillary acidic protein (GFAP), is an astrocyte marker that increases in the brain, following injury, deafferentation, adrenalectomy, or with aging. In this study, the hormone regulatory mechanisms of GFAP gene expression were investigated by linking the 2 kb of upstream region of rat GFAP gene to the chloramphenicol acetyl-transferase (CAT) gene in the promoterless pUC vector. The modified vector was transfected into an astrocyte tumor cell line (C6 glioma) via electroporation. Doses of corticosterone (CORT) and dibutyryl cyclic AMP (dbcAMP) were introduced to transfected and non-transfected C6 glioma. Endogenous GFAP mRNA changes were detected by Northern blotting. The GFAP promoter activity was monitored by CAT assay. CORT (1 uM) and dbcAMP (0.25 mM) alone or in combination increased CAT activity (2-3 fold) in the transfected C6 glioma and increased GFAP mRNA in the non-transfected C6 glioma. CORT in a range of 0.1 - 10 uM increased CAT activity and GFAP mRNA. However, 100 uM CORT depressed CAT activity and GFAP mRNA transcription from the endogenous gene. We note that CORT has the opposite effect on GFAP in vivo (O'Callaghan et al., Brain Res.494:159-161, 1989; Nichols et al., Mol. Brain Res.7:1-7,1990; Laping et al., Mol. Brain Res.10:291-297,1991). These results indicate that the transfected C6 glioma responded to the CORT treatment in a dose dependent manner, and the regulation of GFAP mRNA is mediated at the level of GFAP promoter activity.

TRANSCRIPTIONAL REGULATION OF GLIAL FIBRILLARY ACIDIC PROTEIN mRNA BY GLUCOCORTICOIDS. N.J. Laping*, C.J. Huang, S.A. Johnson, J.R. Day, and C.E. Finch. Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089-0191.

Glial fibrillary acidic protein (GFAP) and its mRNA is decreased by glucocorticoids in vivo (O'Callaghan et al., Brain Res.494:159-161, 1989; Nichols et al., Mol. Brain Res.7:1-7, 1990; Laping et al., Mol. Brain Res.10:291-297, 1991). This study examined if this regulation occurs at the transcriptional level. Adult male F344 rats received systemic injections of 1 mg glucocorticoids (GC) and were sacrificed 8 hours later. Nuclei were isolated from cortex or pooled hippocampus. Nascent transcript levels for GFAP mRNA were determined by nuclear run-on assay. GC elevated GFAP transcription rate 3-4 fold in the hippocampus over oil injected controls. In the cortex, GC also elevated GFAP transcription 4 fold ($p<0.05$, $n=4$).

GC also increases the GFAP promoter activity in vitro. GC (1 μM) increased chloramphenicol transferase (CAT) activity 2-3 fold in C6 glioma transfected transiently with a construct containing the rat GFAP promoter attached to the CAT reporter gene. These findings suggest that decreased GFAP mRNA levels in vivo seen after GC treatment are not due to decreased transcription initiation and are probably due to altered mRNA stability or translocation to the cytoplasm. However, decreased mRNA transcripts with intact polyadenylation sequences might also be due to RNA polymerase pausing within the gene, thus overriding the increased transcription initiation induced by GC. This hypothesis will be tested using specific probes for the 3' untranslated region of the GFAP mRNA.

IDENTIFICATION OF INSERTION MUTANTS OF VASOPRESSIN mRNA IN THE HOMOZYGOUS BRATTLEBORO RAT.

[1]A.P. Evans, [2]F.W. Van Leeuwen, R. Ivell, J.F. Axelson*, and [1]J.P.H. Burbach. [1]Rudolf Magnus Inst., Univ. of Utrecht, Utrecht, The Netherlands, and [2]Netherlands Inst. for Brain Research, Amsterdam, The Netherlands.

A single base deletion in the vasopressin (VP) gene is the cause of diabetes insipidus (di) in the homozygous (di/di) Brattleboro rat. The di/di rat expresses a mutant VP precursor with an altered C-terminus. A striking feature of the di/di rat is the appearance of apparently normal VP gene products together with the mutant precursor protein in solitary hypothalamic neurons, indicating a heterozygous (+/di) phenotype of these cells. In new-born animals only 0.1% of the VP neurons displays the +/di phenotype, but the number increases proportional to age to 3% in old animals.

The +/di phenotype of these VP neurons in the di/di rat suggests the existence of VP mRNAs which code for the normal VP precursor protein. The aim of the present study was to elucidate the nucleotide sequence of these VP mRNAs of the di/di rat. The strategy used included specific amplification of VP cDNAs by PCR, followed by cloning of VP cDNAs in an expression vector. Clones containing VP cDNAs with restored reading frame were selected by immunoscreening using a rat glycopeptide antiserum. Sequence data, obtained so far, indicate that different, single nucleotide insertions are present in the mutated VP mRNAs. These insertions occur in the same region as the original deletion, which suggests this region is sensitive to mutations.

ISOLATION OF A DROSOPHILA CUT-LIKE HOMEOPROTEIN WHICH BINDS THE MINIMAL TISSUE-SPECIFIC ELEMENT OF THE RAT TYROSINE HYDROXYLASE GENE. S.O. Yoon* and D.M.Chikaraishi. Dept. of Molecular Biol. and Microbiol., and Program in Neuroscience, Tufts Univ. Sch. of Med., Boston, MA 02111.

The minimal tissue-specific element of the rat tyrosine hydroxylase (TH) gene consists of the AP1 motif and an overlapping E-box containing dyad symmetry element (Yoon and Chikaraishi, Neuron, in press). In conjunction with the AP1 motif, the dyad element activates transcription in TH-positive PC cells, but suppresses it in TH-negative neuroblastomas cells. Therefore, the dyad element was used to probe a cDNA expression library from TH-positive Pc8b cells to clone factors involved in TH expression.

We isolated a partial 3.3 Kb clone, TAD, which binds the TH-dyad in a sequence-specific manner; it fails to bind another closely-related E-box motif (PAN). Surprisingly, TAD also binds the AP1 motif, but fails to bind the CRE which is only one base different from the AP1 site. By sequence analysis, TAD contains a homeodomain and two regions which are strikingly homologous to the "cut" repeat, a region repeated three times in the Dosophila cut gene involved in sensory neuron determination. Neufeld et al. (Nature Genetics 1: 50-55, 1992) have recently cloned a cDNA, CDP, from Hela cells which contains cut repeats and a homeodomain. This gene and TAD are almost identical except for several very divergent regions, which may represent alternative exons. Therefore, TAD along with CDP, may belong to a new family of transcription factors that contain homeodomains and cut repeats.

REGIONAL DISTRIBUTION OF ACETYLCHOLINE RECEPTOR ALPHA-SUBUNIT mRNA IN THE RAT SPINAL CORD. M. Dauzvardis*, S. Sayers, R. Shahid, C. Trausch, T. Khan. Rehabilitation R&D Center, Hines VA Hospital, Hines IL 60141

A cDNA clone for the alpha-subunit of the acetylcholine receptor (AChR) has been previously identified by J. Boulter (J. Neurosci. 5: 2553, 1985). Variations in the distribution of this specific mRNA have been studied in hindlimb muscles of the rat following transection of the sciatic nerve. The present study demonstrates the presence and distribution of AChR alpha-subunit mRNA in the different levels of the spinal cord

The spinal cords of five anesthetized young adult rats were rapidly harvested and divided into five sections each; Section 1 (C1-C8), Section 2 (T1-T4), Section 3 (T5-T8), Section 4 (T9-T13), and Section 5 (L1-L5). Total RNA was prepared using the method of Chomczynski and Sacchi. The total RNA was slot-blotted onto Gene Screen Plus membranes and the membranes were subsequently hybridized with 32P-labeled riboprobe transcribed from the cDNA clone which codes for the AChR alpha-subunit. The membranes were subjected to autoradiography, the autoradiographs were scanned, linear regression lines were plotted (µg total RNA vs. integration units obtained from scanning the autoradiographs), and then the slopes of the lines were compared.

The amount of total RNA/g of tissue varied in the five different spinal cord sections. After normalizing for the total µg of RNA, the AChR alpha-subunit mRNA levels were also found to vary. Assigning a value of 1 to the slope obtained from Section 1, Section 2 was 3.8 times higher, Section 3 was 9.8 times higher, Section 4 was 1.8 times higher, and Section 5 was 5.3 times higher (see diagram below). Our results show that AChR alpha-subunit mRNA levels are highest in the mid-thoracic level (T5-T8). *In situ* hybridization experiments are underway to further localize expression of AChR alpha-subunit mRNA in the rat spinal cord.

EFFECTS OF AF64A ON ChAT ACTIVITY AND N-*MYC* EXPRESSION IN THE LA-N-2 HUMAN NEUROBLASTOMA CELL LINE.

L.R.Santiago[1], M.T.Ivy[3], B.W. Futscher[4], L.C. Erickson[1,2], and I. Hanin[1]* Depts. of [1]Pharmacology and [2]Medicine (Section of Hematology/Oncology) Loyola Univ. Chicago Stritch Sch. Med., Maywood, IL 60153, [3]Dept. Life Sciences, Indiana State Univ., Terre Haute, IN 47809 and [4]Dept. of Hematology/Oncology, Arizona Cancer Center, Tucson, AZ 85724.

AF64A, which shares structural similarity to choline, may enter cholinergic cells via the high affinity uptake system (HAChT) to exert its cytotoxic effects. In order to further investigate the mechanism of action of AF64A in an *in vitro* model, we used the LA-N-2 cholinergic human neuroblastoma cell line to study the effects of AF64A on choline acetyltransferase (ChAT) activity and on the steady state expression of the N-*myc* gene. ChAT: Following 1 hr exposure to 25, 50 and 100 µM doses of AF64A, ChAT activity was significantly decreased by approximately 15, 25 and 30 % ($p < .05$), respectively. The addition of 1 mM choline or hemicholinium-3 (HC-3) inhibited the decrease of ChAT activity observed at 25, 50 and 100 µM doses of AF64A. The protective effects may be explained by competition (choline) and inhibition (HC-3) of the HAChT system by which AF64A enters cholinergic cells. N-*myc*: Using an S1 nuclease protection assay and doses of 50, 100 and 250 µM AF64A, we observed decreased steady state levels of N-*myc* mRNA at 3 and 6 hours after drug removal. At t=3 hr, N-*myc* mRNA levels were significantly reduced by 40 and 75% ($p < .05$) at doses of 100 and 250 µM, respectively. At the lower doses (50 and 100 µM), the levels of N-*myc* mRNA began to recover at t=6 hr to their initial steady state levels. We are currently examining the possibility that AF64A-induced changes in ChAT activity may be due to AF64A's effect on genes critical for the maintenance of a cholinergic phenotype.

REGULATION OF ETHANOL-RESPONSIVE GENES IN NEURAL CELLS. M.W. Sganga, N. Wilke, G. Gayer, W. Chin, S. Barhite, and M.F. Miles*. Ernest Gallo Research Center and Clinic, UCSF, San Francisco, CA 94110

We are currently exploring the hypothesis that changes in neuronal gene expression may underlie the phenomena of tolerance to and dependence on ethanol seen in chronic alcoholics. Our lab has identified a number of genes which are induced or repressed 50-300% in cultured neuroblastoma cells exposed to levels of ethanol seen in actively drinking alcoholics (25-100mM). Three ethanol-inducible genes, Hsc70, Grp78 and Grp94 have been identified and are known to have widespread effects on protein trafficking in mammalian cells. In an attempt to characterize the molecular mechanisms underlying ethanol-responsive gene expression, we have investigated the trans-acting and promoter elements required for coordinate induction of these genes by ethanol. Transient transfection analyses of NG108-15 cells have been used to identify ethanol-responsive cis-acting elements in the Hsc70, Grp78 and Grp94 promoters. Subsequent in vitro studies have confirmed the existence of a specific transcription factor which binds to these sequences. Finally, we have also performed dose-response and mixing studies comparing ethanol and other known inducers of Hsc70, Grp78 and Grp94. Our studies may add substantially to the understanding of central nervous system adaptation to ethanol as seen in alcoholism.

562.20

HIGH LEVELS OF EXPRESSION OF UNIQUE mRNAs ENCODING A NUCLEAR MATRIX PROTEIN IN SPECIFIC REGIONS IN THE BRAIN AND TESTIS. S. Vijayaraghavan, G. Nilaver[1], D.T. Stephens, S.R. Nagalla[2], and M.H. Melner * Div. Reprod. Sciences. and Div. of Neurosciences[2], Oregon Regional Primate Research Center, Beaverton, OR 97006, Dept. of Neurology[1], Oregon Health Sciences Univ., Portland, OR 97201.

The nuclear matrix protein network is thought to be involved in the control and regulation of DNA replication and gene expression. One of these proteins, matrin 3, was recently cloned from a rat insuloma cDNA library (Belgrader et al. 1991, JBC, 266:9893). Here we report the presence of unique forms of matrin 3 in bovine testis. We have isolated 15 cDNA clones from bovine testis that encode unique and distinct forms of this protein. Sequence analysis showed 90% homology at the amino acid level with matrin 3. However, a significant difference in the testis form was found in the region containing the putative nuclear location signal (KKKLKK). In the testis, this signal sequence is embedded in an unique 53 amino acid segment with no homology to matrin 3 suggesting alternative splicing or an alternate exon in the testis. The cDNA inserts of the 15 clones could be categorized into at least 5 distinct classes based on their unique 3' untranslated regions and at least 3 distinct classes based on restriction site analysis. Northern blot analysis detects high levels of expression of a ~4 kb message in the testis and brain. *In situ* hybridization localized high levels of expression of these mRNAs in testis interstitial cells and the brain hippocampus, suggesting specific differentiation or hormone dependent gene expression in these regions.

SYNAPTIC STRUCTURE AND FUNCTION I

563.1

COMPARISON OF DIVALENT CATION BINDING TO BRAIN AND ERYTHROCYTE SPECTRINS. J. A. Babitch*, C. J. Wallis and E. F. Wenegieme. Chemistry Dept., Texas Christian Univ., Fort Worth, TX 76129.

Previously we examined calcium binding to brain spectrin [J. Biol. Chem. 267 (1992) 4333]. Here we report differences in divalent cation binding between brain and erythrocyte spectrins which appear to relate to differences in spectrin function in these two tissues. Flow dialysis and equilibrium dialysis of erythrocyte spectrin revealed two binding components: high affinity, calcium-specific sites with $K_d = 4x10^{-7}$M and n = 100±20 per dimer and a low affinity (millimolar) divalent cation component. The entropy increase upon binding suggests that calcium stabilizes the native conformation of repeat structures. These data support the hypothesis that calcium binding to red blood cell spectrin has become specialized to stabilize the cytoskeletal network and the cell under the stressful conditions of blood circulation, whereas brain spectrin, having fewer high affinity sites, responds to fluctuating calcium levels by altering its interactions with other proteins. Supported by NIH (NS-26518).

563.2

NEURAL DEPENDENCE AND INDEPENDENCE OF THE EXPRESSION OF A NMJ-ASSOCIATED ANTIGEN. Stephanie H. Astrow*, Young Jin Son and Wesley J. Thompson, Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Our lab has generated a monoclonal antibody (mAb 3G2) that recognizes a subsarcolemmal, Z-disc-associated component of neuromuscular and myotendinous junctions in adult rats. On immunoblots, mAb 3G2 reacts with a relatively insoluble protein of 41 kD. To examine the neural regulation of synaptic localization, we have induced novel neuromuscular junctions in adult muscles. The soleus muscle was cross-innervated by implanting the deep branch of the peroneal nerve onto the muscle surface. Two weeks later, the muscle was denervated by tibial nerve resection. This procedure resulted in the formation of novel, ectopic neuromuscular junctions (as revealed by α-bungarotoxin labeling) at the site of implantation of the foreign nerve, 2-3 weeks after denervation. Ectopic junctions were immunoreactive with mAb 3G2. Thus, the nerve is able to induce expression of the mAb 3G2 epitope at synapses in adult animals. This result further suggests that the effects of innervation on the accumulation of mAb 3G2 immunoreactivity are localized to the site of contact. In contrast, innervation-independent mAb 3G2 immunoreactivity was observed in myotubes formed *in vitro* from rat cell lines and primary cultures. In the rat myogenic cell line, L6, mAb 3G2 labels a filamentous network in the cytoplasm of differentiated cells, confirming previous observations that the epitope is ubiquitously expressed in nascent muscle fibers. Primary cultures also contain filamentous labeling that is particularly prominent at the ends of well-fused myotubes, reminiscent of the myotendinous labeling observed *in vivo*.

563.3

THE RECEPTOR-ASSOCIATED PROTEIN GEPHYRIN IS A COMPONENT OF MANY SYNAPSES IN THE RAT CENTRAL NERVOUS SYSTEM.

J. Kirsch, D. Langosch, P. Prior, B. Schmitt, and H. Betz (Spon: European Neuroscience Association) Dept. of Neurochemistry, Max-Planck-Institute for Brain Research, Deutschordenstr. 46, 6000 Frankfurt 71, Germany

Gephyrin was originally identified as peripheral membrane protein which is localized at the cytoplasmic face of glycinergic postsynaptic membranes of the rat spinal cord. Recent immunofluorescence studies using two different monoclonal antibodies against gephyrin demonstrate its widespread distribution at supramedullary synapses. Tubulin overlay and co-polymerization studies revealed a high-affinity interaction of gephyrin with microtubules (MTs). From cDNA clones, the primary structure of different gephyrin variants has been deduced; these are distinguished by the presence of different inserts (C1-C4) within the amino-terminal half of the protein. Co-polymerization experiments using *in vitro* translated deletion mutants of gephyrin suggest that the invariant carboxy-terminal region is implicated in the MT interaction. Our data suggest an important role of this polypeptide in postsynaptic receptor topology and architecture.

563.4

OCCURRENCE AND ENRICHMENT OF PROTEIN TYROSINE PHOSPHATASE (PTPase) IN A POSTSYNAPTIC DENSITY (PSD) FRACTION ISOLATED FROM ADULT RAT BRAIN.

X.N. Wang[1,2], K. Wu[1,2*], J.L. Xu[2], Y. Huang[3], T.W. Kim[1,2] and I.B. Black[1,2], [1]Graduate Program in Physiology and Neurobiology, Rutgers-The State University of New Jersey, New Brunswick, N.J. 08854, [2]Dept. of Neuroscience and Cell Biology, UMDNJ/Robert Wood Johnson Medical School, Piscataway, N. J. 08854 and [3]Div. of Neuroscience, NYSPI, New York, N.Y. 10032.

Protein tyrosine phosphorylation plays an important role in the regulation of cell growth and differentiation in developing brain. In addition, recent studies showing high levels of protein tyrosine kinases (PTKs) at synapses suggest that tyrosine phosphorylation may be involved in the modulation of synaptic communication and plasticity. The regulation of tyrosine phosphorylation of substrate proteins is achieved by a balance of the activities of PTKs which phosphorylate and PTPase which dephosphorylates the substrate proteins. So, remarkably, synaptic PTPase remains to be identified and characterized. Since PTKs were found to be enriched in the PSD (a functionally important, disc-shaped proteinaceous structure attached to inner surface of postsynaptic membrane), we examined the existence of PTPase in this structure with Western blot analysis, using a highly specific antibody against a 37-kDa human recombinant T-cell truncated protein tyrosine phosphatase (TCΔC11PTPase). Our results revealed that the antibody specifically recognized a 60 kDa polypeptide in total homogenate (H), synaptic membrane (SM) and postsynaptic density (PSD) isolated from cerebellum (CBL), olfactory bulb (OB) and cerebral cortex (CTX) of adult rat brain. There was at least a 20-fold enrichment of the 60 kDa species in the PSD over H and SM, suggesting that the enzyme may play a role in postsynaptic mechanisms. Moreover, the 60 kDa protein exhibited differential expression in CTX, CBL and OB. We conclude that the PTPase-like 60 kDa protein is a PSD component that may play a regulatory role in synaptic function.

563.5

IMMUNOREACTIVITY OF ß-AMYLOID PROTEIN PRECURSOR (ß-APP) SEQUENCES AT THE POSTSYNAPTIC DOMAIN OF HUMAN NEUROMUSCULAR JUNCTIONS (NMJs).

R.B. Alvarez, V. Askanas, W.K. Engel*. USC Neuromuscular Center, Los Angeles, CA 90017-1969.

The amyloidogenic fragment of ß-APP, ß-amyloid protein (ß-AP) in the brain has received attention for its putative role in the pathogenesis of Alzheimer's disease. Outside the brain, we recently demonstrated pathologic accumulation of ßAP in vacuolated muscle fibers of patients with inclusion-body myositis (Askanas et al., Lancet 339:560-561, 1992). We have now immunolocalized 3 sequences of ßAPP, C-terminal, amino-acids 676-695 (C-ßAPP), N-terminal sequence 45-62 (N-ßAPP) and ßAP sequence, at the NMJs in 16 normal human muscle biopsies (total 200 NMJs), using four well-characterized antibodies. In all biopsies, all the NMJs identified by alpha-bungarotoxin (α-BT) binding had very strong immunoreactivity (IR) for all 3 ßAPP sequences. N-ßAPP-IR compared exactly to co-localized bound α-BT and dystrophin-IR. ß-AP-IR and C-ßAPP-IR extended slightly deeper into the muscle fiber end-plate region than bound α-BT. By immunogold-EM, C-ßAPP-IR was localized in the muscle fiber postsynaptic domain a) in small tufts along the muscle-fiber side of the folds and b) in the form of clusters on small bits of membrane scattered throughout the end-plate region. We suggest ßAPP may have an important role in normal junctional biology, and possibly in some diseases affecting NMJs. (We are grateful to GG Glenner, DJ Selkoe, B Frangione and D Levartovsky for generous gifts of antibodies.)

563.6

A RAT POSTSYNAPTIC DENSITY PROTEIN, PSD-95, IS A HOMOLOGUE OF THE DROSOPHILA DISCS-LARGE PROTEIN AND CONTAINS A GUANYLATE KINASE DOMAIN.

K.-O. Cho, C. A. Hunt, J. L. Rawlings and M. B. Kennedy*. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

To understand the structure and function of the postsynaptic density (PSD), we set out to study biochemical and molecular properties of several proteins in the PSD fraction from rat brain. We isolated cDNA clones encoding a protein of apparent M_S 95 kDal that is tightly associated with the PSD by screening a rat brain cDNA library with DNA probes designed from tryptic peptide sequences of the protein. The cDNAs encode a protein of 724 residues with a MW of 80,465. The deduced PSD-95 protein sequence has high similarity to the *Drosophila* tumor suppressor protein, lethal (1)discs-large-1 (*dlg*), and lower similarity to human erythrocyte protein p55. All three proteins contain an SH3 domain and a guanylate kinase domain that can catalyze synthesis of GDP from GMP. PSD-95 and *dlg* also contain three internal repeats of a motif termed "GLGF repeats". In Drosophila imaginal discs, the *dlg* protein is associated with septate junctions. Immunoblots with a polyclonal antiserum generated against bacterially expressed PSD-95 show that it is enriched in PSD fractions. The same antibody stains dendrites of neurons in the cortex and hippocampus of rat brain. PSD-95 mRNA was only detected in brain, suggesting that PSD-95 is a brain-specific guanylate kinase. The phenotype of Drosophila *dlg* mutants suggests that GDP synthesis by these proteins may be regulated by external signals and that the locally regulated GDP:GTP ratio in turn regulates G proteins such as ras.

563.7

DISTRIBUTION OF THE POSTSYNAPTIC DENSITY PROTEIN, PSD-95, IN RAT BRAIN.

C.A. Hunt*, K.-O. Cho, and M.B. Kennedy. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

This laboratory has recently cloned a cDNA encoding a prominent protein in rat postsynaptic density fractions, of apparent molecular weight 95Kd, termed PSD-95. It is highly similar to the Drosophila lethal(1)disc-large-1 (*dlg*) tumor suppressor protein, which is associated with septate junctions in developing flies. Confocal immunofluorecense and peroxidase immunohistochemistry with an affinity-purified rabbit polyclonal antiserum to PSD-95 have shown that the protein is present in neurons in many regions of rat brain. Thionin-counterstaining of 15μ immunostained sections suggests that not all neurons contain PSD-95. In hippocampus, dentate granule cells and pyramidal neurons in CA1 and CA3 are stained, as well as mossy fibers in CA3, while most interneurons appear unstained. In neocortex, PSD-95-positive neurons are present throughout laminae II-III and V-VI; staining is particularly intense in layer V pyramidal neurons. Fewer immunoreactive neurons are present in layer IV. In both hippocampus and neocortex, PSD-95 immunoreactivity is absent from cell nuclei and is more intense in dendrites than in somata. Staining is not homogeneous in dendrites, but is concentrated in small discrete spots, consistent with the possibility that PSD-95 is highly concentrated in postsynaptic densities. In cerebellum, PSD-95 does not stain Purkinje cell somata, but is present in somata and dendrites of stellate cells in the molecular layer. In addition, immunostaining is very intense in a plexus surrounding each Purkinje cell and concentrated at its basal end, suggesting that basket cell axons synapsing onto Purkinje cells contain high levels of PSD-95.

PRESYNAPTIC CONTRIBUTION OF A 130 kDA PROTEIN TO POSTSYNAPTIC DENSITY PREPARATIONS.

J.A. Garner*, USC School of Medicine, Los Angeles, CA 90033

The morphological correlate of vertebrate CNS synapses, synaptosomes, can be enriched by subjecting homogenized brain tissue to sucrose gradient density fractionation. The isolated synaptosomes contain most pre- and postsynaptic features of synapses, and release neurotransmitter in a calcium-dependent fashion. A subcomponent of the synapse, which morphologically appears to be the postsynaptic density, can be further enriched by detergent extraction of synaptosomes. Newly synthesized radioactive proteins in guinea pig retinal ganglion cells were axonally transported as slow component b (SCb) to their terminals. Synaptosomes were prepared from the radiolabeled terminal regions, and subjected to the detergent fractionation scheme developed for enriching the postsynaptic density. A single labeled (presynaptic) protein at ~130 kDa, was found in the fraction enriched for postsynaptic density structures. Whether this protein is actually incorporated within the postsynaptic structure, or is a presynaptic remnant of the synaptic cleft peripherally associated with the postsynaptic density is not yet clear. Triton-x-114 extraction of transported proteins in the presynaptic axons reveals approximately equal distribution of this protein in the aqueous and detergent phases. Once the protein reaches the terminal regions, it is found almost exclusively in the detergent or hydrophobic phase.

EXCLUSIVELY NEURONAL LOCALIZATION OF THE SYNAPSE PROTEIN SNAP IN *DROSOPHILA MELANOGASTER*.

C. Risinger*, V. A. Pieribone#, D. Nässel§, A. Lambertsson¶, L. Brodin#, and D. Larhammar. Dept of Medical Genetics, Box 589, Uppsala University, S-751 23 Uppsala, Sweden. #Nobel Inst. f. Neurophysiolgy, KI, Stockholm, Sweden. §Dept. of Zool., Stockholm Univ., Sweden. ¶Dept. of Biology, Oslo Univ., Norway.

SNAP (synaptosome-associated protein) is a 25-kDa protein which is expressed exclusively by neurons in mammals. It is localized to presynaptic nerve terminals and it is associated with the inner side of the cell membrane in presynaptic nerve terminals. Its expression starts at the time of synaptogenesis.

We have previously shown that SNAP is an extremely well-conserved protein which implies important functions. The chicken and mouse SNAP proteins are identical throughout the 206 amino acids (S. Catsicas et al., PNAS 88, 785-789, 1991), and SNAP of goldfish, ray *(Torpedo marmorata)*, river lamprey, and *Drosophila melanogaster* show extensive similarity to the mouse protein (Abstract 154.14, NM 1990). The *Drosophila* SNAP gene has a complex structure with eight exons spanning more than 65 kbp (Abstract 458.6, NM 1991).

We have now started to explore the anatomical and temporal aspects of SNAP expression in *Drosophila*. Northern blot analysis reveals a single mRNA of approximately 2.5 kbp in both larvae and adult flies. In situ hybridization to *Drosophila* tissue sections gives specific labelling to neuronal cell bodies in the brain and in the ventral ganglion. No specific binding to the intestine or the muscles was observed.

Thus, SNAP is a highly conserved protein exclusively expressed by neurons in *Drosophila* . The large size of the gene may indicate an important role in the development of the nervous system.

563.10

EXPRESSION AND GENETIC ANALYSIS OF *DROSOPHILA* SYNAPTOTAGMIN.

J.T.Littleton, H. Bellen#, M.S. Perin*. Division of Neuroscience, # Institute of Molecular Genetics and Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX 77030

Synaptotagmin, an integral membrane protein of synaptic vesicles, is well conserved from invertebrate through vertebrate evolution and has been suggested to play a role in synaptic vesicle docking and fusion. To investigate synaptotagmin function further, we have examined synaptotagmin's developmental expression in *Drosophila* and have initiated a genetic analysis of the gene. Low stringency screens to identify additional synaptotagmin cDNAs derived from *Drosophila* embryos failed to isolate isoforms differing from the adult message, suggesting the presence of a single synaptotagmin gene. Whole mount *in situ* hybridization of *Drosophila* embryos indicate that synaptotagmin transcription begins in the central nervous system during stage 13, and in the peripheral nervous system during stage 15. Synaptotagmin message appears in all neurons of the PNS, and in most, if not all, CNS neurons. Antibodies prepared to bacterially produced recombinant *Drosophila* synaptotagmin and to an amino-terminal synaptotagmin peptide, recognize a 70 kD protein on western blots of crude *Drosophila* synaptic vesicles. Antibody staining of embryos indicate that protein expression begins in the CNS and PNS during stages 14 and 16, respectively. Antibodies to synaptotagmin strongly label the two longitudinal tracts in the ventral nerve cord and brain, as well as many other areas of the CNS. In addition, the antibody recognizes many peripheral axons, with intense staining localized to the neuromuscular junction. We have localized the synaptotagmin gene to the second chromosome at 23B-C, and have identified a deficiency (23A1-3-23C) to which synaptotagmin maps. Embryos or first instar larva with this deficiency are homozygous lethal and are the subject of further work to define the consequences of loss of synapotagmin expression on neurotransmission. These data indicate that synaptotagmin expression in *Drosophila* is widespread in both the peripheral and central nervous systems and correlates to a period of development when synaptic activity begins to occur.

563.11

SYNAPTIC VESICLE PROTEINS IN DROSOPHILA.

A. DiAntonio, R.W. Burgess, and T. L. Schwarz*. Dept. of Molec. and Cell. Physiology, Stanford Univ. Med. Sch., Stanford, CA 94305

We are undertaking a genetic analysis in Drosophila to understand the function of several synaptic vesicle proteins. Drosophila has homologues of at least three mammalian vesicle proteins, p65 (synaptotagmin) [Perin *et al.*, JBC 266, 615, 1991], Rab3a [Johnston *et al.*, Neuron 7, 101, 1991], and VAMP (synaptobrevin) [Sudhof *et al.*, Neuron 2, 1475, 1989]. We have recently identified a novel Drosophila VAMP. This VAMP as well as the p65 and Rab3A homologues are localized to the nervous system as shown by Northern analysis and *in situ* localization. The previously published Drosophila VAMP is not localized to the nervous system [Chin *et al.*, mns. in prep.] In addition, immunocytochemistry with a rat serum raised to rat p65 [gift of Scheller lab] demonstrates that the Drosophila p65 protein is localized to the neuropil. These data suggest that these proteins' functions may have been conserved from Drosophila to mammals.

To study the function of these proteins we are in the process of making mutations in each. Large chromosome deficiencies have been obtained that remove each gene. We are saturating these regions for lethal complimentation groups by EMS mutagenesis. The study of the mutant phenotype for each gene should allow an analysis of the function of each protein and a starting point for a search for interacting genes.

563.12

STRUCTURAL COMPOSITION OF SYNAPTIC VESICLE PROTEOGLYCAN.

K.Noremberg * and S.M.Parsons. Department of Chemistry, University of California, Santa Barbara CA 93106, USA.

Proteoglycan constitutes about 25% of the protein in cholinergic synaptic vesicles obtained from the electric organ of Torpedo. In order to study domain structure, the proteoglycan (PG) was purified and subjected to partial degradations. Western blot analysis indicates that anti-SV1 and anti-SV2 recognize carbohydrate epitopes of PG that are removed by keratanase digestion. Additionally, chemical deglycosylation of PG with HF resulted in a complete loss of PG immunoreactivity. Incubation of PG with other glycosaminoglycan degrading enzymes revealed a heterogeneous composition of PG sugars. PG treated with HF or trifluoromethanesulfonic acid generated 62 kDal and 5 kDal polypeptides. The 5 kDal polypeptide is susceptible to proteinase K but not trypsin. The complex nature of PG demonstrated by these experiments suggests that the protein subunits are assembled post-translationally or derived from a larger precursor.

563.13

SYNAPTIC VESICLES IN GLUTAMATE, GABA AND GLYCINE-IMMUNORECTIVE SYNAPSES IN THE LAMPREY SPINAL CORD HAVE DISTINCT MORPOLOGICAL CHARACTERISTICS

O.Shupliakov[1,2], L.Brodin[1], O.P.Ottersen[3] and J.Storm-Mathisen[3],Nobel Institute for Neurophysiology (1), Department of Anatomy (2) Karolinska Institute, Stockholm, Sweden and Anatomical Institute (3), University of Oslo, Oslo, Norway.

The lamprey spinal cord is particularly useful to study the regional distribution of amino acids in synapses, as synaptic vesicle clusters and axoplasmic compartments in most axons can be anatomically separated. The ultrastructural distribution of glutamate, aspartate, GABA and glycine immunoreactivity was analysed in spinal cords fixed in 3% glutaraldehyde in 0.1 M phosphate buffer, using the immunogold postembedding technique. An accumulation of immunoreactivity over clusters of synaptic vesicles was revealed for GABA, glutamate and glycine in the respective immunoreactive axons, but not for aspartate. Hence, only the former three amino acids can be assumed to act as neurotransmitters. The labelled synaptic junctions displayed distinct morphological characteristics. Axons with GABA-ir vesicle clusters contained spherical to pleomorphic vesicles, numerous glycogen granules and some dense core vesicles, while glycine-ir vesicle clusters contained flattened vesicles. Axons with glutamate-ir vesicle clusters contained spherical vesicles. Glutamate-ir axons formed asymmetrical synapses, which often contained gap junctions. Glycine-ir synapses were symmetrical, while GABA-ir terminals established both symmetrical and asymmetrical synaptic junctions.

The results emphasize that axons utilizing different amino acids as neurotransmitters can have distinct ultrastructural features in glutaraldehyde fixed tissue. The distinct shape of vesicles in these axons will significantly simplify the structural analysis of neuronal circuits in the lamprey spinal cord.

563.14

SYNAPTIC ULTRASTRUCTURE ON TRIGEMINAL MESENCEPHALIC NEURONS

Norman F. Capra* and Dean Dessem. Dept. of Physiology., Univ. of Maryland Dental School, Baltimore MD 21201.

Sensory endings of masticatory muscle spindles and of many periodontal ligament receptors are innervated by central neurons located in the mesencephalic nucleus of the trigeminal nerve (Vmes). Although these are primary afferent neurons, they possess several features not generally recognized in peripheral sensory ganglia. Synaptic boutons on Vmes somata were demonstrated by Hinrichsen (1968). The purpose of this study was to compare the morphology of boutons on Vmes spindle and periodontal afferent neurons in cats (n=3) and rats (n=6). Peripheral injections of horseradish peroxidase (HRP; Sigma VI) were made into the mandibular periodontal ligaments or the masseter muscle. Periodontal and spindle afferent somata were identified by the presence of reaction product following diaminobenzidine (DAB) histochemistry for demonstration of transported HRP. Labeled Vmes neurons were prepared for and examined with transmission electron microscopy. One to three boutons were observed along the perimeter of most labeled cells in both species. There were no apparent differences related to the peripheral structures innervated nor between species. Most of the boutons contained a relatively dense accumulation of spherical synaptic vesicles although boutons with a few dense-cored vesicles were also observed. Pre- and postsynaptic densities, indicative of synaptic contact, were not always obvious, but they did occur and examination of serial sections would probably reveal such specializations at most boutons. Although the synaptic density along Vmes neurons is relatively low, and these boutons are likely to originate from several sources, some of these contacts may account for the inhibition of Vmes spindle afferent activity that has been reported following electrical stimulation of the ventral diencephalon (Dessem et al., 1991). MEMBRANE CYCLING AND ENDOSOMES IN CELL BODIES AND TERMINALS OF FROG RETINAL PHOTORECEPTORS.
M. Santa-Hernandez, E. Augenbraun, R. St. Jules and E. Holtzman*. Columbia Univ., N.Y. 10027

Membrane cycling between cell surfaces and intracellular compartments in neuronal cell bodies is poorly understood. We find that Brefeldin A does not prevent access of endocytosed Wheat Germ Agglutinin to trans-Golgi related systems, probably reflecting interactions of the persistent trans-Golgi elements with endosomes. We also find that some of the endocytic structures that form rapidly in the cell bodies contain synaptophysin, strengthening our suspicion that cycling of synaptophysin via endosomes and Golgi structures in the cell bodies coexists with recycling in the presynaptic terminals.

Vacuolation by weak bases is one line of evidence for participation of endosomes in recycling in terminals (J. Neurocytol. 18:529). We find that weak bases which are only weakly vacuologenic by themselves can engender prominent vacuolation when administered with elevated K gluconate, which also is only mildly vacuologenic. This synergy supports our view that the terminals contain acidified endocytic compartments comparable to endosomes of other cell types.

SYNAPTIC STRUCTURE AND FUNCTION II

564.1

SEGREGATION OF CHEMICALLY-DEFINED VARICOSITIES UPON PARTICULAR DENDRITES OF A NEURON: A NOVEL MORPHOLOGICAL BASIS FOR NEURONAL MODULATION?
D. R. Onstott* and A. J. Beitz, Department of Veterinary PathoBiology, Univ. of Minnesota, St. Paul, MN 55108

The segregation of chemically-defined synaptic inputs to neurons based upon their proximity to the cell soma has been examined in several studies. However, we are unaware of any reports documenting the segregation of such inputs on particular dendrites of a cell. Here we report selective substance P (SP) innervation of portions of the dendritic tree of neurons in the periaqueductal gray (PAG). Retrogradely labeled PAG neurons were injected iontophoretically with Lucifer yellow (LY), and SP immunoreactivity was detected in the same sections using fluorescence immunocytochemistry. Separate series of optical sections of injected cells and of SP-immunoreactive (SP-IR) varicosities were produced using confocal laser microscopy. Individual, coplanar images from each series were merged and the site of apposition of each SP-IR varicosity was marked on LY-filled neuronal structures. LY images were them merged to produce a projection of the entire neuron. Some cells and the corresponding series of SP images were also reconstructed into stereo pairs, merged, and appositions identified independently on the three dimensional images. Among the 10 cells thus far studied in detail, three have exhibited SP-IR appositions that appear to be preferentially associated with one or more dendrites. Some dendrites of each cell exhibited a high innervation density ($\bar{x}$=5.7 appositions/100μm), while other dendrites exhibited no SP innervation or low innervation density ($\bar{x}$=1.4 appositions/100 μm). These results suggest that chemically-defined inputs to neurons may be spatially segregated by selectively contacting certain dendrites of an individual cell. This pattern may be of functional significance in providing a morphological basis for differential modulation of cellular activity. Alternatively, it may represent the most efficient configuration for providing multiple contacts with adjacent cells.

AUDITORY IMPRINTING LEADS TO NEURON SPECIFIC ULTRASTRUCTURAL CHANGES IN THE MNH OF CHICKS
H. Faber, H. Wicht* and H. Scheich; Institute of Zoology, Technical University Darmstadt, Germany

In the rostral forebrain of chicks an area called medio-lateral Neostriatum and Hyperstriatum ventrale (MNH) is relevant for auditory filial imprinting. Wallhäußer and Scheich (Dev. Brain Res.31; 29-44, 1987) characterized 3 types of Golgi-impregnated neurons and noticed a large reduction (47 %) of spines for the largest neurons (type I) after successful imprinting. These events on the postsynaptic side suggest a synaptic selection process but events on the presynaptic side, which could support this hypothesis, remained to be determined. In order to resolve this issue a Golgi-technique for combined light- and electron microscopic studies was applied. The Golgi-Colonnier method was modified for chicks and LM-identified isolated type I-neurons were prepared with a gold-toning procedure for EM. In series of more than 100 sections it was possible to identify and reconstruct spines. With an interactive image analyzing computer system which was adjusted to the electron microscope we investigated several ultrastructural parameters. It was found that all spines of type I-neurons from isolated control chicks carried immature-like synapses. All spines on type I-neurons of imprinted chicks of the same age also carried synapses but exhibited larger presynaptic areas with more vesicles, longer postsynaptic densities and frequently with one mitochondrium. For the type II- neurons no significant subsynaptic changes were demonstrated. Consequently, there exists a correlation between the loss of spines and the loss of synapses during imprinting. Moreover, there is no numerical shift from spine synapses to shaft synapses during imprinting. The ratio for control chicks came to 3:1 and for imprinted chicks it was 2,4:1. This implies that even shaft synapses are lost during the synaptic selection process.

CONFOCAL IMAGING OF THORNY EXCRESCENCES ON HIPPOCAMPAL PYRAMIDAL NEURONS.
David B. Jaffe[1]* and T.H. Brown[1,2] Depts. of Psychology[1] and Cellular & Molecular Physiology[2], Yale Univ., New Haven, CT 06520

The function of dendritic spines is not known, although spines have long been proposed to participate in mechanisms of long-lasting forms of synaptic plasticity, such as long-term potentiation (LTP). The mossy fibers synapse onto proximal dendritic spines of CA3 pyramidal neurons, referred to as thorny excrescences or thorns, that are perhaps the largest in the mammalian CNS. Their large size and close proximity to the soma makes this synapse ideal for studying the morphology and biophysical function of a living dendritic spine.

We have used the high-spatial resolution of confocal laser scanning microscopy (LSCM) to image mossy fiber thorns on CA3 pyramidal neurons within thick (400 μm) rat hippocampal slices. Droplets of DiI-oil solution (Fine et al., *Soc. Neurosci. Abstr.*, 17, 1991) were placed within stratum pyramidale or stratum oriens of area CA3. Following 30-60 minutes, fluorescence was detected at low-power in pyramidal neurons within the vicinity of the oil droplets. Mossy fiber thorns were then visualized using a long-working distance (500 μm) 63X objective (NA=1.25).

Large dendritic spines (1-3 μm) were identified on the proximal apical dendrites corresponding to stratum lucidum. On some cells, spines were also observed on the proximal basal dendrites. These structures clearly originated and were readily distinguished from the dendritic shaft. We are currently using LSCM to measure directly changes in $[Ca]_i$ within thorny excrescences using long-wavelength Ca-sensitive dyes. *Supported by NIH and ONR.*

564.4

VISUALIZATION OF HIPPOCAMPAL MOSSY FIBER SYNAPSES IN LIVING BRAIN SLICES.
T.-P. Yu*[1] and T.H. Brown[1,2]. Depts. of Psychol.[1] and Cell. & Molec. Physiol.[2], Yale Univ. New Haven, CT 06520.

Granule cells of the dentate gyrus send their mossy-fiber (mf) axons to the CA3 region, where they make synapses onto the proximal dendrites of the pyramidal neurons. The electrotonic proximity of the mf synapses to the cell soma (Siegel et al, *Soc. Neurosci. Abstr. 18*, in press) makes them ideal for voltage-clamp analysis of synaptic microphysiology and use-dependent plasticity (Xiang et al, *Soc. Neurosci. Abstr. 18*, in press; Greenwood et al, *Soc. Neurosci. Abstr. 18*, in press).

We have been interested in microscopic techniques that enable good visualization of the mf synapses in living brain slices (Keenan et al, *Soc. Neurosci. Abstr. 16*, 660, 1990). Here we describe progress using laser scanning confocal microscopy (LSCM) applied to relatively thick (400 - 450 μm) rat hippocampal slices, which were cut perpendicular to the long axis of the hippocampus or else at 15 - 30° from the perpendicular. Slices were attached to a glass coverslip that forms the bottom of our recording/observation chamber (Keenan et al, *Brain Res. Bull. 21*, 373, 1988). Dyes that we explored included dil or diA, FM1-43, and Fluo-3. Images were obtained with a Bio-Rad MRC 600 LSCM system using a long working distance (500 μm) 63X objective (NA = 1.25).

The presynaptic mf boutons, which could be clearly identified after staining with dil or diA, exhibited a trimodal size distribution. When the dye was injected into the stratum granulosum and the slices were sliced perpendicularly, almost all of the stained mf axons were cut before reaching region CA3. Fewer mf axons were cut in the non-perpendicular slices. Using FM1-43, we are currently attempting to visualize vesicle recycling, as previously observed in the neuromuscular junction (Betz and Bewick, *Science 255*, 133, 1992). *Supported by NIH and ONR.*

564.5

SYNAPTIC ENHANCEMENT BY LOCAL PRESYNAPTIC STIMULATION AFFECTS THE SHORT-TERM PLASTICITY OF INDIVIDUAL RETICULOSPINAL EPSPs DIFFERENTLY

L. Brodin* O. Shupliakov and V. Pieribone, The Nobel Institute for Neurophysiology, Karolinska Institutet, S-104 01 Stockholm, Sweden

The short-term plasticity of mixed electrochemical EPSPs evoked in lamprey spinal neurons by single giant reticulospinal nerve cells was studied using paired-pulse stimulation (interval 65 ms). During stimulation of cell bodies the amplitude of the second chemical EPSP (kainate/AMPA-mediated, AP-5 present) was always larger than the first EPSP, i.e. facilitation predominated over depression, while the electrical component was unaltered. The degree of facilitation of the chemical EPSP varied considerably in different spinal neurons, from a slight increase to more than a two-fold increase, even among EPSPs evoked by the same presynaptic neuron. When axons were impaled and stimulated close to the synaptic area (about 100-500 μm), the postsynaptic response was found to depend strongly on the stimulation parameters. The amplitude of the chemical EPSP increased if the depolarizing current pulse used to trigger action potentials was increased, or if the distance between the stimulating electrode and the synapse was decreased. This synaptic enhancement could alter the EPSP plasticity, such that less paired-pulse facilitation occurred. In many cases the second EPSP even had a lower amplitude than the first, i.e. depression predominated over facilitation, while both electrical components had the same amplitude. However, an enhancement of the EPSP did not always alter the EPSP plasticity. In some cases a pronounced facilitation remained, albeit the amplitude of the first EPSP was markedly increased. These data imply that individual reticulospinal synapses have different plasticity properties which, at least in part, depend on mechanisms linked to the presynaptic element.

564.6

SIZE AND NUMBER OF ACTIVE ZONES IN MAUTHNER CELL INHIBITORY AFFERENTS INCREASE FROM SOMA TO DENDRITE.

C. Sur, A. Triller* and H. Korn. Institut Pasteur, Paris.

Morphological characteristics of inhibitory active zones were analysed at the level of Mauthner cell's (M-cell) axon-cap, soma, and the medial and distal parts of the lateral dendrite (150-200 and 350-450 μm away from axon-cap, respectively). For this purpose, presynaptic grids were stained with ethanolic phosphotungstic acid (EPTA). Both glycine and GABA were visualized by post-embedding immunogold labeling on semi-thin (0.5 μm) sections. In the axon-cap and soma, the afferent boutons have small sized glycinergic presynaptic grids with respective areas of 0.066 ± 0.02 μm^2, (mean ± S.D., n = 30), and 0.075 ± 0.03 μm^2, (n = 46). 96% of these terminals in the axon-cap and 82% of these on the soma have only one active zone; the rest are mainly boutons with two grids. On the dendrite, both glycinergic and gabaergic dendritic afferents have larger release sites. Specifically, the surface of each active zone is increased to 0.135 ± 0.08 μm^2, (n = 113; GABA), 0.141 ± 0.08 μm^2, (n = 148; glycine) on the middle portion and 0.139 ± 0.08 μm^2, (n = 125; GABA), 0.147 ± 0.1 μm^2, (n = 115; glycine), on the distal dendrite. These values are similar for both gabaergic and glycinergic boutons, and are significantly different from somatic ones (Student t tests). Furthemore, the proportion of profiles displaying two (31% for GABA; 30% for glycine) and three to four (4% for GABA; 7% for glycine) active zones, is greater on the dendrite than on the soma. These results suggest that the probability of transmitter release is higher at dendritic inhibitory afferents than at somatic ones. Such could also be the case for the size of quanta when occurring at more widespread postsynaptic receptor aggregates.

564.7

BACKFIRING AT MIXED SYNAPSES ON THE MAUTHNER (M) CELL.

Alberto Pereda* and Donald S. Faber. *Dept. of Physiology, SUNY-Buffalo, Buffalo, NY 14214.*

Single eighth nerve afferents terminate on the M-cell's lateral dendrite as large myelinated club endings which have both gap junctions and chemical synapses with the cell. Low threshold extracellular stimulation of the posterior branch of the eighth nerve produces a mixed excitatory post-synaptic potential (VIIIth EPSP) consisting of a fast electrotonic potential, followed by a chemical glutamatergic component. Intracellular recordings of these afferents were obtained, alone or while simultaneously recording from the M-cell. Membrane potential ranged from -65 to -73 mV. Coupling potentials can be recorded from these afferents either when the M-cell is activated antidromically by stimulation of its axon in the spinal cord or when an VIIIth stimulus is subthreshold for the impaled axon. In the latter case, an attenuated composite VIIIth nerve evoked EPSP is recorded in the afferent. Backfiring of these afferent fibers was obtained in a number of situations: i), following stimulation of the VIIIth nerve at a strength subthreshold for the recorded axon, ii), pairing a weaker VIIIth nerve stimulus with antidromic activation of the M-cell, and iii), pairing the antidromic stimulus with a presynaptic depolarizing current. We also found that the coupling potentials recorded from a fiber are voltage dependent, increasing with fiber depolarization and decreasing with hyperpolarization. Current/voltage relationships obtained from the fibers suggest that both membrane and junctional properties may be involved. Backfiring associated with physiological activation of eighth nerve afferents could serve as a positive feedback, recruiting additional fibers and enhancing the EPSP in the M-cell. It could also impart a significant non-linearity to the input-output relationship of the population response.

564.8

TEMPORAL INTERACTION OF SYNAPTIC INPUTS IN VAGAL MOTONEURONS.

R. Nitzan, I. Segev & Y. Yarom*, *Dept. of Neurobiology, Hebrew University, Jerusalem, Israel.*

Temporal synaptic interactions in motoneurons from the dorsal motor vagal nucleus (DMVN) of guinea pigs were studied in brain stem slices. The submerged slice technique and conventional intracellular recordings were used in this study. Synaptic responses were elicited by stimulating non-specific presynaptic axons at the nucleus surroundings (peri-vagal stimulus, Yarom et al. *Neurosciense* 16:4, 719-737, 1985). The temporal interactions were studied by analyzing the responses to trains of stimuli at various inter-train intervals that where delivered at different frequencies. At inter-train intervals longer than 10 msec and a frequency of 0.2 Hz, the peaks of all synaptic potentials in a train tend to reach the same level. Summation of synaptic potentials occurs only at shorter inter-train interval. The decay phase of the response to a train of stimuli (in most cells) is governed by two time constants (20msec, 100msec). Both are slower then the passive membrane time constant (τ_0=10msec). This finding indicates that the train of stimuli activates a long lasting conductance change. Trains of stimuli, delivered at frequencies of 0.25 Hz or higher, induced synaptic potentiation that lasts for 30 sec. Ten trains of 5 stimuli each, elicited at a frequency of 0.25Hz, were sufficient to double the amplitude of the synaptic potential but did not change the pattern of the temporal summation. A detailed model of DMVN motoneurons (Nitzan et al. *J. Neurophysiol.* 63: 333-346, 1990) was used to study temporal interaction in these cells, assuming passive dendrites. Using this model we estimated the non-linearity of synaptic interactions in these motoneurons by comparing the temporal summation as preformed by the actual cell and that expected in a passive model. The results suggest that a bursting input to DMVN motoneurons is more effective than a single input only if the bursting occurs at a frequency around 0.2 Hz, where the response is potentiated.

MINIATURE EXCITATORY SYNAPTIC CURRENTS (mEPSCs) IN MOTONEURONS (MN) OF ORGANOTYPIC RAT SPINAL CORD DORSAL ROOT GANGLION COCULTURE.

D.Ulrich* and H.-R. Lüscher, Dept. of Physiology, University of Bern, 3012 Bern, Switzerland

In order to study the quantal events at central synapses mEPSCs were recorded from voltage clamped MNs in whole cell configuration after bath application of 3 μM Tetrodotoxin, 3 μM Strychnine, 10 μM Bicuculline and 100 μM D-2-Amino-5-phosphonopentanoic acid (D-APV) in 2mM Ca^{++}. Cells were identified morphologically and immunohistochemically with a monoclonal antibody against Choline acetyl-transferase. The mEPSCs were reversible blocked with 10 μM of the competitive non-NMDA receptor antagonist 6-Cyano-7-nitroquinoxaline-2,3-dione (CNQX). A detection algorithm selected individual currents from continuous recordings sampled at 10 kHz. Most mEPSCs could be fitted by the sum of two exponentials of which amplitude, halfwidth and risetime were calculated. Amplitude histograms were skewed towards larger events. Individual peaks were not unambiguously resolvable. The mean of the modes was -19 pA (SD=7.7 pA, n=8) with a maximal range of -4 pA to -160 pA. Amplitude distributions compiled from currents with identical risetime or from the whole population were similar. We conclude that the broad range of mEPSCs amplitudes cannot be explained by electrotonic attenuation of currents from different dendritic locations. (SNF 31-27553.89)

MODULATION OF SPONTANEOUS EPSPS IN RAT MOSSY CELLS.

B.W. Strowbridge* and P.A. Schwartzkroin. Depts. of Physiology & Biophysics, and Neurological Surgery, Univ. of Washington, Seattle, WA 98195.

We have carried out a series of experiments to characterize spontaneous postsynaptic potentials (PSPs) in rat mossy cells and their modulation by intracellular depolarization. Spontaneous PSPs appear to be almost exclusively excitatory since they are blocked by the non-NMDA receptor antagonist, CNQX (10-50 uM) and alterations of the membrane potential consistently fail to reveal hyperpolarizing synaptic potentials. Previous studies suggested that at least some spontaneous EPSPs may be due to active granule cell terminals, discharging independently of the usually hyperpolarized soma. In four mossy cells, we observed that bath application of TTX (1 uM) dramatically reduced (but did not abolish completely) the frequency of spontaneous EPSPs, suggesting that granule cell axons and/or terminals can generate sodium spikes spontaneously. However, unlike in hippocampal pyramidal cells, TTX-resistant EPSPs in mossy cells were quite large (3-4 mV), of a magnitude similar to that observed before treatment (up to 10-15 mV).

We also have obtained evidence that spontaneous EPSPs can be modulated by depolarization of the postsynaptic neuron. We previously demonstrated that treatments which result in depolarization of mossy cells, including direct current injection into a single neuron, can potentiate both the amplitude and frequency of spontaneous EPSPs for prolonged periods. We now report that intracellular injection of the calcium chelator, BAPTA, significantly deceases the basal level of spontaneous EPSPs, and that strong (1-2 nA) depolarizing current pulses (similar to those which potentiated spontaneous EPSPs) evoke calcium spikes. These data support a role for postsynaptic calcium levels in the modulation of spontaneous EPSPs in mossy cells.

Supported by NIH grants NS20482 and NS07097.

LOCAL CIRCUIT, SINGLE AXON EXCITATORY POSTSYNAPTIC POTENTIALS (EPSPs) IN DEEP LAYER NEOCORTICAL PYRAMIDAL NEURONES.

A.M. Thomson*, D.C. West and J. Deuchars. Dept. Physiology, Royal Free Hospital School of Medicine, London NW3 2PF, UK.

Previous studies of single axon pyramidal-pyramidal connections in neocortex concentrated on layers II/III and IV. EPSPs exhibited a relatively rapid time course, despite an unconventional voltage relation and frequency-dependent potentiation with postsynaptic depolarization beyond -70mV and limited fluctuations in amplitude. The depression in average amplitude with increases in presynaptic firing rate or with paired pulse depression, were consistent with a decrease in presynaptic release probability. The present study aimed to determine whether the properties of connections between deeper pyramidal neurones were similar. Simultaneous intracellular recordings were obtained from pairs of neurones in rat neocortical slices. Pyramidal neurones were identified electrophysiologically and subsequently, morphologically on histological examination. All properties typical of superficial local circuit EPSPs were apparent. The only clear difference, at this stage, was the higher probability with which EPSPs of >1mV average amplitude were encountered in deeper layers. This was approximately 1 in 50, compared with 1 in 100. In addition, the largest events could be 7mV in amplitude.

NEUROMUSCULAR COMMUNICATION: INFERENCES FROM COMPUTER SIMULATIONS OF MINIATURE ENDPLATE CURRENTS. J.R. Stiles, T.M. Bartol, H.L. Fernandez*, E.E. Salpeter and M.M. Salpeter. Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

Lizard (*Anolis carolinensis*) intercostal muscle miniature endplate currents (MEPC's) were recorded under 3 conditions: untreated, acetylcholinesterase (AChE) inhibition, and AChE inhibition + ~70% nicotinic acetylcholine receptor (nAChR) binding site blockade. Mean amplitude (A_c), 20-80% rise time (t_r), and e-fold fall time (t_f) for each condition were reproduced (± 5%) by Monte Carlo MEPC computer simulations. Fixed model features included: geometry of 1° cleft and junctional folds; nAChR site density, identical ACh binding sites, and single bi-liganded open state; rate constants for AChE association and hydrolysis. We performed simulations iteratively to determine parameter sets corresponding to different assumed values of $g = \beta/(\alpha + \beta)$, where α and β are rate constants for channel closing and opening, respectively. Each parameter set included: quantal size (N); ACh diffusion coefficient; rate constants for nAChR association (k+) and dissociation (k-); (α+β); AChE site density (σ_e). For each parameter set, we also quantified molecular binding, unbinding, opening and closing events. For $0.8 \leq g < 1$, parameter set values all fell within suggested literature ranges, but nonetheless varied between sets from < 20% (σ_e) to > 20-fold (k-). Based on preliminary MEPC shape analysis, the optimal value for g is ≥ 0.95. With AChE active t_f exceeded mean burst duration by less than 30%, yet single ACh molecules bound nAChR multiple times (e.g. ~2.4 times at g = 0.8, and ~9.0 times at g = 0.975). Clearly, channel opening probability ($\beta/[\beta + 2k_-]$) decreased dramatically as g approached 1, even though MEPC efficiency (A_c/N) increased. Furthermore, ACh rebinding frequency was sensitive to σ_e variation in the range where A_c, t_r, and t_f were little affected. This suggests that trophic ACh/nAChR interactions could be regulated through σ_e without compromising efficacy of electrical signal transduction.

Supported by NIH grants NS09315 (M.M.S.) and 1F32NS09126-01 (J.R.S.). Simulations were conducted at the Cornell National Supercomputer Facility.

ISOLATED SNAKE NEUROMUSCULAR BOUTONS RELEASE 2-3 QUANTA WHEN ACTIVATED. R.S. Wilkinson* and S.D. Lunin. Department of Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO 63110.

Despite their importance as the anatomical substrate of quantal release, little is known about the function of individual synaptic boutons, in part because axon terminals typically comprise many synchronously active boutons. We have developed a technique which permits dissociation of living boutons from both their motor nerve terminal and their postsynaptic (endplate) site. The individual boutons may be studied either in isolation, which provides access to the presynaptic membrane, or after attachment to vacant endplate sites, for quantal analysis of 'reconstructed' one-bouton NMJs.

Boutons became nearly spherical when micromanipulated from their endplate site with a glass suction pipette. A second pipette (loose patch configuration) was used for stimulation and recording. Boutons remained healthy for >1 hr, as evidenced by uptake of the supravital probes 4-Di-2-ASP (mitochondrial) and sulforhodamine 101 (activity-dependent), and by spontaneous quantal release (MEPPs recorded from reconstructed NMJs). When stimulated, boutons exhibited 4-aminopyridine-sensitive terminal currents similar to those recorded from boutons of intact NMJs. Transmitter release (0.2 Hz stimulus rate) underwent quantal fluctuations about a mean of 2-3 quanta, with occasional failures. Maximum observed quantal content was 7. Serial EM of similar boutons (from intact NMJs) revealed ~6-7 active zones, suggesting that the probability of release was ~0.3-0.4. Supported by NIH grant NS24752 and the MDA.

HOW MANY VESICLES ARE RELEASED AT A CENTRAL SYNAPSE? N. Hessler*, R. Malinow. Neuroscience Program and Dept. of Physiology and Biophysics, University of Iowa.

We are addressing this question by looking at the AMPA and NMDA components of elicited excitatory postsynaptic currents in hippocampal slices under various release conditions. Under normal conditions we measure the NMDA/AMPA ratio (synaptic amplitude at 40 ms / 5 ms). We apply an APV concentration to produce a 50% decrease in this ratio. After washout of APV, we add an agent to the bath that increases the release of transmitter (Ca^{++}, phorbol esters, adenosine antagonist). We then measure the NMDA/AMPA ratio under increased release conditions. If multiple vesicles are released at a synapse, and NMDA receptors are saturated, then one would expect a decrease in the NMDA/AMPA ratio with increased transmitter release. We then apply APV at a concentration that produced a 50% reduction in the NMDA/AMPA ratio under normal release conditions. If NMDA receptors are saturated we expect less than a 50% reduction in the NMDA/AMPA ratio during increased release conditions. On the other hand, if a single vesicle is released per synapse, then increased release probability will merely recruit more synapses, and the NMDA/AMPA ratio should not change. APV should have the same relative effect in normal as high release conditions.

TRANSMISSION-DEPENDENT DEPRESSION COEXISTS WITH FACILITATION AT HIPPOCAMPAL EXCITATORY SYNAPSES

Johan F. Storm*, *Inst. of Neurophysiology, University of Oslo, Norway.*

Hippocampal synapses show facilitation, which appears to be presynaptic since it is independent of prior synaptic transmission (Neurosci.Abstr.17, p.1486). Here I report that these synapses also show depression, which is dependent on prior transmission, and usually masked by the facilitation.

CA1 pyramidal cells in slices from young rats were voltage-clamped (whole-cell) at -70 to -85 mV, with 2 mM Ca and 10 µM bicuculline in the bath. Pairs of minimal stimuli (STIM1 and 2; interval 40-60 ms) from a glass pipette in str. radiatum, evoked synaptic currents (EPSC1 and 2) of variable amplitude, alternating with ~50 % clear failures. Normally the average EPSC2 was larger than EPSC1 (**facilitation**) when the failures were included in the average (**A**). In contrast, when all failures were omitted, the mean EPSC2 was smaller (**depression**, in ~20% of the cells; **B**) or equal to EPSC1. Unlike the facilitation, the depression was use-dependent, i.e. it disappeared when EPSC1 failed (**C**). Thus, the mean of EPSC1 (**B**) and the mean of all EPSC2s preceded by a failure (**C**), were equal. The depression may be due to smaller quanta (e.g. receptor desensitization, dissipation of ionic gradients in the spine, or less transmitter per vesicle), or fewer quanta (e.g. depletion of transmitter). The reduced number of failures seems to argue against depletion and for a reduction in quantal size. [Supported by NAVF/RMF]

QUANTAL ANALYSIS OF EPSCs RECORDED FROM SMALL NUMBERS OF SYNAPSES IN RAT HIPPOCAMPAL CULTURES.

J. M. Bekkers* and C. F. Stevens. Division of Neuroscience, JCSMR, Australian National University, Canberra, ACT 2601, Australia, and The Salk Institute, Howard Hughes Medical Institute, La Jolla, CA 92037.

Current evidence supports the notion of quantal synaptic transmission in central neurons, as revealed by the presence of discrete peaks in histograms of synaptic amplitudes. However, we were unable to resolve such peaks when recording EPSCs from pairs of profusely-connected hippocampal pyramidal neurons in culture (*Nature* 341, p 230, 1989). A possible explanation is that quantal size is variable across synapses in culture, and recording from many synapses obscures the underlying quantal nature of transmission. Accordingly, we attempted to minimize possible synaptic heterogeneity by performing quantal analyses on small numbers of active synapses.

Dual whole-cell recordings were made from pairs of CA1 neurons. The bath solution omitted calcium, to block transmission at the majority of synapses, while a puffer-suction arrangement was used to locally apply bath solution containing 5 mM calcium to short lengths of dendrites. After many sweeps were recorded, a separate puffer was used to apply hypertonic bath solution to the same region, eliciting miniature EPSCs. Finally, Synapsin I antibody was used to count the number of synapses within the activated region.

The synapse count ranged from 5 to 20 in 13 experiments. Peaks were often visible in the amplitude histograms of evoked and miniature EPSCs. The general shapes of evoked histograms were well-fitted by assuming a binomial release process and a quantal size distribution given by the observed distribution of miniature EPSC amplitudes. We conclude that the quantal model is applicable to small numbers of synapses in culture.

BAYESIAN INFERENCE TECHNIQUES FOR SEPARATION OF SYNAPTIC POTENTIAL COMPONENTS IN HIPPOCAMPUS. D.A. Turner*, M. West and G. Cao. Neurosurgery, Neurobiology and Institute of Statistics and Decision Sciences, Duke University and Durham VAMC, Durham, NC 27710.

Bayesian inference has been applied to the analysis of fluctuations of synaptic potentials. The statistical model assumes the synaptic signal to be composed of a mixture of Gaussian components, with unknown means and noise SD (s_N). Component attributes include arbitrary spacing and probability, representing synaptic sites at varying electrotonic distances with nonuniform amplitudes. The analysis was applied to minimal EPSPs evoked in CA1 hippocampal neurons.

Datasets of peak EPSP values were tested for trends and stationarity and normality of noise data was confirmed (χ^2 test). Analysis output included: 1) component mean±SD values; 2) conditional probability of numbers of components; 3) relative probability of each component; 4) predictive pdf and cdf. A proximal EPSP (n=500, s_N=0.18 mV) analyzed to 3 primary components and sums (0.60 mV/16%, 1.32 mV/50%, 1.71 mV/24%). A distal EPSP (n=500, s_N=0.12) also showed 3 primary components (0.12 mV/22%, 0.21 mV/55%, 0.26 mV/20%) and sums. The predictive pdf/cdf were not different from the raw histogram (χ^2 test: p=0.99). These results were typical for CA1 EPSPs.

The advantages of Bayesian inference over MLE/deconvolution of a mixture distribution include: 1) parameter information can be included in a prior distribution; 2) the conditional probability of the number of components is estimated; 3) the s_N value is only an initial estimate of the component variances; 4) the component parameters include uncertainty estimates; and 5) the predictive distributions include variability. However, component separation remains dependent on the s_N value, to an extent. Further theoretical work will include more accurate noise description and simulation of known distributions with noise perturbations. Supported by NINDS RO1 NS29482-01 and VAMC.

POSTSYNAPTIC MECHANISMS I

565.1

THE EFFECT OF MEMBRANE POTENTIAL ON CALCIUM ACTIVATED POTASSIUM CURRENTS. A. R. Martin* and P. A. Fuchs. Dept. of Physiology, Univ. of Colorado Sch. of Med., Denver, CO 80262.

Previous experiments on chick cochlear hair cells have shown that calcium entering though synaptic channels activates calcium-dependent potassium currents (Fuchs and Murrow, *J. Neurosci.* **12**:800-809, 1992). In voltage clamp experiments the potassium currents increased with membrane depolarization and then decreased, approaching zero at about +20 mV, more than 170 mV negative to the calcium equilibrium potential. To account for this unexpected decrease in potassium current at small positive potentials we present a model in which calcium accumulates in a restricted space under the postsynaptic membrane. A second model is also presented to describe the voltage dependence of extrasynaptic potassium currents activated by calcium entry through voltage sensitive calcium channels in chick hair cells (Fuchs, Nagai and Evans, *J. Neurosci.* **8**:2460-2467, 1988). In both models the marked diminution of the potassium currents at positive membrane potentials can be accounted for by (1) an exponential dependence on membrane potential of calcium entry through open channels and (2) a dependence of the potassium current on the fourth power of the intracellular calcium concentration. With these factors the theoretical calculations provide an accurate description of the previous experimental results. (Supported by NIH Grants NS09660 and DC00276)

ADENOSINE MODULATES A TRANSIENT OUTWARD CURRENT IN RAT LOCUS COERULEUS NEURONS. W. J. Pan* and S. A. Shefner. Dept. of Physiology and Biophysics, University of Illinois, College of Medicine, Chicago, IL 60612.

We have previously shown that adenosine decreases the duration of the action potential in locus coeruleus (LC) neurons. In the present study, the mechanism by which adenosine affects the shape of the action potential was examined. Intracellular recordings from LC neurons were obtained in a submerged rat brain slice preparation. All drugs were administered by bath application. LC neurons fired spontaneously at rates of 1.0 to 3.5 Hz. Ba^{2+} (1 mM) was administered to prolong the duration of the action potential. Adenosine (100-300 μM) reduced the duration of the Ba^{2+} spike measured at 33% of the peak amplitude by 11.5±2.8% (n=7). In these same cells, administration of 4-aminopyridine (4-AP) (30-100 μM) in addition to Ba^{2+} further increased the duration of the action potential. Administration of adenosine then failed to decrease the duration of the Ba^{2+} and 4-AP enhanced action potential.

An I_A-like transient outward current was investigated using single-electrode voltage clamp in the presence of 0.5 μM TTX and 20 mM Mg^{2+}. Inactivation curves were obtained in 5 cells; I_A was measured following a 1 sec prepulse to a holding potential between -100 and -40 mV, followed by a 200 ms depolarization to between 0 and +10 mV. This outward current was reduced by 30-100 μM 4-AP and blocked by 1 mM 4-AP. On the average, the I_A-like current was 50% inactivated at a holding potential of -60±1.0 mV, and 80% inactivated at a holding potential of -56±0.9 mV, which is very near the threshold for LC neurons. At threshold, adenosine (300 μM) shifted the inactivation curve in a parallel manner in the positive direction by 4.7±0.5 mV, and increased I_A by 132±23%. These data suggest that adenosine decreases the duration of the action potential in LC neurons by potentiating an I_A-like current.

MUSCARINE-SENSITIVE, INWARDLY-RECTIFYING K^+ CONDUCTANCE IN A SYMPATHETIC NEURONE. D.E. Kurenny, H. Chen & P.A. Smith*, Dept. Pharmacol., Univ. Alberta, Edmonton, Canada T6G 2H7.

The inwardly-rectifying K^+ conductance activated in submucosal neurones by noradrenaline, somatostatin and [Met^5] enkephalin involves 30-65, 120-160 and 220-260pS channels (Shen *et al.,* J. Physiol., **445**:581,1992) whereas that activated by acetylcholine in atrial cells involves a single type of unitary conductance (20pS 'I_{ACh}' channel; Clark *et al.,* J. Physiol., **424**:229,1990). A question therefore arises as to whether the conductance activated by muscarinic agonists in neurones involves one type of unitary conductance or whether multiple unitary conductances are involved. Also, the mechanism of this inward rectification remains to be elucidated. We studied the action of 10μM muscarine on the small (C) cells of bullfrog sympathetic ganglion using whole-cell and single channel recording techniques (*see* Selyanko *et al.,* J. Physiol., **425**:471,1990). The activation curve for the muscarine-sensitive conductance was fitted by Boltzmann-type kinetics (potential for half activation = -53mV; valency = -2.3). The extent of inward rectification was increased by elevating $[K^+]_o$ but was not influenced by changing $[Mg^{2+}]_i$ or $[Na^+]_i$. Thus, the rectification does not result from the internal blocking of the channel by Mg^{2+} or Na^+ (Vandenberg, Proc. Natl. Acad. Sci. USA., **84**:2560,1987). Muscarine increased the activity of at least two types of channel in outside-out patches (20pS and 50pS with $[K^+]_o$ = 20mM; $[K^+]_i$ = 110mM). The 20pS channel exhibited linear I-V characteristics. Possible interpretations of these data are that some channels are controlled by a voltage-sensitive gate which is opened by hyperpolarization or that rectification involves blockade of the channel by the outward movement of K^+. In these aspects, the inhibitory action of muscarine on peripheral neurones resembles that of adrenoceptor and peptidergic agonists. Supported by the MRC of Canada.

565.4

IS DIACYLGLYCEROL INVOLVED IN THE EFFECT OF MUSCARINE ON SYMPATHETIC GANGLION CELLS? H. Chen*, D.E. Kurenny and P.A. Smith. Dept. Pharmacol., Univ. Alberta, Edmonton, T6G 2H7, Canada.

Muscarinic agonists depolarize frog sympathetic ganglion cells and this effect involves suppression of a voltage-dependent, non-inactivating K^+-current known as the M-current (I_M, Brown & Adams Nature **283**:673,1980). We used whole-cell patch-clamp recording techniques to investigate the transduction mechanism for this response. Although muscarine (0.5-1μM), phorbol-12-myristrate-13-acetate (2-20μM) and phorbol dibutyrate (1-10μM) all inhibited I_M, their effects were insensitive to the kinase inhibitor, H-7 (1-(5-Isoquinolinylsulfonyl)-2-methylpiperazine; 50-75μM). Responses to 1-oleoyl-2-acetyl-*sn*-glycerol (5-20μM) were weak and inconsistant. Since muscarinic agonists promote hydrolysis of membrane phospholipid in these cells (Pfaffinger *et al.,* Neuron **1**:477,1988) and the action of muscarine seems independent of membrane phosphorylation (Chen & Smith, Br. J. Pharmacol., **105**:329,1992), these data raise the possibility that diacylglycerol (DAG) functions as a second messenger for I_M suppression which acts *directly on the channel without the involvement of protein kinase C.* This possibility is unlikely because inhibition of DAG catabolism with the DAG kinase inhibitor, R 59022 (20-50μM, Janssen Biotech) and/or the non-specific lipase inhibitor, quinacrine (up to 2mM) failed to potentiate the effects of muscarine. Also, high concentrations of phorbol esters (up to 20μM) could not produce the same maximal response as muscarine.

Supported by the MRC of Canada.

EFFECTS OF MUSCARINIC AGONISTS ON INTRACELLULAR CALCIUM CHANGES IN ACUTELY DISSOCIATED SYMPATHETIC NEURONS. S. Foucart* and R.J. Miller. Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637, USA.

In this study, we evaluated the effects of carbachol (Cch) and oxotremorine (OXO) on intracellular calcium $[Ca^{2+}]_i$ in neurons acutely dissociated from the superior cervical ganglion of adult rats. The neurons were dissociated enzymatically, plated on poly-l-lysine treated coverslips and used within the next 20 hours. The cells were loaded with Fura2-AM (3 μM, 30 min) and mounted in a perfusion chamber. The perfusion medium contained 2 mM $CaCl_2$, 138 mM NaCl, 5 mM KCl, 2 mM $MgCl_2$, 10 mM HEPES and 10 mM glucose, (7.4). The $[Ca^{2+}]_i$ was estimated by microfluorometry. The basal $[Ca^{2+}]_i$ was 52 ± 3 nM (n=90). Application of Cch (10 μM) or OXO (10 μM) increased the $[Ca^{2+}]_i$ by 86 ± 7 nM and 38 ± 10 nM, respectively. The effects of Cch and OXO were blocked by atropine (1 μM) but not by hexamethonium (10-50 μM). Caffeine sensitive store depletion, pertussis toxin treatment and application of staurosporine (1 μM) or thapsigargin (0.1 μM) did not affect the actions of the muscarinic agonists but omission of Ca^{2+} from the perfusion medium as well as Ca^{2+} channel block with TA 3090 (50 μM) abolished it. These results suggest that the increase in $[Ca^{2+}]_i$ produce by muscarinic agonists does not involve the mobilization of intracellular calcium stores, but rather is mediated by Ca^{2+} influx through voltage-sensitive calcium channels.

CHOLINERGIC MODIFICATION OF SYNAPTICALLY INDUCED Ca TRANSIENTS IN HIPPOCAMPAL CA1 PYRAMIDAL NEURONS. H.Miyakawa*, K.Ito, I.Nakamura, H.Kato, Dept. of Physiology, Yamagata Univ. Sch. of Med., Yamagata, 990-23 JAPAN

Hippocampal CA1 pyramidal neurons receive cholinergic inputs from septal area. Although this input is thought to play a crucial role in memory, the specific nature of the role is not understood. If cholinergic input to hippocampus is really important in memory, cholinergic agonists might be expected to modify long-term potentiation (LTP) because LTP is believed to underlie memory mechanism. Indeed, it has been reported that cholinergic agonists enhance LTP (Blitzer et.al., Shulz & Johnston). Then, what is the mechanism by which cholinergic agonists enhance LTP? Here we report that cholinergic agonists prevent synaptically induce Ca transients from quickly returning back to basal level.

We prepared guinea-pig hippocampal brain slices, injected Ca indicator dye fura-2 into a CA1 pyramidal neuron through an intracellular pipette, and monitored intracellular Ca level at its dendrites and the soma while recording membrane potential from the soma. In standard medium, Schaffer collateral synaptic stimulation evoked a transient Ca rise both at dendrites and at the soma. The Ca rise was linked to synaptically evoked action potentials. The Ca level started to decline immediately after the input and quickly recovered to basal level. In contrast, in the presence of 5-10μM carbachol, the decay time of Ca transients became twice as slow as in the standard medium. Although evoked action potentials became wider in carbachol, amplitude of Ca increase driven by supra-threshold synaptic input was not significantly different in both conditions. These facts imply that some secondary processes are responsible for the prolonged Ca transients.

We surmise that prolonged duration of elevated Ca level after conditioning inputs could be the mechanism by which cholinergic inputs enhance LTP. (supported by MESC grant #02259105 and HFSP)

PATTERN OF CAFFEINE-INDUCED CALCIUM RELEASE IN CULTURED MOUSE HIPPOCAMPAL NEURONS. K. J. Seymour-Laurent* and M. E. Barish. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

The spatial and temporal pattern of ryanodine-sensitive caffeine-induced calcium release have been investigated using calcium-sensitive dyes (Fluo-3 and Calcium Green) and confocal microscopy. Mouse hippocampal neurons were dissociated on embryonic days 15-17 and studied after 1-12 days in culture. Cells were continually perfused with normal Hank's BSS containing 0.3 μM glutamate and 10 μM glycine. Changes in [Ca]i, measured when 10 mM caffeine was puffed onto single cells, were spatially non-uniform. In most pyramidally-shaped cells the caffeine response was first seen in the apical region of the cell within 2 seconds of initiation of the caffeine pulse, irrespective of pipette position. It then spread to the remaining parts of the cell over a period of 3 to 5 seconds. The nucleus was the last area to show elevated [Ca]i, and [Ca]i in the nucleus remained high after the cytoplasm had returned to resting levels. The change of [Ca]i in the nucleus usually exceeded that in the cytoplasm, and thin (1 μm), rapidly aquired (0.4 seconds/frame) optical sections revealed radial invasion of the nucleus. Organelle-specific dyes showed that endoplasmic reticulum and mitochondia are concentrated in the cell's apical region. We suggest that caffeine initiates propagating calcium release in regions of highest endoplasmic reticulum density and that nuclear invasion may be due to diffusion from the cytoplasm.

565.8

CALCIUM SIGNALLING IN POSTSYNAPTIC SPINES VISUALIZED WITH CONFOCAL MICROSCOPY. A. Hernandez-Cruz*, M.P. Charlton and G.J. Augustine. Dept. Neurosciencias, UNAM, Dept. Physiology, Univ. Toronto, Dept. Neurobiology, Duke Medical Center and MBL, Woods Hole.

We have used the Noran real-time confocal microscope to measure dynamic changes in postsynaptic Ca concentration produced by synaptic activity. The fluorescent Ca indicator, Ca green, was microinjected into the postsynaptic neuron of the squid giant synapse. This neuron forms synaptic contacts at small spines at the end of branched dendritic processes. Brief trains of presynaptic activity (50 Hz, 1-5 s) produced prompt rises in postsynaptic Ca concentration that decayed over several seconds. No such changes occurred during directly evoked postsynaptic action potentials, indicating that Ca was entering through transmitter-activated (CNQX-sensitive) channels rather than through voltage-activated channels. The synaptically-induced rises in Ca were largest in the spine tips, but smaller changes were observed throughout the entire dendritic structure. No measurable changes in Ca could be detected in other regions of the postsynaptic neuron, probably because the large volume of this neuron diluted the Ca signal. In summary, postsynaptic Ca signals are not as acutely compartmentalized in these spines as in hippocampal spines (e.g. *Nature* 354: 73&76, 1991). Supported by a Kuffler Fellowship and grants from CONACyT, MRC and NIH.

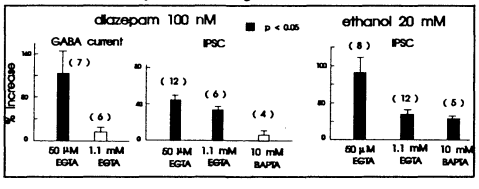
Does intracellular Ca^{2+} play a role in diazepam- or ethanol-induced potentiation of $GABA_A$ currents in hippocampal neurons?

L. Zhang*, J.L. Weiner, A.A. Velumian & P.L. Carlen, Playfair Neurosci. Unit, Toronto Hospital, Depts. of Physiology & Pharmacology, Bloorview Epilepsy Prog., Addiction Res. Found., U. of Toronto, Canada M5T 2S8.

We studied $GABA_A$-mediated IPSCs and GABA currents in rat CA1 hippocampal neurons using whole-cell patch recordings in brain slices. Our standard internal solution contained in mM: K-gluconate 130, KCl 20, Mg-ATP 2, GTP 0.2, HEPES 10, EGTA 1.1, $CaCl_2$ 0.1. In neurons dialysed with the standard internal solution or an internal solution containing 50 μM EGTA, bath application of 100 nM diazepam, midazolam, or 20 mM ethanol significantly potentiated the $GABA_A$-mediated responses. In neurons dialysed with the internal solution in which EGTA/Ca was replaced by 10 mM BAPTA, the potentiation of $GABA_A$-mediated responses by diazepam or ethanol, but not by midazolam, was much less pronounced (see graph below). The underlying mechanisms are currently under investigation.



565.10

REBOUND POTENTIATION OF INHIBITORY SYNAPTIC CURRENTS IN CEREBELLAR PURKINJE CELLS.
M. Kano, J. Dreessen, U. Rexhausen and A. Konnerth*. Max-Planck-Inst. biophys. Chemie, 3400 Göttingen, Germany.

The best known form of synaptic plasticity in cerebellar Purkinje cells (PCs) is a long-term depression (LTD) of excitatory parallel fiber (PF) synapses, resulting from repetitive and conjunctive stimulation of PFs and climbing fibers (CFs). Here we report a new form of synaptic plasticity in cerebellar PCs in which stimulation of the excitatory CF synaptic input leads to a long-lasting (several hours) potentiation of $GABA_A$ receptor-mediated inhibitory postsynaptic currents (IPSCs), a phenomenon which we termed rebound potentiation (RP). By using simultaneous whole-cell patch-clamp recordings and fura-2 video-imaging of intracellular calcium concentration ($[Ca^{2+}]_i$), we found that a CF-induced transient increase in postsynaptic $[Ca^{2+}]_i$ triggers RP. Several lines of evidence indicate that RP is caused by a Ca-dependent up-regulation of postsynaptic $GABA_A$ receptor function in PCs. The possible role of other second messengers for this up-regulation will be discussed. We propose that RP of IPSCs is a cellular mechanism which, in addition to the LTD of excitatory PF synapses, contributes to motor learning in the cerebellum.

CHANGES IN pH MODULATE NMDA- AND HIGH-$[K^+]_o$-EVOKED RISES IN CYTOSOLIC FREE CALCIUM CONCENTRATION IN RAT HIPPOCAMPAL PYRAMIDAL NEURONS. K. Abdel-Hamid* and J. Church. Depts. of Physiology and Anatomy, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1Z3.

NMDA receptor-mediated responses are sensitive to changes in $[H^+]_o$, which might in part account for the anticonvulsant and neuroprotective effects of cerebral acidosis. Ca^{2+} entry via voltage-gated Ca^{2+} channels may also be important for the genesis of convulsive and neurodegenerative phenomena. We have investigated the effects of changes in pH_o and pH_i on rises in $[Ca^{2+}]_i$ evoked by NMDA and high-$[K^+]_o$ in Fura-2-loaded rat hippocampal pyramidal neurons prepared from 18-day-old embryos. In HCO_3^--buffered media, pH was altered by changing $[HCO_3^-]_o$ at a constant P_{CO_2} (5%); in HCO_3^-/CO_2-free, HEPES-buffered media, pH was manipulated with NaOH. All ionic changes were made by substitution for NaCl on an equimolar basis.

In both HCO_3^-/CO_2- and HEPES-buffered media reducing pH to 6.9 attenuated, and raising pH to 7.8 enhanced, rises in $[Ca^{2+}]_i$ evoked by NMDA or high-$[K^+]_o$, compared to responses obtained at pH 7.4. Experiments with methylsulfate-substituted media (pH 7.4) demonstrated that the effects of perfusion with high-HCO_3^- did not reflect changes in $[Cl^-]_o$. Reducing or raising pH_i (at a constant pH_o) by perfusion with media containing weak acids (propionate, butyrate) or a weak base (trimethylamine), respectively, had little effect on either NMDA or high-$[K^+]_o$-evoked responses although small falls and small rises in resting $[Ca^{2+}]_i$ were often noted in response to intracellular acidification and alkalinization, respectively.

The results suggest that changes in pH_o may modulate Ca^{2+} influx via voltage-gated, as well as NMDA receptor-operated, channels.

NMDA INDUCED REGENERATIVE CALCIUM INFLUX IN HIPPOCAMPAL PYRAMIDAL CELLS. Q.X. Chen* and R.K.S. Wong. Dept. of Pharmacology, SUNY/HSC, Brooklyn, NY 11203.

Whole-cell voltage-clamp was carried out in internally perfused neurons acutely dissociated from the CA1 region of the hippocampus of adult guinea-pigs. Introduction of elevated Ca^{2+} containing medium into the cell activated an outward potassium current followed by an inward current. The Ca^{2+}-dependent inward current has the following properties: (1) It is activated by intracellular Ca^{2+} $\{[Ca^{2+}]_i\}$. (2) Its activation is not voltage-dependent. (3) It can be blocked by extracellular cadmium (1 mM). (4) It is in part carried by Ca^{2+}. We termed this inward current $I_{in(Ca^{2+})}$. Because of the dependency on $[Ca^{2+}]_i$ and its Ca^{2+} permeability, we found that $I_{in(Ca^{2+})}$, once induced, became self-sustaining and regenerative. That $[Ca^{2+}]_i$ level progressively increased following the induction of $I_{in(Ca^{2+})}$ is indicated by the growth in amplitude of the Ca^{2+}-dependent K^+-current. Intense stimulation of NMDA receptors, via NMDA bath application (100 uM, >5s), in the adult hippocampal cells activated $I_{in(Ca^{2+})}$. In contrast, activation of other glutamatergic receptors by kainate and QUIS to the same magnitude did not elicit $I_{in(Ca^{2+})}$. Our previous studies show that $GABA_A$-responses in the hippocampal pyramidal cells are suppressed by a dephosphorylation process when $[Ca^{2+}]_i$ is elevated (Chen et al 1989, *J. Physiol.* 420). We now demonstrate that through this mechanism, intense neuronal excitation via NMDA-receptor can suppress $GABA_A$-receptor mediated reponses of the same neuron following the induction of $I_{in(Ca^{2+})}$.

NMDA and non-NMDA Receptors Mediate Extracellular Alkalinizations in the Rat Hippocampal Slice. J. C. T. Chen* and M. Chesler; Dept of Physiology & Biophysics and Dept of Neurosurgery, NYU Medical Center, 550 First Ave. N. Y., NY 10016.

Stimulation of Schaeffer collaterals or local application of glutamate evokes picrotoxin-insensitive alkalinizations in area CA1 (1). We have extended our studies of these responses using pH-sensitive microelectrodes.

Cd^{2+} (100μM), TTX (1μM), and zero Ca media did not affect glutamate-evoked alkalinizations, suggesting that Na channels and Ca-dependent mechanisms do not directly mediate these responses. Dihydrokainate (200μM) had no effect on afferent stimulus-evoked alkalinizations, excluding a role for glutamate uptake.

In normal media, CNQX (10μM) blocked Schaeffer collateral-evoked alkalinizations while APV (20-50μM) had no effect. During CNQX superfusion, removal of voltage-dependent block of NMDA channels by withdrawal of Mg^{2+} revealed an APV-sensitive alkalinization similar in magnitude to control. These results suggest that NMDA receptors can also contribute to stimulus-evoked alkalinizations.

We tested whether involvement of both receptor subtypes was simply due to the firing of the CA1 population. Pure antidromic activation of the CA1 cells (by stimulation of subicular alveus during superfusion with CNQX, APV and PTX) evoked extremely small alkalinizations. Despite a population spike of comparable size, orthodromic stimulation evoked 5-fold greater alkalinizations. These data indicate that synaptically-evoked alkaline shifts cannot be attributed to cell firing per se.

Our data indicate that the mechanism underlying the stimulus-evoked alkaline shift is closely linked to the activation of excitatory amino acid receptors. These results support the hypothesis that this phenomenon is generated by passage of proton equivalents through ligand-gated ion channels.

SPONTANEOUS TO EVOKED NMDA CURRENTS IN CEREBELLAR GRANULE CELLS. E.D'Angelo, P.Rossi, E.Parati*, V.Taglietti, Institute of General Physiology, University of Pavia, 27100 Pavia, Italy. *Istituto Neurologico C. Besta, 20133 Milano, Italy.

The aim of present work is to compare spontaneous to evoked NMDA current kinetics. Conventional whole-cell recordings of excitatory currents were obtained from granule cells in cerebellar slices at P10-P14 . Spontaneous NMDA currents could be observed in the presence of the non-NMDA receptor inhibitor 10 μM CNQX, and were suppressed by 50 μM APV (n=19). Individual currents were small (<5pA at -40 mV) and noisy, and in virtual Mg^{++}-free solution (n=6) showed evident single channel transitions generating irregular shapes. In order to compare spontaneous to evoked NMDA currents, unstimulated current traces were displayed (off-line) on computer monitor, a baseline was selected and spontaneous events were picked-up semi-automatically (signals with signal-to-noise ratio <2 were rejected). When averagings were obtained by aligning individual currents on their starting or half-rise point, good correlation was found with the (slow) time-course of evoked NMDA currents in the same cells. However, a fast initial component (10-90% rise-time <1ms) was often generated by synchronizing spontaneous events at their peak. This fast component should be distinguished by the fast non-NMDA currents, which were virtually observed in isolation at -80 mV and presented 200-400 μs 10-90% rise-times.

IPSPs STRONGLY INHIBIT CLIMBING FIBER ACTIVATED $[Ca^{2+}]_i$ INCREASES IN THE DENDRITES OF CEREBELLAR PURKINJE NEURONS. J.C. Callaway*, W.N. Ross and N. Lasser-Ross. Dept. of Physiology, New York Medical College, Valhalla, NY 10595.

The interaction between IPSPs and climbing fiber (CF) evoked EPSPs was analyzed in the guinea pig cerebellar slice preparation using intracellular recording and high speed fluorescence imaging of intracellularly injected fura-2. All-or-none CF responses were evoked by stimulation of the white matter; IPSPs, blockable by 10 μM bicuculline, were generated by off-beam stimulation in the molecular layer.

CF responses generated large, transient $[Ca^{2+}]_i$ increases due to Ca spikes which usually extended over all dendritic regions. When IPSPs and CF responses were activated simultaneously the Ca transients were reduced in amplitude, sometimes by more than 90%. Most often the Ca transients in the distal dendrites were reduced more than those in the proximal dendrites. The peak amplitude of the somatically recorded CF potential was not reduced by this interaction. The most significant change in the electrical response was a small reduction in the shoulder which followed the peak potential.

If the inhibitory stimulation preceded the CF response by 10-20 msec (the rise time of the IPSP) the Ca transients were still inhibited, but earlier stimulation had no effect. Somatic hyperpolarization by double the IPSP amplitude did not reduce the CF induced Ca transients. These experiments suggest that the increased inhibitory conductance, not the potential, caused the reduction by preventing the generation and/or propagation of dendritic Ca spikes.

FUNCTIONAL TOPOGRAPHY OF INHIBITION IN RAT SOMATOSENSORY CORTEX. P.A. Salin and D.A. Prince*. Department of Neurology and Neurological Sciences, Stanford University School of Medicine, Stanford, CA, 94305.

Postsynaptic inhibition is an important mechanism for regulating neuronal excitability and synchronization in normal cortex, however functional details regarding its laminar distribution are incomplete. We used the whole cell patch clamp technique to record postsynaptic inhibitory currents (IPSCs) mediated by $GABA_A$ receptors in identified pyramidal neurons of layers 2-3 and 5 in adult rat somatosensory cortex (S1). The frequency (3.4-35 Hz) and the amplitude (5-310 pA, for V_{hold}= 0 mV and E_{Cl}= -45 mV) of spontaneous IPSCs was highly variable. The mean amplitude of 19.7 pA would correspond to an inhibitory potential of -3.9 mV under the above experimental conditions (R_N= 200 MΩ). In most cases IPSCs decayed with a single time constant close to 7 msec. Preliminary results indicate that inhibitory input varies in part with the cortical laminar organization since layer 5 cells generated a higher frequency of spontaneous IPSCs (mean: 20.2 Hz, n= 8) than those in layer 2-3 (mean: 10.5 Hz, n= 10, p<0.02, Mann-Whitney U test). The topography of inhibitory cortical circuits was examined by applying focal electrical stimulation at different measured distances from the recorded neuron. In solutions containing D-APV (100μM) and CNQX (10μM), threshold monosynaptic IPSCs were evoked in layer 2-3 and 5 cells when stimulating electrodes were in layer 1. Stimuli delivered up to 670 μm lateral to the layer 5 cell, outside the barrel field of the recorded neuron, could evoke IPSCs. These results demonstrate that somatosensory cortex pyramids receive extensive functional inhibitory contacts that may be differentially expressed in cells of different laminae. The strength of the inhibition could play a key role in synchronization mechanisms in layer 5. (supported by NIH grants NS12151, NS07280 from NINDS. P.S. is a fellow of the Fyssen Foundation).

A LOW-FREQUENCY SUBTHRESHOLD RESONANCE IN NEOCORTICAL NEURONS GENERATED MAINLY BY I_h. B. Hutcheon* and E. Puil, Department of Pharmacology & Therapeutics, University of British Columbia, Vancouver, B.C., Canada. V6T 1Z3

The rhythmic, low-frequency events that characterize the EEG during various behavioral states reflect the coordinated activities of large groups of neurons. We propose that many neocortical neurons are follower rather than pacemaker cells, and have investigated the possibility that the intrinsic properties of the follower neurons predispose them to be driven at particular frequencies -- a feature that could contribute to intercellular synchronization. We examined, using whole-cell patch-clamp techniques, the subthreshold responses of neurons in neocortical slices to intracellular injections of oscillatory inputs in order to determine membrane impedance as a function of frequency. The neurons exhibited properties that bias their responses towards low frequencies (< 10Hz).

The magnitude of the impedance in some neurons declined steeply, and monotonically, with frequency (1/2 magnitude, 5-20 Hz). In other neurons, the impedance magnitude function near rest (-50 to -60 mV) showed a voltage-dependent resonant hump with a maximum between 1-3 Hz. The resonance shifted to higher frequencies (3-6 Hz) and gradually became less distinct with lower overall impedance as the cell was hyperpolarized by 10-50 mV. When voltage clamped near rest, and hyperpolarized, these neurons showed slow inward currents with a voltage dependence and time course which could be predicted from the resonance. These results suggest that the resonance is mainly due to the hyperpolarization-activated cation current, I_h. The resonance and the inward currents were reduced in extracellular Cs^+ -- also consistent with an involvement of I_h. The shape and position of the resonant hump did not depend on the time course of the input function, or whether current or voltage was used as input. Modeling of I_h in the absence of other slow voltage-gated currents such as I_T, showed that I_h by itself is capable of producing the resonance in neocortical neurons.

DIFFERENCES IN REPETITIVE FIRING BETWEEN ADULT AND IMMATURE RAT SENSORIMOTOR CORTICAL NEURONS MIMICKED BY CALCIUM CHELATION. Lorenzon, N. M*, and Foehring, R. C., Dept. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38103-4901.

In adult cortical pyramidal cells, long current injections result in regular, repetitive firing followed by a slow afterhyperpolarization (sAHP). In immature (P6-10) neurons, the sAHP following repetitive firing is much larger and is greatly prolonged relative to adult cells, resulting in more prominent spike-frequency adaptation in the immature cells. Some immature neurons will not fire longer than 200 ms. Several potential mechanisms could explain these age-dependent differences. One possibility is that Ca^{2+}-handling differs at the two ages. A recent study in cat motor cortex (Schwindt *et al.* 1992. Neuroscience 47:571) reported increased sAHP amplitude and duration, and more phasic firing, when low doses of the Ca^{2+} chelator BAPTA were included in the intracellular electrode. We tested whether the immature firing pattern could be elicited in adult rat cortical neurons impaled with electrodes including 2mM BAPTA (in 2M K-methylsulphate), and whether higher doses of BAPTA (200 mM) resulted in loss of the sAHP and spike-frequency adaptation in young and mature neurons. Intracellular recordings were obtained from an in vitro slice preparation.

We found that 200 mM BAPTA greatly reduced AHPs and adaptation at both ages. 2 mM BAPTA caused adult neurons to have enlarged, prolonged AHPs and the immature firing pattern. The BAPTA-enhanced sAHP in adults was reduced by 100 µM isoproterenol and when extracellular Ca^{2+} was replaced with Mn^{2}.

POSTSYNAPTIC MECHANISMS II

566.1

SIGNAL DELAY IN PASSIVE DENDRITIC TREES. I. Segev* and H. Agmon-Snir. *Dept. of Neurobiology, Hebrew University, Jerusalem, Israel.*

The signal delay of neurons is significantly affected by the cable properties and morphology of the dendrites. This dendritic delay plays an important role in information processing and in plastic processes at the neuron. A novel analytical approach for calculating the delay of electrical signals in any passive dendritic tree is introduced. The ***dendritic delay*** (D_Delay) is defined hereby as the difference between the *center of gravity (the centroid)* of the transient current input and the *center of gravity* of the resultant voltage transient, measured at any point in the tree. The D_Delay measured at the input point is non-zero and is called the ***local delay*** (L_Delay). ***Propagation delay*** (P_Delay) is then defined as D_Delay - L_Delay. Using the Laplace transform of the one-dimensional passive cable equation, and the mathematical relation between this Laplace transform and the centroid, an analytical expression for the D_Delay between any two points in the tree can be found.

With these definitions for delays, several general theorems are proven. For example: i) D_Delay between two points (x,y) in a given tree is independent of the properties (shape and duration) of the transient current input. ii) In a given tree, D_Delay(x,y) = D_Delay(y,x) iii) Both the P_Delay and the signal's speed of propagation are independent of the morphology of the tree "behind" the signal, and of the input location.

The delay in an isopotential, isolated, soma is τ, the time constant of the membrane. In an infinite cylinder with uniform properties, the local delay is $\tau/2$ and the speed of propagation is $2\lambda/\tau$, where λ is the space constant. In realistically complicated trees, the dendritic delay from distal dendritic input to the soma may range from 1-2τ. The delay between adjacent dendritic branches, however, may be as small as 0.3τ. The significance of the results for computation and learning at the neuronal level will be discussed.

566.2

SPACE-CLAMP ERRORS ASSOCIATED WITH MEASUREMENT OF ELECTROTONICALLY REMOTE SYNAPTIC EVENTS. *N. Spruston*, D. Jaffe, S.H. Williams & D. Johnston*, Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

The frequency-dependent voltage attenuation and resultant space-clamp errors associated with the measurement of synaptic current are evaluated both in equivalent cylinder models and in a detailed compartmental model of a hippocampal CA3 pyramidal neuron. We show that in both models, as expected, higher-frequency voltage changes are attenuated to a much greater extent than steady-state or low-frequency voltage changes.

The effect of increases in membrane resistivity (R_m) were also examined and found to dramatically reduce steady-state voltage attenuation, while having only small effects on the non steady-state components of synaptic responses. The consequence of the frequency-dependent reduction in voltage attenuation by increases in R_m is that experimentally increasing R_m (e.g., with the use of Cs^+-containing patch-clamp electrodes) can result in improvements in the accuracy of measured reversal potentials (which are in error according to the steady-state electrotonic distance of the synapse) without substantial improvements in the accuracy of peak current, conductance, rise time, or decay time constant measurements (which are in error according to the electrotonic distance for the high-frequency components in fast synaptic responses).

Finally, we use simulations from a morphological model of a CA3 pyramidal neuron to demonstrate the distortion of mossy fiber and commissural/associational synaptic currents at the soma, and to estimate the electrotonic distances of mossy fiber and perforant path synapses. We conclude that the error associated with synaptic current measurement can be extremely large for synapses located at electrotonically remote sites in the dendritic tree. 566.3

INTEGRATIVE PROPERTIES OF HIPPOCAMPAL, CORTICAL AND THALAMIC NEURONS STUDIED BY WHITE NOISE ANALYSIS H. Jahnsen* and S. Karnup Institute of Neurophysiology, Blegdamsvej 3 c, DK-2200 Copenhagen N, Denmark.

Synaptic potentials in nerve cells activate intrinsic membrane properties and synaptic integration is therefore a result of complex interactions in space and time.

In an attempt to study these processes in mammalian central neurons intracellular recordings were obtained from hippocampal, cortical and thalamic neurons in slices or slice cultures. The cells were stimulated with a band-pass filtered white noise signal to simulate a synaptic barrage and the responses were analyzed in the frequency domain.

Our results show that at least four factors are important for the spectral characteristics of neurons below the threshold for firing of action potentials: the passive membrane properties, the average membrane potential, presence or absence of a Q-current and the presence or absence of a low-threshold Ca^{2+} spike. In the frequency domain these four factors are seen to give their own characteristic contribution to the integrative properties of central neurons.

566.4

BIOPHYSICAL MODEL OF HIPPOCAMPAL MOSSY FIBER SYNAPSES. M.Siegel[1], R.Gonzales[4], N.T.Carnevale*[1,3], B.Claiborne[4] and T.H.Brown[1,2,3]. Departments of Psychology[1] and Cellular and Molecular Physiology[2] and Center for Theoretical and Applied Neuroscience[3], Yale Univ., New Haven, CT 06520, and Division of Life Sciences[4], Univ. Texas, San Antonio, TX 78249.

The mossy fiber (MF) inputs to CA3 neurons, which are among the largest synapses in the mammalian brain, terminate on "thorny excrescences" (thorns) located on proximal apical dendrites. Because of their size and strategic location, these have been regarded as "detonator" synapses that might serve as "teacher signals" in the mnemonic operations of the hippocampus. We have probed their biophysical properties and functional implications using models based on quantitative morphometry and biophysical measurements.

Three-dimensional reconstructions, noting locations of thorns, were obtained from rat CA3 neurons that had been injected with horseradish peroxidase. Ultrastructure of thorns was based on 3-D reconstructions from electron micrographs (Chicurel & Harris, personal communication). Compartmental models (Claiborne et alia in: *Single Neuron Computation*, Academic Press, in press) were constructed from these data and whole cell patch clamp measurements (Xiang et al., *Soc. Neurosci. Abstr. 18*, in press). MF synapses represented by alpha functions were located on the heads of thorns (see Jaffe and Brown, *Soc. Neurosci. Abstr. 18*, in press).

Three principal conclusions emerged from these simulations. First, thorns have essentially no effect on transfer of potential, current or charge from spine head to dendritic shaft. Second, synaptic current rise time can be used to judge the "quality" of whole-cell voltage clamp recordings so that synaptic reversal potential, charge transfer, peak conductance and peak current can be determined accurately for many MF inputs. Third, MF synapses are not "detonators"—at least 10 must be activated to trigger a somatic spike. *Supported by ONR and NIH.*

MODELING DENTATE GRANULE CELLS WITH "OLD" AND "NEW" ELECTROTONIC PARAMETER VALUES. W.R. Holmes*, Neurobiology Program, Dept. of Biological Sciences, Ohio University, Athens, OH 45701.

Recent studies indicate that the typical values of the electrotonic parameters Rm and Ri used in models need to be revised. For dentate granule cells, studies with perforated-patch electrodes (Spruston and Johnston, 1992) suggest that Rm and Ri values of 40 kΩcm2 and 210 Ωcm are more appropriate than older estimates of 12 kΩcm2 and 70 Ωcm. Results are compared when these old and new sets of values are used in models of a dentate granule cell whose morphology is known from serial reconstructions.

Single action potentials and action potential trains due to current injection were modeled (conductances modified from Yuen and Durand 1991). The gbars in simulations with the old Rm and Ri values were nearly double those with the new values to get comparable action potentials. The DAP following a single action potential decayed much faster with the old values. With the new values, the action potential was more severely attenuated as it spread to the dendrites, but the dendrites were depolarized much longer because of the longer DAP. Spike train adaptation was greater with the old Rm and Ri values.

Synaptic activation in the mid-dendritic region was modeled. Synaptic conductance parameters were adjusted to give comparable peak EPSPs with both sets of Rm and Ri. When synapses were activated at 100 Hz, the peak potential was larger (due to action potential invasion), but average potential was smaller, and consequently, calcium influx through NMDA receptor channels was smaller with the old Rm and Ri values than with the new ones.

It might be possible to compensate for some of these differences by changing conductance kinetics, or by adding additional conductances. To limit the number of degrees of freedom, one must fix appropriately and accurately as many parameters as possible, beginning with Rm and Ri.

566.6

Voltage-Clamp and Current-Clamp Investigation of Ionic Conductances in Hippocampal CA1 Pyramidal Neurons using QX-314. J.Isaac, S.B.Colling, and H.V.Wheal(SPON: Brain Research Association) Dept. Physiology & Pharmacology, University of Southampton, Bassett Cres.East, Southampton, SO9 3TU, UK.

The excitatory afferents onto CA1 pyramidal cells in the hippocampus have recently attracted considerable attention in the investigation of long term potentiation (Malinow & Tsien, 1990 *Nature*,**346**,177-180). However by the use of QX-314, we have previously reported (Colling *et al.*, 1991, Neurosci.Abstr. **17**,605.8) that there is a Na^+ spike generating system in the apical dendrites of these cells which may effect Hebbian mechanisms. In order to clarify exactly which conductances QX-314 acts on, voltage- and current-clamp investigations were carried out on CA1 pyramidal cells in rat hippocampal slices maintained *in vitro*. Current-clamp data revealed that intracellular injection of QX-314 (35mM) blocks somatic and dendritic action potentials in a time dependent manner (30-56 minutes, n=5, at twice threshold stimulation), with no noticeable effect on the underlying EPSP's. When QX-314 (20mM) was introduced via whole-cell patch electrode the synaptically evoked Na^+ spike responsible for the action potential was blocked within 10 minutes (n=5, at twice threshold stimulation) and no adverse effects were observed on the underlying EPSC's. Observation of cellular voltage-gated conductances revealed that QX-314 blocked all the Na^+ currents leaving only inward Ca^{2+} currents. In comparison externally applied 0.5μM tetrodotoxin blocked the same voltage-gated currents but also blocked the EPSC. Thus QX-314, when used intracellularly, blocks the voltage-gated Na^+ conductances responsible for the action potential without adversely effecting either the EPSP/EPSC or voltage-gated Ca^{2+} currents making it ideal for the isolation and investigation of the synaptic mechanisms of these cells. (Supported by grants from the Wellcome Trust and MRC. QX-314 kindly donated by Astra Pharmaceuticals)

PREGNENOLONE SULFATE EFFECTS UPON CA1 HIPPOCAMPAL NEURONS IN A SLICE PREPARATION. J.H. Meyer * and D.L. Gruol, Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla CA, 92037.

Steroids have both genomic and non-genomic effects on neuronal function. For example, previous studies using cultured neurons under voltage-clamp conditions have demonstrated that neurosteroids such as pregnenolone can rapidly affect $GABA_A$-associated chloride conductances (e.g. Majewska et al., 1988; Neurosci Lett 90:279). To gain an understanding as to the range of steroid influences, we have initiated studies on the effects of neurosteroids on hippocampal CA1 pyramidal neurons in a slice preparation.

Hippocampal slices from female Sprague-Dawley rats were placed in an interface-type slice chamber and perfused with artificial CSF (ACSF). Current clamp recordings (electrodes: 3M potassium acetate) were used to assess membrane resistance and cell responses to hyperpolarizing or depolarizing pulses. Repeat recordings were made after a 1/2 hour time period during which slices were perfused with either ACSF (control group) or ACSF containing pregnenolone sulfate (PS; 50 µM; experimental group). Over the 1/2 hour monitoring period, PS exposure did not appear to affect cell membrane resistance. Similarly, the amplitudes of the after-hyperpolarization, occurring after a depolarizing pulse, and the off-response, seen after a hyperpolarizing pulse, were not affected by PS. There was, however, a tendency for increased excitability in PS-treated cells: Spike frequency associated with depolarizing current pulses increased in 6/9 PS-treated cells, while 2/6 control cells exhibited only slight increases in spike frequency. These preliminary findings suggest that neurosteroids may affect active cell responses as well as synaptic transmission. Supported by AA6420 and AA0756.

A SYSTEM FOR THE ELECTRICAL STIMULATION AND MEASUREMENT OF *c-fos* AND PPT GENE EXPRESSION IN RAT SUPERIOR CERVICAL GANGLION CELLS M.Hodaie[1], M.W.Salter[2] and A.Roach[1]* [1]S.Lunenfeld Research Institute and Dept. Mol. and Med. Gen.,Univ. of Toronto, [2]Div. Neurosci., Hosp. for Sick Children, and Dept. Physiol. Univ. of of Toronto, Toronto, Ontario, Canada

We are interested in the influence of neuronal activity on gene expression in the nervous system. Towards that end, we are developing complementary systems of electrical stimulation and measurement for neural-specific gene expression using intact explants of newborn rat superior cervical ganglia (SCG) as a model. The genes being studied are pre-protachykinin (PPT) and *c-fos*, both of which are regulated by neuronal activity. In order to assess the adequacy of the stimulation parameters, electrophysiological studies done using whole-cell patch recording on primary dissociated cultures showed that action potentials can be reliably generated and the stimulation parameters that elicited single action potentials were identified. In cells loaded with fura-2 AM, stimulation produced an increase in $[Ca^{2+}]_i$, dependant on the frequency of stimulation.

We have adapted a method for quantitating mRNA using competitive PCR. Internal controls corresponding to deletion fragments of the genes of interest were constructed, enabling the use the same set of primers for the RNA and its control. PCR reactions contain 0.5μCi [^{32}P]-CTP and the signals are quantitated using phosphorimager technology. To quantitate the mRNA levels, the PCR product from the mRNA sample is compared with that from serial dilutions of known amounts of control RNA. We found co-amplification of the *c-fos* and PPT RNA and their respective controls are parallel over the studied range of 2 ng to 0.2 pg of starting SP6 RNA. The accuracy of this technique was determined by comparing it to quantitation using RNA blots. These findings indicate that competitive PCR used in this way is a reliable method of quantitation of RNA and can accurately determine mRNA levels from 15 ng total SCG RNA.

These techniques will allow the study of defined patterns of electrical activity and gene expression in rat superior cervical ganglion neurons.

DENDRITIC LOCALIZATION AND SYNAPTIC REGULATION OF MAP KINASE IN BRAIN. R.S. Fiore*, T.H. Murphy, V. Bayer, S.L. Pelech, J.A. Cooper, and J.M. Baraban. Dept. of Neurosci. Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

To assess the role of mitogen-activated protein kinase (MAPK) in neuronal systems, we have examined its localization in brain immunohistochemically and its regulation by neurotransmitters in primary cortical cultures. Light-microscopic studies reveal prominent staining of neuronal cell bodies and dendrites particularly in the hippocampal CA3 region and dentate gyrus, pyramidal cells in the cortex, and Purkinje cells in the cerebellum. At the ultrastructural level, intense staining is localized to dendritic microtubules, as well as the Golgi apparatus.

In primary cortical cultures, picrotoxin, which enhances spontaneous excitatory synaptic activity, induces tyrosine phosphorylation and activation of MAPK. Activation by picrotoxin occurs within 10 min and persists for the duration of a 30 min stimulation. Activation by picrotoxin is blocked by preincubation with tetrodotoxin. Both ionotropic and PI-linked glutamate receptor agonists stimulate MAPK activity suggesting that multiple pathways may mediate synaptic activation of this enzyme. Our findings that MAPK is enriched in neuronal dendrites and cell bodies in the brain and responds rapidly to synaptic activity point to a key role of MAPK in neuronal signal transduction.

ASSEMBLY AND PKC-PHOSPHORYLATION OF RC3(NEUROGRANIN) IN RAT BRAIN SYNAPTOSOMES AND VOLTAGE-CLAMPED XENOPUS OOCYTES. P.M. Coulter II, R.W.Cohen, J.E. Margulies and J.B. Watson*. Mental Retardation Research Center and Dept. of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine, Los Angeles, CA 90024.

RC3 (neurogranin) is a forebrain-enriched 78 amino acid protein containing overlapping sites for protein kinase C (PKC) phosphorylation and calmodulin binding that are shared with GAP-43. In contrast to GAP-43's presynaptic localization, RC3 accumulates primarily in dendritic spines of forebrain neurons. Here we use combined biochemical and immunological methods to examine RC3's state of assembly and PKC-phosphorylation in brain synaptosomal fractions. Concurrent electro-physiological studies of RC3 heterologously expressed in Xenopus oocytes test the hypothesis that phosphorylated RC3 has a function in PKC-activated signal transduction pathways. Western blot studies: brain synaptosomal RC3 monomers and dimers are resistant to most biochemical treatments but are solubilized by non-ionic detergents (triton X-100, sarcosine), guanidine hydrochloride, and alkaline conditions. We conclude that RC3 is tightly associated with synaptosomal membranes presumably through ionic interactions with postsynaptic membranes. Immunoprecipitation experiments (in progress) may reveal linkage between RC3 assembly and PKC-phosphorylation. Voltage-clamp experiments: folliculated Xenopus oocytes expressing RC3 show enhanced responses to acetylcholine (2-3 fold), measured as calcium-activated Cl^- currents. RC3 enhanced acetylcholine responses are dampened to control levels by the PKC-inhibitor H-7. Phorbol ester-treated oocytes expressing RC3 exhibit significant calcium/chloride currents that are not observed in control oocytes. The cummulative data suggest that PKC-phosphorylated RC3 modulates calcium ion levels in dendritic spines of forebrain neurons.

ELECTROPHYSIOLOGICAL AND ANATOMICAL IDENTIFICATION OF CHOLINERGIC CELLS IN THE MEDIAL SEPTUM/DIAGONAL BAND. L. Taylor*, H.T. Chang[1], M.C. Jasek and W.H. Griffith. Dept. of Medical Pharmacol. & Toxicol. College of Medicine, Texas A&M University, College Station, TX 77843, and [1]Dept of Anat. and Neurobiol, College of Medicine, The Univer. of Tennessee, Memphis, TN 38163.

We have electrophysiologically and anatomically identified cholinergic cells in the MS/nDB using a double labelling technique. These results extend earlier work on identified cholinergic cells using acetylcholinesterase histochemistry. Intracellular recordings were made from MS/nDB neurons from adult guinea pig in vitro. Cells were identified based on their electrophysiological properties and then filled with intracellular injection of biocytin (1%, 10-60 min). The biocytin injected neurons were visualized by reaction with avidin-Texas Red. Cholinergic neurons (immunoreactive for choline acetyltransferase, ChAT) in the same sections were revealed using FITC-linked secondary antibody. All cells that exhibited a slow-afterhyperpolarization (700ms - 2s; S-AHP) stained positively for ChAT (n=13). In contrast, rapidly firing cells did not stain for ChAT (n=10). Two cells characterized as burst-firing were not cholinergic. Both excitatory and inhibitory postsynaptic potentials were generated in both cholinergic and non-cholinergic cells. [Supported AG07805 (WHG) and AG05944 (HTC)]

D_1-D_2 INTERACTIONS ON cAMP PRODUCTION IN CULTURED RAT STRIATAL CELLS. S.Schinelli*, M.Paolillo, S. Preda and G.L.Corona. Institute of Pharmacology, University of Pavia, 27100 Pavia, ITALY.

The simultaneous dopamine stimulation of D_1 and D_2 receptors triggers some functional responses whose biochemical basis have not been explained yet. Cultured striatal neurons may represent a suitable model to investigate this interaction. Papain dissociated striatal cells from 16-17 days old rat embryos were seeded in 12 multiwell plates at a density of two million cells/well, grown in 10% fetal bovine serum and then incubated for 10 days in vitro. Intracellular cAMP was measured by prelabeling cells with tritiated adenine; cells were then stimulated for 15' with D_1 and D_2 selective agonists and antagonists. D_1 receptors, when stimulated with SKF38393 1μM increased cAMP levels while D_2 receptors, after stimulation with LY171555, counteracted the forskolin-induced cAMP production. These effects were respectively blocked by the selective antagonists SCH23390 and sulpiride. When striatal cells were simultaneously treated with D_1 and D_2 agonists or dopamine neither synergism nor antagonism on cAMP production was observed, compared to stimulation with D_1 alone. These data seem to suggest that the biochemical basis of the proposed synergism between D_1-D_2 dopamine receptors imply the involvement of other second messengers signalling systems.

RAPID COMMUNICATION BETWEEN NEURONS AND ASTROCYTE SYNCYTIA IN PRIMARY CORTICAL CULTURES. J.M. Baraban*, L.A. Blatter, W.G. Wier, and T.H. Murphy. Johns Hopkins University Sch. of Med. and University of MD Sch. of Med., Baltimore, MD.

Although the electrophysiological properties of isolated astrocytes have been well studied, much less is known about how astrocytes and neurons communicate *in situ*. To investigate the physiology of neuron-astrocyte signalling, we have applied both calcium imaging and whole-cell recording techniques to primary cortical cultures to identify physiological activity in astrocytes related to neuronal firing. Although a subset of astrocytes displayed slow calcium transients, these did not appear to be related to neuronal activity. In contrast, whole cell voltage clamp recordings of identified astrocytes revealed fast inward currents that coincide closely with neuronal activity. Inclusion of lucifer yellow within patch pipettes confirmed that astrocytes were extensively coupled to each other but not to adjacent neurons. Currents coincident with neuronal firing were observed in dye-coupled astrocytes several hundred microns away from neuronal clusters. In contrast to astrocytes, other glutamate responsive, presumed nonneuronal cells that are not dye-coupled did not show currents coincident with neuronal activity. These findings suggest that astrocytes respond rapidly to neuronal activity and these electrical signals are propagated effectively through astrocyte syncytia.

UNITARY CONDUCTANCE AND VOLTAGE DEPENDENCE OF GAP JUNCTION CHANNELS BETWEEN DISSOCIATED PAIRS OF RAT PINEALOCYTES EXPRESSING CONNEXIN26. A.P. Moreno,* J.C Sáez, and D.C. Spray. Dept. of Neuroscience, A. Einstein Coll of Med., Bronx, NY, 10461.

Pinealocytes are neurosecretory cells found in the pineal gland that are responsible for the synthesis and release of melatonin. They are postsynaptic to sympathetic neurons and respond to norepinephrine with a rise in intracellular Ca^{2+} (see abstract by Sáez, et al). Previous studies have shown that these cells are electrically coupled by gap junctions, and that connexin26 (Cx26) is the primary gap junction protein. Using a dual whole cell voltage clamp method with patch-type electrodes, we have characterized the physiological properties of pinealocyte gap junction channels after dissociation of cell pairs. 25% of the cell pairs studied showed electrical coupling, with junctional conductance values between 200 pS and 2 nS. The unitary conductances of the junctional channels were 40-50 pS; in some cell pairs simultaneous openings of clusters of channels were recorded, suggesting a novel type of cooperativity between the channels. Voltage dependence of macroscopic junctional conductance (g_j) was slightly asymmetric; whereas transjunctional voltages (V_j) of both signs decreased g_j, V_0 (the V_j value at which the voltage sensitive component of g_j is reduced by 50%) was about ± 40 mV, and the equivalent gating charge was ~ 2.5, the proportion of g_j remaining at high voltages was about 0.3 for depolarization and about 0.5 for depolarization. These channel characteristics differ from those seen for other connexins expressed in other tissues, therefore providing additional evidence that the junctional protein may be connexin26.

RAT PINEALOCYTES: NOREPINEPHRINE INDUCES DESENSITIZING Ca^{2+} RELEASE FROM INTRACELLULAR STORES AND NONDESENSITIZING Ca^{2+} INFLUX FROM THE MEDIUM. J.C. Sáez, A.P. Moreno, L.C. Barrio*[1] and D.C. Spray. Dept. of Neurosc., Albert Einstein Coll. of Med., Bronx, NY 10461 & [1]Depto. de Invest., Hospital Ramón y Cajal, Madrid, Spain.

Synthesis and secretion of melatonin by mammalian *epiphysis cerebri* is elicited by norepinephrine (NE) secreted by sympathetic neurons. Changes in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) induced by NE were studied in rat pinealocytes using the Ca^{2+} indicator fura-2. Pineal glands were obtained between 4-6 PM from adult female or male Sprague-Dawley rats (150-200 g) maintained on a 12:12 light dark cycle. Glands were enzymatically dissociated, cells were plated on glass coverslips coated with polylysine and cultured in RPMI/F12 supplemented with 10% FCS as described (Brain Res. 1991;568:265-275). Cells were loaded with the Ca^{2+} indicator fura-2 by incubating them with fura-2AM (10 μM) for 30 min. Twenty four hour old cultures were used in all experiments and while recording, cells were perfused with medium at 30-34°C. Application of NE (10^{-6}M) induced a rapid and transient increase in $[Ca^{2+}]_i$ from ~100 nM to ~700 nM, followed by a decrease to a plateau level of around ~350 nM. In Ca^{2+}-free saline, the initial phase of the NE-induced $[Ca^{2+}]_i$ response was as large and rapid as in Ca^{2+}-containing saline but $[Ca^{2+}]_i$ returned to basal levels, suggesting that the initial phase involved Ca^{2+} release from intracellular stores. Upon repetitive application of NE the transient $[Ca^{2+}]_i$ response became progressively smaller until it was undetectable, indicating desensitization. Then, readdition of Ca^{2+} to the bath induced a rapid increase in $[Ca^{2+}]_i$ to ~350 nM, the plateau level, suggesting that nondesensitizing Ca^{2+} influx was involved in the plateau phase of the response. NE thus appears to increase $[Ca^{2+}]_i$ in pinealocytes by inducing 1) phasic Ca^{2+} release from intracellular stores, and 2) sustained Ca^{2+} influx from the extracellular medium.

THE VARIABILITY OF SYNAPTIC TRANSMISSION. A. Shirke, N. Otmakhov, A. Kay* & R. Malinow. Depts. of Physiology & Biophysics and Biology, Univ. of Iowa & Inst. of Theoret. and Experim. Biophysics, Russian Academy of Sciences.

The impact of probabilistic transmission on the input-output characteristics of individual neurons has received some theoretical, but little experimental evaluation. If action potential generation requires the summed input of a large percentage of the 1000+ synapses on an average CNS neuron, the total response will show little inter-trial variation even though individual synaptic events are variable.

In this study we investigate the trial-to-trial variability of postsynaptic responses in hippocampal neurons given a constant afferent stimulus that recruits sufficient presynaptic fibers to produce a postsynaptic action potential. We note a significant inter-trial variability that is of synaptic origin and can be modulated by physiological manipulations. Two identified cell populations have different variability at threshold.

Theoretically, pre- or postsynaptic modifications will have different effects on trial-to-trial variability. We find a decrease in inter-trial variability associated with LTP. If postsynaptic responses are returned to the threshold level by recruiting fewer fibers, the trial-to-trial variability returns to that observed before potentiation. We thus observe maintained variability of the input-output relations despite the large gain changes observed with LTP.

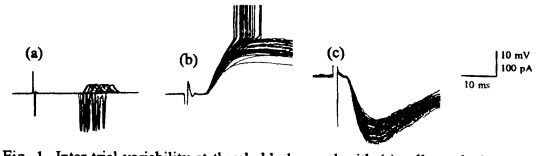

Fig. 1. Inter-trial variability at threshold observed with (a) cell-attached patch, and whole-cell recordings in (b) current-clamp and (c) voltage-clamp.

GLUTAMATE INDUCED LTP IN THE ABSENCE OF AFFERENT STIMULATION AND ENDOGENOUS NEUROTRANSMITTER RELEASE. R.J. Cormier*, M. D. Mauk and P. T. Kelly. Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX 77225.

Previous studies have shown that the induction of many forms of long-term potentiation (LTP) require presynaptic afferent stimulation. Using *in vitro* hippocampal slices we have tested the hypothesis that the induction of LTP requires evoked presynaptic activity. Repeated iontophoresis (5 pulses in 5 min) of glutamate in the stratum radiatum of CA1 produced LTP in the absence of afferent stimulation ("ionto-LTP"). Glutamate iontophoresis reliably induced LTP (56% increase of EPSP slopes, n = 5) which persisted at least an hour. Ionto-LTP was also induced in the absence of afferent stimulation in medium containing adenosine (200 μM). These adenosine conditions severely inhibit several neuronal processes, including transmitter release. Preliminary results indicate that the induction of ionto-LTP can also be achieved in the presence of TTX, under conditions in which EPSPs and presynaptic-fiber volleys were undetectable. Ionto-LTP was blocked when extracellular Ca^{2+} was chelated with EGTA, or when slices were pre-treated with MK-801. Thus, like LTP induced by high-frequency stimulation, ionto-LTP requires Ca^{2+} and activation of NMDA receptors. These results demonstrate that the induction of LTP by glutamate iontophoresis occurs in the absence of certain types of presynaptic activity and support the notion that presynaptic mechanisms are not required for the induction of ionto-LTP. Moreover, these results place constraints on the roles of presynaptic mechanisms and putative retrograde messengers in the persistent expression of LTP in that their involvement must be effective in the absence of certain forms of presynaptic activity. Indeed, these data suggest that application of a putative retrograde messenger should induce potentiation in the absence of presynaptic activity.

CAN HEBBIAN RISES IN CALCIUM PRODUCE LTP IN THE ABSENCE OF SYNAPTIC TRANSMISSION ? J.I. Gold and I. Mody*. Dept. of Neurology & Neurological Sciences, Stanford Univ. Sch. of Med., Stanford, CA.

The simultaneous activation of pre- and postsynaptic elements, and an accompanying rise in intracellular Ca^{2+} concentration, is a necessary condition for LTP induction. We have tested the hypothesis that simultaneous (Hebbian) rises of pre- and postsynaptic Ca^{2+} are sufficient to induce LTP in the absence of fast glutamatergic and GABAergic neurotransmission.

Extracellular recordings were done in the str. radiatum of the CA1 region of rat hippocampal slices maintained at 34-35°C. Schaffer collateral-commissural fibers were stimulated once every 30 s in the presence of 100 μM picrotoxin and the rate of rise of field EPSPs was recorded for a control period ranging between 15 and 30 min. The non-specific glutamate antagonist kynurenic acid (10 mM) was perfused for 5 min, resulting in the complete abolishment of synaptic field potentials. Once all synaptic activity was blocked, an orthodromic tetanus (100 Hz/0.5 s) was given, followed 200 ms later by an identical tetanus delivered via an antidromic stimulating electrode positioned in the str. oriens. Following washout of kynurenic acid, this stimulation paradigm resulted in a lasting and significant potentiation (126.3 ± 2.1% of control; 45-50 min following the tetani) of the EPSP's rate of rise. Either an antidromic or an orthodromic tetanus delivered alone did not potentiate the orthodromic EPSP. The potentiation was also blocked by raising the extracellular Mg^{2+} concentration from 2 mM to 4 mM, presumably as a consequence of reduced Ca^{2+} entry through voltage-gated Ca^{2+} channels. Our results are consistent with the hypothesis that a simultaneous rise in pre- and postsynaptic Ca^{2+} levels even in the absence of NMDA and non-NMDA receptor-mediated synaptic transmission is sufficient to induce long-term potentiation. Supported by NINDS grant NS 27528.

NMDA RECEPTOR ACTIVATION AT SYNAPSES ON CA1 NEURONS IS NOT NECESSARY FOR THE INDUCTION OF LTP. A. C. Field, S. J. Redman and C. Stricker*. Division of Neuroscience, JCSMR, Australian National University, Canberra, ACT 2601, Australia.

The induction of LTP at synapses on hippocampal CA1 neurons is believed to occur as a result of calcium influx through NMDA channels, since it is prevented by the NMDA receptor antagonist 2-amino-5-phosphono-pentanoic acid (AP5). However, an AP5-resistant component of LTP has been observed when the rate of tetanic stimulation of presynaptic fibres was increased to 200 Hz (1).

We have investigated the AP5-sensitivity of LTP induced by pairing low frequency (2 Hz) activation of small numbers of afferents with depolarization of the postsynaptic neuron to 0 mV, under whole-cell voltage clamp conditions and with caesium-based intracellular solutions, in CA1 pyramidal cells in 400 μm rat hippocampal slices. In the absence of AP5, an enhancement of EPSC amplitude (mean increase 80%) lasting at least 15 minutes was observed in 14/26 cells following pairing. When the bath contained 20 μM AP5, the same conditioning protocol produced a similar enhancement of EPSC amplitude (mean increase 65%) in 16/46 cells, and this potentiation could be maintained for at least 1 hr. Preliminary results indicate that AP5-resistant potentiation is specific to the synapses that were active during postsynaptic depolarization. Thus, NMDA receptor activation is not necessary for the induction of LTP in CA1 pyramidal cells by pairing when using the whole-cell recording technique.

Synaptic plasticity in the rat prefrontal-accumbens pathway studied in vitro. C.M.A. Pennartz*, R.F. Ameerun and F.H. Lopes da Silva, Dept. of Experimental Zoology, University of Amsterdam, Kruislaan 320, 1098 SM, Amsterdam, Netherlands.

In this study we examined what types of plastic changes can be found in the projection from prefrontal cortex to nucleus accumbens (Acb), a structure implicated in reward-dependent learning. Intracellular recordings were made in parasagittal slices (400 μm thick) from male Wistar rats. Stimulus electrodes were positioned at the border between infralimbic cortex and Acb. Picrotoxin (10 μM) was present in the bathing medium. Resting membrane potential, input resistance and action potential amplitude of the recorded neurons (N=75) were -78 ± 2 mV, 42 ± MΩ and 93 ± 1 mV. Tetanization (2 sec., 50 Hz) induced 3 types of changes in the AMPA/kainate receptor-mediated EPSP: long-term potentiation (21 cells), decremental potentiation (8 cells) and long-term depression (8 cells). Expression of LTP and LTD was not accompanied by changes in passive membrane properties. No correlation was found between the occurrence of potentiation/depression and various parameters of the tetanic depolarization (e.g. peak voltage, integral under curve). The NMDA receptor antagonist D-AP5 (50 μM) prevented LTP induction in 7 out of 9 slices that proved to be capable of producing LTP following D-AP5 washout. No difference in LTP was found between dopamine-treated slices (10 μM; N=15) and controls (N=14). Likewise, slices treated with the D1 receptor antagonist Sch 23390 (1 μM) and S(-)-sulpiride (1 μM; N=6) generated a similar amount of LTP as controls (N=10). In conclusion, both LTP and LTD can be induced in the prefrontal-Acb pathway. LTP strongly depends on NMDA receptor activity, but is not significantly affected by 10 μM dopamine.

LONG-TERM POTENTIATION OF PERFORANT-PATH INPUT TO CA3 PYRAMIDAL NEURONS IN HIPPOCAMPAL SLICES. *S.-F. Chen* & D. Johnston*, Dept. of Molecular Physiol. and Biophys. & Div. of Neuroscience, Baylor Col. of Med., Houston, Tx 77030.

Direct projections of perforant path (PP) fibers from entorhinal cortex to the hippocampal area CA3 have been demonstrated anatomically but their physiological properties have only recently begun to be investigated (Yeckel and Berger, 1990, *Proc. Natl. Acad. Sci. USA* 87:5832-5836). As a prelude to further study of the cellular events associated with distal dendritic inputs, we examined by field recordings and lesion methods whether direct PP input to CA3 can be selectively activated and whether action potentials and LTP can be evoked by this input in the rat hippocampal slice preparation.

In slices with part of CA1 and DG removed, paired-pulse facilitation could be recorded in S. lacunosome-moleculare (SLM) and S. pyramidale of CA3 by stimulating remnant SLM of CA1 or residual SM of dentate gyrus (DG). The latencies of the pEPSPs were ≈3 ms, which is consistent with a monosynaptic response. Lesion of the PP termination zone between stimulating and recording electrodes completely blocked the pEPSPs as did application of DNQX (10μM) plus D-APV (50μM). These results suggested that the PP has functional monosynaptic input to CA3 pyramidal neurons via SM of both CA1 and DG in the slice preparation.

Tetanizing stimuli of 400Hz (0.1s, ×10) delivered to the outer third of SM of DG could induce a 122±6% (S.E.) increase in the slope of the pEPSP in intact slices (n=3), but only a 56±16% (S.E.) increase in slices with a cut between CA3 and DG (n=5). The induction of the LTP could be blocked in D-APV (50μM) solution. These results suggest that LTP of the PP inputs to CA3 can be observed in the slice preparation and at least a component of the LTP can be blocked by D-APV. (MH44754,MH48431)

L-TYPE CALCIUM CHANNELS ARE INVOLVED IN THE INDUCTION OF NMDA RECEPTOR-INDEPENDENT LONG-TERM POTENTIATION (LTP) IN ADULT RAT VISUAL CORTEX. V.A. Aroniadou*, A. Maillis, E. Koutsoukos, E. Angelopoulos, T.J. Teyler and C. Stefanis. Univ. of Athens, Dept. of Psychiatry, Eginition Hospital, 11528 Athens, Greece, and Northeastern Ohio Coll. of Med., Rootstown, OH 44272 U.S.A.

In visual cortical slices from Wistar rats (age 60-80 days) the field potential in layer III elicited by white matter stimulation consisted of a negative component (N1) with peak latency 4-8 msec, which was unaffected by bath applied APV. In a few slices a second component was present (peak 12-19 msec) which was insensitive to APV in most of these slices. Bath applied DNQX blocked N1 and revealed the presence of an APV-sensitive component (peak 9-20 msec). Tetanic stimulation in normal medium induced LTP (138-385%) of N1 in 72% of the slices. In the presence of APV, LTP of N1 (145-279%) was induced in 75% of the slices. Potentiated responses were unaffected by APV. Bath application of the dihydropyridine antagonist nifedipine did not affect control responses. Following tetanic stimulation in the presence of nifedipine no change or long-term depression was observed in 80% of the slices, while a small magnitude LTP (130-150%) was induced in the remaining slices. The known reduction of NMDA receptor activity with age is accompanied by an increased importance of voltage-gated Ca++ channels in maintaining synaptic plasticity.

567.8

DEXAMETHASONE BLOCKS THE INDUCTION OF HIPPOCAMPAL PRIMED BURST POTENTIATION. David M. Diamond*, Berrilyn Branch, M. Catherine Bennett, Monika Fleshner and Gregory M. Rose. Department of Pharmacology, UCHSC and VAMC, Denver, CO 80262

There is a negative correlation between corticosterone (CORT) levels and PB potentiation, a form of long lasting hippocampal plasticity induced by physiologically patterned stimulation (*Psychobiol.*, 19:301, 1991). In the present study, we investigated the possibility that this effect was mediated by the Type II glucocorticoid receptor.

We stimulated the hippocampal commissure and recorded CA1 population spikes in urethane-anesthetized adrenalectomized rats. PB stimulation (5 pulses: a priming pulses followed 170 ms later by a burst of 4 pulses at 200 Hz) was delivered 3-4 hours after administration of dexamethasone phosphate (DEX; 300-900 μg, i.p.), a selective Type II agonist. A dose-dependent inhibition of the incidence and magnitude of PB potentiation by DEX was observed. PB depression, a lasting decrease in the amplitude of the population spike, occurred at the 900 μg dose. PB depression was originally identified in animals with high levels (> 60 μg/dl) of CORT. Therefore, DEX mimicked the effects of elevated levels of CORT.

These findings suggest that occupation of the glucocorticoid Type II receptor results in inhibition of hippocampal plasticity. Our observations imply a role for CORT in mediating the effects of stress on hippocampus-dependent learning.

567.9

EFFECT OF TRIMIPRAMINE, AN ANTIDEPRESSANT, ON HIPPOCAMPAL SYNAPTIC PLASTICITY. G. MASSICOTTE*, M. OHAYON AND J. BERNARD. Lab. of Neurobiology, Université du Québec à Trois-Rivières, Québec, Canada, G9A 5H7

The effect of trimipramine (TRIM), an antidepressant agent, on both the induction and the maintenance of long-term potentiation (LTP) was investigated in field CA_1 of hippocampal slice preparation. Chronic administration (7-9 days) of TRIM in rat caused a large reduction in the magnitude of LTP induced by a theta burst stimulation (TBS) paradigm. Trimipramine had no significant effect on either the degree of facilitation in postsynaptic responses occurring during TBS or the amount of paired-pulse facilitation. Furthermore, the facilitation of postsynaptic responses occurring in the first two minutes following the high frequency stimulation was not reduced by trimipramine administration. These results indicate that TRIM interfere with the formation of LTP; an effect that is not due to alteration of physiological event that triggers LTP. The data suggest that the loss of LTP maintenance is more likely the result of the disruption by trimipramine of cellular processes that follow LTP induction. In addition, the present results provide evidence for a possible correlation between reduction in LTP expression and learning deficit produced by chronic administration of trimipramine.

PATHWAY SPECIFICITY OF METOPROLOL-INDUCED PLASTICITY IN THE DENTATE GYRUS. *R. D. Kirkby*, M. R. Pelletier, and M. E. Corcoran. Dept. of Psychology, U. of Victoria, BC, Canada, V8W 3P5.*

Previous research has demonstrated that application of β-noradrenergic agonists in vitro can produce long-lasting potentiation (LLP) of field responses evoked in the dentate gyrus (DG) by stimulation of the medial perforant path (PP) and long-lasting depression (LLD) of responses evoked by stimulation of the lateral PP [Dahl & Sarvey, PNAS, 1989; Pelletier, Kirkby & Corcoran, Soc. Neurosci. Abstr., 1991]. We report here that β-noradrenergic blockade produces LLD of responses evoked by stimulation of the medial PP and LLP of responses evoked by stimulation of the lateral PP.

Transverse hippocampal slices from male hooded rats were placed in an interface chamber, and field EPSPs were recorded from the outer or middle molecular layer. After stable baseline responses were obtained, the β,-adrenergic antagonist (±)-metoprolol (+)-tartrate (MET; 20 μM) was bath applied for 30 min, followed either by a 30 min wash and tetanization (TET) or by a 60 min wash with no TET.

MET produced LLD and LLP of responses evoked by stimulation of the medial PP and the lateral PP, respectively, that persisted for the 60 min wash. TET of the medial PP potentiated evoked responses back to baseline levels, above the depression produced by MET. TET of the lateral PP produced additional potentiation above that produced by MET.

These results provide further evidence for the pathway specificity of β-noradrenergic plasticity of responses evoked in the DG, and they also suggest that antagonism of β-adrenoceptors has long-lasting effects on synaptic transmission in the DG.

WIDELY DIVERGENT LONG TERM POTENTIATION OF POPULATION SPIKE AND EPSP IN VISUAL CORTEX OF THE ADULT RAT IN VIVO. X. Wang* and W.T. Greenough, Neurosci. Prog., Beckman Inst., Univ. of Illin., Urbana, IL 61801.

Previous studies have shown that LTP in layer II/III of visual cortex is difficult to induce and of a limited size (in terms of percent change in amplitude of field potentials) in adult rats (Perkins & Teyler, 1988; Kato et al., 1991). Moreover, seemingly identical stimulation regimes may induce either long term depression (LTD) or LTP (Berry et al., 1989). Here, we present a new form of LTP in adult rat visual cortex. In our experiments, extracellular recording electrodes were placed in layer II/III of rat visual cortex, while stimulating electrodes were located in the white matter lateral to the recording electrode. Evoked responses were examined only if population spike-like spikes (PS-like spike,onset latency from 3 ms to 7.5 ms), EPSP-like potentials (peak before 12 ms) and long-lasting inhibitory responses following EPSP-like potentials all were present. We find that PS-like spike amplitudes were increased to about 200% (some times more) of control levels after tetanus in most cases. In many cases the onset latency of PS-like spikes was shortened after tetanus. In contrast, the sizes of EPSP-like potentials showed decreases (7 cases), no clear changes (4 cases) or an increase (1 case). Thus, there is a mismatch between EPSP-like potentials and PS-like spikes during cortical LTP. Many cases could be viewed as indicating LTD if only the EPSP-like potentials were measured. However, if only the amplitude of the PS-like spike is considered, we find that there is still a substantial apparent induction of LTP. Because of this mismatch, the measurement of PS-like spikes may be a more sensitive measurement of LTP in visual cortex.

EFFECTS OF BURST STIMULATION ON NEIGHBORING SINGLE CA1 NEURONS IN RAT HIPPOCAMPUS. P.D. Martin, N. Lake*, M.L. Shapiro. Depts. of Psychology & Physiology, McGill University, Montreal, Quebec, Canada, H3A 1B1.

The effects of burst stimulation (ten 25 ms bursts of 400 Hz pulses at 200 ms intervals) on single CA1 neuron activity were recorded with stereotrodes placed in the pyramidal layer of CA1 and stimulating electrodes implanted in the contralateral CA3 of urethane anesthetized rats. Individual units were distinguished by waveform parameters, and the firing pattern of each unit was analyzed separately. The latency of evoked unit firing was commensurate with the latency of evoked field potentials. Four of nine discriminated cells fired spontaneously. Five cells fired upon stimulation, and no cells fired both spontaneously and upon stimulation. Burst stimulation increased field EPSP amplitude (>30 min) and decreased spontaneous firing in three of four spontaneously firing cells. Of the five cells that displayed evoked firing, burst stimulation increased the firing probability in one cell, reduced the firing probability in one cell, and had no effect on three cells. Thus, neighboring cells recorded simultaneously were affected differentially by burst stimulation. Changes in both feed forward excitatory and inhibitory connections may contribute to the pattern of altered neural responses produced by burst stimulation and LTP induction.

567.13

LONG-TERM POTENTIATION OF THE IPSILATERAL-ASSOCIATIONAL PATHWAY IN THE RAT DENTATE GYRUS. P.A. Hetherington*, K.B. Austin, and M.L. Shapiro. Dept. of Psychology, McGill Univ., Montreal, Quebec, Canada, H3A 1B1.

Mossy fibers from granule cells in the dentate gyrus of the rat hippocampus project to mossy cells in the hilar region, which in turn make excitatory synapses in the inner one-third of the molecular layer of the dentate gyrus. To relate physiological and anatomical properties of this excitatory feedback system, multiple electrodes (100μ, tungsten rod) were located along the longitudinal axis of the dorsal leaf of the dentate gyrus in the urethane-anesthetized rat (2.0 g/Kg, Long Evans). Single pulses delivered to the hilar region evoked negative-going, mono-synaptic electrical field potentials (EFP s) in the inner one-third of the molecular layer. These EFP s were recorded simultaneously at four locations, the peak amplitude of which varied linearly with distance from point of stimulation, and could be elicited either rostral or caudal to the stimulating electrode. A stimulus train (ten 25ms bursts of 400 Hz pulses at 200ms intervals) was delivered to the hilar region, and the initial slopes of the recorded EFP s were potentiated (21%). Potentiation lasted at least two hours and was specific to responses from the tetanized stimulating electrode: the responses to a second stimulating electrode in the hilus and a third in the angular bundle of the perforant path did not change. The results suggest that the ipsilateral association system of the dentate gyrus supports long-lasting and synapse-specific changes in electrical response.

FURTHER EVIDENCE THAT MOSSY FIBER POTENTIATION IS EXPRESSED BY A CHANGE IN RELEASE VARIABLES. U.Staubli*[1], J.Larson[2] and G.Lynch[2]. [1]Dept. Psychology, McGill University, Montreal, H3A 1B1; [2]Center for Neurobiology of Learning & Memory, Univ. California, Irvine, Ca 92717.

Previous studies have shown that paired-pulse facilitation, a presynaptic effect, is markedly reduced by mossy fiber potentiation (MFP) but is unaffected by LTP. Conversely, the nootropic drug aniracetam which selectively increases currents mediated by the AMPA subclass of glutamate receptors, has smaller effects on the amplitude of synaptic responses following induction of long-term potentiation (LTP) in field CA1 but not after induction of MFP. This pattern of results indicates that expression of MFP involves distinctly different changes than LTP.

Subsequent studies have found that aniracetam acts by prolonging the open time of the AMPA receptor channel (Tang et al., 1991) and thereby changes the waveform of synaptic responses, an effect that is altered in a characteristic fashion after induction of LTP: the drug i) produces a smaller increase in the amplitude of potentiated responses, ii) shifts the initial slope of the potentiated response to the right and iii) is delayed in its facilitatory effect in the rising phase of the potentiated EPSP. These results are consistent with the hypothesis that LTP is due to modified glutamate receptors.

Here we report data from intracellular recordings of CA3 neurons to afferent stimulation of mossy fibers and show that the effects of aniracetam on the peak amplitude, displacement of initial slope and onset of response facilitation were not detectably different in seven control slices and 4 slices with mossy fiber potentiation. These results are consistent with the hypothesis that mossy fiber potentiation reflects a change in release variables.

LTP CHANGES THE WAVEFORM OF SYNAPTIC RESPONSES: PROXIMAL VERSUS DISTAL APICAL DENDRITIC SYNAPSES. A. Kolta,* J. Larson, P. Xiao, & G. Lynch. CNLM, Univ. of Calif., Irvine, CA 92717

In a previous study, we demonstrated that long-term potentiation (LTP) was accompanied by a decrease in the decay time constant of excitatory synaptic field potentials in field CA1 of hippocampus, suggesting that potentiation alters the mean open time of AMPA-type glutamate receptor channels. However, the degree to which synaptic location affects measured time constants or correlates with channel kinetics is not known. In the present experiments, we compared field potentials evoked by stimulation of axons at proximal and distal levels of the apical dendritic tree, and measured waveform parameters of responses recorded at corresponding locations during paired pulse facilitation (PPF) and LTP.

Excitatory responses in minislices of field CA1 were isolated by blocking GABAergic responses with picrotoxin and 2-hydroxysaclofen. Decay time constants (DTCs) were measured by exponential fitting. LTP was induced by theta burst stimulation and PPF was measured at inter-pulse intervals of 85 msec.

Under control conditions, responses were larger when recorded locally (at the same proximal-distal position as the stimulation), indicating that the stimulation electrodes activated spatially distinct synapses. DTCs were longer for responses recorded proximally, regardless of stimulation locus. PPF had no effect on DTCs; however, LTP significantly reduced the DTC for all responses. LTP was larger when recorded proximally, regardless of stimulation position; PPF was not affected by either stimulation position or recording position.

Comparison of PPF with LTP provides further support for the hypothesis that LTP involves changes in postsynaptic receptors. PPF did not change response DTCs whereas LTP did. Differences between proximal and distal synapses suggest spatial variations in LTP induction and/or expression mechanisms.

REVERSAL OF LTP BY STIMULATION AT THE THETA FREQUENCY. J. Larson,* P. Xiao, & G. Lynch. CNLM, Univ. of Calif., Irvine, CA 92717

Long-term potentiation (LTP) is optimally elicited by brief high frequency bursts repeated at the frequency of the endogenous limbic theta EEG rhythm (5 Hz). The present experiments tested the effects of single pulses repeated at the theta frequency on control and potentiated synapses; the results indicate that theta frequency stimulation shortly after LTP induction causes a reversal of LTP.

Stimulation electrodes were placed in the CA1 field of hippocampal slices to activate two independent sets of Schaffer/commissural fibers; field EPSPs were recorded in the apical dendritic region. LTP was induced by theta burst stimulation (4-pulse, 100 Hz bursts repeated at 5 Hz). Theta pulse stimulation (30-60 sec. of 5 Hz stimulation) was used to reverse LTP.

In control medium, a 1-min. episode of 5 Hz stimulation beginning 1-3 min. after LTP induction had no effect on the degree of LTP measured 30 min. later. However, in the presence of norepinephrine (200 μM), 5 Hz stimulation reduced LTP by 29% ($\pm$7). Theta pulse stimulation was only effective when administered within 10 min. of LTP induction and had no lasting effects on control synapses. Stimulation at 1 Hz did not reverse LTP and stimulation at 10 Hz was no more effective than 5 Hz stimulation. LTP could be nearly completely reversed (86% $\pm$15) by theta pulse stimulation when potentiation was induced by milder and more naturalistic stimulation patterns (burst pairs) . Under these conditions, LTP reversal was blocked (only 18% $\pm$8) by an adenosine A_1 receptor antagonist (8-cyclopentyl-1,3-dipropylxanthine, 200-350 nM).

These results suggest that the hippocampal theta rhythm promotes both the induction of LTP and its subsequent reversal with the latter process being facilitated by norepinephrine and involving adenosine receptors. LTP reversal may function to refine or sharpen recently encoded representations.

FACTORS REGULATING THE MAGNITUDE OF LONG-TERM POTENTIATION INDUCED BY THETA PATTERN STIMULATION. A.Arai* and G.Lynch. Center for the Neurobiology of Learning and Memory, University of California, Irvine, CA 92717-3800.

Electrical stimulation patterned after the hippocampal theta rhythm produces robust and stable long-term potentiation (LTP). The present studies sought to relate response parameters occurring during theta stimulation to the degree of LTP following it. Comparisons were made using 5 or 10 burst stimulation which respectively induce sub-maximal or near maximal degree of LTP in field CA1. An adenosine A1 receptor antagonist (DPCPX) was used to enhance the depolarization produced by individual theta bursts; this markedly increased the amount of stable LTP induced by 5 theta bursts but did not affect that resulting from 10 bursts. Similar effects on the size of the burst response and on the degree of LTP were obtained with aniracetam, a nootropic drug acting on AMPA receptors. Forskolin, an activator of adenylate cyclase, blocked the hyperpolarization present between theta bursts. This drug also augmented the degree of LTP resulting from 5 theta bursts, however, in contrast to DPCPX and aniracetam, forskolin nearly doubled that obtained with 10 bursts. These results raise the possibility that the magnitude of NMDA receptor mediated currents affects the degree of potentiation produced by individual theta bursts while the duration of the currents sets a limit on the maximum LTP induced by a series of bursts. (Supported by Grant #N00014-89-J-1255 from the Office of Naval Research).

PRIMING OF ASSOCIATIVE LTD IN THE DENTATE GYRUS BY THETA-FREQUENCY SYNAPTIC ACTIVITY.
B. R. CHRISTIE * AND W. C. ABRAHAM
Department of Psychology and the Neuroscience Research Centre, University of Otago, Dunedin, New Zealand

The present study evaluated associative (ASS) and non-associative (N-ASS) LTD in the lateral (LPP) perforant path projections to the dentate gyrus in barbiturate anaesthetized rats. ASS synaptic interactions were investigated using short 100 Hz trains delivered at 5 Hz to the MPP in association with single pulses to the LPP, interleaved between the MPP trains. N-ASS interactions were studied using the MPP conditioning trains alone. Paired-pulses (50 ms interpulse interval) were administered prior to and 30 minutes following the application of the conditioning stimuli.

Normally only non-associative, NMDA-dependent (N-methyl-D-aspartate), LTD is elicited in naive LPP pathways with either protocol (Christie and Abraham, Synapse 10: 1-6, 1992). LTD is significantly increased in the LPP by the ASS protocol (ASS: -40$\pm$3%, N=5; N-ASS: -13$\pm$4%, N=13; $t_{(16)}$=3.8, p<0.05), however, after being "primed" by a brief period of synaptic activity at a theta rhythm frequency (5 Hz). 5 Hz priming of ASS LTD lasts at least 2 hrs, and significantly enhanced LTD is not seen following priming activity at 1 Hz (-24$\pm$9%, N=7) or 15 Hz (-13$\pm$4%, N=5), nor when the N-ASS protocol is administered following 5 Hz priming (-9$\pm$9 %, N=5). NMDA-receptor activation is critical for establishing the priming effect, but not for the subsequent induction of ASS LTD. The ASS, but not N-ASS, LTD is also accompanied by an increase in paired-pulse facilitation following its induction (ASS:15$\pm$4%, $t_{(4)}$=3.6, p<0.05). This suggests that ASS and N-ASS LTD involve different expression mechanisms, and that ASS LTD may involve a decrease in presynaptic transmitter release.

INPUT ASYNCHRONY PROLONGS THE RISING PHASE OF MOSSY FIBER-EVOKED EPSCS IN RAT HIPPOCAMPAL CA3 PYRAMIDAL CELLS. R. B. Langdon*, J. W. Johnson, and G. Barrionuevo, Depts. of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260

Investigation of LTP at mossy fiber (MF) synapses depends upon discrimination of monosynaptic, MF-evoked EPSCs (MF EPSCs) from higher order EPSCs, based upon expectations for MF EPSC kinetics. Using whole-cell recording, we have examined EPSCs evoked by stimuli applied to the *s. granulosum*. Rise-time durations ranged from 0.7 to 5.0 msec (mean = 2.5 msec; N = 27). Most rising phases were inflected, implying asynchronous arrival of inputs. Hypothetically, this could be due to "contamination" via activation of local axon collaterals. If so, then generalized suppression of neurotransmission should alter not only the amplitude but also the shape of waveforms. However, exposing slices to CNQX + APV, or low $[Ca^{++}]$, high $[Mg^{++}]$ medium (using a submersion-type slice chamber) did not shorten long rise-times or remove inflections (N = 5; amplitudes were reduced 64 to 88%).

We examined the kinetics of MF impulse activity by recording (from slices in medium that blocked neurotransmission) the extracellular potential generated by action currents in MFs (the MFV). Typical MFVs lasted 3 to 4 msec, with long and complex negative phases, implying impulse asynchrony (N = 15). This temporal dispersion could be the result of (*hypoth.1*) dispersion of MF conduction velocities, (*hypoth.2*) dispersion of conduction distances, or (*hypoth.3*) unconventional MF physiology. We dismiss hypoth.1 because antidromically activated granule cell population spikes broaden only slightly as a function of distance between stimulating and recording sites. Hypoth.2 would contribute to asynchrony if impulses travelled antidromically in hilar MF collaterals, then orthodromically in MFs. However, lesions that would interrupt such impulses did not produce brief, simple (triphasic) MFV waveforms. Therefore, long and inflected MF EPSC rising phases may be due to intrinsic physiology of MF axons or their boutons. Support: NS24288 and MH45156.

QUANTAL ANALYSIS IN THE CA3 REGION OF THE HIPPOCAMPUS BY MAXIMUM LIKELIHOOD ESTIMATION. S. Smerin*, R.B Langdon, D. Henze, G. Barrionuevo, and T.R. Chay. *Departments of Behavioral Neuroscience and Biology, University of Pittsburgh, Pittsburgh, PA 15260.*

Quantal analysis by the method of maximum likelihood estimation was applied to the mossy fiber synapse and the fimbrial synapse, both of which are on the CA3 pyramidal neuron of the hippocampus. The hippocampus of the rat was sliced and maintained *in vitro*. Stimulating electrodes were placed in the fimbria and in the *s. granulosum* of the dentate gyrus. Two hundred to 500 EPSCs evoked from each stimulation site were collected in whole-cell voltage clamp configuration. The probability of observing the peak EPSC amplitudes was formulated into a likelihood function under the hypothesis that the probability of release (**p**) of the quantum follows a simple binomial distribution and the amplitude (**a**) of the quantum is normally distributed. We obtained the values of **p** and **a** by maximizing the likelihood function using an algorithm on the Pittsburgh Supercomputer Center's Cray-YMP.

At the mossy fiber synapse we found that **p** = 0.7-0.8 and **a** = 9-12 pA, and at the fimbrial synapse **p** = 0.3-0.9 and **a** = 9-10 pA. In this initial study all estimations assumed that the number of release sites was ten. Higher numbers of release sites (up to 600 for the mossy fiber synapse, and up 10,000 for the fimbrial synapse) will be assumed for future estimations. Quantal analysis by maximum likelihood estimation is now being applied before and during the induction of LTP at these synapses. Supported by NS24288.

QUANTAL ANALYSIS OF PLASTICITY IN RAT HIPPOCAMPAL MOSSY-FIBER SYNAPSES. A.C. Greenwood*[1], Z.Xiang[2], E.M. Landaw[3], E.W. Kairiss[2], and T.H. Brown[1,2]. Depts. of Cell. & Mol. Phys.[1] and Psych.[2], Yale Univ., New Haven, CT 06520 and Dept. of Biomath.[3], Univ. of Calif., Los Angeles, CA 90024.

We have developed a maximum likelihood (ML) approach to quantify uncertainty within the context of several testable models. Systematic Monte Carlo simulations amplify the method's power and justify the application of ML theory to each specific data set.

These methods of quantal analysis were applied to rat hippocampal mossy-fiber (mf) synapses, which offer a number of advantages for studies of synaptic microphysiology (Siegel et al, *Soc. Neurosci. Abstr. 18*, in press; Yu and Brown, *Soc. Neurosci. Abstr. 18*, in press; Jaffe and Brown, *Soc. Neurosci. Abstr. 18*, in press; Xiang et al, *Soc. Neurosci. Abstr. 18*, in press). Whole-cell voltage-clamp recordings were made of evoked currents that satisfied appropriate criteria for mf origin (Xiang et al, *Soc. Neurosci. Abstr. 18*, in press).

In a study of mf paired-pulse facilitation, a mf input was stimulated twice in rapid succession for several hundred trials. For various measures, the first and second response amplitude distributions could be well-fit by a Poisson or binomial probability function for quantal release and a gamma or Gaussian probability density function for quantal size. The mean quantal size did not increase with facilitation. Facilitation resulted, instead, from an increase in the mean quantal content. We are currently investigating the quantal basis of long-term potentiation in mf synapses. *Supported by NIH and ONR.*

MEASUREMENT AND ANALYSIS OF HIPPOCAMPAL MOSSY-FIBER SYNAPSES. Z. Xiang*[1], A.C. Greenwood[2], and T.H. Brown[1,2]. Depts. of Psych.[1] and Cell. & Mol. Physio.[2], Yale Univ., New Haven, CT 06520

The hippocampal mossy-fiber (mf) synapse is attractive for neurophysiological and optical studies of plasticity because of its large size (Yu and Brown, *Soc. Neurosci. Abstr. 18*, in press; Jaffe and Brown, *Soc. Neurosci. Abstr. 18*, in press) and electrotonic proximity to the soma (Siegel et al, *Soc. Neurosci. Abstr. 18*, in press). The complex circuitry of the CA3 region of the hippocampus, however, makes it difficult to excite the mf synapses selectively when using extracellular microstimulation.

We have devised a set of procedures and criteria for isolating and identifying mf excitatory postsynaptic currents (EPSCs) (Xiang et al, *Soc. Neurosci. Abstr. 17*, 1991; Claiborne et al, submitted). Here we report results of whole-cell recordings of mf EPSCs from rat hippocampal slices that satisfy these criteria and procedures. Slices were cut on a vibratome (450 µm thick) in the plane of the mf projection system (Yu and Brown, *ibid*). An attempt was made to activate unitary mf inputs by delivering small stimulating currents through optimally positioned 25 µm bipolar stimulating electrodes. The patch pipette access resistance was less than 15 MΩ.

The mf peak conductance averaged about 1.2 - 4.7 nS and the net charge transfer from a -80 mV holding potential averaged about 1.3 - 3.4 pC. For quantal analysis (Greenwood et al, *Soc. Neurosci. Abstr. 18*, in press) we explored several response measures, including the peak current, slope of the rising phase, total charge, and partial charge. The fit of quantal models and the estimated quantal parameters depended on the response measure. *Supported by NIH and ONR.*

HEBBIAN LEARNING IS JOINTLY CONTROLLED BY ELECTROTONIC AND INPUT STRUCTURE. B.A. Pearlmutter*[1] and T.H. Brown[1,2]. Departments of Psychology[1] and Cellular & Molecular Physiology[2], Yale Univ., New Haven, CT 06520.

Hebbian learning in a linear isopotential neuron with instantaneous response has been shown to cause the synaptic weights to tune to the principal eigenvector of the instantaneous input correlation matrix Q, $Q_{ij} = \langle \xi_i \xi_j \rangle$ (Amari 1977 *Bio. Cyb.*; Oja et al 1985 *J. Math. Anal.& Appl.*) Here, we show that in the nonisopotential case, the important matrix is $\hat{Q}$, $\hat{Q}_{ij} = \int Q_{ij}(s) A_{ij}(s) ds$, where $Q_{ij}(s) = \langle \xi_i(t) \xi_j(t-s) \rangle$ is the cross-temporal correlation of the input and A the matrix of Green's (electrotonic transfer) functions of the neuron. That is, if a unit charge is injected at synapse j, $A_{ij}(s)$ is the voltage change recorded s seconds later at synapse i.

If $\hat{Q}$ has a principal eigenvector then the weights tune to it. This is qualitatively similar to the isopotential situation, but with the correlation matrix smeared and skewed in both space and time. But because $\hat{Q}$ is asymmetric, it need not have a principal eigenvector. In that case, $\hat{Q}$ must perform a rotation on the 2D principal eigenspace, and the weights tune to this space and rotate within it.

The theory can be applied to a cable in order to derive a characteristic length scale of cluster formation when confronted with unpatterned input, thereby predicting a relationship between lamination scale and the dendritic length constant at the input's temporal frequency. *Supported by ONR and DARPA.*

HETEROSYNAPTIC POST-TETANIC DEPRESSION (PTD) IN AREA CA1 OF ADULT RAT HIPPOCAMPUS: RESTRICTION TO SPECIFIC DENDRITIC DOMAINS. L.M. Grover and T.J. Teyler. Neurobiology Dept., N.E. Ohio Univ. Col. Med., Rootstown, OH 44272.

Tetanic stimulation of afferents to area CA1 can induce heterosynaptic PTD. Tetanic stimulation of one input pathway (25 Hz, 15 sec) reduced EPSPs evoked by test stimulation of a second input pathway 60-80%, lasting 4-5 min, when both input pathways converged on the same dendritic domain (apical or basilar dendrites). When inputs did not converge on the same dendritic domain, PTD averaged only 20-25%. This pattern of results was seen for both K/APMA and NMDA receptor mediated EPSPs. Tetanic stimulation was followed by a post-tetanic hyperpolarization (PTH) of 3-4 mV, lasting 1-2 min. PTD was not prevented by 20 µM DNQX, 50 µM AP5, 500 µM AP3, 500 µM CGP 35348, 3 mM Cs^+, or internal BAPTA and internal Cs^+. PTH was blocked by DNQX, and external and internal Cs^+, but not by by AP5, AP3, CGP 35348, or internal BAPTA. PTD may be presynaptic in origin and induced by limited diffusion of an external messenger.

SHORT & LONG-TERM SYNAPTIC DEPRESSION IN THE NEOSTRIATUM. E. C. Tyler*, D. M. Lovinger and A. Merritt. Dept. of Mol. Physiol. Biophys., Vanderbilt Med. Sch., Nashville TN 37232.

The neostriatum, a part of the basal ganglia involved in motor control and cognitive function, receives a large glutamatergic input from the cortex. Synaptic plasticity at corticostriate synapses has not been well characterized. Using patch/slice and field potential recordings in slices of 2-4 wk old and adult rat neostriatum, we have found that high frequency stimulation of glutamatergic afferents leads to both short- and long-term depression of synaptic transmission. Studies were done using sustained trains (4, 100Hz trains 1s duration, 1/10s) and bursts (5 pulses at 100Hz given 5/s for 5s). The burst paradigm was included because cortical neuron firing probably more closely resembles bursting than sustained trains. Field potential studies showed that following the train paradigm there was a decrease to 45.1±6.2% (n=23) of control in the population spike (PS) evoked by single stimuli while the burst paradigm showed a decrease to 49.7±13.3% (n=7) of control. The mean time to recovery was 7.4±2.3 min in the train paradigm and 4.4±2.4 min in the burst paradigm. Overall 30% of slices showed depression that lasted >20 min. Patch/slice studies showed a decrease to 55.4±9.5% (n=7) of control in the EPSP following sustained trains and to 68.75±14.72% (n=4) of control after bursts. For all slice/patch cells that showed depression the mean recovery was to 80.6±6.9% of control and this occured within 5-15 min. For cells that recovered fully the mean time to recovery was 2.7±.25 min. 47% of cells showed depression lasting >10 min. It was also observed that phorbol diacetate (PDAc) inhibits the decrease in the PS after trains. Without PDAc there was a reduction to 53±5.6% of control but with PDAc a reduction to 95±9% of control was seen (n=5).

PRIOR SYNAPTIC ACTIVITY ENHANCES THE INDUCTION OF LONG-TERM DEPRESSION (LTD) IN HIPPOCAMPUS E.M. Wexler* and P.K. Stanton. Dept. Neuroscience, Albert Einstein Coll. Med., Bronx, NY 10461

Long-term potentiation (LTP) is an extensively studied form of synaptic plasticity and putative memory mechanism. While constraints on LTP amplitude are often assumed, it is still unclear whether LTD could play a role in either memory processing or regulating dynamic system stability. Associative LTD can be elicited at Schaffer Collateral-CA1 synapses when a low-frequency input is negatively correlated in time with a separate high-frequency train of bursts. In contrast to LTP, associative LTD is not blocked by antagonists of N-Methyl-D-Aspartate (NMDA) receptors. Instead, the induction of this form of LTD is blocked by 2-amino-3-phosphonopropionic acid (AP3; 25μM), a relatively selective inhibitor of glutamate-stimulated phosphoinositide turnover. We report here that low-frequency Schaffer collateral stimulation (1-5Hz/15min) in area CA1 of *in vitro* hippocampal slices induces a non-associative homosynaptic LTD (LF-LTD) of extracellular epsp's, but only at previously potentiated synapses (100hz/1sec; 30min before LF stimulation). Unlike associative LTD, induction of LF-LTD was blocked by either the metabotropic antagonist AP3 or the NMDA blocker D-2-amino-5-phosphonovalerate (AP5; 10μM). Furthermore, ionotophoretic application of NMDA to CA1 apical dendrites was insufficient to prime synapses for LF-LTD. However, induction of a series of short-term potentiations (6x 30Hz/0.3sec) did prime synapses for subsequent LF-LTD These results suggest that the threshold for the induction of LTD can be lowered by the previous history of synaptic activity. *(Supported by NIMH Grant #45752 and the Office of Naval Research)*

NMDA RECEPTOR BLOCKADE UNMASKS LONG-TERM DEPRESSION (LTD) OF HIPPOCAMPAL SYNAPTIC TRANSMISSION IN THE DEVELOPING RAT. L. Velíšek, S.L. Moshé* and P.K. Stanton. Depts. of Neurology, Neuroscience and Pediatrics, Albert Einstein Coll. Med., Bronx, NY 10461, U.S.A.

High-frequency stimulation activates postsynaptic N-methyl-D-aspartate (NMDA) receptors and causes influx of calcium into neurons, leading to long-term potentiation (LTP) of synaptic transmission. We hypothesized that a) when NMDA receptors are blocked during high-frequency stimulation, homosynaptic LTD would be unmasked and b) this effect may be age dependent. We stimulated Schaffer collateral-CA1 synapses in hippocampal slices from 15, 30 and 60 day old rats. Two stimulating electrodes were placed in Schaffer collateral axons on opposite sides of extracellular recording electrodes in CA1 pyramidal cell and apical dendritic layers. After a stable baseline period, we tetanized one input (50 Hz, 2 s, 50 μs pulses, 6 trains) while the other served as control. After a brief both homo- and heterosynaptic reduction in responses, we observed either LTP or LTD (30 min post-stimulus) of population spike and e.p.s.p.s in the tetanized input. LTP was observed in 60% of slices from 60 day old rats (138±5% of baseline; n=30), in 57 % of slices from 30 day old rats (128±6%; n=16) and in 65% of slices from 15 day old rats (156±14%; n=23), whereas LTD was seen in only 13%, 6% and 13% in slices from 60, 30 and 15 day old rats, respectively. In contrast, when the NMDA antagonist D-2-amino-5-phosphonovaleric acid (AP5; 25 μM) was added, LTD occurred in 42% of slices (80±3% of baseline; n=19) from 60 day olds, in only one of 14 slices from 30 day olds, and in 47% of slices from 15 day olds (27±6%; n=17), whereas the incidence of LTP decreased to 15%, 14% and 29% in slices from 60, 30 and 15 day old rats, respectively. These studies demonstrate: a) that LTP is largely NMDA dependent in 30 and 60 day old, but not in 15 day old, rats; b) an unmasking of LTD by blockade of NMDA receptors in slices from 60 and 15 day old rats. Developmental differences in the amplitude of LTD, as well as the amount of NMDA versus non-NMDA LTP, may contribute to age-dependent differences in both physiologic plasticity and seizure susceptibility. *(Supported by American Epilepsy Society and Klingenstein Foundation.)*

LONG TERM DEPRESSION IN RAT CEREBELLAR PURKINJE CELL IN VITRO, IS INDUCED BY COACTIVATION OF IONOTROPIC (AMPA) OR METABOTROPIC GLUTAMATE RECEPTORS AND VOLTAGE-GATED CALCIUM CHANNELS.

H. Daniel, N. Hemart, D. Jaillard and F. Crepel *,
Laboratoire de Neurobiologie, Université PARIS XI, URA CNRS 1121, ORSAY, FRANCE.

Long Term Depression (LTD) of synaptic transmission at Parallel-Fiber (PF)-Purkinje Cell (PC) synapses following coactivation of PCs by PFs and by climbing fibers (CFs) has been proposed as the cellular basis of motor learning in the cerebellum. According to the scheme initially proposed by ITO, LTD is due to a desensitization of AMPA receptors of PCs at PF-PC synapses, following their activation by glutamate released by PFs and the transient increase in internal calcium (Ca^{2+}) due to activation of CFs.

In an in vitro slice preparation, using intracellular and whole-cell patch-clamp techniques, a LTD at PF-PC synapses is induced by coactivation of AMPA receptors and voltage-gated calcium channels by stimulation of PFs and direct depolarisation of the PC respectively. The cascade of events leading to this AMPA-dependent form of LTD involves the production of NO, thus confirming earliers observations (Crepel and Jaillard, Neuroreport 1:133).

On the other hand, coactivation of mGLU receptors and voltage gated Ca^{2+} channels seems sufficient to induce an AMPA-independent LTD, whereas activation of mGLU receptors alone induces fully reversible depression of PF-mediated EPSPs.

567.29

LONG-TERM DEPRESSION (LTD) OF SHAFFER-COLLATERAL TRANSMISSION TO CA1 NEURON INDUCED BY REPEATED APPLICATIONS OF GABA X.-D. Yang* & D. S. Faber Neurobiology Lab, SUNY at Buffalo, Buffalo, NY 14214

While repeated strong stimulation of glutamatergic pathway results in LTP, we previously reported that pairing postsynaptic inhibition with weak tetanization of the excitatory pathway led instead to LTD (PNAS vol 88:4299-4303, 1991). The present study shows that repeated application of the inhibitory transmitter GABA alone can also cause LTD of glutamatergic transmission. Intracellular recordings were obtained from CA1 neurons in hippocampal slices. The Shaffer collateral pathway was stimulated at 0.1 Hz to produce the test EPSP. Repeated pressure applications (150 ms) of 10 mM GABA (10 at 40 sec) to the vicinity of the postsynaptic neuron resulted in a 50% depression of the EPSP that lasted up to 50 minutes. The duration of the depression tended to be shorter when less GABA was applied (n=12). The depression was not due to a decreased input resistance of the postsynaptic neuron, and it could be reversed by high frequency stimulation, the paradigm typically used to induce LTP. This depression could be induced in the presence of 50 μM of APV (n=6). Furthermore, 10 mM of baclofen (n=5) could induce a depression similar to that induced by GABA. The above results suggest that repeated action of the inhibitory transmitter GABA causes prolonged depression of glutamatergic transmission, which is most likely mediated through the activation of $GABA_B$ receptors. Together with LTP, this inhibition-induced LTD may play an important role in activity-dependent, long-term synaptic plasticity in mammalian brain.

A RISE OF $[Ca^{++}]_i$ IN THE POSTSYNAPTIC CELL IS NECESSARY AND SUFFICIENT FOR THE INDUCTION OF LONG-TERM DEPRESSION (LTD) IN NEOCORTEX. A. Artola*, T.Hensch and W.Singer. Max Planck Institute for Brain Research, Frankfurt/M, FRG.

In slices of the visual cortex of adult rats synaptic responses were recorded intracellularly from layer III pyramidal cells (Vmr from -96 to -67 mV) after electrical stimulation of white matter (w.m.) and of tangential intracortical (i.c.) pathways. In all cells whose Vmr was less negative than -79 mV (n=8), raising extracellular $[Ca^{++}]_0$ transiently from 2 to 4 mM for 10 min produced, after return to 2 mM $[Ca^{++}]_0$, a marked (>-10% and up to -35%:-17.2 ± 7.5%, ± S.D.) and lasting (>90 min) depression of w.m. and i.c. EPSPs. This Ca^{++}-induced LTD affected both amplitude and rising slope of the EPSPs and was equally pronounced for both w.m. and i.c. responses. In more polarized cells (Vmr above -79 mV) transiently raising $[Ca^{++}]_0$ had no lasting effect on synaptic transmission (+1.4 ± 8.6%, n=5). However, in these hyperpolarized cells, low intensity tetanic stimuli, which under control conditions did not induce synaptic modifications, produced LTD (-27.4 ± 2.4%, n=5) when applied during the Ca^{++} pulse. This depression was selective for the tetanized pathway and could be blocked by loading the cell with BAPTA before stimulation (n=3). In cells with Vmr below -79 mV, in which already high Ca^{++} alone induced LTD, tetanic stimuli applied in conjunction with the Ca^{++} pulse caused no further enhancement of LTD: Depression was of similar amplitude for the tetanized and non-tetanized input. These results suggest that both Ca^{++}- and tetanus-induced LTD depend for their induction on the same postsynaptic process. The trigger signal in both cases appears to be a surge of intracellular Ca^{++} which results at least in part from Ca^{++}-entry through voltage-gated Ca^{++} conductances.

A POSTSYNAPTIC ACTION OF SODIUM IONS IS REQUIRED FOR THE INDUCTION OF CEREBELLAR LONG-TERM DEPRESSION IN CULTURE
D.J. Linden*, M. Smeyne, and J.A. Connor, Department of Neurosciences, Roche Institute of Molecular Biology, Nutley, NJ 07110.

Long-term depression (LTD) of responses to AMPA test pulses in the tissue cultured mouse Purkinje neuron (PN) is induced when iontophoretic quisqualate pulses and PN depolarization are given together. Both AMPA and metabotropic receptor activation are necessary for LTD induction in a voltage-clamp paradigm: in PNs clamped to -80mV in TTX saline, LTD may not be induced by depolarization together with pulses of *t*-ACPD or (quisqualate+CNQX). The AMPA receptor in these PNs does not appear to exert its effect by directly gating Ca influx (P_{Ca}/P_{Na} <0.2 for AMPA, >5.0 for NMDA). Replacement of external Na during quis/depolarization conjunction with either the impermeant ions NMG or TEA or the permeant ion Li, caused a blockade of LTD induction, suggesting that Na influx through the AMPA associated channel is necessary for this process. To determine whether activation of voltage-gated Na channels could substitute for AMPA receptor activation, responses to AMPA pulses were measured in current clamp mode following ACPD/depolarization conjunction in TTX-free saline. LTD was induced 3/16 times in normal medium and 7/16 times in veratridine (2 μM) indicating that while Na influx via voltage-gated channels may suffice to induce LTD infrequently, activation of AMPA receptors is more effective. Na influx might exert its effects through Na_i/Ca_o exchange, a process not stimulated by Li_i. Antiserum to a bovine cardiac Na/Ca exchanger shows strong immunoreactivity in our cultured PNs. We are currently employing microfluorometric imaging of Na and Ca to evaluate the potential contribution of this process to LTD induction.

LONG-LASTING DEPRESSION OF LATERAL PERFORANT PATH SYNAPTIC TRANSMISSION IN THE RAT HIPPOCAMPAL DENTATE GYRUS IS NOT MEDIATED BY ADENYLATE CYCLASE ACTIVATION.
A.T. Gage and P.K. Stanton*. Depts. of Neuroscience & Neurology, Albert Einstein Coll. Med., Bronx, NY 10461.

Norepinephrine (NE) elicits long-lasting potentiation (LLP) of perforant path synaptic transmission in the hippocampal dentate gyrus. NE LLP is mimicked by the β agonist isoproterenol (ISO), and by forskolin, a direct activator of adenylate cyclase. Both compounds presumably act by increasing intracellular cyclicAMP. The perforant path can be separated anatomically and physiologically into distinct medial (med) and lateral (lat) components. While ISO causes LLP of med responses, it elicits long-lasting depression (LLD) of lat synaptic transmission. Since it is not known if lat LLD is also mediated by cAMP, we tested the effects of forskolin on med and lat synaptic evoked potentials in hippocampal slices *in vitro*.

Separate stimulating electrodes alternately activated axons of med and lat every 60s. Potentials were recorded from glass microelectrodes placed in the proximal (med) or distal (lat) half of stratum molecularé. After a baseline period, forskolin (100μM) was perfused for 30min. As reported previously, NE (50μM) elicited LLP of med and LLD of lat perforant path responses. In contrast, forskolin persistently potentiated both med and lat evoked potentials. These results suggest that only med LLP is mediated by an increase in intracellular cAMP, whereas lat LLD is independent of cAMP. Since both NE LLP and LLD are blocked by NMDA receptor antagonists, LLD may represent a heterosynaptic depression secondary to enhancement of med NMDA receptor activation by NE, similar to heterosynaptic LTD after high-frequency stimulation.

DIFFERENTIAL EFFECTS OF GANGLIOSIDES ON TETANUS-INDUCED SYNAPSE POTENTIATION AND KAINATE-INDUCED SYNAPSE SUPPRESSION.
H.-M. Hwang*, J.-L. Teng and T.-H. Chiu. Dept. of Anatomy, Chang Gung Med. College, Taoyuan, Taiwan 33333 and Dept. of Physiology, National Yang Ming Med. College, Taipei, Taiwan 11221, R.O.C.

Gangliosides are found to be enriched in the synaptic membranes of the mammalian CNS. Among members of gangliosides, monosialogangliosides such as GM1, and disialoganglioside, GD1a, are most abundant in the CNS. Treatment with enzyme neuraminidase (NA) was found to increase mono- and di-sialoganglioside contents. To elucidate extent of their influence, two modes of activity changes in CA1 areas of rat hippocampal slices were used, i.e. synapse potentiation by 3 trains of 100 Hz stimuli on Schaffer's collaterals and synapse suppression by infusing 5 uM kainate for 20 min. While GM1 enhanced synapse potentiation, GD1a and NA did not have obvious effects. NA prevented 80% of synaptic suppression, but GM1 and GD1a only prevented 40%. NA raised up input resistance of CA1 pyramidal cell and reduced depolarization potential. No change of resting membrane potential was found after NA treatment. However, NA prevented change of input resistance during kainate perfusion. (supported by CMRP324)

SYNAPTIC PHARMACOLOGY I

568.1

INHIBITION OF NEUROTRANSMITTER RELEASE FROM PC12 CELLS BY THE CA^{2+}/CALMODULIN-DEPENDENT PROTEIN KINASE II INHIBITOR, KN-62.
Erik S. Schweitzer*[1] & Claude Wasterlain[2]. [1]Department of Anatomy & Cell Biology, and [2]VA Medical Center Department of Neurology, UCLA Medical School, Los Angeles, CA 9002.

PC12 cells secrete catecholamines in a depolarization and Ca^{2+} dependent manner. We have examined the effects of a variety of pharmacological agents on regulated secretion from PC12 cells by monitoring the rate of release of ^{3}H-norepinephrine from PC12 cells previously loaded with this neurotransmitter. Treatment of these cells with the selective Ca^{2+}/calmodulin-dependent protein kinase II inhibitor, KN-62, results in an inhibition of the regulated secretion of neurotransmitter. KN-62 inhibits norepinephrine release in a manner that is rapid, reversible, and dose-dependent. Half-maximal inhibition is obtained at 3 μM KN-62, and the extent of regulated secretion returns halfway to control values approximately 6 minutes after washout. These results, together with the effects of other agents that affect calmodulin-dependent cellular processes, suggest the involvement of both calmodulin and protein kinase II in the regulated release of catecholamine neurotransmitters.

568.2

FACILITATION BY DOPAMINERGIC MECHANISM OF ATP-ACTIVATED CURRENTS AND DOPAMINE RELEASE IN PC12 CELLS.
K. Inoue*, K. Nakazawa, T.Watano, K.Fujimori and A. Takanaka, Div. Pharmacology, NIHS, 1-18-1 Kamiyoga, Setagaya, Tokyo 158, Japan

We have previously reported that ATP stimulates P2y-like purinoceptor, activates Ca-permeable cation channels, stimulates Ca influx and dopamine (DA) release in PC12 cells (a revew in NIPS, April, 1992). Though DA doesn't evoke currents nor release from these cells, it is presumably that released-DA modifies the ATP-evoked responses. We report here that both DA receptor agonists and antagonists facilitate ATP-activated currents and DA release from PC12 cells.

DA(10μM) enhanced ATP(100μM)-activated inward current by about 50%. Similar enhancement of the ATP-evoked current was observed with apomorphine(10μM), a non-selective DA receptor agonist, SKF-38393(10μM), a selective D1 receptor agonist, and quinpirole(10μM), a selective D2 receptor agonist. Moreover, SCH-23390(30μM) and sulpiride (30μM), selective D1 and D2 antagonist, respectively, enhanced the current. These agonists and antagonists stimulated ATP(100μM)-induced DA release from PC12 cells at the same concentration. These data suggest that the ATP-evoked responses are facilitated by dopaminergic mechanisms through a kind of DA-receptor subclass which is not characterized yet.

SYNAPTIC PHARMACOLOGY OF RAT SYMPATHETIC NEURON AND CARDIAC MYOCYTE CO-CULTURE. P.T. Toth*, V.P. Bindokas, and R.J. Miller. Dept. Pharm/Phys. Sci., U. of Chicago, Chicago, IL 60637.

We are studying the pharmacology of synapses formed between neurons isolated from neonatal rat superior cervical ganglia (SCG) and atrial myocytes in co-cultures maintained for up to 2 weeks with the goal of determining the types of calcium channels (VSCCs) involved in transmitter release. We have found multiple types of VSCCs in these neurons including α_{1A}, α_{1C}, α_{1D} and α_{1x} (see also Marubio et al., this vol.). SCG neurons co-cultured with myocytes are able to release multiple transmitters (Matsumoto et al., J.Neurosci., 7:380, 1987). Evoked synaptic activity was monitored by fura-2 microfluorimetry of spontaneous calcium oscillations in myocytes. Neurons were stimulated by whole-cell patch clamp method, holding cells at -75mV and stimulating at 4 or 10 Hz. Stimulation of 51 pairs examined resulted in increased myocyte oscillation frequency or basal $[Ca^{2+}]_i$ (57%), decrease of basal $[Ca^{2+}]_i$ or inhibition of oscillation frequency (31%), and no apparent effect (12%). Frequency increases are mimicked by noradrenaline (NA) and blocked by phentolamine. Frequency decreases are mimicked by carbachol (CCh) or by NA and blocked by atropine and atenolol, respectively. CCh decreased, and NA increased, basal $[Ca^{2+}]_i$. In addition, some synapses appear to be purinergic and/or peptidergic. The pharmacology of the VSCCs involved in transmitter release is being studied by application of toxins. ω-Conotoxin GVIA (CgTx; 5μM) was focally applied by pressure ejection. Excitatory and inhibitory effects of stimulation were largely blocked by CgTx. These results indicate, that ω-CgTx sensitive VSCCs (N-channels) play an important role in the regulation of release of a variety of transmitters from sympathetic nerves.

DIFFERENTIAL EFFECTS OF NOREPINEPHRINE ON FIELD POTENTIALS IN LAYERS 1A AND 1B OF RAT OLFACTORY CORTEX. M.C.Vanier and J.M.Bower*, California Institute of Technology, Pasadena, CA 91125.

In rat olfactory (piriform) cortex, layer 1a contains afferents from the olfactory bulb while layer 1b contains intrinsic pyramidal cell associational fibers. We have previously demonstrated (Hasselmo and Bower, J. Neurophysiol. 1992) that the cholinergic agonist carbachol, when bath-applied in a brain slice preparation, causes a large suppression of synaptic transmission in layer 1b of rat olfactory (piriform) cortex while having essentially no effect on layer 1a. These effects were shown to be computationally significant when incorporated into a computer model of olfactory cortex (Hasselmo, Anderson, and Bower, J. Neurophysiol. 1992). In the present study, we examined the effects of bath-applied norepinephrine in a brain slice preparation on extracellular field potentials in layers 1a and 1b of piriform cortex. We found that 25 mM NE decreased field potential height in layer 1b to 33.2 ± 11.5% of control, while NE increased field potential height in layer 1a to 139.6 ± 15.1% of control. Both effects were reversible after washout of NE. Thus NE has an effect very similar to ACh in layer 1b, but, unlike ACh, NE increases field potential height in layer 1a. Based on previous modeling efforts, these results are consistent with a role for this neuromodulator as a "state switch" for associative learning in piriform cortex.

PHARMACOLOGICAL DISTINCTIONS BETWEEN PRE- AND POST-SYNAPTIC DOPAMINE RECEPTORS IN INTERMEDIATE PITUITARY. P.J.WILLIAMS,* T.V. DUNWIDDIE, & G.A.GERHARDT, Dept. Pharmacology, University of Colorado Health Sciences Center, 4200 E. Ninth Ave, Denver, Colorado, U.S.A. 80262

The intermediate lobe of the pituitary (IL) receives a monosynaptic DA projection from the arcuate nucleus which synapses onto a single class of postsynaptic cells, the melanotrophs, which bear D2 receptors. DA release from the neurons innervating the IL is modulated by presynaptic autoreceptors which are inhibited by D2 antagonists. The IL thus contains both pre- and post-synaptic D2 receptors with different physiological functions. Both pre- and post-synaptic D2 receptor function were assessed simultaneously in a single IL by measuring electrically stimulated (SS) DA release using carbon fiber electrochemical electrodes. (to assess autoreceptor status) and simultaneous intracellular recording from the melanotrophs (to assess postsynaptic D2 receptor status). Haloperidol, a D2 antagonist, increased DA release while simultaneously abolishing the postsynaptic response to SS. Sulpiride, another D2 antagonist, increased presynaptic DA release by 100% at 500nM, however, sulpiride did not block the postsynaptic hyperpolarization due to SS. Domperidone, (1μM) another D2 antagonist, blocked the postsynaptic response to SS without increasing DA release. S(-)PPP, thought to effect autoreceptors selectively, increased DA release but had no effect on postsynaptic response while R(+)PPP caused a postsynaptic hyperpolarization but had no effect on DA release. The ability of these agents to distinguish between these two sets of D2 receptors suggests that they may represent subtypes of the D2 receptor. Supported by USPHS 0634 and VA Med Research Service

ESTROGEN ATTENUATES α_2-ADRENERGIC INHIBITION OF NOREPINEPHRINE RELEASE FROM HYPOTHALAMIC SLICES. G.B. KARKANIAS* AND A.M. ETGEN. Depts. of Psychiatry and Neuroscience, Albert Einstein College of Medicine, Bronx, NY, 10461

The purpose of this study was to determine whether norepinephrine (NE) release in the hypothalamus is controlled by α_2-adrenergic inhibition and whether this mechanism is regulated by estrogen. Slices were prepared from female Sprague-Dawley rats that were bilaterally ovariectomized and treated with oil (OVX) or 2 μg of estradiol benzoate (EB) 24 and 48 hrs. prior to sacrifice. Slices were preincubated for 45 min. with .1 μM ^{3}H-NE and washed for 30 min. in the chambers of a superfusion apparatus at a flow rate of 1ml/3min. Slices were stimulated twice for 3 min. with 10 mM KCl (S1 and S2). S1 and S2 were separated by 24 min. The α_2 antagonists idazoxan (IDA) or RX821002 (RX) at 10 μM were applied 15 min. prior to S2 and were present until the end of the experiment. Basal ^{3}H-NE release was not affected by α_2 antagonists or hormone pretreatment. KCl-evoked release of ^{3}H-NE was Ca^{2+} dependent. The amount of ^{3}H-NE released during S1 was 20% greater in slices from EB-treated animals than in slices from OVX animals. When IDA or RX were infused prior to S2 in slices from OVX animals, ^{3}H-NE release was increased 50-80% relative to S1. In contrast, IDA and RX had little or no influence on ^{3}H-NE released during S2 in slices from EB-treated animals. Similar effects of estrogen administration were observed in slices from the preoptic area. These results suggest that α_2-adrenergic inhibitory mechanisms are active in the hypothalamus of OVX animals and that these mechanisms are attenuated by estrogen.

SLOW EPSPS AND RESPONSES TO SUBSTANCE P OF DORSAL HORN NEURONS IN THE ADULT RAT SPINAL CORD SLICES. M. Yoshimura*, T. Shimizu and S. Nishi. Dept. Physiol., Kurume Univ. Sch. Med., Kurume, 830 Japan

To study the effect of substance P (SP) on nociceptive transmission in the dorsal horn of the spinal cord, intracellular recordings were made from substantia gelatinosa (SG, lamina II) and lamina IV-V neurons of the adult rat spinal cord slices.

Substance P applied by perfusion produced no changes in membrane potential or conductance in 18 of 18 SG neurons but it increased spontaneous EPSPs in amplitude and frequency in 30 % of the SG neurons examined. In 50 % of lamina IV-V neurons, SP produced a concentration-dependent depolarization associated with a decreased membrane conductance. The depolarization decreased in amplitude with membrane hyperpolarization and was nullified at about -90 mV. The SP-induced depolarization was not affected by tetrodotoxin, while it was blocked by Co^{++}.

Repetitive dorsal root stimulation with intensity sufficient to activate C afferent fibers evoked slow EPSPs which were associated with a decreased membrane conductance in 20 % of lamina IV-V neurons. The slow EPSPs decreased in amplitude with membrane hyperpolarization and was nullified at about -90 mV. These neurons were also depolarized by SP. The slow EPSPs and SP-induced depolarization were attenuated by SP receptor antagonist spantide.

These observations suggest that SP mediates the slow EPSPs at the synapse between primary afferent and lamina IV-V neurons in the SG.

SYNAPTIC MODULATION OF RAT MEDIAL VESTIBULAR PACE-MAKER DISCHARGE. Y. Lin* and D. Q. Carpenter. Wadsworth Labs, NYS Dept. Health and School of Public Health, Albany, NY 12201.

Medial vestibular neurons in rat brain slices show an endogenous pacemaker discharge. Synaptic modulation of this activity was evaluated by combining recording of spontaneously active neuronal activity, and iontophoretic application and bath application of various neurotransmitter receptor agonists and antagonists.

Iontophoretic application of the muscarinic receptor agonist, oxotremorine-M, increased the firing rate of most neurons and decreased the firing rate in a few. The non-selective muscarinic receptor antagonist, atropine (50 μM), depressed the firing rate (10-27%) in most neurons. Application of the muscarinic M_2 receptor antagonist, gallamine (50 μM), initially increased the firing rate (35-65%) followed by a decrease (10-15%). Little effect was observed with the muscarinic M_1 receptor agonist pirenzepine (50 μM) in most neurons.

2-Amino-4-phosphonobutyrate (AP4 100 μM), an agent known to block presynaptic neurotransmitter release, decreased firing rate (10-33%). The $GABA_A$ receptor antagonist, bicuculline (50 μM), increased the firing rate (21-60%) whereas GABA decreased it. Application of bicuculline during the presence of AP4 failed to induce excitation.

Conclusion: The endogenous pacemaker activity of medial vestibular neurons is modulated by various neurotransmitters. Even in isolated brain slice preparations, release of transmitters from presynaptic terminals appears to influence spontaneous neuronal activity, since application of antagonists alters firing rate. Supported by the Aaron Diamond Foundation & NS23807.

ROLE OF SYNAPTIC TRANSMISSION AND CHLORIDE CONDUCTANCE IN THE ELECTROPHYSIOLOGICAL EFFECTS OF LINOPIRDINE ON CA1 HIPPOCAMPAL NEURONS *IN VITRO*. P. A. Murphy and B. S. Brown*. CNS Diseases Research, The DuPont Merck Pharmaceutical Co., Wilmington, DE 19880-0400

Because linopirdine (DuP 996) is known to enhance neurotransmitter release *in vitro*, it was of interest to determine whether its previously reported electrophysiological effects on CA1 neurons in the hippocampal slice (reduced spike frequency adaptation, prolonged spike duration and increased spontaneous firing) represented direct somatic effects and, if so, to assess the possible role of chloride conductance in mediating these responses. Standard intracellular recording techniques were used to study the effects of 10 μM linopirdine under conditions of synaptic transmission blockade (omega-conotoxin, CnTX) and an altered chloride equilibrium potential (KCl electrodes). The presence of 0.3 μM CnTX had no influence on the effects of linopirdine recorded with K acetate electrodes. Conversely, the use of KCl electrodes completely blocked the electrophysiolgical effects of linopirdine but had no effect on those of muscarine (thought to act through K channel blockade). These results suggest that linopirdine exerts direct effects on the CA1 hippocampal soma which may be mediated by the block of a chloride conductance.

568.10

INTERNEURONAL ELECTROTONIC COUPLING IN A SYSTEM MODEL USING WHITE NOISE ANALYSIS: ETHANOL UNCOUPLES NEURONS. P.Fu, N. Wright, B.L. Bardakjian and P.L. Carlen*. Playfair Neuroscience Unit, The Toronto Hospital, 399 Bathurst St., and the Addiction Research Foundation, Toronto, Ont., Canada, M5T 2S8.

A system model of dentate granule neurons (Fu et.al.,IEEE Trans Biomed Eng, 36,1:55-64) using white noise analysis is used to study the electrotonic properties. The model is based on a multi-compartmental circuit including interneuronal coupling, and comprises a combination of resistors and capacitors. Analytical expression of the input resistance is written using the Z-transform. The model parameters are estimated using an optimization procedure from in vitro voltage recording of white noise current injected into dentate granule neurons of the rat. White noise analysis allows extraction of the linear component (the first Weiner kernel) of the voltage response. The most appropriate fit to the experimental data (input impedance) required interneuronal electrotonic coupling. Also, the membrane capacitance obtained was close to 1 $\mu F/cm^2$. Acute ethanol exposure (50mM) caused a large increase in the junctional resistance resulting in uncoupling of neurons, as has been shown with higher order alcohols in other cellular systems.

EFFECTS OF NEUROTRANSMITTERS ON PYRAMIDAL AND NON-PYRAMIDAL NEURONS IN HIPPOCAMPAL SLICES. N. Otmakhov, R.Malinow & R.E .Fellows*. Dept. of Physiology and Biophysics, Univ. of Iowa & Instit. of Theoret. and Experim. Biophysics, Russian Academy of Sciences.

Whereas there are many studies on phenomenology and underlying mechanisms of neurotransmitter actions on principal cell types of CNS, only a few reports investigate the pharmacological sensitivity of local-circuit interneurons. We investigated effects of acetylcholine (ACh), norepinephrine (NE), 5-hydroxytryptamine (5-HT) and gamma-aminobutyric acid (GABA) on extracellular recorded single cell spontaneous firing activity in the CA3 field of guinea pig hippocampal slices. Three groups of neurons were investigated: nonpyramidal neurons of stratum radiatum-moleculare (N), neurons with single spike discharges of stratum pyramidale (SS) and neurons with complex spike discharges (CS) in the same stratum. Effects of ACh and NE were also tested on p-_sumed interneurons of str. oriens-pyramidale (I). Similarity between N, I and SS units and their difference from CS units may be suggested on the basis of drug action. Activity of CS units was suppressed by NE, 5-HT and GABA, while in half of these units ACh had biphasic (inhibitory, then excitatory) effects. In contrast, N, I and SS units were activated by NE and ACh. Though 5-HT and GABA suppressed the activity in some N and SS units, many of them were activated. Excitatory influence of NE, ACh and 5-HT on N was preserved with the blockade of synaptic transmission (Fig.1). The data suggest direct excitatory influence of NE-, ACh- and 5-HT-ergic afferents on nonpyramidal cells and therefore an indirect inhibitory influence on hippocampal pyramidal cells.

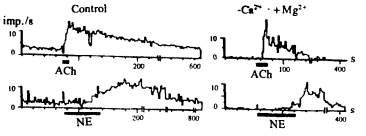

Fig.1. Preservation of excitatory actions of ACh and NE on hippocampal nonpyramidal neurons during synaptic blockade.

SYNAPTIC RESPONSES RECORDED FROM BIOCYTIN LABELLED NEURONS IN MOUSE CINGULATE CORTEX IN VITRO. M. Kiraly* and P.I. Magistretti. Institut de Physiologie, Université de Lausanne, CH-1005 Lausanne, Switzerland.

In a submerged slice (300 μm thick) preparation, intracellular recordings were combined with biocytin injections to characterize the membrane properties, synaptic responses and morphology of 3-4 week old mouse anterior cingulate cortex neurons.

On the basis of their firing pattern in response to depolarizing current pulses, neurons were classified as regular spiking (36/42) and bursting (6/42). The resting membrane potential (-75 mV vs -73 mV), the input resistance (51 MΩ vs 56 MΩ), the time constant (11 ms vs 7 ms), the action potential amplitude (84 mV vs 79 mV) and duration (1.8 ms vs 1.7 ms) of these two populations were quite similar. Biocytin labelling of regular spiking and bursting neurons revealed pyramidal shaped cells located mainly in layer V and, in a few cases, layers II/III. Stimulation of corpus callosum elicited four synaptic potentials in both cell types : (i) early, monosynaptic EPSP (time-to-peak 6.6 ± 2.4 ms; amplitude 8.7 ± 3.7 mV) blocked by the non-NMDA receptor antagonist CNQX 20 μM. (ii) early monosynaptic IPSP (time-to-peak 11.0 ± 6.4 ms; amplitude 7.0 ± 0.8 mV) blocked by the $GABA_A$ antagonist bicuculline 20 μM. (iii) late EPSP (time-to-peak 32.2 ± 6.9 ms; amplitude 10.5 ± 5.9 mV) blocked by the NMDA receptor antagonist AP5 50 μM. This late potential could be enhanced by removal of extracellular Mg^{2+} and by tonic depolarization of the neuronal membrane. (iv) late IPSP (time-to-peak 101 ± 44 ms; amplitude 3.6 ± 0.5 mV) abolished by the $GABA_B$ antagonist saclofen 300 μM and showing a reversal potential of ≈ -90 mV, suggesting a K^+-channel involvement.

568.13

AMPHETAMINE-INDUCED INCREASE IN [^{3}H]TCP INTACT CELL BINDING OF PRIMARY CULTURED NEURON. H.Yamamoto[1], T.Yamamoto[1], N.Sagi[1], K.Yang[1], A.Baba[1], T.Moroji[1] and K.Yoshikawa*2 [1]Dept. of Psychopharmacology, Tokyo Inst. of Psychiatry, Tokyo 156, [2]Dept. of Mol. Biol., Tokyo Metropolitan Inst. for Neurosci., Tokyo 183, Japan.

To investigate factors regulating [^{3}H]TCP binding sites under the physiological condition, we conducted intact cell binding studies in primary cultured neuronal cells derived from fetal rat telencephalon. In modified Locke medium (with 95% O_2/5% CO_2, 25°C), [^{3}H]TCP(4nM) binding to the intact cells was saturable, reversible, and displaced by non-competitive NMDA receptor antagonist or σ ligand. Displacement studies of [^{3}H]TCP intact cell binding by σ/PCP ligands (haloperidol, desipramine, PCP, DTG and GBR12909) revealed the potency of the inhibition with IC_{50} values of 0.448, 1.649, 7.02, 12.71 and 1.296 μM, respectively. The [^{3}H]TCP binding of cells cultured with serum was more sensitive to APV than that of the cells cultured without serum. However, the potency of inhibition by σ ligand was not influenced by the culture condition (serum or serum-free medium).

Subchronic exposure to amphetamine induced increases in the amount of [^{3}H]TCP intact cell binding in a dose-dependent manner. The inhibition of [^{3}H]TCP intact cell binding by σ ligands was not influenced by amphetamine treatment. These results suggest that amphetamine-induced change in neuronal cells is involeved in a cellular excitability and formation of reverse tolerance. Furthermore, σ ligands may modulate the amphetamine-induced changes through NMDA receptor coupled ion channels.

INHIBITORY EFFECT OF LITHIUM ON PROTEIN PHOSPHORYLATION SYSTEM ASSOCIATED TO NEURONAL CYTOSKELETON. J. Perez, R. Zanardi §, S. Mori, C. Cagnoli, L. Formica, D. Tinelli, N. Brunello* and G. Racagni. Center of Neuropharmacology, § San Raffaele Hospital, University of Milan, Italy.

Lithium is the most effective drug in the treatment of manic-depressive illness. Its therapeutic action includes antimanic and antidepressant effects, as well as prevention by reducing frequency or intensity of bipolar episodes. Likewise, lithium could be used in the prophylaxis of recurrent unipolar depressive illness. Although the molecular basis of its therapeutic efficacy is still unclear, the biochemical action of lithium is mainly based on signal transduction processes beyond the receptor level. Protein phosphorylation-dephosphorylation represents a fundamental step for signal transduction in the CNS, and recently evidence obtained in our laboratory suggests that it could be involved in the therapeutic effect of antidepressant drugs. We have now extended these studies to determine whether protein phosphorylation system associated to rat cerebrocortical microtubule fraction may also be a neurochemical target for the action of lithium. In vitro addition of lithium (0.5 to 2 mM) was able to inhibit of 20% the basal ^{32}P incorporation in microtubule fraction after 30 minutes of incubation. Moreover, the presence of high lithium concentration (5 mM) induced decrease of 30% and 40% in the basal phosphorylation of microtubule fraction after 5 and 30 minutes of incubation respectively. Since, cAMP protein kinase type II is known to be associated with microtubules, we have investigated the cAMP dependent endogenous phosphorylation. In this experimental condition 5 μM of cAMP caused a 3 fold increase in the initial rate of ^{32}P incorporation into MAP_2, a phosphoprotein associated to neuronal microtubules which is itself a substrate for cAMP dependent protein kinase. Lithium 1 and 5 mM decreased the initial rate of ^{32}P incorporation into MAP_2 from 3 to 2.4 and 1.8 respectively. By contrast, Rubidium 5 mM was unable to affect the rate of ^{32}P incorporation into MAP_2. These studies support the hypothesis that protein phosphorylation system associated with microtubules might be a neurochemical target for the action of lithium.

569.1

SYNAPSES IN THE MEDIAL AND LATERAL PERFORANT PATHWAYS EXAMINED WITH THE WHOLE-CELL VOLTAGE CLAMP IN THE RAT HIPPOCAMPAL DENTATE GRANULE NEURONS. S. Wang, A. Baskys and J.M. Wojtowicz*. MRC group, Department of Physiology, University of Toronto, Toronto, ONT, M5S 1A8.

Lateral (LP) and medial (MP) perforant pathways terminate on distal and medial portions of dendrites of the dentate granule neurons. Several differences between synapses of LP and MP have been described previously. We examined the properties of transmission at these synapses using the whole-cell voltage clamp technique. Experiments were performed on granule neurons in the hippocampal slices taken from 15-30 day old Wistar rats. MP and LP were activated selectively by means of stimulating electrodes placed in the molecular layer. A putative glutamate receptor blocker L-AP4 (20 μM) selectively antagonized synaptic transmission in LP (55% inhibition, S.E.=9.4%, n=5). With the use of quantal recordings we have shown that its action was presynaptic. Similar presynaptic actions on LP were obtained with application of an NMDA blocker D,L-APV (50 μM). However, in MP the effect of D,L-APV was mainly postsynaptic. The results confirm different locations and characteristics of glutamate receptors in the two pathways. Possible roles for these receptors during high-frequency activity are under investigation. Supported by MRC of Canada.

SPERMINE DEPRESSES POPULATION EPSPs AND MONOSYNAPTIC POPULATION IPSPs IN THE RAT HIPPOCAMPAL SLICE PREPARATION. P.G. DiScenna*, P.A. Ferchmin, E. Rivera, V. Eterovic & T.J. Teyler. Neurobiology Department, NEOUCOM, Rootstown, OH 44272 and Department of Biochemistry, School of Medicine, Universidad Central del Caribe, Bayamon, P.R. 00960.

Spermine, a polyamine, is present in the brain in significant concentrations and is known to affect several receptors, protein kinases and other neural regulatory processes. High concentrations of extracellular spermine are observed after strong depolarization and ischemia. It has been proposed that spermine released during ischemia is partially responsible for its pathogenesis. We examined the effects of spermine on extracellular evoked responses in area CA1 of the rat hippocampal slice preparation. Spermine depressed both excitatory and inhibitory synaptic potentials. An effect of spermine was detectable at 50uM. At 2mM (10-20min @ 0.5ml/min), spermine reversibly depressed the population EPSP and spike by 75-100%, population NMDA responses (DNQX/0mM Mg) by 65-75% and monosynaptic population IPSPs (DNQX/APV) by 50-65%.

Given the known effects of spermine, the most likely explanation is that presynaptic calcium currents are depressed or mitochondrial uptake of calcium from the presynaptic terminal is enhanced. Therefore we are presently comparing the effects of spermine with low calcium ACSF.

Rather than contribute to ischemic damage, perhaps spermine could reduce damage by depressing synaptic transmission.

569.3

INHIBITION OF NMDA RECEPTOR-MEDIATED SYNAPTIC CURRENTS BY A MU OPIOID AGONIST IN DISINHIBITED DENTATE GRANULE CELLS. C.W.Xie* and D.V.Lewis. Pediatric Neurology, Duke Univ. Med. Ctr., Durham, NC 27710.

We have previously reported that the mu opioid agonist PL017 suppressed GABAergic inhibition and thus indirectly enhanced NMDA receptor-mediated responses in hippocampal dentate gyrus. The present study examined the direct effect of PL017 on NMDA receptor-mediated excitatory postsynaptic currents (EPSCs) of granule cells in the absence of $GABA_A$ inhibition. Isolated NMDA EPSCs were evoked by outer molecular layer stimulation and recorded from granule cells using whole cell voltage clamp techniques in the presence of DNQX (AMPA antagonist, 10 μM) and bicuculline methiodide ($GABA_A$ antagonist, 10-50 μM). The current was enhanced by removing magnesium from the perfusion medium, and completely blocked by D-APV. Bath application of PL017 (3-10 μM) significantly reduced the amplitude of isolated NMDA EPSCs by 27-43%. This effect could be reversed by opiate antagonist naloxone (10 μM). These results indicate a direct inhibition of NMDA currents by mu receptor activation in the dentate, which may serve as a protective mechanism to limit the hyperexcitability of NMDA channels during opioid disinhibition.

569.4

METABOTROPIC RECEPTOR-INDUCED SUPPRESSION OF SYNAPTIC TRANSMISSION IS NOT BLOCKED BY L-2-AMINO-3-PHOSPHONO-PROPIONIC ACID (L-AP3). J. W. Goh* and M. A. Musgrave, Department of Pharmacology & Toxicology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Activation of a metabotropic glutamate receptor (mGluR), found in various brain regions, produces an increase in phosphoinositide (PI) metabolism. 1-Aminocyclopentane-*trans*-1,3-dicarboxylic acid (*trans*-ACPD), a specific agonist of a mGluR, stimulates PI turnover that is antagonized by AP3. However, some electrophysiological actions of *trans*-ACPD, including slow depolarization and inhibition of the late after-spike hyperpolarization, are not blocked by AP3. We report here that inhibition of hippocampal excitatory postsynaptic potentials (EPSPs) by the mGluR agonist is also resistant to blockade by AP3. Experiments were conducted on rat hippocampal slices, where EPSPs were evoked by stimulation of stratum radiatum and recorded in the CA_1 dendritic region. 1S,3R-ACPD and L-AP3, the active isomers of *trans*-ACPD and AP3, respectively, are used in the present studies. 1S,3R-ACPD (100 μM) produces a suppression of EPSPs (24 ± 3% (SEM) of control, n = 4), an action that is not antagonized by L-AP3 (500 μM) (21 ± 3% of control, n = 8). L-AP3 (500 μM) application alone does not result in any significant change in the synaptic response (86 ± 6% of control, n = 8). A washout period of 20 minutes reverses inhibition of the EPSP by 1S,3R-ACPD application alone (73 ± 11% of control, n = 4) or in combination with L-AP3 (74 ± 12% of control, n = 6). Since AP3 blocks PI metabolism induced by trans-ACPD but not many of its electrophysiological actions, we suggest that i) an alternate effector system and/or ii) a different subtype of mGluR is involved in the resistant responses.

L-AP4 AND *trans*-ACPD REDUCE PAIRED-PULSE DEPRESSION RECORDED FROM THE RAT DENTATE GYRUS MOLECULAR LAYER. J.S. Kahle* and C.W. Cotman Department of Psychobiology, University of California, Irvine, CA 92717.

The glutamate analogue, L-2-amino-4-phosphonobutanoic acid (L-AP4), has been shown to be a ligand at several glutamate binding sites including: glutamate autoreceptors or AP4 receptors, chloride-dependent transport sites, metabotropic receptors, and NMDA receptors. At low concentrations (10μM), L-AP4 activates the glutamate autoreceptor and reduces field potentials recorded from select pathways. We have recently observed that applications of low concentrations of L-AP4 (10-20μM) also reduce paired-pulse depression recorded from the medial perforant path, without a reduction in field potential amplitude. The possibility that L-AP4 may be producing this effect by binding to transport sites, the metabotropic receptors, or NMDA receptors was examined. Paired-pulse depression of field potentials (40-800 ms interstimulus intervals) was recorded from the middle third of the dentate gyrus molecular layer of rat hippocampal slices *in vitro*. The transport inhibitors L-*trans*-pyrrolidine-2,4-dicarboxylic acid (250μM) and L-α-aminoadipate (200μM) did not alter or mimic the effect of L-AP4 on paired-pulse depression. The NMDA antagonist 2-amino-5-phosphonopentanoic acid (20μM) did not block the action of L-AP4. These results suggest that L-AP4 is not acting at the NMDA receptor or glutamate transport site to reduce paired-pulse depression. However, applications of the metabotropic receptor agonist 1-aminocyclopentane-*trans*-1,3-dicarboxylic acid (*trans*-ACPD; 50μM) reduced paired-pulse depression similarly to L-AP4. It has been shown that L-AP4 has a low affinity for the metabotropic receptor and *trans*-ACPD may also activate AP4 receptors (Trombley and Westbrook, *J. Neurosci.*, in press). One hypothesis consistent with these results is that *trans*-ACPD and L-AP4 activate the glutamate autoreceptor to reduce paired-pulse depression.

ACUTE AND CHRONIC EFFECTS OF GLUTAMATE RECEPTOR ANTAGONISTS ON EPILEPTIFORM ACTIVITY IN CULTURE. W.J. Koroshetz, and E.J. Furshpan*, Neurology Dept., Mass. General Hospital and Dept. of Neurobiology, Harvard Medical School, Boston Ma. 02215.

Hippocampal neurons grown chronicaly with blocking agents (e.g. 1mM kynurenate and 11.3 mM Mg^{2+}) show intense epileptiform activity when the blockers are removed (Furshpan and Potter [19189] Neuron, 3:199). Prominent components of this activity are synchronous events resembling paroxysmal depolarization shifts (PDSs); they are abolished by the combination of NMDA (APV) and non- NMDA (CNQX) antagonists. We report that PDSs occurred when either APV or CNQX was present alone. The currents (PDCs) underlying these PDSs were recorded with two-electrode voltage clamp. In the absence of antagonists, the initial phase of current (duration, 30-75 ms) was often followed by a tail of variable amplitude and duration. In APV this tail was reduced and the PDCs occurred at higher frequency, in clusters. In CNQX the PDCs had much slower rising phases, were more prolonged and less frequent. As the holding potential was made more positive, PDC amplitude increased sharply before decreasing and reversing sign near 0 mV. However, NMDA currents were adequate to synchronize the activity of the neuronal population even when most neurons were initially at resting potential.

Epileptiform activity is seen in unblocked cultures prior to a period of neuronal death. Long term neuronal survival and PDS activity is markedly enhanced in the blocked cultures. Many lucifer yellow injected neurons in months old blocked cultures had complex dendritic arbors; neurons in unblocked cultures had relatively simple dendritic arbors. The opportunities for neurons to make recurrent excitatory synapses are enhanced in blocked cultures and may contribute to intense seizure-like activity.

NMDA AND AMPA RECEPTOR COMPONENTS OF EPSCS FROM RAT DENTATE HILAR INTERNEURONS. T.A. Brown* and R. Dingledine. Dept. Pharmacology, Univ. North Carolina-Chapel Hill, 27599.

Spontaneous excitatory postsynaptic currents (EPSCs) from interneurons located in the hilus of the dentate gyrus of neonatal rat hippocampal slices were isolated at both positive and negative membrane potentials in 1 μM tetrodotoxin and 10 μM bicuculline. Cells were morphologically identified by a biocytin staining protocol. Marked heterogeneity exists in cellular morphology and degree of NMDA and non-NMDA contribution to EPSC kinetics. At -70 mV EPSCs rose within 2 ms and decayed with a time constant of less than 15 ms which was well fit by a single exponential. The NMDA receptor antagonist D-APV (50 μM) had little or no effect on EPSC kinetics or amplitude at -70 mV while CNQX, a non-NMDA receptor antagonist, nearly abolished all activity. At +50 mV a variety of EPSC kinetics and amplitudes were observed between neurons. Some neurons had decay phases best fit with 2 exponentials while others were best fit with one. D-APV always completely blocked the EPSC component best fit with the longer decay time constant. Interestingly, in 5 interneurons, 2 tentatively identified as dentate pyramidal basket neurons and 1 as aspiny fusiform, EPSCs at +50 mV decayed with a single rapid time constant which was unaffected by D-APV. Diversity in NMDA and non-NMDA receptor contribution to EPSCs suggests different roles for subpopulations of these neurons and may help explain differential sensitivity to insult. REDOX MODULATION OF THE NMDA-MEDIATED COMPONENT OF SYNAPTIC FIELD POTENTIALS IN HIPPOCAMPAL AREA CA1. D. L. Tauck*, J. E. Tullis, and R. L. Sasich, Department of Biology, Santa Clara University, Santa Clara, California, 95053.

Accumulated evidence suggests a role for redox modulation of NMDA currents in a variety of neuronal preparations. The present study shows that the sulfhydryl redox agents dithiothreitol (DTT) and 5-5-dithio-bis-2-nitrobenzoic acid (DTNB) reversibly antagonize each other's effects on synaptic transmission in rat hippocampus. To reveal the NMDA-mediated component of the synaptic responses, the field potentials evoked by single stimuli were compared to those generated by the fifth of 5 stimuli at 10 Hz. All experiments were performed in saline containing 5 mM K^+ to increase the magnitude of NMDA-mediated responses. The conditioned response was 62.5 ± 7.4% (mean ± S.E.M.) larger than the response to a single stimulus (n=12). The NMDA antagonist D,L-2-amino-5-phosphonovaleric acid (250 μM) blocked the potentiation induced by conditioning stimuli. DTT (1 mM) and DTNB (1 mM) were repeatedly applied in the bath. DTT reversibly potentiated the NMDA component of the synaptic potentials (79.7 ± 7.0%, n=17) while DTNB had the opposite effect (40.0 ± 3.8%, n=17). DTNB did not reverse the potentiation induced by DTT in slices exposed to 300 μM N-ethylmaleimide, an alkylating agent (n=7).

DIFFERENTIAL DEPRESSION OF NMDA RECEPTOR-MEDIATED SYNAPTIC RESPONSES BY MK-801 AND CPP. B. Esplin* and R. Čapek. Dept. of Pharmacology and Therapeutics, McGill Univ., Montreal, Quebec, H3G 1Y6, Canada.

The influence of repetitive synaptic activation on depression of the NMDA receptor-mediated synaptic responses by a non-competitive antagonist, MK-801, and a competitive antagonist, CPP, was studied in the hippocampal slice preparation of the rat. These responses, evoked by stimulation of the stratum radiatum and recorded in the stratum pyramidale of the CA1 region in slices superfused by a Mg^{2+}-free medium, consisted of a burst of population spikes (PSs) which followed the primary PS. Both, MK-801 (2 to 100 μM) and CPP (0.2 to 10 μM) applied by superfusion, depressed the number and the amplitudes of the secondary PSs in a concentration-dependent manner. The primary PS remained unaffected. In the absence of a drug, repetitive stimulation at 0.2 Hz for 5 min was without any consistent lasting influence on the PS burst. Such stimulation also failed to alter a partially diminished burst during superfusion with the competitive antagonist CPP. In contrast, during superfusion with MK-801, the secondary PSs were greatly diminished immediately after the repetitive stimulation even with low concentrations of the drug, which produced no or only minimal depression without stimulation. The responses depressed by CPP fully recovered within 30 min, whereas those depressed by MK-801 did not, even after 60 min of superfusion with the drug-free medium. These results demonstrate that, similarly to responses evoked by the exogenous NMDA-receptor agonist in cultured cells (MacDonald and Nowak, TIPS 11:167,1990), the NMDA receptor-mediated synaptic responses evoked by the endogenous neurotransmitter in the slice preparation are depressed by MK-801 in a use-dependent manner.

A NON-GENOMIC ACTION OF ESTROGEN ON SYNAPTIC TRANSMISSION IN THE HIPPOCAMPUS. M. Wong* and R.L. Moss. Dept. Physiology, UT Southwestern Medical Center, Dallas, TX 75235.

Steroids exert rapid neurophysiological effects that are independent of the classical genomic mechanism mediated by intracellular steroid receptors and most likely involve direct interactions with specific membrane receptors. Estrogen can induce a short-term potentiation of the extracellular CA1 field potential in the hippocampus (Teyler et al. 1980, Landgren 1992) and of responses to exogenous glutamate in the cerebellum (Smith et al. 1988). The present study investigated the rapid effects of estrogen on responses of individual CA1 neurons to synaptic stimulation and local application of glutamate agonists. Intracellular recordings were made from CA1 neurons in rat hippocampal slices. Synaptic responses were elicited by Schaffer collateral stimulation with a metal electrode and glutamate agonists were applied to the CA1 neurons through an iontophoretic electrode.

Superfusion of 10^{-8} M 17β-estradiol, but not 17α-estradiol, significantly increased the amplitude of the Schaffer collateral-induced EPSP, causing a previously subthreshold EPSP to reach threshold. This facilitation of the EPSP by 17β-estradiol usually occurred within minutes and was reversible shortly after washout, suggesting a direct membrane action. The synaptic facilitation still occurred in the presence of the NMDA antagonist, AP5, but was blocked by the non-NMDA antagonist, CNQX. 17β-estradiol also potentiated depolarizing responses to iontophoretic pulses of glutamate and non-NMDA agonists, but not to NMDA. These results suggest that estrogen can induce a rapid potentiation of excitatory synaptic transmission in the hippocampus that involves postsynaptic non-NMDA receptors. (MH47418)

INWARDLY RECTIFYING SYNAPTIC CURRENTS ON HIPPOCAMPAL INTERNEURONES. C.J.McBain* and R.Dingledine. Dept. of Pharmacology, Univ. of North Carolina, Chapel Hill, NC 27599-7365.

Spontaneous miniature EPSCs (mEPSCs) and kainate-evoked currents were recorded from interneurones of CA3 st. radiatum of neonate rat hippocampal slices in the presence of TTX (1μM) and bicuculline (5μM). Two distinct populations of interneurone (Type I and Type II) were identified. The I-V relation of kainate in Type I interneurones was linear (Erev = ~0mV). The kainate I-V relation in Type II interneurones was strongly inwardly rectifying with little or no outward current at potentials up to +50mV. At -70mV mEPSCs received by Type I interneurones had fast rise times (~1msec) and decay time constants (~5msec) and were mediated by AMPA receptors. mEPSCs on Type I interneurones reversed polarity at ~0mV. At +50mV the kinetics of the mEPSCs on Type I interneurones were slowed and were comprised of both AMPA and NMDA receptor mediated components. The kinetics of mEPSCs on Type II interneurones were markedly slower than their Type I counterparts at -70mV. mEPSCs received by Type II interneurones showed extreme inward rectification with no interneurones possessing fast events at +50mV. In a few cells slowly rising and slowly falling mEPSCs were observed at +50mV. These events were abolished by D-APV and were therefore mediated solely by NMDA receptor activation. On both Type I and II interneurones the rise times of individual mEPSCs were correlated with their halfwidth and decay time constant, suggesting that the shape of the mEPSC is in part determined by the dendritic origin of the synaptic input. The inward or outward rectification observed in the two interneurone types is likely to be due to expression of different glutamate receptor subunits. Supported by NS17771 and Bristol-Myers Squibb.

KETAMINE DEPRESSES NMDA TRANSMISSION AND DOES NOT ENHANCE $GABA_A$ INHIBITION IN ISOLATED NEONATAL RAT SPINAL CORD. D. Brockmeyer and J. J. Kendig*. Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305-5123

Proposed anesthetic mechanisms include depression of excitatory neurotransmission and enhancement of inhibition. We investigated the anesthetic ketamine, which blocks NMDA receptors, in isolated superfused spinal cords from 1-6 day old rats. Lumbar dorsal root stimulation elicits a fast monosynaptic reflex and a slow ventral root potential (slow VRP) in the corresponding ipsilateral ventral root, and a dorsal root potential (DRP) in the adjacent dorsal root. The monosynaptic reflex is CNQX, but not APV, sensitive. The slow VRP is depressed by APV. The DRP reflects $GABA_A$-mediated presynaptic inhibition, and can also be elicited by direct focal application of the $GABA_A$ agonist muscimol.

Ketamine (1-50 μM) depressed the NMDA-mediated component of the slow VRP with an approximate ED_{50} of 25 μM; its actions resembled those of APV. The monosynaptic reflex was not affected. Ketamine depressed both the dorsal root-evoked DRP (1-20 μM) and the muscimol-evoked DRP (10 μM). Ketamine's serum anesthetic concentration is ~3 μM. Ketamine's effects on the spinal cord can be explained by block of NMDA receptors. Unlike some other anesthetics, ketamine does not enhance $GABA_A$ inhibition at concentrations in its clinically effective range.

569.13

ISOFLURANE DEPRESSES A $GABA_A$ INHIBITORY PATHWAY IN ISOLATED NEONATAL RAT SPINAL CORD. L. M. Gibbs* and J. J. Kendig. Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305-5123

Volatile general anesthetic agents have been suggested both to depress glutamate excitation and enhance $GABA_A$ inhibition. The volatile anesthetic isoflurane (0.2-1.2 vol %) was applied in the gas phase to the isolated spinal cords of 1-6 day old Sprague-Dawley rat pups (adult rat anesthetic partial pressure = 1.4 vol %). The dorsal root potential (DRP) is a population-evoked response which reflects $GABA_A$-mediated depolarization of primary afferent nerve terminals. DRP's were recorded from a lumbar dorsal root in response to stimulation of an adjacent dorsal root. Isoflurane reversibly depressed the DRP at all partial pressures. DRP's were also sensitive to both APV (10 μM) and CNQX (10 μM), suggesting that the GABA-ergic interneurons which mediate the DRP are activated by glutamate acting on both NMDA and non-NMDA receptors. We have previously shown that isoflurane (0.2-1.2 vol %) depresses both NMDA and non-NMDA receptor-mediated ventral root potentials in this preparation. Isoflurane may act directly on $GABA_A$ receptors to increase inhibition. However, in the circuit which generates the DRP, isoflurane's depressant effect on glutamatergic excitation of the inhibitory interneurons is overriding, and inhibition is depressed. Isoflurane thus differs from anesthetic barbiturates, which enhance the DRP.

EVIDENCE FOR $GABA_A$ RECEPTOR MEDIATED SLOW INHIBITORY POSTSYNAPTIC POTENTIAL (sIPSP) IN THE RAT LATERAL PARABRACHIAL NUCLEUS (LPBN). J.A. Zidichouski and J.H. Jhamandas. Dept. of Medicine (Neurology & Div. of Neuroscience), Univ. of Alberta, Edmonton, Alberta, Canada T6G 2E1.

The LPBN is the recipient of a diverse array of autonomic inputs from more caudal levels of the brainstem. Our prior data demonstrated that both N-methyl-d-aspartate (NMDA) and non-NMDA receptors mediate evoked fast excitatory post-synaptic potentials *in vitro* (Neurosci Abs 17: 246, 1991). In addition, we have recorded sIPSPs from LPBN neurons and this study examined the role of gamma-aminobutyric acid (GABA) receptors in mediating inhibitory synaptic transmission within this pontine nucleus.

LPBN neurons were recorded from coronal (400 μM) slices using whole-cell patch recording. IPSPs were evoked using platinum bipolar electrodes (10-70V @ 0.2 Hz) placed at the dorsomedial pole of the LPBN. Exogenous application of GABA (1 mM), the selective $GABA_A$ receptor agonist muscimol (1-10 μM) and the $GABA_B$ agonist baclofen (10 μM) all produced a membrane hyperpolarization (or outward current) that was accompanied by a decrease in the input resistance. Stimulus-evoked sIPSPs or slow inhibitory post-synaptic currents (sIPSCs) reversed at or about the reversal potential of chloride (E_{Cl}). sIPSPs or sIPSCs were attenuated by $GABA_A$ receptor antagonists bicuculline (10-30 μM) or picrotoxin (100 μM) but were unaffected by $GABA_B$ antagonists saclofen or CGP-035348.

These results suggest that evoked sIPSPs and sIPSCs observed in the LPBN are mediated by an increase in membrane conductance to chloride ions and support a role for $GABA_A$ receptors in mediating inhibitory neurotransmission within this nucleus.

MULTIPLE FACTORS MODULATE THE $GABA_B$ IPSP IN GUINEA PIG VENTRAL TEGMENTAL AREA *IN VITRO*. D.L.Cameron* and J.T.Williams. Vollum Institute, Oregon Health Sciences University, Portland OR 97201.

The ventral tegmental area (VTA) has been implicated by a number of studies in the mediation of addictive behavior. Intracellular recordings were made from VTA cells in a horizontal slice preparation. The majority of cells (35/52) were hyperpolarized by dopamine (100µM) while a smaller proportion (14/50) were hyperpolarized by [met^5]-enkephalin (ME, 10µM). Approximately half (13/24) of the cells tested were depolarized by 5-HT (30µM). When bipolar electrical stimulation was applied to the preparation, most (29/38) cells exhibited a slow IPSP that was blocked by the $GABA_B$ receptor antagonist, 2-hydroxysaclofen (100µM). The magnitude of this IPSP was reduced by ME, the κ-agonist U69593 and 5-HT. While naloxone (1µM) reversed the actions of the opioids, the action of 5-HT was not affected by either the $5\text{-}HT_{1A}$ receptor antagonist NAN-190 (100nM) or the $5\text{-}HT_{1B}$ receptor antagonist cyanopindolol (100nM). These results indicate that GABA mediated synaptic potentials in the VTA can be modulated through both µ and κ opioid receptors and by 5-HT, possibly via $5\text{-}HT_{1D}$ receptors. These findings have important ramifications for understanding the actions of drugs of abuse such as morphine and cocaine in the VTA. Supported by an NH&MRC C.J.Martin Fellowship to D.L.C. and by NIH grants DA04523 and MH45003 to J.T.W.

INHIBITORY SYNAPTIC CURRENTS IN THE IMMATURE ZEBRA FISH BRAIN. P. Legendre* and H. Korn. Institut Pasteur 75015 Paris, France.

Synapses on the Mauthner (M-) cell of the Zebrafish (Brachydario Rerio) are morphologically differentiated after hatching (50 hours of gestation). Patch recordings were performed under direct visualization on the isolated brain of newly hatched larvae with pipettes containing (mM) CsCl 165 (or KCl 165), MgCl2 2, NaATP 4, EGTA 10 and HEPES 10. Brains were quickly removed, mounted on coverslips using plasma-thrombin embedding and stored for 1/2h prior to experiments, in an oxygenated recording solution containing (mM), NaCl 145, KCl 5, CaCl2 2, MgCl2 1, NaH2PO4 1.25, NaHCO3 26, glucose 10. During whole cell recording (165mM [KCl]i) the input resistance (Ri) of the M-cell was close to 35.9MΩ (± 6.1 SD; n=5) with a Vm of -56.2mV (±2.8 SD; n=5). Ri was increased to 66.1MΩ (±10.8 SD; n=13) after substitution of [KCl]i by [CsCl]i. Ongoing electrical activity consisted of fast Cl-dependent synaptic currents of various amplitudes blocked by 0.5 µM strychnine but not by bicuculline (50µM). TTX (1µM) reduced the mean amplitude and the frequency of these currents with the time to peak and decay time of the remaining ones being close to 500µs and 6ms respectively. Amplitude Histograms of TTX-resistant IPSCs from cells held at a membrane potential of -50 mV had an initial and prominent peak of 50-60 pA. Adding 10mM [MgCl2]o and decreasing [CaCl2]o to 0.1mM did not modify this distribution. In outside-out patches, glycine-activated single channels fell into three conductance states : 34.2 pS (±2.1SD; n=6), 42.7pS (±2.3SD ; n=8) and 82.1pS (±6.4SD; n=6), the 43pS one being dominant. The open time histogram of the latter was well fitted with two exponentials with time constants of 0.81 ms (±0.3,SD; n=6)and 4.8 ms (±1.0,SD; n=6). Therefore, glycinergic quanta correspond to the opening of 20 to 30 Chloride channels. Channel Open-state probability was remarkably voltage-dependent, nPo increasing 7-fold from -50mV to +50mV, a property also reported for glycinergic currents in the adult M-cell.

CELLULAR EFFECTS OF CHOLINERGIC INPUT IN SEPTO-HIPPOCAMPAL SLICES. R. Bianchi[1,2] and R.K.S. Wong*,[1]. [1]Dept. of Pharmacology, SUNY-HSC, Brooklyn, NY 11203 and [2]Dept. of Physiology and Biochemistry, Pisa (Italy) 36100.

In the mammalian CNS the Medial Septum/Diagonal Band complex provides a strong cholinergic projection to the Hippocampal Formation (HF). We prepared Septo-Hippocampal (SH) slices acutely isolated from adult guinea pigs, in order to study the cholinergic input to the CA3 hippocampal pyramidal cells (HPCs). In such preparation the gyrus dentate, CA1 and CA3 areas of the HF, the septal complex and the fimbria connecting the septum and the hippocampus were readily identifiable. Intracellular recording from CA3 HPCs showed that these cells retained passive and active membrane properties comparable to those described in transversal hippocampal slices. Occasionally, electrical tetanic stimulation of the septal complex or, more often, of the fimbria induced depolarization associated with increase in input resistance and firing in the CA3 HPCs. These effects were mimicked by "bolus" application of carbachol (CCh), increased by bath application of eserine (1uM) and blocked by bath-applied atropine (1uM). Addition of excitatory amino acid blockers (CNQX and CPP 10-20 uM each) did not affect the above described effects. We also observed that electrical tetanic stimulation (septal area or fimbria) and CCh application elicited phasic depolarizations when the cells were held more hyperpolarized than -70mV. Such depolarizations were associated with a decrease of input resistance and blocked by atropine (1uM).

EFFECT OF Cd++ AND FUNNEL WEB SPIDER TOXIN (FTX) ON TRANSMITTER RELEASE AT THE MOUSE NEUROMUSCULAR JUNCTION D.A.Protti, V.Sanchez, B.D.Cherskey, M.Sugimori, R.R.Llinas and O.D.Uchitel* Inst. Biol Cel. Faculty of Medicine Univ. Buenos Aires and Dept. Physiol Biophys. New York Univ Med Ctr.

FTX is a potent blocker of presynaptic Ca++ currentes and transmitter release at the mammalian neuromuscular junction (Uchitel et al PNAS 1992). We further studied synaptic transmission in a curarized nerve muscle preparation in order to analyzed the effect of Cd++ and FTX on transmitter release at low and high frequency nerve stimulation . As expected quantal content was diminished by both agents .In the absence of the blockers high frequency stimulation (40Hz) produces a decline in endplate potential amplitude due to a decrease in quantal content. In contrast in the presence of Cd++ or FTX and early facilitation and subsequent less pronounced decline in quantal content was observed. similar to the small facilitation seen in mammalian neuromuscular junctions of animals treated with IgG from Eaton Lambert human patients

ACTIONS OF ANABASEINE AND DMAB-ANABASEINE UPON NEURONAL $\alpha_4\beta_2$ AND PC12 CELL NICOTINIC RECEPTORS. W.R. Kem*[1] and R.L. Papke[2], [1]Dept. of Pharmacol. Ther., Univ. of Fla. Coll. Med., Gainesville, FL 32610-0267 and [2]Mol. Neurobiol. Lab, Salk Institute, San Diego, CA 92138.

The marine worm toxin anabaseine (2-(3-pyridyl)-3,4,5,6-tetrahydropyridine) structurally resembles nicotine, but is even more potent at the frog neuromuscular junction. Previous ligand binding experiments with rat brain synaptosomes demonstrated that anabaseine and its 3-(4-dimethylaminobenzylidene) adduct interfered with (^{3}H)methylcarbamyl choline binding at 100–200 nM concentrations. In contrast with muscle nicotinic receptors, neuronal receptors (rat $\alpha_4\beta_2$ subtype expressed on *Xenopus* oocytes and PC12 cell subtypes) displayed less physiological response to anabaseine relative to ACh ($\alpha_4\beta_2$) or nicotine (PC12). On the $\alpha_4\beta_2$ subtype anabaseine acted only as a partial agonist (EC_{50} ~ 30 μM, relative to ACh EC_{50} ~ 2 μM); the peak current was less than half of the ACh maximum inward current. On PC12 cells, anabaseine acted as a full agonist on $^{86}RB^+$ efflux, but was approximately 5x less potent. In contrast, DMAB-anabaseine acted primarily as a nicotinic antagonist on $\alpha_4\beta_2$ and PC12 neuronal nicotinic receptors as well as upon neuromuscular receptors. However, at 100 μM, DMAB-anabaseine produced a small inward current (2% of the maximal ACh-induced current); thus it may possess an extremely small partial agonist activity, at least on the $\alpha_4\beta_2$ neuronal subtype. KINETIC AND EQUILIBRIUM CHARACTERIZATION OF HIGH-AFFINITY ANALOGS OF VESAMICOL. G.A. Rogers*, W.D. Kornreich, K. Hand, S.M. Parsons. Dept. of Chemistry, Univ. of California, Santa Barbara, CA 93106.

Twelve derivatives of vesamicol have been synthesized that exhibit from three to one thousand times higher affinity for the vesamicol receptor (VR) in Torpedo synaptic vesicles. Kinetic data for the dissociation of analogs from the VR were obtained using a 'back-titration' assay (Rogers and Parsons, Neuroreport 1, 22-25, 1990). Equilibrium data were obtained by determining IC_{50} values for displacement of [^{3}H]vesamicol from synaptic vesicles at very low concentrations (0.2 μg protein/ml) and for long incubation periods (24 hr). Three analogs were resolved and the individual enantiomers were characterized. The VR exhibited an enantiomeric selectivity ratio of 250 for cis-4-fluoromethylvesamicol. One derivative, 4-aminobenzovesamicol (ABV), was radiolabelled with tritium which allowed a direct determination of the equilibrium binding isotherm as well as rates of association and dissociation. (-)-ABV binds to the VR with a K_D value of 6.5 ± 0.5 pM. The rate constants for association and dissociation are (1.0 ± 0.1) X 10^8 $M^{-1}min^{-1}$ and (8.4 ± 0.05) X 10^{-4} min^{-1} ($t_{1/2}$ = 14 hr), respectively. ABV represents a valuable new tool for studies of the cholinergic presynapse.

MEMBRANE PROPERTIES OF HUMAN FETAL BRAINSTEM NEURONS *IN VITRO* S. Chung, P.J. Kontur, L.L. Kaczmarek, R. Robbins, B.S. Bunney* Departments of Pharmacology and Psychiatry, and Neuroendocrinology, Yale Univ. Sch. of Med., New Haven, CT 06510

The whole-cell patch clamp method was used to characterize membrane potentials and currents in human fetal brainstem neurons. Cultures were prepared from fetuses of 9-12 weeks gestation and maintained in culture for 8-13 days prior to recordings. Some cells showed spontaneous membrane depolarizations. In most cells, depolarizing currents triggered short (< 10 ms) action potential that appeared to be mediated by calcium and potassium currents. The majority of inward current was not blocked by TTX. In contrast, 1 mM Co^{2+} blocked the current completely indicating that the inward current was probably carried largely by calcium channels. Two major components of outward potassium current were observed. The fast transient component was blocked by 4-AP but not by TEA. The slow transient component was blocked by TEA but not by 4-AP.

In summary, we have identified both potassium and calcium currents in developing human neurons. These cultured brainstem neurons may provide a valuable means to characterize ion channels in human neural membrane.

IONIC MECHANISMS OF OSCILLATORY FIRING ACTIVITY OF RAT CEREBELLAR PURKINJE CELLS. W. Chang*, H. K. Strahlendorf and J. C. Strahlendorf, Departments of Physiology and Neurology, Texas Tech Health Sciences Center, Lubbock, TX 79430.

Rhythmic firing patterns of neurons have been shown to be mediated by the sequential activation of a set of conductances. However, mechanisms of intrinsic rhythmicity vary considerably among neurons. This study is investigating the contribution of sodium current (I_{Na}), inward rectifying cationic current (I_h), transient outward K^+ current (I_A) and Ca^{2+}-activated K^+ current ($I_{K(Ca)}$) to oscillatory firing of Purkinje cells. We have confirmed that oscillatory firing activity can be initiated and sustained by membrane ionic conductances in the absence of effects of action potential-induced release of extrinsic neurotransmitters. Adding TTX to the superfusion solution produced a typical pattern of repetitive burst firing consisting of Ca^{2+} dependent action potentials and long periods of hyperpolarization. We used the I_h blocker, cesium, and found that this current probably is not involved with initiation of oscillation, but plays an important role in maintenance of rhythmicity. Cs^+ produced long duration hyperpolarization after bursting to very negative membrane potentials (-130 mv) which exceeded the K^+ equilibrium potential. Low doses of 4-aminopyridine (4-AP, I_h blocker) induced oscillatory firing whereas, high doses changed the pattern and frequency of firing, especially the duration and amplitude of action potentials. Apamin ($I_{K(Ca)}$ blocker) reduced part of the afterhyperpolarization during and after bursting and terminated oscillatory activity. These data indicate an important contribution of I_{Na}, I_h, I_A and $I_{K(Ca)}$ to rhythmic pacemaker firing of Purkinje neurons.

DUAL PATCH-CLAMPING OF MAMMALIAN PURKINJE CELLS IN CEREBELLAR SLICES. M. Sugimori* and R. Llinás, Dept. Physiology/Biophysics, NYU Medical Center, 550 First Avenue, NY, NY 10016.

Double somatic patch recording (P_1 and P_2) was implemented to study the electrophysiology of Purkinje cells under patch-clamp conditions. One electrode (P_1) was utilized to patch-clamp the neuron while the second (P_2) recorded voltage in a current-clamp configuration. The access resistance for electrodes was on the order of 1 mega-ohm and was monitored continuously for P_1, by computing the difference in voltage between the two electrodes (P_1–P_2). Voltage-clamp depolarization steps resulted in either a fully controlled sodium current or, more often, in the generation of action potentials. The latter event occurred most often in cells with less than optimal viability where the leakage resistance was high.

The voltage electrode demonstrated action potential generation at the somatic level, even in conditions where the Purkinje cells were properly patched and the access resistance of electrodes was low (1–2 mΩ).

In order to test whether non-somatic sodium spikes could be generated, dendritic depolarization was obtained with glutamate iontophoresis at the distal dendrites. The firing level for the sodium spike in Purkinje cells that ensued was unmodified by voltage-clamp conditions which held the somatic potential at –90 mv and was generated by the initial activation of a low-threshold noninactivating sodium current, even in the absence of voltage-dependent calcium conductances. This finding indicates that only one site for sodium spike generation is present in Purkinje cells.

The results indicated that sodium spikes and Purkinje cells arise at or near the somatic membrane and that dendrites are unlikely to support sodium spikes, in accordance with previous results. (Supported by NS13742 and AG09480)

INTRINSIC MEMBRANE POTENTIAL OSCILLATIONS IN RAT PIRIFORM CORTEX PYRAMIDAL CELLS.

E. Barkai* and M.E. Hasselmo, *Dept. Psych., Harvard Univ., Cambridge, MA 02138.*

The rat piriform cortex displays oscillatory field potential and EEG dynamics with peaks in the power spectra at 3-10 Hz and 40-60 Hz. These oscillatory properties may provide the optimal dynamics for associative memory function in this region (Hasselmo et al., *J. Neurophys.* 67:1230-1246). The oscillations have been linked to the time constant of inhibition within the cortex (Wilson and Bower, *J. Neurophys.* 67:981-995). However, recent evidence from this laboratory suggests that piriform cortex pyramidal cells may show intrinsic oscillatory membrane dynamics as well.

In brain slice preparations of piriform cortex, we performed intracellular recording in layer II from a population of pyramidal cells (n=32, Vm = -74.3 ±5.2 mV, spike height = 102 ±7.5 mV, Rm = 23.2 ±7.1 MΩ, firing threshold = 17.1 ±4.8 mV). A large number of these cells (n=15) show low amplitude (up to 6mV) oscillations of membrane potential during a 1 sec. current injection which depolarizes the cell membrane above -60mV. These oscillations in membrane potential also appear during a sustained depolarizing current injection. Hyperpolarizing current injections did not induce membrane potential oscillations. The oscillations show a predominant peak to peak interval of between 140 and 50 msec. (7 to 20 Hz), with some change in frequency with increased depolarization. Frequently, spiking activity was synchronized with the peak of oscillatory activity, such that the spike intervals during the later portions of a 1 second current injection were strongly correlated with the wave length of the subthreshold membrane oscillations. The membrane potential oscillations were still present during perfusion with a low Ca/high Mg solution or with zero Ca and cadmium chloride (100μM). In addition, perfusion with the cholinergic agonist carbachol (100μM) did not appear to strongly alter the oscillatory properties of these neurons. These oscillations do not fully match the predominant frequencies in field potential data, but may interact with circuit characteristics to contribute to the oscillatory dynamics of piriform cortex activity. *Supported by The French Foundation for Alzheimer Research.*

TONIC ACTIVATION OF I_h IN CA1 PYRAMIDAL NEURONS

*Maccaferri, G., Janigro, D. *, Mangoni, M., Lazzari, A., Costa, L.G. *✦ & DiFrancesco, D.*

*Depts of Neurosurgery and ✦Environmental. Health, Univ. of Washington, Seattle, WA & Dip. di Fisiologia e Biochimica Generali., Milano, Italy

The whole cell variation of the patch clamp technique was used to investigate the role of the hyperpolarization activated inward current (I_h) in CA1 pyramidal cells from hippocampal slices maintained *in vitro*. Under voltage clamp, I_h was activated at potentials between -50 and -150 mV and displayed no time-dependent decay. Manipulations of extracellular K^+ and Na^+ concentrations both affected current amplitude due to its mixed ionic nature. External Cs^+ ions (2-10 mM) reversibly blocked the current. In current clamp experiments, 2 mM Cs^+ elicited a small (around 4 mV) hyperpolarization at cell resting potential (-56 to -65 mV); this hyperpolarizing shift was enhanced by cell hyperpolarization by negative tonic current injection. In addition, the relatively small Cs^+-induced hyperpolarization was sufficient to prevent neuronal firing evoked by depolarizing current steps (20 pA for 2 seconds) from cell resting potential. Taken together, our results suggest that I_h may play a role in the regulation of resting membrane potential in hippocampal pyramidal cells, thus contributing to the regulation of cellular excitability.

CALCIUM CURRENTS AND CALCIUM INFLUX IN CULTURED RAT MYENTERIC NEURONS: A FUNCTIONAL ANALYSIS.

D.J. Fickbohm* & A.L. Willard[1,2]. Curriculum in Neurobiology[1] and Dept. of Physiology[2], Univ. of North Carolina, Chapel Hill, NC 27599.

We have been studying the effects of chronic depolarization on the development of rat myenteric neurons in cell culture. Previously, we found that growth in medium containing elevated potassium (25 mM), which depolarizes these neurons to a mean resting membrane potential of -40 mV, decreases the density of voltage-dependent Ca currents and causes persistent elevation of intracellular Ca ($[Ca]_i$) (Franklin et al., J. Neurosci., 1992). Here we report a test of the hypothesis that the decreased density of Ca currents leads to decreased Ca influx in response to neuronal action potential activity.

Myenteric neurons dissociated from intestines of 2-3 d old rat pups were grown in cell culture for 3-5 d in medium containing control (5 mM) or elevated (25 mM) KCl. $[Ca]_i$ was monitored in fura-2-loaded cells, using video-based image analysis. Calcium current density was determined by whole cell tight-seal recordings in solutions designed to isolate Ca currents from other voltage-gated currents. Neurons were stimulated with a pair of extracellular Pt wire electrodes. Antagonists of Ca currents and other drugs were applied from extracellular pipets.

Brief (300 msec, 25 Hz) trains of pulses (2.5 ms) elicited rapid (< 3 sec to peak) increases in $[Ca]_i$ that decayed back to baseline within 30 sec. The absolute height of the peak varied from cell to cell, but typically, chronically depolarized cells had peaks that were 50-70% of those observed in control cells. In both types of cell, conotoxin- and dihydropyridine-sensitive components were observed. We conclude that the effects of chronic depolarization on Ca current density are functionally significant, resulting in significantly reduced Ca influx during neuronal electrical activity. LUNG-SPECIFIC VISCERAL C-FIBER NEURONS IN THE GUINEA PIG NODOSE GANGLION EXPRESS A CHARYBDOTOXIN-SENSITIVE K^+ CONDUCTANCE THAT CONTRIBUTES TO ACTION POTENTIAL REPOLARIZATION.

E.P. Christian* and J. Togo. Department of Pharmacology, ICI Americas, Inc., Wilmington, DE 19897.

Afferent neurons in the nodose ganglion innervate organs in the cardiovascular, respiratory, and gastrointestinal systems. These neurons are also heterogeneous with regard to several ionic conductances. Experiments were thus conducted to determine whether nodose neurons innervating the lung show any distinctive electrophysiological features, relative to neurons that were sampled without regard to end organ innervation. Rhodamine or fast blue fluorescent dye was instilled into the airways via an endotracheal catheter in anesthetized guinea pigs. After 5-8 days nodose neurons were acutely dissociated. From 2-5% of the dissociated neurons were retrogradely labeled, and thus taken to be lung-specific. Single microelectrode current- and voltage-clamp techniques revealed physiologically acceptable passive and active membrane parameters in dye-labeled neurons. Lung-specific C-fiber neurons as a population did not differ from non-labeled neurons with respect to several electrophysiological and pharmacological parameters. The most notable exception was a concentration-dependent broadening of the action potential duration in 24/26 lung-specific C-fiber neurons in response to either charybdotoxin or iberiatoxin (1-100 nM). In contrast, the action potential in only 13/23 non-labeled neurons was affected by these peptide toxins. Thus lung-specific C-fiber afferent neurons may be enriched in the expression of a Ca^{2+}-activated K^+ channel that is known to be blocked selectively by these peptide toxins.

GAP JUNCTIONS BETWEEN CHICK PINEALOCYTES: ULTRASTRUCTURE, IMMUNOCYTOCHEMISTRY AND POSSIBLE INVOLVEMENT IN MELATONIN SECRETION.

V.M. Berthoud[1], R. Dermietzel[2], M. Zatz*[3], E.C. Beyer[4] and J.C. Sáez[1]. [1]Dept. Neurosci., Albert Einstein Coll. Med., NY 10461. [2]Institut für Anatomie, Universität Regensburg, Regensburg, Germany. [3] NIMH, Bethesda, MD 20892. [4] Dept. of Pediatrics, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The chick pineal gland secretes the hormone melatonin with a circadian rhythm regulated by light. Chick pinealocytes in primary cell culture retain their ability to secrete melatonin rhythmically; the rhythm is light-entrainable, and secretion is maximal in the middle of the night. Synchronization of function between cells might be facilitated by intercellular communication through gap junction (GJ) channels which are permeable to ions and small molecules. The protein monomers of these channels are termed connexins (Cx), which are encoded by a gene family. Pineal glands were dissected from White Leghorn chicks one day after hatching, and fixed for morphological studies or dissociated enzymatically for primary cell cultures that were maintained in a light-dark cycle. The functional state of GJs was evaluated by dye coupling (Lucifer yellow). Secretion of [^{14}C]-melatonin (derived from [^{14}C]-tryptophan) into the culture medium was measured. In thin sections, septilaminar GJs were seen between pinealocytes. In freeze-fracture replicas, GJs of the crystalline-arrayed type were rare and integrated within tight junctional networks. Immunofluorescence of pineal cells in culture revealed Cx43 and Cx45 immunoreactivity at appositional membranes. Dye coupling between pineal cells in culture was extensive. Octanol inhibited dye coupling and nocturnal melatonin secretion in a dose-dependent manner and more potently than hexanol. It is suggested that GJs between chick pinealocytes might favor melatonin secretion.

REAL-TIME VOLUME MEASUREMENTS IN PRIMARY HIPPOCAMPAL CULTURES BY CONFOCAL MICROSCOPY.

M. Riepe, M. Feitl, D. Szarowski, D. O. Carpenter and J. N. Turner*. Wadsworth Center for Laboratories and Research, Albany, NY 12201

Activation of non-NMDA channels depolarizes cells by sodium influx and is believed to partially account for cell swelling after anoxia or exposure to excitatory agents. Simultaneous measurement of ion fluxes and cell volume may expand the understanding of the cellular regulation of these parameters. Observation of both cell volume and membrane potential can be achieved by simultaneous application of physiologic and microscopic methods. Due to superior depth resolution, confocal microscopy is particularly well suited for real-time imaging of fluorescence labeled live cells. The use of an inverted microscope permits to simultaneously record electrophysiologically while imaging in the confocal mode.

DiI is known to label cell membranes with little fading even after repeated exposure to the laser light source. Primary hippocampal cultures were incubated for one hour in medium containing 1 μM of DiI and pluronic F-127 (0.02%) to facilitate the incorporation of the dye in the cell membrane. Depolarization after application of kainic acid (40 μM) was accompanied by an increase in cell volume after 30 minutes. Cell processes retracted during this time.

We conclude that cell swelling after application of kainic acid succeeds depolarization with a time lag of several minutes.

SIMULATION OF SPACE-CLAMP ERRORS.

D.K. Hartline*, B.R. Jones, and M.C. Bieda Bekesy Laboratory, Univ. of Hawaii, Honolulu, HI 96822.

Recent voltage-clamp studies have used poorly space-clamped cells, despite the methodological flaws involved. We investigated space-clamp errors using computer simulations of monopolar model cells with a single primary neurite and a single voltage-dependent channel type having various spatial distributions. Peak I(V) curves were fitted with an equation of the form:

$$I = \bar{g}(V-V_{rev})/(1+\exp((V_o-V)/v)).$$

Uniform distribution of outward current channels: We find that non-soma current is reduced by negative feed-back from the outward sign of the current, the steep voltage-dependence of the channels, and foreshortened length constants. In a typical case, when $\bar{g}$ density in the neurite is increased 100x, only a *ca.* 6x increase in contamination of the soma clamp-current results. For moderate conductance densities (e.g. 10x rest), parameters most affected by the poorly space-clamped membrane are $\bar{g}$ (reduced) and V_{rev} (positive shift). With higher $\bar{g}$ densities, fitted $\bar{g}$ errors are larger and other errors tend to be smaller.

Outward current in neurite only: When the same number of channels are confined to the neurite farther from the soma, $\bar{g}$ and V_{rev} errors continue to increase, V_o shows a positive shift and v increases. An electrically compact cell with 10x rest conductance concentrated at the neurite tips can show errors of 20x in fitted $\bar{g}$, 2x in v, over 30 mV in V_{rev}, and over 80 mV in V_o.

Inward current: Most errors are in the same direction as with outward current but are of greater magnitude. Errors in v can be somewhat smaller. Even without overt evidence of regenerative escape at distant sites, severe distortion of quantitative parameters can occur.

In all cases, significant distortions of measured current kinetics can occur as well. Support: NSF BNS-8920698.

570.11

ROLES OF Ca^{+2} AND K^+ IN NERVOUS SYSTEM TUMOR CELL GROWTH. Y.S. Lee, M. Weber, and R.D. Wurster*. Dept. of Physiology, Loyola Univ. of Chicago Sch. of Med., Maywood, IL 60153.

The roles of Ca^{+2} and K^+ fluxes in the tumor cell growth were evaluated. A human neuroblastoma cell line (SK-N-MC) and a human astrocytoma cell line (U-373 MG) were grown for 2 days with or without various ion-channel-related compounds after 1 day culture for cell attachment. The number of cells was measured using a hemocytometer. K^+-channel blockers (tetraethylammonium-TEA and 4-aminopyridine-4-AP) and Ca^{+2} channel blockers (verapamil, Ni^{+2}, and Co^{+2}) inhibited the growth of both tumor cells in a concentration-dependent manner. Both cell lines showed a tremendous decreased cell number when grown in media depleted of free calcium ions by titration with relatively high concentrations (2-3mM) of EGTA. High extracellular K^+ or Ca^{+2} induced a significant decreased cell growth. The responses of the neuroblastoma cell line were more sensitive to all manipulations used than those of the astrocytoma cell line. Because moderate concentrations of EGTA (0.1-1.0mM) were ineffective, neoplastic cells may have the capacity to continue to proliferate at low Ca^{+2} levels. Increased intracellular Ca^{+2} seems to have dual effects: growth-promoting and growth-inhibiting effects. The very steep response-curves of the cells to all the drugs except TEA suggest that these tumor cells have very precise regulatory mechanisms of ion fluxes relating to cell proliferation. K^+-channel activity and high $[K^+]_o$-induced depolarization may influence Ca^{+2} influx through activation of Ca^{+2} channels or changes in the electrochemical gradient for Ca^{+2} ions. Taken together, the results further suggest that although the mechanisms of Ca^{+2} influx and existence of Ca^{+2} channels in both cell lines remain to be established, Ca^{+2}-regulating mechanisms may play an important role in tumor-cell growth and that ion channels may be potential targets for the management of tumor development.

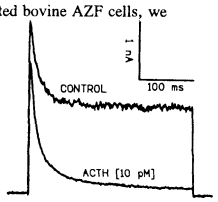
570.12

A NOVEL POTASSIUM CURRENT IN ADRENAL ZONA FASCICULATA (AZF) CELLS IS INHIBITED BY ADRENOCORTICOTROPIC HORMONE (ACTH) AND ANGIOTENSIN II (AII). B. Mlinar@, B.A. Biagi#,* and J.J. Enyeart@ . Depts. of Physiology#, Pharmacology and Neuroscience Program@, The Ohio State University, Columbus, OH 43210-1239.

Adrenal corticosteroid secretion is regulated by peptide hormones including ACTH and AII. The ionic conductance changes associated with peptide-stimulated cortisol secretion have not been identified. In whole cell patch clamp recordings from enzymatically dissociated bovine AZF cells, we have identified two separate K^+ currents, including a rapidly inactivating A-type current and a novel rapidly activating, non-inactivating, high unitary conductance channel whose expression is abolished by including 200 μM GTP-γS in the pipette.



This novel K^+ current was potently and completely blocked by ACTH (IC_{50} = 10 pM, n=18) by a mechanism which required several minutes to develop (see figure). AII also reduced this current (IC_{50} = 118 pM, n=14) but inhibition was incomplete (mean = 83%). ACTH and AII also depolarized adrenal cells by a maximum of 53 mV and 48 mV respectively with half maximal effects observed at 10 pM and 253 pM. These results indicate that this new K^+ channel may set the resting potential of AZF cells. Further, two different peptide hormones known to work through different second messengers might trigger depolarization-dependent cortisol secretion by selective inhibition of this channel.

EXCITATORY AMINO ACIDS: EXCITOTOXICITY VI

571.1

SOURCE-SPECIFICITY OF Ca^{2+} NEUROTOXICITY IN CULTURED NEURONS. C.H. Tator, M. Tymianski, R. Robitaille', M.P. Charlton. U. of Toronto, and Playfair Neuroscience Unit, Toronto, Ont. M5T 2S8.

The Ca^{2+} neurotoxicity hypothesis dictates that neurotoxic phenomena are triggered when free cytoplasmic Ca^{2+} ($[Ca^{2+}]_i$) rises too high, for too long. We asked whether depolarization-induced and excitatory-amino acid (EAA)-mediated neuronal injury was due solely to a sustained elevation in $[Ca^{2+}]_i$. Cultured murine spinal neurons were exposed to 50 min challenges with EAA's or high-K^+. $[Ca^{2+}]_i$ was imaged with the Ca^{2+} indicator fura-2. Neuronal death was gauged with trypan blue and ethydium homodimer staining. In 1mM Ca^{2+}, challenges with glutamate (GLU; 250μM) or K^+ (50mM) evoked a transient peak rise in $[Ca^{2+}]_i$ followed by a decay to a lower "plateau". 100% of neurons which died underwent a second, irreversible sustained rise in $[Ca^{2+}]_i$, unaffected by switching perfusions to Ca^{2+}-free solutions- indicating that decompensation of neuronal Ca^{2+} homeostasis precedes a loss of plasma membrane integrity. GLU neurotoxicity was not manifest in zero Ca^{2+}. GLU and high-K^+ evoked equivalent peak- and mean increases in $[Ca^{2+}]_i$, but the toxicity of GLU was 5 times greater than that of high-K^+. The relationship between Ca^{2+} influx and neurotoxity was dissected further with EAA agonists and antagonists. In the absence of NMDA blockade, GLU (250μM) and NMDA (100μM) challenges were lethal within 1.5 hrs of the EAA challenge (85% neuronal death). APV (50μM) attenuated GLU neurotoxicity to 16$\pm$6% ($p<0.0001$), but NOT the rise in $[Ca^{2+}]_i$, which was only blocked by adding the AMPA/Kainate antagonist CNQX (50μM). Kainate (KAIN; 100μM) produced a marked rise in $[Ca^{2+}]_i$ which was NOT neurotoxic. The lack of KAIN neurotoxicity was not a consequence of reduced Ca^{2+}-load, because pre-treatment of neurons with Concanavalin-A increased KAIN-and GLU-induced increases in $[Ca^{2+}]_i$, but had NO effect on neurotoxicity ($p=0.34$). We conclude that the trigger for Ca^{2+} neurotoxicity is source-specific, and depends not only on a sustained, elevated Ca^{2+}-load, but on the route of Ca^{2+} influx.

571.2

GLUTAMATE-INDUCED $[Ca^{2+}]_i$ CHANGES IN RAT CORTICAL NEURONS: CORRELATION WITH NEURONAL DEATH. S.Rajdev* and L.J.Reynolds. Dept. Pharmacology, Univ. Pittsburgh, Pittsburgh,PA 15261.

It is widely believed that glutamate released during conditions such as ischemia kills neurons by increasing $[Ca^{2+}]_i$. However, the precise mechanism responsible for increased $[Ca^{2+}]_i$, especially during ischemia is not clear. We have previously shown (Soc. Neuro. abstract # 314.14, 1991) that addition of KCN in glucose-free buffer (to simulate *in vitro* chemical ischemia) significantly increased the $[Ca^{2+}]_i$ changes induced by glutamate, NMDA, kainate and high K^+ in single rat forebrain neurons. We are further studying whether KCN also increases the neurotoxicity of these agonists.

By using a dual detection system we have been able to simultaneously study the $[Ca^{2+}]_i$ changes and neurotoxicity in cultured neurons. Cells are loaded with fluo-3AM (5μM, 60min), and recordings are made with propidium iodide (4μM) in the buffer during the experiment. Fluorescence from PI is observed as cells die as this probe is excluded from healthy cells.

Almost all the neurons exposed for 5 min. to glutamate 3μM and glycine 1μM, or kainate show an initial $[Ca^{2+}]_i$ increase and most recover from this Ca^{2+} load. However, many of those treated with glutamate show a latent rise in $[Ca^{2+}]_i$ with a variable time delay (2-3 hrs). KCN (5mM) pretreatment appears to enhance the initial $[Ca^{2+}]_i$ rise and also shorten the latency period for the delayed irreversible $[Ca^{2+}]_i$ rise. However, most neurons treated with 100 μM kainate or KCN and kainate did not show a delayed $[Ca^{2+}]_i$ rise within 3.5 hrs of experiment duration. Cell death, measured by an increase in PI fluorescence, usually occurs following the late $[Ca^{2+}]_i$ rise.

571.3

Ca^{2+} BINDING PROTEINS IN CHICK RETINA AND SENSITIVITY TO EXCITOTOXICITY. G.D. Zeevalk* and D.M. Jacobowitz. Neurology Dept.,UMDNJ-RWJ Med.Sch., Piscataway, N.J. 08854 and Lab.of Clin.Sci.NIMH, Bethesda, MD. 20892.

Uncontrolled Ca^{2+} flux is thought to orchestrate cell death due to excitatory amino acids. Studies suggest a relationship between Ca^{2+} binding proteins (CaBPs) and resistance to excitotoxicity. It is not clear, however, if neurons survive due to an absolute resistance to the excitotoxin. For example, in chick retina, NMDA kills most amacrine and some ganglion cells, whereas other retinal populations are unaffected. The resistance of neurons in the outer layers of retina is due to the absence of NMDA receptors on these cells. Amacrine neurons in retina are ideal to study the relationship between CaBPs and excitotoxicity because most amacrines are sensitive to NMDA in a dose dependent manner and the CaBPs, parvalbumin,(PV); calretinin,(CR); and calbindin, (CB) are found in this layer. Exposure of embryonic day 19 chick retina for 60 min to either 25, 100, 250 or 500μM NMDA caused a dose dependent increase in LDH release measured after 24hr of recovery. At 24hr, retina was fixed and processed for PV, CR and CB immunoreactivity. The number of amacrine cells positive for the CaBPs were counted and correlated to LDH release. Statistical analysis showed a negative correlation between NMDA mediated LDH release and loss of PV + amacrines and no correlation with loss of CR or CB + amacrines. Thus, as LDH increased, the number of PV cells, but not CB or CR cells declined. Exposure to 500 μM NMDA for 24hr resulted in a near total loss of PV and CB and 66% of CR + amacrines. These data suggest that although CB and CR + amacrines show a relative resistance to NMDA, the presence of CaBP, per se, is not sufficient to confer resistance.

INTRA-NEURONAL Ca^{2+}-BUFFERING WITH BAPTA ENHANCES GLUTAMATE EXCITOTOXICITY IN VITRO AND ISCHEMIC DAMAGE IN VIVO. K.G. Baimbridge* and K.M. Abdel-Hamid. Dept. of Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1Z3.

Primary cultures of rat hippocamapal pyramidal neurons were exposed for 30 min at room temperature to various levels of glutamate. Survival was assessed 48 h later using the fluorescent vital stains, calcein/am and ethidium homodimer. Compared to controls, prior loading of the neurons for 60 min in a 10 μM solution of the fast Ca^{2+}-buffer BAPTA-AM greatly increased the excitotoxic effect of glutamate. BAPTA-AM loading alone had no observable toxicity although it was demonstrated using fura-2 that the rate of rise and maximum amplitude of glutamate induced transients $[Ca^{2+}]_i$ were reduced whereas their decay times were considerably extended; consistent with the action of an enhanced Ca^{2+}-buffering capacity.

An in vivo hemorrhagic hypotensive model of ischemia in the rat was also used to test the effects of prolonged microinjection of BAPTA-AM, or the vehicle DMSO, in the region of the dorsal CA1 pyramidal cell layer. No sparing of CA1 neurons occurred in the BAPTA loaded regions. On the contrary, when the injection site included parts of the subiculum (usually spared form ischemia-induced cell death), the damage was considerably enhanced. In addition, parvalbumin containing interneurons in the CA1 region were also lost in regions exposed to BAPTA-AM whereas they are spared in controls or DMSO injected rats.

These results demonstrate that enhanced Ca^{2+}-buffering exacerbates, rather than ameliorates, the direct excitotoxic effect of glutamate in vitro and similarly enhances ischemia induced cell death in vivo. It is possible that increased Ca^{2+}-buffering may promote the influx of Ca^{2+} by reducing the Ca^{2+}-dependent inactivation of voltage operated Ca^{2+}-channels.

DIMINISHED GLUTAMATE-INDUCED INFLUX OF EXTRACELLULAR CALCIUM IN THE EPILEPTOGENIC HUMAN HIPPOCAMPUS *IN VIVO*

Dennis D. Spencer* and Matthew J. During
Section of Neurosurgery and Neuroendocrine Program, Yale University School of Medicine, New Haven, CT 06510.

We have developed and characterized a microdialysis probe suitable for chronic implantion in the human hippocampus. These probes were implanted bilaterally in patients with intractable complex partial epilepsy. To test the hypothesis that clinical, spontaneous-onset seizures elevate glutamate to potentially excitotoxic concentrations and that repeated exposure to these concentrations results in a loss of glutamate receptor-mediated responses, we measured extracellular fluid glutamate during spontaneous-onset seizures and the flux in Ca^{++}_o following the local perfusion of exogenous glutamate.

During seizures, extracellular glutamate reached concentrations which are potentially neurotoxic (>100μM). Moreover, the increase was greater and sustained in the epileptogenic hippocampus. Furthermore, glutamate-induced calcium influx was diminished in the epileptogenic hippocampus (39±6% decrease in the non-epileptogenic vs. a 17±7% decrease in the epileptogenic side) consistent with prior excitotoxic injury and suggesting loss of receptors and/or cells which express glutamate-gated calcium channels.

KINETICS OF ^{45}Ca FLUX IN BRAIN SLICES: EFFECTS OF GLUTAMATE AND THICKNESS.

G. Newman, F. Hospod*, M. Maletic-Savatic, C. Patlak. Dept. of Neurology, SUNY at Stony Brook, New York, 11794.

Glutamate and excitatory neurotransmitters stimulate calcium influx into neurons and glial cells. Excess calcium accumulation may underlie ischemic brain injury as well. To study kinetics of calcium influx and efflux in response to glutamate or ischemia, we measured ^{45}Ca uptake and washout from hippocampal brain slices. ^{45}Ca kinetics was studied in 500μ thick control slices, 500μ slices in the presence of 0.1, 1, 10, 100, 1000 μM glutamate, or in 1000μ thick hippocampal slices which serve as our model of the ischemic penumbra.

We have derived three and four compartment kinetic models but report results only for a serial three compartment, four parameter model fit by weighted least squares analysis. Results with this kinetic model show that glutamate increases influx of calcium into the first tissue compartment without affecting efflux from the first compartment or either parameter for the second tissue compartment. Results with ischemic 1000μ slices show that first compartment constants are the same as control 500μ slices but that entry into the second compartment is significantly increased. Concentration-response curves for the stimulation of calcium influx into 500μ slices revealed relatively little variation with concentration, with a trend toward highest calcium influx at or below 1 μM.

Our results suggest that calcium accumulation in brain during ischemia occurs as a result of factors not solely related to glutamate excitotoxicity, but also to factors that increase calcium in intracellular compartments which are not affected by glutamate under physiological conditions. Further work will be done to clarify the kinetic models, study lower glutamate concentrations and receptor analogues and extend the method to autoradiography.

571.7

POST-ISCHEMIC GLUCOCORTICOID EXPOSURE DOES NOT AUGMENT EXCITATORY AMINO ACID OVERFLOW IN THE RAT HIPPOCAMPUS.

G.C. Tombaugh* and R.M. Sapolsky. Dept. of Biol. Sciences, Stanford University, Stanford, CA 94305.

Exposure to glucocorticoids (GCs) can enhance hippocampal neuron loss following ischemia in rodents. Recent findings from our lab suggest that GCs, when present both before and after kainic-acid infusion, increase the extracellular level excitatory amino acids (EAAs) in the rat hippocampus (J. Neurochem, 1992). This implies that GCs may aggravate injury by exacerbating excitotoxic cascades. In light of this, we asked whether post-ischemic exposure to GCs could influence the extracellular levels of EAAs in the rat hippocampus after transient forebrain ischemia. Rats (n=10) were surgically prepared for 4-vessel occlusion, adrenalectomized, and food-deprived overnight while given access to 0.9% saline. The next day, animals were subjected to 20' of global forebrain ischemia under halothane anesthesia. Rectal temperature was maintained at 37°C with heating lamps and cortical EEG amplitude was monitored throughout the experiment. Immediately after occlusion, half of the rats received injections of corticosterone (CORT) resulting in plasma CORT levels that matched those seen in intact rats following a 20' ischemic insult; control rats received equivalent vehicle injections. Hippocampal microdialysis samples were collected during and for 6 hours after ischemia and then analyzed for selected amino acids by HPLC. A large transient rise in EAAs was seen in both treatment groups during the ischemic period, but no differences between groups were detected at any time point for any amino acid. These results suggest that post-ischemic GC exposure in ADX rats does not endanger hippocampal neurons by elevating interstitial levels of EAAs.

A MASS-FRAGMENTOGRAPHIC SEARCH FOR 6-HYDROXYDOPAMINE (6HO-DA) IN THE RAT BRAIN FOLLOWING THE ADMINISTRATION OF PSYCHOSTIMULANTS: A NEGATIVE FINDING.

F. Karoum* and R.J. Wyatt. NPB, NIMH, St. Elizabeth Hospital, Washington, D.C. U.S.A.

Non-enzymatic formation of 6HO-DA from dopamine following the administration of psychostimulants has been hypothesized to mediate their neurodegenerative effects. Direct support for this hypothesis came from the report of a 6-OH-DA-like substance in the rat striatum (ST) following the administration of high doses of methamphetamine (Pharmacol. Biochem. Behav. (1984), 21, 29-31). Although the identity of this 6-OH-DA-like substance was established by indirect pharmacological approaches, its structure has not been confirmed by direct methods. We used a mass-fragmentographic method to search for 6-OH-DA in the rat frontal cortex (FC) and ST following the administration of 6-hydroxydopa and a number of drugs that stimulate dopamine release. 6-OH-DA identity was based on the presence of specific fragments in it spectra produced by positive and negative chemical ionization. While both I.P. and I.C.V. administrations of 6-hydroxydopa (2 mg/kg and 200 μg respectively) produced measurable concentrations of 6-OH-DA in the FC and ST, no 6-OH-DA was detected after 25 or 50 mg/kg of methamphetamine, amphetamine or after 20 mg/kg of cocaine. It is concluded that if these agents can cause the formation of 6-OH-DA, the concentrations produced are below the detection level of our assay (less than 50 pg/mg protein).

TRANSNEURAL MECHANISM OF SELECTIVE DEATH OF CA1 NEURONS BY AN NMDA RECEPTOR AGONIST, L-CCG-IV.

T. Shigeno*[1], G. Kato[2], Y. Yamasaki[3], M. Ishida[4], and H. Shinozaki[4]
[1]Neurosurgery, Saitama Medical Center, [2]Neuronatomy, Chiba College of Medical Science, [3]Taiho Pharmaceuticals, [4]Pharmacology, The Tokyo Metropolitan Institute of Medical Science, Bunkyo, Tokyo 113, JAPAN

We have previously reported that intracerebral injection with a potent NMDA receptor agonist, the (2S,3R,4S) isomer of α-(carboxycyclopropyl)glycine (L-CCG-IV) induced selective death of the CA1 neurons in the rat hippocampus. Although the injection site was unilateral CA1, neuronal death frequently occurred in the bilateral CA1 sector. Therefore, we aimed to investigate whether or not the severance of corpus callosum would influence the events in the contralateral side. We employed three groups of adult rats under halothane anesthesia; (1) injection of L-CCG-IV (50nmole in 1μl vehicle) into the unilateral CA1, (2) severance of corpus callosum followed by injection of L-CCG-IV and (3) injection of a metabotropic receptor agonist, the (2S,3S,4S) isomer (L-CCG-I) (50nmole in 1μl vehicle) into the unilateral CA1. After 1 week, the brain was examined for histopathology. The intact neurons in the CA1 sector were counted. As shown below, L-CCG-IV significantly killed neurons ipsilateral to injection. There was also massive reduction in cell number contralateral to injection, though statistical significance could not be obtained. By contrast, when combined with severance of corpus callosum, there was no neuronal death in the bilateral CA1 sector. L-CCG-I did not cause neuronal death either, as we previously reported. We conclude that transneural mechanism is a prerequisite for selective death of CA1 neurons by glutamate excitotoxicity. The intrinsic neuronal circuitry in and around the hippocampus would underlie this phenomenon.

Neuronal Density in the CA1 Sector (cells/mm)	(n)	ipsilateral	contralateral
L-CCG-IV	(5)	19±14 sig.p<0.01	76±93
Severance of Corpus Callosum & L-CCG-IV	(11)	160±28	164±30
L-CCG-I	(6)	171±30	162±29

HOW LONG A PERIOD OF DEPOLARIZATION INDUCED BY HIGH EXTRACELLULAR POTASSIUM IS NEEDED TO KILL RAT AMYGDALA NEURONS *IN VIVO*?

D.G. Fujikawa*, A.H. Daniels and J.S. Kim. Exp. Neurol. Lab., VA Med. Ctr., Sepulveda, CA 91343 and Dept. of Neurology and Brain Res. Inst., UCLA Sch. of Med., Los Angeles, CA 90024.

In vivo perfusion of rat amygdala with a microdialysis probe containing 100 mM KCl for 3 h results in edema and neuronal necrosis up to 370 μm from the probe, as well as large increases in extracellular aspartate, glutamate and taurine (Fujikawa *et al., Soc. Neurosci. Abstr., 17:* 789, 1991). To determine the minimal time required to damage neurons, we shortened the exposure times to 20 and 60 min. Bilateral intracranial guide cannulae were implanted in adult Wistar rats, and the next day probes were inserted into the basolateral amygdaloid nuclei and perfused with Krebs-Ringer-bicarbonate (KRB) solution for 2 h. One side was switched to 100 mM KCl in modified KRB for 20 (n=4) or 60 min (n=5). At a probe efficiency of 6%, this delivered 6 mM K^+ to the tissue, increasing the extracellular K^+ ($[K^+]_o$) immediately adjacent to the probes to about 10 mM. Rats then underwent brain perfusion-fixation for histological examination. After 60 min of high-$[K^+]_o$, severe edema extended up to 121 ± 20 μm (mean ± S.E.), compared to mild edema up to 54 ± 0 μm on the control (KRB) side (p=0.03). In 108 x 540 μm areas adjacent to each probe, there were only 8 ± 3 normal neurons on the high-$[K^+]_o$ side, compared to 18 ± 3 on the control side (p=0.05). No differences between the high-$[K^+]_o$ and control sides were found after 20 min. Thus, the minimal high-$[K^+]_o$ time needed to kill amygdala neurons is between 20-60 min. A 40-min exposure time is currently under investigation. (Supported by the VA Research Service.)

NEURODEGENERATION MEDIATED BY PLATELET-ACTIVATING FACTOR (PAF) RECEPTORS P.V. Desai, M.V. Hogan*, E. Kornecki[1], and Y.H. Ehrlich CSI/IBR Ctr. Dev. Neurosci. and Dev. Disab., CUNY at Staten Island, NY 10301 and [1]Dept. Cell Biol. Anat. SUNY Brooklyn.

Platelet-Activating Factor (PAF) is a naturally occurring alkyl-ether phospholipid which serves as an intercellular messenger in a variety of physiological and pathological processes. The use of antagonists in experimental models has implicated PAF in a wide range of diseases, including brain damage induced by anoxia and ischemia. The ability of PAF to cause an increase in intraneuronal levels of calcium-ions (Kornecki and Ehrlich, Science, 240: 1792, 1988; Lipids, 26: 1247, 1991) has suggested that, in analogy to the action of glutamate, PAF may have excitotoxic activity. In the present study we have examined this possibility directly by testing the effects of PAF on primary cultures of central nervous system neurons. CNS neurons were cultured from the telencephalon of 7-day chick embryos and maintained in-vitro for a 5-day period during which they undergo differentiation and maturation. Neurodegeneration was observed microscopically and quantitated by measuring release of lactate dehydrogenase (LDH). PAF-induced degeneration of these cultured CNS neurons was found to be both concentration-dependent (1nM to 1μM) and time-dependent (30 min to 96 hrs). At saturation, PAF caused 35% neurodegeneration. Presumably, only those neurons in the heterogenous population that have PAF receptors are sensitive to its excitotoxic action. This possibility was supported by the finding that two structurally different antagonists of PAF receptors, the thienotriazolodiazepine WEB2086 and the ginkgolide BN52021, completely blocked the neurodegenerating effects of PAF. Antagonists of PAF may prove useful in the treatment and/or prevention of neuronal degeneration induced by stroke and spinal cord injury. Supported in part by a grant from the American Paralysis Association .

INTRATHECALLY ADMINISTERED ACROMELIC ACID INDUCES LONG-LASTING SPASTIC PARAPARESIS WITH DAMAGE OF SPINAL NEURONS IN THE RAT. Kwak S.*, Aizawa H., Nakamura R.. National Institute of Neuroscience, Kodaira, Tokyo 187, Japan.

Since systemic administration of acromelic acid (ACRO) induces selective damage of spinal interneurons in the rat, direct neurotoxic activity of ACRO was investigated in the spinal neurons in vivo. ACRO, kainic acid and AMPA were injected intrathecally at a constant rate for 2 h through a small tube placed in the L5/6 subarachnoid space of adult rats. ACRO induced sequential behavioral changes in a dose dependent manner at the concentrations above 2 μM; forced extension of hindlimbs, defecation, fasciculation and tremor of hindlimbs and flaccid paraplegia. At the concentrations exceeding 8 μM of ACRO, some rats developed spastic paraparesis on the next day with degenerating small or medium sized neurons in the caudal spinal segments, as seen in the spastic rats induced by systemic administration of ACRO. The paraparesis remained unchanged for months. Co-injection of 1 mM CNQX but not APV ameliorated the behavioral and neuropathological changes induced by ACRO. Kainic acid also induced similar behavioral and neuropathological changes but is more than 10 times weaker than ACRO. AMPA induced quite different behavioral changes; rats extended their hindlimbs periodically at concentrations above 1 mM with pathological changes in the spinal neurons. This study suggests that ACRO has potent kainate-like, rather than AMPA-like, excitotoxic activity on the spinal neurons in vivo. ACRO-induced neuron damage provides a useful tool for investigating neuronal death of spinal neurons and also for the investigation of spastic paraparesis of spinal origin.

571.13

THE EFFECTS OF IBOTENIC ACID LESIONS OF THE VENTRAL TEGMENTUM ON BRAIN STIMULATION REWARD. R. Anderson*, M. Trzcinska and E. Miliaressis. Behavioural Neurophysiology Lab., Univ. of Ottawa, Sch. of Psy., 275 Nicholas St., Ottawa, Ontario, K1N 6N5.

Until recently, it was not possible to differentiate between the role of cell bodies and fibers of passage in brain stimulation reward (BSR). If BSR within the ventral tegmentum (VT) is due to the activation of cell bodies, an intra-VT injection of ibotenic acid (IBO, a neurotoxin that destroys cell bodies while presumably sparing fibers of passage) should then decrease the rewarding efficacy of the stimulation. We obtained the rate-frequency functions (RF) of VT self-stimulation (relating barpressing rate to the frequency of cathodal pulses) for a series of pulse intensities, before and after an intra-VT injection of 4 ug of IBO in rats implanted with a chemitrode (a combination of electrode and injection cannula). The injection of IBO shifted the RF functions toward higher frequencies, indicating a decrease in rewarding stimulation efficacy. If subsequent histology reveals no primary demyelination, the data will point to an important role of VT cell bodies in BSR.

571.14

SYNAPTIC SPECIFICITY OF EXCITOTOXICITY IN ISCHEMIC HIPPOCAMPAL SLICES. G. Capocchi*, M. Cecconi, G. Della Torre§, M. Zampolini. Inst. Neurol. and §Inst. of Human Physiol., Univ. Sch. of Med., Perugia, 06100, Italy

The activation of the excitatory amino acids plays an important role in the physiopathology of ischemic damage in the central nervous system (CNS) mediating the increase of intracellular levels of Ca^{++}. This increase could be due to both synaptic (NMDA receptors) and extrasynaptic (Ca++ voltage-gated channels) mechanisms. To understand the synaptic specificity of excitotoxicity we stimulated a synaptic input with a patterned high frequency stimulation (HFS) in ischemic hippocampal slices.

The experiments were carried out in rat hippocampal slices maintained in vitro with Krebs-bicarbonate solution at 32°C gassed with 95% O_2 and 5% CO_2. Stimulation electrodes (St1 and St2) were applied in the Ca1 area in order to activate different groups of Schaffer collateral and to evoke field potentials in Ca1 pyramidal cells. In stable conditions of the recorded potentials, evoked by low frequency stimulation, 1 st every 20 sec (LFS) the O_2 was substituted with N_2 (95%). After 5 minutes patterned HFS was applied in St1 and LFS in St2. In normal conditions, patterned HFS (10 bursts of 35 msec at 100 Hz) induces LTP. In ischemic conditions the HFS in St1 induced a greater synaptic potentiation than in normal conditions while no changes were observed in St2. After 1-2 minutes there was a rapid and very similar decrease of the potential in both St1 and St2. When the decrease reached 90% of the pre-ischemic conditions, the N_2 was substituted with O_2 (95%). In these conditions the potentials increased and after 20-30 minutes stabilized at pre-ischemic levels without significant differences between St1 and St2.

In ischemic conditions, the decrease of both potentials after HFS of one of them indicates that the damage is not only synaptic but the synaptic activation also induces a more general cellular damage

571.15

AMINOOXYACETIC ACID (AOAA) POTENTIATES EXCITOTOXIC BRAIN INJURY IN PERINATAL RATS. J.W. McDonald* and D.D. Schoepp. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285

AOAA, an inhibitor of mitochondrial malate-aspartate shunt, was assessed for its ability to potentiate excititoxic brain injury in perinatal rats. Unilateral intrastriatal stereotaxic injection (AP=0, L=2.5, D=4 relative to Bregma) of AOAA in PND 7 rats produced prolonged, dose-dependent tonic-clonic seizures and unilateral brain injury over a 1-4 μmol dose range. Intrastriatal injection of 1 μmol/0.5 μl AOAA on PND 7 resulted in significant brain injury when assessed on PND 12 by comparison of cerebral hemisphere weight disparities ($p<0.05$ ANOVA,1.5±0.3% damage,mean±SEM, n=5, AOAA treated vs vehicle treated, 0.1±0.5% damage, n=5). Co-intrastriatal injection of 1μmol AOAA with subtoxic doses of either NMDA, AMPA or 1S,3R-ACPD markedly potentiated the severity of behavioral seizures and resulting brain injury (see table). Co-administration (i.p.) of 1 mg/kg MK-801, but not the AMPA antagonist GYKI 52466 (20 mg/kg), prevented the brain injury induced by intrastriatal injection of 4 μmol AOAA when assessed by hemisphere weight disparities.

	%Damage		
	NMDA (1nmol)	AMPA (1nmol)	1S,3R-ACPD (250 nmol)
Vehicle	-0.5 ± 0.5	1.0 ± 0.7	0.9 ± 0.5
AOAA 1 μmol	3.6 ± 0.2*	3.0 ± 0.3*	3.1 ± 0.2*

*1-way Anova $p<0.001$, Duncan Post-hoc Test $p<0.05$ vs vehicle co-injection.

The results indicate that AOAA markedly potentiates excitotoxic brain injury mediated by the selective excitatory amino acid agonists NMDA, AMPA and 1S,3R-ACPD. AOAA has been shown to disrupt mitochondrial electron transport and intracellular energy metabolism. The data suggest that impairment of intracellular energy metabolism augments excitotoxic injury in perinatal rats.

571.16

EFFECT OF SOMAN AND ACh ON GLUTAMATE-INDUCED NEUROTOXICITY IN CULTURED CEREBRAL CORTICAL NEURONS. S.S. Deshpande, R. Ray* and M.G. Filbert, Neurotoxicology Branch, Pathophysiology Division, USAMRICD, Aberdeen Proving Ground, MD 21010-5425.

Soman (pinacolylmethylphosphonofluoridate), an irreversible inhibitor of acetylcholinesterase, causes seizure-related brain damage in animals. Extensive neuropathology has been observed in the pyriform cortex, hippocampus, amygdala and thalamus of rats and guinea pigs (Churchill et al, NeuroToxicology 6, 81-90, 1985; Sparenborg et al, NeuroToxicology, 11, 509-520, 1990). To investigate the link between soman-induced neuropathology and glutamate (GLU) excitotoxicity, we used dissociated cell cultures derived from rat embryonic (E17 days) cerebral cortex. After 14 days in culture, the cells were exposed to GLU (50 uM) alone or in combination with ACh (100 uM) and soman (100 nM). Cytotoxicity was assessed after 24 hr by trypan blue dye uptake and LDH release to the extracellular medium. Complete inhibition of AChE by 100 nM soman had no effect on the cell viability. Exposure to a nontoxic concentration of GLU (50 uM) in the presence of 100 uM ACh produced a 3 fold increase in LDH release confirming earlier observations of Mattson (Brain Res., 497, 402-406, 1989) that ACh lowers the threshold for GLU-induced neurotoxicity. Exposure to 50 uM GLU plus 100 uM ACh in combination with 100 nM soman contrary to the expectation did not significantly potentiate cytotoxicity further. In conclusion, soman does not exert a direct toxic effect on cerebral cortical neurons in culture. The degeneration-potentiating effect of ACh emphasizes the importance of multiple transmitter inputs involved in neuronal degeneration.

572.1

ISOLATION OF NOVEL METABOTROPIC GLUTAMATE RECEPTOR CDNAS FROM RAT OLFACTORY BULB. J. A. Saugstad, T. P. Segerson, E. R. Mulvihill+ and G. L. Westbrook*. Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences Univ., Portland, OR 97201 and +Departments of Molecular and Cellular Biology and DNA Chemistry, Zymogenetics, Seattle, WA 98105.

Glutamate receptors are grouped into two broad classes; the ionotropic receptors which are cation-selective ion channels, and the metabotropic receptors (mGluRs) which are G protein-coupled receptors. Several distinct metabotropic receptor cDNAs have been isolated to date (Masu *et al.*, 1991; Houamed *et al.*, 1991; Tanabe *et al.*, 1992). Characterization of these receptors reveal that they couple to different G proteins to effect various intracellular transduction mechanisms. In addition, pharmacological data has shown that in brain, L-AP4 binds to a presynaptic glutamate receptor that inhibits transmitter release at several pathways. This inhibition is blocked by PTX, suggesting a direct interaction via a Gi/Go protein with voltage dependent calcium channels. L-AP4 does not activate mGluR1. Therefore, this receptor appears to be pharmacologically and functionally distinct. In physiological experiments (Trombley and Westbrook, 1992) the AP4-specific receptor(s) appear to be abundant on mitral cells of the olfactory bulb. In order to identify and characterize the AP4-specific receptor, we have amplified rat olfactory bulb cDNA using the polymerase chain reaction and degenerate oligonucleotide primers to the conserved transmembrane domains three and six of mGluR1 and mGluR4. Sequence analysis of the amplification products revealed the presence of at least three cDNAs that are distinct, but related to the previously isolated metabotropic receptor cDNAs. We are currently screening a rat olfactory bulb cDNA library with the amplification products to isolate full-length cDNA clones. As several of the previously cloned mGluRs show distinct expression patterns in the olfactory bulb, isolation and expression of these related receptors should provide a basis for exploring the function of these receptors in the olfactory system. Supported by the Klingenstein Foundation and NIH T32 DK07680.

572.2

INHIBITION OF cAMP FORMATION BY METABOTROPIC RECEPTOR AGONISTS IN BRAIN SLICES: DEVELOPMENTAL PROFILE AND PHARMACOLOGICAL CHARACTERIZATION. A.A. Genazzani, G. Casabona, G. Aleppo, M. Di Stefano, E. De Bernardis, M.A. Bortino* and F. Nicoletti. Institute of Pharmacology, University of Catania, Italy.

$1_S,3_R$ACPD inhibited forskolin-stimulated cAMP formation in slices from adult rat hippocampus and hypothalamus. Quisqualate and ibotenate were much less efficacious than $1_S,3_R$ACPD in inhibiting forskolin-stimulated cAMP formation, whereas BMAA, AMPA or NMDA were inactive. Stimulation of cAMP formation by forskolin was attenuated by the enzyme adenosine deaminase (ADA), which depletes the endogenous adenosine. The inhibitory action of ACPD was no longer visible when forskolin was added to the slices in the presence of ADA. In addition, ACPD failed to inhibit forskolin-stimulated cAMP formation in hippocampal or hypothalamic slices prepared from rats at 1, 8 or 15 days of postnatal life. These results suggest that hippocampal or hypothalamic slices express a metabotropic receptor subtype that is negatively coupled to adenylate cyclase, is preferentially activated by ACPD, is expressed in the adult life and interacts with endogenous adenosine through a mechanism that remains to be elucidated.

572.3

METABOTROPIC GLUTAMATE RECEPTOR-MEDIATED INCREASES IN CYCLIC AMP ACCUMULATION IN THE HIPPOCAMPUS. P.J. Conn* and D.G. Winder. Dept. of Pharmacol. and Program in Neuroscience, Emory Univ., Atlanta, GA 30322.

The most well characterized metabotropic glutamate receptor (mGluR) subtype is coupled to activation of phosphoinositide hydrolysis. However, little is known about other second messenger systems that are activated by mGluRs. Thus, we performed a series of experiments to test the hypothesis that mGluR activation leads to increases in cAMP accumulation in rat hippocampus. We found that the selective mGluR agonist (1S,3R)-1-aminocyclopentane-2,3-dicarboxylic acid (1S,3R-ACPD) induces a concentration-dependent increase in cAMP accumulation in cross-chopped hippocampal slices. Furthermore, 1S,3R-ACPD enhanced the cAMP response to activation of other receptors that activate adenylate cyclase. As with other responses to mGluR activation, the effect of 1S,3R-ACPD was not mimicked by 1R,3S-ACPD. However, 1S,3S-ACPD stimulated the response with similar potency and efficacy to 1S,3R-ACPD. The response to 1S,3R-ACPD was blocked by the mGluR antagonists L-serine-O-phosphate (L-SOP), L-2-amino-3-phosphono- propionic acid (L-AP3), L-2-amino-4-phosphonobutyric acid (L-AP4), but not by selective antagonists at ionotropic glutamate receptors. Taken together, these data suggest that 1S,3R-ACPD-stimulated increases in cAMP accumulation are mediated by activation of mGluRs.

572.4

ENDOGENOUS ADENOSINE MEDIATES INCREASES IN cAMP ACCUMULATION INDUCED BY ACTIVATION OF METABOTROPIC GLUTAMATE RECEPTORS D.G. Winder* and P.J. Conn. Department of Pharmacology and Program in Neuroscience, Emory University, Atlanta, GA 30322.

We have found that activation of metabotropic glutamate receptors (mGluRs) results in an increase in cAMP accumulation in rat hippocampal slices. Previous studies suggest that cAMP increases induced by other excitatory amino acids may be mediated by adenosine. Thus, we tested the hypothesis that adenosine mediates the 1S,3R-ACPD-stimulated increase in cAMP levels in rat hippocampal slices. We report that the selective mGluR agonist (1S,3R)-1-aminocyclopentane-1,3-dicarboxylic acid (1S,3R-ACPD) potentiates adenosine-stimulated increases in cAMP accumulation. Adenosine receptor antagonists inhibited 1S,3R-ACPD-stimulated cAMP accumulation with an order of potency that corresponds to their affinity at A_2 adenosine receptors. Additionally, an adenosine uptake blocker potentiated the cAMP increases induced by 1S,3R-ACPD. Finally, preincubation of slices with adenosine deaminase abolished the cAMP response to 1S,3R-ACPD and this response was restored by addition of concentrations of 2-chloroadenosine that did not increase cAMP levels in the absence of 1S,3R-ACPD. These data support the hypothesis that 1S,3R-ACPD increases cAMP accumulation in the hippocampus by potentiating responses to endogenous adenosine.

572.5

THE METABOTROPIC GLUTAMATE RECEPTOR IS COUPLED TO ADENYLATE CYCLASE IN PRIMARY CULTURES FROM MOUSE CEREBRAL CORTEX. E. Ratti[1], P. Michieli[1], F. Ferraguti[1], F.Th.M. van Amsterdam[1], G. Gaviraghi[1], E. Cavicchini[1]* and F. Nicoletti[2]. (1) *Glaxo* Research Laboratories, Verona, Italy; (2) Institute of Pharmacology, University of Catania, Italy.

Recent evidence has suggested the existence of multiple subtypes of metabotropic glutamate receptors (Tanabe et al, Neuron, 8, 1992). Whereas the mGluR1 subtype is coupled to polyphosphoinositide (PPI) hydrolysis, the mGluR2 subtype is negatively linked to adenylate cyclase. *In situ* hybridization demonstrated that mGluR1 and mGluR2 receptors differ in their anatomical distribution, with the latter being expressed at high density in the cerebral cortex. We now report the presence of a metabotropic receptor negatively coupled to adenylate cyclase in primary cultures from mouse cerebral cortex. Cultures at 14 days of maturation *in vitro* were stimulated with forskolin or isoproterenol, which both increase cAMP formation. This stimulation was largely attenuated by the metabotropic receptor agonists, quisqualate and 1S,3R-ACPD, which also reduced basal cAMP levels. These results support the existence of a metabotropic receptor subtype coupled to adenylate cyclase in cortical cells.

TRANS-1-AMINOCYCLOPENTANE-1,3-DICARBOXYLIC ACID-INDUCED PHOSPHOINOSITIDE HYDROLYSIS AND MODULATION OF NEURONAL EXCITABILITY DO NOT UNDERGO PARALLEL DEVELOPMENTAL REGULATION. V. Boss*, M.A. Desai, T.S. Smith and P.J. Conn. Pharmacology Dept., Emory University, Atlanta, GA.

The selective metabotropic glutamate receptor agonist, *trans*-1-aminocyclopentane-1,3-dicarboxylic acid (*trans*-ACPD), stimulates phosphoinositide hydrolysis and elicits a number of electrophysiological responses in hippocampus. If these effects are mediated by the same receptor, then they should undergo parallel developmental regulation. Therefore, we compared the phosphoinositide hydrolysis response and the electrophysiological responses to *trans*-ACPD at two different developmental stages. *Trans*-ACPD-stimulated phosphoinositide hydrolysis was much greater in hippocampal slices from immature (6-11d old) rats than from adults. In contrast, *trans*-ACPD elicited decreases in spike frequency adaptation and in the amplitude of the slow afterhyperpolarization in roughly equal percentages of immature and adult CA1 pyramidal cells. Similar results were obtained using the putative endogenous agonist, glutamate. These data support the hypothesis that certain electrophysiological effects of *trans*-ACPD are mediated by a metabotropic glutamate receptor that is distinct from the phosphoinositide hydrolysis-linked glutamate receptor.

572.7

MODULATION OF NMDA RECEPTOR-MEDIATED TRANSMISSION IN CEREBELLAR GRANULE CELLS BY METABOTROPIC GLUTAMATE RECEPTOR AGONISTS AND NITRIC OXIDE.

D.J. Rossi*, G.A. Kinney and N.T. Slater. Dept. of Physiology, Northwestern Univ. Med. School, 303 E. Chicago Ave., Chicago, IL 60611.

Excitatory synaptic transmission at the mossy fiber (MF)-granule cell (GC) synapse in cerebellum is mediated by both AMPA and NMDA subtypes of glutamate receptor. However, little is known of the mechanisms which regulate synaptic efficacy at this synapse in situ. We have examined the actions of metabotropic glutamate receptor (mGluR) agonists and the NO donor nitroprusside (SNP) in both intact turtle cerebellum and thin slices of rat cerebellum *in vitro*. Turtle Purkinje cells were impaled with sharp microelectrodes, and the disynaptic EPSP evoked by MF stimulation was recorded. Bath application of quisqualate (1 μM) and the 1S,3R- and 1S,3S-isomers of the mGluR agonist ACPD (1-50 μM) reversibly potentiated the MF-evoked EPSP, but were without effect on the monosynaptic parallel fiber-evoked EPSP. These effects were blocked by the NMDA antagonist D-AP5 (50 μM), but were not blocked by forskolin (25 μM), calphostin C (1 μM), the phorbol ester TMA (10 μM), L-AP3 (1 mM), 1R,3S-ACPD (25-500 μM), nor SNP (1 mM), although calphostin C, TMA and SNP reduced the initial EPSP amplitude. By contrast, in rat GCs recorded using the perforated patch-clamp technique, 25 μM 1S,3R-ACPD did not affect the MF-evoked EPSC, nor responses to NMDA, but both responses were reversibly blocked by SNP (100-250 μM). However, in the majority of cells the response to NMDA was potentiated by higher doses (100 μM) of 1S,3R-ACPD. These results demonstrate opposing roles for the regulation of NMDA sensitivity of GCs by mGluR agonists and the NO donor SNP. (Supported by USPHS Grant NS17489 to N.T.S.)

572.8

ACTIVATION OF METABOTROPIC EXCITATORY AMINO ACID RECEPTOR POTENTIATES AMPA AND NMDA RESPONSES OF SPINAL DORSAL HORN NEURONS.

R. Cerne*, K. Rusin and M. Randic. Department of Veterinary Physiology and Pharmacology, Iowa State University, Ames, IA 50011.

In freshly isolated spinal dorsal horn neurons (laminae I-IV) of the young rat, the effects of activation of metabotropic glutamate receptor with trans-ACPD [(±)-trans-1-aminocyclopentane-1,3-dicarboxylic acid], 1S,3R-ACPD and 1R,3S-ACPD on inward currents induced by glutamate (GLU), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and N-methyl-D-aspartate (NMDA) were studied under whole-cell voltage-clamp conditions. When the cells were clamped to a holding potential of -60mV, application of 1S,3R-ACPD (100μM) reversibly enhanced the peak amplitude of the initial transient component of the glutamate-induced current. The enhancing effect lasted up to 40 min after removal of 1S,3R-ACPD. In addition, 1S,3R-ACPD (140.8 ± 13.9%, 10/12 cells), 1R,3S-ACPD (124.4 ± 6.5%) and (±)-trans-ACPD potentiated both the initial transient and the steady-state components of AMPA-induced current in most of tested cells. These effects were Ca^{2+}-sensitive and lasted 10-45 min depending upon both dose and length of application. (±)-Trans-ACPD also reversibly enhanced (146.1 ± 7.8%, 11/12 cells) the peak amplitude of the initial fast component of NMDA-induced current. In a smaller proportion of dorsal horn neurons, the enhancing effect was preceded by a transient depression of the responses to GLU, AMPA and NMDA. These results are consistent with the possibility that the activation of metabotropic glutamate receptor may contribute to the regulation of the strength of excitatory amino acid-mediated primary afferent neurotransmission, including nociception. (Supported by BNS 8418042).

572.9

ACTIVATION OF METABOTROPIC RECEPTORS DIFFERENTIALLY MODULATES EXCITATORY AND INHIBITORY SYNAPTIC TRANSMISSION BETWEEN RAT HIPPOCAMPAL NEURONS IN CULTURE.

M. B. Ghasemzadeh*, K. S. Wilcox and M. A. Dichter. Depts. of Pharmacology, Physiology and Neurology, Univ. of Pennsylvania School of Medicine and Graduate Hospital, Philadelphia, PA 19104.

Glutamate receptors can be classified into ionotropic and metabotropic receptors; the latter possibly mediating their effects through an increase in membrane phosphoinositides hydrolysis. We have studied the effects of metabotropic receptor activation on synaptic transmission in hippocampal cultures using the whole-cell voltage-clamp technique.

Application of 1S,3R-ACPD (100 μM) (in the presence of appropriate ionotropic receptor antagonists) reversibly decreased the amplitude of spontaneous NMDA and non-NMDA receptor-mediated EPSCs with no consistent change in frequency. By contrast, 1S,3R-ACPD as well as glutamate (2-5 μM) and quisqualate (2-5 μM), produced a reversible increase in the frequency and a transient increase in the amplitude of IPSCs. The origin of these metabotropic effects seems to be at a presynaptic site since postsynaptic responses to pressure applied NMDA, AMPA and GABA did not change. Preliminary paired cell recordings also reveal a similar potentiation effect of quisqualate on evoked IPSCs. The effects of 1S,3R-ACPD on IPSCs were only partially blocked by L-AP3 (1 mM) and L-aspartate-ß-hydroxamate (100 μM), two potent inhibitors of IP_3 turnover. Activation of presynaptic glutamate receptors by L-AP4 (50-100 μM) decreased the amplitude and frequency of IPSCs while decreasing amplitude of EPSCs with little change in frequency.

The differential modulation of excitatory and inhibitory synaptic transmission by metabotropic receptor activation, with a net result of enhanced inhibition may have important implications for development, synaptic plasticity and some neuropathological states. (Supported by GM 34781)

METABOTROPIC GLUTAMATE RECEPTOR ACTIVATION EVOKES THE RELEASE OF ENDOGENOUS GABA FROM RAT CORTICAL SYNAPTOSOMES.

L. DIAZ-ARNESTO, K.M. KENDRICK† and P.C. EMSON.* MRC Group and Department of Neurobiology†, AFRC Institute of Animal Physiology and Genetics Research, Babraham, Cambridge, CB2 4AT, U.K.

Metabotropic glutamate receptor (mGluR) mRNA is expressed by many cells of the mammalian cerebral cortex, including interneurones (Masu *et al*, Nature 349,760-765, 1991), and it is likely that the major inhibitory GABA-ergic basket cells, may also do so. Therefore, *in vivo* activation of mGluRs by endogenous glutamate may directly influence the release of GABA from these interneurones.

The effects of mGluR activation on GABA release were examined using an *in vitro* preparation of superfused cortical synaptosomes. Endogenous GABA efflux was measured by HPLC with pre-column derivatization and fluorescence detection. Following a 5 min exposure to the selective metabotropic agonist t-ACPD (300 μM, racemic mixture), cortical synaptosomes showed a 52.1 ± 10.8 % (n=12) increase over basal levels. A control stimulus of 40 mM KCl, which is known to open voltage sensitive calcium channels, evoked a 294.9 ± 33.5 % (n=8) increase under the same conditions. Omission of Ca^{++} from the superfusion medium significantly attenuated but did not abolish the t-ACPD-evoked GABA release, (35.9 % reduction, $p<0.05$), possibly indicating the mobilization of Ca^{++} from internal stores.

These data suggest that activation of the mGluR on GABA-ergic nerve terminals may provide a mechanism for local inhibitory GABA-ergic feedback onto excitatory cortical neurones.

572.11

POTENTIATION OF IONOTROPIC GLUTAMATE RECEPTOR RESPONSES BY METABOTROPIC RECEPTORS IN THE RAT DORSAL HORN.

D. Bleakman*, K.J. Rusin, P.S.Chard, S.R. Glaum & R.J. Miller. Dept. Pharmacol. and Physiol. Sciences, Univ. of Chicago, Chicago, IL 60637.

Using both acutely isolated dorsal horn neurons or slices of the adult rat spinal cord (9-16 days) we have examined the effects of the metabotropic glutamate receptor agonist (1S,3R) 1-amino cyclopentane-1,3-dicarboxylic acid ((1S,3R)-ACPD) (1-50μM) on responses mediated by the ionotropic glutamate receptor agonists, N-methyl-D-aspartate (NMDA), kainate (KA) and α-amino 3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA). We measured $[Ca^{2+}]_i$ in isolated neurons using fura-2 based microfluorimetry and found that in approximately 50% of neurons examined, (1S,3R)-ACPD (threshold concentration 20μM) produced increases in the $[Ca^{2+}]_i$ which could be prevented by blockers of voltage sensitive calcium channels. In addition, increases in $[Ca^{2+}]_i$ produced by NMDA (100μM), KA (1-10μM) and AMPA (1-10μM) were markedly potentiated by (1S,3R)-ACPD (1-50μM). Potentiation required simultaneous application of both (1S,3R)-ACPD and the ionotropic agonist. However, potentiation was observed at concentrations of (1S,3R)-ACPD which did not increase responses produced by elevated concentrations of KCl (10-50mM). (1S,3R)-ACPD potentiated ionotropic responses in all cells examined and reversed rapidly upon washout of (1S,3R)-ACPD.

Dorsal horn neurons of the spinal cord slice preparation were whole cell voltage clamped. In these cells (1S,3R)-ACPD also potentiated inward currents evoked by the pressure application of AMPA, NMDA and KA, an effect which was also rapidly reversible. These short term effects of (1S,3R)-ACPD may play an important role in the regulation of ionotropic responses mediated by glutamate in the spinal cord.

INTERACTIONS BETWEEN PHOSPHOLIPASE C-COUPLED AND NMDA RECEPTORS IN CULTURED CEREBELLAR GRANULE CELLS: PROTEIN KINASE C-MEDIATED INHIBITION OF NMDA RESPONSES.

[1]M.J. Courtney, [1]K.E.O. Åkerman, [2]J.M. Pocock* and [2]D.G. Nicholls [1]Dept. of Biochemistry, University of Dundee, Dundee DD1 4HN, Scotland, UK and [2]Dept. of Biochemistry and Pharmacy, Åbo Akademi, SF 20500, Turku, Finland.

The NMDA receptor of rat cerebellar granule cells in primary culture is inhibited by phospholipase C-coupled receptor activation. In the absence of NMDA, stimulation of muscarinic, metabotrophic glutamate or endothelin receptors induces an elevation of the cytoplasmic free calcium ($[Ca^{2+}]_c$) monitored with the fluorescent probe fura-2. The response is consistent with the ability of phospholipase C-coupled receptors to release an intracellular pool of Ca^{2+} and induce subsequent Ca^{2+} entry into the cell; both responses can be abolished by discharge of intracellular Ca^{2+} stores with low concentrations of ionomycin or thapsigargin. In cells stimulated with NMDA the $[Ca^{2+}]_c$ response to the phospholipase C-coupled agonists is complex and agonist-dependent; however in the presence of ionomycin each agonist produces a partial inhibition of the NMDA component of the $[Ca^{2+}]_c$ activator 4β-phorbol dibutyrate. It is concluded that NMDA receptors on cerebellar granule cells are inhibited by phospholipase C-coupled receptors via activation of protein kinase C.

572.13

EFFECTS OF THE METABOTROPIC AGONIST *t*-ACPD ON PYRAMIDAL NEURONS IN RAT PIRIFORM CORTEX SLICES. M. Fejtl*, N. Hori, and D.O. Carpenter. NYS Dept. of Health, Wadsworth Center, and School of Public Health, Albany, NY 12201.

The metabotropic subtype of glutamate receptor in mammalian CNS is thought to be exclusively coupled to a receptor protein mediating second messenger processes such as an increase of $[Ca^{2+}]_i$ and activation of PKC. Here we report that activation of the metabotropic receptor leads to an increase of the iontophoretically evoked AMPA and QUIS responses, whereas NMDA responses are unaffected.

Piriform cortex slices (450 μm) were taken from male rats (150-200g) and incubated in Ringer solution for 2h. After transfering the slices into the recording chamber, intracellular recordings were obtained from pyramidal neurons using 60-80 MΩ electrodes filled with 3M KAc. 50 μM *t*-ACPD, a selective agonist for the metabotropic receptor, 1-10 mM AP-3, and 1 mM Ni^{2+} were bath applied, whereas AMPA, QUIS and NMDA were applied iontophoretically (5-20 nA for 1s, 30 s autocycle).

t-ACPD caused a depolarization accompanied by an increase in input resistance and membrane noise. Although the depolarization was blocked by 10 mM AP-3 the increase in noise was not. Neither hyperpolarization nor depolarization appeared to alter the noise increase. Surprisingly it is blocked by 1 mM Ni^{2+} and this may reflect the involvement of presynaptic Ca^{2+} channels which trigger other postsynaptic mechanisms. *t*-ACPD also enhanced the iontophoretically applied AMPA and QUIS but not NMDA responses, possibly due to increased sensitivity of the AMPA receptor caused by phosphorylation.

Our studies in adult rats and in piriform cortex differ from those reported from neonatal hippocampus. Thus these results may reflect either developmental or regional differences of the metabotropic receptor(s). 572.14

METABOTROPIC GLUTAMATE RECEPTOR MEDIATED AFTERDEPOLARIZATION IN RAT NEOCORTICAL NEURONS. C.C. Greene, P.C. Schwindt, and W.E. Crill*. Dept. of Physiology & Biophysics, University of Washington, Seattle, WA. 98195.

Metabotropic receptors (mGluR) are a family of G-protein linked glutamate receptors. Like muscarinic agonists, metabotropic agonists block the afterhyperpolarization (AHP) in hippocampal pyramidal neurons (Stratton et al, 1989). We used intracellular recording to determine if mGluR mediate a similar effect on the spike-evoked slow AHP (sAHP) of rat neocortical neurons in a submerged brain slice preparation. Slices were bathed in artificial CSF containing kynurenic acid (2 - 4 mM) or CNQX (50 μM) and APV (50 μM) to block ionotropic receptors, atropine (5 μM) to block muscarinic receptors, and s-propranolol (15 μM) and phentolamine (30 μM) to block adrenergic receptors. Medium and slow duration AHPs followed 20 action potentials individually evoked by current pulses at 100 Hz. When 1-aminocyclopentane-1,3-dicarboxylic acid, 1S,3R-ACPD (14 - 50 μM), a relatively selective metabotropic agonist, was added, a large afterdepolarization (ADP) replaced the sAHP. Glutamate (0.1-1 mM) and quisqualate (0.1 - 5 μM), but not the ionotropic agonist AMPA (0.5 μM), elicited a similar ADP. The ADP represents a new type of mGluR mediated excitatory response which caused persistent self-sustained firing following the cessation of the repetitive firing stimulus in several neurons and could contribute to pathophysiologic conditions like epilepsy. We have previously shown that muscarinic agonists induced a comparable ADP in cat Betz cells. Hence, our finding supports the hypothesis that metabotropic receptor activation mimics many of the effects of muscarinic agonists (Miller, R.J., 1991). TRANS-ACPD AND QUISQUALATE CAN INHIBIT EPILEPTIFORM ACTIVITY IN THE RAT NEO-CORTEX. M.J. Sheardown*. Novo Nordisk A/S, CNS Division, DK-2760 Maaloev, Denmark.

The compounds (±)-trans-ACPD and quisqualate are agonists at the so-called metabotropic quisqualate receptor (mGluR). Recently, the sequences of four mGluR's have been published, one ($mGluR_1$) which stimulates inositol polyphosphate formation. This study shows the effects of trans-ACPD and quisqualate on the spontaneous epileptiform spike activity observed in rat neo-cortex slices bathed in magnesium-free medium containing 10 μM NBQX. (±)-trans-ACPD and quisqualate reduce the frequency of the spikes in a concentration-dependent fashion, the IC_{50} values being 16 and 26 μM, respectively. These responses were not inhibited by AP3 at concentrations upto 1 mM. The order of potency of the agonists was (±)-trans-ACPD > quisqualate suggesting that the $mGluR_1$ receptor is not involved and that the $mGluR_{2,3\ or\ 4}$ receptor subtypes may be responsible. As this spiking activity is Ca^{2+}-dependent and sensitive to TTX and NMDA receptor blockade, it is possible ACPD and quisqualate are acting by reducing glutamate release.

572.16

ACTIVATION OF POSTSYNAPTIC METABOTROPIC GLUTAMATE RECEPTORS BY TRANS-ACPD EVOKES A MEMBRANE HYPERPOLARISATION IN NEURONES OF THE BASOLATERAL AMYGDALA (BLA). **D. G. Rainnie* and P. Shinnick-Gallagher. Dept. of Pharmacology, Univ. of Texas Medical Branch, Galveston, TX 77550.**

Intracellular recordings were made from 51 neurones of the BLA *in vitro*. Application of the metabotropic glutamate receptor agonist (±)-1-amino-1,3-cyclopentane-trans-dicarboxylic acid (trans-ACPD, 100-200 μM) and its active isomer, (1S, 3R)-1-aminocyclopentane-1,3-dicarboxylic acid (1S, 3R ACPD, 100 μM), evoked either membrane hyperpolarisation (29/51 neurones) or hyperpolarisation and subsequent depolarisation (22/51 neurones). The hyperpolarisation was associated with a decrease in neuronal input resistance (R_N) and the depolarisation with an increase in R_N. The hyperpolarisation persisted in the presence of tetrodotoxin (TTX, 0.5 μM) and was unaffected by the ionotropic glutamate receptor antagonists, 2-amino-5-phosphonovaleric acid (APV, 50 μM) or 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX, 10 μM), suggesting a direct action at postsynaptic metabotropic glutamate receptors. The reversal potential of the agonist evoked hyperpolarisation was -83 ± 5 mV (n = 6), close to that of potassium (-87 mV, estimated from the Nernst Equation). Hyperpolarising responses to both agonists were abolished in neurones impaled with microelectrodes containing either the non-hydrolysable GTP analogue, guanosine 5'-O-(3-thiotriphosphate) (GTP-γ-S, 10mM) or the calcium chelator, 1,2-bis(2-aminophenoxy)ethane-N,N,N',N'-tetraacetic acid (BAPTA, 200 mM). These data suggest that the initial hyperpolarising response of BLA neurones to postsynaptic metabotropic receptor activation might result from a G-protein mediated increase in a calcium-dependent potassium conductance. Supported by NS-24643.

SPECIFIC IONOTROPIC AND METABOTROPIC GLUTAMATE RECEPTOR AGONISTS MODULATE FREE INTRACELLULAR CALCIUM IN ACUTELY DISSOCIATED EMBRYONIC RAPHE CELLS. N. König * [1], M.J. Drian [1], M. Pariat [1], O.J.J. Manzoni [2] and F. Sladeczek [2], [1] EPHE-INSERM U336, USTL, Place E. Bataillon, and [2] CCIPE, Rue de la Cardonille, 34095 Montpellier Cedex, France.

There is increasing evidence that glutamate receptors not only play a prominent role in postnatal development, but that they are present already in the embryonic brain. We dissected the basal plate parts of the rostral and the caudalmost rhombencephalon (including the raphe) from rat embryos at 13 and 14 days of gestation. The cells were dissociated, plated, and loaded with the calcium-marker FLUO-3 after 1 to 5 h *in vitro*. Relative changes of fluorescence were evaluated using video or confocal microscopy. When the tissue was taken from day 13 embryos, all the agonists used (kainic acid, AMPA, NMDA, and 1S,3R-ACPD) were able to elicit rises in free intracellular calcium. However, the number of responding cells was quite low. When the tissue was taken at day 14, the proportion of responding cells was higher, and the responses were more stable and reproducible. Some cells responded to more than one agonist. In conclusion, ***functional* ionotropic as well as metabotropic receptors** seem to be expressed in early developing regions of the embryonic rat brain **by day 13,** which rises the question about their role at these early stages.

572.18

METABOTROPIC RECEPTOR-SPECIFIC AGONISTS STIMULATE POLYRIBOSOME AGGREGATION IN SYNAPTONEUROSOMES. I.J. Weiler*, W.S. Childers, W.T. Greenough, Depts. Psychol. and Cell & Struct. Biol, Neurosci. Prog, and Beckman Inst.,Univ. Illinois, Urbana-Champaign, IL 61801.

We showed (Mol.Cell. Neurosci.2:305, 1991) that K+ stimulation of synaptoneurosome preparations triggers rapid aggregation of polyribosomes and transient acceleration of incorporation of methionine into TCA-precipitable polypeptides. We now show that this response is elicited by the neurotransmitter glutamate and have investigated its analogs.

At a dose of 10 μM, quisqualic acid, ibotenic acid, and the selective metabotropic receptor agonist trans-ACPD are all effective in stimulating polyribosomal aggregation. NMDA is ineffective at this concentration; the NMDA antagonist APV does not block the response to K+. CNQX, a selective inhibitor for the ionotropic quisqualate response, does not hinder aggregation, indicating that the metabotropic quisqualate activity is still present..

The cell-permeant diacylglycerol analog OAG (1-oleoyl-2-acetyl-glycerol) was able to mimic the effect of glutamate in inducing a typical polyribosomal aggregation response. This suggests that the phosphoinositol second messenger system may influence protein synthesis near nerve terminals. Supported by ONR N0014-89J-1556 and MH35321.

FURTHER CHARACTERIZATION OF THE INDUCTION OF GLUTAMINE SYNTHETASE ACTIVITY BY *trans*-ACPD IN CULTURED ASTROCYTES. S. Miller[1]*, C.W. Cotman[1], and R.J. Bridges[2]. Departments of Psychobiology[1] and Neurology[2], Univ. of California, Irvine, CA 92717.

Glutamine synthetase is a glial-specific enzyme which catalyzes the conversion of glutamate and ammonia to glutamine, playing a crucial role in nitrogen and excitatory amino acid metabolism. We have recently reported that 1-aminocyclopentane-*trans*-1,3-dicarboxylic acid (*trans*-ACPD), an agonist of phosphoinositide-coupled metabotropic glutamate receptors, induces glutamine synthetase activity in cultures of rat cortical type I astrocytes (J. Neurochem. *in press*). The action of *trans*-ACPD, which is dose-dependent, stereoselective, and sensitive to cycloheximide suggests a role of metabotropic glutamate receptors in the induction mechanism. However, other excitatory amino acid agonists, such as β-L-ODAP, can also induce glutamine synthetase activity yet have little activity at metabotropic glutamate receptors. These pharmacological inconsistencies prompted us to investigate the hypothesis that the induction of glutamine synthetase by *trans*-ACPD may be mediated at an alternative site. We found that dihydrokainate, an inhibitor of excitatory amino acid transport blocks the induction of GS activity by 100 μM *trans*-ACPD. The induction was inhibited in a concentration-dependent manner and completely blocked with 10 mM dihydrokainate. It is possible that this effect of dihydrokainate is mediated by inhibition of phosphoinositide hydrolysis, an action which has been reported for other transport inhibitors (Littman et al. Soc. Neurosci. Abs. 17: 1338, 1991). Alternatively, a more parsimonious explanation is that *trans*-ACPD has activity at an intracellular site, indicating that the effects of this agonist may not be limited to activation of cell-surface metabotropic glutamate receptors.

PROPERTIES OF A GLUTAMATE AUTORECEPTOR IN RAT NEOSTRIATUM D.M. Lovinger*, E. Tyler and A. Merritt, Dept. Mol. Physiol./Biophys., Vanderbilt Univ. Med. School, Nashville, TN 37232

The neostriatum receives a large glutamatergic afferent input from the neocortex. Transmission at striatal glutamatergic synapses is modulated presynaptically by a putative glutamate autoreceptor activated by the metabotropic receptor agonist t-ACPD (Lovinger, Neurosci. Lett., 129, 17-21, 1991). We have examined this receptor using field potential recording from adult rat neostriatal slices and whole-cell recording from neurons in slices from 2-4 wk. old rats. In adult slices, a synaptically-driven population spike (PS) evoked by local electrical stimulation was decreased by bath application of 5-100μM t-ACPD (IC_{50} of 50μM). This is similar to the potency with which t-ACPD depressed the amplitude of EPSPs in striatal neurons. Depression of the PS was stereospecific with 100μM 1S,3R-ACPD producing an 88±6% decrease in amplitude while 100μM 1R,3S-ACPD had no effect. The effect of t-ACPD on the PS or EPSP was not altered by the metabotropic receptor antagonist AP3 (100μM). Phorbol diacetate (PDAc), an activator of protein kinase C (PKC) reduced the synaptic depressant effect of 50μM t-ACPD (%inhib of PS=48±10 in the absence and 12±5 in the presence of 5.5μM PDAc, $p<0.005$; %Inhib of EPSP=74±4 in the absence and 39±5 in the presence of 3 or 5.5μM PDAc, $p<0.005$). Alpha-PMA, a phorbol ester which does not activate PKC, did not reduce the effect of t-ACPD (43±5% inhib of PS in 5μM alpha-PMA). t-ACPD inhibits voltage-activated Ca^{2+} current and activation of PKC inhibits this effect (Swartz & Bean, this meeting). The synaptic depressant effect of t-ACPD may involve an AP3-insensitive metabotropic glutamate receptor. We hypothesize that this receptor is negatively coupled to voltage-activated calcium channels via PKC-sensitive intracellular processes. Supported in part by grant #AA08986 from NIAAA.

PEPTIDES: RECEPTORS V

573.1

COMPARATIVE MODULATORY ACTION OF A GUANINE NUCLEOTIDE DERIVATIVE ON NEUROPEPTIDE Y_1 AND Y_2 RECEPTOR SUBTYPES IN RAT BRAIN. Y. Dumont[1]*, A. Fournier[2], S. St-Pierre[2] and R. Quirion[1] (1) Douglas Hospital Res. Ctr., McGill University, Montréal, Québec, Canada, H4H 1R3. (2) INRS-Santé, Pointe-Claire, Québec, Canada, H3R 1G5.

It has been suggested that the Y_1 and Y_2 neuropeptide Y (NPY) receptor subtypes are G protein-coupled. Consequently, we investigated the effect of the stable GTP analogue, GTPγS (100μM), on the competition profile of the specific Y_1 agonist [Leu^{31},Pro^{34}]-NPY and that of PYY for [^{125}I] PYY binding sites in homogenates prepared from the frontoparietal cortex or the hippocampus, two preparations respectively enriched with the Y_1 and Y_2 receptor subtype. As expected for G-protein coupled receptors, specific [^{125}I] PYY binding decreased in the presence of 100μM GTPγS in both the frontoparietal cortex (68 ± 15 to 39 ± 9 fmol/mg prot.) and the hippocampus (148 ± 9 to 98 ± 11 fmol/mg prot.). However, the slopes of the competition curves of [Leu^{31},Pro^{34}]-NPY and PYY were not altered by the nucleotide. A detailed computer analysis of the competition profile best fitted to a two binding site model in both membrane preparations and in the presence or absence of the GTP analogue. It thus appears that a certain proportion of Y_1 and Y_2 receptors in the two regions investigated exist in an affinity state (high) which can be shifted to a lower one by uncoupling from the relevant G-protein. Moreover, the still biphasic nature of the competition profiles observed in presence of GTPγS suggests the possible existence of additional sites which are not coupled to a G-protein in those regions of the rat brain. Supported by MRCC.

***IN VIVO* INTERACTION BETWEEN NEUROPEPTIDE Y, PEPTIDE YY AND SIGMA RECEPTORS IN THE MOUSE HIPPOCAMPUS.** Bouchard, P.*[1,3], Dumont, Y.[1], St-Pierre, S.[4], Fournier, A.[4] and Quirion, R.[1,2,3] (1) Douglas Hospital Research Center, Verdun, Que., Can. (2) Department of Psychiatry and (3) Neurology and Neurosurgery, Mc Gill Univ. and (4) INRS-Sante, Pointe-Claire, Que., Can.

Recently, it was proposed that neuropeptide Y (NPY) and peptide YY (PYY) could act as endogenous ligands for sigma binding sites since both NPY and PYY compete with high affinity (nM) for [^{3}H](+)SKF 10047 binding in rat brain membrane homogenates (Roman et al., 1990). However, several laboratories have failed to provide direct evidence for an interaction between NPY, PYY and sigma receptors. In order to clarify this apparent discrepancy, we investigated the effects of various peptides on *in vivo* [^{3}H](+)SKF 10047 binding parameters in the mouse brain. Mice were injected with haloperidol (i.p. 2 mg/kg) or saline to define specific binding. At t=15 min., animal received either a peptide injection (3 μl i.c.v.), or saline. At t=30 min., each animal were injected with 5 μCi [^{3}H](+)SKF 10047 (200 μl i.v.). Animal were sacrificed at t=60 min. and the binding of [^{3}H](+)SKF 10047 measured. In the hippocampus, haloperidol competed for up to 90% of [^{3}H](+)SKF 10047 labelling. At a dose of 1500 pmol, NPY, NPY_{2-36}, [$Leu^{31}Pro^{34}$] NPY and PYY competed for 20 to 40% of specific [^{3}H](+)SKF 10047 binding. Other peptides, like neurotensin and VIP, did not compete with [^{3}H](+)SKF 10047 binding but surprisingly, CGRP competed for up to 30% of the total binding. It thus appears that NPY, PYY and related peptides, as well as CGRP may interact with sigma binding sites *in vivo*. It now remains to be established if the effects of these differents peptides families at sigma sites, are mediated via similar or different mechanisms.

IDENTIFICATION OF RECEPTOR BINDING PHARMACOPHORES OF GROWTH HORMONE-RELEASING FACTOR IN RAT ADENOPITUITARY. L.Lefrançois and P. Gaudreau*. Neuroendocrinology Laboratory, Notre-Dame Hospital Research Ctr., Dept. Medicine, University of Montreal, Montreal, Canada, H2L 4M1.

Previous structure-activity studies on growth hormone-releasing factor (GRF) have mainly been carried out in pituitary cell culture assays. In such systems, the molecular features necessary to increase GRF receptor affinity cannot be fully differentiated from those that improve proteolytic resistance. To assess the affinity of GRF analogues, we have recently characterized [^{125}I-Tyr^{10}]hGRF(1-44)NH_2 binding to rat adenopituitary, developing a reliable binding assay in which GRF carboxamide-related peptides are stable (Abribat et al. Brain Res., 528:291, 199Q). In the present study, we have synthesized two series of analogues in which the entire sequence of hGRF(1-29)NH_2 was scanned with alanine and D-amino acid substitutions. An Alanine substitution at Tyr^1, Asp^3, Ile^5, Phe^6, Thr^7, Tyr^{10}, Arg^{11}, Lys^{12}, Arg^{20}, Lys^{21}, Leu^{23} or Gln^{24} decreased GRF affinity while it did not induce major changes at Asn^8, Val^{13}, Leu^{14}, Gln^{16}, Leu^{17}, Ser^{18}, Leu^{22}, Asp^{25}, Ile^{26}, Met^{27} or Arg^{29}. Interestingly, it increased GRF affinity at Ser^9, Gly^{15} and Ser^{28}. A D-amino acid substitution in position 3, 4, 5, 6, 7, 11, 13, 14, 17, 18, 19, 20, 23, 25, 26, 27 or 28 decreased GRF affinity but had little influence in position 1, 2, 9, 10, 12, 15, 16, 21, 24 or 29. It increased GRF affinity in position 8 and 22. Altogether these results allow to pinpoint residues that are involved in a structural role and those responsible for receptor contacts.

CEREBELLAR NUCLEI EXPRESS A NEW TYPE OF SOMATOSTATIN RECEPTORS WHICH EXHIBIT LOW AFFINITY FOR OCTREOTIDE AND MK 678. P. Leroux*, C. Bucharles and H. Vaudry. European Inst. Peptide Res., Lab. Molecular Endocrinology, CNRS URA 650, UA INSERM, University of Rouen, 76134 Mont-Saint-Aignan, France.

The presence of selective somatostatin (SS) receptor subtypes (SSR1 and SSR2) has been demonstrated in different brain areas on the basis of differential binding potency of octreotide. Both SSR1 and SSR2 bind with high affinity the SS analogs [Tyr^0,$DTrp^8$]S14 and [Leu^8,$DTrp^{22}$,Tyr^{25}]S28. In a previous study, we have observed preferential binding of iodinated [Leu^8,$DTrp^{22}$,Tyr^{25}] S28 in a few brain areas. In the present study we have characterized these binding sites in the lateral cerebellar nuclei (LCN) by quantitative autoradiography. The binding of [Leu^8,$DTrp^{22}$,^{125}I-Tyr^{25}]S28 in the LCN was saturable (Bmax= 219 fMol/ mg Prot.) and of high affinity (KD= 0.50 nM). In contrast, no labeling was detected in LCN using [^{125}I-Tyr^0,$DTrp^8$]S14. However both S14 and S28 analogs could displace [Leu^8,$DTrp^{22}$, ^{125}I-Tyr^{25}]S28 binding, indicating that these sites do not represent S28 preferring receptors. The efficiency of both octreotide and MK 678 in competition tests was very low. The order of potency for 10 SS analogs to compete with the binding of [Leu^8,$DTrp^{22}$,^{125}I-Tyr^{25}]S28 in the LCN was: S14 (2.02 ± 0.51 nM) > [Tyr^0]S28 (2.25 nM) > [Leu^8, $DTrp^{22}$,Tyr^{25}] S28 (2.66 ± 0.13 nM) > S28 (5.15 ± 1.76 nM) > [Tyr^{11}]S14 (7.34 nM) > [Tyr^0, $DTrp^8$]S14 (8.52 ± 2.64 nM) > [Tyr^0]S14 (15.9 ± 3.4 nM) > N-Ahep(7-13)S14Bzl (564 ± 229 nM) > Octreotide (> 1 μM) > MK 678 (55.2 ± 15.7 uM). In contrast to [^{125}I-Tyr^0,$DTrp^8$]S14 binding, divalent cations were not required to obtain maximal binding of [Leu^8,$DTrp^{22}$,^{125}I-Tyr^{25}]S28, and the potency of guanine nucleotides to inhibit the binding was much lower (IC50 > 50 μMfor GTP and GDP). The present results show that the SS receptors observed in the LCN represent a pure population of sites which are distinct from SSR1 and SSR2 receptor types present in the cortex and hippocampus.

573.5

UP-REGULATION OF CORTICAL SOMATOSTATIN RECEPTOR BINDING SITES FOLLOWING LONG TERM UNILATERAL LESION OF THE NUCLEUS BASALIS IN THE RAT. D. Cécyre*, J.C. Martel and R. Quirion, Douglas Hospital Research Center and Dept. of Psychiatry, McGill University, Montréal, Québec, Canada, H4H 1R3.

It has recently been reported that cortical somatostatin-like immunoreactivity (SRIF-IR) is altered following long term uni- or bilateral ibotenic acid lesions of the nucleus basalis magnocellularis (nbm) in the rat (Arendash *et al*, Science 238, 1987; *ibid*, Neurochem. Res., 14, 1989). Earlier data had shown that, contrary to expected results, both SRIF-IR and SRIF receptor binding sites were decreased in Alzheimer's brains (Beal *et al*, Science 229, 1985). Using quantitative *in vitro* receptor autoradiography, we examined the potential effects of long term changes in cortical SRIF levels observed following nbm lesions on its binding sites. Uni- and bilateral ibotenic acid lesions of the nbm were performed in three-months old rats. Eighteen months later, animals were sacrificed and brain sections prepared for receptor autoradiography. As reported elsewhere (Krantic *et al*, Neuroscience 39, 1990), [^{125}I]-Tyr^0,D-Trp^8-SRIF$_{14}$ ([^{125}I]-SRIF$_{14}$) binding sites are concentrated in various cortical laminae, the hippocampal formation and the amygdala body. A long term unilateral nbm lesion induces a significant (compared to sham control) up-regulation of [^{125}I]-SRIF$_{14}$ binding in the ipsilateral parietal and temporal cortices while no modification in labelling profile and intensity was detected in the amygdala. Surprisingly, the bilateral lesion failed to induce any significant change in [^{125}I]-SRIF$_{14}$ labelling. Thus, as observed for SRIF-IR, cortical alterations of [^{125}I]-SRIF$_{14}$ binding can be observed following long term lesions of the nbm but these are dependent on the nature of the lesion performed. Supported by MRCC.

MODULATION OF NEUROPEPTIDE FF RECEPTORS IN RAT BRAIN AND SPINAL CORD MEMBRANES BY GUANINE NUCLEOTIDES AND CATIONS.

K. PAYZA and H.Y.T. YANG. LBG, NIMH Neuroscience Center, WAW-113, St. Elizabeth's Hospital, Washington, D.C. 20032.

Neuropeptide FF (NPFF) is a mammalian FMRFamide-related peptide of the sequence FLFQPQRFamide. NPFF antagonizes morphine analgesia and appears to be involved in morphine tolerance and dependence. In this study, guanine nucleotides, NaCl and $MgCl_2$ were tested for modulatory effects on NPFF receptor binding in membrane preparations of rat brain and spinal cord. Specific binding of ^{125}I-YLFQPQRFamide to NPFF receptors in both brain and spinal cord preparations was stimulated by NaCl and $MgCl_2$ and inhibited by GTP and its nonhydrolyzable analogs. The GTP effect was observed in the presence and absence of Na^+ and Mg^{2+}. The specificity of the GTP effect (GTP[γ]S>GppNHp>GTP>GDP; no effect of GMP or ATP) suggests that NPFF receptors are coupled to G-proteins in these tissues. The ionic effects suggest that Na^+ and Mg^{2+} ions are required for maximal receptor binding but not for receptor-G-protein coupling.

DISTRIBUTION OF NEUROPEPTIDE FF RECEPTORS IN RAT BRAIN AND SPINAL CORD.

C. AKAR, K. PAYZA AND H.Y.T. YANG*. LBG, NIMH Neuroscience Center, WAW 113, St. Elizabeth's Hospital, Washington, D.C. 20032.

Neuropeptide FF (NPFF, FLFQPQRF-NH_2) is an endogenous neuropeptide with anti-opiate activity. NPFF is unevenly distributed in the rat CNS with the highest concentrations in the spinal cord and hypothalamus. In this study, the distribution of NPFF receptors in rat CNS was examined using radioligand binding assays.. The specific ^{125}I-YLFQPQRFa bindings (dpm/mg protein/dpm total) in various regions of rat CNS were: dorsal spinal cord: 0.123±0.020, medulla oblongata: 0.1044±0.008, hypothalamus: 0.0998±0.0023, midbrain: 0.0789±0.0086, striatum: 0.0396±0.0035, hippocampus: 0.0163±0.0019, cerebellum: 0.0161±0.0072, cortex: 0.0037±0.0024, ventral spinal cord: 0±0.023. The radioligand binding in midbrain, medulla oblongata and dorsal spinal cord was inhibited by GTP[γ]S showing that the binding was NPFF receptor specific. The receptor distribution in this study correlated with the NPFF distribution in various regions of brain and spinal cord.

NEUROMEDIN B RECEPTORS AND FIBROBLAST GROWTH FACTOR ARE PRESENT IN C6 GLIAL GRAFTS. T.W. Moody*, F. Cuttitta , J. Battey, K. Engleka , T. Maciag and J. Rosenstein. Depts. Anatomy, Biochemistry & Mol. Biol., George Washington Univ. Med. Ctr., Washington, D.C. 20037, DPCP, NCI, 5516 Nicholson Lane, Kensington, MD 20895, Lab. Neurochemistry, NINDS, NIH, Bethesda, MD 20892 and Dept. Mol. Biol., Holland Lab., American Red Cross, 15601 Crabbs Branch Way, Rockville, MD 20855.

Rat glioma C6 cells have functional neuromedin B (NMB) receptors. Previously, we reported that NMB bound with high affinity, elevated cytosolic Ca^{2+} and stimulated the growth of C6 cells in tissue culture. Here NMB receptors were characterized in C6 transplants into the rat forebrain. Cultured C6 glioma cells (10^6) were transplanted into the rat forebrain. After a postoperative time of 1-3 weeks, the tumors and surrounding host brain were analyzed for NMB receptors and fibroblast growth factor (FGF) by immunocytochemistry using the PAP method. Antisera to the NMB receptor was elicited against a C-terminal fragment (S-16-L) conjugated to hemocyanin. The NMB receptor antisera strongly reacted with numerous cellular elements but not blood vessels within the C6 glioma. Also, using autoradiographic techniques high grain densities were present for NMB receptors in the graft. In contrast, antisera to FGF strongly reacted with blood vessels within the tumor and adjacent brain. The FGF may stimulate angiogenesis and the NMB receptors facilitate growth within the C6 tumor. Supported in part by NSF grant BNS88-15133 (T.W.M.) and NIH grants NS-17468 (J.R) and HL-32348 (T.M.).

RICIN CYTOTOXIN CELL TARGETING REVEALS UNIQUE ROLES FOR ANP AND CNP IN WATER DRINKING AND PROLACTIN SECRETION. W.K.Samson* and R.J.Fulton. Anatomy/Neurobiology,U MO Schl Med, Columbia MO 65212 and Inland Labs, Dallas TX 75207.

Centrally administered A-type and C-type natriuretic peptides (ANP and CNP) exert opposite actions on water intake and prolactin (PRL) secretion. While ANP is inhibitory, CNP is stimulatory suggesting actions of the peptides via unique receptors. ANP and CNP were conjugated to the A chain of the plant cytotoxin ricin and conjugates injected icv in adult rats. Two weeks later rats received icv injections of maximally effective doses of either ANP or CNP. In rats pretreated with ANP-ricin A chain, the inhibitory action of ANP on PRL secretion was absent yet the stimulatory effect of CNP was still present. The opposite was true in rats pretreated with CNP-ricin A chain conjugate. Following 18h water deprivation, rats pretreated with ANP-ricin A chain conjugate drank significantly more water than controls, while those pretreated with CNP-ricin A chain consumed significantly less. These results indicate that the opposing actions of these two members of the natriuretic peptide family are expressed via unique receptors, in all likelihood the ANPR-A and ANPR-B subtypes.

PRIMARY STRUCTURE OF RF-AMIDE NEUROPEPTIDE PRECURSORS FROM COELENTERATES C.Schmutzler, D.Darmer, R.K. Reinscheid, and C.J.P.Grimmelikhuijzen*; Centre for Molecular Neurobiology, University of Hamburg, Martinistr. 52, D-2000 Hamburg 20, F.R.G.

In the simple and evolutionary old nervous systems of coelenterates neuropeptides are highly abundant and play an important role in neurotransmission. From several coelenterate species we have isolated a family of neuropeptides with the common C-terminus Arg-Phe-NH_2 (RFamide). Thus, these peptides belong to the class of the RFamide peptides which have been found throughout the animal kingdom, the prototype being the molluscan FMRFamide.

We have cloned cDNAs encoding precursor proteins for the RFamide neuropeptide Antho-RFamide (<Glu-Gly-Arg-Phe-NH_2) from the anthozoans *Anthopleura elegantissima, Calliactis parasitica,* and *Renilla köllikeri* which show a highly repetitive organization (containing 13, 19, and >36 copies of immature Antho-RFamide, respectively). We also cloned the precursor proteins for the hydrozoan RFamide heptapeptides Pol-RFamide I and II from *Polyorchis penicillatus* and Hydra-RFamide I, II, and IV from *Hydra magnipapillata.*

At the C-terminal side of these peptides precursor cleavage occurs at conventional processing sites (mono- or dibasic residues). However, we have to postulate "non-classical" mechanisms to explain correct peptide processing at the N-terminus.

CHARACTERIZATION OF OPIOID MATERIAL IN THE PERIOESOPHAGAL GANGLIA OF *HELIX ASPERSA*. M. Sanchez-Alvarez+, M. Leon-Olea+, E. Piros, E. Talavera+, K. F. Faull*, C. J. Evans Division de Inv. en Neurociencias+, Instituto Mexicano de Psiquiatria. AP. 14370, Mexico, D.F. Department of Pshychiatry. UCLA School of Medicine. Los Angeles, CA 90024.

In molluscs, the first evidence for the existence of opioid peptides was presented by Martin *et al.* (1). In *H. aspersa* the anatomical distribution of enkephalin-like immunoreactivity has been mapped using immunohistochemical techniques (2), and the amount of enkephalin-like material has been determined by RIA experiments (3). The majority of the opioid-like material in invertebrates has been detected with antibodies raised against vertebrate enkephalins. Therefore, we decided to characterize the opioid-like material present in the perioesophageal ganglia of *H. aspersa* using an immunoassay that identifies all the vertebrate opioid peptides. Guanidine isothiocyanate extracts of 176 ganglia were used and co-chromatographed on Sephadex G-50. The gel filtration chromatography indicates the presence of opioid-like immunoreactive material with a molecular weight between the 1 to 1.5 KD range, which is under further characterization.

N^{α}-ACETYLATED VASOPRESSIN IN THE RAT PITUITARY GLAND AND HYPOTHALAMUS.

F.M. de Bree[1], F.W. van Leeuwen* and J.P.H. Burbach[1]. [1]Rudolf Magnus Institute, University of Utrecht, 3521 GD Utrecht, The Netherlands; *Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam, The Netherlands.

Recently N^{α}-acetyl-vasopressin (Ac-VP) and N^{α}-acetyl-oxytocin (Ac-OT) were purified and identified from bovine pineal gland. Indirect determination of these forms by HPLC combined with a radioimmunoassay using a C-terminal specific VP antiserum revealed nanogram amounts of the acetylated forms in the rat neurointermediate lobe (NIL), while the brain itself contained only picogram amounts. The extent of acetylation differed markedly: in the NIL only a few percent of the peptide was acetylated, whereas in the pineal gland about 70% was acetylated. This indicates a possible regulatory role for this new kind of modification of VP and OT. In order to analyze and localize Ac-VP directly, antisera were raised against this peptide. Cross-reactivity studies in a radioimmunoassay and dot-tests revealed Ac-VP recognizing antibodies with no or low cross-reactivity for VP, Ac-OT, OT, N^{α}-acetyl-ß-endorphin and αMSH. One of the antisera (#F5) was used in a radioimunoassay to determine Ac-VP in NIL and hypothalamus. In the NIL F5 detected only Ac-VP and no VP indicating a high specificity of F5. The hypothalamus contained no measurable amounts of Ac-VP. In immunocytochemistry F5 showed after preadsorption with VP and Ac-OT a fibre-like staining in the posterior lobe. F5 showed no staining in the hypothalamus after preadsorption. In conclusion VP might be acetylated during axonal transport.

574.4

AN ANTISENSE OLIGODEOXYNUCLEOTIDE INHIBITS PROOPIOMELANOCORTIN TRANSLATION IN AtT-20 CELL LINE. S. Spampinato*, M.Canossa, L.Carboni, G.Campana, and S. Ferri. Dept. Pharmacology, Univ. Bologna, Irnerio 48, 40126 Bologna, Italy.

Gene expression in mammalian cells can be suppressed by nucleic acid sequences complementary to endogenous transcripts. In actual fact, these "antisense" sequences can hybridize to primary RNA transcripts and prevent translation of the target gene at ribosomal level. We employed this strategy to obtain a significant reduction of the synthesis of peptides derived from the precursor proopiomelanocortin (POMC) in a murine neuroendocrine cell line (AtT-20) that highly expresses this gene. Cells grown in suspension in DMEM supplemented with 10% fetal calf serum were seeded at $4x10^6$ cells per dish and exposed to a 30-base pair oligodeoxynucleotide TACGGTGGCTTCATGACCTCCGAGAAGAGC complementary to mRNA nucleotides which are translated into the first ten aminoacids of mouse ß-endorphin, an opioid peptide derived from POMC. In alternative, AtT-20 cells were treated with a sense 30-base pair oligonucleotide. After 24 h cells were harvested and ACTH (another peptide spliced from POMC and positioned upstream to ß-endorphin) was evaluated, by RIA, in acetic acid extracts of the cells. A significant reduction of ACTH content was observed in cells treated with the antisense oligonucleotide [26.62 ± 2.2 vs 12.03 ± 0.18 ng/10 cells (n=7); $p < 0.01$]. These results indicate that antisense oligonucleotides block the synthesis of neuropeptides in cell lines and may be useful in delineating their functions.

574.5

SELECTIVE RELEASE OF THE NEUROPEPTIDE VIP IN SHEEP EXPOSED TO THREE LUNG DAMAGING ORGANOHALIDES: CORRELATION WITH CYCLOOXYGENASE METABOLITES. [1]A.W. Assaad, [2]A. Absood, [2]M. Trotz, [1]C. Woodard, [1]W. Baze, [1]D. Martin, [1]J.P. Apland*, and [2]S.I. Said. [1]U.S. Army Med. Res. Inst. of Chemical Defense, Edgewood, MD 21010; and [2]S.U.N.Y. at Stony Brook, N.Y 11794.

Certain neuropeptides, e.g., tachykinins, can promote inflammation while others, e.g., vasoactive intestinal peptide (VIP), can modulate inflammation. We have examined the release of VIP and 3 cyclooxygenase metabolites (CM), after the inhalation of 3 different organohalides that cause lung toxicity. Three groups of sheep (n=10 each) were exposed for 10 min to 323 ppm/min of perfluoroisobutylene (PFIB), a pyrolysis product of Teflon, or 364 ppm/min of bis(trifluoromethyl)disulfide (TFD), a pesticide, or 767 ppm/min of phosgene, an industrial precursor. Plasma was collected immediately before and at 15, 30, 60, 120, 180 & 240 min after exposure, and assayed by RIA for VIP and metabolites of PGI_2, TXA_2 & PGF_{2a}. All three gases produced acute lung injury and elevated CM levels ($p<0.05$) for up to 60 min. VIP levels increased only with TFD ($p<0.05$) and paralleled those of CM. These data suggest that: 1) the release of VIP was selective, whereas that of CM occurred with all three gases; 2) the release of CM and VIP was both immediate and sustained with TFD; and 3) the mechanism of TFD-induced VIP release is unexplained, but it may be an attempt to modulate the injury.

574.6

MICRODIALYSIS OF OPIOID PEPTIDE RELEASE FROM THE NUCLEUS ACCUMBENS AND VENTRAL PALLIDUM OF THE FREELY MOVING RAT M. Bertolucci*, C. J. Evans and N.T. Maidment. Department of Psychiatry, NPI and BRI, UCLA, Los Angeles, CA 90024.

We previously described a method for the measurement of opioid peptides in basal ganglia microdialysates of the anesthetized rat (Maidment et al., 1989, Neuroscience, 33: 549-557). We have now extended these studies to the freely moving animal and to limbic regions in view of the proposed role of these structures in reward processes. Basal release of opioid peptides was detectable in the nucleus accumbens and the ventral pallidum for at least 3 days after the dialysis probe was inserted in the brain, although the quantity of material recovered was progressively reduced with time. Similar to previous studies in anesthetized rats the extracellular levels of the opioid peptide were enhanced by reverse dialysis of veratridine (50 uM) by approx 10-fold - an effect blocked by tetrodotoxin (2uM). However, contrary to the situation in anesthetized animals, the basal efflux was significantly reduced by both tetrodotoxin and the calcium ion chelator EGTA (10 mM) indicating a synaptic origin of the peptides. Having thus validated the methodology, studies are currently in progress to evaluate the inflence of abused drugs on this system.

SIMULTANEOUS MEASUREMENT OF CCK AND NEUROTENSIN FRAGMENTS IN MICRODIALYSATES OF THE RAT FOREBRAIN: EFFECTS OF MIDBRAIN 6-HYDROXYDOPAMINE LESIONS. N. Villafranca, J.D. Barchas* and N.T. Maidment, Department of Psychiatry and Biobehavioral Sciences, N.P.I. and B.R.I., UCLA School of Medicine, Los Angeles, CA 90024.

We previously described a procedure for simultaneous determination of CCK and neurotensin fragments in rat dialysates of the caudate nucleus and posterior nucleus accumbens (Maidment et al., 1991, Neuroscience, 45: 81-93). In view of the well documented localisation of these peptides within subpopulations of midbrain dopamine neurons we sought to determine what proportion of the CCK and neurotensin measured extracellularly originated from dopamine terminals. As a first step in this process we injected 5 rats with 6-hydroxydopamine (10ug in 2ul) unilaterally in the substantia nigra and ventral tegmental area. Four rats received vehicle alone. Three weeks later the animals were tested for contralateral rotational behavior following injection of apomorphine (0.5mg/kg, I.P.). Four weeks following lesioning the animals were re-anesthetized and microdialysis conducted in the posterior nucleus accumbens and medial caudate nucleus ipsilateral to the lesion. Release was evoked by reverse dialysis of veratridine (50uM for10min) for two 30 min samples separarated by 2h. Dialysates were analyzed sequentially for the peptides by solid-phase radioimmunoassay. Veratridine induced an approximate 10-fold increase in extracellular CCK release in both regions. The neurotensin response in the nucleus accumbens was smaller (approx 3-fold) and less consistent and no stimulation was observed in the caudate. The preliminary data failed to demonstrate a clear effect of the lesion on the release of either peptide in the regions studied. This may reflect a non-dopaminergic origin of the peptides measured extracellularly or a compensatory increase in the releasable pool of the peptides within spared dopamine neurons similar to that described for dopamine itself (Robinson and Wishaw, 1988, Brain Res., 450: 209-224).

STEROID DEPENDENCY OF GALANIN NEURONS IN THE BED NUCLEUS OF THE STRIA TERMINALIS BY IN SITU HYBRIDIZATION. M.A. Miller*, P.E. Kolb, and M.A. Raskind, Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA 98195.

We have recently observed that the majority of vasopressin (VP) synthesizing cells in the bed nucleus of the stria terminalis (BNST) also express galanin (GAL) mRNA. VP neurons in the BNST have been implicated in a variety of functions including learning and memory and antipyresis. We have previously reported that VP gene expression in the BNST is steroid dependent (Endocrinology 125(5):2335-2340, 1989). Castration of adult male rats results in a decline in VP gene expression in these cells which is reversed by testosterone replacement. To determine whether testosterone also regulates GAL gene expression in the BNST, we have used in situ hybridization and quantitative autoradiography to measure GAL mRNA levels in neurons in the BNST of intact (plasma T level: 5.2±1.2 ng/ml; n=7), castrated (plasma T level: 0.05±0.01 ng/ml; n=7), and castrated adult male rats treated with testosterone (plasma T level: 2.5±0.2 ng/ml; n=7).

Frozen brain sections (20μm) were hybridized with a cRNA probe complementary to GAL mRNA, coated with NTB2 emulsion, and developed. Sections through the BNST were anatomically matched (4/animal) and read blindly. The number of labeled cells (unilateral) and the average number of grains/cell (based on readings of up to 10 cells/slide) were compared across groups.

Castration significantly decreased ($p<0.05$) the number of GAL expressing cells in the BNST (X±SEM: 156±8, intacts; 115±13, castrates) and reduced ($p<0.001$) the average number of grains/cell (X±SEM: 98±5, intacts; 58±3, castrates). Testosterone treatment of castrated rats reversed the effects of castration on cell number (175±9) and grains/cell (103±6). These results indicate that GAL gene expression in the BNST, like VP gene expression, is regulated by testosterone and/or its metabolites. Although the function of GAL in the BNST is not known, these results suggest that it may be influenced by steroid state.

EFFECTS OF LENGTH OF STORAGE AND STORAGE CONDITIONS ON THIOL LEVELS IN RAT SCIATIC NERVE. K. K. Nickander, N. Lendvai and P. A. Low*. Neurophysiology Laboratory, Department of Neurology, Mayo Clinic, Rochester, MN 55905.

Comparison of the effect of length of storage and storage conditions on rat sciatic nerve levels of reduced and oxidized glutathione (GSH and GSSG, respectively) and the corresponding ratio was studied. Two groups of rat sciatic nerves were homogenized (in either 0.25 M perchloric acid or 5% 5-sulfosalicylic (SSA) acid) and centrifuged. A third group was excised and frozen immediately in liquid nitrogen. Samples were stored at -70° C for 0, 7, or 26-28 days. The thiols were measured using reverse phase high pressure liquid chromatography and electrochemical detection (Stein et al., 1986). GSH was decreased 56% by 7 days and 72% by 26-28 days when stored as a 0.25 M $HClO_4$ supernate. Consequently, the increase in level of GSSG was 806% by 7 days and remained high (765%) at 26-28 days. The decrease in the GSH/GSSG ratio was also highly significant at these time points (95% and 94% respectively). The changes were much less significant when stored as a 5% SSA supernate. The thiol levels and ratio remained unaltered when frozen immediately in liquid N_2 and stored at -70° C. Therefore, we conclude when storage of rat sciatic nerve tissue is necessary, to freeze immediately in liquid N_2 and store at -70° C until analysis. Homogenization should then be done in 5% SSA for best preservation of the thiol levels. (Reference: Stein AF, Dills RL, Klaasen CD. J. Chromatogr. 381:259-270, 1986.)

RAT BRAIN TRANSGLUTAMINASE AND RELATED PROTEINS. Y. Takeuchi*, P.J. Birckbichler, M.K. Patterson, Jr., K.N. Lee, M. Maxwell and B. Howell. Biomedical Division, The Samuel Roberts Noble Foundation, Ardmore, OK 73402.

To obtain basic information of transglutaminase (TGase) in mammalian brain, a 100,000 x g supernatant fraction was prepared from whole rat brain homogenate. SDS-PAGE analysis followed by immunoblotting of this soluble fraction gave 75 kDa/79 kDa proteins and 48 kDa protein that were detected by polyclonal antibodies against human erythrocyte TGase and guinea pig liver TGase, respectively. However, these immunopositive proteins were catalytically inactive and were separated from protein with TGase activity by DEAE Sephadex ion exchange chromatography. TGase activity which did bind to the ion exchange column was eluted with a gradient of NaCl and then applied to a GTP-agarose affinity column. TGase activity was recovered in both the KCl eluate and the GTP-unbound fraction. When the latter fraction was reapplied to the affinity column, the TGase activity was again recovered in the unbound fraction. These results suggest the presence of two different types of TGase in rat brain using the criterion of affinity for guanine nucleotide. It is interesting to note that an immuno-positive 48 kDa protein was also shown to bind GTP.

PLASMA CYCLO (HIS-PRO) IN AFFECTIVE DISORDERS. G.K. Tsuboyama, C. Prasad, R.C. Young, T. Kakuma and G.P. Smith*, Cornell U.Med. College, White Plains, New York 10605, and Louisiana State University, New Orleans, Louisiana 70112.

Cerebrospinal fluid thyrotropin-releasing hormone (TRH) is elevated in major depression. The metabolism of TRH ultimately yields acid TRH and cyclo (His-Pro), peptides with intrinsic biologic activity. Therefore, we have begun to measure cyclo (His-Pro) in affective disorders.

An unselected group of inpatients with major depression (n=5) or bipolar disorder, manic (n=4) was studied during treatment with antidepressants or mood stabilizers, respectively, and while on a low-monoamine diet. The mean concentration of plasma cyclo (His-Pro) determined by radioimmunoassay was 2557 +/- 212 pg/ml. This concentration is significantly higher than that reported by Hilton et al (Neuropeptides 13:65, 1989) in euthyroid control subjects (829 +/- 64 pg/ml, n=14, $p< 0.0005$). No difference between the two patient groups was found.

Limitations and confounds such as varying illness state and treatment make interpretation premature.

COMPUTATIONAL SIMULATION OF NEUROPEPTIDE-LIPID INTERACTIONS: A NEW CONCEPT OF DIRECT EFFECT BY ENDOTHELIN-1 AT NEURONAL MEMBRANES. *D.F. Weaver*, S.T. Kim and P.M. Gross*, Departments of Chemistry, Medicine, Surgery & Physiology, Queen's University & Kingston General Hospital, Kingston, Canada K7L 3N6

Neuroactive agents may exert their effects on transmembrane ion channels specifically via channel protein receptors or nonspecifically by direct interactions with the neuronal membrane (e.g., local anesthetics). To explore potential membrane interactions for the neuropeptide endothelin-1 (ET), we applied computer-assisted conformational analyses to: 1) ascertain a family of low-energy ET conformers, 2) study the effects of different environments on the shape of ET, and 3) simulate ET's interaction with a model neuronal membrane under physiological conditions. Commencing with the NMR conformation of ET, we sought to identify the shape of the molecule having the lowest energy by applying molecular mechanics calculations. MM2, AMBER and DREIDING-2 semi-empirical force-field equations were combined with procedures for both first- and second-derivative energy minimization. Since ET was demonstrated to be a highly flexible molecule, its conformational space was further scanned using molecular dynamics calculations that required several hundred hrs of CPU time on an IBM RS/6000 550 RISC computer. Both vacuum and aqueous environments were simulated at 37°C. Finally, a fully hydrated ET conformer with the lowest energy was positioned adjacent to a phospholipid membrane surface and its molecular motions were simulated randomly over a period of 100 psec. These calculations demonstrated that the acyclic hexapeptide tail of ET inserted among the alkyl chains of the lipid membrane in an energetically favorable orientation that affected the shape and dynamic properties of the lipid molecules. The simulation thus revealed a novel mechanism of instantaneous insertion by a neuropeptide into a neuronal membrane. In addition to receptor binding, therefore, ET may invade lipid bilayers directly.

CCK PARTIAL AGONISTS : DIFFERENTIAL FUNCTIONAL ACTIVITY IN THE RAT. R. Simmons*, J. Zongrone, R. Julien, F. Kaiser and J. Rosamond, Depts. of Biology and Chemistry, Fisons Pharmaceuticals, Rochester, New York, 14603.

CCK peptide analogs were evaluated for selective CCK-A receptor agonist activity both in vitro, using pancreatic amylase release and phosphatidyl inositol (PI) turnover assays, and in vivo, using a 21 hour fasted rat feeding inhibition assay. The compounds tested showed a full range of in vitro activity from potent full agonists to weak partial agonists as compared to CCK-8, (CCK= HpaSE[MePhe^6 > Boc[Lys^2,MePhe^4] CCK-4 > Boc CCK-4 > Boc[MePhe^4] CCK-4. The feeding inhibition potency and efficacy were compared with the in vitro functional activity which was further correlated with the Ki binding values for the CCK-A, (pancreatic membranes) and CCK-B receptor (cortical membranes). A good correlation exists between CCK-A but not CCK-B binding affinity, in vitro functional potency and in vivo anorectic potency. However, for partial agonists, in vitro and in vivo efficacy did not correlate. This is probably not related to a difference in receptor subtype interaction (CCK-A vs. CCK-B) since the CCK-A selective antagonist (MK-329) but not the CCK-B antagonist (L365,260) completely inhibits CCK induced P.I. turnover and feeding inhibition. Differences in activity could therefore reflect differences in tissue receptor reserve between the CCK-A receptors in pancreas and those involved in the mechanism of CCK-8 induced feeding inhibition.

SUPER-REACTIVITY OF THE SERINE^4 RESIDUE IN GONADOTROPIN-RELEASING HORMONE AGONISTS IS NOT EVIDENT IN ANTAGONISTS. B.T. Miller*, T.J. Collins and A. Kurosky. Depts. of Anatomy & Neurosciences and of Human Biological Chemistry & Genetics, University of Texas Medical Branch, Galveston, TX 77555.

The critical roles of gonadotropin-releasing hormone (GnRH) in reproductive physiology have led to intensive study of the chemistry, structure and function of this peptide. We have previously demonstrated that the Ser^4 hydroxyl in native GnRH and several GnRH agonist peptides displays unusually high intrinsic reactivity toward activated esters of biotin (Miller et al, 1992, J Biol Chem 267, 5060). In this study, we report that the Ser^4 residues of two peptide analogs which are potent GnRH antagonists are virtually unreactive. Neither [D-Phe^2,Pro^3,D-Phe^6]GnRH nor [D-pGlu^1,D-Phe^2,D-Trp^{3,6}]GnRH reacted significantly with N-hydroxysuccinimide-biotin esters, whereas native GnRH and its agonists were readily O-acylated at Ser^4 under identical conditions. These results further emphasize the importance of the seryl residue in structure/function considerations of GnRH and its related peptides. OPIATE RECEPTORS: INTERACTIONS WITH OTHER SYSTEMS

575.1

μ and K OPIOID AGONISTS ALTER IN VIVO 3H RACLOPRIDE (D2) BINDING: OPPOSING EFFECTS IN THE E21 RAT FETUS AND P10 PUP. P. Kehoe[1], K. M. Ward[1], S. L. Andersen[2], S. M. Umphress[2], S. R. Robinson[2] and W. P. Smotherman*[2]. [1]Department of Psychology, Trinity College, Hartford, CT 06106; [2]Laboratory of Perinatal Neuroethology, Center for Developmental Psychobiology, SUNY-Binghamton, Binghamton, NY 13902-6000.

The endogenous opioid system is thought to interact with the dopamine system in the adult; different classes of opioid ligands produce different effects on dopamine activity. Evidence from in vivo dialysis of adult rats has shown that μ opioid agonists promote dopamine release while K agonists suppress release. Recent developmental studies of neonatal and fetal rats confirm the early existence of this opioid-dopamine interaction. The present study employed an in vivo binding technique with a tritiated ligand for the D2 receptor (3H-raclopride) to further examine the development of interactions between the opioid and dopamine systems in the term rat fetus (E21) and rat pup (P10). Subjects were injected with μ or K agonists prior to administration of 3H-raclopride. Specific D2 activity was measured in tissue samples from the striatum, septum and hypothalamus. In P10 pups, μ stimulation resulted in decreased raclopride binding while K stimulation increased specific binding relative to saline-injected controls. Changes in specific binding imply that μ receptor stimulation promoted D2 receptor occupation (i.e., increased dopamine release) and K stimulation suppressed D2 receptor occupation. In sharp contrast, μ receptor stimulation resulted in increased specific binding at the D2 receptor in E21 fetuses, while K stimulation produced no change in binding relative to controls. These data suggest a developmental discontinuity in the pattern of interaction between opioid and dopamine receptors during the first 1-2 weeks after birth.

EFFECTS OF INTRANIGRAL APPLICATION OF THE KAPPA OPIATE AGONIST U50,488 ON LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) AND ROTATIONAL BEHAVIOR IN THE RAT. A.G. Hohmann*, R.W. Clement and J.M. Walker. Schrier Research Laboratory, Department of Psychology, Brown University, Providence, RI 02912.

Unilateral microinjection of kappa-selective opiates in the substantia nigra induces contralateral circling behavior via actions on nondopaminergic neurons in the pars reticulata. However, the functional pathways activated downstream from the substantia nigra are poorly understood. The present study investigates changes in regional metabolic activity and rotational behavior following intranigral application of U50,488 using the 2-deoxy-D-[1-^{14}C]glucose ([^{14}C]DG) method as adapted for use in freely moving rats. Animals were unilaterally microinjected with 10 or 20 nmol U50,488 or normal saline just prior to the infusion of [^{14}C]DG. Behavioral data were collected concurrently via microcomputer. U50,488 induced dose-dependent contralateral circling, confirming the potent locomotor stimulation produced by this ligand. ANOVA revealed significant depressions in local cerebral glucose utilization (LCGU) in basal ganglia and related circuitry following intranigral U50,488. Bilateral decreases in LCGU were observed in the pedunculopontine n., substantia nigra pars compacta, substantia nigra pars reticulata and cingulate cortex. The effects suggest extensive collateralization in these regions. By contrast, significant decreases in LCGU were only observed ipsilateral to the injection site in the pontine n., fastigial n., inferior colliculus, ventral tegmental area and red n. Structures exhibiting significant contralateral decreases in LCGU included the vestibular n., globus pallidus, anterior caudate n. and parietal cortex. The observed motor activation and alterations in glucose utilization are consistent with a kappa-mediated inhibition of GABAergic reticulata cells and consequent decrease in the afferent supply to output structures. MU AND DELTA OPIOID-REGULATED ADENYLYL CYCLASE ACTIVITY IN RAT CAUDATE-PUTAMEN AND NUCLEUS ACCUMBENS. B. Büzás, S. Izenwasser, and B. M. Cox*. Uniformed Services University, Bethesda, MD.

Activation of opioid receptors leads to inhibition of adenylyl cyclase activity. Adenylyl cyclase activity was examined in crude membrane preparations of nucleus accumbens and the rostral portion of the caudate-putamen using a cAMP radioligand binding assay. Basal adenylyl cyclase activity (expressed relative to membrane protein) in the caudate-putamen was twice that in the nucleus accumbens. The μ-agonists DAMGO and TAPS maximally inhibited approximately 30% of basal adenylyl cyclase in both brain regions. Both of these μ-opioid ligands were less potent for inhibiting adenylyl cyclase activity in the nucleus accumbens than in the caudate-putamen. DPDPE was equally effective in both brain regions, inhibiting less than 30% of basal adenylyl cyclase activity. DSLET, however, inhibited almost 40% of basal cyclase activity in both brain regions. U69,593 had no effect on adenylyl cyclase in either brain region. The μ-opioid selective antagonist CTOP blocked the inhibition of adenylyl cyclase by DAMGO or TAPS, but had no effect on inhibition by DSLET, suggesting that μ-opioid receptor activation did not contribute significantly to the DSLET effect. When the animals were pretreated with naloxonazine (30 mg/kg, s.c. 24 hours prior to assay), the effects of DAMGO and TAPS were attenuated but there were no changes in inhibition of cyclase in the caudate putamen by either DPDPE or DSLET. Similarly, β-FNA pretreatment (20 μg, icv, 24 hours prior to assay) attenuated the effects of DAMGO and TAPS but had no effect on DSLET. These findings suggest that both DAMGO and TAPS act predominantly through a naloxonazine-sensitive μ-opioid receptor to inhibit adenylyl cyclase in these brain regions. Furthermore, DSLET had a greater inhibitory effect than either DAMGO or DPDPE, but was not antagonized by any of the μ-opioid receptor antagonists. (Supported by a grant from NIDA).

REGULATION OF OPIATE RESPONSES IN BRAIN NORADRENERGIC NEURONS BY THE cAMP CASCADE: CHANGES WITH CHRONIC MORPHINE. R. Shiekhattar*, G. Aston-Jones. Department of Mental Health Sciences, Division of Behavioral Neurobiology, Hahnemann University, Broad and Vine, Philadelphia, PA 19102, U.S.A.

Intracellular recording from locus coeruleus (LC) neurons in brain slices revealed that the μ-opiate receptor-mediated responses of these neurons are regulated through the adenylate cyclase cascade. The hyperpolarization induced by 30 μM morphine was enhanced by forskolin (FSK, 20μM), an activator of adenylate cyclase, (+36%, p=0.008). Furthermore, intracellular diffusion of adenosine 3',5'-monophosphate (cAMP) from the microelectrode potentiated morphine responses by 44% (p=0.004). Application of FSK also potentiated the response of every cell examined with 0.3-30 μM enkephalin (+25+5%, p<0.001; n=7). The inactive FSK analog 1,9 dideoxyforskolin had no effect on enkephalin responses (p=0.5, n=3). The potentiation of the opiate response was blocked by agents (H-8, KT5720, RpcAMPS) that inhibit cAMP-dependent protein kinase (PKA). Moreover, the inhibitors reduced the opiate response below baseline values indicating that μ-opiate responses are regulated by a basal kinase activity. The response to 50 nM clonidine was also potentiated (p=0.005, n=4). Only 2 of 8 neurons showed potentiation of opiate responses by FSK following chronic morphine treatment and overall this was not significant (p=0.4). Furthermore, appliaction of H8 alone decreased the baseline enkephalin response in chronically morphine treated animals, similar to results for naive animals. These results indicate that opiate responses in LC are regulated by the cAMP-PKA system, and that such regulation is subject to change by chronic opiate treatment.

INHIBITION OF SYNAPTIC TRANSMISSION BY EXOGENOUS AND ENDOGENOUS OPIOID IN THE SUPERIOR CERVICAL GANGLION OF THE CAT. C. Zhang*, M. Bachoo and C. Polosa. Dept. of Physiology, McGill University, Montreal, Quebec, Canada H3G 1Y6.

Effects of opioid agonists and of heterosynaptic preganglionic conditioning stimulation on nicotinic transmission were studied in the superior cervical ganglion (SCG) of anesthetized, paralyzed and artificially ventilated cats. The cervical sympathetic trunk was dissected and split into two bundles, one for conditioning stimulation and the other for testing stimulation. The compound action potential was recorded from the external carotid nerve. A heterosynaptic stimulus train (5 Hz, 40 s) inhibited nicotinic transmission. The inhibition was antagonized by naloxone, suggesting mediation by endogenous opioids. Agonists selective for μ, δ and κ opioid receptors, injected through the lingual artery, also produced naloxone-sensitive inhibition. The synaptic inhibition was occluded by those produced by μ-, δ-, but not κ-selective agonists. The synaptic inhibition was antagonized by the δ-selective antagonist ICI 174,864, but not by the κ-selective antagonist Nor-BNI. The μ-selective antagonist CTAP produced a partial antagonism of the inhibition. It is concluded that all three main types of opioid receptors are present in the SCG but only μ and δ receptors are involved in the endogenous opioid-mediated inhibition of ganglion transmission. Supported by the Medical Research Council of Canada.

575.6

INHIBITORY EFFECTS OF OPIOID PEPTIDES ON NEONATE RAT SYMPATHETIC PREGANGLIONIC NEURONS *IN VITRO*. H. Tan* and N. J. Dun. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Whole-cell-patch recordings were made from sympathetic preganglionic neurons (SPNs) in transverse spinal cord slices and the effects of opioid peptides on these neurons and on synaptic transmission were studied. Two types of responses were detected. First, bath or pressure application of met-enkephalin (Enk 5,10 μM) induced an outward current or hyperpolarization accompanied by increased membrane conductance; the reversal potential was close to E_K. The δ and μ receptor agonists D-PEN and DAMGO and the antagonists ICI 174,864 and CTOP mimicked and blocked the response. Second, superfusion of Enk (1-10μM) depressed the excitatory postsynaptic currents (EPSCs) evoked by stimulation of either dorsal roots or lateral funiculus, without affecting the inward current induced by pressure ejection of glutamate. This inhibition of EPSCs could also be mimicked by either the δ or μ agonist. The results indicate that opioids inhibit the activity of SPNs by either a postsynaptic mechanism in opening K channels or by a presynaptic mechanism in reducing the transmitter release. THE SUCKLING INDUCED PROLACTIN INCREASE IS MEDIATED BY β-ENDORPHIN THROUGH THE KAPPA OPIATE RECEPTOR SUBTYPE. Rebecca Parman, James Janik and Phyllis Callahan*, Miami University, Zoology Dept, Oxford, Ohio 45056

Administration of β-endorphin to virgin female rats, at doses as low as 25 ng, produced a prolactin secretory response which is the same order of magnitude as the suckling induced prolactin increase. This response was completely abolished by nor-Binaltorphimine (nor-BNI), a specific κ receptor antagonist. The purpose of this study was to determine whether or not β-endorphin played a physiologically signficant role in the suckling induced prolactin increase.

Post-partum lactating female Sprague-Dawley rats were used for all experiments. On day 2 post-partum, animals were implanted with chronic intraventricular (ivt) cannula into the lateral ventricle. Following recovery, each animal was implanted with a chronic jugular cannula. On the day of the experiment, pups were separated from the dams for 6 hours. One group of females received vehicle or Nor-BNI (10 nmol, ivt) 45 minutes prior to the pups return. A second group of females received vehicle or antiserum to β-endorphin (3, 7.5 or 15 μg total protein, ivt) immediately prior to pup return. Blood samples were withdrawn immediately prior to and 15, 30, 45, and 60 minutes after suckling was initiated.

Both β-endorphin antiserum and Nor-BNI pretreatment totally abolished the suckling induced prolactin increase in post-partum female rats. These results indicate that β-endorphin is involved in the suckling induced prolactin secretory response via its activity at the kappa opiate receptor subtype.

575.8

NALOXONAZINE BLOCKS β-ENDORPHIN INDUCED PROLACTIN SECRETION IN FEMALE RATS James Janik* and Phyllis Callahan, Miami University, Zoology Dept, Oxford, OH 45056

The prolactin secretory response to β-endorphin administration was determined in post-partum female rats and during the diestrous stage of the estrous cycle. The effects of Naloxonazine (NAZ) pretreatment were also determined since this μ_1 antagonist effectively blocks the morphine induced prolactin increase.

Female Sprague-Dawley rats were used for all experiments. Virgin females in diestrus and post-partum lactating females were implanted with chronic intraventricular (ivt) cannula into the lateral ventricle. Lactating females were implanted on day 2 post-partum. One day prior to the experiment, animals were surgically implanted with a chronic jugular cannula. On the day of the experiment, pups were separated from the dams for 2 hours.

The lowest dose of β-endorphin to produce a prolactin secretory response was 25 ng and this dose elicited a prolactin increase which is the same order of magnitude as the suckling induced prolactin increase. This was true in both post-partum female and virgin female rats. Lower doses of β-endorphin, i.e. 2.5, 5 and 10 ng, did not produce a change in circulating levels of prolactin. This prolactin increase was completely abolished by NAZ.

These results indicate that β-endorphin is a potent stimulus for secretion and may act in an "all or none" manner. In addition, it seems that β-endorphin, like morphine, can elicit a prolactin secretory response via its activity at the μ_1 opiate receptor subtype.

575.9

POSSIBLE ROLE OF PHOSPHATIDYLINOSITOL METABOLISM IN THE MECHANISM OF KAPPA OPIOID- AND MK-801-INDUCED NEUROPROTECTION IN PRIMARY RAT CORTICAL NEURONAL CULTURES. D.L. Yourick*, M.A. DeCoster and F.C. Tortella. Dept. Med. Neurosci., Walter Reed Army Inst. Research, Washington, D.C. 20307-5100.

The kappa agonists, CI-977 and PD117302 and the noncompetitive NMDA antagonist MK-801, have been shown to be neuroprotective (reduced LDH release) in primary rat cortical neuronal cultures treated with exogenous glutamate. These kappa agonists have also been shown to reduce glutamate-stimulated inositol phosphate accumulation while slightly stimulating phosphatidylinositol metabolism when used alone. Glutamate (40 μM), in the presence of phenol red, elevated inositol phosphate accumulation to approximately 400% of basal metabolism, and CI-977 (50 nM) and PD117302 (50 nM) reduced this response by as much as 47%. It was the purpose of the present study to evaluate whether MK-801 could also reduce glutamate-stimulated inositol phosphate accumulation. MK-801 (50 nM) did not reduce glutamate-stimulated phosphatidylinositol metabolism and did not alter basal inositol phosphate accumulation. However, when given alone at higher concentrations (100-500 nM), MK-801 reduced basal inositol phosphate accumulation by approximately 20-50%. In conclusion, the effects of the kappa opioid agonists and MK-801 are different with respect to basal and glutamate-stimulated phosphatidylinositol metabolism. While CI-977 may prevent neuronal death, in part, by reducing glutamate-stimulated inositol phosphate accumulation, the only apparent effect of MK-801 was on basal metabolism, implying an interaction between the metabotropic glutamate receptor subtype and the NMDA receptor channel complex.

575.10

MU AND MU/DELTA INTERACTIONS MEDIATE OPIOID-INDUCED RELEASE OF ADENOSINE VIA N-TYPE Ca^{2+} CHANNELS FROM DORSAL SPINAL CORD SYNAPTOSOMES. C.M. Cahill*, T.D. White and J. Sawynok. Dept. of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4H7.

The release of adenosine (ADN) from the spinal cord contributes to spinal antinociception by morphine (TIPS 10:186,1989). Morphine (1-100 μM) has been shown to release ADN from dorsal spinal cord synaptosomes (JPET 243:557,1989), but more recently, a nanomolar component of release was revealed when synaptosomes were partially depolarized with K^+ (unpublished). Release of ADN by morphine is Ca^{2+}-dependent. The present study examined the opioid receptor subtypes involved in the release of ADN from dorsal spinal cord synaptosomes and the Ca^{2+} channels involved in such release. DAMGO (a μ agonist) evoked two components (nM and μM concentrations) of ADN release similar to the biphasic response with morphine. DPDPE (a δ agonist) had little effect on the release of ADN by itself but when combined with DAMGO, a synergistic effect was evident as 1 μM DPDPE eliminated the trough component in the DAMGO dose-response curve. Combinations of a range of DAMGO and DPDPE doses significantly enhanced the release of ADN, and this was inhibited by ω-conotoxin (100 nM), which previously was shown to inhibit morphine evoked release of ADN. This study demonstrates that both μ and δ receptors are involved in the release of ADN from spinal cord synaptosomes, and that such release appears to involve Ca^{2+} entry via activation of N-type Ca^{2+} channels. *(Supported by MRC Canada).*

576.1

A DELTA OPIOID AGONIST REDUCES GABAERGIC IPSPS EVOKED BY LOW-, BUT NOT HIGH-INTENSITY, ELECTRICAL STIMULATION IN RAT HIPPOCAMPUS IN VITRO. C.R. Lupica*, and T.V. Dunwiddie. Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

We have reported that μ opioid receptor activation reduces IPSP amplitudes and increases EPSPs in CA1 pyramidal neurons. However, when the δ-selective agonist DPDPE was used EPSPs were increased, spontaneous IPSPs decreased, and evoked IPSPs were unaffected. We concluded that while δ opioid receptor activation increased pyramidal neuron excitability by reducing GABAergic inhibition, this inhibition was difficult to elicit and characterize. The present study was conducted to determine the conditions under which this δ-sensitive inhibition could be characterized. Whole-cell recordings of synaptic potentials, elicited by low-intensity stimulation, were obtained from CA1 pyramidal neurons in rat hippocampal slices. In agreement with Turner (J. Physiol., 422:333,1990), at low stimulus intensities, we found that IPSPs could be evoked in the virtual absence of significant EPSP components (IPSP= -1.88$\pm$.08mV, EPSP= .26$\pm$.04mV, n=6). Bath application of DPDPE (.1μM) reduced these IPSPs (to -.93$\pm$.06mV) and increased the EPSPs (to 1.01$\pm$.1mV), but had no effect upon IPSPs evoked with more intense stimulation. To evaluate the possibility that these IPSPs were mediated *via* low-threshold excitatory afferents to interneurons, glutamate receptors were blocked using the antagonists APV (10μM) and DNQX (40μM). Under these conditions monosynaptic IPSPs generated by low-, but not high-intensity stimuli were again reduced by DPDPE. These data suggest that either 1. δ opioid agonists reduce a novel form of low-threshold feed-forward inhibition, or that 2. δ agonists hyperpolarize interneurons and reduce IPSPs at low-stimulus intensity, but at a higher stimulus intensities interneurons contributing to the IPSP are reliably activated, in spite of the δ-induced hyperpolarization. ELECTROPHYSIOLOGIC EFFECTS OF SELECTIVE OPIOID AGONISTS AND NALOXONE IN THE DENTATE GYRUS. JH Mayer*, SC Steffensen, SJ Henriksen. Dept. Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037

We have studied in vivo the electrophysiologic responses of two selective opioid agonists and systemic naloxone in the dentate gyrus of the hippocampus. [D-Ala^2, NMe-Phe^4, Gly-ol]-Enkephalin (DAGO), a selective mu receptor agonist, and U50488, a selective kappa receptor agonist, were applied iontophoretically in anesthetized rats. This study represents a continuation of a previous study in which effects of systemic morphine and preliminary data on the effects of locally applied DAGO were reported. The effects of these opioids on spontaneous single cell activity and on activity evoked by stimulation of the perforant path were recorded. Cells were classified electrophysiologically as either dentate granule cells (DGCs) or dentate interneurons (INTs) using stringent criteria. The responsiveness of the dentate to stimulation of the perforant path was assessed by measuring population spike amplitudes and constructing input/output curves (I/O) and via paired-pulse (PP) paradigms. The effect of naloxone on long term potentiation (LTP) was also studied. There was a tendency for DAGO to produce a decrease in the spontaneous activity of DGCs. This opioid had little consistent effect on the spontaneous activity of INTs; however, DAGO did tend to decrease the number of post-stimulus interneuronal discharges, induced by perforant path stimulation. As previously reported, DAGO increased the responsiveness of the dentate gyrus to evoked field potential activity. As opposed to DAGO, U50488 was found to have little significant effect on either the spontaneous activity of DGCs and INTs, or on evoked activity. Naloxone, administered systemically, readily reversed the effects of DAGO on both single unit firing and on population spikes, and, in preliminary studies, reduced perforant path-induced long term potentiation in the dentate gyrus. (Supported by DA 00143 to JHM)

ENDOGENOUS KAPPA OPIOIDS INHIBIT EXCITATORY TRANSMISSION IN THE DENTATE GYRUS OF THE GUINEA PIG HIPPOCAMPUS. J.J. Wagner* and C. Chavkin. Dept of Pharmacology, Univ of Washington, Seattle, WA. 98195.

Our previous pharmacological studies demonstrated that kappa$_1$ receptor activation inhibited excitatory synaptic transmission in the dentate gyrus. Those observation have been extended using whole-cell voltage clamp recordings of dentate granule cells performed in guinea pig hippocampal slices (500μm). EPSCs were isolated with CsCl (120 mM) in the recording pipet (to block K^+ currents postsynaptically) and biccuculline (10 μM) in the perfusion buffer (to block spontaneous and stimulus evoked IPSCs). A stimulating electrode placed in the outer molecular layer was used to elicit monosynaptic, (CNQX-sensitive) EPSCs from perforant path (PP) fibers. U69,593 (500 nM), a kappa$_1$ selective opioid agonist, decreased the amplitude of the PP EPSCs by 45%. This effect was reversed by the kappa opioid antagonist norbinaltorphimine (100 nM) (NBNI). Application of NBNI (100 nM) alone resulted in a 30% increase in the amplitude of the PP EPSC compared to predrug control values. This result suggests that tonic release of endogenous kappa opioids (i.e. dynorphins) also regulate glutamate release from the perforant path afferents. In order to evoke the release of additional endogenous kappa opioids, a second stimulating electrode was placed in the hilus to antidromically activate granule cells via their mossy fibers. After establishing a baseline PP EPSC response, a single high frequency train (10-50 Hz, 1 sec) (HFS) given in the hilus resulted in a 15% decrease in the amplitude of the PP EPSC. This effect was blocked by naloxone (1 μM) or NBNI (100 nM). We conclude that the stimulated release of dynorphins from dentate granule cells can act to inhibit EPSCs at the PP synapse. KAPPA OPIOIDS INHIBIT LONG-TERM POTENTIATION IN THE DENTATE GYRUS OF THE GUINEA PIG.HIPPOCAMPUS G.W. Terman*, J.J. Wagner, A. Schatzki and C. Chavkin. Departments of Anesthesiology and Pharmacology, University of Washington, Seattle, WA. 98195.

We have previously demonstrated a kappa opioid-mediated inhibition of excitatory synaptic transmission in the dentate gyrus of the guinea pig hippocampal slice. In this series of studies we evaluated the effect of kappa opioids on the induction of long-term potentiation (LTP) in this preparation.

Our initial studies defined the stimulus properties of tetanic stimulation in the lateral perforant pathway sufficient to produce LTP in the granule cell layer of the dentate gyrus bathed in artificial CSF and 10 μM bicuculline. A tetanus paradigm producing significant but sub-maximal LTP was chosen for the remainder of our studies. Three 20msec 100Hz trains of 0.3msec 300μA pulses were given at 10 sec intervals and the effect on the population spike amplitude was measured 30 min later. Whereas, this stimulus produced a significant ($p<0.01$) LTP when compared to untetanized controls, this effect was blocked by pre-treatment with 1 μM of the kappa selective opiate agonist U69593. Moreover, pretreatment with the opiate antagonist naloxone (1μM) significantly ($p<0.01$) enhanced LTP from this stimulus.

Thus, kappa opioids appear to inhibit long-term potentiation either when exogenously applied or when released from endogenous stores. Supported by DA04123 and GM07604.

HERPES SIMPLEX VIRUS-1 RECOMBINANTS FOR EXPRESSION OF THE PROENKEPHALIN GENE IN NEURONS. **C Gravel, C Meaney, M Comb and X O Breakefield*, Dept of Neurology, & Neurosci Ctr, Mass Gen Hosp, & Neurosci Prog, Harvard Med Sch, Boston, MA.**

The enkephalins are a class of endogenous opioid peptides thought to be involved in many physiological functions in the nervous system. In particular, many lines of evidence point to their role in the modulation of nociception. In order to assess the actions of enkephalins both *in vivo* and in culture, and to develop potential means to modulate nociception *in vivo*, we have devised a series of herpes simplex virus-type 1 (HSV) recombinants aimed at expressing the human proenkephalin gene in neural cells following infection. We and others have previously shown that HSV recombinant viruses can be used to confer long term expression of a foreign gene in post-mitotic neurons either in culture, or directly in the nervous system (Dobson et al, 1991; Andersen et al, submitted.)

To construct the recombinant viruses, the human proenkephalin cDNA, under the control of various promoter elements, was inserted into the coding region of the viral thymidine kinase gene (*tk*) in a plasmid vector. These transcriptional units were then inserted into the viral genome by homologous recombination between plasmid and viral DNA at the *tk* site. Some of the proenkephalin constructs were fitted with a minimal human proenkephalin promoter coupled to one or multiple copies of a cAMP/pKC-inducible enhancer element. Alternatively, a proenkephlain construct bearing the Moloney murine leukemia virus LTR promoter/enhancer element was also constructed. Different HSV viral genomes have been selected for insertion of the proenkephalin transcription units within their *tk* gene: wild-type KOS virus, and also mutant viurses with compromised replication or reduced cytopathogenicity. Preliminary results will be presented on the expression characteristics of these viral vectors in cell culture and in sensory neurons *in vivo*.

PREPROENKEPHALIN mRNA EXPRESSION IN THE VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS AND LUMBAR DORSAL HORN OF FEMALE RATS FOLLOWING GONADAL STEROIDS AND FORMALIN INJECTION . **D.A. Holtzman*, P.J. Brooks, D.W. Pfaff and S. Schwartz-Giblin. Rockefeller University, N.Y., N.Y. 10021.**

This study examines the interactions between estrogen (E), progesterone (P) and a noxious stimulus, 5% formalin s.c. (FORM), on preproenkephalin (PPE) mRNA expression in the ventromedial nucleus of the hypothalamus (VMH) and dorsal horn of the lumbar spinal cord (DH), as measured by in situ hybridization. 36 ovariectomized (OVX) rats were divided equally into 3 hormone groups: E, E+P, and OVX. Rats receiving steroids had 100% E silastics implanted 2 weeks prior to stimulus injection. P was injected 4 h prior to sacrifice. From each hormone group, 6 rats received a saline (SAL) injection (s.c.) and 6 received a FORM injection (s.c.) into a hindfoot pad, and rats from all 6 groups were sacrificed 24 h afterward. Frozen sections were hybridized with a single-stranded, ^{3}H-DNA probe complementary to rat PPE mRNA encoding amino acids 1-68. To date, mean grains (pixels)/cell have been analyzed from a minimum of 113 cells/group for the VMH with 2-4 rats/group and from at least 157 cells/group for the DH with 2-3 rats/group. At 24 h, no difference in PPE mRNA levels were seen between sides or between SAL and FORM injections in either the DH or VMH. 6 OVX rats that received no injection have been added as a stimulus control. So far, analysis of mean pixels/cell in laminae I-V of the DH from 2-3 rats/group shows no apparent effect of steroid treatment or injection solution alone but suggests a trend for an interaction between these factors ($p=0.07$). Similar analysis of the VMH data from 2-4 rats/group shows an effect of hormone treatment ($F=7.87$, $p=0.002$) but no apparent effect of injection solution or interaction between hormone and injection. In the VMH, post-hoc Tukeys show that the mean pixels/cell are greater in both E and E+P than in OVX rats ($p<0.05$). Mean pixels/cell are greater in OVX-FORM than OVX-SAL rats, suggesting that when PPE mRNA levels are low in the VMH, as in OVX rats, FORM can increase PPE transcription.

KAPPA OPIOID REGULATION OF THE SECRETION OF PROLACTIN AND α-MELANOCYTE-STIMULATING HORMONE IN MALE AND FEMALE RATS. J. Manzanares,* E.J. Wagner, K.E. Moore and K.J. Lookingland. Department of Pharmacology & Toxicology, Michigan State University, MI 48824.

Previous studies from our laboratory have demonstrated a sexual difference in the responsiveness of tuberoinfundibular dopamine neurons to kappa opioid receptor agonists and antagonists (Neuroendocrinol. 55: 301, 1992), but it is not known if this difference is reflected by similar differences in the secretion of prolactin. The purpose of the present study was to examine the effects of the kappa opioid agonist U-50,488 and antagonist nor-binaltorphimine (NOR-BNI) on the secretion of prolactin in male and diestrous female rats. For comparison the effects of U-50,488 and NOR-BNI on the secretion of α-melanocyte stimulating hormone (αMSH) were also examined. On the day of the experiment, rats were implanted with a right atrial cannula under diethylether anesthesia, and serial blood samples were taken -30, 0, 30, 60, 120, 240, 480 min relative to drug administration. Activation of kappa opioid receptors with U-50,488 (5 mg/kg; sc) caused a marked and time-dependent (30-120 min) increase in plasma prolactin concentrations in female rats, but produced only a transient increase in prolactin secretion in males. Blockade of kappa opioid receptors with NOR-BNI (25 μg/rat; icv) had no effect on plasma prolactin concentrations in female rats, but produced a pronounced and time-dependent (30-480 min) decrease in prolactin secretion in males. These results reveal a sexual difference in kappa opioid receptor-mediated regulation of prolactin secretion. In contrast, there was no sexual difference in kappa opioid regulation of αMSH secretion since administration of U-50,488 increased and NOR-BNI decreased plasma αMSH concentrations in both male and female rats. (Supported by ADAMHA Grant MH 42802).

INHIBITION OF THE TIME-DEPENDENT INWARD RECTIFICATION IN VASOPRESSIN CELLS OF THE GUINEA PIG SUPRAOPTIC NUCLEUS BY THE MU OPIOID AGONIST DAMGO. K.R. Erickson*, O.K. Ronnekleiv , A.R. Lagrange, S.A. MacMillan and M.J. Kelly . Dept. of Physiology, Oregon Health Sci. U., Portland, OR 97201-3098.

Guinea pig magnocellular neurosecretory cells (MNCs) exhibit a time-dependent inward rectification (TDR, or I_h) which depolarizes the cell from hyperpolarized membrane potentials (below -65 mV). This increases the excitability and, in vasopressinergic (AVP) neurons, leads to phasic firing (Erickson, et al., **Soc Neurosci.** 1991). In the present study, the μ-opioid agonist DAMGO (500 nM - 1 μM) was bath-applied to guinea pig supra-optic nucleus (SON) MNCs. Intracellular recordings were made in an in vitro slice preparation using biocytin-filled electrodes, thus permitting immunocytochemical identification. Six cells were identified as AVP-containing. Two others were not AVP positive. Five of the six AVP cells responded to DAMGO (0.5 - 1 μM), whereas neither of the two AVP-negative cells responded (χ^2, $p<0.05$). All five responding cells exhibited a TDR in current clamp or an I_h in voltage-clamp. DAMGO hyperpolarized and inhibited the TDR in current clamp (N=2); and in voltage clamp, DAMGO produced an outward current and inhibited the I_h on steady-state ramp I/V measures (N=2). Naloxone (1 mM) depolarized the membrane by 2 mV and increased the TDR in an AVP neuron from a morphine treated guinea pig, indicative of an antagonism of tonic opioid tone. The results suggest that the TDR (I_h) in guinea pig AVP MNCs is modulated by μ-opioid receptor activation. (Supported by PHS grant DA05158)

ESTROGEN AND PROGESTERONE MODULATION OF AN INTRINSIC OPIOID ANALGESIC SYSTEM(S). M.E. Dawson-Basoa* and A.R. Gintzler. Dept. of Biochemistry, SUNY Health Science Center at Brooklyn, N.Y. 11203, USA.

It has been demonstrated in rats as well as in humans, that pregnancy and parturition are associated with an opioid-mediated elevation in maternal pain threshold. This analgesia has been shown to involve a spinal opioid system(s). Simulation of the pregnancy blood profile of 17-β-Estradiol (E_2) and Progesterone (P) in non-pregnant, ovariectomized rats resulted in statistically significant elevations in pain threshold. The increase occurred at doses of E_2 and P that approximated that which occurs during late pregnancy (1-3 days before birth) and parturition, the time of actual pregnancy during which analgesia is also observed. Administration of pregnancy levels of P alone or E_2 with the delayed addition of P (starting with dose 3, the dose at which initial increases in pain threshold occur) is not sufficient to produce the increase in pain threshold. Therefore, the entire pregnancy profile of steroid hormones is responsible for the manifestation of analgesia. Administration of the narcotic antagonist naltrexone blocked the increase in pain threshold achieved during hormone-simulated pregnancy, indicating that it is mediated via an endogenous opioid system(s), as is the analgesia of actual pregnancy. The striking similarities between the analgesia of hormone-simulated pregnancy and actual gestation strongly suggest that the profile of change in plasma E_2 and P are parameters of the pregnant condition essential to the manifestation of elevated pain thresholds.

576.10

ROLE OF OVARIAN SEX STEROIDS IN THE REGULATION OF SPINAL CORD CONTENT OF DYNORPHIN, ENKEPHALIN AND PROENKEPHALIN. V. Medina*, M. Dawson-Basoa, L. Wang and A.R. Gintzler. Dept. of Biochemistry, SUNY Health Science Center at Brooklyn, N.Y. 11203, USA.

In laboratory animals and humans, pregnancy is associated with an opioid receptor-mediated increase in the threshold for maternal responsiveness to aversive stimuli. This analgesia results, at least in part, from the activation of a spinal cord dynorphin/kappa opioid receptor system. During late pregnancy, (day 22) there is a significant elevation in the content of dynorphin (1-17 or 1-8; 34 and 48%, respectively). This increase is specific to the lumbar cord. Elevated content of dynorphin (1-17) is also observed in the lumbar spinal cord obtained from non-pregnant, ovariectomized rats following simulation of the profile of change in the concentration of plasma estrogen and progesterone that occurs during actual pregnancy. As was observed during actual gestation, elevated levels of dynorphin (1-17) were not observed in the cervical or thoracic cord during hormone-simulated pregnancy. Levels of met-enkephalin remain unchanged in the lumbar cord on gestational day 22, but are elevated in the cervical and thoracic cord (28 and 23%, respectively). The level of the enkephalin precursor, proenkephalin, is also elevated on gestational day 22 in cervical and thoracic cord (64 and 60% respectively) and, to a lesser extent, in the lumbar region (26%). These results suggest that during late pregnancy at least two spinal opioid analgesic systems are activated. Changes in circulating levels of estrogen and progesterone appear to be at least one aspect of the pregnant condition responsible for the increase in lumbar dynorphin (1-17).

ESTROGEN RAPIDLY ATTENUATES THE RESPONSE OF GUINEA PIG HYPOTHALAMIC NEURONS TO μ-OPIOIDS. A.H. Lagrange, O.K. Rönnekleiv and M.J. Kelly*. Department of Physiology, Oregon Health Sciences U., Portland, OR 97201-3098.

Neurons of the hypothalamic arcuate nucleus are hyperpolarized by μ-opioids via an inwardly-rectifying potassium conductance. Ovariectomized guinea pigs (GPs) treated with estrogen 24 hours prior to sacrifice show a rightward shift in the dose response curve to the μ-opioid agonist, DAMGO, versus oil-injected controls. There is no change in the maximal response to DAMGO or the K_e for antagonism by naloxone. Presently, we have made intracellular recordings in hypothalamic slices prepared from ovariectomized, oil-treated GPs to show a more rapid effect of 17β-estradiol (E_2). Dose-response curves to DAMGO, followed by washout of the opioid and perfusion with 200nM E_2 for 20 minutes showed the same three-fold rightward shift when a second dose response curve to DAMGO was performed ($p<0.001$, n=8). The EC_{50} shifted from 80 ± 16nM to 236 ± 67nM . This effect did not appear to be homologous desensitization by DAMGO as multiple dose-response curves, both before and after estrogen, did not show this shift. Moreover, the change in sensitivity to DAMGO was seen in slices treated with E_2, without prior exposure to exogenous μ-opioids. The effect of E_2 could be seen for up to 3 hours after washout of this steroid. Histochemical double labelling identified a subpopulation of these cells as β-endorphin neurons. These actions of E_2 imply a direct effect on the receptor-G protein-K^+ channel effector system. (Supported by PHS grants DA05158 & HD00718)

SLEEP-WAKEFULNESS AND VEGETATIVE EFFECTS MEDIATED BY OPIATES IN THE NUCLEUS OF THE SOLITARY TRACT. F. Reinoso-Barbero and I. de Andrés*. Dpto. Morfología. Fac. Medicina, Univ. Autónoma. 28029 Madrid, SPAIN.

The Nucleus of the Solitary Tract (NST) has dense concentrations of opioid receptors and is involved in the control of both cardiovascular reflexes and electrocortical activity. We evaluated the involvement of the NST opioid system in hypnogenic and vegetative functions by making single microinjections of opiate agonists in NST, and monitoring sleep-wakefulness cycle (SWC) states, as well as heart and breath rates (HR and BR). Under general anesthesia, nine cats were implanted with a cannula stereotaxically aimed at the NST, and with EEG, EOG, EMG and lateral geniculate nucleus electrodes. Microinjections of 50 nl. of saline, morphine sulphate, morphicetine (specific μ agonist), D-pen-2-D-pen-5-enkephaline (∂ agonist) and U-50488H (κ agonist) were made with a 0.5 μl Hamilton syringe introduced in the implanted cannula. The doses ranged between 0.8-2.4 nmols. Following the microinjections, simultaneous sleep-wakefulness, EKG and BR recordings were obtained. Mu agonists produced a statistically significant increase of slow wave sleep (SWS) accompanied by a decrease in HR and BR in each state of the SWC. All these effects were blocked by prior intraperitoneal administration of naloxone. The ∂-agonist also produced a hypnogenic effect, but only a general decrease of HR and BR was observed because the enhancement of SWS. The κ-agonist caused no changes in HR, BR or SWC. These results indicate that μ and ∂ opioid receptors are involved in the syncronization of the EEG generated in NST, while only μ receptors seem to participate in the control of NST vegetative responses. Kappa receptors, by contrast, seem not to be involved in the functions explored.

INCREASED OPIATE SENSITIVITY AND DECREASED RECEPTOR -G-PROTEIN COUPLING IN THE NEONATAL RAT. R.T. Windh and C.M. Kuhn*. Dept. of Pharmacology, Duke Univ. Med. Center, Durham, NC 27710.

Despite considerable research on the outcome of perinatal opiate exposure, ontogenic changes in u receptor function and biochemistry have not been reported. The present studies were undertaken to evaluate u receptor function, number and G-protein coupling in neonatal and mature rats. Rats 10, 15, 20 and 27 days old were tested for morphine and sufentanil antinociception in the paw lift assay, and ED50s for morphine and sufentanil were determined. Contrary to previous reports, neonatal rats were more sensitive to opiate antinociception than were mature animals. Analysis of serum and brain morphine levels after 5 mg/kg morphine on days 10 and 27 indicated that morphine elimination is slightly faster in neonates than weanlings, yet both brain and serum levels are higher and remain elevated longer in neonates, largely due to a more rapid redistribution phase in weanlings (t1/2= 26 min.) than in pups (t1/2= 2.5 hrs.). Additionally, comparing brain morphine levels at equipotent analgesic doses in each age revealed that the effect was acheived in neonates at brain morphine levels that were half those in weanlings. Radioligand binding studies indicated that the number of u receptors increased 2 fold without change in affinity between days 10 and 27, and the GppNHp was nearly twice as effective in shifting the u receptors from high to low affinity on day 27 than on day 10. This weaker GppNHp regulation of agonist binding affinity apparently contradicts the enhanced antinociceptive sensitivity in neonates, and may result from a larger spare receptor population relative to G-proteins. Supported by DA 02739.

THE CAPSAICIN FLARE OF VASA NERVORUM D.W. Zochodne*, L.T. Ho, Queen's University, Kingston, Ontario Canada K7L 3N6

In previous work we identified prolonged and intense hyperemia of rat sciatic endoneurial vasa nervorum from epineurial capsaicin. In additional work, we studied further pharmacological aspects of the flare using serial hydrogen clearance in anesthetized rats. The capsaicin flare was interrupted by: removal of the epineurial vascular plexus; topical coadministration with capsaicin of spantide, spantide II (SP antagonists), or hCGRP (8-37) (CGRP antagonist); desensitization by prior capsaicin; pretreatment with combined systemic H1 and H2 histamine receptor antagonists, cromolyn sodium or morphine. Combined systemic morphine and naloxone pretreatment restored the flare. The above treatments did not alter baseline endoneurial perfusion. Interruption of central afferent connections by sectioning the nerve proximally did not influence baseline perfusion or the flare. The findings suggest that capsaicin-induced endoneurial hyperemia is local, mediated through an intact epineurial plexus and involves SP, CGRP and mast cell release of histamine. Inhibition by morphine suggests that there are opiate receptors on peptidergic fibers innervating vasa nervorum.

POSSIBLE INTERACTION OF μ-OPIOID AND α_2-ADRENOCEPTORS IN DERMORPHIN-INDUCED BRADYCARDIA IN CONSCIOUS RATS. O.M. Adeyemo and A-L. Sirén*. Dept. of Neurology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

Picomole doses of the selective μ-opioid agonist dermorphin (DM) increased mean arterial pressure (MAP) and heart rate (HR) after intracerebroventricular (i.c.v.) administration by a μ_1-opioid receptor mechanism while nanomole doses of DM i.c.v. induced bradycardia which was related to activation of μ_2-opiod receptors (Paakkari P. et al., Neuropharmacol.1992). Bradycardia is also associated with stimulation of central α_2-adrenoceptors. In the present study the influence of α_2-adrenoceptors on the cardiovascular effects of DM i.c.v. was examined in conscious male Sprague-Dawley rats (250-300 g, n=30) using the α_2-agonist clonidine (CLDN) and SK&F 86466 (6-chloro-N-methyl-2,3,4,5,-tetrahydro-1-H-3-benzazepine), a selective non-imidazoline α_2-adrenoceptor antagonist (Hieble J.P. et al.,J.Pharm.Exp.Ther.236: 90-96,1986). In order to block any μ_1-opioid receptor mediated effects, naloxonazine (NLZ), a μ_1-antagonist, (50 μg/rat, i.c.v.), was administered 20 h before the interactions between DM and the α_2-adrenoceptor drugs were tested. DM (3-10 nmol/rat i.c.v.) induced a dose-dependent bradycardia in NLZ treated rats. SK&F 86466 (1 μmol/rat, i.c.v., 30 min before DM) had no effect on MAP and HR but blocked the bradycardic effect of DM (3 or 10 nmol/rat). CLDN (10 μg/rat, i.c.v., 30 before DM) had no effect on heart rate and did not modify the DM-induced bradycardia. These data suggest that α_2-adrenoceptors interact with the μ_2-opioid receptor associated bradycardia.

THE EFFECT OF MORPHINE ON QUANTAL TRANSMITTER SECRETION FROM VISUALIZED SYMPATHETIC VARICOSITIES. Nickolas A. Lavidis* Neurobiology Lab., Dep. of Physiology, University of Sydney, NSW, Australia 2006.

Morphine reduces the amount of transmitter secreted by nerve terminals during electrical stimulation. Two mechanisms have been proposed to explain this action of opiates: (a) μ-type opioid receptors increase the conductance of K^+ ions resulting in hyperpolarization of neuronal cells (Morita & North, 1982, Brain Res. 242, 145-150). (b) κ-type opioid receptors decrease the influx of extracellular Ca^{2+} ions following nerve stimulation, resulting in a decrease in the amount of transmitter secreted (Bennett & Lavidis, 1980, Br. J. Pharmac.69, 185-191; Bixby & Spitzer, 1983, Nature 301, 431-432; Gross & MacDonald, 1987, Proc. Natl. Acad. Sci. 84, 5469-5473). At the amphibian motor nerve terminal, morphine was shown to decrease the probability of quantal secretion (p) uniformly along the length of terminal branches without affecting the action potential (Lavidis 1987, Int. Cong. Pharmac. 10, P164).

The effect of morphine on quantal secretion ($\bar{m}$),p and the propogation of the action potential along visualized sympathetic nerve varicosities of the mouse vas deferens has been evaluated. $DiOC_2$-fluorescence was used to visualize the varicosities while placing an electrode over a group of varicosities to record the terminal action potential and the excitatory junctional currents (Lavidis & Bennett, 1992, J. Physiol. In Press).

Morphine (0.5 μM) produced a 51±4% decrease in $\bar{m}$ and a 8±6% decrease in the amplitude of the terminal action potential (n=8). Morphine (1μM) produced a 72±3% decrease in $\bar{m}$ and only 2 of the 9 experiments showed a significant decrease in the action potential. This action of morphine was partly reversed by naloxone (1μM) or by increasing the frequency of stimulation from 0.1 Hz to 0.5 Hz or 1.0 Hz or by increasing the extracellular calcium concentration from 4 mM to 7 mM.

The significant decrease in $\bar{m}$ produced in the presence of morphine occurred without a significant change in the size of the terminal action potential. This decrease in $\bar{m}$ was mainly due to a decrease in the probability of quantal secretion from known numbers of varicosities.

CATECHOLAMINES: NOREPINEPHRINE

577.1

MONOAMINERGIC INNERVATION OF RAT PIRIFORM CORTEX

M. Ennis*, T.A. Rizvi and M.T. Shipley Department of Anatomy & Cell Biology, University of Cincinnati, Cincinnati, OH 45267.

Piriform cortex (PC), the main target of the olfactory bulb, plays a key role in olfactory information processing. PC receives noradrenergic (NE), dopaminergic (DA) and serotonergic (5-HT) afferents. The organization of these modulatory inputs to PC has not been characterized, however. Here, we directly compare the distributions and relative densities of NE, DA and 5-HT fibers in PC using antibodies against dopamine-B-hydroxylase (NE), tyrosine hydroxylase (DA) and 5-HT.

The densities of these monoamines in PC is generally greater than their innervation of hippocampus and neocortex. As in other cortical regions, 5-HT provides the densest innervation of PC, followed by NE, then DA. These systems also exhibited laminar specificity. Layers I and III of PC contain a moderate plexus of NE fibers; layer II is sparsely innervated. The density and laminar distribution of NE fibers is relatively uniform along the rostrocaudal axis of PC. By contrast, DA innervation exhibited a marked rostrocaudal gradient. Rostrally, DA fibers are relatively sparse and confined primarily to layer III. The density of innervation systematically increases at more caudal levels and DA fibers progressively invade more superficial layers. The 5-HT innervation of PC is very heavy in layer I and the superficial half of layer III.

In light of the potent modulatory actions of NE, DA, and 5-HT in hippocampal and neocortical circuits, these transmitters likely play important roles in olfactory information processing. Like PC, the olfactory bulb receives dense and laminar specific extrinsic NE and 5-HT inputs; by contrast, DA innervation of the bulb is derived exclusively from intrinsic DA neurons. Thus, NE and 5-HT may *coordinately* regulate olfactory circuits whereas DA *differentially* modulates neural processing in PC and MOB.

PROJECTIONS FROM THE MEDIAL PREOPTIC AREA (MPO) TO NUCLEUS LOCUS COERULEUS (LC) AND THE PERICOERULEAR REGION. T.A. Rizvi*, M. Ennis, P. Luppi, G. Aston-Jones and M.T. Shipley. University of Cincinnati, Cincinnati, OH 45267; Hahnemann University, Philadelphia., PA 19102.

LC is the sole source of noradrenergic (NE) innervation of the olfactory bulb. NE plays an important role in olfactory learning, sexual behavior and pheromonal regulation of pregnancy. However, circuits linking the olfactory system *to* LC are unknown. Here, we report a novel pathway from MPO to LC. MPO, a structure critical to sexual behavior and neuroendocrine function, receives olfactory bulb inputs via the medial amygdala.

Injections of retrograde tracers in LC and peri-LC labeled neurons in MPO. Injections of the anterograde tracer, PHA-L, into MPO densely labeled fibers and terminals in the dorsolateral pontine central gray, including the Barrington's nucleus and the dorsolateral tegmental nucleus. Fiber labeling in LC proper was more modest but there was very heavy labeling in a focal zone rostral and medial to LC (rostromedial peri-LC). Our recent studies show that this zone contains a dense plexus of LC dendrites. This suggested that MPO axons may preferentially terminate on extranuclear LC dendrites rather than LC proper. Double labeling studies showed that MPO fibers (PHA-L) are densely aggregated in the focal plexus of TOH-immunolabeled LC dendrites in rostromedial peri-LC.

Olfactory stimuli evoke significant NE release in the bulb. Projections from both the main and accessory olfactory bulbs terminate in the medial amygdala which, in turn, projects heavily to MPO. The present findings, therefore, suggest a possible di-synaptic pathway by which olfactory bulb outputs activate LC neurons, thus releasing NE in the bulb. *(Support: NIH DC00347, NS20643, NS24698, NS29218 & NS29635).*

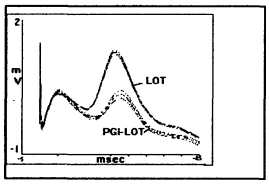
NUCLEUS PARAGIGANTOCELLULARIS STIMULATION REDUCES LATERAL OLFACTORY TRACT EPSPS IN THE DENTATE GYRUS

D.M.Babstock and C.W. Harley*, Psychology Department & Faculty of Medicine, Memorial University, St. John's, NF, Canada A1B 3X9

In vitro norepinephrine (NE) potentiates the dentate gyrus response to medial perforant path (PP) input, while depressing response to lateral PP input (Dahl & Sarvey, PNAS 86:4776, 1989). The present study asks whether a similar selectivity occurs with NE release via locus coeruleus (LC) activation in vivo.

Four .5 msec pulses at 333 Hz in the nucleus paragigantocellularis (PGi) were used to activate the LC input to dentate gyrus in urethane-anesthetized rats. Such PGi stimulation produces maximal potentiation of the medial PP population spike at latencies which are consistent with mediation by LC and this potentiation is blocked by propranolol as has been shown for direct LC and NE-induced potentiation.



To selectively activate the lateral PP input to dentate gyrus stimulating electrodes were placed in the lateral olfactory tract (LOT). Single LOT pulses were used to initiate field EPSPs in the dentate gyrus and were preceded by PGi pulses at intervals which would result in co-incident release of NE and lateral PP glutamate. PGi activation consistently reduced LOT EPSPs (see graph) and also reduced EPSPs evoked by stimulating lateral PP fibers directly. PGi stimulation in the same experiments potentiated the medial PP population spike. The data suggest LC-NE is a highly selective promoter of input-evoked responses in the dentate gyrus.

5-HYDROXYTRYPTAMINE NEURONS TONICALLY INHIBIT NOREPINEPHRINE NEURONS TERMINATING IN THE HYPOTHALAMUS

M.J. Eaton,* Y. Tian, J.L. Goudreau, K.J. Lookingland and K.E. Moore. Dept. Pharm/Tox, Michigan State University, E. Lansing, MI 48824

The medial zona incerta (MZI) and dorsomedial nucleus of the hypothalamus (DMN), which contain cell bodies and terminals of the incertohypothalamic dopamine (DA) neurons, are innervated by norepinephrine (NE) neurons and 5-hydroxytryptamine (5-HT) neurons. The purpose of the present study was to examine the role of 5-HT neurons in the regulation of NE and DA neurons in the MZI and DMN in rats. Catecholamine neuronal activity in these brain regions was estimated by measuring the accumulation of 3,4-dihydroxyphenylalanine (DOPA) after administering a decarboxylase inhibitor and the concentrations 3,4-dihydroxyphenylacetic acid (DOPAC), indices of synthesis and metabolism, respectively. Inhibition of 5-HT neurons with the 5-HT_{1A} agonist 8-hydroxy-2-(DL-n-propylamino)tetralin (8-OH-DPAT) increased the accumulation of DOPA in the DMN and the concentration of DOPAC in the MZI and DMN, indicating an activation of either NE or DA neurons in these regions. The concentrations of 3-methoxy-4-hydroxyphenylethyleneglycol, the primary metabolite of NE, in the MZI and DMN were increased by 8-OH-DPAT or following destruction of 5-HT neurons, confirming that NE neurons in these regions were, indeed, activated following a decrease in 5-HT neuronal activity. After destruction of NE neurons projecting to the MZI and DMN, 8-OH-DPAT no longer increased DOPAC concentrations in these brain regions, indicating the lack of a direct effect of this drug on incertohypothalamic DA neurons. Taken together, these results reveal that 5-HT neurons tonically inhibit NE neurons terminating in the MZI and DMN, but not the incertohypothalamic DA neurons located in these regions. EFFECT OF LOCUS COERULEUS (LC) LESION ON C-FOS RESPONSE TO METRAZOL (PTZ) IN RAT BRAIN

Y. Zhang*, G. Bing, D. Filer and E.A. Stone. Dept. Psychiatry, New York Univ. Sch. Med., New York, NY 10016

The convulsant PTZ has been shown to greatly induce c-fos in the rat CNS. We and others have shown that norepineprine (NE) which has antiseizure activity and may be released during seizures also can induce brain c-fos. The present study was undertaken to determine if part of the c-fos response to PTZ is the result of the activation of the LC noradrenergic system. Rats were given unilateral lesions in the LC with 6-OHDA. After 7 days the animals were convulsed with an i.p. dose of PTZ (50 mg/kg) and after 2 hrs anesthetized and perfused for immunohistochemistry of c-fos and tyrosine hydroxylase (TH). Completeness of LC lesion was verified by TH immunohistochemistry. It was found, in agreement with previous research, that PTZ greatly increased c-fos immunoreactivity in various telencephalic structures on the side of the brain with the intact LC. The LC lesioned side showed a significant attenuation of the response to PTZ in the frontal, parietal and piriform cortices. These results support the notion that part of the c-fos response to PTZ is a result of noradrenergic activation as an apparent compensatory antiseizure response. Supported in part by grants AFOSR 89-0208, MH45265 and MH08618.

PROTECTIVE ACTION OF LOCUS COERULEUS NORADRENERGIC SYSTEM ON SUBSTANTIA NIGRA (SN) OF MICE TREATED WITH MPTP.

G. Bing*, Y. Zhang and E.A. Stone. Dept. Psychiatry, New York Univ. Sch. Med., New York, NY 10016

In addition to its immediate neurophysiological functions, the LC noradrenergic system has been hypothesized to have trophic effects in the CNS (Behav. Brain Sci. 6:535,1983). Recently, in support of this, it has been found that LC lesions in the monkey greatly retard the recovery of SN lesions caused by the neurotoxin MPTP (Neurosci. 41:507,1991). Because of the potential clinical significance of these findings to Parkinsons's disease (PD) we have attempted to replicate them in the mouse MPTP model. Mice were given unilateral LC lesions with 6-OHDA and after a 10 day period challenged with MPTP at a dose known to be subtoxic to SN dopamine (DA) containing neurons. After an interval of 7 days the animals were sacrificed and immunohistochemical studies of tyrosine hydroxylase (TH) and Nissl staining of the SN and LC were undertaken. It was found that the LC lesion dramatically enhanced the toxic effect of MPTP as reflected in a marked reduction in the number of TH positive cells in the ipsilateral SN after subtoxic MPTP. Nissl staining studies confirmed the loss of neurons in the ipsilateral SN. DA levels in the striatum are currently under investigation. The results support the notion that the LC has marked trophic actions on the SN and may be involved in the etiology of PD. Supported in part by grants AFOSR 89-0208, MH45265 and MH08618.

SEXUALLY DIMORPHIC AND AGE-RELATED DIFFERENCES IN THE IMPACT OF A STRESSOR ON HYPOTHALAMIC NOREPINEPHRINE TURNOVER

SuJean Choi* and Carol Kellogg. Dept. of Psychology, University of Rochester, Rochester, N.Y. 14627.

Previous studies have indicated an age-related influence on hypothalamic norepinephrine (NE) turnover in male rats. The decrease in NE levels following synthesis inhibition followed a markedly different pattern at 42 days of age (midpuberty) than at either 28 (juvenile) or 70 (young adult) days (Neurosci. Abstracts, 17, 415; 1991). Whereas at 28 and 70 days, NE levels decreased to reach 50% of basal values by 4 hours after synthesis inhibition, at 42 days, NE levels had decreased this amount by 60 min after inhibition. Moreover, in adult rats, exposure to a stressor (2 hours restraint) accelerated the loss of NE after synthesis inhibition. This present study investigated the impact of a stressor on hypothalamic NE neurons as a function of pubertal development and gender. Male and female rats at 28, 42, and 70 days of age were given alpha-methyl-p-tyrosine (MT; 250mg/kg) immediately before being placed in an acrylic restraint chamber for either 45 or 60 minutes. For males at all ages 45 min of restraint retarded the NE decrease in the presence of MT. NE levels increased over basal values, even in the presence of the inhibitor. At 28 and 70 days of age, hypothalamic NE levels in males began to decrease following 60 minutes of restraint plus MT. However, at 42 days NE levels continued to increase after 60 min of restraint plus MT. In contrast to males, hypothalamic NE levels in females of all ages decreased over time following restraint and synthesis inhibition with MT. This may suggest that in the hypothalamus there is a sexually dimorphic and age-related difference in kinetic aspects of the tyrosine-hydroxylase enzyme in response to stressors. Grant No DA07080.

PRAZOSIN ENHANCES *IN VIVO* NOREPINEPHRINE SYNTHESIS IN YOHIMBINE-TREATED RAT HIPPOCAMPUS AND LOCUS CERULEUS.

D. Huston-Lyons*, M. Hartmann, E.R. Marsh, R.J. Baldessarini Department of Psychiatry and Neuroscience Program, Harvard Medical School, Mailman Research Center, McLean Hospital, Belmont, MA 02178.

The adrenergic pharmacology of norepinephrine (NE) synthesis was evaluated in rat hippocampus (HP) and locus ceruleus (LC, contained within dorsal pons-medulla) *ex vivo* by accumulation of DOPA in adult male rats given a decarboxylase inhibitor (NSD-1015, 100 mg/kg, ip, 5 min post-drug). Test agents were injected (ip) at 35-40 min prior to decapitation and brain dissection. DOPA content was assayed by HPLC with electrochemical detection. As expected, yohimbine (YOH) which blocks α_2-receptors and may directly stimulate NE release dose-dependently increased DOPA accumulation in HP and LC. The potent α_1- (and weak α_{2B}) receptor antagonist, prazosin (PRZ), increased NE synthesis only slightly, even at high doses. Low, ineffective doses of PRZ plus a maximally effective dose of YOH, however, enhanced DOPA accumulation significantly above levels obtained with YOH alone, indicating potentiation. In contrast, chlorpromazine, which has similar α-receptor affinities as PRZ, had no effect alone and failed to enhance YOH's effects, suggesting that α-receptor activity may not explain PRZ's effects, the basis of which remains unclear. COMPARISON OF AIMAX AND DIETHYLDITHIOCARBAMATE (DDC) ON RAT HYPOTHALAMIC MONOAMINE LEVELS. W-J. Chang[1], C.R. Barb[2], L.S. Leshin*[2], G.B. Rampacek[1], B. Johnson[2], R.R. Kraeling[2] and J.T. Wright[2]
[1]University of Georgia, Athens 30602 and [2]USDA-ARS, Athens, GA 30613.

DDC reduces brain norepinephrine (NE) content and subsequent LH secretion in the rat. AIMAX, also a carbamate compound, suppresses LH secretion. However, the mechanism of AIMAX action is unknown. Concentrations of monoamines in the hypothalamus were compared after DDC or AIMAX in ovariectomized rats primed with an injection of 50 μg estradiol benzoate followed 48 h later by 2.5 mg progesterone (d 0) sc. Treatments were: 1) injection sc of 650 mg DDC/kg BW (n=5) on d 0; 2) daily injection of 20 mg AIMAX/kg BW sc (n=6) from d-7 to d 0; 3) or saline (C; n=6). Injections were given between 1000 and 1030 h. Rats were decapitated on d 0 between 1530 and 1630 h. Monoamine content within the medial basal hypothalamus (MBH) and retrochiasmatic area (RCA) were determined. AIMAX reduced ($P<0.05$) NE and increased ($P<0.05$) dopamine (DA) content in MBH and RCA compared to C rats. Similar patterns in NE and DA levels were observed in DDC rats. However, DDC elevated epinephrine (EPI) content in MBH and RCA compared to AIMAX rats. Therefore, like DDC, AIMAX is an apparent NE synthesis inhibitor.

MONOAMINE LEVELS IN A RAT BRAIN SUBJECT TO A STATIC MAGNETIC FIELD. K.Hyodo* and K.Homma. Biomechanics Div., Mech. Eng. Lab., Agency of Industrial Science and Technology., Tsukuba, 305JAPAN

To study the rapid influence which a static magnetic field has upon brain metabolism by means of in vivo microdialysis , dopamine (DA), dihydroxyphenylacetic acid (DOPAC), homovanillic acid(HVA), 5-hydroxyindoleacetic acid(5-HIAA) and norepinephrine(NE) in a rat caudate putamen were monitored during the application of a 250 gauss static magnetic field, applied to a whole body by a 2 tesla(T) MRI superconductive magnet. A 28 week old male Wister rat (n=7) was placed in a black cloth-covered free moving unit while monitoring. After 2 hours of monitoring, in 15 minute intervals, during the application of the magnetic field, the changes in monoamine levels were not significant when compared to normal changes in the absence of the field. By using a static magnetic field of 250 gauss, rapid influence was not determined by changes in monoamine levels in the rat caudate putamen. In response to the report that the B.B. barrier function is altered by a magnetic field, the change may not have been rapid or it may not have had a direct influence upon the monoamine levels in caudate putamen. If a magnetic field dose have an influence on the brain metabolism, not only for monoamine levels in the caudate putamen but also other metabolisms, it may appear after long time monitoring or in the presence of a stronger magnetic field.

EFFECTS OF S-2(3-METHYLAMINOPROPYLAMINO) ETHYLPHOSPHOROTHIOIC ACID (WR-3689) ON THE CONTENT OF CATECHOLAMINES IN MOUSE ADRENALS. D.L. Palazzolo*, W.A. McLean and K. Sree Kumar, Radiation Biochemistry Department, AFRRI, Bethesda, MD 20889.

Simultaneous administration of caffeine and WR-3689 mitigates impairment of locomotor activity in mice treated with WR-3689 alone. This combination of drugs also decreases the caffeine-induced increase of catecholamines in mouse hypothalamus. In the current studies, we determined the effect of *i.p.* injections of WR-3689 on the catecholamine content of the adrenals. Mice were treated with saline (control) or WR-3689 (100 or 200 mg/kg), adrenals removed at 0, 1, 2, 4, and 8 hrs after injections and dopamine (DA), norepinephrine (NE), and epinephrine (EPI) determined using HPLC. Treatment with 100 mg/kg WR-3689 had no effect on DA; 200 mg/kg WR-3689 increased ($p<0.05$) DA content from a control value of 29±5 to 37±5 ng/mg wet weight 1 hr after treatment. With both 100 and 200 mg/kg WR-3689, NE content decreased ($p<0.02$) from 664±50 to 396±59 and 437±80 ng/mg, respectively, 4 hrs after treatment. EPI content decreased ($p<0.04$) from 1178±179 to 852±122 ng/mg 4 hr after treatment with 100 mg/kg WR-3689, but increased ($p<0.03$) from 1315±149 to 1784±179 ng/mg 1 hr after treatment with 200 mg/kg WR-3689. These results indicate that WR-3689 alters catecholamine metabolism.

INTRACEREBROVENTRICULAR INJECTION OF ANGIOTENSIN II INCREASES PLASMA NOREPINEPHRINE LEVELS.

B Kimura, M I Phillips* and C Sumners. Dept. of Physiology, University of Florida, Gainesville, FL 32610.

Centrally mediated effects of Angiotensin II (AII) include increases in blood pressure, drinking and release of vasopressin (AVP). The increase in blood pressure has been postulated to occur both through the increase in AVP and an increase in peripheral sympathetic activation. We investigated the effect of intracerebroventricular (i.c.v.) injections of AII on the release of peripheral norepinephrine (NE) and epinephrine (E) in Sprague-Dawley male rats. NE and E were measured by radioenzymatic assay. To determine whether release of NE from the adrenal played a role in the response NE in plasma was measured after adrenalectomy. The result shows that i.c.v. injections of AII (50 ng - 500 ng in 2 μl) caused a significant increase in plasma NE levels. The highest dose of AII (500 ng) also caused an increase in E levels. Adrenalectomy lowered E concentrations to below the detection limit of the assay. The AII-stimulated increase in NE levels persisted in the adrenalectomized rats, and at a dose of 250 ng AII i.c.v. the effect was not significantly different from intact animals. However at 500 ng AII i.c.v. this response was significantly attenuated. The results confirm that central AII releases NE and E peripherally. The source of E appears to be by stimulation of the adrenal gland, but high doses of AII are required. The source of NE is the peripheral sympathetic nervous system at low doses and the adrenal medulla at the high dose.

THE EFFECTS OF CHRONIC OPIATE TREATMENT ON [^{3}H]NOREPINEPHRINE UPTAKE PROPERTIES OF NORADRENERGIC LOCUS COERULEUS NEURONS IN VITRO. H.K. Raymon* and F.M. Leslie, Dept. of Pharmacology, University of California, Irvine, CA. 92717.

Endogenous opioids have been implicated in the control of developmental events, such as cell proliferation and differentiation. The cell types that are under opioid control during development have not been clearly identified. The purpose of this study was to determine whether the maturation of noradrenergic locus coeruleus (LC) neurons in vitro could be influenced by chronic opiate treatment. LC cells were obtained from the rostral rhombencephalon of rats at embryonic day 14. Cells were dissociated and plated in either a serum-containing or serum-free, fully defined medium. [^{3}H]Norepinephrine (NE) uptake was used as a marker for the growth of noradrenergic cells in culture. LC cells treated chronically with fentanyl citrate for 4 days in serum-containing medium showed a significant decrease in [^{3}H]NE accumulation. The dose-response curve was U-shaped, with a maximal effect at 10 nM and a reduced effect at the highest dose (1 μM). Fentanyl inhibition of [^{3}H]NE uptake was reversed by the opiate antagonist, naloxone. Kinetic constants derived from uptake velocity curves for control and drug-treated cultures were, K_m = 206 nM and V_{max} = 65.3 fmol/min and K_m =302 nM and V_{max} = 67.4 fmol/min, respectively. This indicates a change in the affinity of the NE transporter with chronic opiate treatment. No significant differences in uptake were found in fentanyl-treated cultures grown in defined medium. The lack of effect in defined medium may be due to the development of tolerance. Experiments utilizing opioid inhibition of [^{3}H]NE release as an index for functional opioid receptor activity in serum-containing and defined medium are currently being undertaken to determine whether tolerance develops after chronic fentanyl treatment. Overall these data suggest that chronic opiate treatment influences monoamine transporter function in developing LC neurons. *Supported by NIH grants NS19319 and MH09737.*

INFLUENCE OF PROTEIN SYNTHESIS INHIBITORS ON THE NICOTINIC-MEDIATED INCREASE IN TYROSINE HYDROXYLASE (TH) GENE EXPRESSION IN BOVINE ADRENAL CHROMAFFIN CELLS. G.L. Craviso[1]*, R.W. Moore[1], V.B. Hemelt[2] and J.C. Waymire[2]. [1]Dept. Pharmacology, Univ. Nevada Sch. Med., Reno, NV 89557 and [2]Dept. Neurobiology and Anatomy, Univ. Texas Med. Sch., Houston, TX 77225.

In isolated bovine adrenal chromaffin cells, the selective nicotinic agonist dimethylphenylpiperazinium (DMPP; 1 μM) produces a rapid calcium-dependent pulse of increased TH gene transcription (2 to 3-fold within 30 min, with a return to basal levels by 2 hr), followed by a 2-fold rise in TH mRNA levels by 8-18 hr. The requirement for protein synthesis in this regulation of TH gene expression was examined by treating cells with either cycloheximide (5 μM), puromycin (100 μM) or anisomycin (100 μM) prior to addition of the agonist, and analyzing both TH gene transcription and TH mRNA levels. Basal TH transcription rates were either unaffected or slightly decreased by a 2 hr exposure to the protein synthesis inhibitors; longer exposure (8 hr) significantly reduced transcription. None of the inhibitors blocked the increase in transcription elicited by DMPP. Furthermore, the rapid downregulation of the transcriptional response was also not affected. This contrasts with the superinduction of *c-fos* transcription by DMPP in the presence of these inhibitors. Despite its inhibitory effect on basal transcription, cycloheximide elevated TH mRNA levels 2-fold, measured at 12 or 24 hr. This increase was not always additive with the rise in TH mRNA levels produced by DMPP. Our results suggest that protein factors may be involved in regulating basal TH transcription rates but not the increase produced by DMPP. The rise in TH mRNA levels by cycloheximide could be due to increased TH mRNA stability whereas the apparent blockade of the effects of DMPP on TH mRNA by this inhibitor may indicate a role for protein synthesis in pre-TH mRNA processing. USPH NS27550.

VIP, SECRETIN, AND PACAP ACT AT DISTINCT RECEPTORS TO INCREASE TYROSINE HYDROXYLASE GENE EXPRESSION IN PC12 CELLS. R. Basiboina, C. Hale, J.W. Haycock and R. Strong*. Departments of Pharmacological and Physiological Science and Internal Medicine, St. Louis University School of Medicine, and GRECC, St. Louis VA Medical Center, St. Louis, MO, 63125 and Dept. of Biochem. and Mol. Biol., Louisiana State Univ. Med. Ctr., New Orleans, LA.

As the rate limiting enzyme in catecholamine biosynthesis, tyrosine hydroxylase (TH) is important in determining sympathetic tone. Vasoactive intestinal polypeptide (VIP) has been established as a neurotransmitter within the splanchnic nerve which innervates the adrenal medulla (Wakade,89). We have reported that both VIP and secretin, homologous peptides within the glucagon family, increase TH gene expression in PC12 cells, through a cyclic AMP-dependent mechanism. Recently, PC12 cells have been shown to possess receptors for pituitary adenylate cyclase activating polypeptide (PACAP), a peptide that has 68% homology to VIP in the first 27 amino acids. Moreover, PACAP is several orders of magnitude more potent than VIP in eliciting increases in cAMP. We undertook a series of studies using VIP and secretin antagonists to determine whether VIP, secretin, and PACAP induce changes in TH gene expression through the same receptor.

Experiments were performed in PC12 cells, a rat chromaffin cell line. Preconfluent cells were incubated 6 hours with various concentrations of hormone. Following total RNA extraction, Northern and slot blots were performed using a full length TH.36 cDNA probe. We found that the order of potency for the compounds on TH gene expression was PACAP > secretin > VIP. The secretin antagonist (secretin [5-27]) reduced the effects of secretin but not VIP or PACAP. The VIP antagonist (VIP [10-28] inhibited the effects of VIP but not PACAP or secretin. Neither receptor antagonist had an effect by itself. These studies suggest that VIP, secretin and PACAP work through distinct receptors to increases TH gene expression.

578.3

ACUTE COLD STRESS LEADS TO AN INCREASE IN TYROSINE HYDROXYLASE GENE TRANSCRIPTION IN RAT ADRENAL MEDULLA MEASURED BY INTRONIC *IN SITU* HYBRIDIZATION. Maureen K. Hahn* and Thomas G. Sherman. Department of Cellular and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260-7700.

Tyrosine hydroxylase (TH), the rate-limiting enzyme that converts tyrosine to DOPA in the catecholamine biosynthetic pathway, is modulated in the rat adrenal gland by stress. Both the enzymatic activity of and mRNA levels for TH increase in response to various stressors. Because cold stress produces an increase in TH mRNA and another stimulus, nicotine, induces TH gene transcription, as measured by nuclear run-on assay, we sought to determine the extent to which acute cold stress itself will increase TH gene transcription using the novel method of intronic *in situ* hybridization. We have shown previously, in a different system, that measures of vasopressin gene transcription by intronic *in situ* hybridization yield changes that are quantitatively similar to those determined by nuclear run-on assay. Male Sprague Dawley rats were shaved, exposed to 5°C for 3 hr, decapitated and the adrenal glands removed. This stress paradigm is sufficient to cause an increase in mRNA for adrenal TH as measured by Northern and RNase protection assays. *In situ* hybridization was performed on post-fixed tissues at 54°C using either a 509 nucleotide TH cDNA riboprobe or a 365 nucleotide riboprobe coding for intron 2 of the TH gene. Using the riboprobe for TH intronic sequences, 3 hr of exposure to cold stress produces a 3-fold increase in medullary grain density. The signal for TH intron that appears in the adrenal glands from cold-stressed animals is virtually absent in control animals. This occurs in conjunction with a 61% ($p<.03$) increase in cytoplasmic TH mRNA as measured by *in situ* hybridization with the riboprobe coding for TH exonic sequences. These results indicate that the increase in TH mRNA seen in response to acute cold stress in the rat adrenal medulla is due to transcriptional activation of the TH gene. Supported by grant MH29670-14.

TRANSCRIPTIONAL AND POSTTRANSCRIPTIONAL CONTROL OF TYROSINE HYDROXYLASE (TH) GENE EXPRESSION BY OXYGEN IN PC12 CELLS. M.F. Czyzyk-Krzeska*, B.A. Furnari, E.E. Lawson and D.E. Millhorn. University of North Carolina, Chapel Hill, N.C.

We reported recently that TH mRNA is substantially enhanced in carotid body O_2 sensitive (type I) cells by acute (1-48hr) exposure to low oxygen (J.Neurochem 58: 1992). Carotid body type I cells closely resemble pheochromocytoma (PC12) cells with regards to their catecholamine phenotype, morphology and embryonic origin. The present study was performed to determine if TH gene expression is modulated in PC12 cells by low O_2 in a manner similar to that measured in type I cells We report here that TH mRNA is enhanced (3-4 fold) by acute exposure (1-48 hr) to low O_2 (5%). Experiments were performed to identify the mechanism by which TH gene is regulated by O_2 in PC12 cells. Findings from nuclear runoff assays revealed a 2-3 fold increase in nascent transcripts in response to exposures to low O_2 (1-48 hr). To identify the 5' flanking region of the TH gene that is responsible for transcriptional regulation during hypoxia, CAT assays were performed using different TH promoter constructs. We found that promoter region of TH gene that extends from -272 to +27 mediates the increased transcriptional activity associated with hypoxia. When constructs that contained sequence more upstream, the increase in transcription was repressed. This finding implies that transcription of TH gene during hypoxia is regulated by an interaction of enhancer and silencer factors. To determine if TH gene expression during hypoxia is also regulated posttranscriptionally, PC12 cells were pretreated with α-amanitin to block transcription, exposed to low O_2 (1-24 hr), and TH mRNA quantitated by northern blot analysis. We measured a substantial increase (3-5 fold) in TH mRNA over control (cells not exposed to low O_2) at all time points. This finding indicates that TH mRNA is stabalized during low O_2. Thus, the TH gene in PC12 is regulated by a dual mechanism involving both transcription and translation.

PARALLEL UPREGULATION OF CATECHOLAMINE SYNTHESIZING GENES IN ADRENOMEDULLARY TUMOR CELLS *IN VIVO*: OVEREXPRESSION OF TH, AADC, AND DBH BUT SUPPRESSION OF PNMT. T.C. Wessel*, K.S. Kim, H. Baker and T.H. Joh. Cornell Univ. Med. College at the Burke Medical Research Institute, White Plains, NY 10605.

Adrenomedullary cells are segregated into two distinct populations: the majority of medullary cells express all four catecholamine synthesizing enzymes and have the capacity to produce epinephrine, while a minority lack PNMT and produce norepinephrine. This second group of medullary PMNT-negative cells contains higher mRNA levels for TH, AADC, and DBH. Interestingly, catecholamine-secreting tumors of the adrenal medulla are frequently found in rats >12 months of age. *In situ* hybridization and immunohistochemical analysis of these tumors revealed that the mRNA and protein levels for TH, AADC and DBH are markedly increased, while PNMT expression is suppressed. In addition, TH enzyme activity in adrenal glands with visible tumors is increased >10-fold over age-matched controls. To delineate the mechanisms underlying the differential regulation of these enzyme genes, we examined the expression of several trans-acting factors known to be involved in catecholamine regulation. Message levels for CREB, c-fos, c-jun and glucocorticoid type 2 receptor examined on adjacent tissue sections as well as immunochemical staining for CREB and Fos protein revealed no differences between normal medullary and tumor tissue. These data suggest that increased enzyme gene expression is not correlated with altered steady-state levels of these trans-acting factors.

578.6

STUDIES ON THE COORDINATE REGULATION OF GENES ENCODING TYROSINE HYDROXYLASE AND TETRAHYDROBIOPTERIN (BH_4) BIOSYNTHETIC ENZYMES IN CULTURED PC12 CELLS. P.Z. Anastasiadis* and R.A. Levine. Lab of Molecular Neurobiology, Lafayette Clinic, and Cellular and Clinical Neurobiology Program, Wayne State University, Detroit, MI, 48207.

Tetrahydrobiopterin (BH_4) is the naturally occurring cofactor for tyrosine hydroxylase (TH) and tryptophan hydroxylase (TPH), which are the initial and rate-limiting enzymes in catecholamine (CA) and serotonin (5-HT) synthesis, respectively. Genetic deficiencies in BH_4 biosynthesis occur in newborns (atypical PKU), and altered BH_4- and CA-related gene expression may be involved in Parkinson's and Alzheimer's disease, familial dystonia, and depression. Elevation of cellular BH_4 levels increases TH and TPH activities, whereas inhibition of BH_4 synthesis causes CA and 5-HT deficits. Therefore, cultured pheochromocytoma (PC12) cells are being used to study BH_4 and catecholamine metabolic interactions with emphasis on the coordinate regulation of TH and BH_4-related gene expression. Incubation of PC12 cells with exogenous BH_4 caused a marked rise in intracellular BH_4 levels and a stimulation of dopamine (DA) synthesis. Inhibition of GTP cyclohydrolase and sepiapterin reductase, the initial and final BH_4 biosynthetic enzymes, by 2,4-diamino-6-hydroxypyridine (DAHP) and N-acetylserotonin, respectively, significantly reduced BH_4 levels and DA synthesis. Conversely, incubation of PC12 cells in the presence of nerve growth factor (NGF) for 24 hours significantly elevated BH_4 levels (180% of control). Using these and other pharmacological manipulations of BH_4 and CA metabolism, the hypothesis that the expression of TH, GTP cyclohydrolase, and sepiapterin reductase genes are coordinately regulated is being investigated by measuring mRNAs, enzyme content, enzyme activity, and end products of BH_4 and CA biosynthesis.

ELECTROCONVULSIVE SHOCK INCREASES TYROSINE HYDROXYLASE AND NEUROPEPTIDE Y MESSENGER RNA IN THE LOCUS COERULEUS.

S. Kapur*, M.C. Austin, M.D. Underwood, V. Arango and J.J. Mann . Laboratories of Neuropharmacology, University of Pittsburgh, Pittsburgh, PA 15213.

Electroconvulsive shock therapy (ECT) is an effective antidepressant treatment for certain cases of depression that are not responsive to pharmacologic treatments. Elucidation of the mechanism of antidepressant action of ECT may permit development of more effective drugs. Multiple electroconvulsive shock (ECS) enhances noradrenergic activity by an increase in norepinephrine (NE) levels and tyrosine hydroxylase (TH) activity in the rat cortex and brainstem, respectively. A recent study found that multiple ECS increases TH gene expression in the rat LC suggesting an effect on gene expression may contribute to increased TH activity. ECS effects on neuropeptide Y (NPY), which coexists with NE in perikarya of the rat LC, are unknown. Using *in situ* hybridization, we sought to determine whether multiple ECS treatments regulate NPY gene expression and to determine the anatomical specificity of TH gene regulation by ECS. Male Sprague-Dawley rats were divided into three groups: a) ECS group received isoflurane anesthesia followed by 120 volts for 1s delivered through ear clips; b) sham group received anesthesia followed by attachment of ear clips with no electricity; c) control group received no anesthesia or ECS-related manipulation. Treatments were administered daily for 10 days. Rats were sacrificed 24h after the last treatment and coronal tissue sections of the LC and substantia nigra (SN) were processed for *in situ* hybridization. Multiple ECS produced an 80% increase in TH mRNA and a 32% increase in NPY mRNA in the LC ($p < 0.05$). No change in TH mRNA was observed in the pars reticulata or pars compacta of the SN of rats that received ECS. These results indicate that ECS selectively increases TH mRNA concentrations in the noradrenergic LC and, in addition, demonstrates that gene expression for the coexisting peptide, NPY, can be similarly regulated by ECS. LOCUS COERULEUS LESION REDUCES TYROSINE HYDROXYLASE IMMUNOREACTIVITY AND mRNA LEVELS IN RAT SUBSTANTIA NIGRA. Y. Watanabe*, G. Bing, Y. Zhang, B.S. McEwen and E.A. Stone Lab. of Neuroendocrinology, the Rockefeller University and Department of Psychiatry, NYU Medical Center, NY, NY.

Recent work has suggested that the noradrenergic (NA) system is involved in long term adaptive responses of the central nervous system to stress. It has also been found that the dopaminergic (DA) system may play an important role in the stress response of the CNS. A number of studies have shown the interrelations between these two systems. Since NA projections from the locus coeruleus (LC) to the substantia nigra (SN) are predominantly unilateral, the present study was designed to futher elucidate the NA-DA relationship by assessing the effects of unilateral lesions of the LC on DA containing neurons in the SN. Unilateral LC lesions were produced stereotaxically by injection of 2 μl (2μg/μl) 6-OHDA into the right LC. Seven days after the lesion, the animals were injected with yohimbine (5mg/kg) to release NA from non-lesioned terminals, so as to accentuate the difference in NA function between the two sides. Animals were sacrificed after 2 hours. Immunohistochemical assay using a monoclonal antibody against tyrosine hydroxylase (TH) revealed marked reduction in immunoreactivity in the SN on the side of LC lesion compared to the intact side. In situ hybridization using oligonucleotide probes from TH cDNA also demonstrated a significant reduction of TH mRNA in the ipsilateral SN. These reductions were especially dramatic in the anterior portion of the SN pars compacta. Thus, the NA system may exert a supportive and facilitative effect on DA substantia nigra neurons. EFFECTS OF PREFRONTAL CORTICAL LESIONS ON TYROSINE HYDROXYLASE GENE EXPRESSION IN MIDBRAIN DOPAMINE NEURONS. H. E. Nye and A. Y. Deutch*. Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06508, and VA Medical Center, West Haven, CT 06516.

Retrograde tracer studies have demonstrated innervation of the ventral tegmental area (VTA) from a variety of sites, including the medial prefrontal cortex (PFC). In particular, the infralimbic (IL) and ventral prelimbic (PL) parts of the PFC project to the VTA. Both of these PFC areas increase Fos expression in response to stress, while other afferents to the VTA do not. Since stress increases dopamine (DA) metabolism and release in the PFC and VTA, and since ibotenic acid lesions of the PFC prevent the stress-induced increase in DA release in subcortical sites, similar lesions may decrease functional activity of certain midbrain DA neurons and may alter tyrosine hydroxylase (TH) gene expression. We therefore examined the effects of PFC lesions on TH mRNA in the VTA. The IL and PL were lesioned by microinjection of NMDA; NMDA lesions of the parietal cortex and sham-operated animals served as two types of controls. Animals survived for either 5-6 or 21-22 days before being sacrificed. TH mRNA was determined by Northern blots.

Lesions of the PFC involved the IL and ventral PL in all cases; in some cases lesions extended dorsally. Lesions of the PFC did not appear to alter TH mRNA in the total VTA (21 days survival). *In situ* hybridization studies are in progress to determine if PFC lesions alter TH mRNA in a restricted portion of the VTA, i.e., in those cells projecting to the PFC. Supported by MH-45124, TG GM-07324, and the VA National Centers for Schizophrenia and PTSD at the West Haven VA Medical Center.

EFFECT OF STRIATAL CELLS ON TYROSINE HYDROXYLASE GENE EXPRESSION IN CULTURED MESENCEPHALIC DOPAMINE NEURONS. Y. Solberg*, Y. Pollack and W.F. Silverman. Units of Morphology and Microbiology & Immunology, Corob Center for Health Sciences, Ben-Gurion University of the Negev, Beer Sheva, Israel.

Our previous work has shown a temporal correlation between establishment of dopaminergic mesostriatal connections and an increase in the expression of the tyrosine hydroxylase (TH) gene in selected portions of the substantia nigra (SN). We have prepared cultures of embyonic mesencephalon as well as co-cultures with embryonic neostriatal cells to test whether the presence of the striatal cells is required to produce this effect on TH gene expression. Mesencephalic and striatal cells were obtained by microdissection from E15 stage rat embryos and were cultured as pure mesencephalic cells or together with the striatal cells. Processes were first observed at about 48 hours extending from putative neurons within the cultures, and continued to increase with time, most dramatically in the co-cultures. *In situ* hybridization using a ^{35}S-labeled RNA probe complementary to TH mRNA was performed on 2, and 6 day old cultures. The amount of signal in selected, labeled neurons was quantified as autoradiographic grains per cell area. No difference was observed in TH gene expression in the pure SN cultures between 2 and 6 days. Cells from 2 day old co-cultures exhibited a higher amount of TH mRNA than their pure SN cultured counterparts, while at 6 days, this difference was yet more pronounced. These data support a role for the striatum on TH gene expression in mesencephalic dopamine neurons which project to it. Supported by Israel Academy of Science and Humanities Grant ## 285-90.

FOUR TYPES OF TYROSINE HYDROXYLASE mRNA TRANSCRIPTS ARE EXPRESSED IN ADULT AND IN FETAL MONKEY BRAINS OF DIFFERENT DEVELOPMENTAL STAGES. S.-Y. Tam*, J.D. Elsworth, D.E. Redmond, Jr., S.J. Galli, and R.H. Roth. Depts. of Pathology, Beth Israel Hospital and Harvard Med. Sch., Boston, MA 02215 and Depts. of Pharmacology and Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06510.

Tyrosine hydroxylase (TH) is encoded by a single gene in humans, but four distinct mRNA transcripts are generated by alternative splicing from a single transcript. In monkeys, two types of TH mRNA and protein isoforms have been reported to exist in the brain. As part of our effort to study the development of mesencephalic dopamine (DA) neurons in the primate, we have examined the expression of TH mRNA transcripts in brains of embryonic, fetal and adult African green monkeys. Total RNAs extracted from adult monkey tissues and fetal brains of 42, 59, 81, 91, and 150 days after gestation were reverse transcribed and the cDNAs were further amplified by PCR techniques using a pair of primers based on human TH sequences. In adult monkeys, four distinct PCR fragments corresponding to each of the four types of TH transcripts were detected in adrenal medulla and in midbrain regions such as the substantia nigra and the ventral tegmental area. The observed sizes of these PCR products were identical to those predicted for different human TH mRNA subtypes. DNA sequencing of these PCR fragments is in progress. In developing fetal monkey brains, TH transcripts were barely detectable at 42 and 59 days, but at 81, 91, and 150 days after gestation, four types of TH mRNA species were detected in the midbrain regions. In contrast to previous findings, these results indicate a lack of divergence in TH mRNA splicing pattern among primates, and that in the monkey, four types of TH mRNA transcripts are present in brains of both the adult and the developing fetus. Experiments are in progress to study the expression of some of the neurotrophic factors and their receptors whose actions may influence the development of the mesencephalic DA neurons. Supported by AI-22674, AI-23990, MH-14092 and the Axion Research Foundation.

MULTIPLE ISOFORMS OF TYROSINE HYDROXYLASE ARE SPECIFIC TO PRIMATES, BUT ONLY HUMANS HAVE FOUR ISOFORMS. John W. Haycock*. Dept. Biochem. & Molec. Biol., Louis. State Univ. Medical Center, New Orleans, LA 70119

Tyrosine hydroxylase (TH) is encoded by a single gene in all species studied to date. In subprimates, TH is synthesized from a single form of mRNATH. In humans, however, alternative splicing results in four mRNATH species--recently shown to be translated *in vivo* by the identification of all four TH protein isoforms (Types 1-4) in human adrenal medulla using isoform-specific anti-peptide antibodies. These antibodies have been used here in Western blots of mammalian adrenal samples to determine the evolutionary appearance and development of multiple TH isoforms.

Antibodies to Type 1 TH (-EAIMS^{31}PRF-) labeled a ~62 kDa band in all mammalian species tested except mouse, rat and hamster. Rodents have a slightly different amino acid sequence (-EAVTS^{31}PRF-) although, notably, guinea pig TH reacted with the Type 1 antibodies. The ~62-64 kDa Type 2 band was not detected in subprimates. Among primate species, Type 2 was present in members of Anthropoidea (humans, great apes, Old World and New World monkeys) but not Prosimii (5 species from 3 families). By contrast, Types 3 and 4 TH (66 kDa) were detected only in humans--both in adrenal medulla and brain. Neither a sensitive pan-specific antibody nor the isoform-specific antibodies detected the presence of these higher M, isoforms even after partial purification of monkey TH. Thus, one splicing variant (Type 2) arises with, and is expressed throughout, Anthropoidea whereas the additional splicing event that produces Types 3 and 4 occurs uniquely in humans.

GENERATION OF STATE-SPECIFIC ANTIBODIES TO A SEGMENT OF TYROSINE HYDROXYLASE (TH). J.Y. Lew, K.Y. Lee, M. Goldstein* and A. Y.Deutch. Neurochem. Res. Lab., N.Y. Univ. Med. Ctr., N.Y., N.Y. 10016 and Dept. Psychiatry, Yale Univ. Med. Sch., New Haven, CT. 06508

Previously we have reported that antibodies to a synthetic peptide, TH-16, corresponding to a serine (Ser)-40-containing segment of TH recognize catecholaminergic neurons and processes in the CNS (Lee, K.Y. et al., J. Neurochem. 53:1238-44, 1989). We have now generated and characterized polyclonal antibodies to TH-16 phosphorylated at Ser-40 by protein kinase A and designated them as anti-pTH-16. Anti-pTH-16 recognize the phosphorylated, but not the nonphosphorylated state of TH. Thus, a positive ELISA response against phosphorylated TH purified from PC12 cells and a negative response against the nonphosphorylated enzyme were obtained. Immunoprecipitation of TH with anti-pTH-16 results in a decrease of TH activity of the phosphorylated form, but not of the nonphosphorylated. Immunohistochemical studies reveal that anti-pTH-16 recognizes norepinephrine neurons in the locus coeruleus, as well as noradrenergic and adrenergic neurons of the ventrolateral medulla. It also recognizes a small subset of midbrain dopamine (DA) neurons, staining some neurons in the nucleus interfascicularis of the ventral tegmental area and in the posterior aspects of the A10 cell group. However, other DA neurons including the A9 (SN) and A8 (retrorubral field) cell groups were not, or very weakly, immunoreactive. In the forebrain there was weak or absent staining in the neostriatum and in the cerebral cortex. These results suggest that the phosphorylated form of TH recognized by anti-pTH-16 is present in relatively high concentrations in noradrenergic, but in low abundance in dopaminergic cells. These studies were supported in part by NIMH 43230 and NIMH 45124.

DELINEATION OF CNS AND PNS DNA RESPONSE ELEMENTS RESPONSIBLE FOR CELL-TYPE SPECIFIC EXPRESSION OF TYROSINE HYDROXYLASE. Y.J. Oh*, S.C. Wong, M. Moffat, D. Ullrey+, A.I. Geller+ and K.L. O'Malley. Dept. of Anat.& Neurobiol., Wash. U. Sch. of Med., St. Louis, MO 63110; +Div. of Endocrinology, Children's Hospital Boston, MA 02115.

In order to define cell-type specific elements that regulate expression of the tyrosine hydroxylase (TH) gene, we are using a defective Herpes Simplex Virus-1 vector system to deliver genes into both PNS and CNS neurons in primary culture. Deletion mutants of the rat TH promoter region were subcloned in front of the reporter gene, lacZ, and then packaged into viral particles. In preliminary studies, viral particles containing 685 bp of the TH promoter were used to infect primary neuronal cultures prepared from superior cervical and dorsal root ganglion in the PNS as well as mesencephalic and corpus striatal neurons in the CNS. One day after infection, expression of β-galactosidase was visualized by X-gal histochemistry. β-galactosidase activity was observed predominantly in the TH-expressing superior cervical ganglion neurons but infrequently in dorsal root ganglion neurons. In contrast, both mesencephalic and corpus striatal neurons showed a relatively similar level of β-galactosidase expression. These results seem to indicate that 685 bp of the rat TH promoter contain sufficient information for cell-type specific expression in the PNS, but not in CNS neurons. Experiments using other deletion mutants are being investigated to further delineate these elements. In the future, such sequences may aid in the targeting of relevant gene products in clinical models of catecholamine dysfunction.

PRESENCE OF TYROSINE HYDROXYLASE mRNA IN THE CEREBELLUM AND PITUITARY NEUROINTERMEDIATE LOBE OF ADULT RATS: POSSIBLE AXONAL LOCALIZATION. K.R. Melia*, A. Trembleau, P.P. Sanna, and F.E. Bloom. Neuropharmacology, Scripps Res. Inst., La Jolla, CA 92037.

Although both the cerebellum (CB) and the neurointermediate lobe (PIT) are densely innervated by catecholaminergic fibers, catecholamines or their biosynthetic enzymes have not been previously detected in the perikarya of adult CB or PIT tissue. However, we have recently detected mRNA for the biosynthetic enzyme, tyrosine hydroxylase (TH), in CB and PIT of adult male Sprague Dawley rats. Total RNA was extracted from these regions using a GIT/CsCl gradient. TH mRNA was first converted into single stranded cDNA using a specific downstream primer and then subjected to polymerase chain amplification (PCR) in the presence of oligo primers 5' and 3' to TH introns 11 and/or 12. PCR products were resolved by agarose gel electrophoresis, transferred to nylon membranes and probed with a ^{32}P-labeled oligo complementary to nucleotides 1233-1267 of the TH cDNA. Specific amplification products ranging in size from 127-429 bases were produced when various combinations of 4 different primers were used. Because the primers recognized sequences lying on different exons, products amplified from genomic DNA vs cDNA could be easily distinguished. The origin of TH mRNA in these regions is presently unknown. Based on preliminary non-radioactive in situ hybridization experiments it is possible that this message is contained within axons innervating these structures. Studies are in progress to evaluate the validity of this hypothesis and to examine whether levels of TH mRNA in the CB or PIT can be regulated by pharmacological stimuli.

IONIC FACTORS AFFECTING THE INTERACTION BETWEEN SOLUBLE TYROSINE HYDROXYLASE AND CHROMAFFIN GRANULE MEMBRANES. K.Morita* and H.Houchi. Dept. of Pharmacol., Tokushima Univ. Sch. of Med., Tokushima 770, Japan.

Tyrosine hydroxylase has previously been shown to be reversibly associated with chromaffin granule membranes under the experimental conditions which may approximate the intracellular environment of the resting cell. This enzyme has therefore been considered to be localized in association with the surface of the granules within the adrenal medulla cell. In the present study, the effects of ions and pH on the interaction of the soluble enzyme with the granule membranes were studied to elucidate an influence of the cytoplasmic environment alterations on the subcellular localization of the enzyme. The enzyme-membrane interaction was inhibited by elevating the Na+ concentration, but this interaction was not affected by increasing the Ca2+ concentration and the ATP level, or lowering pH in the mixture. These findings suggest that the association of tyrosine hydroxylase with chromaffin granules may be modulated by a rise in the Na+ level in the cell cytoplasm, thus proposing the possibility that stimulation of the cell may induce an alteration in the subcellular localization of the enzyme as a consequence of modulating the cytoplasmic ionic environment.

SEROTONIN RECEPTORS: BEHAVIORAL ACTIONS

579.1

FURTHER EVIDENCE FOR 5-HT-1C MEDIATED POTENTIATION OF APOMORPHINE-INDUCED LOCOMOTOR ACTIVITY. P.B. Hicks*, R.J. Zavodny and K.A. Young. Department of Psychiatry, Scott and White Clinic; Department of Medical Pharmacology and Toxicology and Department of Medical Anatomy & Neurobiology, Texas A&M College of Medicine, Temple, Texas 76508.

As reported previously (S. Neurosci. Abstr. 17, 407), the 5-HT-1C/2 antagonist mesulergine potentiated apomorphine-induced locomotor activity (AILA) at a low dose that had no effect on spontaneous locomotor activity. DOI, which has high affinity for 5HT-1C receptors as an agonist, reversed this potentiation. The current study further characterizes this putative 5HT-1C effect. Doses of mesulergine significantly lower than the AILA potentiating dose of 0.1 mg/kg SC had no effect on AILA, while mesulergine doses including and higher than 0.5 mg/kg supressed AILA. This information suggests that mesulergine maximally potentiates AILA between 0.05 and 0.3 mg/kg. The 5-HT-2 receptor antagonists ketanserine and MDL 100,907, tested over a wide range of doses, suppressed AILA at higher doses but did not potentiate AILA at low doses. Furthermore, DOI did not block suppression of AILA by the relatively specific 5HT-2 receptor antagonist MDL 100,907. These findings provide further evidence that mesulergine's potentiation of AILA is a 5HT-1C mediated effect and suggest an important modulatory role for 5HT-1C receptors in motor behaviors associated with DA neurotransmission.

579.2

EVIDENCE OF PRE OR POST-TRAINING ACUTE ADMINISTRATION OF 8-OH-DPAT IN ASSOCIATIVE LEARNING. A. Meneses* and E. Hong. Sección de Terapéutica Experimental,Departamento de Farmacología y Toxicología, CINVESTAV-IPN, México,D.F.

Diverse evidences suggest a role for 5-HT_{1A} receptor agonists in learning and memory. In the present work, it was determined the pre or post-training injection (ip) of 8-OH-DPAT (DPAT) on autoshaping lever press response, a model for associative learning. Animals were individually trained to find 15 US in the food magazine. Once that the animal ate the USs, one session began. Each session consisted of 20 trials and each trial consisted of illumination of a retractable lever for 8 sec (conditioned stimulus, CS) followed by the delivery of a food pellet (unconditioned stimulus, US) each 60 sec. If the animal pressed the lever (conditioned response, CR) the trial was shortened and the lever was retracted, the light was turned off and US was delivery. The results showed that DPAT improved the consolidation of CR when this was injected post-training, but impaired it when administered before training. Both effects were time-dependent. When DPAT was injected pre or post--training to free-feeding or pre-feeding rats, they did not learn the CR. When DPAT was administered to overtrained animals (90-100% of CR), the compound did not elicit any effect. These results strongly suggest an effect of DPAT on the consolidation of learning. The pre-training administration impaired the learning but also the food intake and exploration.

579.3

THE INTERACTION OF 5-HT_{1A} AND 5-HT_2 RECEPTORS IN THE RAT MEDIAL PREFRONTAL CORTEX: BEHAVIORAL STUDIES.
Martin I. Granoff,* Chau Lee, Adrian Jackson, Kavin Patel, Yanira Martinez, Charles R. Ashby, Jr. and Rex Y. Wang. Dept. of Psychiatry and Behavioral Sciences, SUNY at Stony Brook, Stony Brook, NY 11794.

A recent iontophoretic study indicated that there is an interaction between 5-HT_{1A} and 5-HT_2 receptors at the neuronal level in the medial prefrontal cortex (mPFc). In this study, we examined the head-twitching (HTW) response produced by injection of 5-HT_2 receptor agonists directly in the mPFc of freely moving, male Sprague-Dawley rats. One week prior to testing, bilateral cannula were implanted in the mPFc. Local injection of (-)DOB (1-4 µg in 1 µl each side), but not saline, dose-dependently increased the HTW. (-)DOB-induced HTW was prevented completely by the pretreatment with ritanserin (1mg/kg ip.). The effect of DOB is stereospecific, i.e. (-)DOB is much more potent than (+)DOB in eliciting HTW. The rank order of potency of various compounds tested is: (-)DOB ≥ (+)LSD > (+)DOB > lisuride = BL3912A. As a control, a group of animals were injected with (-)DOB in the ventral tegmental area. These animals exhibited no significant increase in HTW above the saline baseline, suggesting that the HTW induced by (-)DOB in the mPFc is not a result of drug-diffusion to the brainstem. To examine the effect of the 5-HT_{1A} agonist 8-OH-DPAT on (-)DOB-induced HTW, groups of rats were pretreated with increasing i.p. doses of 8-OH-DPAT 30 minutes prior to a 4 µg intracranial injection of (-)DOB. A dose-dependent supression of (-)DOB induced HTW was observed. These results, taken together, suggest that 5-HT_2 receptors in the mPFc may be important in the HTW response. This supports the hypothesis that there is a 5-HT_{1A} and 5-HT_2 receptor interaction in the mPFc. (Supported by USPHS grants MH-41440 and DA-07193)

579.4

THE INTERACTION OF 5-HT_{1A} AND 5-HT_2 RECEPTORS IN THE RAT MEDIAL PREFRONTAL CORTEX: IONTOPHORETIC STUDIES.
C.R. Ashby, Jr.* and Rex Y. Wang. Dept. of Psychiatry and Behavioral Sciences, SUNY at Stony Brook, Stony Brook, NY 11794.

Recent data obtained from behavioral and radioligand binding studies suggest that there is an interaction between 5-HT_{1A} and 5-HT_2 receptors in the rat brain. In this study, we examined the interaction between 5-HT_{1A} and 5-HT_2 receptors in the medial prefrontal cortex (mPFc) of anesthetized, male Sprague-Dawley rats. This was accomplished using the techniques of single cell recording and iontophoresis. The iontophoresis of the 5-HT_{1A} receptor agonist 8-hydroxy-di-n-propyl-aminotetralin (DPAT) produced a current-dependent suppression of mPFc cell firing. This effect was selectively antagonized by the 5-HT_{1A} antagonist NAN-190 but not by the antagonists eticlopride (D_2), atenolol (ß), prazosin (α_1), idazoxan (α_2), granisetron (5-HT_3) or SR 95103 ($GABA_A$). The suppressant action of DPAT was prolonged and potentiated by the iontophoresis of the 5-HT_2/5-HT_{1C} receptor antagonist ritanserin and the selective 5-HT_2 antagonist (+)-MDL 11,939. The systemic administration of ritanserin (0.1-0.5 mg/kg, i.v.) also potentiated and prolonged DPAT's action. In contrast, neither the iontophoretic nor systemic (0.1-0.5 mg/kg, i.v.) application of granisetron potentiated or prolonged DPAT's suppressant action. The iontophoresis of a low current of the 5-HT_2/5-HT_{1C} agonist (±)-DOI potentiated L-glutamate (GLU)-induced excitation of mPFc cells. This effect was significantly attenuated by the coiontophoresis of DPAT at currents that had little or no effect on L-GLU-induced excitation alone. Overall, these results indicate that there is an interaction between 5-HT_{1A} and 5-HT_2 receptors at a neuronal level.

579.5

CHARACTERIZATION OF PHOSPHOINOSITOL PHOSPHATE ACCUMULATION INDUCED BY THE 5-HT_3 RECEPTOR AGONIST 2-METHYL-5-HT.
R.Y. Wang,* C.R. Ashby, Jr. and E. Edwards. Department of Psychiatry and Behavioral Sciences, SUNY at Stony Brook, Stony Brook, NY 11794.

The aim of the present study was to examine the effect of manipulations of calcium (Ca^{++}) concentrations and activation of protein kinase C (PKC) on 2-methyl-5-HT-induced phosphoinositide (PI) hydrolysis in the rat medial prefrontal cortex. The omission of added Ca^{++} from the Krebs incubation medium significantly reduced the ^{3}H-inositol phosphate accumulation from pre-labelled phospholipids (from 41 ± 3% to 23 ± 1% above baseline level). Removal of Ca^{++} by pre-incubation with EGTA (0.5 mM) as well as the addition of the calcium channel blocker Lanthanum (10 µM) abolished the 2-methyl-5HT-stimulated PI response. By contrast, the calcium ionophores A 23187 and ionomycin stimulated PI hydrolysis and their effect was additive to that of 2-methyl-5-HT.

The increase in phosphoinositide hydrolysis induced by 2-methyl-5-HT was dose-dependently inhibited by phorbol dibutyrate (PDBu) and phorbol myristate acetate (PMA), but not by an inactive isomer 4α-phorbol, indicating that the activation of PKC may provide negative feedback to the PI response induced by 2-methyl-5-HT. The effect of PDBu on 2-methyl-5-HT stimulated PI metabolism was reversed by the PKC inhibitors staurosporine, calphostin and chelerythrine (10 µM) respectively. However, pertussis toxin (0.5 & 1 µg) had no effect on 2-methyl-5-HT stimulated PI hydrolysis suggesting that this response is not associated with the G_i or G_0 GTP binding protein. In conclusion, these results suggest that 2-methyl-5HT stimulated PI turnover is a Ca^{++}-dependent process. Furthermore, the process is subjected to a negative feedback inhibition via PKC. (Supported by USPHS grants MH-41440 and DA-07193).

579.6

FOOD INTAKE, LOCOMOTOR AND TEMPERATURE EFFECTS OF 5-HT_3 ANTAGONISTS AND AGONISTS.
Pascale Mazzola-Pomietto, Charanjit S. Aulakh, Mary E. Michel*, and Dennis L. Murphy. Lab. of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

We studied the effects of various doses (0.1, 1.0 and 10.0 mg/kg) of MDL-72222 (a 5-HT_3 antagonist) and 1-(m-chlorophenyl)-biguanide (a 5-HT_3 agonist) on food intake using food-deprived paradigm, locomotor activity and rectal temperature in male Wistar rats.

Administration of MDL-72222 produced dose-dependent suppression of food intake. However, statistically significant decreases were observed with 1.0 and 10.0 mg/kg doses but not with 0.1 mg/kg dose. On the other hand, only the highest dose (10.0 mg/kg) of MDL-72222 produced significant decreases in locomotor activity. Administration of various doses of 1-(m-chlorophenyl)-biguanide did not have any significant effect on food intake except for a small (24%) nonsignificant decrease at the highest dose (10 mg/kg) during the first hour. However, there was a significant increase (56%) in food intake during 1-4 hours with the highest dose only. These findings suggest that the locomotor effects of the 5-HT_3 antagonists and agonists may partially contribute to their effects on food intake. We will also present data on changes in rectal temperature following administration of various doses of 5-HT_3 antagonists and agonists.

579.7

HINDLIMB SCRATCHING IN RATS DICRIMINATES AMONGST SUMATRIPTAN AND OTHER 5-HT1D AGONISTS.
J.M. Palacios*, C. Salcedo, J. Puig, R.W. Gristwood and A.G. Fernández. Research Institute, Laboratorios Almirall, Cardener, 68-74. 08024 BARCELONA (Spain).

There is a lack of reliable animal models to screen in vivo 5-HT1D ligands. Recently, the hindlimb scratching (HS) induced by serotonergic compounds in rats has been suggested to involve peripheral 5-HT1D-like receptors although no selective 5-HT1D ligands were used. We have compared the HS inducing properties of the non-selective 5-HT1D agonists: 5-carboxamidotryptamine (ED50 mg/kg s.c.; 5-CT=5.1), 5-methoxytryptamine (5-MeOT=3.5) and ergotamine (ERG=0.4), with those of the selective 5-HT1B and 5-HT1D agonists, CP-93129 (CP= no effect up to 50) and sumatriptan (SUM = no effect up to 50). Pretreatment with ERG (0.1-0.3 mg/kg s.c.) and, surprisingly, SUM (20-50 mg/kg s.c.), but not CP, potentiated significantly the HS induced by submaximal doses (2.5-5 mg/kg) of 5-MeOT. Both direct and potentiated responses were inhibited by methiotepin (0.1-1 mg/kg s.c.).

Involvement of 5-HT1A, 5-HT1C and 5-HT2 receptors on HS induction was excluded previously 1 . CP inactivity indicates that 5-HT1B receptors are also not involved. Results obtained suggest that receptors mediating HS may be different to those recognized by SUM in bovine caudate and vascular tissue and that they can be positively modulated by a SUM-sensitive receptor.

579.8

ADAPTATION OF DOI-INDUCED EAR-SCRATCH RESPONSE FOLLOWING ACUTE AND REPEATED ADMINISTRATION OF DOI AND KETANSERIN.
N. A. Darmani*. Department of Pharmacology, KCOM, MO 63501.

The 5-$HT_{2/1C}$ selective agonist DOI can produce both the head-twitch (HTR) and the ear-scratch response (ESR) in mice. Effects of withdrawal following acute and repeated administration of DOI and ketanserin on DOI-induced ESR was subject of this study.

In acute studies mice were treated with either a single injection of DOI (2.5 mg/kg) or ketanserin (1 mg/kg). In chronic studies different groups of mice were treated once daily with the cited doses of DOI (4 or 13 days) or ketanserin (5 days). Different groups of mice were challenged with DOI at different time intervals after cessation of acute or chronic treatments and the ESR was scored for 20 min following DOI injection. DOI administered 24h following its first injection reduced the ESR frequency by 80-97% but had no effect when the time lag between the first and second dose was greater than 72h. A single injection of ketanserin reduced (51%) the DOI-induced ESR 120h following its injection. Chronic DOI treatment reduced the ESR score by 80-97% throughout the treatment schedule. Following cessation of such treatment, the ESR score returned to control level in a time dependent manner. Repeated ketanserin treatment significantly reduced ESR score by 46% when tested 24-48h following cessation of antagonist treatment. These results suggest that serotonergic drugs may have the ability to change independently 5-HT receptor sensitivity and density.

579.9

EVIDENCE FOR INVOLVEMENT OF 5-HT_{1C} and 5-HT_2 RECEPTORS IN THE FOOD INTAKE SUPPRESSANT EFFECTS OF 1-(2,5-DIMETHOXY-4-IODOPHENYL)-2-AMINOPROPANE (DOI). James L. Hill, Charanjit S. Aulakh, Audrey Reid*, and Dennis L. Murphy. Lab. of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

We studied the effects of various 5-HT receptor subtype selective antagonists on DOI-induced decreases in food intake using the food-deprived paradigm in male Wistar rats. The effects of the antagonists when administered alone were also examined. Administration of DOI to rats produced dose-related decreases in one-hour food intake. Pretreatment with spiperone (5-HT_{1A}/5-HT_2/D_2 antagonist), propranolol or CGP361A (β-adrenoceptor antagonists that also have binding affinities for 5-HT_{1A} and 5-HT_{1B} sites) and MDL-72222 (5-HT_3 antagonist) did not attenuate DOI-induced suppression of food intake. In contrast, pretreatment with metergoline (5-HT_1/5-HT_2 antagonist) completely blocked whereas mesulergine, mianserin and ritanserin (5-HT_{1C}/5-HT_2 antagonists) partially blocked DOI's effect on food intake. On the other hand, pretreatment with MDL-72222 but not with m-chlorophenylpiperazine (m-CPP) significantly potentiated DOI-induced suppression of food intake. Furthermore, the food intake suppressant effects of various doses of DOI were found to be similar in the Fawn-Hooded (FH) rat strain as compared to the Wistar rat strain. These findings suggest that DOI-induced suppression of food intake is mediated by stimulation of both 5-HT_{1C} and 5-HT_2 receptors.

SEROTONIN: RECEPTOR MODULATION

580.1

5-HT_3 RECEPTORS ALTER THE REPETITIVE FIRING ACTIVITY IN VAGAL MOTONEURONS THROUGH MODULATION OF T TYPE CALCIUM CHANNELS. C.L. McNair* and M.S. Dekin, School of Biological Sciences, University of Kentucky, Lexington, KY 40506-0225.

In a previous study, we demonstrated that serotonin (5-HT) reduces spike frequency adaptation (SFA) and increases the post-burst hyperpolarization (PBH) observed in motoneurons from the dorsal motor nucleus (DMX) of the vagus nerve (McNair and Dekin, *Neurosci. Abstr.*, 17: 545.9, 1991). In this report, we have used a brainstem slice preparation (400 um thick) from adult guinea pigs to study the specific serotonergic receptor subtype responsible for this effect. Bath applied quipazine dimaleate (50 uM), an agonist for 5-HT_1 and 5-HT_2 receptors, did not effect either SFA or the PBH. In addition, serotonergic modulation of SFA and the PBH were not affected by the 5-HT_1 and 5-HT_2 antagonist cyproheptadine HCl (40 uM). 2-methyl-serotonin maleate (2-M-5-HT) (50 uM), a selective agonist for 5-HT_3 receptors, reduced SFA and increased the PBH with a similar magnitude and time course of action as 5-HT. Both the 5-HT and 2-M-5-HT reduction of SFA and augmentation of the PBH were effectively blocked by the selective 5-HT_3 antagonist MDL 72222 (30 uM). We have also attempted to further characterize the ionic mechanism underlying the action of 5-HT. Addition of 200 uM Ni^{++} to the bath had no effect on SFA or the PBH in control solutions but did block the effects of 5-HT and 2-M-5-HT. In contrast, 200 uM Cd^{++} in the bath completely eliminated SFA and the PBH. In the presence of both 5-HT and Cd^{++}, SFA and the PBH returned. These data suggest that 5-HT modulates the repetitive firing activity of vagal motoneurons through a 5-HT_3 receptor subtype acting on a Ni^{++} sensitive conductance such as T-type calcium channels. (Supported by NIH grants HL40369, HL02314, and RR07114).

MDL 100,907, A POTENT AND SELECTIVE 5-HT_2 ANTAGONIST WITH AN ATYPICAL NEUROLEPTIC PROFILE. S.M. Sorensen*, C.J. Schmidt, T. M. Humphreys, and J.H. Kehne Marion Merrell Dow Research Inst., Cincinnati, OH 45215

Progress toward understanding the role of the 5-HT_2 receptor in the therapy for schizophrenia has been hampered by the lack of agents with high selectivity for this receptor. Here we report on MDL 100,907 (R(+)-a-(2,3-dimethoxyphenyl)-1-[2-(4-fluoro-phenylethyl)]-4-piperidine-methanol), an extremely potent 5-HT_2 antagonist (Ki=0.4 nM) with a 300 fold or greater selectivity for the 5-HT_2 receptor over the 5-HT_{1c}, D_2 and other receptors (Carr et al., 1990). In order to characterize the contribution of 5-HT_2 antagonism to antipsychotic activity, we compared MDL 100,907 with haloperidol (HAL) and clozapine (CLOZ) in behavioral, electrophysiological, and neurochemical models predictive of antipsychotic potential and extrapyramidal side effect liability. Only MDL 100,907 blocked amphetamine (AMP)-stimulated locomotion in mice without antagonizing apomorphine-stimulated climbing. In acute recordings from A10 and A9 dopamine (DA) neurons, MDL 100,907 and CLOZ blocked the AMP-induced slowing of A10 neurons but caused only small increases in the number of spontaneously active DA neurons. Chronically, MDL 100,907 and CLOZ selectively reduced the number of active A10 neurons. HAL reduced these in both A9 and A10 brain regions. HAL produced marked changes in DOPAC and HVA in the A9 and A10 regions but MDL 100,907 and CLOZ had no significant effect on DA turnover. Following pretreatment with amfonelic acid (AFA), HAL caused massive increases in DA turnover whereas CLOZ or MDL 100,907 produced no such increase. The results indicate that MDL 100,907 has a profile which is similar to the atypical antipsychotic CLOZ. Furthermore, since MDL 100,907 is an extremely selective 5-HT_2 antagonist with no measurable D_2 affinity , the data suggest that MDL 100,907's 5-HT_2 antagonism may be sufficient to explain its antipsychotic potential.

580.3

IN VIVO STUDIES ON THE REGULATION OF DOPAMINE RELEASE BY THE 5-HT_2 RECEPTOR ANTAGONIST, MDL 100,907. C.J.Schmidt*, C.K.Sullivan, V.L.Taylor and G.M. Fadayel. Marion Merrell Dow Research Institute, Cincinnati, OH 45215

In vivo microdialysis in awake-freely moving rats was used to study the influence of 5-HT_2 receptor blockade on the release of dopamine produced by the amphetamine analogue, 3,4-methylenedioxymethamphetamine (MDMA). Peripheral administration of the selective 5-HT_2 antagonist, MDL 100,907 (1mg/kg, s.c.) reduced the increase in extracellular concentrations of striatal dopamine produced by MDMA (20 mg/kg, s.c.) by 46% ($P<0.05$). This occurred in the absence of any effect of the antagonist on basal dopamine efflux. To determine the location of the 5-HT_2 receptors involved in this effect, MDL 100,907 was infused into the striatum via the dialysis probe at 0.1 and 1.0 μM. Direct infusion of the antagonist resulted a concentration-dependent reduction in the efflux of dopamine produced by peripheral administration of MDMA (57% at 1.0 μM, $P<0.05$). In contrast, superfusion of striatal slices with 1.0 μM MDL 100,907 had no effect on the MDMA-induced release of preloaded [^{3}H]dopamine. Subsequently, rats were implanted with dialysis probes in both the substantia nigra and striatum to allow infusion of MDL 100,907 directly into the cell body region while measuring dopamine efflux in the striatum. Under these conditions, 1.0 μM MDL 100,907 was without effect on MDMA-induced dopamine release. These results suggest that striatal 5-HT_2 receptors can regulate the increase in dopaminergic activity produced by indirect agonists such as MDMA.

580.4

α_{2A}-HETEROCEPTORS AND 5-HT_{1B} AUTORECEPTORS MEDIATE THE OXYMETAZOLINE-INDUCED SUPPRESSION OF RAT VENTRAL HIPPOCAMPAL 5-HT RELEASE *IN VIVO*. *S. Hjorth* and R. Tao, Department of Pharmacology, University of Göteborg, Medicinareg. 7, S-413 90 Göteborg, SWEDEN*

There is evidence that both 5-HT_{1B} autoreceptors and α_2-heteroceptors participate in the control of transmitter release from 5-HT nerve terminals *in vivo* (Hjorth & Tao, EJP **209**: 249, 1991; Tao & Hjorth, NSAP **345**: 137, 1992). However, the subtype of α_2-adrenoceptor involved in this action has not been defined. We have used the α_{2A}-adrenoceptor selective agonist oxymetazoline (OXY) to further characterize the mechanism(s) regulating 5-HT release *in vivo*. The studies were carried out by means of *in vivo* microdialysis (probes placed in the ventral hippocampus) in chloral hydrate-anaesthetized male S-D rats (250-350 g). Drugs were introduced via the perfusion medium after a control period of 2-3h (to establish stable baseline 5-HT output). OXY (0.3-10 μM) concentration-dependently suppressed the 5-HT output (max. drop ≈ 40-50%). The effect of OXY (10 μM) was abolished by co-perfusion with the 5-HT_{1B} receptor blocker methiothepin (1 μM) plus the non-selective α_2-adrenoceptor blocker idazoxan (10 μM), but at best partly antagonized by either drug given alone. The α_{2B}-adrenoceptor antagonist prazosin (10 μM) did not affect the OXY response. The OXY-induced reduction of the 5-HT release in rat ventral hippocampus *in vivo* appears to be due to the combined 5-HT_{1B} and α_2-adrenoceptor agonistic properties of the compound, thus supporting the idea that there is a functional synergism between 5-HT- and NA-mediated control of 5-HT release. In this regard, the results of the agonist-antagonist interaction experiments suggest that the α_2-adrenoceptors involved are α_{2A}-heteroceptors situated on the 5-HT neuronal terminals.

CHRONIC ADMINISTRATION OF THE 5-HT_{1A} RECEPTOR AGONIST 8-OH-DPAT PRODUCES DESENSITIZATION OF 5-HT_{1A} AUTORECEPTORS. I. Lucki* and D. S. Kreiss. Depts. of Psychiatry and Pharmacology, Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, PA 19104.

The function of 5-HT_{1A} autoreceptors was examined by measuring the ability of the 5-HT1A receptor agonist 8-OH-DPAT to reduce the release of serotonin (5-HT) in the striatum and the hippocampus using *in vivo* microdialysis. 5-HT release was measured in the ventral caudate nucleus and the ventral hippocampus of rats maintained under chloral hydrate anesthesia. Acute systemic administration of 8-OH-DPAT (1.0 mg/kg, s.c.) reduced the release of 5-HT in both the striatum and the hippocampus. Chronic treatment with 8-OH-DPAT (1.0 mg/kg, s.c.) for 7 days attenuated the effect of an acute challenge dose of 8-OH-DPAT in the striatum. Treatment with 8-OH-DPAT for 1 day did not significantly alter the effects of the agonist challenge on striatal 5-HT release. In contrast, the inhibition of 5-HT release in the hippocampus by 8-OH-DPAT was not altered by chronic treatment with the 5-HT_{1A} receptor agonist for 7 days. These results indicate that *in vivo* microdialysis can be used to study the effects of activation of 5-HT_{1A} autoreceptors on 5-HT release and the regulation of 5-HT release by chronic administration of psychoactive drugs. Moreover, this study indicates that the regulation of 5-HT release in different brain regions by 5-HT_{1A} autoreceptors may be selectively sensitive to regulation by chronic administration of the 5-HT_{1A} receptor agonist 8-OH-DPAT.

EFFECTS OF BMY 14802 ON RAT SOCIAL INTERACTION: EVIDENCE FOR 5-HT_{1A}-MEDIATED ANXIOLYTIC ACTIVITY.

Herbert L. Smith*, F. Fatima Matos, Frank D. Yocca, and Richard B. Carter, Department of Neuropharmacology, Bristol-Myers Squibb Pharmaceutical Research Institute, Wallingford, CT 06492.

The potential anxiolytic efficacy of BMY 14802 was determined in a modified rat social-interaction paradigm. Unfamiliar pairs of male rats were placed into a novel high-light arena. Locomotor activity was recorded concurrently with observation of socially-interactive behaviors (e.g., mutual grooming and sniffing, following). BMY 14802 (0.025-1.0 mg/kg, i.p.) produced dose-dependent increases in social exploration with minimal effect on locomotor activity. Increases were comparable to those produced by buspirone (0.025-1.0 mg/kg, i.p.). In rats undergoing withdrawal following cessation of subchronic diazepam treatment (10.0 mg/kg, i.p., *bid*, 7 days), buspirone (0.5 mg/kg, i.p.) failed to increase time spent in social interaction, whereas BMY 14802 (0.1 mg/kg, i.p.) and ondansetron (0.1 mg/kg, i.p.) retained their anxiolytic-like effects. In rats treated subchronically with diazapam, flumazenil (10.0 mg/kg, i.p.) decreased social interaction without affecting locomotor activity, indicative of an anxiogenic-like action. BMY 14802 (0.1 mg/kg, i.p.) increased time spent in social exploration under conditions of precipitated diazepam withdrawal. *In vivo* microdialysis was used to study the effects of BMY 14802 on neural activity. BMY 14802 (5.0-20.0 mg/kg, i.p.) and buspirone (1.0-5.0 mg/kg, i.p.) produced dose-related decreases in extracellular 5-HT levels in the hippocampus of awake rats. The decrease in 5-HT produced by BMY 14802 (10.0 mg/kg, i.p.) was blocked by infusion of 1.0 mM (-)pindolol into the dorsal raphe nucleus. These data indicate that BMY 14802 produces anxiolytic-like effects in the rat that are maintained under conditions of diazepam withdrawal; these effects may arise from weak partial agonist actions at 5-HT_{1A} receptors.

IMMUNOCHEMICAL CHARACTERIZATION OF RECOMBINANT MOUSE TRYPTOPHAN HYDROXYLASE EXPRESSED IN E. COLI.

D.H.Park*, D.M.Stone, K.S.Kim and T.H.Joh, Cornell Univ. Med. Coll., Burke Med. Res. Inst., White Plains, NY 10605.

Tryptophan hydroxylase (TPH) is the first and rate-limiting enzyme in serotonin biosynthesis. In order to produce the large quantity of purified TPH for the purpose of biochemical characterization and antibody production, recombinant DNA technology was used. In the present study a mouse cDNA containing the full coding region for TPH was cloned by the polymerase chain reaction, using poly A^+ RNA prepared from mouse dorsal raphe nuclei and oligonucleotide primers. The final construct was expressed in an expression plasmid under control of the tac promoter. Cultures of E.coli host strain MC 1061 were grown overnight in a liquid medium containing ampicillin, induced with 2 mM IPTG and pelleted by centrifugation. Large quantities of enzymatically active recombinant TPH were expressed in a highly insoluble form. However, more than 95% of total enzyme activity could be solubilized by lysis and repeated sonication. A band corresponding to TPH protein was eluted from SDS-polyacrylamide gels and extensively dialyzed to remove SDS. TPH protein eluted from the gel was injected subcutaneously into rabbits to raise specific antibodies. The magnitude of specific enzyme activity of recombinant TPH was similar to that of purified native enzyme. Western blot analysis indicated that the antibody directed against recombinant TPH recognized not only TPH but also tyrosine hydroxylase (TH) and phenylalanine hydroxylase (PH). Immunochemical titration data showed that the antiserum immunoprecipitated both TPH and TH proteins in a dosage-dependent manner. These data demonstrate that these methods can be used to produce large quantities of enzymatically active TPH. Supported by MH44043.

A 5-HT_{1D} AGONIST FOR THE TREATMENT OF MIGRAINE: PHARMACOLOGICAL STUDIES WITH MDL 100,687.

J. Sprouse*, C. Schmidt, M. Petty, E. Hamel, M. Dudley, I. McDonald and R. Bernotas. Marion Merrell Dow Research Institute, Cincinnati, OH and Strasbourg, France and Montreal Neurological Institute, Montreal, Canada.

The classification of 5-HT_1 receptors into various subtypes tantalizingly suggests specific targets for drug therapy. Yet, with the exception of 5-HT_{1A} receptors in the treatment of anxiety, the designation of a "disease for every subtype" remains unrealized. Even sumatriptan (SUM), which is effective in abolishing migraine attacks, is often described as acting at "5-HT_1-like" sites. In the present study, MDL 100,687 (MDL; 6-[[2-(5-hydroxy-1H-indol-3-yl)ethyl]amino]-N-[4-(trifluoromethyl)phenyl]-hexanamide, monohydrochloride), a novel compound targeted for migraine, was characterized in various assays of 5-HT_{1D} specificity and function.

MDL bound to 5-HT_{1D} sites in bovine caudate membranes with an IC_{50} of 34 nM compared to 81 nM for SUM. In guinea pig cortical slices, MDL inhibited K^+-induced release of [^{3}H]-5-HT by activating terminal 5-HT_{1D} autoreceptors; IC_{50} for MDL was 123 nM and for SUM, 1002 nM. MDL suppressed forskolin-stimulated adenylate cyclase in guinea pig substantia nigra with an IC_{50} of 398 nM vs. 1910 nM for SUM. In functional tests relevant to the treatment of migraine, both MDL and SUM reduced cat carotid arterial blood passing through arteriovenous anastomoses (MDL, 66% decrease at 1 mg/kg i.v.; SUM, 48%) and MDL dose-dependently constricted human pial arteries (pD_2 = 7.14 for MDL and 5-HT). The results indicate that MDL is clearly a 5-HT_{1D} agonist; its relative effectiveness in migraine awaits clinical trials.

DIRECT SEQUENCE AND SSCP ANALYSIS OF THE HUMAN TRYPTOPHAN HYDROXYLASE GENE.

J. S. Ellison, D. A. Nielsen, C. H. McDonald, L. Akhtar, M. Linnoila, and D. Goldman*. Lab. of Neurogenetics, National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD 20892.

Tryptophan hydroxylase (TPH) is rate-limiting for the synthesis of serotonin, a neurotransmitter whose function may be perturbed in several neuropsychiatric diseases with a genetic component. The human cDNA sequence and mouse genomic DNA sequence, including intron/exon boundaries, were utilized to prepare primers for the PCR amplification and automated sequencing of the TPH gene from human genomic DNA. The exon portions of ten overlapping PCR fragments were sequenced and also compared by the single strand conformational polymorphism (SSCP) method. Intron 7 was sequenced also and the nature of a polymorphism detected by the SSCP method and located within this intron was determined. For SSCP analysis for mutations, DNA segments ranging from 121 to 3310 bp in length were amplified with fluorescent dye-labelled primers and the larger fragments were enzymatically digested prior to nondenaturing electrophoresis. Fragment mobility variants were argon laser detected using an ABI 373A Sequencer. Templates for PCR and sequencing were derived from individuals low in CSF 5-hydroxyindoleacetic acid, an index of serotonin turnover, from individuals with behaviors correlated with altered serotonin function (including alcoholics, murderers, firestarters, and suicide attempters), and from normal individuals.

580.10

REGULATION OF 5-HT_2 RECEPTOR mRNA LEVELS BY 5-HT_2 RECEPTOR AGONISTS AND ANTAGONISTS IN CULTURED CEREBELLAR NEURONS.

J. Akiyoshi*, C. Hough and D.-M. Chuang. Biological Psychiatry Branch, NIMH, Bethesda, MD 20892

We have studied effects of 5-HT_2 receptor agonists (5-HT, DOI) and antagonists (mianserin, ketanserin) on 5-HT_2 receptor mRNA expression in cerebellar granule cells cultured in vitro for 8 days. Pretreatment with 5-HT or DOI induced a rapid desensitization of 5-HT_2 receptor-mediated PI response and a subsequent increase of ^{3}H-ketanserin binding to 5-HT_2 receptors in crude membranes and intact cells. The increase in 5-HT_2 receptor binding sites was dependent on the concentration of the prestimulating agonist and associated with an increase in both the B_{max} and K_d value of ^{3}H-ketanserin binding. Moreover, the up-regulation was temporally correlated with an increase of 5-HT_2 receptor mRNA level (from1-24 hr after treatment). Total RNA and mRNA for m_3-muscarinic receptors and ß-actin were not significantly affected by 5-HT or DOI pretreatment. Conversely, preexposure to the 5-HT_2 antagonists mianserin and ketanserin induced a time-dependent decrease of 5-HT-induced response but a concurrent loss of 5-HT_2 receptor binding sites. At least in the case of cells preexposed to mianserin, 5-HT_2 receptor down-regulation was accompanied by a marked loss of 5-HT_2 receptor mRNA. Thus in cerebellar granule cells, the number of 5-HT_2 receptors and 5-HT_2 receptor mRNA level are regulated by 5-HT_2 receptor agonists and antagonists in an unusual manner.

DIFFERENTIAL REGULATION OF SEROTONIN RELEASE BY THE DORSAL AND MEDIAL RAPHE NUCLEI. D.S. Kreiss* and I. Lucki. Institute of Neurological Sciences, Depts. of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

The regulation of serotonin (5-HT) release by somatodendritic 5-HT_{1A} autoreceptors was examined using *in vivo* microdialysis. 5-HT release was measured in the ventral caudate nucleus and the ventral hippocampus of rats maintained under chloral hydrate anesthesia. Systemic administration of 8-OH-DPAT (1.0 mg/kg, i.p.) completely reduced the release of 5-HT in both the striatum and the hippocampus. Infusion of 8-OH-DPAT (3.2 µg in .25 µl over 5 min) into the dorsal raphe nucleus completely inhibited 5-HT release in the striatum, but did not alter 5-HT release in the hippocampus. Conversely, infusion of 8-OH-DPAT into the medial raphe nucleus reduced 5-HT release in the hippocampus, but not in the striatum. Simultaneous microinjection of the antagonist (-)propranolol (5.6 µg in .25 µl over 5 min) into the dorsal raphe nucleus with systemic administration of 8-OH-DPAT (1.0 mg/kg, i.p.) completely blocked the inhibition of 5-HT release in the striatum without affecting the inhibition of release in the hippocampus. Conversely, simultaneous microinjection of propranolol into the medial raphe nucleus with systemic 8-OH-DPAT blocked 5-HT release from being inhibited in the hippocampus, but not in the striatum. These results indicate that 5-HT release in certain areas of the striatum and the hippocampus are differentially regulated by 5-HT_{1A} autoreceptors of the dorsal and medial raphe nuclei.

Supported by USPHS grants MH 36262 and MH 48125.

580.12

CP-110,330, A DIMETHYLTRYPTAMINE DERIVATIVE WITH HIGH BINDING AFFINITY FOR 5-HT_1 RECEPTORS AND DOPAMINE UPTAKE INHIBITING ACTIVITY. B.K. Koe*, L.A. Lebel, C.B. Fox, and J.T. Nowakowski. Central Research Div., Pfizer Inc, Groton, CT 06340

The discovery of serotonin receptor (5-HT_1) subtypes and the introduction of therapeutic agents with a serotonergic mechanism of action (serotonin reuptake inhibitors as antidepressants; 5-HT_{1A} agonists as anxiolytics and antidepressants; a 5-HT_{1D} agonist as antimigraine agent) have kindled interest in novel 5-HT_1 agonists. We describe a new N,N-dimethyltryptamine (DMT) derivative, 5-(5-anilinomethyl-2-thiazolyl)-DMT (CP-110,330), that exhibits potent binding affinity (IC_{50} in parenthesis) for 5-HT_{1A} (3.0 nM), 5-HT_{1B} (6.6 nM), and 5-HT_{1D} (3.8 nM) receptors with weak binding to 5-HT_{1C} (1.0 µM) or 5-HT_2 (14 µM in [^{3}H]ketanserin; 0.55 µM in [^{125}I]DOI) receptors. Agonist (5-HT_{1B}) character of CP-110,330 is suggested by a Gpp(NH)p shift to lower affinity in [^{125}I]iodocyanopindolol binding. In addition, CP-110,330 shows marked inhibition of DA uptake (IC_{50} 0.11 µM; cf. mazindol, IC_{50} 0.14 µM). The high binding affinity for 5-HT_1 sites is readily rationalized, because CP-110,330 is a C5-substituted DMT. The DA uptake blocking activity, however, is more difficult to explain. The conformation of CP-110,330 may allow the terminal phenyl ring and N of the aminoethyl sidechain to approximate a phenethylamine-like or a phenylbutylamine-like configuration spatially, thus permitting binding to the DA uptake site (IC_{50} 0.6 nM in [^{3}H]BTCP). The S.A.R. of some close analogs appears to be consistent with this possibility.

580.13

ANTIDEPRESSANT-LIKE ACTIVITY OF 8-OH-DPAT IS MEDIATED BY POST-SYNAPTICALLY LOCATED 5-HT_{1A} RECEPTORS. A. Singh* and I. Lucki. Depts. of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

This study examined whether the antidepressant-like behavioral effects of the 5-HT_{1A} agonist 8-OH-DPAT, in the forced swimming test, are mediated by pre- or post-synaptically located 5-HT_{1A} receptors. 5-HT neurones were destroyed using 5,7-DHT (200 µg, icv) which resulted in a 90% reduction of 5-HT concentrations in the cerebral cortex and hippocampus. Forced swimming sessions were conducted 10-19 days following surgery. Sham- and 5,7-DHT-lesioned rats received three subcutaneous injections of 8-OH-DPAT (0.125-0.5 mg/kg) at time points corresponding to 0.5, 19 and 23 hours after the 15 min pretest swim session. Behavioral immobility was measured during a 5 min test session, which occurred one hour after the last injection.

8-OH-DPAT produced an identical dose-dependent reduction of immobility time in the sham- and 5,7-DHT-lesioned rats. The apparent absence of a shift to the left in the 5,7-DHT-treated group suggests that these post-synaptically located 5-HT_{1A} receptors are not sensitized. In contrast, the post-synaptically located 5-HT_{1A} receptors which mediate the 5-HT behavioral syndrome demonstrated a 3-fold shift to the left of the dose-response curve in the same group of rats. The results of this study confirm that the antidepressant-like effects of 8-OH-DPAT are mediated by post-synaptic 5-HT_{1A} receptors which are regulated differently from those mediating the 5-HT behavioral syndrome.

Supported by USPHS grants MH 36262 and MH 48125.

580.14

DIFFERENTIAL REGULATION OF RELEASE OF ENDOGENOUS 5-HT AND ^{3}H-5-HT BY NERVE TERMINAL AUTORECEPTORS. W.A. Wolf, R.E. Arthur Jr., L.D. Alphs and D.M. Kuhn*. Labs of Neurochemistry and Molecular Pharmacology, Dept. of Psychiatry, Wayne State University School of Medicine and Lafayette Clinic, Detroit, MI 48207.

Neuronal serotonin (5-HT) release is modulated, in part, through activation of nerve terminal autoreceptors (of the 5-HT_{1B} type in rat). This conclusion is based, in large part, on brain slice superfusion studies in which the release of ^{3}H from slices prelabelled with ^{3}H-5-HT is measured. However, such release may not totally reflect 5-HT release in vivo. Brain dialysis experiments can measure the regulation of endogenous 5-HT release in vivo. However the lack of sufficiently selective 5-HT_{1B} agonists, and the uncertainty of the drug concentrations achieved after systemic or even local application of such agonists can raise uncertainties as to the mechanism underlying their effects. The present work represents a comparison of the effects elicited by 5-HT_{1B} agonists on release of endogenous 5-HT versus ^{3}H-5-HT from superfused slices of rat striatum (400 uM thick). Striatal slices which were pre-loaded with ^{3}H-5-HT (70 nM for 30 min at 37°C in the presence of 10 uM nomifensine) released 0.88 ± 0.08 % of tissue ^{3}H upon depolarization (20 mM K^+, 4 min) at S1 and 0.73 ± 0.09 % of tissue ^{3}H at S2 (S2/S1 = 0.82 ± 0.08). The 5-HT_1 agonist RU 24969 (100 nM), reduced ^{3}H release at S2 to 0.34 ± 0.03 % of tissue ^{3}H (S2/S1 = 0.40 ± 0.02). In contrast, RU 24969 (100 nM) had no effect on release of endogenous 5-HT. Under control conditions 5-HT release at S2 was 0.275 ± 0.015 pmoles (2.06 ± 0.13 % of tissue 5-HT; S2/S1 = 0.89 + 0.01). In the presence of RU 24969 (100 nM) 5-HT release was 0.281 ± 0.007 pmoles (2.15 ± 0.20 % of tissue 5-HT; S2/S1 = 0.88 ± 0.02). These results suggest that although RU 24969 can inhibit release of ^{3}H-5-HT, release of endogenous 5-HT is not significantly altered. The effects of other 5-HT_{1B} agonists, stimulation parameters (electrical vs. K^+) on endogenous 5-HT and ^{3}H-5-HT release will be presented.

INTERACTIONS BETWEEN 5-HT_{1A} AND 5-HT_2 RECEPTOR ACTIVATION IN VIVO. L.G. Kirby*, J.G. Hensler & A. Frazer. Institute of Neuroscience, Depts. of Psychiatry & Pharmacol., Univ. of Penna. School of Medicine, DVA Med. Center, Philadelphia, PA 19104.

Previous studies by others have shown that either acute or chronic treatment of rats with 5-HT_{1A} agonists decrease a 5-HT_2 receptor-mediated behavior, quipazine-induced head shakes. We have studied further interactions between 5-HT_{1A} and 5-HT_2 receptor activation in vivo. Administration of the 5-HT_2 receptor agonist DOI (1 mg/kg, i.p., q.d.) to rats for 8 days resulted in an attenuation of the hypothermic response induced by the 5-HT_{1A} agonist DPAT (0.05 mg/kg, s.c.), measured 48 hrs after cessation of drug treatment. Chronic administration of the 5-HT_{1A} agonist gepirone (40 mg/kg/day, s.c.) by osmotic minipump also resulted in an attenuation of the hypothermic response induced by DPAT, which was not accompanied by changes in ^{3}H-DPAT binding. Chronic administration of gepirone to rats also decreased head shake behavior elicited by DOI (1 mg/kg, i.p.) measured 24 hrs after terminating gepirone treatment. Acute pretreatment of rats with gepirone (3 mg/kg, s.c.) 15 min prior to DOI administration (2 mg/kg, s.c.) reduced the number of head shakes elicited by DOI, but this effect was not seen in rats pretreated with gepirone 6 hrs and 24 hrs prior to injection of DOI. Chronic treatment with either 5-HT_{1A} or 5-HT_2 receptor agonists can inhibit a 5-HT_{1A} receptor-mediated response, whereas chronic treatment with 5-HT_{1A} agonists decrease a 5-HT_2 receptor-mediated behavior. To understand the mechanisms underlying these receptor interactions, it will be useful to develop model systems to study this in vitro. DIFFERENTIAL REGULATION OF 5-HT_{1A}-MEDIATED RESPONSES. P.A. Scott* & A. Frazer. Dept. of Psychiat., Univ. of Pa. Sch. of Med. and Vet. Affairs Med. Ctr., Phila. PA 19104.

Studies of the 5-HT_{1A} receptor are of interest because agonists for this subtype display both anxiolytic and antidepressant (AD) properties clinically. Some responses elicited by activation of this receptor show subsensitivity after chronic administration of some ADs or 5-HT_{1A} agonists. In the rat, 5-HT_{1A} receptor activation causes hypothermia and the 5-HT syndrome (flat body posture, forepaw treading, side-to-side body movement, and resting tremor). The effects of several 5-HT_{1A} agonists administered s.c. (gepirone; 8-OH-DPAT; (+) S-20499) on both hypothermia and the 5-HT syndrome were studied. All 3 drugs were much more potent in causing hypothermia than in eliciting the syndrome. The same maximal drop in body temperature (ca 2.5° C) was elicited by all three drugs with DPAT being the most potent (ED_{50} = 0.05mg/kg), followed by gepirone (1.8mg/kg) and (+) S-20499 (16mg/kg). The syndrome was reliably observed only at doses of 3-4mg/kg DPAT; doses up to 100 mg/kg of gepirone or (+) S-20499 did not produce any syndrome behavior. The effect of 14 day treatment of rats with either (+) S-20499 (24mg/kg/day; osmotic minipump) or the AD sertraline (5mg/kg, bid, i.p.) on either DPAT-induced hypothermia (E_{max} dose of 2.0mg/kg) or the syndrome (4mg/kg) was measured 18-24 hours after drug administration ceased. Both (+) S-20499 and sertraline completely blocked the syndrome. Chronic (+) S-20499 treatment significantly attenuated hypothermia produced by DPAT whereas chronic sertraline treatment did not. Differential regulatory influences may be exerted on 5-HT_{1A}-mediated responses by sertraline or novel anxiolytic/AD drugs depending, perhaps, on the anatomical location involved in producing the response and/or the presence of receptor reserve associated with particular responses. HUMAN BRAIN KYNURENINE AMINOTRANSFERASE I: PURIFICATION AND CHARACTERISTICS. [1]H. Baran*, [2]E. Okuno, [2]R. Kido and [1]R. Schwarcz. [1]Maryland Psych. Res. Ctr., Baltimore, MD 21228 and [2]Wakayama Med. Coll., Wakayama, Japan.

Two kynurenine aminotransferases (KAT I and KAT II) are capable of producing the neuroinhibitory brain metabolite kynurenic acid from L-kynurenine in human brain tissue. We have now purified KAT I to homogeneity and characterized its catalytic properties. The enzyme was purified approximately 2,000-fold with a yield of 2%. Assessed by polyacrylamide gel electrophoresis, KAT I migrated toward the anode as a single protein with a mobility of 0.5. The pure enzyme is a dimer consisting of two identical 57 kDa subunits. Among oxo acid tested, KAT I showed highest activity with 2-oxoisocaproate. Using this co-substrate, kinetic analyses revealed an apparent K_m of 1.8 mM for L-kynurenine. KAT I activity was potently inhibited by glutamate, phenylalanine and tryptophan. Anti-KAT I antibodies were produced and partially purified. Subsequent Ouchterlony double diffusion, immunotitration and immunoblotting analyses confirmed that KAT I is distinct from other known kynurenine aminotransferases. Taken together, pure human KAT I and its antibody can be expected to serve as valuable tools in future studies of kynurenic acid production in the human brain under physiological and pathological conditions (cf. Jauch et al., this meeting).

PURIFICATION AND CHARACTERIZATION OF SOLUBLE GLUTAMATE DECARBOXYLASE FROM PORCINE BRAIN. J. Bao*, B. Nathan, and J.-Y. Wu. Dept. of Physiology & Cell Biology, Univ. of Kansas, Lawrence, KS 66045-2106

Soluble L-glutamate decarboxylase (GAD) was isolated from porcine brain by homogenzing the brain tissue in water at 4°C. GAD was first purified by DEAE-cellulose and hydroxylapatite chromatography. Two peaks of GAD activity were obtained on hydroxylapatite column. The major activity peak, referred to as soluble GADI (sGADI), was further purified by a combination of gel filtration column, preparative nondenaturing 7.5% and 5-25% gradient polyacrylamide gel electrophoresis (PAGE). The purified preparation showed a single protein band on nondenaturing 5-25% gradient PAGE, which coincided with GAD activity. The molecular weight of native sGADI was calculated to be 123±1.0 KD from the nondenaturing gradient PAGE and 131± 1.0 KD from Sephadex G-200 column. The purified sGADI preparation was dissociated into two protein bands of 64±1.0 KD and 59±1.0 KD on SDS-PAGE, suggesting that sGADI is either a heterodimer composed of 64 KD and 59 KD subunits or a homodimer composed of either 64 KD or 59 KD subunits. Polyclonal antibodies were produced by immunizing rabbits with ~150 µg purified sGADI preparation. The specificity of anti-GAD serum was established by immunodiffusion, immuno-precipitation and Western blotting. Similar studies for the other forms of soluble GAD are in progress. [Supported by grants NS 20978 (NIH) and BNS-8820581 (NSF)].

581.3

PURIFICATION AND CHARACTERIZATION OF MEMBRANE ASSOCIATED GLUTAMATE DECARBOXYLASE FROM PORCINE BRAIN. B. Nathan*, J. Bao, and J.-Y. Wu. Dept. of Physiology & Cell Biology, Univ. of Kansas, Lawrence, KS 66045-2106

Several lines of evidence point to the conclusion that multiple forms of L-glutamate decarboxylase (GAD), the synthetic enzyme for GABA, are present in mammalian brain. Here, we describe purification and characterization of a membrane associated GAD, referred to as mGAD, from porcine brain. The purification involved solubilization of mGAD with 0.5% Triton X-100, followed by column chromatography on anion exchanger, DE-52. Three mGAD activity peaks were obtained, one of which was further purified to homogeneity by additional column chromatographies on ACA-34, hydroxylapatite, Sephadex G-200 and preparative SDS-PAGE. The molecular weight of native mGAD was calculated to be 125 ±10 kDa from gel filtration. The molecular weights of the probable subunits identified in analytical SDS-PAGE were found to be 71 & 74 kDa. Hence, the enzyme thus purified contains either a single form of mGAD which is a heterodimer of 71 and 74 kDa; or two forms of mGAD, one a homodimer of 71 kDa and the other a homodimer of 74 kDa. These results suggest that the mGAD thus obtained is different from soluble GAD in its molecular structure (see Abstract in this volume, Bao, J. et al.), but similar to soluble GAD in its kinetic properties, as well as in its sensitivity towards heat treatment and various GAD inhibitors like AOAA, PCMB and 3-MPA. The physiological role of mGAD in the brain remains to be determined.

THE GLUTAMINE CONTENT OF ASTROCYTES: REGULATION BY pH, cAMP AND HYDROCORTISONE. N. Brookes*. Dept. of Pharmacol. & Exptl. Therap., Univ. of Maryland School of Medicine, Baltimore, MD 21201.

A change in extracellular pH from 7.4 to 7.8 caused a >3-fold increase in the free glutamine content (Gln_i) of mouse cerebral astrocytes that were incubated with glutamate (Glu) and NH_4^+ (Brookes, J. Neurochem., 1992, in press). This effect of pH does not appear to result from increased free NH_3 concentration or from changes in transport of Glu or Gln. Does the mechanism involve regulation of glutamine synthetase (GS) activity by pH_i? To examine the effect of induction of GS activity on Gln_i and on the response of Gln_i to pH, astrocyte cultures were pretreated with dibutyryl cAMP (dbcAMP, 0.25 mM in serum-free MEM, changed twice during 6 d) or with hydrocortisone (HC, 1 μM in MEM supplemented with 5% fetal calf serum for 2 d). Then the cultures were preincubated to deplete them of free amino acids [1 h at 35°C in HEPES-Tris-buffered salts solution (HTB), pH 7.4], and then incubated for 30 min with 0.1 mM Glu and 0.1 mM NH_4^+ in HTB at pH 7.4 or 7.8. Values of Gln_i (measured by reversed phase HPLC with precolumn dabsylation) were as follows:

Cultures	Gln_i, nmol.mg^{-1}protein ± sem (n) pH 7.4	pH 7.8
Untreated	15.5 ± 1.1	54.4 ± 4.3 (6)
dbcAMP-treated	42.2 ± 14.5	104.1 ± 19.3 (3)
HC-treated	77.8 ± 3.7	228.9 ± 38.8 (3)

Clearance of Glu from the solution was 26-39% at 30 min. The results show that induction of GS activity markedly increased Gln_i, but that the pH effect remained large. This effect of pH may underlie the increased level of brain glutamine observed in hyperammonemia. (Supported by USPHS grant ES03928).

MDMA AND PCA INCREASE 5-HT LEVELS EXTRACELLULARLY IN CULTURED RAPHE CELLS GROWN IN SERUM FREE MEDIA: POTENTIATED BY DEPRENYL AND DEPOLARIZATION AND ATTENUATED BY RESERPINE AND NIMODIPINE. X.F.Gu* and E.C.Azmitia Dept. of Biology, New York University, Washington Square East, New York, N.Y. 10003

A novel serum-free microculture system coupled with HPLC-EC was developed in order to investigate the direct effects of 3,4-methylenedioxymethamphetamine (MDMA) and p-chloroamphetamine (PCA) on fetal raphe neurons. MDMA (10^{-5}M) and PCA (10^{-5}M) increased media 5-HT (20-40 nmoles; PCA > MDMA) as compared to non-detectable 5-HT levels in control cultures. After 48 hours of exposure to MDMA, 5-HT levels in the media increased from nmole range to µmole range. Exposure of the cultured cells to deprenyl (10^{-7}M), a monamine oxidase B inhibitor localized inside serotonergic neurons, increased the media 5-HT levels induced by MDMA by 30%. Intracellular storage of 5-HT was diminished by reserpine (10^{-6}M) and the MDMA or PCA induced increase in media 5-HT levels was attenuated by 17% or 47% respectively. Furthermore, MDMA and PCA-induced release of 5-HT could be blocked by fluoxetine at 10^{-8}M. The MDMA induced release appears to be both Ca^{++} dependent and independent since it was augmented by KCl at 50mM and attenuated by nimodipine at 10^{-8}M (an L-type Ca^{++}-channel blocker). Supported by NIDA contract# 271-90-7403.

ACCUMULATION OF [^{3}H]-(+)MDMA INTO RAT BRAIN SYNAPTOSOMES AND ASTROCYTES.

J.C. Poblete[1], X. Zhang[2], P.M. Whitaker-Azmitia[2] and E.C. Azmitia[1].

1. Dept. of Biology, New York University, NY, NY 10003, and 2. Dept. of Psychiatry, SUNY-Stony Brook, Stony Brook, NY 11794.

Previous studies have shown that 3,4-methylenedioxymethamphetamine (MDMA or ecstasy) inhibits [^{3}H]-5HT uptake and stimulates Ca^{++}-independent release of [^{3}H]-5HT. These actions of MDMA are mediated by the serotonergic high affinity uptake site. It has been suggested that the mechanism by which MDMA releases 5-HT is via the exchange diffusion mechanism, ie. MDMA is exchanged for 5-HT from the cytoplasmic pool. Thus, MDMA is accumulated into the terminal from which 5-HT is released.

Our present study characterizes the accumulation of [^{3}H]-(+)MDMA (0.568 Ci/mmol) into rat brain synaptosomes (P2) and astrocytes. Saturation analysis (0.2-20uM) for the accumulation of [^{3}H]-(+)MDMA into synaptosomes indicated an apparent Km of 3uM and a Vmax of 80 pmol/mg protein/2min. Sonication produced a 40% decrease in [^{3}H]-(+)MDMA (5uM) accumulation, while [^{3}H]-5HT (50nM) uptake was reduced by 70%. The accumulation of 5uM [^{3}H]-(+)MDMA was not significantly decreased by 100uM ouabain, while [^{3}H]-5HT uptake was diminished by 70%. Long-term degeneration of serotonergic terminals with a single dose of 10mg/kg p-chloroamphetamine (PCA) did not alter the accumulation of 5uM [^{3}H]-(+)MDMA, while it decreased the [^{3}H]-5HT uptake by 40%. This result suggests that [^{3}H]-(+)MDMA accumulation is not into 5-HT terminals.

Our results in culture indicate that [^{3}H]-(+)MDMA is accumulated into rat brain astrocytes. Saturation analysis of [^{3}H]-(+)MDMA accumulation into astrocytes exhibit an apparent Km of 6 uM and a Vmax 65 pmol/mg protein /2min, and has regional specificity. (Research Supported by NIDA contract # 271-90-7403)

SELECTIVITY OF VARIOUS SUBSTITUTED AMPHETAMINES FOR MAO-A.

E.T. KOKOTOS LEONARDI* X.P. HOU AND E.C. AZMITIA.
Dept. of Biology, New York University NY,NY 10003.

PCA, methamphetamine (METH), fenfluoramine (FEN) and MDMA are substituted amphetamines that release serotonin from serotonergic terminals. PCA,FEN and MDMA have been linked to serotonin neuropathology. We have previously shown that MDMA inhibits MAO-A but not MAO-B activity. MAO-A catabolizes serotonin with a higher affinity than does MAO-B; serotonergic cells contain mostly MAO-B. Dopamine is metabolized with equal affinity by both MAO subtypes. The selectivity of PCA, METH and FEN for MAO subtype was examined in the brain stem and hippocampal rat brain homogenates. Selectivity for MAO-B was determined by pre-treating homogenates with 100 nM clorgyline, a specific MAO-A inhibitor, for 10 mins., 37° C. Amphetamines were added at final concentrations of 10 $^{-4}$M-10^{-7}M, 10 mins, 37°C. ^{3}H-DA at 5 uM was added as substrate; homogenates were incubated for 30 min., 37°C. MAO-A activity was determined with 5 uM ^{3}H-5-HT as substrate. Radiolabelled metabolites of both reactions were measured by scintillation counting.

We found no significant effects by any of the amphetamines tested on MAO-B activity. MAO-A was significantly inhibited with PCA>>METH>FEN, with IC_{50}s of 1uM, 25 uM and >100uM respectively. In cultured serotonergic cells treated with 10 uM MDMA, the development of the uptake of ^{3}H-5-HT was inhibited by 43% ($p<0.001$). This MDMA inhibitory effect was potentiated in cultures that were treated with clorgyline (10nM-100nM) (58% inhibition, $p<0.01$). These results suggest that inhibition of MAO-A may contribute to the neurotoxic properties of these drugs. This work was supported by NIDA contract #271-87-8144.

EXPRESSION OF CATECHOL-O-METHYLTRANSFERASE (COMT) IN RAT BRAIN AND PERIPHERAL TISSUES. T.Karhunen*, C.Tilgmann, I. Julkunen, I. Ulmanen and P. Panula. Dept. Anatomy, Univ. Helsinki, Orion Pharmaceuticals, Espoo, and National Public Health Institute, Helsinki, Finland.

Antisera against rat recombinant COMT were raised in guinea pigs to reveal the distribution of COMT in rat tissues. Immunoprecipitation of in vitro-synthesized membrane-bound and soluble COMT proteins indicated that both forms were effectively recognized by the antisera. Western blotting analysis showed that both forms were detected in rat kidney, liver, brain, stomach and adrenal.

Indirect immunofluorescence technique showed specific immunoreactivity in the ependymal cells lining cerebral ventricles, plexus choroideus, median eminence, Bergmann glia of the cerebellum, and pituicytes of the posterior pituitary. Cells lining the intermediate lobe were intensely immunoreactive. Hepatocytes, epithelial cells in the stomach and duodenum, muscle layer of the gut, islet cells of the pancreas, and kidney tubules were also immunoreactive. Preadsorption of the antisera with recombinant rat COMT protein abolished all staining, and preimmune serum did not stain any structures.

The results suggest that COMT is a widespread enzyme both in the brain and peripheral organs.

581.9

CHRONIC COCAINE AND HALOPERIDOL ELEVATE 3-METHOXYTYRAMINE IN THE ANTERIOR PITUITARY OF THE MALE RAT. S. J. Chrapusta, F. Karoum, M. F. Egan and R. J. Wyatt*. Neuropsychiatry Branch, NIMH Neuroscience Center at St. Elizabeths, Washington, D.C. 20032, U.S.A.

According to previous reports, changes in tuberoinfundibular dopamine neuron (TIDA) activity do not correlate with the anterior pituitary dopamine (DA) content. Since the TIDA terminals do not form classical synapses and are juxtaposed to blood vessels, it is also unclear whether 3-methoxytyramine (3MT; a DA metabolite used as an indirect index of DA release) can reflect activity of these neurons.

We measured 3MT in the anterior pituitary of male rats using gas chromatography/mass spectrometry with negative chemical ionization. The animals were treated chronically or acutely with 0.4 mg/kg of haloperidol (HAL) (3 weeks of daily ip injections of HAL followed by HAL or vehicle (VEH) injection 1 hour before sacrifice, or 3 weeks of daily ip VEH injections followed by HAL or VEH injection 1 hr before sacrifice), or cocaine (10 mg/kg twice daily for 1 week followed by 1 week withdrawal versus twice daily injections of VEH followed by 1 week withdrawal). An injection of monoamine oxidase inhibitor pargyline (75 mg/kg, ip) was given to the rats 0, 10 or 20 min before sacrifice by microwave brain irradiation.

Increased 3MT accumulation (133-142% of control, $p<0.001$) was observed in the rats treated chronically and/or acutely with HAL. Chronic cocaine treatment significantly elevated steady-state 3MT levels (164% of control, $p<0.05$) and tended to increase 3MT rate of formation (160% of control). These findings indicate that anterior pituitary 3MT - in contrast to DA - may be a useful index of TIDA neuronal activity.

581.10

Uptake and stimulus-dependant release of [32]P-labelled Vasopressin RNA by hypothalamic primary cell cultures

D. Maciejewski-Lenoir,*G. F. Jirikowski, F. E. Bloom
Dept. of Neuropharmacology, Scripps Research Institute, La Jolla CA 92037

We recently showed that magnocellular hypothalamic neurons in Brattleboro rat can accumulate, transport and translate exogenous vasopressin (VP) mRNA. To investigate the mechanisms of RNA uptake, transport and secretion, we incubated primary cultures of dissociated fetal (ED 17) rat hypothalamus with [32]P-labelled VP cRNA. Autoradiograms revealed that a distinct portion of cells, mostly neurons, accumulates RNA in perikarya and processes. This group of cells includes VP immunoreactive perikarya but is not limited to this cell type. We could further demonstrate that depolarization of the cells with 50 mM KCl increased the amount of radioactivity released into the culture medium, indicating a stimulus dependant secretion of VP RNA. This effect was in part Ca^{++} dependent. Stimulation of the cultures with 10^{-6} M of either synthetic Arg-vasopressin or oxytocin resulted in release of incorporated exogenous VP RNA, but 1mM glutamate did not facilitate any release. Our results indicate that a stimulus dependant secretion of certain RNAs might be a common physiological feature of hypothalamic neurons, thus providing for a novel way of interneuronal communication.

581.11

Coexistence of vasopressin and oxytocin in rat magnocellular neurons upon intrahypothalamic injections with vasopressin RNA. G.F. Jirikowski*, D. Maciejewski-Lenoir, F.E. Bloom. Dept. of Neuropharmacology, Scripps Res. Inst., La Jolla, CA 92037

In previous studies we demonstrated that magnocellular hypothalamic neurons in the homozygous Brattleboro rat are capable of accumulating, transporting and translating exogenous vasopressin (VP) RNA, resulting in a temporary correction of diabetes insipidus. In the present study intact adult Wistar rats were stereotaxically injected into the hypothalamo neurohypophysial tract with [32]P-labelled VP cRNA. After a survival time of 18h, radiolabelling could be observed in most of the VP immunostained neurons. In addition a fraction of the oxytocin (OT) cells as well as in the posterior lobe were labelled, indicating that VP cRNA was taken up and transported anterogradely as well as retrogradely by both VP and OT cells. Immunocytochemistry of consecutive semithin hypothalamus sections revealed that in RNA injected animals about 15% of the OT immunoreactive perikarya contained VP. This indicates that OT neurons can be recruited into translation of exogenous VP RNA. In preliminary experiments, RNA binding sites were localized on cryostat sections of rat hypothalamus by autoradiography after in vitro incubation. Radiolabelled VP RNA is intensely bound by fiber tracts, but was absent in the magnocellular nuclei. The present findings indicate that uptake, axonal transport and translation of VP cRNA by magnocellular hypothalamic neurons is not restricted to the genedeficient Brattleboro rat but may represent a feature of the hypothalamic neurons generally. Exchange of RNAs between neurons could allow for the transitory coexistence of otherwise unrelated neuropeptides.

581.12

METABOLIC AND BIOCHEMICAL EFFECTS OF DIFFERENT GROWTH CONDITIONS IN THE PHEOCHROMACYTOMA CELL LINE, PC12. T. Flanagan*, M. Palmatier, T. Wright, W. Bell, M. Lavoie. CytoTherapeutics, Inc., Providence, RI 02906

The PC12 cell line is derived from a rat pheochromacytoma. PC12 cells grow better at high cell densities rather than low cell densities and under these conditions metabolize glucose quickly . We examined the effect of plating density and acute or sustained glucose depletion of >90% of initial medium level on the growth rate, viability, media levels of lactate and glucose, and dopamine storage in these cells.

Sustained (>3 days), but not acute (<1 day), glucose depletion decreased the growth rate of PC12 cells. Unexpectedly, the viability was unaffected by either sustained or transient glucose depletion. Under normal growth conditions, lactate is produced by PC12 cells and media levels rise. However, under sustained glucose depletion, media levels of lactate fall and lactate is consumed by PC12 cells. Consumption of lactate develops slowly as PC12 cells which were acutely glucose starved did not consume lactate, suggestive of a shift in the metabolic state of the cells. This apparent shift was reflected in changes in the storage of dopamine. The amount of stored dopamine was five-fold less per cell after sustained glucose depletion than in PC12 cells grown under optimal conditions.

A five-fold difference in plating densities, 3 $X10^{5}$/ml vs 6 $X10^{4}$/ml, with no depletion of medium glucose, did not affect the growth rate, viability, or the amount of stored dopamine in PC12 cells at the end of a 9 day culture period.

Taken together, these results indicate that rapidly developing changes in culture conditions can lead to shifts in metabolic pathways in PC12 cells. Differences in the internal metabolism of separate cultures of PC12 cells plated from a common cell suspension correlate with quantitative differences in secretory product stores. Thus, closely monitored growth conditions are important in predicting the behavior of PC12 cells.

DIFFUSIONAL PROPERTIES OF DOPAMINE IN A RAT MODEL OF PARKINSON'S DISEASE AS MEASURED BY MULTIPLE IN VIVO ELECTROCHEMICAL DETECTOR ARRAYS. C.G. van Horne*, J. Hudson, B.J. Hoffer, and G.A. Gerhardt. Departments of Pharmacology and Psychiatry and The Rocky Mountain Center for Sensor Technology, University of Colorado Health Science Center, Denver, Colorado 80262.

Parkinson's disease (PD) is characterized by the loss of dopaminergic neurons in the substantia nigra with a subsequent depletion of dopamine (DA) and DA nerve terminals, which contain a high-affinity DA uptake system, in the striatum. Although current treatments include DA replacement strategies, the fate of DA in the extracellular space is poorly understood. The goal of this study was to determine the temporal and spatial diffusional properties of locally applied DA in the 6-hydroxydopamine (6-OHDA) lesioned striatum as compared to the intact non-lesioned striatum and two control brain regions, the cerebral and cerebellar cortices, which are naturally devoid of DA nerve terminals. Male rats were unilaterally lesioned with 6-OHDA to remove the nigro-striatal DA-ergic pathway. Rats with greater than 95% depletions of striatal DA, determined by apomorphine rotational analysis, and non-lesioned rats were studied. DA (200 uM) was pressure ejected locally and detected by utilizing high-speed in vivo chronoamperometry with 4 Nafion coated carbon-fiber electrodes (30 um tip diameter) assembled in a linear array. Distances from the first electrode to the DA source and between each subsequent electrode measured between 200 and 300 um. Results showed that increasing volumes of DA were required to consistently detect signals at 200-300 um in the different brain regions and were as follows: 10-13 nl in the cerebral and cerebellar cortices, 50 nl in the 6-OHDA lesioned striatum, and 110-250 nl in the non-lesioned striatum. With respect to changes in the concentration of DA over time and distance, i.e. clearance, the intact striatum showed the greatest capacity for clearing extracellular DA, with a clearance time (the time required for a signal to decrease from 80 to 40 % of maximal amplitude) of 10-20 seconds and a 90-96% decrease in signal amplitude over 200-300 um. Lower capacities for DA clearance were found for the cerebral (30-70 seconds and an 80-90% decrease over 200-300 um) and cerebellar (60-120 seconds and a 70-80% decrease over 200-300um) cortices. The lesioned striatum showed the lowest capacity for DA clearance (120-200 seconds and a 40-70% decrease over 200-300 um). Thus DA appears to diffuse for greater distances and is cleared more slowly in brain regions which lack DA fiber systems. (Supported by USPHS grants AG06434, NS09199, and AG00441). (NSF BNS-911030)

581.14

OVEREXPRESSION OF GAP-43 IN AtT20 CELLS. C. Gamby, R. G. Allen* and L. Baizer, R. S. Dow Neurological Sciences Institute, Good Samaritan Hospital and Medical Center and C.R.O.E.T., Oregon Health Sciences University, Portland, Oregon 97209.

GAP-43 is a membrane bound phosphoprotein expressed primarily in neurons. While its precise function remains to be determined, it is concentrated in the growth cone, where it may be involved in the membrane addition associated with axonal growth. GAP-43 may also play a role in neurotransmitter and hormone release by facilitating the fusion of secretory vesicles with the plasma membrane. We have investigated the role of GAP-43 in secretion of adrenocorticotrophic hormone (ACTH) by a pituitary-derived neuroendocrine cell line (AtT20).

Western blot analysis demonstrates high levels of GAP-43 expression in AtT20/D16-16 cells. Rat or chicken cDNAs for GAP-43 under the control of the RSV promoter were transfected into AtT20/D16-16 cells and expression of exogenous GAP-43 was tested by RNase protection and western blot analyses. Cell lines over-expressing both rat and chicken GAP-43 have been isolated; none exhibit significant changes in cellular morphology. Spontaneous release of ACTH (measured by radioimmunoassay) by the clones overexpressing chicken or rat GAP-43 is similar to that in control cells, but the CRF-stimulated release is reduced by 30 to 40 %. Supported by NIH #NS26806.

SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS: ANATOMY

582.1

VARIABILITY IN THE CYTOARCHITECTURAL PATTERN OF THE BODY REPRESENTATION WITHIN THE PRIMARY SOMATOSENSORY CORTICAL AREA OF ADULT CATS. S.S. Leclerc*, C. Avendaño, I. Salimi, R.S. Waters and R.W. Dykes. Centre de recherche en sciences neurologiques, Dept. Physiologie, Faculté de médecine, Univ. de Montréal, P.Q., Canada, H3C 3J7.

Cat primary somatosensory cortex classically includes four cytoarchitectonic subdivisions, areas 3a, 3b, 1 and 2 (Hassler and Muhs-Clement, '64) and each band appears to be functionally distinct. Anatomical and electrophysiological mapping techniques used to correlate somatotopic and functional organization within more than fifteen cats revealed important idiosyncrasies in the size and distribution of pyramidal cells within layer V of area 3b as observed from Nissl-stained material. In most cases there appeared to be significant changes along the lateral-to-medial axis in the number and size of large pyramidal cells associated with major body parts within area 3b. Layer V pyramidal cells located in the hindlimb representation appeared larger and more intensely stained than those observed in the forelimb representation. This pattern was not gradual but periodic and interrupted. In some occasions, large pyramidal cells within layer V formed a continuous band spanning across all primary somatosensory cytoarchitectonic areas. However, in other cases, only a few scattered large pyramidal cells were observed throughout the entire medial-to-lateral extent of the body representation within area 3b. Layer IV thickness was also found to vary within area 3b in the same animals. Confirmation of some cytoarchitectonic borders were obtained using AChE histochemistry. The pattern of large pyramidal cells in layer V of cat primary somatosensory cortex appears to be an idiosyncratic feature and cannot be used alone as a factor for the determination of cytoarchitectonic borders. It has yet to be determined if these variations have any functional implications in the processing of sensory information. Support by DGCyT fellowship to C.A. and MRC grant MA 8700.

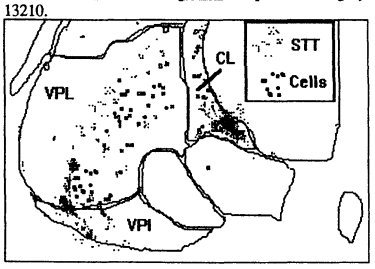
ELECTROPHYSIOLOGICAL AND MORPHOLOGICAL PROPERTIES OF LAYER 6 CELLS IN THE RAT NEOCORTEX. J.F.M. van Brederode* and G. L. Snyder. Dept. of Biol. Structure, Univ.of Washington, Seattle, WA 98195.

In vitro studies performed in brain slices have shown that cortical neurons differ in their intrinsic membrane properties. We used a combination of intracellular recording and dye-filling to study the electrophysiological and morphological characteristics of layer 6 cells in the rat sensorimotor cortex, which have received little attention. Anatomical reconstruction of filled cells showed them to be a morphologically diverse group consisting of regularly- and irregularly-oriented pyramidal cells and spiny nonpyramidal cells. Regular layer 6 pyramidal cells had either long, straight or short, sinuous apical dendrites, and differed in the extent of their axonal arborizations. Irregularly-oriented pyramidal cells consisted of sideways or inverted pyramidal cells of variable size and morphology, often characterized by U-turn axons. Spiny nonpyramidal cells included bitufted and multipolar cell types that differed in soma size and extent and orientation of their dendritic trees and axonal arborizations. Intracellular stimulation revealed that this morphological diversity was mirrored by a similar electrophysiological diversity. Most layer 6 cells were capable of firing trains of action potentials characterized by an initial doublet or triplet followed by a train of single spikes (phasic-tonic or PT mode). The majority of layer 6 cells could fire either single spikes only (tonic or T mode) with low strength input or in PT mode with stronger stimulation. A minority were either PT mode-only or T mode-only cells. The size and sequence of spike afterpotentials during slow repetitive firing was highly variable among layer 6 cells. Hyperpolarizing inward rectification was common and hyperpolarizing sag was present in most cells although the amount was variable. We were unable to establish a clear relationship between cell morphology and firing properties among layer 6 cells, possibly due to the large variety of cell types found in this layer. This work was supported by NIH grants EY 01208, EY 04536, EY 07031, and RR 00166.

582.3

SPINOTHALAMOCORTICAL INPUT IS NONPREFERENTIALLY DISTRIBUTED TO SUPERFICIAL AND DEEP CORTICAL LAYERS. T. Shi, J. Tessier, R.T. Stevens*, and A.V. Apkarian. Dept. Neurosurgery, SUNY HSC, Syracuse, NY 13210.



The VPL, VPI and CL in monkeys are a major connection between the spinothalamic tract (STT) and the primary somatosensory cortex (SI; Gingold et al. JCN 1991). Rausell and Jones (J Nsci 1991) recently suggested that nociceptive information preferentially accesses the superficial layers of SI. We studied this question in 1 macaque and 3 squirrel monkeys. DY was deposited on the surface of the mapped hand SI and WGA-HRP was injected in the contralateral C6-T1. Thalamic DY-labeled cells located within 100um of STT terminals were considered overlapping and thus having STT inputs. Despite smaller numbers (10%of the total SI projection), surface injections produced a pattern of label no different than that of complete SI injections either in locations, proximity to STT terminals or proportion of overlap from each thalamic nucleus. On an average 100um section, 49 of 148 (33%) SI surface projecting cells had STT inputs, as compared to 507 of 1695 (30%) of total SI projecting cells. The result suggests that the STT afferent can be relayed into layer I of SI by VPL, VPI and CL but they are not preferential pathways.

582.4

DISTRIBUTION OF $GABA_A$ RECEPTORS IN CAT SOMATOSENSORY AND MOTOR CORTEX. J. Li and H.D. Schwark*. Department of Biological Sciences, University of North Texas, Denton, TX 76203.

Rapidly-adapting (RA) and slowly-adapting (SA) submodality-specific regions have been described in area 3b of cat primary somatosensory (SI) cortex (Sretavan & Dykes '83). Compared to SA regions, a higher proportion of neurons in RA regions are sensitive to locally applied bicuculline (Dykes et al. '84), suggesting differences in the organization of GABAergic systems between these two regions.

To determine whether $GABA_A$ receptor densities might correlate with the segregation of submodalities, we have examined the distribution of [^{3}H]muscimol binding sites in film autoradiographs of parasagittal sections through SI. Reliability of patterns was determined in series of 4-6 closely spaced sections. Density histograms were used to measure the distribution of [^{3}H]muscimol binding along the vertical extent of cortical columns in areas 2, 1, 3b, 3a, 4 and 6.

Although initial visual inspection of muscimol binding in area 3b failed to reveal density differences related to submodality segregation, the issue is presently being addressed by quantitative image analysis. Average binding density in areas 3b, 3a, 4 and 6 was approximately 18% higher than in areas 1 and 2. Within each area, the highest levels were in layers I and II (average values 170-390 fmoles/mg). Below layer II, the levels of binding decreased with depth, except that in most of the density histograms through SI, upper layer IV showed a peak in binding density. Supported by NIH grant NS25729.

582.5

THE ORGANIZATION OF CORTICOCORTICAL AND CALLOSAL PROJECTION NEURONS AND CALBINDIN-IMMUNOREACTIVE NEURONS IN THE RAT SECOND SOMATOSENSORY CORTEX. K. A. Baskerville*, P. Herron, and H. T. Chang. Dept. of Anatomy and Neurobiology, The Univ. of Tennessee, Memphis, Col. of Medicine, Memphis, TN 38163

We investigated the spatial distributions and collateralization of corticocortical and callosal projection neurons in the rat second somatosensory cortex (SII) and investigated whether these projection neurons were immunoreactive for calbindin. In double-labeling studies, retrograde tracers were injected into electrophysiologically-identified homotopic areas of ipsilateral primary somatosensory cortex (SI) and motor cortex (MI), contralateral SI and SII, or SI of both hemispheres. In some animals, the SII representation area was mapped to determine the congruence of retrogradely labeled corticocortical and callosal neurons in the lateral SI-suprarhinal area with the SII somatotopic map. Injections into homotopic areas of contralateral SI and SII, ipsilateral SI and MI, or SI of both hemispheres resulted in two overlapping populations of neurons in appropriate homotopic areas of SII. Very few double-labeled cells were found. Neurons immunoreactive for calbindin were located principally in the same laminae as corticocortical and callosal neurons in SII; however, very few corticocortical or callosal neurons were immunoreactive for calbindin. These results suggest that corticocortical and callosal neurons in SII with collaterals to two or more homotopic areas are relatively rare and that those immunoreactive for calbindin are even rarer. Given their laminar proximities to corticocortical and callosal neurons, calbindin-containing neurons may be the targets of reciprocal corticocortical and callosal axonal terminals in the SII cortex. (Supported by NIH grant AG05944 and The Center for Neuroscience of The Univ. of Tennessee, Memphis).

DIFFERENTIAL EXPRESSION OF GAD AND CAM II KINASE-α mRNA DURING DEVELOPMENT OF THE MOUSE SOMATOSENSORY CORTEX. J.L. Massengill, M.M. Huntsman and E.G. Jones* Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717

In situ hybridization with specific riboprobes was used to examine differential expression of 67 kDa GAD and CAM II kinase-α mRNA during development of the mouse somatosensory cortex. Animals were particularly examined during the first postnatal week when correlative physiological studies (Agmon and O'Dowd, J. Neurophysiol., in press) indicate that the normal GABA-mediated disynaptic inhibitory thalamocortical response is maturing. CAM II kinase-α is expressed in cortical excitatory neurons and absent from GABA neurons. GAD and CAM II kinase-α are expressed early in cortical neurons but preliminary findings suggest that expression of GAD lags behind that of CAM II kinase-α during the critical postnatal period and this may correlate with the earlier maturation of the monosynaptic excitatory thalamocortical response. Supported by NIH grant NS21377.

582.7

COLUMNS IN RAT SOMATOSENSORY CORTEX SEEN WITH DEOXYGLUCOSE AUTORADIOGRAPHY. *S. M. Feldman* and L. L. Brown†*. *Center for Neural Science, New York University, New York, NY 10003 and †Department of Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

Deoxyglucose autoradiography was used to examine cortex during somatosensory stimulation applied to forelimb (FL; n=10), hindlimb (HL; n=5), trunk (TR; n=5) or FL+HL (n=5) in awake rats. A plexiglass restraining device permitted automated stroking by a nylon bristle (0.5 or 2.5g @3-4/sec). The path of the bristle was up to 2.0 cm within the receptive field of individual cells (Chapin & Lin, 1984). Radiolabelled deoxyglucose was injected iv 10 min after onset of a 55-min period of stimulation, after which rats were sacrificed and brains were prepared for autoradiography. Controls (n=5) received no stimulation.

Stimulation of FL, HL or TR activated cortex in regions expected on the basis of electrophysiological studies. Regions of activation had columnar shapes, when viewed in coronal sections, and were most prominent in Layers III, IV, Va and Vb. At 0.5g, FL and HL columns were 0.2-0.4 mm in diameter mediolaterally, and extended 0.3-1.0 mm anteroposteriorly. At 2.5g, the mediolateral extent was 0.4-0.8 mm. Also at 2.5g, TR columns extended 0.6-0.8 mm mediolaterally and 0.4-0.5 mm anteroposteriorly. Comparison of the autoradiograms with stained alternate sections revealed that columns were confined to regions defined by the granular strips in Layer IV, regions also sparsely invested with large Layer Vb cells. Deoxyglucose activation was not seen in perigranular regions. TR and HL were represented bilaterally in granular cortex; FL representation was contralateral only. The results confirm, in conscious animals, electrophysiological localization of cutaneous activity, and permit visualization of neural activity in all cortical layers.

582.8

SPECIALIZED VASCULARIZATION OF THE RAT SOMATIC SENSORY CORTEX. D.Zheng, D. Riddle and D. Purves*. Dept. of Neurobiology, Duke Univ. Med. Center, Durham, NC 27710

We have analyzed vascular density across the primary somatic sensory cortex in the rat to obtain a picture of differential metabolic demands, and, by inference, of differential electrical activity in this region. Adult Sprague Dawley rats were anesthetized, and perfused through the heart with saline followed by 10% glycerol and 20ml of ink (Rapidograph Universal 3080). The cerebral cortices were removed, flattened, and frozen at -20°C. Serial tangential cryostat sections were stained for succinic dehydrogenase, and the complete map of SI was reconstructed as previously described (Riddle et al, 1992 J. Neurosci. in press). Blood vessel density was measured using a computerized image analysis system. Capillary density was greatest in barrels and barrel-like structures of the major somatic representations (whisker pad, anterior snout, lower jaw, forepaw and hindpaw). The vascularization was least in the interbarrel regions, where the density averaged 40% less than that within the barrels; an intermediate density was found in the dysgranular cortex within and around SI. These findings, which are consistent with earlier observations in the monkey visual cortex (Zheng et al, 1991 J. Neurosci. 11:2622), indicate systematically different metabolic demands in various regions of the rat somatosensory cortex. Because the majority of energy consumption in the adult cortex is devoted to maintaining the ion gradients needed for neural signaling, these differences presumably reflect different average levels of electrical activity across SI.

582.9

HETEROGENEOUS DISTRIBUTION OF $GABA_A$ RECEPTOR COMPLEX IN RAT SOMATOSENSORY CORTEX (SMI). P.W. Land*[1], N.A. Reddy[1] and A.L. de Blas[2]. [1]Neurobiol., Anat. and Cell Sci., Univ. of Pittsburgh, Pittsburgh, PA 15261 and [2]Div. Mol. Biol. and Biochem., UMKC, Kansas City, MO 64110, USA.

Monoclonal antibody 62-3G1 was used to study distribution of $GABA_A$ receptor complex ($GABA_AR$) in rat SmI. This antibody recognizes the β_2 and β_3 subunits of $GABA_AR$ (de Blas, et al., 1988). $GABA_AR$ immunostaining occurs on neuronal somata and throughout the neuropil of all cortical laminae. Immunostaining is most intense in laminae IV and VI while laminae I - III and Va are moderately stained. Lightest staining occurs in Vb. Thus, except for the pattern observed in lamina Vb, $GABA_AR$ distribution parallels both the arrangement of GABA containing terminals and the intensity of cytochrome oxidase (CO) activity described previously for rat SmI.

Interestingly, $GABA_AR$ immunostaining is not uniform within lamina IV. The CO-dark hollows of vibrissae-related barrels and barrel-like structures representing distal extremities are intensely immunoreactive. By contrast, barrel septa and surrounding dysgranular cortex stain lightly. These data indicate that regional variations in $GABA_AR$ expression in the cortex reflect 1) density of GABAergic input, and 2) overall level of neuronal activity.

582.10

GLUTAMATE AND ASPARTATE IMMUNOREACTIVITY IN TERMINALS OF THALAMOCORTICAL FIBERS V.N. Kharazia*, A. Rustioni and R.J. Weinberg. Dept. of Cell Biology & Anatomy, University of North Carolina, Chapel Hill, NC 27599.

Pharmacological and biochemical studies suggest that thalamocortical afferents use an excitatory amino acid transmitter. We have combined anterograde transport of HRP with postembedding immunocytochemistry to study the content of glutamate, aspartate, and GABA in terminals of thalamocortical fibers within rat somatosensory cortex (SI). WGA-HRP aminocaproate (E-Y labs, 2% in 2% DMSO) was injected into the thalamus of anesthetized rats. Injections were targeted at VPL, but also spread into other nearby thalamic regions. After 48 h survival, animals were perfused with 2.5% glutaraldehyde, 0.5-1% paraformaldehyde, and 0.2% picric acid in phosphate buffer pH 7.4. Brains were postfixed in the same fixative 2-8 h. Vibratome sections of somatosensory cortex were cut and reacted for peroxidase histochemistry using a tungstate/TMB method. Thin sections from plastic-embedded wafers were mounted on nickel mesh grids and processed for EM postembedding immunocytochemistry for glutamate, aspartate and GABA, using primary antisera from Arnel.

Thalamocortical terminals in SI (identified by crystals of reaction product) contained low levels of GABA, and significantly higher levels of glutamate than did dendrites, glia, or nearby synaptic terminals identified by their high concentration of GABA staining as likely to be GABAergic. Thalamocortical terminals also contained more aspartate than did GABA-positive terminals; however, dendrites and neuronal somata contained more aspartate than either class of terminal. These results support the hypothesis that thalamocortical synapses use glutamate as neurotransmitter, and raise the possibility that some may also use aspartate.

582.11

AXOSOMATIC SYNAPSES ONTO INTRINSICALLY BURSTING NEURONS IN RAT SmI (BARREL) CORTEX.

E.L. WHITE*, Y. AMITAI and M. J. GUTNICK, FACULTY OF HEALTH SCI., BEN-GURION UNIV., BEER SHEVA, ISRAEL.

Recording under threshold conditions for synchronization shows that most regular spiking cells have strong and dominant inhibitory potentials, while intrinsically bursting cells show little evidence of inhibition (Chagnac-Amitai and Connors, 1989). This study is part of a broader effort to determine if differences in inhibitory responses are reflected in the numbers or in the spatial distribution of symmetrical, presumed inhibitory synapses. Our approach is to use intracellular recording to classify neurons by their intrinsic firing properties, and to label them using HRP or biocytin. Then the neurons are processed for EM and serial thin sectioned. The somata and proximal dendrites are reconstructed and the distribution of their synapses displayed, using a newly developed system for capturing video images directly from the electron microscope and for making 3-D reconstructions from them. Two somata of intrinsic bursters were calculated to have surface areas of 541 μm2 and 855 μm2. These cells had 54 and 86 synapses respectively, that is, one axosomatic synapse per 10 μm2 of somatic surface area. The results of ongoing studies will determine whether this ratio of synapses to somatic area holds for other bursting neurons and whether it is shared by regular spiking neurons. NIH 20149, Israel Acad. of Sciences 236/90.

MORPHOLOGY OF ELECTROPHYSIOLOGICALLY IDENTIFIED NEURONS IN ADULT RAT NEOCORTEX.

R. Schröder* and H.J. Luhmann. Institute of Neurophysiology, University of Cologne, D-5000 Cologne 41, FRG.

We were interested in the morphological and electrophysiological properties of single supragranular cells in primary somatosensory cortex of mature rats. Intracellularly recorded neurons were analyzed *in vitro* in their intrinsic membrane properties and their synaptic inputs. After functional characterization neurons were labelled by intracellular injection of biocytin. Out of 85 stained cells, 33 neurons with a relatively complete axonal and dendritic arborization pattern were selected for detailed graphical reconstruction and subsequent morphometrical analysis. Resting membrane potential V_m was -81.2 ± 4.6 mV (mean ± SEM) and neuronal input resistance R_N was 38.9 ± 4.6 MΩ. All cells, including four sparsely spiny neurons, were classified as regular spiking cells with a prominent inhibitory synaptic input, consisting of a biphasic IPSP. Somatic area ranged from 96 to 744 μm^2 and did not correlate with R_N. The horizontal extent of the basal dendritic field (310 μm) was significantly (*t* test, $p<0.01$) larger than the lateral spread of the apical dendritic field in layer I / upper layer II (207 μm), indicating that synaptic inputs are integrated over a larger spatial domain in more proximal regions. Descending axons could be traced up to 1.4 mm from the soma and total length of intracortical axon collaterals ranged up to 6 mm.

We were unable to detect any significant correlation between the morphological and electrophysiological properties tested, suggesting that supragranular regular spiking cells represent a functionally homogeneous group.

Supported by SFB 194/B4 and a grant from Ministerium für Wissenschaft und Forschung in NRW (HJL).

SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS: PHYSIOLOGY

583.1

CENTRAL EFFECTS OF HISTAMINE ON THE STATISTICAL FEATURES OF UNIT ACTIVITIES IN SOMATOSENSORY CORTEX OF CATS.

Yang Tsau, Yu-Zhong Yao, Gan-Quan Liu, Pei-Xi Chen, Lawrence B Cohen*. Dept. of Physiol., Sun Yat-Sen U. of Med. Sci., Guangzhou, P.R.O.China.

We studied the effects of histamine (HA) on unit activities in the somatosensory cortex of cats. Microiontophoresis and t-test of mean value of inter-spike intervals (MISIs) and normalized power spectrum density function (NPSDF) methods were used. We found that: 1) HA (0.5M) both raised (n=14) and reduced (n=6) MISIs in the recorded neurons (n=20), suggesting HA has both inhibitory and excitatory effects on the cortical neurons. 2) Cimetidine (0.1M) excited the neurons slightly and blocked the inhibitory action of HA (n=10), suggesting the inhibitory effect of HA is via the H2 receptor. Diphenhydramine (0.1M) inhibited neurons and did not block the inhibitory action of HA (n=9), suggesting the excitatory effect is via the H1 receptor. 3) HA reduced both the peak frequency and value of NPSDF ($p<0.01$, n=20) and induced a 'post-inhibitory rebound' of the peak value with the peak frequency remaining low after iontophoresis, suggesting HA modulates the cortical rhythm and has after-effects.

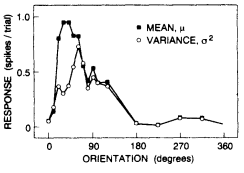
583.2

SPIKE STATISTICS AND RECEPTIVE FIELD PROPERTIES OF NEURONS IN PRIMARY SOMATOSENSORY CORTEX OF RAT.

D. Kleinfeld* and R. A. Stepnoski. AT&T Bell Labs., Murray Hill, NJ 07974.

Neurons within the barrel field of rat S1 cortex encode features of the deflection of a vibrissa (Simons, J. Neurophys. 41, 1978). Here we report on the variability of this code in response to multiple presentations of a stimulus. Our measurements consisted of single unit recordings from adult Sprague-Dawley rats anesthetized with urethane. Each stimulus trial consisted of displacing a vibrissa from its natural position to a new position and, after a brief rest, returning the vibrissa to its natural position. The new positions were chosen at random from a set of up to 24 different combinations of orientation, maximum angular displacement (~ 5° to 10°) and angular velocity (~ 50°/s to 500°/s). Stimuli, chosen at random from the set, were presented at 1 s intervals and the entire set was presented up to 200 times. We observed: (1) The mean number, μ, of spikes elicited in units at the depth of layer 4 was relatively low, $\lesssim 2$ spikes per trial, even for apparently optimal stimuli. The trial-to-trial variance in the number of spikes, σ^2, was equal or significantly less than its mean, *i.e.*, $\sigma^2 \leq \mu$ (Fig.). (2) Units at the depth of layers 2/3 fired multiple spikes per trial and exhibited a large, nonstationary variance. (3) Units with similar orientation preference appear to be spatially clustered within a barrel.

The low variance in layer 4 units is reminiscent of that found in peripheral pathways and, notably, contrasts with the large variance, $\sigma^2 \simeq (2-4)\mu$, for units in cat and monkey V1 cortex (*e.g.*, Tolhurst *et al.*, Vision Res. 23, 1983). The implication of the above observations for population coding is under investigation.



583.3

TEMPORAL INTEGRATION AND TEMPORAL TRANSFER PROPERTIES OF RAT SOMATOSENSORY CORTICAL NEURONS.

K. Selpien and H.R. Dinse. Dept. Neuroinformatic, Theoret. Biol. Ruhr-Univ. Bochum, RUB, D-4630 Bochum, FRG. (Spon: ENA)

We studied the temporal transfer characteristics (TTC) of cortical neurons recorded in the hindpaw representaion of SI in Urethane anesthetized rats. Tactile stimuli (TS) of 8 ms duration were applied by use of a computer-controlled mechanical stimulator as small skin indentations. Neuron responses were quantitatively analysed based on PSTHs. We varied systematically interstimulus intervals (ISI) between 20 and 200 ms and the number of stimuli (NS) in each train (2 to 6). Betweeen each train was a pause of 3 sec. By this we were able to investigate the transition from transient to steady state conditions. In the double-click condition, i.e. using two stimuli, we found the often described TTC with low cut offs at ISIs between 20 and 80 ms. However, this TTC was not replicated when the ISI effect to the third or higher TS was tested. Accordingly, the overall responses depended not only on ISI, but in addition on the number of the stimulus and its ISI condition. Further analysis revealed that amplitude measures of peak height yielded only partial insight in neuron reponse properties. Inhibition seen for short ISIs appeared to be uncorrelated with the preceeding response. This leads to the observation that inhibitory action is restricted to given numbers of TS revealing strong sequencing effects. The results are discussed in respect to modulation of neuron responses under natural conditions that are characterized by severe temporal constraints.

583.4

LAMINAR ANALYSIS OF THALAMOCORTICAL INTERACTIONS IN SOMATOSENSORY SYSTEM OF RATS.

K.D. Alloway*, M.J. Johnson, and M.B. Wallace. Dept. of Neuroscience & Anatomy, M.S. Hershey Medical Center, Penn State University, Hershey, PA.

Thalamocortical neurons terminate within cortical layers IIIb and IV where they synapse upon the soma and proximal dendrites of local neurons, and on distal dendrites extending from neurons located in supra- or infragranular cortical layers. In view of differences in thalamocortical inputs to cortical layers and in interlaminar connections, this study used electrophysiological techniques to detect a laminar sequence of sensory activation.

Single neuron responses to computer-controlled tactile stimulation were simultaneously recorded in the ventrobasal thalamus and somatosensory cortex of halothane-anesthetized rats. Hairy and glabrous skin RFs were activated by either air puffs or mechanical indentations, respectively. Response magnitude and latency analyses clearly indicate that thalamocortical inputs initiate responses in cortical layers IIIb and IV. Response magnitude is next highest in layers II, III, and lowest in layers V, IV. By contrast, response latency was shorter in layers V, VI than in layers II, III. Cross-correlation analyses of laminar differences in thalamocortical connection strength are currently in progress. These preliminary results provide evidence in support of activity proceeding along serial and parallel circuits within a cortical column. Supported by NIH grant NS29363 and PSU RIG430-22.

CROSS CORRELATION STUDIES OF INTRACORTICAL NEURONAL CONNECTIONS IN RAT SOMATOSENSORY CORTEX. S.C. Silbert, T.A. Woolsey* & H. Burton, Dept. Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

We simultaneously identified the responses of several single neurons in the posteromedial barrel subfield. Two independently controlled multibarrel iontophoretic electrodes were positioned in neighboring whisker representations. Anesthesia with chloral hydrate, supplemented with N_2O_2 and halothane, was stable for many hours. On-line spike waveform analysis, perievent time histograms, and cross-correlograms guided identification of related cell pairs. Iontophoresis onto cortical neurons and controlled whisker stimulation enabled characterization of the transmitters used by physiologically connected cells. Several cell pairs, with and without shared whisker inputs, had correlated activity. These studies show whether cortical neurons receive common or direct interbarrel synaptic connections and which transmitters mediate these interactions. (Supported by NINDS 22012)

RESPONSES OF CAT SI RAPIDLY ADAPTING NEURONS TO CONTROLLED MECHANICAL STIMULATION. H. Esteky*, M.J. Pettit and H.D. Schwark. Department of Biological Sciences, University of North Texas, Denton, TX 76203.

Cutaneous rapidly-adapting first order fibers of many mammals have been classified by their responses to the velocity and displacement components of controlled stimuli (Burgess and Perl, 1973). We have used constant-velocity ramp stimuli and a modification of the Burgess and Perl criteria (1973) to study single neurons in the forelimb region of primary somatosensory cortex of anesthetized cats.

Thirty-five of 140 units responded well to single probe stimuli and were analyzed in detail. G_1/F_1 units (8/35) responded to ramp stimuli with 1-3 action potentials at the beginning of the ramp and none during the rest of the ramp. This group had little spontaneous activity and required relatively high ramp velocities. G_2/F_2 units (9/35) responded throughout the ramp. They had higher spontaneous activity and responded to lower ramp velocities than G_1/F_1 units. G_{int}/F_{int} units (14/35) showed intermediate properties: an initial brief response was followed, after a period of low or no activity, by a response during the remainder of the ramp. Five units had responses which were combinations of these patterns, suggesting convergence between groups.

The instantaneous firing frequency of all units generally increased with increasing ramp velocities. The average firing frequency of G_1/F_1 and G_{int}/F_{int} units also increased in a graded manner with ramp velocity, whereas the response of G_2/F_2 units was discontinuous. These results suggest that rapidly-adapting cells in SI cortex which respond to punctate ramp stimuli have response patterns similar to those of first order afferents. Supported by NIH grant NS25729.

583.7

RECEPTIVE FIELD AND RESPONSE PROPERTIES OF SIV SOMATOSENSORY NEURONS. H.R. Clemo* and B.E. Stein. Dept. of Physiology, Med. Coll. VA, VA Commonwealth Univ., Richmond,, VA 23298.

The somatosensory region (SIV) of the anterior ectosylvian sulcus (AES) is an important source of inputs to the superior colliculus (SC) a structure involved in orientation and localization behaviors. SIV also shares reciprocal connections with somatosensory cortical regions, SI and SII, involved with tactile perception and discrimination. However, it is not known whether the properties of SIV neurons are similar to those in SI and SII or to those in the SC. Therefore, this investigation compared the response properties of SIV neurons to those of the SC, SI and SII.

The receptive fields and responses of SIV somatosensory neurons (n=22) in cats (n=3) were examined. All neurons were rapidly-adapting and activated by low threshold mechanoreceptors. While the majority required high velocity stimulation and were broadly tuned to different directions of stimuli, few exhibited directional selectivity or spatial summation, and none showed spatial inhibition. Most exhibited medium to large-sized receptive fields that contained areas ('best areas') where a significantly higher response could be elicited than elsewhere in the receptive field.

The receptive field size, rapidly-adapting nature, and velocity sensitivity of SIV neurons are features more similar to those observed in the SC than SI or SII.

583.8

OPTIC NERVE EXCITATION OF PERICRUCIATE CORTEX IN CAT. A.L. Towe* and Y. Gahery. Dept. of Physiol. and Biophys., Univ. of Wash. Sch. of Med., Seattle, WA 98195

Single neurons were recorded on both sides of the cruciate sulcus in chloralose-anesthetized cats. About 24% of the cutaneous small-field neurons and all of the wide-field neurons were excited by input over each optic tract. In addition, about 7.4% of the neurons failed to respond to skin stimulation, but were excited by optic chiasm input. Response latencies to optic chiasm stimulation fell into four distinct groups. Timing relations suggested the first surge arrived via superior colliculus and the third via visual cortex; the routes for the second and fourth surges remain unidentified. These was no indication that these separate surges converged onto the same neurons. Input via the contralateral optic tract evoked activity at a higher threshold, produced fewer spikes per discharge, and has a longer latency than did the ipsilateral optic tract. The difference in response latencies was largest for neurons responding in the first surge, and decreased progressively through the later surges. The mean latency of response to optic chiasm input was the same as that to contralateral forepaw stimulation, though optic chiasm input evoked more spikes per response. It is suggested that the visual input to pericruciate cortex serves to modulate on-going cortical output and thereby modulates the behavior of the animal. (Supported by USPHS grant NS00396)

583.9

DISTRIBUTION OF PROPRIOCEPTIVE INPUT TO PERICRUCIATE CORTEX OF AWAKE CATS. Jefferson C. Slimp* and Arnold L. Towe. Dept of Rehabilitation Medicine and Dept of Physiology and Biophysics, Univ. of Wash. Sch. of Med., Seattle, Wa 98195.

A previous report (Exp.Neur., 107:78-96) concluded that the data from three restricted but well sampled regions of pericruciate cortex of awake cats failed to support any model of organization that emphasized local, bounded regions within which all neuron response properties are the same. The data reported here, taken from a larger extent of pericruciate cortex in four cats, confirms this conclusion. Focusing only on proprioceptive neurons (ignoring the interspersed cutaneous neurons), most tracks contained a mixture of modalities: joint, muscle/tendon/joint, and active (during movement but not driveable). Many neurons responded to movement or two or more joints. About half of the neurons recorded simultaneously or sequentially showed reciprocal sensitivities (e.g., flexion/extension or adduction/abduction). However, given a neuron with one pattern of response, the probability that the next neuron would show that same pattern was equal to that expected by chance, i.e. the distribution of input was random. Tracks in which many elbow-sensitive and wrist-sensitive neurons were found yielded similar results, although there was a slight tendency for elbow and wrist neurons to clump. Neurons responsive to movement of two joints showed no preferred relationships: e.g., there were equal numbers of elbow flexion/wrist flexion as elbow flexion/wrist extension, etc. These findings suggest that restricted areas of cerebral cortex receive input from more diverse and scattered sources than had previously been thought. Even somatotopy was rather more fuzzy than precise. Neighboring neurons with reciprocal response patterns behaved as though they mutually inhibit one another; they could serve to code joint position through their differential action. SCALP POTENTIAL TOPOGRAPHIES EVOKED BY SURAL NERVE STIMULATION IN MAN. R. Dowman[*1], T.M. Darcey[2] [1]Dept. Psychol., Clarkson University, Potsdam N.Y. 13699, [2]Dartmouth Med. Sch. and V.A. Med. Ctr., White River Jct. VT 05009.

Potentials evoked by sural nerve stimulation were recorded from 30 scalp locations in 15 healthy humans. Eight different stimulus levels were given. The 3 lowest levels were innocuous and the 3 highest were noxious, as defined by physiological criteria.

The 512 ms epoch following the evoking stimulus could be separated into 6 stable periods (SP), i.e., consecutive time points where the patterns were the same. For each SP the onset and offset latencies and the topographic patterns were comparable across subjects. The topographies for each of the first 5 SPs (59-88 ms, 93-117 ms, 135-156 ms, 180-219 ms, and 225-275 ms, respectively) were stable across all stimulus levels, suggesting that the sources (neural generators) underlying a given SP were the same at noxious and innocuous levels. The topographies for SP6 (287-325 ms) were stable across noxious but not innocuous levels, suggesting that the sources underlying SP6 are different at noxious vs. innocuous levels. We are presently analyzing these data using dipole source modeling to test hypotheses about the location of the sources generating these potentials and to quantify the source amplitude and duration. This analysis will help determine whether these putative sources behave similarly to neurons involved in innocuous and noxious somatosensory cortical processes identified in animal studies.

SOMATOTOPIC ORGANIZATION OF SNOUT REPRESENTATION IN THE CORTEX OF THE SWINE REVEALED BY SOMATIC MAGNETIC EVOKED FIELD. Y. C. Okada*, H. Nowak and C. Xu. Center for MEG, V A Med. Center 87131 and Depts. Neurol. & Physiol., Univ. New Mexico Sch. of Med., Albuquerque, NM 87018.

A high-resolution magnetometry was used to determine the representation of snout in the cerebral cortex of the juvenile farm swine (3-6 weeks old, 5-10 kg). Each of five locations on the snout was transcutaneously stimulated with an array of concentric bipolar electrodes (0.3 ms, 6 mA) attached to an isolated stimulator to produce activity in the cerebral cortex of the swine anesthetized with ketamine (10 mg/kg/hr, i.p.) and xylazine (4 mg/kg/hr, i.p.). The somatic magnetic evoked field (MEF) associated with the neuronal activity was measured on a plane 1.2 mm above the apex of the intact dura mater with a 4-channel superconducting magnetometer with a passband of 0.3 Hz to 1 kHz, after removing the scalp and the dorsal half of the skull.The stimulation of each site produced an MEF detectable on single epochs. The topography of averaged MEF normal to the measurement plane indicated that the cortical tissue active at 15 and 19 ms after stimulation was located systematically around the contralateral coronal gyrus, confirming the electrophysiological work of Craner (Ph.D. Thesis, East Carolina Univ., 1988). The lateral, top, midline and bottom regions of the snout were located in the medial, posterior, lateral and anterior portions, respectively, of the snout area. Some areas of the snout were represented in two sulci on each side of the gyrus. Together with the field potential data, these results indicate the existence of a somatotopically organized projection of the snout in the coronal gyrus and in the surrounding sulci.

LOCALIZING DIPOLES OF SOMATOSENSORY EVOKED POTENTIALS IN MONKEY BRAIN RECONSTRACTION. H. Nishijo*, N. Hayashi[1], T.Ono, S. Endo[1], T. Musha[2], and S. Homma[3] Depts. Physiol. & [1]Neurosurg., Fac. Med.,Toyama Med. & Pharmaceu. Univ., Toyama 930-01, [2]Brain Function Lab., Kawasaki 213, and [3]Dept. Physiol., Meiji College of Oriental Med., Kyoto 629-03, Japan.

We developed dipole localization (dipole tracing, DT) by a boundary element method, using a 3-dimensional reconstructed model of the cerebral cortex. The DT was used to investigate dipoles of somatosensory evoked potentials (SEPs) produced by electrical stimulation of the median nerve. Potentials were recorded with 21-27 electrodes placed on the dura in 3 anesthetized monkeys. The estimated dipoles were stereotaxically superimposed on magnetic resonance images and specimens of brain.

The results indicated generators with 7 ms latency located in the contralateral thalamus, and in the posterior wall of the central sulcus, area 3b of the somatosensory cortex with the 9-11 ms latency range. Generators were also located in the anterior parietal cortex, areas 1 and 2, with latencies of 12-13 ms; and in the posterior parietal cortex, area 5, with latencies of 15-20 ms. Locations and latencies of these generators were confirmed by recording multiple unit activity from the sensorimotor cortex, and area 5 of the same monkeys investigated by SEPs. It was concluded that DT could accurately localize electric dipoles, and that successive generators of SEPs by median nerve stimulation are located in the thalamus, and cortical area 3b, areas 1 and 2, and area 5.

DIFFERENTIATION BETWEEN MAGNETIC SIGNALS FROM HUMAN SI AND SII CORTICES. R. Hari*, M. Hämäläinen and J. Karhu. Low Temp. Lab., Helsinki Univ. Technol., 02150 Espoo, Finland.

Peaks around 100 ms in the somatosensory evoked magnetic field (SEF) have been thought to originate at the second somatosensory cortex SII. We confirmed this with 4 different methods, analysing SEFs recorded from healthy humans with a 24-channel planar SQUID gradiometer.

(1) Comparison with functional landmarks: Field patterns to auditory and ipsilateral median nerve stimulation were modeled with equivalent current dipoles (ECDs). ECDs for both SEFs and auditory evoked magnetic fields (AEFs) were close to the Sylvian fissure, with the ECDs for SEFs situated slightly higher than those for AEFs. (2) Comparison of the ECD locations with individual anatomy, derived from MR images, suggested activation of the upper and lower lips of the Sylvian fissure during SEFs and AEFs, correspondingly. (3) Time-varying two-dipole model with fixed source locations satisfactorily accounted for the pattern of SEFs to contralateral median nerve stimulation. One dipole waveform corresponded to activation of hand SI and the other to SII area; the sources were about 4.5 cm apart and had different orientations and time dependencies. (4) Very similar results were obtained with a MUSIC algorithm which automatically determines the number and locations of time-varying dipole sources.

We conclude that it is possible to reliably differentiate between neuromagnetic responses arising from the human SI and SII cortices.

SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS: THALAMUS

584.1

EXPRESSION OF CALCIUM BINDING PROTEINS IN ADULT RAT THALAMUS FOLLOWING CORTICAL LESIONS. V. Rema, M.E. Diamond, L. Van Eldik† and F.F. Ebner* Institute for Developmental Neuroscience and Department of Pharmacology†, Vanderbilt Univ. Nashville, TN 37203.

To test the hypothesis that thalamic cell survival after cortical damage depends on increased expression of calcium binding proteins, we used immunocytochemistry to estimate the levels of three calcium binding proteins (calbindin, parvalbumin, calmodulin) and S100ß at 5, 7 & 14 days following subtotal aspiration lesions of rat SI (barrelfield) cortex. At 5 days Nissl changes and reduced levels of calbindin were visible in the thalamus ipsilateral to the lesion, whereas neuronal changes in parvalbumin and calmodulin expression were not evident. However, a marked increase in astrocytic parvalbumin staining was seen in the posterior nucleus. By 7 days calbindin expression increased on the lesion side. Parvalbumin expression was also elevated in VPM, but most of the reaction product appeared to be in processes arising from the reticular nucleus. All thalamic neurons are normally calmodulin positive, but those labeled in the area affected by the lesion appeared smaller, paler and fewer in number. At 14 days, chromatolytic neurons were swollen, pale, contained vacuolated cytoplasm or were disintegrating with only ghosts remaining. These neurons stained lightly for calbindin and calmodulin, but outside the reactive zone both neurons and glia showed greatly increased parvalbumin expression. Glial cells expressed increasing levels of S100ß protein during the period studied. Our results suggest that in the thalamus there is a progressive increase in the intensity of staining for all four proteins examined during the first two weeks after cortical injury. Most of the increase can be attributed to glial cells, which show dramatically increased staining over time for the calcium binding proteins tested. (supported by NIH grant #NS13031)

584.2

AREAL DISTRIBUTION OF CORTICOTHALAMIC PROJECTION NEURONS TO THE POSTERIOR THALAMIC COMPLEX IN RAT SOMATOSENSORY CORTEX. Karen E. Good* and H. P. Killackey, Department of Psychobiology, University of California, Irvine, 92717-4550.

We previously reported in rats, cortical projection neurons to the Ventral Posterior Nucleus (VP) and to the medial division of the Posterior Thalamic Complex (PoM) have different laminar origins; cortico-VP projections arise from neurons in superficial layer VI (VIa), whereas cortico-PoM projections arise from neurons in deep layer VI (VIb) and layer V. Thalamocortical afferents from VP and PoM to the posteromedial barrel subfield (PMBSF) are distributed in a complementary areal fashion (Koralek et.al., 88; Lu and Lin, 85). Furthermore, corticothalamic neurons whose target is VP have an areal distribution reflecting the pattern of layer IV cell aggregations in the PMBSF (Chmielowska et.al., 89). This study examines if the distribution pattern of cortico-PoM neurons is complementary to that of cortico-VP neurons.

Stereotaxic pressure injections of WGA-HRP or fluorescently labeled beads were confined to PoM. Flattened hemispheres were sectioned at 30-40 um, and the tissue processed for cytochrome oxidase. Preliminary results indicate that retrogradely labeled cortico-PoM neurons are not distributed uniformly. In preliminary analysis of tangential sections, we observed a restricted pattern of labeled cortico-PoM neurons in layer VI. In one case, labeled cells in three consecutive sections at 40 um had a similar pattern of distribution (920-1080 um from pial surface). In layer VI, labeled cells were aligned in one of three parallel bands which appear to correspond to the septae of the PMBSF. Each of these three bands was 60-150 um wide and 1000 to 1500 um long, extending in an anterolateral to posteromedial fashion. Sections were stained with bisbenzamide revealing a uniform laminar cytoarchitecture, thus potential artifactual discontinuities in these sections are unlikely. In addition, labeled cells were found in surrounding areas corresponding to dysgranular cortex. We tentatively conclude that cortico-PoM projection neurons are distinct in both areal and laminar origins from cortico-VP projection neurons.

584.3

ELECTRON MICROSCOPIC ANALYSIS OF CORTICAL INPUTS TO THE THALAMIC RETICULAR NUCLEUS (TRN) IN THE MONKEY. A.M. Williamson*, D.D. Ralston, and H.J. Ralston, III. Dept. of Anatomy and the W.M. Keck Foundation Center for Integrative Neuroscience, U.C.S.F., San Francisco, Ca. 94143.

The TRN is composed of a thin layer of GABA-ergic cells surrounding the lateral and rostral thalamus, and lying medial to the internal capsule. Its function is not completely understood, but appears to integrate ascending information from the thalamus, several brainstem nuclei and collateral innervation from corticothalamic inputs. We examined the input from the somatosensory cortex to determine the nature of the synaptic contacts formed in TRN, and to describe the placement of those contacts on TRN neurons.

To label the cortical inputs into TRN, we injected small amounts (<0.2 µl) of 4% WGA-HRP in the somatosensory cortex of *M. fascicularis*, allowed the animals to survive 2-4 days, perfused with mixed aldehydes, and prepared tissue for electron microscopic visualization of the transported WGA-HRP.

Results of these experiments show that cortical projections to the TRN end as synaptic terminal profiles similar to those described for cortical projections to thalamic sensory nuclei. The terminals are small, contain round vesicles, and form asymmetric contacts with small caliber dendrites in TRN. We have also observed in single section what appear to be dendro-dendritic contacts between TRN neurons. We conclude that cortical projections to TRN neurons can activate these GABA-ergic cells, some of which contact one another, to result in feed forward inhibitory mechanisms. QUALITATIVE ASSESSMENT OF TACTILE RESPONSES IN ALERT MONKEY VENTRAL POSTERIOR NUCLEI. Susan Warren* and Jennifer E. Taylor. Dept. of Anatomy, University of Mississippi Medical Ctr., 2500 North State Street, Jackson MS 39216-4505.

The response properties of ventral posterior (VP) neurons were characterized in the alert monkey by application of a variety of static and moving tactile stimuli. Data were obtained from a total of 75 penetrations in both thalami of an adult, female rhesus macaque. Utilizing tungsten microelectrodes (20-50 MegOhms) yoked with extracellular, chronic recording techniques, 724 single neurons and multiple neuron clusters were recorded. Most cells were spontaneously active, some firing multispike bursts (3-8 spikes/burst). Single VP cells displayed either rapidly adapting (RA) or slowly adapting (SA) responses, or, less frequently, an SA response with an Off discharge in response to application of punctate stimuli. Neurons responsive to motion, some of which displayed a direction preference, were located on the digits and palm or the face. Six cells with receptive fields on the hand were tested with a moving bar pattern on the OPTACON. Fifty percent of the cells tested responded. All tested cells displayed a slowly adapting discharge to static pressure and 5 of the six responded to brushing over the cell's receptive field. Von frey force threshold for OPTACON responsive neurons was 676 mg, that of the unresponsive cells was 1.2 gm. Low frequency stimuli (20 Hz) appeared more effective in driving the OPTACON responsive VP neurons than did high frequency stimuli (100 Hz). These preliminary results suggest that ventral posterior neurons encode specific features of a tactile stimulus including motion, direction and temporal features of a moving bar pattern. Supported by NINDS Grant NS27996.

PHYSIOLOGICAL MAPS OF RETROGRADELY LABELED SI-PROJECTING NEURONS IN THE SOMATOSENSORY THALAMUS OF THE RAT. P. Herron*. Anatomy and Neurobiology, The Univ. of Tennessee, Memphis, Col. of Medicine, Memphis, TN 38163

This study examined the somatotopic organization and modality of inputs to thalamocortical neurons in the somatosensory thalamus retrogradely labeled by injections of retrograde tracers into the forepaw representation area of the primary somatosensory area (SIf). Conventional extracellular electrophysiological mapping techniques were utilized. Injections of retrograde tracers were made into SIf before or after the somatosensory thalamus was electrophysiologically mapped.

Most retrogradely labeled neurons were located in the ventroposterior lateral nucleus (VPL), rostral and medial region of the posterior complex (POm), and the central lateral nucleus of the intralaminar complex. We recorded from labeled neurons in VPL and POm. Combined retrograde labeling and mapping results show that SIf-projecting neurons in VPL: 1) were overwhelming activated by low-threshold mechanical stimulation of small receptive fields on the glabrous skin of the forepaw, 2) had responses that slowly adapted to maintained stimulation, and 3) were somatotopically organized. Retrogradely labeled neurons in POm were not driven as readily as those in VPL; however, when driven, they were typically activated by intermediate- to high-threshold stimulation.

We conclude that SIf-projecting thalamocortical neurons in VPL receive primarily low-threshold, slowly adapting inputs from the cutaneous surface of the forepaw. Given their rostral location within VPL, neurons that project to the SIf digits area do not overlap with those that project to the SII forepaw representation area. (Supported by The Center for Neuroscience of The Univ. of Tennessee, Memphis).

PHYSIOLOGICAL STUDIES OF THALAMOCORTICAL RHYTHMS, RECORDED *IN VITRO* IN A BRAIN SLICE PREPARATION.
Douglas A. Coulter* Department of Neurology Medical College of Virginia, Richmond, VA 23298

The mouse thalamocortical slice, developed by Agmon and Connors (*Neuroscience 41 (1991): 365*), has been employed to study physiological properties of spontaneously occurring and stimulus-evoked thalamocortical rhythms *in vitro*, under conditions where rigorous control of the extracellular environment is possible, and where high resolution current- and voltage-clamp recordings are feasible. This slice maintains the reciprocal connections between somatosensory thalamus and cortex, by slicing the brain at a particular angle.

Stimulation in the ventrobasal complex of the thalamus (VB) elicited orthodromic activation of restricted areas of somatosensory (SS) cortex, which consisted of mono- and polysynaptic E- and IPSPs. In deep cortical layers, stronger VB stimulation could also evoke antidromic activation of a proportion of cortical neurons. Similarly, stimulation of SS cortex elicited orthodromic EPSPs and antidromic activation of VB neurons. In 60% of preparations, at least one slice exhibited spontaneous, low-frequency oscillations, in the frequency range of 3-15 Hz. These oscillations were restricted to SS cortex and VB, and did not occur in slices cut so as to destroy the reciprocal connections between these areas. In paired field recordings, tight coupling between areas of SS cortex and VB was evident. Extracellular single-unit recordings in VB and SS cortex detected spontaneously active neurons firing bursts of spikes coinciding with the thalamocortical rhythms. Intracellular recordings in middle SS cortical layers revealed spontaneously active neurons firing in the range of 10 Hz, generated by underlying bursts of EPSPs.

This slice preparation may prove valuable in exploration of cellular and pharmacological factors important in generation, maintenance, and termination of normal and pathological thalamocortical rhythms.

CORTICOFUGAL INFLUENCE OF SI CORTEX ON VENTRAL POSTERIOR THALAMIC NEURONS IN THE SQUIRREL MONKEY. T. J. Morrow*, J.A. Kiritsy-Roy and K.L. Casey., Depts. of Neurology and Physiology, University of Michigan and VAMC, Ann Arbor, MI 48105.

We recently reported that the somatosensory responsiveness of ventral posterior (VP) thalamic neurons is modulated during changes in arousal in awake monkey (*J. Neurophysiol.*, 67: 305-317, 1992). Shifts in arousal are often accompanied by marked changes in cortical activity as evidenced in the EEG. Accordingly, we wished to investigate how changes in corticofugal activity might alter the somatosensory processing in primate thalamus.

We studied the influence of corticofugal activity on the responses of VP thalamic neurons to repetitive somatic stimuli in the lightly anesthetized squirrel monkeys by suppressing primary somatosensory (SI) cortical activity with topically applied magnesium sulfate. The effect of $MgSO_4$ was confined to SI and the immediately adjacent cortex and suppressed both spontaneous EEG activity and the cortical somatosensory evoked response. Suppression of SI increased the number of somatically evoked spikes discharged by all VP neurons studied. Three neurons exhibited a marked increase in receptive field size during SI deactivation, including one wide dynamic range cell which responded to both noxious pinch and to CO_2 laser stimulation within its RF. Cortical suppression produced no consistent changes in spontaneous activity. **We conclude that, in the anesthetized monkey, SI corticofugal activity serves primarily to inhibit the sensory transmission of ventral posterior thalamic neurons.** This contrasts with our previous work in rat (*J. Neurosci.*, 5: 2871-2978, 1985), which showed SI activity to primarily facilitate VP activation.

584.8

EXCITATORY POSTSYNAPTIC POTENTIALS (EPSPs) EVOKED IN NUCLEUS RETICULARIS BY MINIMAL STIMULATION OF THALAMIC RELAY NUCLEI. S. Radpour, J. Deuchars and A.M. Thomson (SPON: Brain Research Association) Dept. Physiology, Royal Free Hospital School of Medicine, London NW3 2PF, UK.

Nucleus reticularis (RTN), the major source of inhibition in rat thalamus, receives major inputs from cortex via internal capsule (IC) and from thalamic relay neurones. This study compared EPSPs evoked from IC with those evoked by micro-stimulation of relay areas, recorded intracellularly *in vitro* from RTN neurones identified electrophysiologically and morphologically. Both types of EPSPs were fast (width at half amplitude 6.9±2.8, IC and 5.1±1.1 ms, relay) at around -80mV. Although the peak of the EPSP often exhibited a conventional voltage relation, EPSPs increased in duration with depolarization (De Curtis et al). Both EPSPs fluctuated in amplitude, the relay input dramatically, with a peak standard deviation time course of between 30 and 80% of peak EPSP amplitude. Relay EPSPs exhibited profound paired pulse facilitation, but declined in average amplitude with maintained stimulation at 1Hz. Both stimuli could evoke variable and long latency bursts of EPSPs whose time course resembled those of evoked relay EPSPs. These may result from activation of slow spikes and burst firing in presynaptic relay neurones within the slice.

SENSORY AND OSCILLATORY PROPERTIES OF SIMULTANEOUSLY RECORDED MULTI-SINGLE UNITS IN THE THALAMIC RETICULAR NUCLEUS OF THE RAT. T.M. Fisher*, M.A.L. Nicolelis and J.K. Chapin. Department of Physiology and Biophysics, Hahnemann University, Philadelphia, PA 19102.

The thalamic reticular nucleus (RT) is thought to control sensory transmission through the ventral posterior (VP) thalamus, in particular by controlling the oscillatory state of the thalamocortical network. It is also believed that RT neurons are mutually inhibitory. Computer models employing such competitive inhibition phenomena are known to exhibit spontaneous and evoked state-switching activity. The aim of this study was to determine whether such state changes can be seen in the spatio-temporal patterns of activity across neuronal populations in the RT and VP. For this multi-single neurons were simultaneously recorded through chronically implanted electrodes in the face-whisker representations in the RT and VP thalamic nuclei in awake and anesthetized rats. In the pentobarbital anesthetized condition, 8-10 Hz spontaneous oscillatory activity was very prominent. Cross-correlations between simultaneously recorded RT neurons revealed both in-phase and 180° out-of-phase synchronization. Both patterns were often seen between the same neurons, spontaneously switching between in and out of phase oscillations. These RT neurons also exhibited a distinctive series of responses to peripheral stimulation, including: 1) an initial excitation, of 5-15 ms latency and persisting up to 60 ms post-stimulus, 2) a strong inhibition, lasting up to 120-160 ms post-stimulus, and 3) a series of 7-10 Hz oscillatory bursts, which persisted up to 3-4 sec after the stimulus. These bursts were also somewhat synchronous, though they often switched from an in-phase to an out-of phase pattern. Increasing the stimulus frequency from 0.2 Hz to 1.0 Hz resulted in a 180° phase advance, in which most neurons suddenly began their bursting pattern about 60 ms earlier. To conclude, the RT-VP thalamic network does not show simple synchronization, but instead exhibits complex dynamical state changes. Since these phase switching phenomena are quantal, they are reminiscent of the sudden frequency bifurcations characteristic of nonlinear dynamical systems, especially those containing coupled oscillators. *Supported by grants NS23722, AFOSR-90-0266, and AA06965 to JKC.*

MULTIVARIATE STATISTICAL TECHNIQUES ALLOW CHARACTERIZATION OF DISTRIBUTED POPULATION CODES IN SIMULTANEOUSLY RECORDED NEURONAL ENSEMBLES. Bacala, L.*, Nicolelis, M.A.L., and Chapin, J.K., Dept. Elect. Engin., U. of Pennsylvania, and Dept. Physiol/Biophysics, Hahnemann U., Philadelphia, PA.

In recent investigations we have routinely obtained simultaneous extracellular single neuron recordings from up to 24 single neurons in the somatosensory thalamus and/or cortex system of awake, behaving rats. Here we describe use of multivariate statistical techniques to characterize the information and population codes contained within such multi- single neuron ensembles. Discriminant analysis (DA) was used to determine how well a population of simultaneously recorded neurons can discriminate a sensory stimulus. Data from 10-23 neurons recorded during repetitive sensory stimulation were used to generate a matrix of discriminant functions which quantitate the predictive value of each neuron. Though single neurons by themselves were found to be poor predictors of whether a certain stimulus had occurred, this predictability improved greatly when increasing numbers of neurons were used for the discrimination. Furthermore, most of these neurons were found to contribute to several types of discriminations. Principal components analysis (PCA) was used to extract the factors which underly activity in neuronal populations. For this, multi-single neuronal discharge recorded over a range of stimulus conditions was time integrated and used to generate a correlation matrix. This matrix was rotated to generate a series of principal components, i.e. weighted combinations of the original variables (neurons). Each of these reconstructed components was generally found to reveal, in a statistically improved fashion, definable factors underlying activity within the neuronal populations, e.g. different aspects of sensory responses, movements or network oscillations. Similar analyses performed on data obtained from computer models of neuronal networks verified that PCA yields a spectral decomposition of the activity within the network. This optimally summarizes the network's functional organization. In conclusion, both DA and PCA provided evidence for a distributed representation of information within the recorded neuronal populations. *Supported by grants NS23722, AFOSR-90-0266, and AA06965 to JKC.*

DISTRIBUTED PROCESSING OF SOMATIC INFORMATION BY NETWORKS OF THALAMIC CELLS INDUCES TIME-DEPENDENT SHIFTS OF THEIR RECEPTIVE FIELDS Miguel A. L. Nicolelis , Rick C.S. Lin, John K. Chapin. Department of Physiology and Biophysics, Hahnemann University Philadelphia, PA 19102.

Previous recordings in anesthetized animals have suggested that the thalamus contains a detailed somatotopic map of the cutaneous periphery formed by extremely small neuronal receptive fields (RFs). However, very few data are available in awake animals to validate these propositions. We approached these issues through chronic simultaneous recordings of the extracellular activity of up to 24 statistically characterized single neurons per animal in awake adult rats. Overall, 132 neurons located in the ventral posterior (VP) complex of the thalamus were recorded in 10 adult hooded rats in which 8 to 16 50 um microwires were chronically implanted. Sensory stimulation (5-10 degrees, 1Hz, 100 ms) of several single facial whiskers per animal were produced by a computer controlled probe. VP neurons responded vigorously to the stimulation of multiple whiskers at different latencies (mean 6 ms) defining extremely large RFs (covering circular areas of 2-5 whiskers in diameter). Stimulation of single whiskers produced both early and late responses, and the temporal pattern of single cell responses changed when different whiskers were stimulated. In particular, many neurons exhibited time-dependent spatial shifts of their RF center over the 50 ms following the stimulus. We have found that such thalamic RFs are better described by complex and dynamic temporo-spatial surfaces. Thus, for each given stimulus thalamic networks produced a unique temporo-spatial populational response formed by weighted contributions from its neurons. Local subcutaneous injections of lidocaine induced rapid changes in latency, enhancement of secondary responses, and enlargement of VP cell RFs. These results indicate that in behaving animals thalamic maps are rather dynamic representations in which networks of neurons process somatic information through highly distributed time-dependent mapping functions. These may provide the thalamus considerable plastic potential even in adult animals. Supported by grants NS23722, AFOSR-90-0266 AND AA06965 to JKC.

SOMATOSENSORY STIMULATION SUPPRESS 8-12 Hz OSCILLATIONS IN THE VENTRAL POSTERIOR COMPLEX OF AWAKE RATS AS PREDICTED BY A COMPUTER MODEL Amitabha Gupta , Miguel A. L. Nicolelis, and John K. Chapin. Department of Physiology and Biophysics, Hahnemann University Philadelphia, PA 19102.

Thalamic neurons exhibit oscillations which can be clearly correlated with different states of the sleep cycle. However, very little is known about the physiology of oscillations in the range of 7-14 Hz observed in awake animals. To address this we have simultaneously recorded the extracellular activity of up to 24 statistically characterized single thalamic neurons per animal in each of 5 awake rats. Oscillations in the range of 8-12 Hz normally occurred in the ventral posterior complex of awake rats which were not carrying out either active sensory or motor tasks. These oscillations, which resembled sleep spindling and the slow "somatosensory rhythm" described in cats, occurred upon cessation of whisker or paw movement. These oscillations could be promptly disrupted by cutaneous stimulation. Long duration recordings revealed that thalamic neurons dynamically switch from a tonic firing mode (around 7 Hz) to a bursting mode (8-12 Hz). Similar oscillatory behavior was then reproduced in a large scale computer model of the rat somatosensory system which contained multiple brainstem, thalamic, and cortical compartments but no individual pacemaker elements. In this model background oscillations in the spindling frequency range were ubiquous and were disrupted only by sensory volleys that crossed a certain threshold. Upon terminating the stimulus the somatosensory network naturally evolved to a bursting mode. Introduction in the model of more realistic thalamic cells containing a Ca^{++} dependent K^+ current and a low-threshold (T) Ca^{++} current did not alter the main observation but demonstrated that modulatory influences on the T current could damp the background thalamic oscillation. These results suggest that in the awake behaving rat VP neurons dynamically switch from a tonic to a bursting mode and that this latter may be responsible for gating the flow of sensory information conveyed by the thalamus to cortex. *Supported by NS23722, AFOSR-90-0266 and AA06965 to JKC.*

CIRCUIT OSCILLATIONS IN A NEURONAL NETWORK MODEL OF THE SOMATOSENSORY SYSTEM. J.P. Utz* and J.K. Chapin. Department of Physiology, Hahnemann University School of Medicine, Philadel phia, PA, 19102-1192.

As a tool for investigating the mechanisms underlying spontaneous oscillations and sensory response properties in the rat somatosensory thalamocortical system a computer model was developed. This model consists of four layers, each containing a 30x30 sheet of neuron-like elements. The layers are connected in a pattern which resembles, in a simplified fashion, the axonal connections between the ventral basal thalamus (VB), the nucleus reticularis thalami (nRT), the SI cortical layer VI (CTX), and a layer of inhibitory cortical interneurons (INH). Each "neuron" incorporates several biologically realistic features, including: 1) a membrane potential (Vm) calculated from membrane conductances and Nernst potentials for several ion currents (Na^+, K^+, and Cl^-), 2) a membrane leak conductance, 3) a membrane capacitance which produces membrane potential time decays, 4) a voltage-sensitive spike-triggering threshold, and 5) axonal conduction delays. State variables (eg., conductances and Vm) are re-calculated every ms of simulation time. The VB is driven by a 30x30 array of randomly-timed input fibres, with a bar of increased activity serving as a focal stimulus. Each connection fans out in a 5x5 array. This model may exhibit either steady- state random firing, or distinctive spatiotemporal oscillations depending on the values of certain parameters. For example, oscillations may be suddenly induced by: 1) increasing the strength of the corticothalamic excitatory feedback, 2) decreasing the strength of a medium duration afterhyperpolarization (mAHP; τ = 40 ms), and 3) decreasing the inhibitory feedback from the nRT to the VB. *Supported by grants NS23722, AA06965 and AFOSR-90-0266 to JKC.*

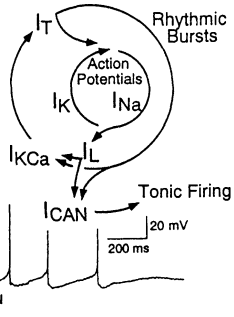
IONIC BASIS OF OSCILLATION AND 30-60 HZ FIRING IN THE THALAMIC RETICULAR NUCLEUS (NRT), A MAMMALIAN PACEMAKER. T. Bal and DAMcCormick*, Sec. Neurobiology, Yale Univ. Sch. Med., New Haven, CT 06510

During slow wave sleep, the nRt synchronizes rhythmic thalamo-cortical activity and contributes to the generation of spindle waves. The ionic mechanisms of rhythmic and tonic firing in nRt cells were investigated with standard *in vitro* slice techniques.

We found that endogenous rhythmic bursting of nRt cells is mainly due to the interaction of a low threshold Ca++ spike (I_T), a Ca++ activated K^+ current (I_{KCa}) and a Ca++ activated non-specific cation current (I_{CAN}) according to the following scheme.



Maximal block of a leak potassium current by 5HT resulted in 30-60 Hz tonic firing owing to the inactivation of I_T and the activation of a persistent sodium current.

A NEW TOOL TO CHARACTERIZE ONGOING NEURONAL DISCHARGE: COUNTING STATISTICS OF f^{-b}-FLUCTUATIONS. K.-D. KNIFFKI, M.K.C. MENGEL and C. VAHLE-HINZ*. Physiologisches Institut, Universität Würzburg, Röntgenring 9, W-8700 Würzburg, Germany.

Temporal fluctuations in natural phenomena in the absence of intentional stimulation are not always the consequence of statistically independent random events. It has been shown that temporal fluctuations found in phenomena as different as membrane currents, earthquakes, intensity of sunspots, heart beat or breathing activity can be characterized by their power spectrum density S(f). In all these different systems S(f) is decaying as f^{-b} at low frequencies with $b \leq 1$. This behaviour of S(f) is called "f^{-b}-noise". Usually S(f) is obtained by Fast Fourier Transformation (FFT). To avoid the well known problems in using FFT for neuronal spike trains, a new simple method (Meesmann, Grüneis, Flachenecker, Kniffki, submitted) is introduced to analyse the low frequency part of S(f) of the recorded action potentials.

The series of recorded action potentials is considered to be a point process described as $y(t) = \Sigma\delta(t-t_i)$, whereby $\delta(t-t_i)$ represents Dirac's delta function, and t_i is the time of occurrence of a particular action potential within the spike train. The entire observation time was divided into counting windows Δt and the variance of counts $Var[N(\Delta t)]$ was determined. This was repeated for different lengths of Δt. If $Var[N(\Delta t)] \sim (\Delta t)^{1+b}$, the power spectral density $S_y(f)$ scales as $S_y(f) \sim f^b$ with $b \leq 1$. In thalamic neurones tested so far, the variance-time curve $Var[N(\Delta t)]$ was proportional to $(\Delta t)^{1+b}$ with a mean $b = 0.6$, thus indicating that the neuronal discharge exhibited f^{-b}-fluctuations. The applied method reliably discriminates these fluctuations from a pure random process, in which case $b \equiv 0$.

We speculate that the basic mechanisms underlying neuronal activity in thalamic sensory systems are expressions of a "self-organized critical state", as introduced by Bak, Tang and Wiesenfeld (Phys. Rev. Lett. 59: 381, 1987).

VISUAL CORTEX: BRAIN IMAGING TECHNIQUES

585.1

FUNCTIONAL BRAIN MAPPING IN HUMANS USING MRI: INTRINSIC SIGNAL CHANGES ACCOMPANYING SENSORY STIMULATION. S.Ogawa♦*, D.W. Tank♦, T.M. Lee♦, R. Menon+, J.M. Ellermann+, S.G. Kim+, H. Merkle+, and K. Ugurbil.+ ♦AT&T Bell Labs, Murray Hill, NJ and +U. of Minn. Med. Sch., Minneapolis, MN.

We have previously shown that changes in venous blood oxygenation produce Blood Oxygenation Level Dependent (BOLD) changes in water proton magnetic resonance signals in mammalian brain (1-3). We demonstrated that the effect is produced by a magnetic susceptibility change in venous blood vessels produced by changes in the concentration of the paramagnetic molecule deoxyhemoglobin and suggested that BOLD contrast imaging could be used for human functional brain mapping. We have now demonstrated that visual stimulation produces an easily detectable (5-20%) transient increase in the intensity of water proton magnetic resonance signals in human primary visual cortex in gradient echo images obtained at 4T field strength.The accompanying figure shows the time course of change in signal intensity produced in a region of primary visual cortex by two periods of a patterned flash binocular visual stimulus.The change is consistent with stimulus-produced neural activity producing an increase in venous blood oxygenation. With the present 4T imaging system, we can follow changes with a temporal resolution of ~3 sec and with 1.6x3.3x10 mm image voxel size. Images have been assembled into real-time movies that show the temporal and spatial changes. The sensory stimulation produced changes in BOLD signal intensity are quite robust and suggest the possibility of functional brain mapping of higher cognitive operations.

MAGNETOENCEPHALOGRAPHIC IDENTIFICATION OF EXTRASTRIATE VISUAL AREAS IN MAN Edward L. Maclin Ph.D.[1,2*], Stephen E. Robinson Ph.D.[1,2], Jeanne E. Knight M.S.[1,3], Kim Paulson[1] 1) Center for MEG, Veterans Medical Center, 2), Dept of Neurology, Univ. New Mexico 3) Dept of Psychology, UNM, Albuquerque NM, 87108.

Sets of stimuli and procedures have been developed for differentially activating primary and secondary visual cortical areas, and using the associated magnetic field responses to localize the activated regions on the subject's MRI. Achromatic or isoluminant colored gratings are first presented in a fixed position, and then abruptly begin drifting. Both pattern appearance and motion onset evoke magnetic responses. The response to motion onset localizes to the region of the temporo-parieto-occipital pit. This response is much smaller for isoluminant stimuli than for achromatic stimuli, as expected for the so called 'motion area' or cortical region V5. Even simple achromatic spot stimuli produce responses from multiple brain regions, and both multiple dipole and distributed current models have been developed to analyze the complex evoked field patterns. We have studied one patient with a scotoma due to a stroke in primary (striate) visual cortex who appears to have no response from primary visual cortex, but who exhibits a robust response over parietal cortex, in the region which appears to subserve motion detection in control subjects.

FUNCTIONAL MRI STUDIES OF HUMAN VISION ON A CLINICAL IMAGER. J.S. George[2], J. Sanders[1], J.W. Belliveau[3], J.D.Lewine[2], A. Caprihan[4], C. J. Aine[2], D. van Hulsteyne[2], E. Maclin[1], and C.C. Wood[2*] 1. Albuquerque VA Medical Center; 2. Los Alamos National Laboratory; 3. Massachusetts General Hospital; 4. Lovelace Medical Foundation. During the past decade, Magnetic Resonance Imaging (MRI) has become the method of choice for imaging the anatomy of the human brain. Recently, Belliveau and colleagues (Science, 254: 621-768,1991) have reported the use of echo planar magnetic resonance imaging (EPI) to image patterns of neural activity. By imaging the passage of a bolus of injected paramagnetic contrast agent through the cerebral microvasculature with and without visual stimulation they estimated changes in regional blood volume associated with neural activation. The MGH group has also shown that intrinsic hemodynamic changes (in the absence of injected contrast agents) can serve as the basis of functional MR Imaging. Here, we report functional MR imaging without the use of contrast agents, and without the extensive hardware modifications required for EPI. Experiments were conducted on a conventional clinical MR Imager (1.5 T Siemens) using a 15 cm diameter surface coil. Computer generated visual stimuli (annular checkerboards subtending ~10° in the lower hemifield, with contrast reversals at 8 Hz) were projected onto a translucent screen over the bore of the magnet using an LCD video projector. Subjects viewed the images in a 45° mirror attached to eyeglass frames. A sequence of T2 weighted gradient echo images (TR=38 ms,TE=26 ms, flip=40°) were obtained at 2.48 s intervals. A single slice (8 mm thick) was aligned along the calcarine fissure in a horizontal oblique, or sagittal plane lateral to the midline. A sequence of images (9-11) was obtained with no stimulus, and during visual stimulation. The cycle was repeated 3 to 6 times. Summed images from the stimulus-off condition (N=6,18,or 36) were subtracted from summed stimulus-on images, disclosing regions of focal activation. Horizontal oblique images showed activation along the midline near the occipital pole and along the lateral rim of occipital cortex. In the sagittal slice, activation was seen near the expected locations of V1, V2 and possibly V3. Another active region was observed near the parietal occipital sulcus on the superior surface of the cerebrum. These locations are consistent with sources observed in neuromagnetic studies of the human visual response.

585.4

EVIDENCE OF RETINOTOPIC ORGANIZATION IN EXTRASTRIATE REGIONS OF HUMAN VISUAL CORTEX: NEUROMAGNETIC MEASURES. C.J. Aine*, S. Supek, E.R. Flynn and D. Ranken. Biophysics Group. Los Alamos National Laboratory. MS M715. Los Alamos, NM 87545.

Studies of human visual cortex have shown evidence of retinotopic organization of striate cortex using a variety of methods (e.g., ERPs, MEG, PET). Using MEG measurements, we have identified two additional cortical regions (occipital-temporal and occipital-parietal) that show evidence of retinotopic organization. Seven circular sinusoids (Targets) were presented sequentially to the lower right quadrant of the visual field at 3°, 4°, 6.5° and 9° beneath the horizontal meridian (horizontal alignment) and to the right of the vertical meridian (vertical alignment). Stimulus sizes ranged from .4°-1.0°. Stimulus duration was 266 msec and the rate of presentation was 1.1-1.8 Hz.

Neuromagnetic responses were recorded from 12-13 placements of a 7-sensor array in each of two subjects. Multiple-dipole models were applied to neuromagnetic field maps constructed at 5 msec intervals and source locations were transformed into MRI coordinates. Striate activity was evident throughout the 80-130 msec sequence. A second source was evident (onsetting at ~100 msec) in occipital-temporal regions whose retinotopy can be characterized as follows: 1) for the vertical alignment, source locations shifted in a medial and dorsal direction as a function of eccentricity; and 2) for the horizontal alignment, source locations shifted in a medial and anterior direction. A third source in occipital-parietal regions, evoked by peripheral stimulus locations in the vertical alignment (6.5° and 9°), also showed evidence of retinotopic organization. The occipital-parietal source was more dorsal (in the parietal-occipital sulcus) for the most eccentric placement. The trends noted here for stimuli in the vertical alignment have been noted in a previous study using 2-dimensional, difference of gaussians stimuli (Supek and Aine, 1992).

585.5

AREA V5 OF HUMAN VISUAL CORTEX IDENTIFIED IN INDIVIDUALS USING PET AND MAGNETIC RESONANCE IMAGING. I D G Watson, S Shipp, R S J Frackowiak* and S Zeki. MRC Cyclotron Unit, Hammersmith Hospital, London W12 0HS and Dept of Anatomy, University College, London WC1E 6BT.

We have previously used positron emission tomography (PET) to find the visual motion centre (V5) by averaging groups of subjects. Now, we report findings from individual subjects scanned with a Siemens-CTI 953B PET camera, with its sensitivity enhanced by removing the collimating septa, to allow collection of data in 3D mode. Images of regional cerebral blood flow (rCBF) were obtained by using intravenous infusions of $H_2{}^{15}O$. 12 subjects viewed computer displays of moving or static checkerboard patterns. Each subject had 6 scans in each of the 2 conditions. Statistical parametric maps (SPMs) were then used to indicate areas of the brain in which significant rCBF changes took place in response to visual motion. We also obtained high resolution magnetic resonance imaging (MRI) scans for all subjects and then coregistered individual PET SPMs onto the respective MR images. Thus we could relate the sites of individual statistically significant activations to specific gyri and sulci of the individual brains.

SPMs revealed bilateral activation of the area previously defined as V5 in all subjects. It was located ventrolaterally in the anterior part of the occipital lobe. The rCBF increase induced in V5 ranged from 2.4 % to 8.6 %. On normalization to Talairach stereotactic co-ordinates the locations of the most significant foci of activation at V5 varied within a range of 24 mm for either hemisphere. In addition to V5, our stimuli activated sites in the cuneus and the lingual gyrus, and these may correspond with the superior and inferior divisions of monkey V2/V3.

PET STUDY OF STEREOPSIS. A. Ptito*, R. Zatorre, M. Petrides, S. Frey, B. Alivisatos and A. Evans. Montreal Neurol. Inst. McGill University, Montreal, Quebec H3A 2B4.

To map the areas of the brain involved in global stereopsis, regional cerebral blood flow was measured by means of positron emission tomography(H_2O^{15} bolus technique) in nine right-handed male adults under three conditions of testing: 1) DEPTH: a random dot stereogram depicting either a vertical or a horizontal bar at 100% binocular correlation. 2) SHAPE WITHOUT DEPTH: a 2-D vertical or horizontal black outline of a bar drawn on a background of random dots. 3) NEUTRAL: random dots without form or depth. Increases in blood flow due to depth perception were assessed by substracting activation in the shape condition from that in the depth condition. Results showed activation on the border of areas 17 and 18 in the right cerebral hemisphere and in areas 18 in the left cerebral hemisphere. When the neutral condition was substracted from the depth condition a focus was obtained only in the right cerebral hemisphere again along the border of areas 17 and 18. These data are concordant with evidence of a right hemisphere superiority for stereopsis, and they indicate that the analysis and processing of unambiguous stereoscopic information high in binocular correlation begins early in posterior visual areas of that hemisphere.

585.7

STIMULUS SPECIFIC INCREASE OF OXIDATIVE METABOLISM IN VISUAL CORTEX S. Marrett*, H. Fujita, H. Kuwabara, Y. Yasuhara, L. Ribiero, E. Meyer, A.C. Evans, A. Gjedde, Montreal Neurological Institute, 3801 University St., Montréal H3A 2B4, Québec.

The mechanisms that mediate the coupling of neuronal activity to blood flow and oxidative metabolism have been the subject of controversy. Previous PET studies have demonstrated an apparent uncoupling of blood flow and oxygen metabolism in both somatosensory and visual cortex (Fox et al, 1988.) The reported changes in oxygen metabolism (5-7%) have been considerably smaller than those reported for blood flow and glucose consumption (25%-50%). Using a newly developed method for measuring oxygen consumption using a single bolus inhalation of $[^{15}O]O_2$ (Ohta et al, 1992) with 3 minutes of multi-frame data acquisition, we confirmed the lack of a coupling of blood flow to oxygen metabolism in somatosensory cortex (Fujita et al, submitted). We hypothesised that a specific visual stimulus would be able to modulate oxidative metabolism in visual cortex, since primate V1 has a heterogeneous distribution of cytochrome oxidase (blobs) that has been correlated with glucose uptake and stimulus variables in the macaque (Tootell et al, 1988).

Measurements of oxygen metabolism and blood flow in normal volunteers were made using separate bolus $[^{15}O]O_2$ and $[^{15}O]H_2O$ PET scans. Subjects had the right eye covered and fixated a cross on a computer monitor with the left eye. During the activation scans a semi-annular reversing contrast stimulus was presented to the left visual field of the left eye at a retinal eccentricity of about 15°. Correlative MRI scans were obtained from all subjects. A focal increase of oxygen consumption (≈30%) was measured in primary visual cortex. This result is consistent with a stimulus specific modulation of oxidative metabolism in visual cortex.

585.8

DEPENDENCE OF VISUALLY EVOKED MAGNETIC FIELDS ON INTERSTIMULUS INTERVAL (ISI). R.J. Ilmoniemi,*S.P. Ahlfors, J. Numminen, and K. Portin. Low Temperature Laboratory, Helsinki University of Technology, 02150 Espoo, Finland.

To develop rapid stimulation sequences for the systematic mapping of the visual field, we studied how the visually evoked magnetic field depends on the stimulus repetition rate.

Black-and-white checkerboard patterns were shown at intervals of 0.25 to 8 sec for 200 ms (100 ms for the 250-ms ISI) in one 45° sector of an annulus lying between 1.7° and 3.7° from the center of the visual field. The magnetic field over the occipital cortex was recorded with a multi-channel SQUID magnetometer. The amplitude of the averaged response 100 ms after the stimulus appearance was smallest for rapidly presented stimuli, grew until an ISI of about 2 seconds, and decreased for longer ISIs. The characteristic time constant of the amplitude rise, obtained from a fit to an exponential, was typically 1 second; it was several seconds for the decrease. The optimal presentation rate for a single stimulus location appears to be 1/sec; for faster rates, the quicker accumulation of responses cannot compensate for the loss of signal.

In the second experiment, the stimuli were presented to different octants of the visual field in pseudorandom order. When the total repetition rate was 4 stimuli per second with one octant repeating itself once a second, the response for this octant was nearly identical with the response obtained when this octant was stimulated separately once per second. It therefore appears that the functions of the visual cortex can be mapped effectively by presenting stimuli in rapid succession in alternating locations of the visual field.

VISUAL BEHAVIOR: CLINICAL STUDIES

586.1

SPATIAL VISUAL FUNCTION LOSS IN ACCIDENTAL HUMAN LASER EXPOSURE. H. Zwick, D.A. Gagliano, J. Gunzenhauser, D.O. Robbins* Letterman Army Institute of Research, San Francisco, CA 94129 and Ohio Wesleyan University, Delaware, OH 43015.

In previous experiments (Zwick et al, Neurosci, 1989) to simulate laser effects on human visual performance, we utilized laser induced deficits obtained in rhesus contrast sensitivity to alter the spatial frequency content of complex images used in human detection and recognition studies. In this paper five human laser accident cases are reported where the spatial characteristics of the relative scotoma have been characterized. Human laser ocular accident injuries suggest the presence of both absolute and relative regions of the scotoma. Visual acuity loss exceeds 20/200 with peripheral retinal fibrosis. Contrast sensitivity measurements reveal high as well as mid to low spatial frequency contrast sensitivity loss relative to non-exposed eyes. Visual threshold field loss may exceed 30 degrees where mid to low spatial frequency sensitivity loss is extensive. Retinal fibrosis, traction, and photoreceptor alteration are suspected in mediating the spatial vision degradation of the relative scotoma. Our results suggest that future perceptual simulations of such retinal injuries should incorporate the complex representations of both the relative and absolute spatial aspects of the induced scotoma into the simulated image.

586.2

RESIDUAL VISUAL FUNCTIONS IN THE BLIND FIELD OF A HEMIANOPIC PATIENT. C.M. Wessinger*, R. Fendrich and M.S. Gazzaniga. Center for Neurobiology, Univ. of California, Davis CA 95616

Previously, we reported the existence of a small island of residual visual function in the blind field of a hemianopic patient, CLT. In a forced choice task, CLT reliably detects a 1 deg black stimulus flashed within this island. Above chance detection was also found along CLT's horizontal and vertical retinal meridians. We now report results of additional testing which further characterize residual visual functions in this patient's blind field.

We performed dense perimetry to map the boundaries of the isolated island within the scotoma. The results of this testing suggest that the island of sparing is primarily confined to an area not much larger than 1 deg. We found CLT could not identify the location of stimuli presented within the island of sparing. He was also unable to direct a saccade toward 1 deg stimuli flashed at this location. Nevertheless, he could discriminate between a diamond and a square (both 1 deg on a side) centered within the island of sparing. However, when we increased the size of the diamond and square to 2 deg on a side, CLT performed at chance. This suggests that discrimination of the smaller stimuli was based on form or edge detection within the island of sparing. Larger stimuli completely blanketed the island depriving the subject of this information.

We also investigated CLT's residual abilities at other locations within his blind field. Near the vertical meridian, CLT was able to direct a saccade toward flashed stimuli, but could not discriminate between a 1 deg diamond and square. On the other hand, he could discriminate between 2 deg diamonds and squares. This demonstrates a dissociation which is in direct contrast to that found at the island of sparing.

DETECTION OF TEXTURE-AND MOTION-DEFINED BOUNDARIES BY NONRETARDED AND MENTALLY RETARDED ADULTS. Stephen Oross III* & Robert Fox. Department of Psychology, Vanderbilt University, Nashville, Tennessee 37240.

Forms defined solely by relative differences in binocular disparity or motion have proven to be difficult for most mildly mentally retarded adults (MMR) to either discriminate between or to detect. Because both binocular disparity and motion are processed preattentively by early components of the visual system, one conclusion supported by these findings is that the neural integrity of the visual system is compromised in MMR. This impairment, however, appears selective because sensitivity to other visual attributes (e.g., contrast) falls within normal limits. To explore the degree to which the impairment can be related to visual rather than response difficulties and to investigate sensitivities to another fundamental visual attribute we examined the ability of MMR and nonretarded adults to detect forms defined by texture and motion. Using signal detection methodology, subjects viewed a randomly textured and moving background and were instructed to indicate the presence or absence of a rectangular form. Texture differences were introduced by varying the grain size of the form relative to the background. Motion differences were introduced by varying the correlation with which the texture elements were displaced across temporal frames. Analyses of d' and response bias indicate that: (1) MMR encountered difficulty in veridically perceiving motion information, (2) both groups responded similarly to texture information, and (3) the impairment in perceiving motion noted in MMR cannot be simply ascribed to response difficulties. These results are discussed with respect to the possible genesis, extent, and impact of these selective impairments.

MOVEMENT IN ORTHOGONAL DIRECTIONS: DISCRIMINATION BY MENTALLY RETARDED AND NONRETARDED ADULTS. Sandy A. Shimp*, Robert Fox, & Stephen Oross III. Department of Psychology, Vanderbilt University, Nashville, Tennessee 37240.

Our prior research has demonstrated that the perception of motion-defined forms is impaired in mildly mentally retarded adults (MMR). The existence of perceptual deficits in MMR suggests underlying neural impairment. Interestingly, multiple sclerosis patients are impaired at perceiving motion-defined forms yet are able to veridically discriminate between different directions of motion. One explanation is that the perception of motion-defined forms and direction of motion involve different neural structures. The present study investigated the ability of MMR and nonretarded adults to discriminate between movement in orthogonal directions. Subjects were asked to discriminate between random-element kinematograms moving either up-down or left-right. The coherence of the motion in the kinematograms was manipulated by varying the correlation (ranging from 0 to 100%) with which the elements were displaced across temporal frames. Both MMR and nonretarded adults were essentially equivalent in their ability to discriminate between the directions. These results are similar to those found with multiple sclerosis patients and are consistent with the explanation relying upon different neural structures. Alternative hypotheses, however, are available that can account for these results. One considers the signal/noise ratios in displays used to test the perception of motion-defined forms and directions of motion. Another postulates that differences between groups would be detected if smaller differences in direction were used. We are currently exploring the validity of these alternatives.

LACK OF VEP EVIDENCE FOR MAGNOCELLULAR DYSFUNCTION IN DYSLEXIA. J. Victor*, M. Conte, L. Burton, and R. D. Nass, Dept. of Neurology and Neuroscience, The New York Hospital - Cornell Medical Center, New York, NY 10021.

It was recently reported (Livingstone et al., PNAS, 1991) that five dyslexic individuals showed loss of the pattern-reversal visual evoked potential (VEP) under conditions designed to isolate the magnocellular pathway: high temporal frequency, low contrast, and low luminance. We measured contrast-reversal VEPs in 9 dyslexic individuals (ages 8 to 46) and in 11 controls (4 with learning disability but not dyslexia, 7 normals) of similar age. For the purpose of this study, dyslexics were defined as subjects of normal intelligence with a history of reading difficulty. We used steady-state conditions similar to those used by Livingstone et al. (16 Hz reversal rate, 2% contrast, 4 cd/m^2, 3 deg checks), and an analytical method (Victor and Mast, EEG J., 1991) which provided rigorous statistical criteria for detection of significant responses and significant differences between responses. Contrary to the findings of Livingstone et al., we found that VEPs were absent in most subjects not only in the dyslexic group, but also in the control group. At lower temporal frequencies (4 and 8 Hz reversal rate), higher luminance (59 cd/m^2) and higher contrast (20%), significant responses were more widely present in both groups, but the response amplitudes and phases did not differ across groups. We find no evidence for a low-contrast, low-luminance VEP abnormality associated with dyslexia.

PUPILLARY LIGHT REFLEX (PLR) AFTER OPEN LOOP RETINAL STIMULATION IN HUMANS. W.B. Pickworth*, J.S. Fosnaugh, J.D. Nichels and E.B. Bunker. NIDA, Addiction Research Center, Baltimore, MD 21224.

Pupil diameter (PD) and the PLR are popular, noninvasive measures of drug action. Ambient light level and an opaque patch over the contralateral eye significantly change prestimulus PD and PLR in closed loop experiments (Pickworth et al, Soc Neurosci Abs 17:1467, 1991). In the present study, ambient light and the stimuli were presented in Maxwellian view (open loop) to nine drug-free volunteers using a Pulse Medical Instruments pupillometer. The PLR was evoked at four levels of ambient light: with both eyes open, a patch over one eye. In both patch conditions, increased ambient light decreased PD from 6.4 to 4.2 mm and constriction velocity (CV) from 6.3 to 3.4 mm/sec. These results differ from the closed loop experiment where the patch doubled CV and increased PD by 50%. Under Maxwellian view binocular summation is eliminated suggesting that midbrain control of PD is diminished.

586.7

AUGMENTING AND REDUCING OF THE VISUAL EVOKED POTENTIAL IN ROMAN HIGH- AND LOW-AVOIDANCE RATS. J. Siegel* and D.F. Sieson. School of Life and Health Sciences, Univ. of Delaware, Newark, DE 19716 and P. Driscoll. Laboratory of Beharioral Biology, ETHZ, Zurich, Switzerland.

Human and cat high sensation seekers (SSs) tend to show increasing amplitudes (augmenting) of the P1 and N1 components of the visual evoked potential (VEP) to increasing intensities of light flash, whereas low SSs show VEP reducing. Roman high- (RHA/Verh) and Roman low-avoidance (RLA/Verh) rats, bred in Switzerland, have behavioral traits comparable to human and cat high and low SSs, respectively. RHA/Verh rats show greater exploration, activity, and aggression than do RLA/Verh rats. Ten male rats of each strain were anesthetized with chloral hydrate and maintained at a stable moderate anesthetic level. Fifty VEPs recorded from visual cortex at each of five flash intensities were computer averaged per rat. The slopes of P1 and P1-N1 amplitudes as a function of flash intensity were significantly greater in the RHA/Verh than the RLA/Verh rats. RHA/Verh rats were clear augmenters; RLA/Verh rats had almost flat amplitude-intensity functions.

This study demonstrates a rat model of SS-related augmenting and reducing that yields advantages of genetic homogeneity and a short generational time, and provides access to a wealth of behavioral data and experimental manipulations available for the rat. In addition, we show that this relationship has a heritable base and extends across species from human, cat, and rat. (Supported in part by ARO Contract DAAL 0388K0043)

586.8

FEASIBILITY OF AN INTRACORTICAL VISUAL PROSTHESIS FOR THE BLIND: I. DESCRIPTION OF AN EXPERIMENT. D.K. O'Rourke, M.J. Bak*, F.T. Hambrecht, C.V. Kufta, E.M. Schmidt, P. Vallabhanath. Surgical Neurology Branch (D.K.O'R, C.V.K), Lab. of Neural Control (M.J.B., E.M.S., P.V.), Neural Prosthesis Program (F.T.H.), NINDS, NIH, Bethesda, MD 20892.

We performed a study to investigate the feasibility of a visual prosthesis for the blind based on electrical intracortical microstimulation of the occipital cortex in a blind volunteer. A healthy, 42 year old woman with a 22 year history of bilateral complete blindness secondary to glaucoma was selected based on a rating system involving eight independent observers. The experimental and time-limited nature of this first study was explained in detail to this patient volunteer who gave her consent.

The surgical procedure was designed based primarily on the fragility of the electrodes and the complex anatomy of the occipital pole region. A strain relief system utilizing silicone tubes and flanges was devised to minimize movement of the electrodes. Parylene insulated iridium "hat-pin" microelectrodes (n=38) with attached gold leads were manually implanted 2mm deep in the visual cortex near the occipital pole. The leads exited the craniotomy site via separate contoured ramps in the skull and penetrated the scalp through four separate incisions.

The occipital cortex was stimulated in daily sessions over four months with occasional respites. Stimulation was never associated with pain or any other discomfort. The sensations produced were typically described as small spots of light varying in color, depth, position, and intensity. Percept qualities could be modulated by adjustment of stimulation parameters, including current amplitude, frequency, pulse duration and train length. Breakages occurred in some electrode leads, which we feel can be prevented with future designs.

The leads and several microelectrodes were removed when testing was completed. There has been no significant morbidity associated with this study.

586.9

FEASIBILITY OF AN INTRACORTICAL VISUAL PROSTHESIS FOR THE BLIND: IV. SUMMARY AND FUTURE. F.T. Hambrecht*, M.J. Bak, C.V. Kufta, D. K. O'Rourke, E.M. Schmidt, and P. Vallabhanath. Neural Prosthesis Program (F.T.H.), Lab. of Neural Control (E.M.S, M.J.B., P.V.) Surgical Neurology Branch (C.V.K. & D.K.O'R.) NINDS, NIH, Bethesda, MD 20892

Using intracortical microstimulating electrodes, cortical phosphenes were produced at the lowest stimulus levels ever reported in humans (see preceding abstracts for details). Reliable and rapid recognition of visual images made up of groups of electrically elicited phosphenes is the most important goal yet to be achieved in developing a visual prosthesis for the blind. Breakage of leads in a patient-volunteer who had been blind 22 years limited the simultaneous activation of multiple intracortical microelectrodes and resulting phosphenes to six in a vertical row which could be recognized as a letter "I".

To further evaluate pattern recognition, a visual cortical implant system with over 200 intracortical microelectrodes arranged in pairs is being developed. In the next, more recently blinded patient-volunteer a percutaneous connector rigidly mounted to the skull is planned. Also a television camera and image processing electronics will be used to provide visual images in addition to computer generated patterns. In a definitive prosthesis a multichannel transcutaneous telemetry system will be needed.

FEASIBILITY OF AN INTRACORTICAL VISUAL PROSTHESIS FOR THE BLIND: II. VISUAL SENSATIONS PRODUCED BY CORTICAL STIMULATION. P. Vallabhanath*, M.J. Bak, F.T. Hambrecht, C.V. Kufta, D. K. O'Rourke, E.M. Schmidt, Lab. of Neural Control (M.J.B., E.M.S., P.V.), HHMI-NIH Research Scholar (P.V.), Neural Prosthesis Program (F.T.H.), Surgical Neurology Branch (C.V.K., D.K.O'R.), NINDS, NIH, Bethesda, MD 20892

Stimulation of 34 of 38 microelectrodes implanted in the area of the visual cortex of a blind patient volunteer (see preceding abstract for details) produced visual percepts (phosphenes). The phosphenes appeared as sensations of light ranging in size from pinpoint to a nickel held at arms length. At currents near threshold, phosphenes were reported to have colors such as violet or blue, while at higher stimulation currents they were reported as white or yellow .

Microelectrode impedance and threshold currents were monitored daily. Many electrodes had thresholds between 2μa and 20μa using cathodal first, biphasic stimulation (train length = 125ms, frequency = 200Hz, pulse width = 200μs). Threshold currents decreased with increasing pulse width, train length, and frequency within certain limits. Thresholds rose at frequencies below 100Hz, and train lengths below 250ms. At a given current, the phosphenes were perceived to be brighter and more distinct at a pulse width of 800μs than at 200μs or 400μs.

Sequential phosphenes produced by stimulation of the same electrode required an inter-train interval greater than 125ms. Electrodes were repetitively stimulated daily with only slight and temporary increase in thresholds. During repetitive stimulation, the phosphenes initially decreased in brightness (accomodation) and then either stabilized or extinguished.

586.11

FEASIBILITY OF AN INTRACORTICAL VISUAL PROSTHESIS FOR THE BLIND: III. MAPPING OF PHOSPHENE LOCATION. E.M. Schmidt*, M.J. Bak, F.T. Hambrecht, C.V. Kufta, D. K. O'Rourke and P. Vallabhanath. Lab. of Neural Control (E.M.S, M.J.B., P.V.) Neural Prosthesis Program (F.T.H.), Surgical Neurology Branch (C.V.K. & D.K.O'R.) NINDS, NIH, Bethesda, MD 20892.

Sequential and simultaneous stimulation of microelectrodes implanted in the area of the visual cortex of a blind patient-volunteer (see preceding abstracts for details) produced multiple phosphenes in the perceived visual field. Phosphene locations were mapped using subject descriptions, a dart board mapping procedure or a pair-wise computer mapping algorithm. All phosphenes were located in the left hemi-field with most near or above the horizontal meridian within 40 degrees of the fixation point. The apparent distance at which phosphenes appeared ranged from a few inches to the location of a "distant star". When multiple phosphenes were produced simultaneously they tended to look alike and appeared at the same depth. When the stimulating current was increased above threshold on some electrodes, a second phosphene appeared in close proximity to the first phosphene. Multiple phosphenes, produced with either single or multiple electrodes, maintained their relative positions as they moved with conjugate eye movements. The relative relationship of the phosphenes in visual space was roughly similar to the placement of the electrodes in the visual cortex.

The apparent spacial concentration of the phosphene map may be due to the anatomical placement of the intracortical electrodes, the length of blindness (22 years) or the type of blindness (glaucoma).

VISUAL BEHAVIOR: PSYCHOPHYSICS AND EYE MOVEMENTS

587.1

A DYNAMICAL MODEL FOR COMPUTING THE POSITION OF AN OBJECT FROM ITS RETINAL LOCATION AND EYE POSITION. A. Pouget, T. Albright* and T.J. Sejnowski. The Salk Institute, La Jolla, CA 92037.

The position of a visual object with respect to the viewer, the egocentric position, can be computed by adding the retinal position of the object with the position of the eyes. An experiment performed by Matin et al. (Science, 248, 1965) suggests that humans use this simple algorithm when localizing visual objects. The task was to localize a point of light briefly flashed (<1 ms) on a screen during a saccade. The subjects could accurately localize the position of the flash in the absence of any other visual stimulus which suggests that the eye position was apparently available to the observer. Additional experiments, however, showed that humans tend to make a systematic localization error in the direction of the saccade (Mateef, Psych. Perc., 24, 1978). Furthermore, the size of the error was a function of the retinal position on which the flash impinged (O'Regan, Psych. Perc., 36, 1984). Thus, the perceived egocentric position of an object is not a static linear sum of the retinal position and eye position.

We have developed a biologically plausible model that computes egocentric position by dynamically combining the retinal position of an object with eye position. The model accurately locates an object when it is presented for a long duration (>100 ms) with the eyes at rest. However, for brief presentations while the eyes are moving, the model exhibits a pattern of errors identical to that reported in humans. Taken together with recent physiological and psychophysical results (Gauthier et al., Science, 249, 1990), our model suggests that the eye position is used for object localization. (Supported by the Howard Hughes Medical Institute).

THE QUANTUM EFFICIENCY OF HUMAN VISION: COMPARING PSYCHOPHYSICS & ANATOMY. Denis G. Pelli* Institute for Sensory Research, Syracuse University, Syracuse, NY 13244-5290.

Transduction efficiency (fraction of corneal photons that produce an isomerization) has received much attention since the time of Hecht, but is still subject to much uncertainty. Pelli (1990) introduced a new psychophysical technique that measures transuction efficiency by measuring the effects of visual noise masking. The X's show preliminary measurements indicating peak transduction efficiencies of 5-10% for both rods and cones. They agree with anatomical estimates shown as curves, which are computed from the known number of receptors and their optical densities and aperture sizes.

587.3

A NETWORK MODEL OF DEPTH CUE INTEGRATION. M.B. Ladner* and D. Zipser. Department of Cognitive Science, UC San Diego, La Jolla, CA 92093-0515.

Many different cues give information about depth, but it is not known how these cues are integrated to form unified percepts. To investigate this, we trained neural network models with biologically realistic visual input to produce depth maps of the same objects used in psychophysical experiments on depth cue integration (Bulthoff & Mallot, *J. Optical Society of America, A5*:1749-1758, 1988). In the psychophysical study, subjects judged the depth of points on computer generated objects with various combinations of shading and stereo cues. Their study showed that perceived depth decreases with fewer cues. Our network model was trained to estimate the depth at the center of its binocular receptive field. The use of targets corresponding to psychophysically measurable quantities for network training ensures that network responses can be directly compared to human responses. Networks trained solely on cue-rich images show a systematic decrease in "perceived depth" to cue-impoverished images similar to that found in humans. Differences between human and network responses highlight local-global cue conflicts in depth perception. By analyzing how these model networks integrate different depth cues, hypotheses can be generated as to how this integration takes place in the brain. These results extend the neural systems identification paradigm (Zipser, *Neuroscience, 47*(4):853-862, 1992) to models that can be compared to psychophysical data.

587.4

INTERACTIVE ACTIVATION MODEL OF HIERARCHICAL PROCESSING OF VISUAL OBJECTS. H. E. Schendan* and G. Ganis. Neurosciences Graduate Office, 0608, UCSD, La Jolla CA, 92093; Dept. of Cognitive Science, 0515, UCSD, La Jolla CA, 92093.

A parallel distributed processing model similar to the interactive activation model of McClelland and Rumelhart (1986) is presented that accounts for some of the main findings from neuropsychological and psychophysical studies of hierarchical processing of visual objects. The input units of the network are feature detectors tuned to a range of different spatial frequencies and orientations. The second layer is composed of letter detectors and each detector receives feedforward projections from all input units for a particular spatial position. Weights coming from input units consistent with the configuration of that particular letter are positive, whereas weights corresponding to input units inconsistent with the configuration of that particular letter are negative. Lateral inhibitory connections between units in the second layer result in a winner-take-all configuration. How low and high spatial frequency filters may contribute to hierarchical processing is explored. Differential hemispheric rates of processing of high versus low spatial frequencies have been postulated to be the best explanation for global and local effects in the processing of hierarchical visual objects (Robertson and Rafal, 1991). The results of the simulations using the interactive activation model support this hypothesis.

VISUAL AFTEREFFECTS IN THE MONKEY: THE JUDGEMENT OF VERTICAL AFTER ADAPTATION TO OBLIQUE CONTOURS.
M. A. Berkley*[1], R. Vogels, G. Sáry & G. A. Orban. Laboratorium voor Psycho-en-Neurophysiologie, Katholieke Universiteit Leuven, Belgium.

In humans, it has been shown that the subjective estimate of the orientation of a contour is shifted by several degrees from its real orientation after extended viewing of contours differing 5-50 degrees from the orientation of the contour to be judged. This phenomenon, called the tilt aftereffect (TAE), has frequently been used in studies attempting to define the neural substratum of contour perception. As a preliminary to making direct studies of neurons that might participate in the TAE, we trained a monkey with an implanted eye coil to fixate a central target (95% contrast sq. wave grating) and report the orientation of a subsequent, briefly presented (100ms) test target (20% contrast sq. wave grating of various orientations) by making a leftward saccade to indicate a counterclockwise (CCW) orientation and a rightward saccade to indicate a clockwise (CW) orientation. After learning the task, the fixation time at the start of each trial was gradually increased to 5 secs, and a 600 ms blank interval introduced before each test target presentation. The proportion of test orientations judged to be CW were used to construct psychometric functions and showed that the monkey's estimate of subjective vertical (orientation at which CW or CCW choices were 50%) was dependent upon the orientation of the grating viewed during the fixation interval. Fixation gratings tilted 15 degs. from vertical produced a shift of 1-1.5 degs in subjective vertical, while fixation gratings orientated vertically or horizontally produced no shift. The TAE observed was slightly smaller than that shown by human subjects tested under the same conditions. The presence of a TAE in monkeys rules out many cognitive explanations for the effect, and demonstrates the feasibility of quantitative investigations of perceptual effects in animals. A NEW EFFECT IN COLOR AND SPATIAL VISION: VISIBILITY OF A TEST PATTERN IN A MASK IS BANDPASSED WITH VIEWING DISTANCE
R.L.P. Vimal and R. Pandey*, New England College of Optometry, Boston, MA

We observed that a masked pattern was often most visible at intermediate viewing distances. We examined this masking effect as a function of the mask's relative spatial frequency (SF) and relative orientation in both chromatic and achromatic modes. A spatially localized test target (e.g. 1 cpd at 80 cm with 30% contrast) and sinusoidal masks (2 cpd with 60% contrast) displayed on a Sony GDM1936 color monitor interfaced with ATVista Graphic System was used. The Red-Green (RG) channel was isolated by the minimum flicker equiluminant criterion and the hue cancellation technique. Two normal observers made magnitude estimations (ME) using ratings between 0 (test pattern was not seen) and 10 (test was most distinctly seen). We found bandpass ME visibility curves (ME rating vs. viewing distance) for both achromatic (reddish and greenish patterns inphase) and RG chromatic (patterns antiphase) modes for vertical test and masks oriented 14.5°, 45° and 90° from the vertical. The visibility of the test pattern increased as the orientation of the mask relative to the test increased at a given distance. Our data showed that the visual system has SF and orientation tuned mechanisms at suprathreshold contrasts (similar to threshold contrasts[1]) in both chromatic and achromatic modes. Low test pattern visibility suggested that the test was processed mostly by the same SF and orientation tuned mechanisms as the mask whereas higher pattern visibility indicated processing by different mechanisms. This masking effect, which is stronger in the chromatic mode, can be explained by SF and orientation tuned mechanisms, and by the apparent contrast of the mask relative to the test at different viewing distances.

SPATIAL SUMMATION OF VISUAL INFLUENCE ON EGOCENTRIC LOCALIZATION: VARIATIONS WITH ECCENTRICITY. L. Matin* and W. Li, Psychology Dept., Columbia Univ., New York, NY 10027.

The elevation of a target set to appear at visually perceived eye level (VPEL) varies linearly with the pitch of a visual field that is complexly-structured or consists of only 1 or 2 vertical lines (Vis Res'89, JEPHPP'92).

The influence on VPEL of the pitch of 1 vertical line of variable length was measured at 2 eccentricities (ecc), 5° and 25°; slopes of VPEL/Pitch functions increased exponentially w/length with space constants of 5° and 13°, respectively. For the shortest line (3°) pitch was 33% more potent at 5° ecc, but this predominance decreased and reversed with longer lines so that at 64° length the more peripheral stimulus was 55% more potent. Max. VPEL/Pitch slopes were 0.36 and 0.55 at 5° and 25° ecc, respectively. However, VPEL is uniformly more sensitive to retinal orientation of the parafoveal line than the peripheral line.

The relative effectiveness for egocentric localization of short and long lines in the parafovea as compared to the periphery and the variation in space constant is in a similar relation to that found for visual acuity and for V1 receptive field size. However, the 13° space constants for VPEL are at least an order of magnitude larger than is appropriate for visual acuity or V1 receptive field size, but they do correspond to receptive field sizes reported in MT, MST, and 7a. 587.8

SPECIFICITY OF SELECTIVE VISUAL ATTENTION FOR ORIENTATION AND SPATIAL FREQUENCY. A.F. Rossi* and M.A. Paradiso. Center for Neural Science, Brown Univ., Prov., RI.

Most studies of visual attention concern the finding that when attention is drawn to one location in the visual field, performance at that location is enhanced. However, there are suggestions from both physiological and psychophysical experiments that there are also feature-specific aspects to selective attention. Our psychophysical experiments quantify the extent to which attention is specific to attributes of visual stimuli such as spatial frequency and orientation. A subject's attention is engaged by performing a temporal forced choice discrimination task with foveal stimuli consisting of Gabor patches. During the experiment a secondary task is performed in which the subject detects the presence of a grating briefly presented in the periphery shortly after the second Gabor target. In order that attention be kept on the primary discrimination task, the subject is prompted to indicate whether a grating is present on only one third of the trials. On only half of these detection trials is a grating actually present. We find that the hit rate for detection of the surround grating is highly dependent on its orientation and spatial frequency relative to the Gabor stimuli. The detection rate is considerably higher for gratings having the same frequency and orientation as the discrimination targets. Performance degrades as the grating frequency and orientation deviate from that of the targets and we have measured bandwidths for these attentional processes. Importantly, performance on the secondary task is selective for both orientation and spatial frequency even though the discrimination task only involves one of these attributes. These data provide quantitative measurements of the extent to which selective attention can be specific to featural attributes in addition to location.

EXPRESS SACCADES ELICITED DURING NATURAL FIXATIONS OF VISUAL SEARCH. M. A. Sommer* and P. H. Schiller, Department of Brain and Cognitive Sciences, Mass. Inst. of Tech., Cambridge, MA 02139.

Very short latency saccadic eye movements (≤105ms) are elicited from primates after extensive training on simple tasks, but do such "express" saccades occur during normal visual search? Highly- and barely-trained macaques with implanted scleral search coils were tested on a "Standard" task (fixation point stays on during presentation of target) in which the fix-spot could appear in one of nine positions (3x3 matrix). Foveation of this point caused a target to appear at one of four locations around it, after a target onset lag (50 to 150 ms). A direct saccade to this target location resulted in juice reward. A second "Free Fixation" task was identical except that fix-spots would appear at the other eight locations along with the one "real" fix-spot at the start of a trial; a monkey had to search over the 3x3 fix-spot array until it foveated this "real" fix-spot, initiating the remaining trial events. In this Free Fixation task, monkeys made saccades every 205 ±60ms for up to 10 sec. to search the array. A subject's ability to execute a direct saccade to a suddenly appearing target decreased with target onset lag, from 90% correct at 50 ms to 30% at 150 ms. Reaction times of correct saccades were 95 ±12ms (unimodal) for highly-trained and 98 ±20ms (often bimodal) for barely-trained monkeys. In contrast, reaction times in the Standard task were 120 ±23 and 130 ±26ms respectively. This suggests that express saccades are a natural means of foveating stimuli that suddenly appear during normal visual search.

587.10

VISUAL SEARCH STRATEGIES OF MONKEY AND MAN. M.R. Dürsteler* and R. von der Heydt, Department of Neurology, University Hospital Zürich, CH-8091 Zürich, Switzerland.

A rhesus monkey was trained on search tasks that produce either parallel or serial search in humans. In a display of 4, 8, or 16 bars he had to detect a bar that differed from the others by a unique color, orientation, or size, or only by a conjunction of two such features in different dimensions. A target combination was rewarded until the animal could detect it reliably, and then replaced by another combination. We found that the monkey could detect feature conjunctions in parallel that humans can find only by searching serially, e.g. color*orientation: 492ms-0.1ms/item for monkey vs. 622ms+ 12.6ms/item for human (reaction times for target-present trials). Signs of serial search were seen during learning phases; however, when performance reached 90% correct search functions became flat. Significantly, transfer to a new target conjunction required several hundred trials of retraining, even after several conjunctions had been learned successfully. For difficult discriminations (size difference 20%) the monkey did use serial search, but conjunctions were found as fast as features (size*orientation: 7.7ms/item, size: 6.5ms/item). We conclude that monkeys accomplish conjunction search differently from humans. Either they employ conjunction detectors that humans cannot use (cells with appropriate joint selectivity are known to exist in monkey visual cortex), or they effectively avoid searching serially by other strategies, similarly as humans can do under certain conditions.

587.11

TIME COURSE OF COVERT ORIENTATION IN A RHESUS MONKEY. M. Davidson, L.J. Thomas-Thrapp, E.A. Witte, M.I. Posner*, C.R. Collazo, Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Covert orienting of visual attention has been widely studied in humans. Following a peripheral visual cue, a target presented at the cued location is responded to more rapidly than when the target occurs at an uncued location (validity effect). When the cue predicts the target location the advantage for the cued side occurs within the first 100 msec following the cue and the validity effect is usually sustained throughout an interval of 1-2 seconds.

An adult female rhesus macaque was trained to do a covert target detection (CTD) task. During the CTD task a trial was initiated when the monkey depressed a bar and fixated a spot in the center of a video monitor. Fixation was checked by measuring eye movements with the scleral search coil method. Following a random delay interval, a peripheral cue was presented to one or both hemifields. Either 100, 400, or 700 msec after the cue a target was presented to either the left or right hemifield. In 57% (8/14) of the trials the cue was presented to the same hemifield as the target (valid condition). In 14% (2/14) of the trials the cue was presented to the opposite hemifield as the target (invalid condition). In 28% (4/14) of the trials a cue was presented to both hemifields (neutral condition). The monkey indicated target detection by releasing the bar.

The results showed a validity effect of 26 msec at a cue-target latency of 100 msec. The size of the validity effect remained at this value at 400 msec and appeared to show a small reversal at 700 msec. These results were quite similar to those found by Bowman et al. for a rhesus monkey trained and tested in a similar way. The data suggest that the orienting of attention to peripheral cues by these animals is similar to that found in humans. However, the monkey seems less influenced by target probabilities than our humans because she did not show evidence of maintaining attention to the cue at the 700 msec cue-target latency. This research was supported by the Pew Memorial Trust and James S. McDonnell Foundations.

587.12

BEHAVIORAL EVIDENCE OF THE FILLING-IN AT THE BLIND SPOT OF THE MONKEY. H. Komatsu* and S. Yamane, Neuroscience Section, Electrotechnical Lab., Tsukuba, Ibaraki, 305 Japan.

It is well known that when a human subject closes one eye, color and brightness fills in to the blind spot from the visual field surrounding it, and that he does not recognize the absence of the visual information at the blind spot. In the present experiments, three monkeys were tested if there is a behavioral indication of the filling-in at the blind spot. The location of the blind spot was determined from the failure of making saccades to a small visual target in a saccade task. The blind spots located on the horizontal meridian at about 14 to 15 deg ipsilaterally from the fixation point and had a vertically elongated ovoid shape with a size of 5 to 6 deg vertically, and 4 to 5 deg horizontally. Then filling-in at the blind spot was tested using a discrimination saccade task. In this task, when the monkey was fixating a central spot, a filled circle and an annulus with the same color and size were presented simultaneously to the right or to the left of the fixation point. The filled circle covered the region in the visual field corresponding to the blind spot of one eye and the edge of the blind spot of the opposite eye located between the outer and the inner circle of the annulus. Monkeys were rewarded if they made a saccade to the filled circle. When both eyes were open, or when one eye was closed and the filled circle was presented on the blind spot of the opened eye, monkeys performed well in a performance rate over 80% correct. However, when one eye was closed and the annulus was presented on the blind spot of the opened eye, the performance dropped to nearly chance level indicating that monkeys were unable to distinguish an annulus from a filled circle. These results suggest that the filling-in occurs at the blind spot of monkeys as is the case in human subjects.

AUDITORY, VESTIBULAR AND LATERAL-LINE HAIR CELLS

CHARACTERIZATION OF THE POTASSIUM CURRENTS IN TYPE I MAMMALIAN AND AVIAN SEMICIRCULAR CANAL HAIR CELLS. K.J. Rennie and M.J. Correia* Depts. of Otolaryngology and Physiology and Biophysics, UTMB, Galveston, TX 77555.

Type I vestibular hair cells differ in their ionic currents from type II hair cells. Isolated pigeon type I cells are known to have significantly lower input resistances than type II cells and a potassium current active above -80mV. We have used the perforated patch technique (amphotericin B) to make whole-cell recordings from type I hair cells, in order to further identify the currents. Cells were dissociated from the semicircular canals of gerbils and pigeons. Two potassium-selective conductances and a putative non-selective cation current modulated by acetylcholine (100μM), have been found so far. At potentials above -40mV, one of the potassium currents is first present. This current is sensitive to externally applied 100μM quinidine, 4mM barium and 37μM nifedipine, properties consistent with it being a calcium-activated potassium current. At potentials positive to -80mV the other potassium current is present and is blocked by externally applied cesium ions at 5mM (n = 10), but not by intracellularly applied cesium (140mM). Large inward tail currents (approx. 1nA) associated with this conductance appear to lead to cell membrane depolarization. This current is also sensitive to calcium, being reduced by externally applied nifedipine (37μM), 4mM barium, 1.2mM nickel and removal of external calcium. At the average zero-current potential in gerbil hair cells (-61mV), this current is 90% activated. Supported by NIH grant DC01273.

CROSSLINKING OF VANADATE-TRAPPED NUCLEOTIDES TO TWO MYOSIN CANDIDATES IN HAIR BUNDLES. P. G. Gillespie* and A. J. Hudspeth. Department of Cell Biology and Neuroscience, University of Texas Southwestern Medical Center, Dallas, TX 75235-9039.

Our model for mechanoelectrical transduction by hair cells (Hudspeth, A. J. [1989] *Nature* **341:** 397-404) invokes an actin-based motor, perhaps a member of the myosin family, to account for adaptation of the receptor current. Because direct evidence for a hair-bundle myosin is lacking, we sought candidate molecules by asking which constituents of purified hair bundles bind nucleotides under circumstances characteristic of myosins.

Irradiation with ultraviolet light efficiently crosslinks underivatized nucleotides to many myosins (Maruta, H. and Korn, E. D. [1981] *J. Biol. Chem.* 256: 499-502). After exposure to [α-^{32}P]ATP or UTP, photocrosslinking labeled proteins of 120 and 230 kD in hair bundles isolated from the bullfrog's sacculus. Vanadate trapping experiments were consistent with their being myosins. After forming a complex with myosin and newly hydrolyzed ADP or UDP, vanadate dramatically decreases the dissociation rate of the bound nucleotide. We found that vanadate was required for tight binding of nucleotide to the 120 and 230 kD proteins. We could eliminate labeling of the two bundle proteins by simultaneous incubation with an excess of unlabeled ATP (but not AMP) or by preincubation with a mixture of ADP and vanadate. A divalent cation (Mg^{2+} or Mn^{2+} but not Ca^{2+}) was required for observation of labeled proteins. The myosin candidates were surprisingly resistant to solubilization by high- salt conditions and sonication. Consistent with this observation, we detected no biotinylated proteins in ATP extracts of isolated hair bundles. We surmise that the 120 and 230 kD proteins are myosins that are tightly attached to a cytoskeletal structure.

DISPLACEMENT - CLAMP MEASUREMENT OF FORCES EXERTED BY GATING SPRINGS IN THE HAIR BUNDLE. F. Jaramillo* and A. J. Hudspeth. Department of Cell Biology and Neuroscience, University of Texas Southwestern Medical Center, Dallas, Texas 75235-9039.

The mechanically sensitive organelle of each hair cell in the auditory and vestibular systems is the hair bundle, a cluster of stereocilia protruding from the apical cellular surface. Deflection of a bundle acts through elastic elements, the gating springs, to open cation-permeable transduction channels atop the bundle. Using a displacement-clamp system on hair cells from the bullfrog's sacculus, we measured the forces that the gating springs exert upon the stereocilia. The position of a hair bundle was clamped with a flexible glass fiber, whose position was monitored with a photodiode imaging system and maintained by negative feedback. To estimate the force exerted at rest by the gating springs, we disrupted them by focal iontophoretic application of the calcium chelator, BAPTA. The ensuing force on the glass fiber indicated that the gating springs are under tension at rest, and exert a negatively directed force of 57 ± 34 pN (mean $\pm$ standard deviation, n = 11) on the hair bundle. Consistent with earlier results, disruption of the gating springs diminished the bundle's dynamic stiffness by at least 27%. We also quantified the mechanical effect on the hair bundle of gentamicin, a drug which blocks transduction channels in the open state. When the channels' gates were held ajar by iontophoretically applied gentamicin, the tension in the gating springs decreased, producing a force on the bundle of approximately 6 pN in the positive direction. This result, which indicates that a channel's gate swings by at least 2 nm, accords with the 4 nm estimate obtained from gating-compliance measurements. This research was supported by National Institutes of Health grant DC 00317.

VOLTAGE-DEPENDENT CURRENTS IN HAIR CELLS OF THE RAT UTRICLE. M. Saeki* and R.A. Eatock. Dept. of Physiology, University of Rochester, Rochester, NY 14642-8642.

Macroscopic currents were recorded from dissociated rat utricular hair cells using the whole-cell tight-seal patch-clamp technique. The average zero-current potential was -68 ± 3.5 mV (mean $\pm$ SEM, n=4). Hyperpolarizing steps from the holding potential of -61 mV elicited an inwardly rectifying current (I_{IR}) that was reversibly blocked by 5 mM external Cs, suggesting a K-selective current. The slope conductance from -80 to -120mV was 6 ± 1.5 nS (n=7). Depolarizing steps from -61mV elicited an outwardly rectifying current (I_o) that sometimes deviated from Ohmic relationship at positive potentials. Over the linear range, the slope conductance was 34 ± 25.7 nS (n=7). I_o always exceeded I_{IR} but the ratio was variable (7 ± 4.1, mean $\pm$ SD). Block of I_o by internal Cs showed that it is K-selective. The lack of N-shape in most current-voltage (I-V) curves suggests that Ca-dependent current is not predominant. I_o shows voltage-dependent recovery from inactivation below about -10 mV and was blocked 72 % by 1 mM 4-AP. With internal BAPTA to block any Ca-dependent current, tail currents following depolarizing steps could be fit by the sum of 2 exponentials (τ's of 0.6 and 9 ms). The slow component was 50% activated at -19 mV. These results are consistent with 2 outward K currents, possibly delayed rectifier and A current. A 50 ms pulse to -41 mV elicited a non-inactivating inward current. With internal Cs to block K current, depolarizing steps positive to -40 mV elicited inward currents that peaked at 0 mV. These are likely to be L-type Ca current.

The Properties of Inward Rectification in Vertebrate Vestibular Hair Cells. J.R. Holt* and R.A. Eatock, Box 642, Department of Physiology, University of Rochester Medical Center, Rochester, NY 14642

An inwardly rectifying current (I_{IR}) was noted early on in the study of hair cell currents (Lewis and Hudspeth, Nature, 1983, 304, 538-541), but has received little attention. We are in the process of characterizing this current in acutely dissociated saccular hair cells of the leopard frog using the whole cell configuration of the patch clamp technique.

I_{IR} was isolated using 2 mM Cd^{2+} externally to block inward Ca^+ current directly and thus, $I_{K(Ca)}$ indirectly. A large inward current that increased to steady-state with a monoexponential time course was activated upon hyperpolarization and deactivated upon depolarization. A small steady-state outward current was apparent up to 40 mV more positive than the K^+ equilibrium potential. The sensitivity of I_{IR} to external Cs^+ and its reversal potential indicated that it is K^+-selective. Externally applied Cs^+ completely blocked inward I_{IR}. A 10 fold change in external K^+ shifted the reversal potential approximately 58 mV, the amount predicted by the Nernst potential for K^+.

Steady-state chord conductance (G_{Chord}), at several K^+ concentrations, was plotted as a function of voltage and fit by a Boltzmann curve. Increase in external K^+ concentration was found to increase the maximal G_{Chord}, as well as shift the voltage at which G_{Chord} was half maximally activated. The slope of the curve was such that an e-fold change in G was elicited by a 10 mV change in voltage (equivalent to 2 to 3 gating charges). In these respects hair cell I_{IR} resembles other K^+-selective I_{IR}'s.

Vandenberg (Proc. Natl. Acad. Sci., 1987, 84, 2560-64) showed in cardiac cells that inward rectification is due to a voltage-dependent Mg^{2+} block. To test the Mg^{2+} dependence in hair cells we added 10 mM EDTA internally to chelate Mg^{2+} to less than 100 nM. The presence of EDTA in the cell was verified by an 80% reduction in $I_{K(Ca)}$, yet low Mg^{2+} had no effect on the steady-state rectification of I_{IR}.

OUTER HAIR CELL MOTILITY UPON FREE-FIELD ELECTRICAL STIMULATION. M.L. Whitehead*[1] and W.E. Brownell[2]. [1]University of Miami Ear Institute (M805), P.O. Box 016960, Miami, FL 33101. [2]Department of Otolaryngology-Head & Neck Surgery, Johns Hopkins University, 522 Traylor, 720 Rutland Ave, Baltimore, MD 21205.

Isolated outer hair cells (OHCs) undergo fast length changes upon a.c. voltage stimulation, which have been proposed to result from shifts of *position* of elements (electrophoresis) or fluid (electro-osmosis) in response to axial voltage drop, or from summed *length* changes of "molecular motors" in response to transmembrane voltage. To distinguish between these models, guinea-pig OHCs were placed in phosphate-buffered saline between Ag/AgCl electrodes, and exposed to transcellular electric fields of ± 0.75 V/mm. When held at one end, in electric fields parallel to the long axis, ~80% of OHCs shortened and ~20% elongated when the apex was near the cathode. For a fixed cell orientation, the polarity of the length change was independent of which end of the OHC was held, inconsistent with electrophoretic and electro-osmotic models. Fast length changes continued for some minutes after membrane ruptures sufficient to prevent fluid pressure gradients within the cell, arguing against electro-osmotic models, which require such pressure gradients. The middle of all intact OHCs bowed towards the anode in electric fields orthogonal to the long axis, consistent with shortening of the depolarized side, and elongation of the hyperpolarized side, as implied by molecular-motor models. Free-floating OHCs demonstrated slow translocations towards the anode of $\leq 5 \times 10^{-9}$ m^2/Vs. Calculations based on this electrophoretic mobility indicate that electrophoresis contributes insignificantly to fast OHC-length changes.

ACETYLCHOLINE MEDIATED CURRENTS IN SOLITARY TURTLE COCHLEAR HAIR CELLS. M. B. Goodman* and J. J. Art. Committee on Neurobiology and Dept of Pharmacology & Physiology. The University of Chicago, Chicago, IL. 60637.

The efferent post-synaptic potential in turtle hair cells consists of a fast depolarization followed by a longer-lived hyperpolarization. Acetylcholine (ACh) is the probable neurotransmitter at the efferent fiber-hair cell synapse. In the turtle, the entire post-synaptic potential is blocked by atropine and *d*-tubocurare. In addition, superfusion with ACh hyperpolarizes the hair cell and eliminates its response to subsequent efferent stimulation (Art, Fettiplace & Fuchs, 1984, *J. Physiol.* **356**: 525-550). The underlying ionic conductances have been studied in solitary hair cells exposed to ACh. Rapid superfusion of ACh produces a net outward current (20-100 pA) in most cells voltage-clamped at their resting potential (22 of 45). The I-V relation of these cells is most simply interpreted as an increase in the amount of $I_{K(Ca)}$ active at all potentials depolarized to rest. This current may reflect a global increase in intracellular Ca^{2+}, which declines in the continued presence of ACh. A few cells (9% of total) generated a fast inward current followed by an outward current when exposed to ACh and voltage-clamped at rest. The time course of the response in these cells is similar to that of the post-synaptic potential observed in the turtle half-head. The I-V curve for the late component reverses near the potassium equilibrium potential, consistent with the notion that an additional K^+ conductance hyperpolarizes the cell during the late, inhibitory post-synaptic potential. EXCITATORY AMINO ACID ANTAGONISTS BLOCK THE BASAL AND THE EVOKED ACTIVITY IN THE INNER EAR AFFERENT FIBERS. Enrique Soto*, Amira Flores y Rosario Vega. *Ciencias Fisiológicas - ICUAP, Univ. Autónoma de Puebla, México.*

To determine the role of excitatory amino acid (EAA) receptors in the inner ear hair cell- primary afferent synapse. We studied the effect of EAA antagonists on the mechanical response (sinusoidal accelerations), and on the basal activity of semicircular canal afferent fibers of the axolotl (*Ambystoma tigrinum*) inner ear.

The extracellular electrical discharge of the afferent fibers was recorded by means of a suction electrode. Drugs 6-cyano-7-nitro-quinoxaline-2,3-dione (CNQX) 0.01 μM - 0.1 mM; 2-amino-5-phosphono pentanoic acid (AP5) 1 μM - 3 mM; 7-Chloro kynurenic acid (7ClKyn) 1 μM - 1 mM and kynurenic acid (Kyn) 1 μM - 1 mM, were applied by pressure ejection. CNQX and 7ClKyn exerted a specific dose dependent inhibitory action on both the evoked and spontaneous activity, while AP5 and Kyn did not significantly modify the mechanical response, except when used at high concentrations. CNQX shows a thousand fold greater potency than AP5. The rank order of potency was CNQX > 7ClKyn > Kyn > AP5. These results further support the idea of a non-NMDA EAA receptor mediating both the spontaneous and the mechanically evoked afferent transmission in the vestibular system.

SYNAPTIC PLASTICITY IN VESTIBULAR HAIR CELLS OF ANIMALS EXPOSED TO MICROGRAVITY. M.D. Ross and T.C. Chimento* Biocomputation Center, NASA, Ames, MS 239-11 Moffett Field, CA 94035-1000

Do synapses in maculas change in number, size or type as a result of exposure to altered gravity during space flights of short duration? This report focuses on results obtained from three maculas of rats flown for nine days on the Spacelab Life Sciences 1 shuttle, and from three matched ground controls. Tissues were obtained within six hours of landing; fixed, post-osmicated, dehydrated, microdissected, and prepared for transmission electron microscopy according to usual methods. Serial sections (0.2 μm) were cut from the medial border of the macula. More than 600 hair cells, containing more than 3000 ribbon synapses, were studied. Synapses in type I hair cells of flight animals increased by 41% compared to type I hair cells of ground controls, and synapses in type II hair cells increased by 57%. This increase was greater in spherule than in rod synapses. There was a significant rise in spherules in both type I (53%; $p \leq .005$, N=301) and type II hair cells (74%; $p \leq .005$, N=320). Most of the additional spherule synapses were present in multiples. In type I hair cells the number of synapse pairs increased from 9% in controls to 18% in flight animals, and in type II hair cells the number of synapse pairs increased from 19% to 52%. Groups of 3-6 spherule synapses in type II cells increased from 2% to 21%. The more numerous multiple synapses in type II cells contacted collaterals rather than calyces. The size of synapses was not significantly different between flight animals and ground controls. The results indicate that macular hair cells exhibit plasticity and that the macular neural network can adapt to an altered gravitational environment.

POSSIBLE MORPHOLOGICAL FEATURES TO DISTINGUISH CALYX VS DIMORPHIC TYPE I VESTIBULAR HAIR CELLS IN THE CHINCHILLA CRISTAE. A. Lysakowski* Dept. of Pharmacol. and Physiol. Sciences, The University of Chicago, Chicago, IL 60637.

A type I vestibular hair cell is enclosed within an ending termed a calyx. A calyx, however, can belong to either a dimorphic unit or to a pure calyx unit (Fernàndez et al., *J. Neurophysiol.* 60:167-181, 1988). Previously, it has been difficult to distinguish type I hair cells belonging to pure calyx units from those belonging to dimorphic units without some form of dye labeling of the afferent fiber. Recently, however, we have observed some morphological features which may serve to distinguish the two types in unlabelled material. Based upon serial section analysis of ten samples from cristae in four animals, there appear to be at least two classes of type I hair cells. The first class has large mitochondria (0.52 μm ± 0.23 in diameter) subjacent to the cuticular plate and thicker stereocilia. These mitochondria were twice as large as those found elsewhere in the same cell. Cells containing these larger mitochondria were found mainly in the central zone at the apex of the crista and occasionally in the intermediate zone. So far they have not been observed in the peripheral zone. The second class of type I hair cells has smaller subcuticular mitochondria (0.24 ± 0.06 μm diameter) and thinner stereocilia. This second class was found in units identified as dimorphic units by the presence of calyceal collaterals. Type II hair cells had subcuticular mitochondria similar in size to the second class. We have confirmed this difference in several HRP-labelled calyx and dimorphic units. Further confirmation will be obtained using an antibody to calretinin, a calcium binding protein apparently found only in calyx units. (Supported by RO3-DC01474.)

IMMUNOHISTOCHEMICAL LOCALIZATION OF S-100 PROTEINS IN AUDITORY AND VESTIBULAR END ORGANS OF THE MOUSE. J.D. Foster[1,2], M.J. Drescher[1,2], S.F. Myers[2]*, and D.G. Drescher[1,2,3]. [1]Lab. of Biotology, Depts. of [2]Otolaryngology and [3]Biochemistry, Wayne State University, Detroit, MI 48201.

Calcium-binding proteins are thought to be involved in the transduction of intracellular calcium signals which mediate cellular responses to extracellular events. In auditory and vestibular end organs, calcium-binding proteins may modulate certain calcium-dependent processes. Utilizing immunohistochemical procedures, we have localized in the mouse labyrinth S-100-like immunoreactivity, the S-100 proteins representing one subfamily of the EF-hand family of calcium-modulated proteins.

Cochlear inner hair cells and neural elements of the spiral ganglion were weakly immunoreactive. The cytoplasm of Deiters' cells and the basal regions of outer hair cells were strongly positive for S-100-like immunoreactivity, while the supranuclear regions of outer hair cells were unreactive. Fibers in the spiral ligament were strongly immunoreactive.

In the vestibular end organs, including the saccule, utricle, and semicircular canals, nerve fibers underlying the sensory epithelium and nerve calyces surrounding type I hair cells were immunoreactive. Types I and II vestibular hair cells appeared weakly immunoreactive, while epithelial supporting cells showed no immunoreactivity.

The localization of S-100-like immunoreactivity to the basal regions of cochlear outer hair cells and to presumed afferent nerve calyces enveloping vestibular type I hair cells is consistent with a functional role for S-100 proteins at these sites in the regulation of calcium-dependent events.

RECEPTION OF LOW INTENSITY MILLIMETER-WAVE RADIATION BY SENSORY ORGAN. G. N. Akoev, V. D. Avelev, P. G. Semenjkov and R. N. Stiles*. I. P. Pavlov Institute of Physiology, Russian Academy of Sciences, St. Peterburg, Russia, Kara-Dag Biological Station, Krimea, Ukraine, and Department of Physiology & Biophysics, University of Tennessee, Memphis.

The effect of low intensity millimeter-wave electromagnetic radiation at 33-55 GHz on electroreceptors (ampullae of Lorenzini) was studied in skates (*Raja clavata*). The onset of millimeter-wave irradiation at a power intensity of 1-5 mW cm^{-2} to the duct opening at 1-10 mm distance caused transient increases in the firing rates of single afferent units, followed by adaptation during 2-5 min to the initial level. The reverse effect was observed after offset of irradiation. When the power intensity was increased, inhibitory responses were also observed. The inhibitory responses were more pronounced in receptors with higher electrical thresholds; these did not show any excitatory response. On the contrary, on irradiation from a distance of 15-20 mm from the duct opening, the receptors responded with a prolonged excitatory activity lasting up to 20 min. Direct irradiation of the sensory cells irrespective of their electrical threshold produced only an inhibition. The maximal effect of millimeter-wave radiation was shown to be at 55 GHz. The mechanism of the effect of low intensity millimeter-wave radiation on the ampullae of Lorenzini will be discussed.

REGENERATIVE CELL PROLIFERATION IN THE MAMMALIAN UTRICLE IN VITRO. M.E. Warchol*, B.J. Goldstein, and J.T. Corwin. Dept. of Otolaryngology-HNS and Dept. of Neuroscience, University of Virginia, Charlottesville, VA 22908

Postembryonic proliferation of supporting cells, which leads to the addition of new hair cells, has been demonstrated in the inner ear sensory epithelia of fish, amphibians, and birds. The vestibular sensory epithelia in mammals share most morphological traits with their counterparts in those groups, but cell proliferation in mammalian vestibular epithelia has been thought to occur only during embryonic development. We have tested this assumption by explanting utricles into organ culture and have observed that regenerative proliferation of mammalian supporting cells can occur.

Utricles were removed from juvenile and sexually mature albino guinea pigs (wt: 400-700 gm), and cultured in Rose chambers at 37°C. Hair cells were lesioned by incubating the cultures in media that contained ototoxic antibiotics (either 0.5-1.0 mM neomycin or 1.0 mM gentamicin). Then the cultures were incubated for 2-6 days in aminoglycoside-free media that contained either ^{3}H-methyl-thymidine (0.8 μCi/ml) or bromo-deoxyuridine, so that DNA would be labeled in any cells that had proliferated during the culture period.

At least four labeled cell nuclei were present in the sensory epithelium in each case. The occurrence of the labeled cells demonstrates that mammalian hair cell epithelia can respond to trauma by renewed proliferation. In addition, these results and others (Forge et al.,submitted) suggest that mammalian vestibular organs are capable of a heretofore unexpected degree of self-repair after hair cell loss.

THE ORGAN OF CORTI RESPONDS TO RETINOIC ACID (RA) AND CONTAINS RA, A NUCLEAR RA-RECEPTOR, AND CRABP DURING THE PERIOD OF HAIR CELL DEVELOPMENT. M.W.Kelley[1]*, X.-M.Xu[1], M.A.Wagner[2], and J.T.Corwin[1]. [1]Dept. of Otolaryngology-HNS and Dept. of Neuroscience, University of Virginia, Charlottesville, Virginia, 22908, [2]Howard Hughes Medical Inst., Columbia University, New York, New York, 10023.

We have demonstrated that the addition of 10 nM retinoic acid to cultured cochleas from mouse embryos causes a significant number of cells to alter their normal developmental fates and to differentiate as supernumerary hair cells. This suggested that retinoic acid might participate in the control of differentiation during the normal development of the organ of Corti.

If retinoic acid does function in the normal development of this organ, then retinoic acid and at least one of its nuclear receptors (RAR's) should be present during development. To test for the presence of endogenous retinoic acid, we have cultured embryonic (E14-P0) organs of Corti on monolayers of F9 teratocarcinoma cells that were engineered to express a ß-galactosidase gene when exposed to retinoic acid (Wagner and Jessell, in press). Intense blue staining in the X-gal reaction demonstrated that retinoic acid is produced by the organ of Corti, but not by negative control tissue, such as skin from the head. Western blots were used to test for the presence of RARß and CRABP. Organs of Corti were dissected from mouse cochleas at three developmental time points (E14, E16, P0), and separately homogenized, run through PAGE, transblotted to nitrocellulose, and incubated with monoclonal antibodies specific for those markers. At each time point, a single band at approximately 50 kD was labeled in blots exposed to anti-RARß. A single densely stained band at 16 kD was observed in blots exposed to anti-CRABP.

The results are consistent with a potential role for retinoic acid in the control of hair cell differentiation during the normal development of the organ of Corti.

EXPRESSION OF A PROTEIN WITH EGF-LIKE IMMUNOREACTIVITY IS TRIGGERED BY TREATMENTS THAT EVOKE HAIR CELL REGENERATION.

X.-M. Xu, and J.T. Corwin*. Dept. of Otolaryngology-HNS and Dept. of Neuroscience, University of Virginia, Charlottesville, VA 22908.

We have used the trauma-evoked response of the avian cochlea to investigate biochemical changes that lead to regeneration of hair cells. Multiple experimental groups of 7 to 9-day-old white leghorn chicks were each given an injection of gentamicin at 100 mg/kg body weight and then exposed to tonal sound stimulation at 1.5 kHz and 120 dB SPL for 24 hr, so as to damage hair cells and trigger regeneration in the cochlea. Immediately after the treatment, the chicks were euthanized and their cochleas were removed. The sensory epithelium was dissected from each and homogenized in a detergent buffer containing protease inhibitors. Supernatants were run through SDS-PAGE under reducing conditions along with samples from age-matched controls. Nitrocellulose blots were reacted with a polyclonal antibody raised against epidermal growth factor from the mouse submaxillary gland.

Our preliminary findings include significant anti-EGF labeling of a protein that runs at approximately 14 kD in all samples from the experimental groups. The strong labeling of this protein in samples from treated cochleas contrasted with an absence of labeling or barely detectable labeling at that position in control lanes. Bands at higher molecular weights were comparably labeled in both controls and experimentals, providing an internal control for the assay. The increased expression of this protein is detectable immediately after a treatment which causes extensive hair cell loss and which evokes hair cell regeneration. This suggests that a small protein with an EGF-like domain may participate in the cascade of events that initiates the replacement of hair cells.

HAIR CELL AND SYNAPTIC RECONSTRUCTIONS IN THE AMPHIBIAN PAPILLA IN LEOPARD FROG, *RANA PIPIENS PIPIENS*.

C. Bertolotto , D.D. Simmons, M. Leong, and P.M. Narins* Dept. of Biology and Brain Research Institute, UCLA, Los Angeles, CA 90024-1606

Amphibians have two auditory organs in each inner ear that are specialized for the reception of airborne sound: the amphibian papilla (AP) and the basilar papilla. In the leopard frog, the AP is innervated by fibers with characteristic frequencies from 100 - 1250 Hz. The AP is believed to be tonotopically organized. To address ultrastructural differences in different parts of the AP, hair cells and their synapses were reconstructed from plastic cross sections. Hair cells from the rostral AP had a mean length of 43.8 μm and a mean area of 519 μm^2. Hair cells from the caudal AP had a mean length of 27.2 μm and a mean area of 292 μm^2. Although the lengths in both caudal and rostral extensions vary systematically, within each region the length decreases along the posterior to anterior axis. In the rostral AP hair cells had 9 to 11 afferent synapses and at least one efferent synapse. In contrast caudal AP hair cells had only 3 to 5 afferent synapses and efferent synapses were not readily observable. Although the present study shows that there are definite morphological correlates of a tonotopic organization, these data additionally suggest that there may be fundamental differences between the rostral and caudal portions of the AP.

RAT UTRICULAR MACULA: BLOOD FLOW AND STEREOLOGICAL ASSESSMENT OF CAPILLARY MORPHOLOGY

M.J. Lyon* and R. PAYMAN Dept. of Otolaryngology, SUNY Health Science Center, Syracuse, NY 13210

Vascular compromise has long been proposed as a cause for inner ear disorders. However, the examination of blood flow and its control mechanisms in the vestibular system has been very limited. Combining stereological techniques with the microsphere injection technique, capillary morphology and regional blood flow were determined for the young adult rat utricular macula. Results are: total utricular blood flow, 0.1581 ±0.0783 μl/min; blood flow to the neuroepithelium (excluding nerve), 0.0995 ± 0.0466 μl/min; blood flow/unit volume, 7.71 ±4.31 $\mu l/min/mm^3$; neuroepithelial volume 0.01322 ±0.0018 mm^3; capillary surface area, 11.75 ±1.78 mm^2/mm^3; mean capillary diameter, 5.84 ±0.56 μm; capillary length/unit volume 627.4 ±78.0 mm/mm^3; volume fraction of capillary lumen, 0.018 ±0.004. Comparisons to data for the posterior canal ampulla (Wanamaker and Lyon, Otolaryngol Head Neck Surg 1990;103:586) indicate that: the mean capillary diameter in the rat utricular macula is smaller; the capillary length/unit volume is greater; the end organs are similar with respect to neuroepithelial volume, capillary surface area/unit volume and blood flow/unit volume. The size of the microsphere used in the present study (9.21 μm), in comparison to the mean capillary diameter (5.84 μm) of the utricular neuroepithelium would indicate that the blood flow data likely represents a minimum value. These findings indirectly indicate that the metabolic rate of the utricular macula is greater than that of the posterior canal ampulla. If there is as much variation in capillary diameter between the neuroepithelium of the other end organs then regional vestibular blood flow studies would have to be performed using microspheres sized appropriately for each end organ

588.18

PRESERVATION OF INNER EAR TISSUES IN THE CHICK FOLLOWING PERFUSION AND MICROWAVE FIXATION.

D.L. Shepard, N.E. Wiener, C.D. Fermin*. Dept. of Pathology, Tulane Univ. Sch. of Med., New Orleans, LA 70112.

The sensory structures of the inner ear are difficult to preserve with conventional fixation methods because such structures are surrounded by bodies of fluid (endo & perilymph). Even intracardiac perfusion can lead to diffusion of molecules from cells and tissues, thus producing poor fixation. This study looks at microwave irradiation as a possible alternative method for fixation of sensitive tissues. The structural preservation of vestibulocochlear tissues is used to compare techniques which utilize a) immersion in primary fixative combined with microwave irradiation; b) intracardiac perfusion combined with microwave irradiation; c) conventional fixation methods of immersion without microwave irradiation; and d) conventional perfusion without microwave irradiation.

Sixteen temporal bones (TB) were harvested from eight chicks and immersed in a 10% formalin solution. Eight of these TB were then fixed by microwave irradiation techniques. Another sixteen temporal bones were harvested from eight chicks perfused intracardially with phosphate buffered saline, followed by 10% formalin. Eight TB from this group were also fixed by microwave irradiation. TB were then embedded in paraffin, sectioned at 6-10μm, stained with hematoxylin & eosin, and inner ear structures were identified. Two blinded investigators then performed a histopathological analysis using light microscopy and graded structural preservation based on a subjective, multi-criterion scale; a value of "1" represented poor preservation,"2" - intermidiate, and "3" - good preservation. The mean values for the four groups are as follows: immersion & microwave, n=2.57; perfusion & microwave, n=2.35; conventional immersion, n=2.33; conventional perfusion, n=2.68.

The general trend of results indicate that tissues perfused intracardially provide the best histological preservation. However, when immersion is used in place of perfusion, microwave irradiation significantly enhances histological preservation and thus may parallel conditions seen in intracardiac perfusion. We are now in the process of determining antigenicity preservation in tissues fixed with the above protocol.

EFFECTS OF SOURCE DISTANCE ON THRESHOLD DETECTION AND SOURCE LEVEL DISCRIMINATION BY THE LATERAL LINE SYSTEM OF THE MOTTLED SCULPIN.

S. Coombs. Parmly Hearing Institute, Loyola University of Chicago, Il. 60626

The feeding response of the mottled sculpin was used to measure (1) threshold levels of detection for 50 Hz vibrations of a small (6 mm diameter) spherical source and (2) just-detectable level increments in on-going 50 Hz vibrations of the same source placed near the head or trunk of the fish at varying distances. At distances between 15 and 60 mm, source level at mean threshold detection (4 fish) increased with distance at an average rate of around 14 dB/distance doubling. Mean level discrimination limens (5 fish) for equivalent 10 dB sensation levels did not change with distance and were around 6.5 dB. These results show that (1) incompressible flow fields (falling off at 18 dB/distance doubling) are more likely to govern detection responses than pressure (falling off at 6 dB/distance doubling), but that (2) spatial patterns of flow amplitude, which change dramatically with distance near the source, do not affect the ability of mottled sculpin to discriminate source levels.

IN SKATE ELECTRORECEPTORS (AMPULLAE OF LORENZINI) INCREMENTAL SENSITIVITY RECOVERS IN THE PRESENCE OF INITIALLY SUPRAMAXIMAL DC SHIFTS, AN ADAPTIVE FEATURE FOR HIGH SENSITIVITY.

D. Bodznick*, G. Hjelmstad, and M.V.L. Bennett [1]. Wesleyan Univ., Middletown, CT, [1]A. Einstein Col. Med., Bronx, NY.

These receptors respond to low frequency μV potentials applied across the receptor epithelium. The afferents are tonically active at c.15/s, and opposite sign stimuli modulate frequency up or down (max. c. 80/s). We recorded from afferent fibers intracranially, stimulated locally close to canal openings to measure sensitivity, and applied DC with a monopolar electrode in the gut. Test responses to weak pulses (e.g. 10μV, 2s) were blocked initially by well suprathreshold DC shifts up to ±1 mV (which is c. 10^3 X threshold), but sensitivity returned to near normal within minutes. As response frequency declined during large excitatory shifts (and after large inhibitory ones) sensitivity often transiently increased above baseline. During large inhibitory shifts (and after large excitatory ones) spontaneous activity returned before recovery of sensitivity. Cellular mechanisms of adaptation appear not to involve widespread changes in $[Ca^{2+}]_i$ (see abstr. by C.J.H. Wong et al.). Adaptation to relatively large DC potentials, such as associated with secretion of Cl^-, should help to maintain receptor function under changing conditions.

588.21

$[Ca^{2+}]_i$-IMAGING OF RECEPTOR CELLS IN AMPULLAE OF LORENZINI OF THORNBACK RAYS. C. J. H. Wong[1], V. Lev-Ram[2], E. L. Winter, M. H. Ellisman[1], R. Y. Tsien[2&3*] and M. V. L. Bennett[4]. San Diego Microscopy and Imaging Resource, [1]Departments of Neurosciences, and [2]Pharmacology and [3]HHMI, Univ. of Cal. San Diego, La Jolla, CA 92093; [4]Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Ampullae of Lorenzini are elasmobranch electroreceptors sensitive to microvolt signals across their sensory epithelia. Neuroepithelial receptor cells transduce these signals and excite primary afferents via glutamatergic synapses. Tonic impulse activity in afferent fibers is increased by lumen-negative stimuli and decreased by lumen-positive ones. Clusin and Bennett (J. Gen. Physiol 73:703, 1979) concluded that apical Ca^{2+}-influx, induced by lumen-negative stimuli, depolarized the basal faces, activating voltage-sensitive Ca^{2+}-channels in them and causing transmitter release. Confocal ratio imaging of indo-1 loaded receptor cells at 0.1-15 frames/sec showed high $[Ca^{2+}]_i$ which did not change during stimulated or spontaneous electrical activity. $[Ca^{2+}]_i$ could be lowered by loading the AM-ester in Ca^{2+}-free EGTA medium or raised by metabolic poisons. Some cells loaded with fluo-3 via its AM-ester showed spontaneous but not externally stimulatable changes in fluorescence, suggesting endogenous fluctuations in $[Ca^{2+}]_i$. Activity-related $[Ca^{2+}]_i$ transients may not have been detected because extensive convergence on afferent fibers means that only a few receptor cells needed to be active. Alternatively, rapid physiologically effective changes in $[Ca^{2+}]_i$ may be restricted to highly localized regions of the receptor cells and not visualizable with these methods.

REFLEX FUNCTION I

589.1

MODULATION OF LARYNGEAL REFLEXES IN HUMANS DURING REPEATED STIMULATION AND VOLITIONAL TASKS. C.L. Ludlow*, G.M. Schulz, T. Yamashita, and J. Koda. Voice and Speech Section, NIDCD-NIH, Bethesda, MD 20892.

In awake humans, electrical stimulation of the superior laryngeal nerve, containing mucosal afferents, elicits two types of responses in the thyroarytenoid muscles, an early ipsilateral R1 response around 17 ms and a late bilateral R2 around 60 ms. Our purpose was to examine inhibitory mechanisms controlling these muscle responses in awake humans during 1) pairs of nerve stimuli presented at rest and 2) when single stimuli are presented at rest and during volitional laryngeal tasks. With double stimulation at different inter-stimulus intervals (ISIs), conditioned R1 amplitudes decreased linearly as ISI durations were reduced from 10 s to 100 ms. Conditioned R2 responses were reduced in amplitude in relation to the time interval between stimuli but became infrequent particularly at the 500 ms ISI. Reflex responses to a single stimulus were studied during quiet respiration and three tasks: forced inspiration, effort closure and phonation. The occurrence and amplitudes of R1 responses were unaffected by task performance. R1 amplitudes were equivalent to the response amplitude in quiet added to the increased baseline activity level for a task. R2 responses, however, became infrequent during task performance in comparison with rest. The R2 response inhibition suggests that these reflexes are normally suppressed during speech. The inhibitory interval affecting the occurrence of R2 responses between 250 and 500 ms following stimulation, may contribute to the cyclic nature of repeated coughs on one exhalation. The results suggest that R1 and R2 are independently modulated.

MECHANICALLY EVOKED PERIORAL REFLEXES IN INFANTS, CHILDREN, AND ADULTS. S.M. Barlow *, D.S. Finan, P.T. Bradford, and R. Andreatta.
Department of Speech and Hearing Sciences and Program in Neural Science, Indiana University, Bloomington, IN 47405.

Experimental observations of upper limb motor function suggest that the transition of simplex reflex processing to more elaborate forms of sensorimotor actions for voluntary reactions is fundamental to motor skill acquisition (Bawa, 1981: *EEG & Clin Neurophys*, 52: 249). Mechanically evoked activity in the orbicularis oris superior and inferior muscle was studied in young infants (N=7), school-age children (N=10), and adults (N=10) during periods of lip muscle activation. A specially designed multi-point array skin contactor, coupled to a servo controlled linear motor, was used to deliver precise mechanical inputs to the lip vermilion in order to characterize the nature of the perioral reflex as a function of age. The evoked R1 response obtained from the infant was of low amplitude relative to the children and adults, and lacked the degree of muscle specificity characteristic of the adult form. The emergence and maturation of mechanically evoked perioral reflexes is discussed in relation to the acquisition of motor skills involving the lower face. Supported by NIDCD (R01 DC 00365-05).

EFFECTS OF ANKLE POSITION ON M- AND H-WAVE AMPLITUDES IN HUMAN SOLEUS HOFFMAN REFLEX TESTING. S.C. Allison and L.D. Abraham*, Kinesiology & Health Education and Institute for Neuroscience, University of Texas, Austin, TX 78712 and Healthcare Rehabilitation Center, Austin, TX 78745.

Numerous researchers have reported a somewhat paradoxical finding of soleus H-reflex suppression with passive ankle dorsiflexion. This study investigated the effects of passive placement in three ankle positions in five healthy adult males. Hugon's (1973) methodology was meticulously followed to reduce extraneous influences. The subjects were tested at nine stimulus intensities in three randomly sequenced ankle positions (zero degrees neutral, five degrees dorsiflexion, and 20 degrees plantarflexion) and the entire procedure was repeated on a second day.

Analysis of variance revealed significant differences ($p < .05$, 2 & 18 df) among H-wave amplitudes in 114 (84.4%) of 135 pairwise positional comparisons. There was a consistent trend of H-wave suppression with ankle dorsiflexion and greater H-wave amplitude with ankle plantarflexion. However, M-wave amplitudes were also significantly different ($p < .05$, 2 & 18 df) in 118 (87.4%) of the same 135 positional comparisons. These results suggest that changes in ankle position during H-reflex testing may consistently alter the effective activation of tibial nerve fibers. For this reason assessment of position-dependent changes in H-wave amplitudes requires greater attention to M-wave changes than has been reported previously.

CONCURRENT BRACHIORADIALIS CHANGES DURING TRAINING OF BICEPS BRACHII SPINAL STRETCH REFLEXES IN SPINAL CORD INJURED PATIENTS. R.L. Segal* and S.L. Wolf. Div. Phys. Ther., Depart. Rehab. Med., Emory Univ. Sch. of Med., Atlanta, GA 30322.

This abstract reports the effects of downtraining the biceps brachii spinal stretch reflex (SSR) on the SSRs of the brachioradialis. Sixteen spinal cord injured subjects with involvement of C-5 and C-6 spinal levels have participated or are participating in the study. Subjects were randomly assigned to control (n=8) and treatment (n=8) groups. For both groups the first 6 sessions (baseline) and last 4 sessions (follow-up) involved no operant conditioning of the biceps brachii. The middle 24 sessions involved operant conditioning for the treatment group while all sessions were the same as baseline and follow-up for the control group. The mean biceps SSR decreased from baseline during training by an average of 25.6% while the mean biceps SSR increased by 1% from baseline for control subjects. The brachioradialis SSR, which was not the target of training, decreased by an average of 32% during training and decreased an average of 15% for control subjects. The results appear to indicate that the non-targeted brachioradialis is downtrained during the downtraining of the biceps brachii in spinal cord injured patients. VIDEO MOTION ANALYSIS OF KNEE SWING IN SPASTIC SPINAL CORD INJURED PATIENTS BEFORE AND AFTER PERINEAL ELECTROSTIMULATION. P.W. Nance*, L.S. Halstead, S.W.J. Seager, Dept. Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3A 1M4 and the National Rehabilitation Hospital, Washington, D.C. 20010-2949

Detection of changes in spastic leg tone using the pendulum test can be quantified by computerized motion analysis of the videotaped movement (Nance, et al. Soc Neurosci Abs, #187.20, 1991). Rectal probe electrostimulation (RPES) has been used in the treatment of male infertility for the purpose of evoking ejaculation; however, it has been noted qualitatively that SCI patients experience a reduction of leg tone after RPES (Halstead, et al. Paraplegia, 29:43-47, 1991). The pendulum test of the left leg of five spinal cord injured (SCI) patients with problematic spasticity, 3 men and 2 women, were videotaped before and immediately after perineal stimulation in the form of RPES. All subjects in the present study showed improvement in the pendulum test after RPES by a significant increase in the amplitude of knee angle displacement oscillations after the initial swing and an orderly decrease in knee angular velocity as the angular displacement gradually decreased. A phase plane plot illustrated the closer approximation of normal tone by the appearance of large concentric circles which appear similar to a "whirlpool" (Brown, et al. J Neurol Neurosurg Psychiatry 51:1178-86, 1988). The present study demonstrates a quantified antispasticity effect of RPES in SCI men and women. Sensory input during treadmill training alters rhythmic locomotor EMG output in subjects with complete spinal cord injury. B.H. Dobkin,* V.R.Edgerton, E. Fowler, Depts. of Neurology and Physiological Sciences, UCLA, Los Angeles, CA 90024.

Previously, we demonstrated that the human spinal cord can generate locomotor-like EMG activity in a Frankel A, thoracic (T6) SCI with complete transection. In this study, we compare how EMG activity changed in that subject and another Frankel A (T4) subject who, by virtue of having EMG activity induced by an upper extremity Jendrassik maneuver, presumably had some supraspinal input. Both chronic paraplegic subjects were suspended in a harness by a hydraulic lift so that the amount of loading on the legs could be adjusted as they were manually placed through a stepping motion on a treadmill belt moving at 0.6 to 1mph. Surface EMG was recorded in tibialis anterior, gastrocnemius, soleus, vastus lateralis, rectus femoris and hamstrings.

With training, reciprocal EMG bursts in a stepping pattern developed for each patient. The amplitude, discretness and timing of bursts were modulated by the pattern of weight support (air stepping vs varying the level of weight supported by a leg) and speed of the treadmill belt. The activity of agonists, antagonists and synergists during different sensory conditions was best appreciated by joint probability density plots (de Guzman, Brain Res 555:202, 1991).

Rhythmical oscillation of the lower extremities enables lumbosacral neurons to organize sensory input to generate locomotor-like output when there is little or no clinical evidence of supraspinal influence.

COORDINATION OF MOTOR POOLS IN SYNERGISTS AND ANTAGONISTS DURING PARTIAL BODY WEIGHT SUPPORT LOCOMOTION IN HUMANS. H. NISHIZONO, E. FOWLER, B. DOBKIN, R. GREGOR*, V. R. EDGERTON. Department of Physiological Science, Brain Research Institute and Department of Neurology, UCLA, Los Angeles, CA 90024.

After complete transection of the spinal cord (T12-13) in the adult cat, full weight-supporting locomotion can be generated (Lovely et al. Exp Neurol 92:421, 1986). Further, it has been shown that proprioceptive modulation related to the loading of the hindlimbs during stepping can affect selected phases of the step cycle of the chronic spinal cat (Edgerton et al. J Neurotrauma 9:s119, 1991). Initial results have shown that humans with a midthoracic "complete" spinal injury also can generate stepping-like EMG patterns on a treadmill when the body is suspended so that the subject's weight can be partially supported and the stepping is assisted manually. To more clearly understand how the level of weight support during stepping in spinal subjects affects EMG patterns, variable levels of weight bearing were studied in 5 control subjects, i.e. free of spinal cord injury, during treadmill locomotion at speeds ranging from 0.6 to 1.8 mph. With increased weight support, EMG amplitude decreased in the medial gastrocnemius (MG) and was unaffected in the soleus (Sol) and tibialis anterior (TA). The MG EMG amplitude increased while Sol EMG amplitude was unchanged as speed increased. The antagonist and agonist EMG temporal patterns observed between the TA and MG and the MG and Sol were unaffected by varying the amount of weight support or treadmill speed. During passive, manually assisted stepping with partial weight support, EMG amplitude decreased markedly in the Sol and TA and slightly in the MG. In addition, the agonist and antagonist EMG amplitude relationships were markedly altered during passive stepping with partial weight support. During voluntary air stepping (no weight bearing) minimal activation was observed in the MG and Sol while TA activity was similar to that observed during weight bearing stepping. These results demonstrate that the activity of motor pools of the lower limb of control subjects are altered significantly during locomotion under reduced loading conditions. POSSIBLE ROLE OF STRETCH REFLEX AND RECURRENT INHIBITION IN SHAPING STATIC ELBOW TORQUE-ANGLE RELATIONSHIPS (INVARIANT CHARACTERISTICS). U.R. Windhorst*. Dept. of Clinical Neurosciences, University of Calgary, Calgary T4N 4N1, Canada

Static torque-angle relationships (invariant characteristics: ICs) as measured by Feldman (1980) at the human elbow joint for constant voluntary effort have a monotonic convex shape determining angle-dependent stiffness. In contrast, for constant activation of elbow flexors, the torque increases, peaks and decreases again with increasing angle because of related moment arm alterations (Hasan and Enoka 1985). Conversion of such constant-excitation torque-angle (CETA) shapes into an IC might result from action of the stretch reflex which adds excitation with increasing joint angle. To test its possible contribution, the following assumptions were made. (i) Muscle fiber length increases nearly linearly with joint angle. (ii) Reflex muscle excitation (EMG) is linearly related to muscle (fiber) length. With these assumptions, IC shape cannot be derived from CETAs because it would be sigmoid at low and straight at large joint angles, whilst real flexor ICs are more convex at large than small angles. A contribution to bending the ICs at large angles may come from recurrent inhibition via Renshaw cells. These show a nonlinear saturating dependence on motor axon input rate and amount of excitation, i.e. number of active axon collateral synapses (Cleveland et al. 1981). These relationships can contribute to shape motoneuron output so as to yield convex ICs. Since recurrent inhibition is increasingly depressed with increasing voluntary muscle activation, its effect on motoneurone output would be consistent with the experimental IC's shape-dependence on joint angle. Together with reflex feedback, recurrent inhibition thus contributes to fine-regulate joint stiffness. (Supported by AHFMR)

LATENCY MEASURES OF SPASTICITY IN MULTIPLE SCLEROSIS PATIENTS. P.A. Anderson, C.T. Bever and G.V. Smith* Depts. of Physical Therapy and Neurology, School of Medicine, University of Maryland, Baltimore, MD 21201-1587.

Spasticity long has been defined as a "velocity-dependent increase in tonic stretch reflexes". However, recent experiments in our lab challenge this definition. As part of an ongoing clinical study of Multiple Sclerosis,* 19 patients were examined using a Kin-Com^R isokinetic testing device. We examined the latency of movement-induced activity in the quadriceps and hamstring muscles during passive isokinetic flexion/extension movements at the knee of 20°-, 100°- and 180°/sec.. The data were analyzed using an Ariel Motion Analysis System^R. The results suggest that although the latencies to the onset of muscular activity were highly variable, they indicate a trend where the relationship between the velocity of movement and the appearance of muscular activity were reversed. While further study is necessary, these results question the standard definition of spasticity, at least, in the MS population. * This study was supported in part by a MS Society Grant # RG-2127-A to C.T.B.

ANESTHESIA AND STRETCH REFLEX ACTIVITY IN THE KETAMINE TREATED CAT AS MEASURED WITH EEG AND EMG ANALYSIS TECHNIQUES. J.S.Taylor*, A.Vasanthakumar, C.J.Vierck and J.B.Munson. Dept. of Neuroscience, Univ. of Florida, Gainesville, FL 32610.

In the course of developing a behavioral model of spasticity in the cat, we have investigated the role of ketamine alone or in combination with fentanyl in maintaining an adequate level of anesthesia while preserving triceps surae stretch reflex activity. Anesthetic properties were determined by characterizing the EEG arousal response following application of a controlled noxious or innocuous mechanical stimulus to the tail. Stretch reflex EMG and torque activity were recorded from the triceps surae group in response to ramp and hold dorsiflexion of the feet in both the unanesthetized and ketamine anesthetized cat. We conclude that intravenous infusion of ketamine at 22mg/kg/hr can block arousal in response to noxious stimulation of peripheral somatic structures while maintaining hindlimb stretch reflex activity. We hope to directly correlate spinal injury-induced reflex changes between the conscious and the acute electrophysiological preparation without the confounding problems associated with anesthetic agents. EFFECTS OF REPETITIVE CUTANEOUS ELECTRICAL STIMULATION ON MOTONEURONAL EXCITABILITY. C. Goulet, M. Levin, A.B. Arsenault*, D. Bourbonnais, M. Goyette. Physiotherapy Program, University of Ottawa, School of Rehabilitation, University of Montreal, and Research Centre, Montreal Rehabilitation Institute, Montreal, Quebec, Canada.

Cutaneous electrical stimulation in the form of TENS has been shown to decrease spasticity. However, effects of repetitive stimulation in normal subjects are controversial and may originate from the use of different methodologies. The present study was aimed at elucidating the effects of repetitive cutaneous electrical stimulation on motoneuronal excitability. Eleven normal subjects with no sensory deficits in the lower limbs were tested in five experimental sessions. The purpose of each session was to evaluate different parameters of stimulation such as stimulation of a mixed nerve versus a sensory nerve (the common peroneal and sural nerves) at two frequencies of stimulation (50 and 99 Hz). A session where no modality was applied provided baseline values. Motoneuronal excitability was quantified using the soleus H-reflex elicited according to the classic protocol of Hugon (1973). The intensity of stimulation of the posterior tibial nerve was chosen to elicit a peak-to-peak amplitude of $H_{max}/2$ as well as a small M response. Within each session, H-reflexes were recorded every 30 s for 45 min. Control values were taken for 5 min prior to (H_{ctrl}) and for 10 min after a 30 min cutaneous stimulation was administered at twice the sensory threshold (TENS Medtronic-Selectra; 250 μs pulses). Although no statistically significant group effects (ANOVA for repeated measures: $p>.05$) were shown, there was a tendancy towards inhibition (≥20% H_{ctrl}) of the H-reflex in 63% of the subjects after 30 min of repetitive stimulation at 99 Hz of either nerve. Thus, these parameters of stimulation appear to be optimal for decreasing motoneuronal excitability in normal subjects. Further experiments will test for the efficacy of these TENS parameters on spasticity.

FAILURE OF LOCAL TWITCH RESPONSES IN RABBIT SKELETAL MUSCLES WITH REPETITIVE NEEDLING. **C-Z. Hong***, **Y.Torigoe** , and **D.G. Simons**, Dept. of Phys. Med. & Rehab., University of California Irvine, Irvine, CA 92717.

In rabbit skeletal muscle fibers, responses similar to **local twitch responses (LTRs)** of myofascial trigger point in man could be elicited by mechanical stimulation on certain "responsive bands", and could be confirmed with electromyographic (EMG) recordings. This study investigated the failure of LTRs by needling the "responsive band". A 27-G needle was inserted into the most responsive site of the band repetitively at a rate of one per second. A bipolar EMG recording needle was inserted into the other relatively "inert" end of the band. The visible LTRs and the EMG activity failed to appear after 3-15 times of repetitive needling. If the lidocaine (0.5%, 0.1-0.2 ml) was injected simultaneously during needle insertion, the visible LTR and EMG activity disappeared with only 1-3 needle insertions. The above findings are consistent with clinical experience that trigger point injections eliminate LTRs at that site.

589.13

AGE-RELATED CHANGES IN THE EXCITABILITY OF THE RESPONDING AND THE NON-RESPONDING MOTONEURON POOLS PRIOR TO MOVEMENT ONSET. J.R. Burke*[1] and G. Kamen[2]. (Motor Control Laboratory, Indiana University, Bloomington, IN). [1]Department of Exercise Science, University of South Carolina, Columbia, SC and [2]Department of Physical Therapy, Boston University, Boston, MA.

Young (n = 20) and old (n = 20) adults were required to perform a rapid plantar flexion in response to a visual stimulus. The changes in the excitability of the responding (right soleus) and non-responding (left soleus) motoneuron pools were assessed by eliciting simultaneous right and left leg tibial nerve H-reflexes (50% of the maximum H-reflex) during the last 500 ms of a 1 second warning period at increments of 100 ms and at increments of 50 ms between the presentation of the response stimulus and the onset of movement. On each trial, simultaneous bilateral H-reflexes were elicited at one of these test intervals. The results supported a general facilitation of the non-responding motoneuron pool prior to movement onset in the young adults only and a delayed facilitation of the responding motoneuron pool in the old adults, as shown for H-reflex amplitude.

EVIDENCE FOR CNS INGROWTH CAUDAL TO CERVICAL SPINAL CORD INJURY IN MAN. Blair Calancie* and James G. Broton, The Miami Project to Cure Paralysis, The University of Miami, Miami FL.

In a recent study we reported the existence of short-latency reflexes evoked in upper extremity (UE) distal musculature by lower extremity (LE) nerve stimulation in subjects with C6 or higher chronic and motor-complete spinal cord injuries (Group A). Conversely, those subjects whose neurological deficits at the acute stage were clinically indistinguishable from those in Group A, but who subsequently recovered even marginal strength in muscles innervated by levels at or caudal to C7, do *not* show such interlimb reflexes, nor do control subjects.

Here, we further characterize properties of these reflexes: 1) LE electrical stimulation of both muscle *and cutaneous* afferents routinely leads to 1:1 following by UE single motor units (SMU) at rates of 15 - 20 Hz, and which may go as high as 85 Hz; 2) intense UE SMU discharge (as high as 220 Hz over a 200 ms period) has been observed in response to application of ice to discrete LE receptive fields; 3) UE SMU 'jitter' can be < 2 ms for LE stimulation; 4) reflexes were *not* observed within 4 months of a functionally-complete cervical transection above C6 (N = 3 subjects), but became evident 9 months post-injury (N = 1 subject). These data show that both cutaneous and muscle afferents are forming strong (probably monosynaptic) connections with upper extremity motoneurons in these individuals.

We suggest that LE primary afferents which are known to pass within the fasciculus gracilis send out collaterals caudal to the region of SCI which excite UE motoneurons. The distribution of muscles which show this reflex activity (hand intrinsics = wrist extensors > wrist flexors) parallels the dependence of these muscle groups on corticospinal input. Thus loss of corticospinal-derived synaptic input to these UE motoneuron pools may make them more susceptible to ingrowth from alternate neural populations. These findings lend encouragement to attempts to promote CNS regeneration for the restoration of function.

NEUROPHYSIOLOGICAL BASIS OF FUNCTIONAL RECOVERY IN NEONATAL SPINALIZED RAT. **J.W. Commissiong***, LMCN-NINDS-NIH†, Bldg. 10/5N214, Bethesda, MD. 20892.

We have recently shown that in the neonatal rat that is spinalized at 7 days after birth (PN7), spontaneous recovery of coordinated stepping in the hindlimbs occurs, and is associated with a robust connectivity of Gp Ia/α-MN in the hindlimb muscles. There is also a widespread bilateral convergence of cutaneous afferents from the hindquarters to the α-MNs of the lateral gastrocnemius (LG) muscle (Exp. Brain Res. 78: 597-603, 1989; Brain Res. Bull. 27: 1-4, 1991; Soc. Neurosci. Abs. 1-7: 197, 1991). Rats that were spinalized at PN14 remained paralyzed, and exhibited severely depressed H-reflexes. Using the same non-anesthetized, intecollicular, decerebrate preparation, we have recorded H-reflexes ipsilaterally from the right tenuissimus anterior (TA) and LG muscles, in response to electrical stimulation of the sciatic nerve. In the PN7 preparation, there was a 2.5 msec delay between the H-reflexes elicited from TA and LG. Since the conduction velocities of the Gp Ia fibres from TA and LG were not different, the results suggest that a temporal delay between the Gp Ia inputs from antagonist hindlimb muscle spindles to α-MNs occurs within the spinal cord, and raises the possibility that Gp Ia/α-MN transmission in this preparation might not be always monosynaptic. We have also transplanted E14 dopaminergic cell suspensions into the middle lumbar spinal cord of spinalized PN14 and young adult rats. In both cases, a rich dopaminergic innervation of the transected lumbar cord was present by two weeks. However, only the PN14 rat exhibited the indices of functional recovery that are characteristic of the untreated, PN7 preparation. These results indicate that there is considerable plasticity of the lumbosacral CPG in the lumbosacral spinal cord of the rat. The results also indicate that morphological reinnervation and functional recovery do not always correlate.

589.16

THE INFLUENCE OF GLYCINE ON SPINAL CORD INJURY INDUCED SPASTICITY. R.K.Simpson*, A.A. Leis, M.M. Gondo, C.S.Robertson, and J.C.Goodman, Neurosurgery Department,Baylor College of Medicine,Houston,TX,77030

Spasticity is a frequent and complex sequel to central nervous system injury. The neurochemical basis for the origin of spasticity is largely unknown. Various neurotransmitters have been implicated such as γ-amino butyric acid (GABA). Drugs designed to mimic GABA activity can influence the severity of spasticity but are limited by side effects. Glycine is among the most abundant neurotransmitters in the spinal cord. However, its role in spasticity has received little attention. We have hypothesized that glycine may modify abnormal motor behavior expressed as spasticity.

Rabbits subject to percutaneous, mid-thoracic spinal cord transections were followed and studied after stabilization of spasticity, as determined clinically by the Ashworth score. A catheter was inserted into the cisterna magna and the spinal cord was bathed with either 100 mmol/l glycine,1 mmol/l strychnine, or artificial CSF for 4 hours. H-reflexes were periodically monitored before and during infusion by stimulating the posterior tibial nerve and recording from the plantar surface of the foot. Amplitudes of the H and M waves at various stimulus intensities were measured and H/M curves were constructed.

Glycine was found to depress the exaggerated H response in spastic animals after approximately 90 minutes of infusion. In addition, the stimulus intensity required to produce the H wave was higher than for controls. Strychnine, in contrast resulted in heightened H waves with prolonged durations and aberrant configurations. The stimulus intensity required to produced these H waves was less than for controls.

Our results indicate that glycine may suppress the degree of spasticity and that a potent glycine antagonist, strychnine, can exacerbate it. Glycine activity may play a role in the development of spasticity. Glycine and glycinergic compounds may, therefore, modify the spasticity observed in patients following neurotrauma and require further investigation.

590.1

INFLUENCE OF AUDITORY PRECUEING ON AUTOMATIC POSTURAL RESPONSE. J.W. McChesney, H. Sveistrup, and M.H. Woollacott*. Exercise and Movement Science, University of Oregon, Eugene, OR 97403.

An experiment was conducted to evaluate the influence of precueing on posture control. Two series of trials were run on each subject to assess the influence of a warning signal on automatic postural response muscle onset latency times in the gastrocnemius (G) and tibialis anterior (TA) respectively.

While standing on a moveable platform, each of four subjects was exposed to an audible tone of 50ms duration that preceded a balance disturbance by 500ms. This tone was used as a precue to warn of the forthcoming balance perturbation. The perturbations were anterior and posterior translations (3cm) at 30 cm/sec. Unilateral electromyograghic activity was recorded from G and TA. In the first half of the experiment (series A), a white noise tone precue as well as no precue and catch trials were utilized in 54 random trials. In the second half of the experiment (series B), 60 random trials utilizing a high/low, directionally specific tone precue, no precue, and catch trials were run.

In series A, a decrease in mean muscle onset latency time was observed in TA (4%: 94 ±8ms to 91 ±11ms) and G (10%: 98 ±11ms to 88 ±8ms) following forward and backward platform perturbations respectively. During series B, the TA and G latencies were decreased by 12% (96 ±10ms to 84 ±11ms) and 13% (100 ±9ms to 86 ±10ms) respectively. In both series, G onset was more sensitive to decrease than TA. The directionally specific tone proved to be more effective as a precue. We thus conclude that prior knowledge of a forthcoming balance perturbation can reduce postural muscle onset latency times.

MECHANICS AND CONTROL OF HUMAN STANDING: ANALYSIS OF THE HIP AND THE ANKLE STRATEGIES. A. D. Kuo and F. E. Zajac*. Mech. Eng. Dept., Stanford University, Stanford, CA 94305, and Rehabilitation R & D Center, VA Medical Center, Palo Alto, CA 94304.

Humans prefer to use the "ankle strategy" over the "hip strategy" in response to small perturbations of the support surface (Horak et al., Exp Brain Res 82:167-177, 1990). The reasons for this preference remain largely speculative. We used a musculoskeletal model of the human body to study the effectiveness of these control strategies in relation to stability and control constraints.

Musculotendon actuator models for 14 muscle groups were combined with a model of the mechanics of the body to produce the dynamical equations of motion, which were used to map the set of all possible muscle forces into the set of all feasible accelerations. When visualized in a coordinate system with axes corresponding to angular accelerations about the ankle, knee, and hip joints, the feasible acceleration set appears as a 3-D polyhedron. A constraint to keep the knees straight, approximating behavior seen experimentally, reduces the set to a polygon. Constraints corresponding to the desire to maintain the feet flat on the ground were also displayed in relation to the polygon.

We found that these flat-feet constraints greatly restrict the feasible accelerations of the body when the ankle strategy is used (i.e., only acceleration about the ankle is permitted) but not when the hip strategy is used (i.e., when ankle flexion is combined with hip extension, or vice versa). This corroborates with data showing that the ankle strategy is used in response to small disturbances, but beyond a certain size of disturbance, the hip strategy is employed.

Analysis of muscular effort indicates that the hip strategy is more efficient and faster than the ankle strategy. This leads to the question of why the ankle strategy is preferred, even for small disturbances. Results from optimal control analysis suggest that neither speed, energy, stabilization of the center of mass, nor maintenance of a stable platform for the head are considerations which explain the preference for the ankle strategy. (Supported by NIH grant NS 17662 and the Dept. of Veterans Affairs.)

POSTURAL CONTROL DURING VOLUNTARY ARM MOVEMENTS: CENTRE OF MASS REGULATION VERSUS COUNTERACTION OF THE REACTIVE FORCES

J.J. Eng*, D.A. Winter, A.E. Patla and C.D. MacKinnon. Dept. of Kinesiology, University of Waterloo, Ontario, Canada N2L 3G1.

Voluntary arm movements result in the application of reactive forces to the body and the alteration of the whole body centre of mass (COM) position. In this study, the effects and interactions of these mechanisms on the postural response during the upright stance position were assessed. Subjects were instructed to rapidly move their arms during four conditions which combined the polarity of the reactive forces applied to the body by the arms and the polarity of the displacement of the mass of the arms. Kinematic, kinetic and EMG analyses of the task were performed. A simulation model was developed to further examine the effects of the reactive forces. Two model conditions were considered a) no counteraction, and b) complete, instantaneous counteraction of the reactive forces. Experimentally, the postural moments (torques) of the hip, knee and ankle peaked simultaneously and were opposite in polarity to the focal moment. The hip/knee peak moment ratio was invariant while the knee/ankle peak moment ratio was highly variable suggesting that the final fine-tuning control of the postural response was the responsibility of the ankle muscles. Furthermore, the experimental and simulation results suggest that the effects of the COM regulation and the counteractive postural moments are inextricably linked to each other. (Supported by NSERC and MRC)

590.4

AN ELECTROMYOGRAPHIC STUDY OF THE STARTLE RESPONSE DURING STEADY SPEED SWIMMING OF FISH. B. C. Jayne* and G. V. Lauder. Dept. Biol. Sci. (ML 6), Univ. Cincinnati, OH 45221; Dept. Ecol. Evol. Biol., Univ. California, Irvine, CA 92717

We recorded muscle activity (EMGs) from both sides in each of five bluegill sunfish, *Lepomis macrochirus*, from fine wire electrodes implanted in superficial myomeric muscle at four standard locations along the length of each fish and from deep myomeric muscle at two positions. All trials were videotaped at 400 images/s, and we placed the fish in a flow tank to obtain steady swimming speeds of about 1.6 lengths/s when needed. At 30 min intervals, we dropped an object into the water to elicit startle responses (C-starts) both from fish during swimming and at a standstill. We obtained a total of 40 C-starts during swimming and 20 from a standstill with equal numbers of observations for each individual. The general features of the EMGs from both types of C-starts were similar, with synchronous onset of high amplitude activity from both superficial and deep muscle along the entire side of the fish that forms the concave side of the C. During steady swimming, the EMGs from the superficial muscles were unilateral and propagated posteriorly, whereas the deep muscles were inactive. For C-starts during steady swimming, the onset of large amplitude EMGs involved in C-formation occurred at any time with respect to the rhythmic pattern of low amplitude EMGs involved in steady swimming. These data suggest that the circuitry involved in the startle response can override the motor pattern generated for continuous swimming.

DIFFERENT CONTROL STRATEGIES FOR MOVEMENT AND POSTURE. M. Dornay*, Y. Uno, M. Kawato and R. Suzuki. ATR Human Information Processing Research Laboratories, Soraku-gun, Kyoto 619-02, and Tokyo Univ. Japan.

An appealing motor strategy for the control of arm posture and movement, suggested by E. Bizzi, N. Hogan, T. Flash and others, suggested that the brain could use a unified treatment for posture and movement: Control of posture results from setting the co-activation levels of agonist and antagonist muscles so that a single attractive equilibrium position of the hand is coded. According to the *virtual trajectory hypothesis*, the ability to maintain stable postures is a building block for arm movements. The nervous system continuously vary the activities of the muscles and generates a time-sequence of attractive equilibrium positions called *a virtual trajectory*. The strategy is attractive if an easy to compute virtual trajectory can reproduce realistic movements (Flash, 1987). The size of the hand stiffness predicted by Flash, were much larger than values measured in humans during posture control.

We proposed an alternative control for hand movement, the *minimum-muscle-tension-change model*. It assumes the nervous system must solve inverse dynamics for generating the muscle tensions during movements. We simulated arm movements using a 17-muscle model of the monkey's arm, and a new algorithm which allows non-zero muscle tensions at the beginning and end points. The simulated horizontal arm movements are quite similar to experimental findings in humans. Furthermore, our simulations predict antagonistic co-activation at the initial and final (equilibrium) points. During the movement, however, the model predicts reduced co-activation of the antagonists in a coordinated manner. Therefore, the hand stiffness was reduced during movement relative to the level during posture control. This is contradictive to the requirements of the virtual trajectory hypothesis (Flash 1987). Our predictions for reduced stiffness during movement are supported by experimental data (Bennet et al, 1992). We conclude that the unified approach for the control of posture and movement, based on a simple virtual trajectory, is not supported by our findings.

IMPAIRED PROGRAMMING OF ANTICIPATORY POSTURAL ADJUSTMENTS IN PARKINSON'S DISEASE. F. Viallet*, R.G. Lee, J. Tonolli, R. Aurenty and J. Massion. Laboratoire de Neurobiologie et Mouvements, CNRS, Marseille, France.

Anticipatory postural adjustments were investigated in 5 patients with Parkinson's disease (PD) and in 5 age matched control subjects. While standing on a force platform , subjects were required to rapidly raise one leg in a lateral direction to an angle of about 45°. Kinematics were monitored using an ELITE system with reflective markers placed at multiple sites on the trunk and legs. Surface EMG recordings were obtained from 4 muscles in each leg. To maintain equilibrium during this task requires a number of postural adjustments which have been well characterized in young normal subjects (Mouchnino et al., J. Neurophysiol. in press). Prior to the onset of lateral displacement of the moving leg (time T2) there is a shift in the center of pressure on the force platform (onset at the time T1), initially toward the side of the moving leg and then a transfer of weight to the support leg. The mean value of T1-T2 interval was 570 ms. These force changes are accompanied by displacements of the trunk markers toward the support side. In the more severely affected patients with clinical evidence of postural instability the following abnormalities were observed: 1. the amplitude of the initial change in the center of foot pressure was diminished. 2. the T1-T2 interval was markedly prolonged (mean value: 1331 ms). 3. the amplitude of displacement of the trunk markers toward the support side was reduced. 4. EMG recordings revealed that most muscles were tonically active and did not show bursts of activity or periods of inhibition around the T1-T2 times which were a consistent feature in the normal subjects. These results suggest that mechanisms for programming anticipatory postural adjustments are impaired in some patients with PD.

THE ROLE OF PERCEIVED VISUAL MOTION AND EXTRARETINAL INPUTS IN POSTURAL SWAY CONTROL M. K. Holden*, P. DiZio, and J. R. Lackner. Ashton Graybiel Spatial Orientation Laboratory, Brandeis Univ., Waltham, MA. 02254.
Extraretinal information influences motion perception, and motion perception influences postural control. Thus, extraretinal inputs might play a significant role in posture control, particularly if retinal inputs are minimal. We tested this idea by evaluating postural sway in sharpened Romberg stance in 32 young subjects for 4 fixation conditions: World-fixed visual (V) or remembered (R) target, Head-fixed visual target (H) and No target (N), in a dark room. Subjects let their eyes wander in the N condition. Sway measures were derived from force platform center-of-pressure outputs; eye movements were measured via AC-coupled electroculograms (EOG). Sway was reduced for conditions V and H, but not R, vs N ($p<0.05$). Subjects maintained good fixation stability in V, H, and R conditions, and made larger and more frequent saccades in the N condition ($p<0.05$). Better fixation was associated with improved performace on posture scores in selected conditions. Our results indicate that extraretinal inputs associated with fixation supression of the vestibular-ocular reflex contribute to posture control, especially when retinal input is limited, and have functional implications for falls among the elderly in reduced light conditions. Supported by NASA Grant NAG 9-295.

STABILIZATION OF POSTURAL SWAY WITH HAPTIC INFORMATION. J.J. Jeka* and J.R. Lackner. Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254.

Different forms of sensory information such as vision and touch influence the ability to maintain an upright posture. We studied the role of haptic information on the stabilization of postural sway while subjects (N=5) maintained a tandem Romberg stance on a Kistler force platform. A metal bar placed laterally aside the force platform was used to measure the amount of force applied with the right index finger during 24 s trials. Subjects were tested in three touch conditions: no support, light touch (< 100 g of pressure) or pressure support (as much force as desired) both with eyes open and eyes closed.

The results showed a significant touch x vision interaction effect ($p<.001$) on mean sway amplitude (MSA). MSA with no support-eyes closed was more than twice that of any other condition. Morever, MSA with light touch-eyes closed was significantly less than with no support-eyes open ($p<.01$). Thus, touch information is more effective than vision in decreasing MSA in the tandem Romberg stance. Average applied force with pressure support (370 g) was almost ten times that of touch support (38g). The latter force has been shown to be less than that necessary for mechanical support (Holden, Ventura & Lackner, (1987). Soc. Neurosci. Abs., 13 (1), p. 348). Supported by NIH Grant F32-NS09025-01 and NASA Grant NAG9-515.

SEPARATE SYSTEMS FOR TONIC, TRIGGERED, AND CENTRALLY INITIATED POSTURAL CONTROL: EFFECTS OF LEVODOPA F.Horak*, J.Frank, C.Shupert, M.Stephens, J.Nutt, and A.Burleigh, R.S.Dow Neurological Sciences Inst. of Good Samaritan Hospital, Portland, OR 97209

Levodopa had an opposite effect on triggered postural responses and on centrally initiated postural movements in 15 parkinsonian subjects. Levodopa increased phasic muscle bursts associated with centrally initiated toe rise movements but decreased the size of phasic bursts triggered in response to surface displacements. Levodopa also reduced baseline tonic muscle activity which reduced resistance to external displacements but increased the ability to generate centrally initiated toe rise movements.

These results suggest that there are three separate postural systems: 1) background tonic, 2) centrally initiated, and 3) peripherally triggered. Parkinsonism affects all three postural systems. However, dopamine replacement directly improves only the tonic and centrally initiated postural systems. Supported by grants from NIA and NSERC.

Modification of Motor Evoked Potentials (MEPs) in Lower Limb Muscles by Motor Task

W. B McKay*, M.R. Dimitrijevic, A.M. Sherwood, G. Grubweiser
Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston Tx 77030

Magnetic transcranial motor cortex stimulation elicits both early (MEP1) and later (MEP2 and MEP3) motor evoked potentials appearing with different latencies in muscles of the limbs. In a group of 7 healthy subjects, age 36.9 ± 13.2 yrs., in the supine position, MEP1 was recorded in relaxation with a latency of 24.2 ± 2.8 ms. from the quadriceps, 27.1 ± 2.9 ms. from the medial hamstring, 26.7 ± 1.6 ms from the lateral hamstring, 31.2 ± 7.9 ms from the *tibialis anterior and 35.0 ± 2.6 ms from the soleus muscle during relaxation*, passive stretch and active ankle dorsi- and plantar flexion. Stimulation was applied over the C_z (10-20 EEG placement system) using a 9 cm coil. MEP1 in all muscles was increased during the active motor task while MEP1 in the agonist muscle showed a much larger increase than in the antagonist. Moreover, the later MEP in the soleus muscle occurring in relaxation at 94.9 ± 53.9 ms latency and 405.6 ± 173.2 μv amplitude decreased in latency to 86.8 ± 3.2 ms and increased in amplitude to 711.5 ± 357.7 μv during voluntary dorsiflexion. Passive movement did not bring such changes when compared to relaxed values. Volitional activity and response to motor cortex stimulation are convergent giving selective modification of MEPs based on the motor task.

INSIGHTS INTO LENGTH-GAUGING MECHANISMS OF MUSCLE SPINDLES IN THE CAPSULARIS MUSCLE OF THE CAT. E. Eldred*, L. Yung, P. Tam and R.R. Roy. Brain Research Institute and Department of Anatomy and Cell Biology, UCLA, L.A., CA 90024.

To gain a better understanding of how muscle spindles function as gauges of muscle length, measurements were taken on 18 spindles identified in serial sections of the capsularis, a small, predominantly slow flexor acting at the hip joint. The muscle was fixed in situ in formalin with the hip extended. The muscle then was embedded in paraffin, sectioned transversely at 10 mm thickness throughout its length and the sections stained with H&E. Individual spindles were traced throughout their lengths using a light microscope and a Eutectics Graphics System. Mean spindle length was 5.1 mm, with the capsule comprising approximately 43% of the length. Fifty percent of the ends of the 108 intrafusal fibers measured did not emerge from the capsule. Thus, for these intracapsular fibers the effects on their sensory wrappings would be secondary to deformation of the capsule. In contrast, two fibers at each pole of the spindle continued, generally in isolation, for distances that together comprised approximately 50% of the spindle length. These presumably nuclear bag fibers, therefore, would be expected to be affected by length changes, passive or active, induced over an extent of muscle septum matching the entire spindle length. If sarcomere lengths shortened by 20% when activated, the nuclear bag regions would be expected to lengthen by 1 mm. This outcome is highly unlikely, however, since the capsular space was only 1.05 mm long. Perhaps mere contractile stiffening of these long fibers would permit length changes to appear at the sensory wrappings primarily as inflections of force. In contrast, short fibers with capsular insertions would be subject to in series tension pulling on the capsule and to tension from the tensing of muscle fibers surrounding the bulging spindle equator. These data suggest that the longer spindle fibers may better suited to monitor length and the shorter fibers stiffness changes in the muscle. (Supported in part by NIH Grant NS16333)

MOTOR UNIT SYNCHRONIZATION ASSESSED FROM SURFACE EMG INCREASES WITH DISCHARGE RATE OF REFERENCE MOTOR UNIT. G. Yue*, A.J. Fuglevand, M.A. Nordstrom and R.M. Enoka. Depts Exercise & Sport Sciences and Physiology, Univ Arizona, Tucson, AZ 85721

One method used to assess the degree of motor unit synchronization involves obtaining averages of unrectified and rectified surface EMGs that are triggered from the discharge of a reference motor unit (Milner-Brown et al. *J Physiol*, 228: 285-306, 1973). The influence of motor unit discharge rate on this estimate of synchronization has not, to our knowledge, been delineated. The purpose of the study was to determine the effect of motor unit discharge rate on surface-EMG estimates of synchronization and to compare these estimates to those obtained from cross-correlograms of motor unit pairs. Motor unit (N=28) synchronization ratio, estimated from the surface EMG of human first dorsal interosseus muscle, was found to increase significantly ($p<0.001$) when the discharge rate of the reference motor unit increased (mean±SD, range = 3.33±1.66, 0.36-6.36 Hz). In contrast, synchronization indices based on the cross-correlogram decreased with increased motor unit discharge rate (Nordstrom et al. *J Physiol*, in press). Simple regression analysis indicated a significant, positive relationship ($p<0.001$) between an upward shift of the rectified surface EMG (due to an increase in both discharge rate and recruitment) and the surface-EMG estimate of synchronization. These findings suggest that the surface-EMG method of assessing motor unit synchronization needs to be modified to account for changes in the level of EMG activity.

EQUILIBRIUM POINT HYPOTHESIS: EXPERIMENTAL VERIFICATION OF THE CONCEPT OF MUSCLE ACTIVATION AREA. H.Qi, T.E. Milner, M.F.Levin and A.G.Feldman*. Ctr Recherche, Inst. de réadaptation de Montréal, Inst. de génie biomédical, Univ. de Montréal, Montreal, Canada H3S 2J4.

Motoneuronal (MN) recruitment is a function of kinematic variables (position and velocity), independent control variables, as well as variables characterising the interaction between MN pools mediated by interneurons via reflex and descending pathways. These properties have been integrated in the concept of muscle activation area (MAA) which has been used to explain EMG patterns associated with single and multi-joint movements (Feldman et al. 1990). To test this concept, we recorded EMG signals from wrist flexor and extensor muscles as well as position and velocity during unloading of the wrist to different torque levels. Initial wrist position was neutral (0°) and torque was fixed at 60% of flexor MVC. Subjects were instructed not to correct the deflections of the wrist arising from unloading. This instruction is assumed to be associated with an invariant control signal. Sudden unloading produced a silent period in flexor muscles and a stretch reflex in extensor muscles, and the wrist stabilized at a new final position dependent on the final torque. The combinations of position and velocity associated with the onsets and offsets of the silent periods were represented by points on the phase plane. The set of points associated with different levels of unloading produced a straight line on the phase plane diagram corresponding to the border of the MAA for given initial conditions. When experiments were repeated from an initial wrist angle of 30° flexion, the border of the MAA shifted correspondingly. The change in the initial position (λ) is assumed to be associated with a change in the control signals and our results suggest that this change can be visualized as a shift in the position of the border of the MAA. The EP hypothesis suggests that the position of the border may be an indirect measure of descending influence to α and static γ MNs, whereas its slope may be a measure of the level of γ dynamic activity of the system (damping coefficient).

RESPONSES OF CAT SOLEUS GOLGI TENDON ORGANS TO DISTRIBUTED VENTRAL ROOT STIMULATION AT TIME-VARYING RATES. M. Hulliger*, J.L.F. Weytjens and U. Windhorst. Dept. of Clinical Neurosciences, University of Calgary, Calgary, Alberta T2N 4N1, CANADA.

Whilst it has been well established that Golgi tendon organs (GTOs) are very sensitive to contractions of the muscle fibers inserting into the collagen fibers they encapsulate, it remains a matter of debate whether or not the afferent signal sent to the central nervous system accurately represents muscle force. The question is often addressed by comparing GTO afferent firing with forces produced by reflex contraction or by stimulation of single or small numbers of motor units (MUs). We have reinvestigated the problem by stimulating most of the soleus MUs in a distributed and rate-modulated way, to assess whether (1) single GTOs and/or (2) populations of GTOs, activated by populations of MUs, carry signals which reflect whole muscle force.

In pentobarbitone-anesthetized cats, GTO afferents from soleus were recorded from dorsal root filaments. Eight ventral root filaments, prepared so as to yield approximately one eighth of the total force on tetanic stimulation, were stimulated in a staggered way such that the times of occurrence of the stimuli were equally distributed over the interstimulus intervals of the leading train. Four different stimulus patterns were used: (1) sine waves; (2) staircase functions, incrementing and decrementing in steps of 5 stimuli/s up to 35/s; (3) ramp functions starting at 5/s, with the stimulus patterns to different filaments starting at different times, so as to mimic recruitment; and (4) staircase functions temporally organized as in pattern (3).

GTOs reacted with vigorous bursts to unfused contractions of the MUs exciting them. At intermediate force levels, instantaneous frequency followed force closely. It plateaued at forces below maximum, and generally also showed adaptation. Beyond those general response characteristics, individual GTOs displayed great variability in their responses to similar stimulus patterns, in particular when staircase functions were used; e.g., a GTO might fire during the entire period of activation, or only during individual steps. Faithful whole muscle force monitoring can therefore at best be provided by populations of GTOs. (Supported by AHFMR and MRC, Canada)

FORCE FIELDS AND MUSCLE USE STRATEGIES THAT UNDERLIE REFLEX BEHAVIORS IN THE SPINAL FROG. Simon Giszter*, Department of Brain and Cognitive Science, M.I.T., Cambridge, MA 02139.

Spinal frogs perform motor tasks requiring complex multi-joint limb motion. We have suggested this ability rests on a few movement primitives residing in the spinal cord. To test this hypothesis the three-dimensional forces that underlie different reflex behaviors were measured in spinal frogs.

The frog's limb was attached to a six-axes force transducer. The muscle activity and force responses were measured in the leg when the reflex behaviors were activated by skin stimulation. The limb was moved to a set of locations forming a 3-D grid. The force response patterns through space were analyzed as three dimensional force fields. These force fields and the electromyogram activity were compared with activity and restraining forces measured during and following free limb responses to the same stimulus.

The analyses showed that: (1) the structures of force field patterns for a particular behavior were almost constant between trials and frogs. (2) Two qualitatively different types of force field patterns were found: position control and force control. (3) The force field patterns showed very little adjustment to alterations of body orientation to gravity. (4) While the active force patterns had fixed structures, the kinematics generated showed variability due to amplitude variations of the elicited force fields. (5) A small set of fixed muscle synergies underlay these force fields. (6) Similarly structured force fields could also be measured when the limb was halted after free motion.

A distributed control model is proposed to account for the organization and interaction of primitives in generating spinal reflexes and behaviors, based on Maes' behavior networks (Maes, 1989, AI Memo 1180, M.I.T.). The results here support the idea that fixed muscle synergies and associated force-fields (movement primitives) underlie several behaviors generated in the spinal cord. These primitives include fields implementing force control as well as equilibrium point strategies. These primitives may also form a basis for more complex behaviors.

SIMULATION OF RENSHAW CELL-MEDIATED EFFECTS ON MOTONEURON SYNCHRONY. M. Maltenfort* and W. Z. Rymer. Sensory Motor Performance Program, Rehabilitation Institute of Chicago, and Departments of Rehabilitation Medicine & Biomedical Engineering, Northwestern University, Chicago, IL 60611.

To study the effects of increasing Renshaw cell (RC) synaptic strength on motoneuron firing synchrony, an RC-motoneuron pool was simulated using the MacGregor point neuron model. Parameters for RCs and motoneurons were generated by matching published data for input resistance, time constants, and current-rate plots. Synaptic strengths of motoneurones on RCs were set to be sufficient to cause burst firing of RCs. The neurons were arranged on a rectangular grid, and the effects of synapses were spatially limited to ± one row or column.

The synaptic current on the motoneuron from each RC terminal was 0.01 nA. The average number of terminals from each RC to each motoneuron was increased, to enlarge both the magnitude and the statistical variation of IPSPs on the motoneurons. This allowed us to look at the effects of increasing RC strength without introducing extra synchrony.

The motoneuron pool was stimulated with constant current levels. Firing synchrony was measured as the coefficient of variation (c.v.) of the total activity of the motoneuron pool; it was assumed that RC-mediated desynchronization would reduce variability in the steady-state firing rate. It was found that the c.v. fell off steeply with the number of terminals until it reached a plateau, then began a shallow rise. This implies that the small magnitude of RC effects is actually optimal for desynchronization of motor pools.

Work is in progress to expand the model to look at effects of RCs on force output, to use simulated afferent activation of the motoneuron pool, and to study the effects of varying synaptic strengths of motoneurones on RCs.

MECHANICAL PROPERTIES OF CAT SOLEUS MUSCLE ELICITED BY SEQUENTIAL RAMP STRETCHES. D.C. Lin* and W.Z. Rymer. Departments of Biomedical Eng. and Physiology, Northwestern University, Chicago, IL 60611.

The objective of this study was to examine the intrinsic mechanical properties of muscle during constant velocity stretches of sufficient amplitude to induce muscle yield, with the goal of establishing the relative magnitude and time-dependence of viscous and elastic components of the mechanical response. The soleus muscle in a deafferented decerebrate cat preparation was activated by the crossed-extension reflex. Two experimental paradigms were employed on a total of five cats.

The first consisted of applying two ramps (each 2 mm amplitude), separated by a variable time interval. The velocities of the two ramps were usually the same and ranged from 10 to 100 mm/s. The primary result was that during the ramp, the force response after yield remained constant until the end of the ramp, and the force level depended solely on stretch velocity, not on previous mechanical events, similar to a viscous damper. However, the force transient recorded prior to the steady-state response was history dependent. Specifically, stiffness measurements taken shortly after the onset of the second ramp depended upon the time elapsed between ramps (when the muscle was isometric). The recovery of the initial stiffness was very fast, such that the measures returned to control values within 30-40 ms.

The second experimental paradigm consisted of superimposing a single, very fast, length pulse onto a ramp at various times before, during, and after the ramp. The force response to the pulse, which is an indication of the mechanical impedance, was observed to decline after ramp onset, and remained constant until the end of the ramp. We concluded that the muscle mechanical characteristics were relatively constant and simple throughout the ramp after the initial yield.

The characteristics of post-yield muscle have not been adequately described to determine whether it can form a stable interface with mechanical loads. The results in this study show that steady-state properties of post-yield muscle resemble a viscous damper, providing damping in many situations. By comparing deafferented with intact muscle responses, we conclude that the stretch reflex acts to transform the muscle's impedance from primarily viscous-like behavior (in post-yield muscle) to primarily elastic behavior.

EFFECTS OF MOTONEURON AND MUSCLE FIBER ABNORMALITIES ON THE FORCE-EMG RELATIONSHIP IN A MODEL OF CAT MEDIAL GASTROCNEMIUS MUSCLE. J.J. Gemperline*, C.J. Heckman, and W.Z. Rymer. Departments of Biomedical Engineering and Physiology, Northwestern University, and Rehabilitation Institute of Chicago, Chicago, Illinois 60611.

When the paretic limb of a hemiparetic human subject is compared to the unimpaired limb, it often shows increased EMG and reduced motor unit rates for a given force. To assess the mechanisms of these abnormalities we constructed a computer model of the motoneuron pool and its muscle. This model is based on the available physiologic data regarding size-dependent properties of motoneurons and muscle fibers, primarily from studies of the cat medial gastrocnemius muscle.

We have added an EMG component to an earlier version of this model, presented previously. Each motoneuron is made to fire with interpulse intervals randomly distributed around its central interval, and the neurons of the pool fire asynchronously. The EMG contribution of each unit is modeled as a biphasic triangular waveform whose duration and amplitude depend on unit size.

Using this model, we studied the effects of two proposed mechanisms of muscle weakness. First, motoneuron rates were lowered while muscle fiber properties were left unchanged.We observed compression of recruitment force thresholds, a shift in the force-EMG relationship to produce more EMG for a given force, and a higher mean power frequency for the EMG.

To simulate atrophy we reduced the maximum force of the larger units and slowed their action potentials. We observed a decrease in the EMG mean power frequency, but depending on the assumptions made about changes in contractile speed, EMG could either increase or decrease for a given force.

Data consistent with both mechanisms were obtained from our population of hemiparetic subjects. The effects of reduced motor unit rates and atrophy may counteract each other if both mechanisms were active in a given subject.

MUSCULOSKELETAL KINEMATICS DURING CONTROLLED HEAD MOVEMENTS IN CATS. E.A. Keshner*, S.D. Garimella, J. Hanson, and B. W. Peterson. Dept. of Physical Therapy, Univ. of IL at Chicago and Dept. of Physiology, Northwestern Univ. Med. School, Chicago, IL 60611. *Supported by grants BNS9109705 and NS22490.*

Patterns of muscle activation during voluntary head movements in the cat were consistent within each animal, but varied between animals producing the same head movement (Keshner et al., Exp Br Res, 1992). One source of this variability could be the relative arrangement of the cervical vertebrae during the head movement. In this study we recorded simultaneous video-flouroscopic and neck muscle (biventer (BIV), complexus (CPX), occipitoscapularis (OCC), and splenius (SPL)) EMG data from a cat performing ±15° sinusoidal (0.25 Hz) head tracking movements in the sagittal plane in order to identify the relations between intervertebral actions and muscle activation. Video-opaque markers were inserted into the anterior/posterior and lateral aspects of C_1-C_7 to measure vertebral displacement every 300 ms during 20 sec of sinusoidal head movement. Vertebral movement phase led stimulus position by as much as 45°, and the extent of motion between vertebrae was unequal. C_1 exhibited 1°-1.5° more motion than did C_2, which moved only about 0.5° more than C_3. The differential motion between C_3 and C_7 was about 1°. Unlike the vertebrae, the head moved *in phase* with stimulus position, and exhibited the greatest displacement, moving as much as 5° more than C_1. BIV phase led head extension. CPX and OCC either phase led peak extension of the head, or peaked in phase with peak downward flexion of the head. The latter behavior was accompanied by small shifts in C_2 and C_3 toward a greater phase lead re peak head extension. SPL exhibited 2 response peaks, leading both peak extension and peak flexion of the head. The overall picture suggests a whiplike motion of the head and neck where the movement is initiated in the vertebrae, and the inertial properties of the head are used to produce a position matched response.

CIRCLING BEHAVIOR IN MICE WITH MISSING OR VARIABLY SIZED CORPUS CALLOSUM. L. Ricceri, D.P. Wolfer and H.-P. Lipp*. Institute of Anatomy, Univ. of Zürich, CH-8057 Zürich, Switzerland.

We studied the consequences of a missing or variably developed corpus callosum (CC) on locomotion of mice (n=107) in an open-field arena by means of computerized analysis of paths during two exposures of 10 min per day. An initial comparison between a strain with a normal CC (C57BL6, n=24) and a strain with congenital agenesis of the CC (I/LnJ, n=39) showed significant strain differences in path length on day 1 and 2 ($p < 0.01$, I/LnJ moving more); in 24h habituation ($p < 0.025$, many I/LnJ showing none) but not in within-session habituation. During the first exposure, I/LnJ mice moved more in the center of the arena ($p < 0.01$) and showed a high incidence of circling either to the left or to the right ($p < 0.001$).

In order to test whether the size of the CC was responsible for the observed strain differences, mice with missing or variably developed CC were bred by means of backcrossing C57 x I/LnJ hybrids to I/LnJ fathers (BX mice). The cross-sectional area of the CC of these animals (12 females, 32 males) was measured after the open-field test and correlated with the behavioral scores. This revealed again a significant negative correlation between callosal size and locomotor activity ($p < 0.05$), closeness to the walls ($p < 0.01$) and circling ($p < 0.01$). For the other behavioral measures, variability increased with decreasing size of the CC.

We conclude that a missing or weakly developed CC in mice is not responsible for hyperactivity itself but facilitates the development of uncontrollable circling during bouts of locomotor activity, while the large behavioral variability of acallosal mice might reflect a more general interhemispheric dyscoordination syndrome. Supp. by SNF 31-9470.

CONTROL OF POSTURE AND MOVEMENT IV

591.1

PROCAINE PARCELS NUCLEUS ACCUMBENS AND LOCUS COERULEUS-MEDIATED EXPLORATORY MOVEMENT OF RATS.
R.M. Chesire*, B.E. Morton+, W.E. Winn+, B.E. Digman, & M.K. Peterman, Departments of Psychology and +Biochemistry, University of Hawaii, Honolulu, HAWAII 96822.

Selective damage of N. accumbens (NA) or locus coeruleus (LC) can increase or decrease locomotion and movement. To identify specific arousal functions of these areas, we first examined their roles in exploration. Six male and female Long-Evans hooded rats survived bilateral implantation of chronic, indwelling cannulae in the LC and NA in a single procedure. After recovery, 0.5 or 1.0 ul of 0.733M, pH 7.4, procaine HCl in normal saline was applied focally to NA, LC, or both structures in counterbalanced order (n=4). Pre- and postdrug movement measures included amount and location of locomotion in an open field, air and surface righting, tonic grasp, position tolerance, tactile and tail-pinch-induced orientation, and movement on an inclined plane. Vocalization, piloerection and form of locomotion were also noted. NA procaine increased amount of forward locomotion, thigmotaxis, barrier-bound loss of postural support, grooming, piloerection and vocalization. LC procaine increased amount of locomotion and non-thigmotactic locomotion and movement. NA + LC procaine abolished forward locomotion and postural support, but left some head scanning intact. Thus, behaviors traditionally associated with "fear" (thigmotaxis, grooming, freezing) are preserved in the presence of accumbens inhibition; behaviors associated with increased exploration (less "fear") exist in the presence of coeruleus inhibition; and loss of most movement occurs when both systems are inhibited. The results suggest that (1) LC and NA subserve different exploratory subsystems (2) the LC and NA subsystems are sufficient to account for exploratory movement in the absence of social stimulation and (3) perhaps these subsystems mediate antagonistic exploratory functions.

IMPAIRED "NATURAL" RECIPROCAL INHIBITION IN PATIENTS WITH SPINAL SPASTICITY. G.I. Boorman, W.J. Becker*, and R.G.Lee, Dept of Clinical Neurosciences, U of Calgary, Calgary, AB.

Voluntary activation of the tibialis anterior (TA) muscle causes a decrease in the size of the soleus H-reflex (Natural Reciprocal Inhibition, NRI) in normal humans. This occurs during isometric TA contractions producing either constant (static) force or dynamic force changes. We measured NRI in patients with partial spinal cord injury (SCI), and compared these measurements with those from normal subjects.

Subjects were seated with their foot strapped to a metal plate which measured force during isometric TA contractions. At force levels which were comparable during the ramp and during static contractions, the tibial nerve was stimulated. H-reflex recruitment curves were obtained during both tasks. Forces were compared by absolute torque levels and percentages of maximal voluntary contraction.

In normals, TA contraction produced NRI during both static and dynamic contractions. NRI was demonstrated at all test reflex amplitudes, even in normal subjects with large resting H-max/M-max ratios. In contrast, partial SCI patients demonstrated a reduction or loss of NRI. Impaired NRI was especially evident when dynamic contractions were compared. Interference with mechanisms producing NRI may contribute to the clinically observed motor deficits in these patients.

INFLUENCE OF INTERLIMB DISTANCE ON THE CONTROL OF QUIET STANCE IN THE CAT. J. Fung*, P. Rougier, C.A. Pratt and J.M. Macpherson. R.S. Dow Neurol. Sci. Inst., Portland, OR 97209

This study examined the biomechanics of stance in the cat at various fore-hind interlimb distances. As stance distance narrows, the freely standing cat can either: 1. maintain a horizontal trunk and change the limb inclination or 2. constrain limb inclination and arch the trunk. Cats stood quietly on 4 force plates mounted at fore-hind distances of 33, 30, 25 and 20 cm. The 3D ground reaction forces and kinematics were recorded. Joint moments were computed for the left hind limb.

At 33 cm, the reaction force vector and limb axis (line from toe to hip) were both inclined forwards and inwards. As stance distance decreased, the force vector inclination gradually decreased to become vertical at 20 cm. The limb axis inclination decreased more rapidly, becoming vertical at 30 cm and backwardly directed at 20 cm. Concurrently, the sagittal knee moment decreased while hip and ankle moments increased. However, the sum of absolute 3D moments at the hip, knee, ankle and metatarso-phalangeal joints remained similar. The line joining the shoulder and the hip remained constant in length and horizontally oriented. Thus, in varying stance distance, cats use the first strategy of constraining the trunk and changing limb inclination. These results complement the study of stance on a tilted surface (Lacquaniti et al., J Physiol 1990; 426:177-192), in that the geometry of the trunk and/or limbs may be controlled, depending on the task. A possible outcome may be conservation of the sum of moments across the hind limb joints.

ORGANIZING PRINCIPLES AND SENSORIMOTOR MECHANISMS FOR SKILLED MOTOR BEHAVIOR : EVIDENCE FROM SPEECH MOTOR CONTROL V. L. Gracco*. Haskins Laboratories, 270 Crown St. New Haven, CT 06511.

In attempting to understand human motor behavior and its neural control one approach is to employ novel and constrained tasks to obtain insight into relevant control variables. Such an approach has yielded significant data on the properties of single and multijoint motion with limited application to functional goal-directed behaviors. It is plausible that isolating movement from function provides an incomplete picture of underlying control principles and a limited representation of the underlying neural mechanisms. An alternate approach is to study more complex behaviors attempting to identify organizational principles which provide a framework to interpret characteristics observed at other levels of analysis.

Data from a number of experiments will be presented that provide an empirical foundation for a hierarchical conceptual model of speech production. Components of the model include functional (sound producing) units of action, a global activation and tuning process, a rhythm generating mechanism, provisions for somatosensory modulation of action units, and a cognitive component that drives the motor control system. Inherent in the neuromotor specification for each functional unit is the coordination among the various articulators involved in the production of specific sounds. These units are then sequenced by an underlying oscillatory process providing the serial timing inherent speech rhythmicity. Speed and accuracy are byproducts of overall changes in oscillatory frequency. An assumption underlying the model is that details of most speech motor actions are not explicity controlled. Rather, characteristic control processes exploit the complex geometry and biomechanical diversity of the speech production mechanism. The result is a dynamic modulation of the vocal tract producing complex kinematic patterns from relatively simple control processes. Supported by NIH

SOURCES OF VARIABILITY OF SIMPLE PRE-PLANNED MOVEMENTS. S.R.Gutman*, G.L.Gottlieb. Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612.

Simple pre-planned movements can be defined as realizations of an original central pattern transformed by a parametric transform. The values of parameters are established by the motor control system prior to the movement. As a first approximation of the transform, we take scaling in space and time. Assume that the original pattern is deterministic and does not contribute to movement variability, and the parameters values are random. Then, variance time profiles of trajectory (Var(x(t))), velocity (Var(v(t))), and acceleration (Var(a(t))) can be expressed as weighted sums of two basic functions by formulae:

$$\mathrm{Var}(x(t))=\frac{\mathrm{Var}_A}{A^2}x^2(t)+\frac{\mathrm{Var}_\tau}{\tau^2}t^2v^2(t),\quad \mathrm{Var}(v(t))=\frac{\mathrm{Var}_A}{A^2}v^2(t)+\frac{\mathrm{Var}_\tau}{\tau^2}(v(t)+t\cdot a(t))^2,$$

$$\mathrm{Var}(a(t))=\frac{\mathrm{Var}_A}{A^2}a^2(t)+\frac{\mathrm{Var}_\tau}{\tau^2}(2a(t)+t\cdot jerk(t))^2,$$

where Var_A and Var_τ are variances of established space scale A and time constant τ, $jerk(t) = d^3x/dt^3$. Note that in the expressions, the first and the second terms are, correspondingly, the spatial and the temporal components of the variances.

Particularly, for a reaching movement, the model predicts that variances time profiles should be uni-modal for trajectories, bi-modal for velocities, and tri-modal for acceleration. The model time profiles of correlations between trajectory, velocity, and acceleration were also calculated. They predict that correspondent curves have to be bi-phasic, tri-phasic, and quadri-phasic. The experimentally measured variance and correlation time profiles demonstrate the predicted properties for different experimental conditions. Their consistency allows one to consider them invariants of reaching movement, analogous to the bell-shape velocity time profile. For a more complex movement, time profiles of variability were also measured and explained by the model.

The study was supported in part by NIH grant AR 33189.

Apraxia Results From a Fractionation of Movement Representations. M. Clark,* A. Merians, H. Poizner, L. Rothi, and K.M. Heilman. Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102, VA Medical Center and University of Florida, Gainesville.

Geschwind (1975) proposed a disconnection model in which an apraxic subject is unable to carry out movements to command because the left hemisphere that comprehended the verbal command is disconnected from the right premotor and motor areas which controls the left hand. An alternate model, however, proposes that apraxia results from destruction of spatiotemporal representations of learned movement stored in the left hemisphere (Heilman, 1979). The disconnection hypothesis would predict that apraxic subjects should be able to correctly imitate gestures and correctly use actual objects since these tasks do not require language. The movement representation model predicts that imitation and actual tool use would also be impaired. Motion analyses were performed on selected gestures made in a series of conditions in which contextual cues were introduced in a graded fashion in two left-lesioned apraxic subjects and two matched neurologically intact subjects. Four cue conditions were presented: no cues (verbal command), object present, tool present and both object and tool present. Movements of the hand, wrist, elbow, and shoulder were digitized from neighboring views, reconstructed in three dimensions, and analyzed graphically and numerically. The apraxic subjects showed movement disturbances across the cue conditions. For example, the calibration that normal subjects showed for movement amplitude with movement time and velocity was disrupted. Adding contextural cues did not restablish the normal relationship among these movement parameters. These data support the hypothesis that the left hemisphere is specialized for aspects of higher order motor control, and that apraxia results from the destruction of spatiotemporal representation of learned movement rather than from a disconnection between the receptive language areas of the left hemisphere and the contralateral motor cortices.

EFFECTS OF PRACTICE AND COMPLEXITY ON HUMAN MOTOR LEARNING IN A CONTINUOUS TASK. Hanneke van Mier* (1,2), Wouter Hulstijn (2), Steven E. Petersen (1). (1)= Department of Neuropsychology, Sch. of Med., Washington Univ., St. Louis, MO 63110, (2)= Nijmegen Inst. for Cognition and Information (NICI), Univ. of Nijmegen, The Netherlands.

Large differences are found between the planning of overlearned movement patterns, like letters, and that of novel, unpracticed movement patterns. This difference stimulated a study in which changes in the planning of a movement were studied as a function of extensive practice. The learning process, in which a novel movement pattern transforms into a well-learned movement pattern, was studied in a maze drawing task. Twelve subjects learned to move a pen through cut-out maze patterns with their eyes closed. Maze patterns consisted of six, eight, ten, or twelve segments that were connected by intersections. Total path length of each maze was 24 cm. Although the mazes could be traced continuously in a clockwise direction, selecting a wrong turn at an intersection led to to a dead end. Performance at intersections was analyzed by determining the number of correct (and incorrect) turns following mechanically forced stops and the number of correctly planned and executed turns without any halt. In addition, mean duration and movement velocity was measured. An increase in the number of correct turns as a function of practice indicated that subjects gradually learned to produce segment chunks of increasing size. A practice-complexity interaction with respect to the number of correct turns showed that chunk size did not increase linearly with the number of maze segments. A non-linear increase in performance speed was found across the six practice sessions.

The results show a gradual change in movement strategy from a sequential, trial-and-error mode in which the planning and execution of movements occurred segment by segment, to a concurrent planning mode in which the preparation of subsequent movements occurred - to a greater or lesser extent - simultaneously with the execution of earlier segments. Finally, the results suggest that this learning process proceeded through qualitatively different learning phases.

L-DOPA TREATMENT DESENSITIZES BOTH D1 AND D2 MEDIATED ROTATION RESPONSES IN 6-OHDA-LESIONED RATS. D.R. Britton* and P. Curzon. Neuroscience Research, Pharmaceutical Discovery Division, Abbott Laboratories, Abbott Park, IL 60064.

Rats with unilateral 6-OHDA lesions of the nigrostriatal tract show contralateral rotation in response to l-dopa with no apparent loss of efficacy of the drug over 4 successive days of testing. The response to l-dopa can be blocked with the D1 antagonist, SCH23390 plus the D2 antagonist, haloperidol when they are administered together but not separately. L-dopa treatment causes a pronounced decrease in the subsequent sensitivity of the rotation response to the D1 agonists SKF-38393 and A68930. The present data demonstrated that there is likewise a decreased response to the selective D2 agonists, bromocriptine (0.8 - 3.3 umol/kg, sc) and LY-171555 (0.032 to 1.0 umol/kg, sc). If the maintained sensitivity to l-dopa in the presence of decreased responsiveness to both selective D1 and D2 agonists were due to the ability of l-dopa derived dopamine to simultaneously stimulate the D1 and the D2 receptors together, animals might be expected to be responsive to other approaches to activation of both receptor subtypes. However, rats pre-treated with l-dopa prior to being tested with either the mixed D1/D2 agonist, apomorphine or with a combination of A68930 plus LY171555 showed a significantly diminished response to these drugs as well. These data suggest the possibility that l-dopa may be acting at non-D1, non-D2 receptors in order to maintain its efficacy in the face of diminished responsiveness to selective D1 and D2 agonists.

DIMINISHED CONCENTRATION OF GLYCINE IN THE CEREBRO SPINAL FLUID OF SPASTIC CHILDREN. **J.A. Lazareff * A. Velázquez J.C. López Flores. Depto. Neurosurgery. Hospital Infantil de México, Dr. Márquez 162 C.P. 06720 México, D. F.**

Glycine is recognized as a mediator in postsynaptic inhibition in the spinal cord. Its depletion has been linked to rigidity after ischaemic damage in experimental animals. The concentration of Glycine in CSF of 10 spastic and 10 non spastic age matched children was determined. The spastic children had antecedents of perinatal asphyxia The values of glycine were measured by HPLC, using a Waters 510 equipment with fluorimetric detector. The aminoacids were separated with a 15 cm. long. Nova Pack C 18 column. A gradient with two solvents was used, solvent A was a phospahte buffer (pH 7), solvent B was 40% of the former buffer and 60% of tetrahydrofurane. The fluoresent intensity was measured at an excitation wavelength of 425 nm. The peak of glycine was identified by comparison with the retention time of the authentic compound. Glycine was quantified by the mesasurement of the peak area using an on-line computer integrator Waters 740 The values detected (mean 2.3 umol S.D. 0.83), in the spastic group were significantly lower ($P<0.001$) than those oserved in the non spastic children (mean 6.6 umol S.D. 1.14). It could be suggested that low CSF glycine reflects loss of inhibitory Renshaw cells. This imbalance could be in part responsible for spasticity

FUNCTIONAL INTERPRETATION OF NUCLEUS AMBIGUUS NEURONS BY COMBINED PETH AND STA ANALYSES. C.R. Larson* and Y. Yajima. Dept. of Communication Sciences and Disorders, Northwestern University, Evanston, IL 60208, and Dept. of Physiology, Hyogo College of Medicine, Nishinomiya, Hyogo, 663 Japan.

A variety of neurons are located within the nucleus ambiguus (NA), such as laryngeal, pharyngeal, palatal and esophageal motoneurons, respiratory-related neurons, neurons related to the cardiovascular system and interneurons. These neurons are involved in vocalization, respiration, swallowing, emesis and other behaviors associated with the upper aero-digestive tract. As a way of analyzing the functions of some of these neurons, we here describe the results of combining Perievent Time Histograms (PETH) and Spike Triggered Averaging (STA) analyses for study of NA neurons. Neurons were recorded from awake monkeys (Macaca nemestrina) trained to vocalize for a fruit-juice reward. Neurons which gave a burst of activity with vocalization, and sometimes with swallowing also, had a STA with a short latency (5-7ms) excitation in a single muscle and were laryngeal motoneurons. Some neurons had a longer latency (10-20 ms) excitatory or suppressed STA response, and PETH analysis revealed a variety of discharge patterns including: suppressed activity during vocalization, respiratory rhythm, and bursting activity with vocalization along with activity before or after vocalization. These are most likely interneurons or respiratory-related neurons. The general finding is that the latency and form of an STA response corroborates other functional measures of neuronal activity.

NEURONS OF THE ANTERIOR CINGULATE MOTOR AREA ARE RELATED TO VOCALIZATION AND OTHER OROMOTOR BEHAVIORS. R. West* and C. R. Larson. Dept. Of Communication Sciences and Disorders, Northwestern University, Evanston, IL 60208.

A large number of anatomical, stimulation and lesion studies have indicated the anterior limbic cortex (perigenual area 24) may play a role in vocal behavior. To further explore this possibility we have recorded neural activity from what we believe is the area of the cingulate sulcus during self-paced conditioned vocal behavior in the awake monkey (Macaca Nemistrina). We also recorded activity while the monkey performed a self-paced jaw opening task to determine whether related units were specific to vocalization. The vast majority of related neurons modulated their activity in the same manner during both tasks, but with different latencies to behavior onset. Vocalization related neurons often had long lead times, and these generally became short lead times during the jaw task. Some cells related to both tasks, however, had drastically different firing patterns. Thus far, a small number of cells related specifically to vocalization and one cell related specifically to jaw opening have been observed. We have also observed cells involved in a variety of other oromotor movements, such as tongue protrusion, lip rounding, and reinforcement consumption. These observations support the earlier findings of other investigators concerning the role of the anterior limbic cortex in vocalization and suggest the neurons of this region play a role in behaviors involving laryngeal, pharyngeal and oral motor systems.

DOES SHAPE OR SURFACE AREA INFLUENCE PREHENSION?. P.L. Weir[1] and C.L. MacKenzie[2], Dept. of Kinesiology, [1]University of Windsor, Canada, N9B 3P4, and [2]Simon Fraser University, Canada, V5A 1S6.

MacKenzie & Weir (1991) have shown that when the available contacting surface area is identical between a dowel with a flat gripping surface (force dowel) and one with a curved surface (cylindrical dowel), the actual area contacted is substantially lower on the cylindrical dowel. This difference between dowels is also reflected in a longer deceleration phase for the transport component prior to contact (Weir & MacKenzie, 1991). The purpose of this experiment was to determine if the surface area contacted or the shape of the grasping surface per se was exerting these effects. To do this, it was necessary to equate the force dowel to the cylindrical dowel for the actual area contacted.

Added to the flat gripping plates of the force dowel was a 1 cm strip of light tape, with subjects being instructed to grasp only the tape. In this condition the dowel was referred to as the precision dowel. All three dowels (force, cylindrical, precision) were equated for weight (155 grams). Trials were blocked for the three dowels. Within each block, two tasks (lift versus place) were counterbalanced. Both kinematic and kinetic measures were used, and the movement was divided into four phases: free motion, dowel acquisition, transport and release. If surface area was exerting the effects in Weir & MacKenzie (1991), the precision dowel should take on characteristics similar to the cylindrical dowel.

Kinematic analysis of the arm transport over the free motion phase prior to contact showed that the precision and cylindrical dowels resulted in a longer deceleration phase as compared to the force dowel. The area contacted on the precision and cylindrical dowels was similar, providing further support for the surface area hypothesis. The kinetic measures, load force and grip force, over the acquisition and release phases also revealed differences between the precision and force dowels. These data suggest that surface area does influence all phases of prehension. (Supported by NSERC)

MODULATION OF CUTANEOUS SENSITIVITY BY ISOMETRIC JAW VERSUS LIMB EXERCISE IN HUMANS. P. Kemppainen*[1,2], H. Leppänen[2] and A. Pertovaara[2]. [1]Dept. of Prosthetic Dent. and [2]Dept. of Physiology, Univ. of Helsinki, Helsinki, Finland.

The effect of isometric exercise on electrotactile thresholds of the skin was studied in human subjects. Exercise consisted of brief (1-10 s) contractions of jaw closing muscles, flexions of the hand or foot against varying loads (10-30 % of the maximum force). A light flash indicated the start and the end of the exercise. The hand exercise produced a load-dependent and rapidly attenuating tactile threshold elevation of the fingers in the exercising hand but not contralaterally. The foot exercise at comparable intensity produced a smaller effect. The threshold elevation was significant also immediately prior to EMG response of the arm but not at the time of light flash (= "go" signal) or prior to it. The jaw exercise induced a significant elevation of tactile thresholds in the lower jaw just prior to and during the early EMG responses of the jaw closing muscles. This threshold elevation was attenuated already before the end of the shortest exercise period (1 s). Thus, isometric exercise produces a phasic, rapidly attenuating threshold elevation to electrotactile stimuli in the exercising limb or jaw but not multisegmentally. A plausible explanation for the threshold increase is the suppression of afferent input due to efferent barrage from motor to sensory areas of the brain.

591.14

CORTICOSPINAL REORGANIZATION AFTER SPINAL CORD INJURY (SCI) IN MAN. **D. Hopkins-Rosseel and B. Brouwer* Dept. of Rehab. Therapy, Queen's Univ., Kingston, ON K7L 3N6.**

It has been suggested that the mature human central nervous system (CNS) has the ability to reorganize following traumatic injury (Levy et al. Brain Research 510:130,1990).

This study used focal transcranial magnetic stimulation (Cadwell Laboratories) to investigate the extent of the motor cortical representation and the activation threshold of each of the biceps, deltoid and triceps muscles in subjects with low cervical lesions of greater than three years duration (n=7) and healthy controls (n=12). Three single stimuli were delivered to the scalp at specific points demarcated with a grid (1.5 cm intervals) centered over the vertex, Cz. Amplitudes were measured from the average of the three evoked compound muscle action potentials (CMAPs).

The number of scalp sites from which CMAPs were elicited and the stimulus intensity required for muscle activation (threshold) did not differ between the two groups ($p > 0.05$) for any of the muscles tested. In addition, the mean relative amplitudes of the short latency CMAPs (normalized to the maximum M-wave elicited by supramaximal electrical stimulation of the muscle nerve) were similar between both groups for all muscles ($p > 0.10$).

These findings do not support the ability of the corticospinal tract to reorganize following longstanding SCI.

591.15

DESCENDING PROJECTIONS OF THE MESENCEPHALIC LOCOMOTOR REGION (MLR) BASED UPON TREADMILL INDUCED C-FOS PROTEIN AND ANTEROGRADE TRACT TRACING. K. Shojania, C.A. Livingston, S. Pylypas, L.M. Jordan* and D.M. Nance. Departments of Pathology and Physiology, University of Manitoba, Winnipeg, MB., R3E 0W3, Canada.

The MLR is operationally defined as the area in the mesopontine region in which low levels of stimulation sustain locomotion in a treadmill. However, variability in effective stimulation sites has hindered the detailed analysis of the projections from the MLR. We report here that exercise on a treadmill induces c-fos protein in the mesencephalon of the rat, and we have used this method to examine the projections from the region of c-fos labeled neurons produced by locomotion. The speed of the treadmill was increased from 0-0.25 m/sec and maintained for 60 min. After perfusion, brain sections were incubated with antibodies to c-fos protein and visualized via the PAP technique. The same or alternate sections were then processed histochemically for NADPH diaphorase (NADPHd). Minimal c-fos labeling was observed in the control animals, but exercised rats showed clusters of c-fos labeled neurons focused primarily in the cuneiform nucleus, ventrolateral central gray as well as the locus coeruleus. Few if any cells in the mesencephalon were positive for both c-fos and NADPHd, but double labeled cells were noted in other areas such as the hypothalamus. Dextran conjugated to rhodamine or biotin was pressure or iontophoretically injected into the mesencephalon, and 7d later the rats were exercised in a treadmill and perfused. Sections were processed for c-fos, dextran and NADPHd. Biotin-dextran labeled cells/terminals were visualized with ABC kits. Injections focused in the area of c-fos labeled cells in the cuneiform nucleus produced terminal labeling in the ventromedial reticular nuclei of the brain stem. Injections located ventral/ventrolateral to the cuneiform nucleus (region of NADPHd positive cells) produced terminal labeling in the ventrolateral medulla. Given the importance of the ventromedial medulla in locomotion, the present results support the idea that the cuneiform nucleus is a functional part of the locomotor pathway. Supported by MRC of Canada, Health Sci. Ctr. Res. Fnd. and National Centres of Excellence.

EVIDENCE FOR FLEXOR REFLEX ALTERATIONS IN HEMIPARETIC STROKE SUBJECTS. J. P.A. Dewald*, J.R. McGuire and W.Z. Rymer, Sensory Motor Performance Program, Rehab. Institute of Chicago, and Dept. of Physical Medicine and Rehabilitation, Northwestern University, Chicago, IL 60611.

In earlier studies of voluntary muscle activation in hemiparetic stroke subjects, we observed gross alterations in the spatial patterns of muscle activation at the elbow, and a significant increase in stereotypic coactivations of muscles acting at the same or adjacent joints, i.e. elbow and shoulder. In an effort to determine the relation between sensory input and disturbed muscle synergic relations in hemiparetic stroke, flexion reflexes were compared in the impaired and unimpaired upper extremities of 7 hemiparetic stroke subjects. The effects of mildly noxious electrical stimuli (500 Hz; pulse duration 1 ms; train duration 20 ms) delivered to the index finger were measured by recording EMG in 12 arm muscles together with torques measured at the wrist in a plane orthogonal to the long axis of the forearm. Rectified EMG and torque signals from 30-40 responses were analyzed for an interval of 250 ms after stimulus initiation.

Our results reveal an earlier torque and EMG onset in the unimpaired limb relative to the impaired arm. In the unimpaired limb, muscles were recruited in a proximal to distal fashion, with most shoulder muscles, especially shoulder extensors and retractors being recruited approximately 10 ms before elbow flexors. In the impaired limb, the EMG onset was delayed, resulting in simultaneous activation of proximal and distal arm muscles. In addition, the number of muscles activated by the electrical stimulation increased in the impaired upper limb. In spite of these timing differences, torque direction orthogonal to the long axis of the forearm did not vary significantly between arms. Stimulation of the unimpaired limb induced an early and increased EMG and torque response on the impaired side, resulting in an earlier onset of torque response not seen during ipsilateral stimulation.

The convergence of onset times of arm muscle on the impaired side mimics the obligatory coactivation observed under voluntary conditions. The delayed onset and the simultaneous recruitment of all arm muscles could result from an obligatory long loop activation of motoneuron pools via ventromedial multisynaptic pathways. Surprisingly, stimulating the unimpaired limb appears to restore short latency activation of motoneuron pools at the impaired side. Supported by NS 19331 to WZR.

EVIDENCE FOR CHANGES IN MUSCLE MECHANICAL PROPERTIES AND STRETCH REFLEX CHARACTERISTICS IN SPASTIC HEMIPARETIC STROKE. J.D. Given, J.P.A. Dewald, J.R. McGuire, T.S. Buchanan* and W.Z. Rymer. Sensory Motor Performance Program, Rehab. Institute of Chicago, and Dept. of Physical Medicine and Rehabilitation, Northwestern University Medical School, Chicago, IL.

The primary goals of this study were to quantify joint impedance in spastic limbs of hemiparetic stroke subjects, and to identify the relative contributions from passive and reflex components of spastic muscle. Slow ramp extensions of the elbow, stretching the triceps brachii muscle, were performed on spastic upper limbs (n=6), and compared with a normal control group (n=4). The passive elastic and viscous stiffnesses were estimated using the torque responses recorded in the absence of any significant triceps or biceps brachii EMG activity. A comparison of spastic and normal subjects revealed significant increases in passive elastic stiffness in the impaired limbs in all but one subject. The increases ranged from 30 to 90% of the averaged normal value which indicates that the passive stiffness is potentially a major contributor to the increased resistance observed by the clinician. Intra-subject variability was found to be insignificant within the normal population. However, a significant reduction in passive elastic stiffness (25%) was identified, between repeated protocols for one hemiplegic test subject, presumably because of an intensive course of physical therapy treatment that took place in the intervening period.

In the hemiparetic population, where the stretch reflex is more excitable, the reflex contribution was calculated by subtracting the estimated passive elastic stiffness contribution from the total elbow joint torque. The resulting torque signal exhibited a non-linear transition representing the onset of the stretch reflex followed by a constant stiffness response. The stretch reflex elastic stiffness contribution to the total torque response was approximately 3-4 times greater than that of the passive elastic stiffness contribution in the hemiparetic limb. A direct correlation appears between the identified passive and stretch reflex elastic stiffnesses.

These findings demonstrate the significance of the passive stiffness contribution to the total elbow impedance in many hemiplegic spastic subjects, which until now was mostly attributed to hypersensitive stretch reflexes.

MOVEMENT PREPARATION IN LEUKOTOMIZED AND UNLEUKOTOMIZED SCHIZOPHRENICS. H. Carnahan*[1], R. Chua[2], D. Elliott[2], V.R. Velamoor[3] and C.J. Carnahan[3]. Dept. of Physical Therapy[1], Univ. of Western Ontario, London, Ont., N6G 1H1 and Dept. of Physical Education[2], McMaster Univ., Hamilton, Ont.,and Victoria Hospital[3], London, Ont. Canada.

The purpose of this study was to investigate the ability of bilaterally leukotomized (L) and unleukotomized (UL) schizophrenic (S) patients to use advance information in the process of movement preparation. Seven LS males, (mean age=66 years), eight ULS males (mean age=70 years), and eight healthy elderly men (mean age=74 years) served as subjects. A manual aiming task was performed in which movements could be defined on the basis of hand used to execute the task, and distance travelled to the target. Subjects were provided with full, partial or no prior information about the upcoming movement by precuing hand, distance, both hand and distance, or by providing no precue. While the leukotomized patients were slower than the control subjects, they showed the same pattern of reaction times (RTs) for the various precue conditions. RTs were not facilitated any more by knowing hand than by knowing distance. Instead RT was influenced simply by the number of stimulus response alternatives. However, the ULS patients did not make use of the advance information that was available. These data are discussed in terms of the role of the frontal lobes in schizophrenia and movement planning. (Supported by NSERC & OMH).

KINESTHETIC PERCEPTION OF OBJECT ORIENTATION IN 3D SPACE. F. Lacquaniti* and M. Carrozzo. INB, CNR, Milan (Italy)

It has been recently proposed that the transformation into a common reference frame might represent a necessary step to produce the movement required to attain the perceptual target (Soechting and Flanders, 1989). These A showed that, when subjects point with their hand to remembered target locations in 3D space, they make substantial errors in matching target distance, but not in matching target direction (azimuth and elevation). They hypothesized that these errors are due to the specific algorithm used to map target location into the angular coordinates of the arm joints. Object location is essentially a static task, the trajectory of the arm being apparently inconsequential to the performance. We investigated kinesthetic perception of 3D orientation by asking subjects to match the remembered azimuth and elevation of a test bar they had previously explored with their hand. Subjects made consistent errors in both dimensions, undershooting the target outside a linear range of $\pm$ 30°. In addition, a variable amount of offset in matching angle was present dependent on the position of the subject relative to the origin of rotation of the bar. The slope of the regression between matching angles and target angles was affected by experimental manipulation of head-centred references, as obtained by asking the subjects to rotate their head in the horizontal plane or by vibrating their neck muscles at 100 Hz thereby inducing an illusory shift of subjective straightahead. None of these errors were observed in control experiments in which the target was presented visually to the subjects. The postulated transformation from the world coordinates of the target into the arm coordinates might then undergo an intermediate craniotopic stage.

AN EEG-BASED BRAIN-COMPUTER PARALLEL INTERFACE: THE IMPORTANCE OF FREQUENCY AND SPATIAL RESOLUTION. D.J. McFarland* and J.R. Wolpaw, Wadsworth Labs, New York State Dept of Health and State Univ of New York, Albany, NY 12201.

Individuals can learn to control the amplitude of 8-12 Hz mu rhythm activity in the EEG recorded over sensorimotor cortex and use it to move a cursor to a target on a video screen. Good one-dimensional control (Electroenceph clin Neurophysiol 78:252-259, 1991) and significant two-dimensional (2-D) control have been achieved. We are investigating the hypothesis that 2-D control can be greatly improved by increasing frequency and spatial resolution.

EEG is recorded from scalp at multiple sites in central head regions. Mu rhythm amplitudes in two bipolar channels, one over central sulcus on each side, are evaluated online by fast Fourier transform 5/sec and used to control 2-D cursor movement. EEG from all sites is stored on disk for offline analysis aimed at testing whether greater frequency and/or spatial resolution would have improved movement accuracy and speed.

Initial results are consistent with evidence that mu rhythm activity comprises several separable components, and suggest that individuals achieve 2-D movement by controlling two components independently. This finding supports the hypothesis that increased frequency and topographic resolution can substantially improve cursor control. Thus, online implementation of such resolution may provide an EEG-based brain-computer parallel interface of value to severely disabled individuals.

INVERTEBRATE MOTOR FUNCTION

592.1

CHOLINERGIC EFFECTS ON THE CRAYFISH SWIMMERET CPG. Götz Braun* and B. Mulloney. Department of Zoology, University of California, Davis, CA 95616.

There are two reasons for examining the effects of cholinergic agonists on the crayfish swimmeret CPG: 1) many primary sensory afferents are cholinergic and play a role in modulating the centrally generated motor pattern, 2) cholinergic (muscarinic) agents elicit rhythmic activity in other crustaceean neural systems (walking in crayfish, stomatogastric ganglion in the lobster).

The present study examines the effects of nicotine (nicotinic agonist), pilocarpine (muscarinic agonist), and carbachol (muscarinic and nicotinic agonist). Can they elicit the rhythm in an inactive preparation, and how do they modulate the frequency and pattern of activity produced by proctolin? Motor neuron discharge was monitored extracellularly with pin electrodes on N_1-nerves , drugs were applied to the bath solution.

Pilocarpine reliably elicited rhythmic activity in inactive preparations with a treshold between 1 and 10 μM. Burst frequency increased with concentration up to 100 μM. When pilocarpine was applied to a preparation already activated by proctolin the burst frequency was slightly reduced.

Nicotine normally failed to elicit the rhythm in an inactive preparation, but when applied to a preparation activated by proctolin, nicotine increased the burst frequency considerably.

Carbachol reliably elicited the rhythm in inactive preparations and also modulated the burst frequency in proctolin activated preparations.

The results suggest that cholinergic transmission is used in two ways: as a component of the central circuitry via muscarinic receptors, and as a mediator for the input from primary sensory afferents via nicotinic receptors.

592.2

NEURONS WITH AXONS IN THE MINISCULE TRACT INFLUENCE THE SWIMMERET RHYTHM IN CRAYFISH *PACIFASTACUS LENIUSCULUS* David Murchison* and Brian Mulloney, Dept. of Zoology, University of California, Davis 95616

In crayfish, the swimmeret abdominal appendages display rhythmic movements coordinated between segments. This coordination is the metachronal rhythm and is characterized by a phase lag in the movement cycle of swimmerets in anterior segments relative to posterior segments. This rhythm can be observed in extracellular records of motoneuron bursts from swimmeret nerves in isolated abdominal nerve cords. The metachronal rhythm is mediated by intersegmental coordinating interneurons that are not well described.

Reducing the isolated abdominal nerve cord to chains of two or three ganglia does not disturb metachronal coordination (Paul and Mulloney, 1986), but if the ganglia are hemisected along the midline, the metachronal coordination on both sides is disrupted. This indicates that some bilaterally projecting neurons are involved in the maintenance of the metachronal rhythm.

Some interneurons which have been implicated in the coordination of swimmerets send bilateral processes through the miniscule tract (MT). This tract passes dorsal to the lateral giant neurons in the abdominal ganglia, just beneath the ganglionic sheath (Skinner, 1985). MT can be selectively sectioned by careful surgery. Bilateral section of the MT in one or more ganglia disrupts metachronal coordination. Bilateral coordination still occurs, but motoneuron burst structures, durations and periods are altered. This indicates that neurons of the MT are involved in intersegmental coordination and also participate in structuring motoneuron bursts. Some of the inputs that shape swimmeret motoneuron bursting are intersegmental.

592.3

MOTOR NEURONS OF THE SWIMMERET SYSTEM: MEMBRANE PROPERTIES OF ANTAGONISTS. C.M. Sherff* and B. Mulloney. Department of Zoology, University of California, Davis, CA 95616.

The muscles that move a single crayfish swimmeret are innervated by about 69 motor neurons. When an isolated nerve cord is generating the swimmeret motor pattern, only a few of these motor neurons fire action potentials; the membrane potentials of the rest oscillate but do not produce spikes. These motor neurons may represent pools of similar neurons, which are recruited in order of increasing size by stronger inputs from the central pattern generator to increase the strength of contraction of the swimmeret muscles. Alternatively, these motor neurons may possess different properties and have different functions in the swimmeret motor output.

We have recorded intracellularly from the neuropil or cell bodies of swimmeret motor neurons and recorded their resting membrane potentials, input resistances, and membrane time constants, their active responses to depolarizing current injection, and their effects on the output of the motor program. We have also looked for feedback from these motor neurons onto the central pattern-generating network.

Most of the motor neurons appear to have similar membrane properties and activities in the swimmeret rhythm. No systematic differences were found between power-stroke and return-stroke neurons, excitatory and inhibitory neurons, or spiking and silent motor neurons with regard to passive membrane properties. Most of these neurons also displayed sustained, tonic firing that did not reset the rhythm when they were depolarized by current injection.

A small number of motor neurons display a different electrical profile. These fired phasically with current injection; the membrane fires several action potentials with the onset of depolarization, and then settles to a steady-state depolarization that persists for the duration of the current injection.

592.4

MODELING ESCAPE RESPONSES: ENCOMPASSING IRREGULAR DISCHARGE SEQUENCES. J.L. Johnson*, USD School of Medicine, Department of Physiology/Pharmacology, Vermillion, South Dakota 57069

Recently, a mathematical model was developed describing the function of the neuronal pathway and longitudinal muscle for earthworm head end escape (Johnson, J.L. Internat. J. Neural Systems, 1 & 2 (1991) 79-90). This model equation could not encompass irregular discharge rates in the brief burst of command neuron action potentials needed to induce the rapid head end escape response. In this study, the additional formulations developed permitted an analysis of the impact of irregular discharge sequences upon end organ function. This new model predicts that in any given action potential sequence delivered to the muscle, where the interpulse interval (IPI) between successive impulse pairs is different, the order-effect these different IPIs will produce less than a 20% variation in the net contractile tension. This interesting property of earthworm head end escape is most important, since head end escape is essentially a "one-shot deal." The required repetitive discharge needed must initiate a rapid and powerful response on the first try because of a subsequent profound degree of habituation to further activation.

592.5

DISTRIBUTED INHIBITORY PATHWAYS IN CIRCUITS CONTROLLING HEAD MOVEMENTS IN CALLIPHORID FLIES

N. J. Strausfeld*, C. Gilbert[1], W. Gronenberg[2], J. J. Milde[3], and Alberta Kong. ARLDN, Univ. of Arizona, Tucson, AZ; [1]Dept. Entomol. Cornell Univ. Ithaca, NY; [2]Zoology Inst., Univ. Würzburg, FRG; [3]Zoology Inst., Univ. Köln, FRG

Recordings from frontal nerve motorneurons (FNMs), supplying neck rotator muscles, demonstrate their directionally selective activation by ipsilateral wide-field motion and selective inhibition by stimuli contralaterally. Recordings from premotor descending neurons (DNs) supplying neck motor neuropil also reveal selective inhibition by wide-field stimuli. In the brain, these DNs give rise to specific dendritic branches that extend into an area of neuropil in the lateral deutocerebrum receiving terminals of certain motion-sensitive wide-field neurons originating contralaterally in the lobula plate. The functional significance of such tangential neurons is suggested by immunocytology using an antibody raised against the inhibitory transmitter γ-aminobutyric acid (GABA). 20-25 immunopositive axons extend from the lobula plate, of which at least 8 match Lucifer yellow filled neurons terminating in this deutocerebral area. The relevance of GABAergic pathways to inhibition of frontal nerve motor neurons has been studied using microlesions made while recording from FNMs. Lesions across GABAergic pathways from the lobula plate first abolish the inhibitory component of the FNM response which then returns after minutes. Lesions across ipsilateral DNs abolish the excitatory FNM response which also then recovers. These results suggest distributed routes of pathways controlling head movements. Neurobiotin and cobalt fills into heterolateral ascending and descending neurons, further supports this hypothesis. **Supported by NIH Grant No. R01 EYO-7151**

592.6

CHARACTERIZATION OF MOTOR PROGRAMS AND NEURONS IN THE FRONTAL GANGLION IN THE MOTH *MANDUCA SEXTA*. C.I. Miles* and R. Booker. Section of Neurobiology and Behavior, Cornell Univ., Ithaca, NY 14853.

The frontal ganglion (FG) of *Manduca* is involved in feeding and ingestion. Because feeding behavior changes dramatically from the larval stage to adulthood, the role of the FG may be altered during development. As a first step in a study of metamorphosis of this simple ganglion, we describe the larval FG motor program and the identities of some of the neurons which produce it. The FG lies on top of the esophagus anterior to the brain. It is small, measuring about 150 µm in diameter, and contains approximately 30 cell bodies. Two nerves exit the FG; the recurrent nerve, which projects posteriorly along the esophagus, and the frontal nerve, which extends anteriorly from the ganglion. The larval esophagus exhibits rhythmic constrictions and dilations which differ in their timing along its length. The esophageal constrictions anterior to the brain are out of phase with those posterior to the brain. Cutting the frontal nerve eliminates movements of the anterior esophagus, while cutting the recurrent nerve stops the posterior movements. Consistent with this finding, we have recorded rhythmic bursting motor patterns from the frontal and recurrent nerves that are out of phase with each other. This motor program can be recorded in isolated brain-FG preparations. If the FG is isolated from the brain, bursting initially stops, but the motor pattern will resume after several minutes. We have identified motoneurons, interneurons, and neurosecretory cells within the larval FG by cobalt backfills and intracellular recording and staining. The activities and roles of a number of FG neurons in generating the larval motor program will be described.

592.7

ANATOMICAL AND PHYSIOLOGICAL ANALYSIS OF A RAPID STEERING MUSCLE OF THE BLOWFLY. M.S. Tu, and M.H. Dickinson*. Department of Organismal Biology and Anatomy, University of Chicago, 1025 E. 57th ST., Chicago, IL 60637

In addition to the large, stretch-activated power muscles, flies possess a set of 17 direct synchronous muscles that are responsible for elaborate turning maneuvers during flight. Of the steering muscles that have been recorded, The First Basilar (B1) stands out due to its ability to fire each and every wing beat, even at frequencies exceeding 200 Hz, making it among the fastest known synchronous muscles. Its unique physiology makes the B1 a prime candidate for controlling the timing of wing pronation during flight. We have been studying the anatomy and physiology of this muscle in *Calliphora* in order to identify specializations associated with its high rate of activation, and to determine its role in flight control.

The central and peripheral morphology of the B1 motor neuron has been determined using low molecular weight dextran tracers. Both the cell body and the most extensive aborizations are ipsilateral, although one branch of the dendrite crosses the mid-line dorsally. The peripheral morphology of the B1 motor neuron is much more striking: the 250 µm axon branches into a large arborous network that interdigitates throughout the muscle. The axon size and terminal geometry are probably specializations for prolonged high-frequency activation.

Repetitive stimulation of the B1 motor axon at wing beat frequency results in tetanus, although discrete isometric force transients can be resolved at frequencies as high as 100 Hz. However, during flight, the B1 muscle is subjected to cyclic length changes at wing beat frequency. Therefore, we are currently investigating the effects of stimulus phase on the mechanical output during imposed sinusiodal length changes that mimic those which occur naturally during flight.

592.8

A NECESSARY ROLE FOR PROCTOLIN IN MAINTAINING TENSION PRODUCTION BY AN INSECT MUSCLE. JH Belanger*[1] and I Orchard[2]. [1]Arizona Res Lab Div of Neurobiology, U of Arizona, Tucson, AZ 85721, USA and [1,2]Dept of Zoology, U of Toronto, Toronto, ON, M5S 1A1, Canada.

We have been using the neuromuscular substrate underlying oviposition digging in the locust (*Locusta migratoria*) as a model system to try to understand the role(s) played by cotransmitters in the control of insect muscle. The ventral opener muscle is the largest of the ovipositor muscles and produces most of the force used to dig the oviposition hole. We have previously reported the presence and some actions of proctolin in this neuromuscular system (Belanger and Orchard 1988, *Soc. Neurosci. Abs. 14*:934). Here, we report that proctolin is released both by electrical stimulation of nerves and during normal activity of the oviposition digging system, and that this release appears to be necessary for the production of normal amounts of tension by the muscle.

Stimulation of some, but not all, units in the nerve supplying the opener muscle produces a frequency-dependent release of proctolin. Five min of 30 Hz stimulation releases approximately 8% of the total proctolin store of the muscle. During oviposition digging, the opener muscle is driven by a central pattern generator which is located in the terminal abdominal ganglion. In *in vitro* ganglion-muscle preparations which are expressing the digging rhythm, release of about 25% of the muscle proctolin store occurs during the first five minutes of activity. This level declines to below detectability over a period of approximately 20 min. There is a concomitant decline in muscle tension production, even though patterned neural activity is still present and EMGs can still be recorded, implying that conventional synaptic function is still present. Adding exogenous proctolin (10^{-9} M) to the superfusate restores the contractions to their original magnitude.

LOCAL CALCIUM SPIKES IN THE DENDRITES OF NONSPIKING LOCAL INTERNEURONS IN THE LOCUST. Gilles Laurent*. Biology Div., 139-74, California Institute of Technology, Pasadena CA 91125.

Nonspiking local interneurons directly synapse onto pools of leg motor neurons and are thus well suited to organize leg movement and posture. During a centrally generated rhythm and in the absence of any sensory feedback, their membrane potential undergoes large polarizations (30mV peak-to-peak) centered on a resting potential of ca. -58mV. Depolarization from -60mV leads to outward rectification, which in turn leads to significant changes in membrane time and space constants. Depolarization to -40mV, however, also evokes, in 20% of dendritic impalements, active responses which can take 2 main forms. The first are fast potential oscillations (10-15mV p-t-p) which only occur within a small window of membrane voltages. The second are 30ms-long TTX-resistant action potentials. Whole-cell patch-clamp experiments on cultured nonspiking interneurons indicate the existence of a low-threshold transient Ca^{++} current analogous to T-type currents described in other neurons. These action potentials can be evoked on rebound from IPSP evoked by presynaptic spiking local interneurons. Interestingly, however, such an active response can often be evoked by one only of several IPSPs which the nonspiking interneuron receives from different presynaptic interneurons. This suggests that the channels underlying those action potentials may only be expressed or functional in some, but not all, dendrites of a nonspiking interneuron. SEGMENT-SPECIFIC FATE OF HOMOLOGOUS MOTONEURONS IN *MANDUCA SEXTA* IS UNCORRELATED WITH DEVELOPMENTAL CHANGES IN MOTONEURON ANATOMY AND PHYSIOLOGY. L. C. Streichert,* D. J. Sandstrom, and J. C. Weeks. Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Metamorphosis of the tobacco hornworm, *Manduca sexta*, is accompanied by the dismantling of neural circuits involved in stage-specific behaviors. The loss of the proleg withdrawal reflex at the larval-pupal transformation is associated with dendritic regression of proleg retractor motoneurons, a weakening of afferent input to these motoneurons, and the programmed death of a stereotyped subset of the motoneurons. For instance, the APR motoneurons, which innervate a proleg retractor muscle, undergo programmed cell death on the second day of pupal life (day P2) in abdominal segments A5 and A6, whereas the APRs in A3 and A4 survive and are respecified in the adult. We examined the possibility that these differences in cell fate are correlated with anatomical and physiological changes by comparing the properties of APR motoneurons in segments A3 and A6 during the larval-pupal transformation.

On the third day of the final larval instar (day L3), the structure of APR's dendritic arbor was similar in A3 and A6. Prior to pupation, the dendritic arbors of APRs from both segments regressed similarly such that they were significantly reduced by day P0. There were also no segment-specific changes in the passive electrical properties of the APRs. Electrical stimulation of the nerve containing sensory afferents that synapse upon the APRs evoked compound EPSPs that were of similar mean size in A3 and A6 on day L3. A developmental reduction in the magnitude of the evoked EPSPs was quantitatively similar in APRs from both segments on day P0. Therefore, none of the features that we examined were correlated with the subsequent segment-specific death or survival of homologous motoneurons. Supported by NIH grants HD07244 and NS23208.

CELLULAR BASIS FOR THE REORGANIZATION OF A PROPRIOCEPTIVE CIRCUIT DURING INSECT METAMORPHOSIS. D.A.Tamarkin* & R.B.Levine. ARL, Div of Neurobiology, Univ of Arizona, Tucson, AZ 85721

During insect metamorphosis, neuronal circuits undergo dramatic reorganization that contributes to the expression of new behavior. We are investigating this reorganization by examining an abdominal proprioceptive circuit during metamorphosis in the hawkmoth, *Manduca sexta*. The effect of activity of a stretch receptor organ (SRO) on intersegmental muscle motoneurons (MNs) was characterized in both the larval and adult stages. The SROs are bilaterally-paired muscle receptor organs that run longitudinally across each abdominal segment. Populations of synergistic and antagonistic MNs are described based on whether contraction of their target muscles would lead to a shortening or lengthening, respectively, of the SRO. In the larva, the synergistic MNs are excited and the antagonistic MNs are inhibited by SRO activation. This pattern of SRO synaptic input changes across metamorphosis, resulting in excitation of both the synergists and antagonists.

Toward understanding this change in the proprioceptive circuit at the cellular level, we have used signal averaging and synaptic latency measurements to examine whether the SRO synaptic input onto individual MNs has a monosynaptic component. Our results suggest that the synergistic MNs that receive the strongest input from the SRO appear to be excited directly in both life stages. Excitatory inputs to other synergistic MNs have a longer latency, but are reliable. The inhibitory SRO synaptic input to the antagonistic MNs in the larva and the new excitatory input to these MNs in the adult is through a purely polysynaptic pathway. The changes in this proprioceptive circuit thus occur through polysynaptic pathways, and implicate the involvement of interneurons in altering synaptic connectivity.

MONITORING GENE EXPRESSION IN SINGLE NEURONS FROM THE LOBSTER CNS. *E.A.Kravitz, H.Schneider*, B.Brooks+ & J.H.Eberwine+, Neurobiology Dept., Harvard Medical School, Boston, MA 02115 and Pharmacology Dept., University of Pennsylvania School of Medicine, +Philadelphia, PA 19104.*

The physiological properties, transmitter phenotypes and structures of individual neurons are unique, ultimately depending on their differential gene expression. Recently, a method has been developed that allows monitoring of gene expression in single identified neurons following intracellular recording (1).

The pool of mRNA from a single neuron is amplified up to a million fold via cDNA-synthesis within the cytoplasm of the neuron, and the use of the T7-RNA polymerase reaction on the extracted cDNAs. Amplified messages are analysed using expression profiles that enable monitoring of several genes at the same time. In preliminary experiments we have tested the method in the CNS of *Homarus americanus* on large GABA-containing inhibitory motoneurons in the 2nd abdominal ganglion, serotonin-proctolin-containing neurons in the 1st abdominal ganglion and octopamine-containing crotch cells in thoracic ganglia. In all cases successful amplifications have been performed. In expression profiles amplified RNA hybridizes with vertebrate-probes corresponding to neurofilament proteins, c-fos, c-jun, GABA-receptors, glycine-receptors, K^+- Na^+-, Ca^{++}-channels, protein kinase C, and tryptophan hydroxylase. In the long run we plan to study gene expression in single cells in differing developmental and behavioral states. (1) Van Gelder et al. 1990, PNAS 87: 1603-1667. Supported by NIH and DFG Schn 368/1-1.

MITOCHONDRIAL CONTENT AND TRANSPORT IN PHASIC AND TONIC MOTOR AXONS OF THE CRAYFISH. C.J.Case, and G.A. Lnenicka*. Dept. of Biol. Sci., State Univ. of New York, Albany, N.Y. 12222

Crayfish tonic motor terminals have a greater mitochondrial content than phasic motor terminals (Lnenicka *et.al., J. Neurosci*, 6:2252, 1986). In this study, we examined whether there are similar differences in the mitochondrial content of the phasic and tonic motor axons. After glutaraldehyde fixation, the phasic and tonic motor axons innervating the claw closer muscle were dissected free. Mitochondria were visualized with DIC microscopy, drawn with a *camera lucida* attachment, and their lengths were measured on a digitizing pad. Individual mitochondrial cross-sectional area was determined using TEM. Results indicate that there are differences in mitochondrial volume in the motor axons which are similar to those previously reported for the terminals. The mitochondrial volume per unit volume of axoplasm is 5-fold greater in tonic motor axons than in phasic motor axons. This difference results from more mitochondria per unit volume of axoplasm and a greater cross-sectional area of individual mitochondria in the tonic axon.

Axoplasmic transport of mitochondria was examined in the phasic and tonic axons using video enhanced-contrast DIC microscopy. Consistent with the results from fixed axons, we found that the density of mitochondrial transport in tonic axons was twice that found in the phasic axons.

In order to determine if the differences in mitochondria content and transport are activity-dependent, we have begun to examine tonically stimulated phasic axons. Preliminary results from mitochondrial measurements in fixed axons indicate that tonic stimulation of a phasic axon results in an increase in mitochondrial content. (Supported by NSF grant BNS-9121757.)

ARE THERE FEEDBACK SUBGROUPS WITHIN CRAYFISH MOTOR POOL? Peter Skorupski and Brian Bush (SPON: Brain Research Association). Department of Physiology, University of Bristol, Bristol BS1 5LS, Bristol, UK.

In the crayfish thoracic ganglia subsets of the leg promotor and remotor pools are excited in positive feedback reflexes resulting from leg movement. Group 1 promotor motoneurons are excited by the thoracocoxal chordotonal organ, which signals leg promotion, and group 1 remotor motoneurons are excited by the thoracocoxal muscle receptor organ, which signals leg remotion (Skorupski et al (1992), J. Neurophysiol. 67, 648-663). Other members of these motor pools lack these inputs and are excited by the opposite directions of movement, which correspond to negative feedback.

The amine octopamine, which is thought to be an inhibitory transmitter or neuromodulator in the crayfish swimmeret system (Mulloney et al (1987), J. Neurophysiol. 58, 584-597) also has inhibitory effects in thoracic ganglia. These effects are selective, however, and correlated with subdivisions of the motor pool on the basis of reflex input. At low concentrations ($1\text{-}10\times10^{-6}$M) octopamine disrupts or slows down any rhythmic activity and selectively depresses positive feedback reflexes. In the case of promotor group 1s, excitatory TCCO input may reverse to become inhibitory. At high concentrations ($50\text{-}100\times10^{-6}$M) octopamine hyperpolarizes some group 1 remotors by 15 mV or more, coupled with a reduction in input resistance of 60-70%. Group 2 remotors, at the same concentration, are depolarized by 1-5 mV, with little or no change in input resistance.

GROWTH AND THE PASSIVE INTEGRATIVE PROPERTIES OF NEURONS. D.H. Edwards*. Dept. of Biology, Georgia State University, Atlanta, GA 30302-4010

Study of the response properties of the lateral giant interneuron in large and small crayfish suggests that its PSPs are increasingly low-pass filtered as the cell grows. To test the effects of size increases on a neuron's passive integrative properties, the responses to current steps and conductance-increase synaptic inputs were calculated for small and large (10X) equivalent cylinder models of neurons. Response rise-times and the attenuation of steady-state responses were significantly greater in the larger model, whereas the input resistance was 50-fold smaller. Increases in the injected current and the maximum postsynaptic conductance restored the peak responses of the large model to the values of the small model, but did not affect the response attenuation or rise-times. Several-fold increases in the specific membrane resistance increased the large model's input resistance and reduced the steady-state attenuation, but also greatly slowed its responses. The response properties of the large model were restored to those of the small model when increases in specific membrane resistance were matched by similar decreases in the specific membrane capacitance.

LOCOMOTION IN THE MEDICINAL LEECH, *Hirudo medicinalis*: ANALYSIS OF A COMPLEX RHYTHMIC BEHAVIOR. A. Baader* and W.B. Kristan Jr., Department of Biology, UCSD, La Jolla, CA 92093-0322.

Locomotor performances are often generated by rhythmic activities of the central nervous system. Leech swimming is a robust rhythmic pattern with a period length of a cycle in the range of 0.5 to 1 sec, whereas crawling is much more variable: a single step can last between 3 and 15 seconds, elongations and contractions of the body may involve some or all segments, and the temporal organization of a complete step is sustained by the additional activity of head and tail suckers. We are determining the neuronal mechanisms by which the leech nervous system generates such a complex behavior.

Tethered animals are suspended in an apparatus in which they perform various behaviors (e.g., swimming, crawling, or shortening), while extracellular and intracellular recordings are obtained. Behaviors and electrophysiological data are video-monitored simultaneously to evaluate the contribution to individual neurons on behavior. Systematic intracellular recordings in midbody ganglia showed that few interneurones are modulated during crawling and their selective activation did not affect the behavior. Recordings from the tail brain revealed many different units to be activated in all phases of crawling. Cutting nerves to various parts of the body showed that sensory input from either one of the suckers is necessary to produce normal crawling behavior. Supported by the NIH (WBK, AB) and the Deutsche Forschungsgemeinschaft (AB).

RECOVERY OF CONSUMMATORY FEEDING BEHAVIOR AFTER BILATERAL CNS LESIONS IN *APLYSIA*. M.L. Scott* and M.D. Kirk Div. Biol. Sci., Univ. Missouri-Columbia, Columbia, MO 65211.

Consummatory feeding behavior in *Aplysia californica* is generated in the buccal ganglia under the control of neural elements in the cerebral ganglion. Consummatory feeding is selectively abolished by cutting the cerebral-buccal connectives (CBCs) bilaterally and does not recover during the subsequent three weeks. We have used the feeding system in *Aplysia* as a model for studies of functional neural regeneration following bilateral CBC crushes. Normal feeding parameters (Rosen et al., '89, J. Neurosci., 9:1562) were tested preoperatively. CBCs of anesthetized subjects (130-300 g) were crushed bilaterally with #5 forceps through a dorsal incision. Subject behavior was tested postoperatively on day 2, then every 4th day through day 30. Subjects were fed a total of one strip of seaweed (dried laver, 1 x 15 cm strip) every 2 days. Appetitive behaviors were not affected by the lesions. Rhythmic biting was initially abolished, and reappeared in all lesioned animals by day 14. Although bite magnitude and bite frequency were initially less than preoperative levels or sham controls, both increased toward control values with additional recovery time. Differences in neuromuscular activity and connections are being explored at various timepoints during recovery using *in vivo* and *in vitro* recordings.

To initially assess the progress of neural regeneration, cobalt backfills into the cerebral and buccal ganglia from the CBCs were performed on days 3, 9, 13, 21, and 30 postlesion. Staining of cell bodies was consistently seen beginning on day 9, and the return of cobalt staining parallels the timecourse of behavioral recovery. Therefore, the feeding system of *Aplysia* will be an ideal model system to study functional neural regeneration *in vivo*. Supported by NIH.

592.18

ORGANIZATION AND FUNCTION OF A MULTIFUNCTIONAL NEUROMUSCULAR SYSTEM DURING FEEDING IN HELISOMA TRIVOLVIS. B.C. Arnett* and A.D. Murphy Department of Biological Sciences, University of Illinois at Chicago, Chicago, Illinois 60680

A feeding cycle in Helisoma is characterized by dynamic stages of protraction, retraction, and hyper-retraction of the buccal mass, radula, and odontophore cartilage. Feeding behavior is generated by a buccal pattern generator comprised of three neuronal subunits (S1, S2 and S3). Each subunit is an independent oscillator but can be linked temporally to either one or two of the other subunits to produce diverse motor patterns. The large intrinsic supralateral radular tensor (SLRT) muscle of the pharyngeal buccal mass plays a role in retraction, tensing, and hyper-retraction of the radula. The SLRT is innervated by at least 8 motoneurons. Two motoneurons driven by S3, and two motoneurons driven by S2 have been identified. Each motoneuron innervates a distinct region of the SLRT. Muscle contractions in different regions of the SLRT and at different times during the feeding cycle confer multifunctionality and allow flexibility during feeding behaviors. The SLRT neuromuscular system is therefore an excellent model to study the contributions of polyneuronal innervation to complex behaviors.

TWO B (OR NOT TO BE) A *THIRTYSOMETHING* CELL IN *APLYSIA*. I. Hurwitz, R. Goldstein*, L. Cleary & A.J. Susswein. Dept Life Sci, Bar Ilan Univ, Ramat Gan, Israel 52 900, and Dept Neurobiol & Anatomy, U Texas Med School, Houston, TX 77025.

The B31/B32 cells in the buccal ganglia of *Aplysia californica* were previously shown to have many unusual electrophysiological features. The somata of these strongly coupled cells do not sustain conventional action potentials. Depolarization of the soma produces a sustained, long-lasting regenerative response, followed by a hyperpolarization. The hyperpolarization is correlated with a patterned burst expressed in most of the neurons of the buccal ganglia. In an attempt to understand the function of these unusual features, we have examined the morphology of the B31/B32 cells. The cells have a rich neuropil with varicosities close to the soma, and a proximal axon that is ~20% of the soma diameter. They also have peripheral varicosity-bearing axons which innervate the I2 muscle of the buccal mass, a major protractor muscle, via fine branches of the radular nerves. However, the cells can be distinguished morphologically. 1) The cells innervate different regions of the muscle. 2) The rich neuropil of one cell arises directly from the soma, while that of the other arises from the proximal segment of the axon. 3) Only one cell has significant neuropil in more distal axonal regions. One such region is at the origin of the buccal commisure, close to neurons B20 and B4. These data suggest that the soma and axon of the B31/B32 may be functionally compartmentalized. Information processing near the soma is accomplished by slow, regenerative potentials, while information processing in the axon and I2 muscle is via conventional action potentials. The neuropil close to the soma should be unaffected by fast, conventional action potentials that occur in the axon, while more distal neuropil should be unaffected by slow potentials in the soma. We are performing electrophysiological experiments to test this possibility.

592.20

AFTERDISCHARGE ACTIVITY OF MOTONEURONS INVOLVED IN FEEDING BEHAVIOR IN PTEROPOD MOLLUSC. T.P.Norekian* and R.A. Satterlie. Dept.of Zoology, Arizona State Univ., Tempe, AZ 85287 and Friday Harbor Laboratories, Friday Harbor, WA 98250.

The pteropod mollusc *Clione limacina* is a highly specialized carnivore which feeds on shelled pteropods and uses, for their capture, three pairs of oral appendages, called buccal cones. Contact with the prey induces rapid eversion of buccal cones, which then become tentacle-like and grasp the shell of the prey. A large group of electrically coupled, normally silent cells (A motoneurons) has been described in the cerebral ganglia of *Clione*, whose activation induces opening of oral skin folds and extrusion of buccal cones.

Brief intracellular stimulation of an A neuron can produce prolonged firing (afterdischarge), lasting up to 40 seconds, in the entire population of A neurons. Afterdischarge activity is based on a slow depolarization evoked by an initial strong burst of A neuron spikes. Obtained data suggest that the afterdepolarization underlying afterdischarge activity is a slow excitatory synaptic input from an unidentified neuron or neurons which in turn recieve excitatory inputs from A neurons, thus organizing positive feedback. The main functional role of this positive feedback is the spread and synchronization of spike activity among all A neurons in the population. In addition, it transfers brief excitatory inputs to A neurons into a prolonged and stable firing pattern, which is required during certain phases of feeding behavior.

592.21
PERIPHERAL MODULATION OF SWIM MUSCULATURE IN THE PTEROPOD MOLLUSC CLIONE LIMACINA. R.A. Satterlie* Dept. of Zoology, Arizona State Univ., Tempe, AZ 85287-1501.

Neuromuscular organization in Clione includes two distinct types of muscle fibers, fast-twitch fatigable and slow-twitch fatigue-resistant, and two types classes of pedal motoneurons separable based on soma diameters and innervation fields. In addition, four serotonin-immunoreactive pedal neurons send axons to the swim musculature. Serotonin-immunoreactive terminals are found associated with slow-twitch fibers only. Activity in the serotonin-immunoreactive neurons does not produce a motor response in the absence of ongoing swimming activity, but does enhance motoneuron-induced electrical activity in slow-twitch muscle cells. This modulatory action is restricted to the periphery, and is reversibly blocked by 10^{-5}M mianserin suggesting that serotonin is the modulatory transmitter. Since bath-applied serotonin produces both central and peripheral modulation of swimming, independent central and peripheral modulatory pathways are suggested.

EFFECTS OF NEUROTRANSMITTERS ON THE ELECTRICAL COUPLING OF ASCARIS SOMATIC MUSCLE CELLS. S. Solórzano, J. Serrato and A. Rivera*. Dept. of Physiology, Centro de Investigación del IPN, México 07000 DF, MEXICO.

Somatic muscle cells from the nematode Ascaris are electrically coupled and receive modulatory neural input from excitatory and inhibitory motorneurons. We have suggested that one factor involved in contractile wave propagation is the pattern of electrical coupling observed between somatic muscle cells. Since several neurotransmitters have been implicated in gap junction channel modulation, it seemed of interest to test whether ACh or GABA had any effect on the gap junction channels of Ascaris muscle cells. Substances were bath applied while recording input resistances and coupling coefficients in pairs of well coupled somatic muscle cells from anterior portions of the animal. Other compounds were also tested, including heptanol and octanol, which have been shown to close junctional channels in many preparations. GABA, 10 μM, hyperpolarized the cells, decreased the coupling coefficient and decreased the input resistance; ACh, 1, 10 and 100 μM, depolarized the cells and caused variable small changes in the coupling coefficient and input resistance; heptanol, 1 mM, induced a small decrease in the coupling coefficient and increased the input resistance, while octanol had negligible effect. The data suggest that gap junction channels from Ascaris somatic muscle are not modulated by the natural transmitters, and close in response to heptanol.

BED NUCLEUS OF THE STRIA TERMINALIS DIRECTLY INNERVATES CRF NEURONS IN THE LATERAL HYPOTHALAMUS. T.S. Gray and D.J. Magnuson,* Dept. of Cell Biology, Neurobiology and Anatomy, Loyola University Stritch Sch. of Med, Maywood, Il. 60153

The bed nucleus of the stria terminalis (BST) projects to the lateral hypothalamus. Numerous CRF immunoreactive neurons are located in this region. The present study investigated the distribution of BST efferents in the lateral hypothalamus and the possibility that BST terminals innervate CRF expressing neurons in this region.

The BST of Long-Evans, black-hooded male rats was injected with *Phaseolus vulgaris* leucoagglutinin lectin (PHA-L) tracer. After 10-16 days rats were overdosed with sodium pentobarbital and their brains were fixed using 4% paraformaldehyde. Tissue was processed using brown DAB staining of PHA-L followed by glucose-oxidase blue immunostaining of CRF.

The heaviest projections to the lateral hypothalamus were observed after injections of PHA-L in ventral and lateral parts of the BST. Most of the BST terminals were located caudally and extended dorsally and ventrolaterally around the fornix. BST terminals contacted numerous CRF immunoreactive neurons in the lateral hypothalamus and the paraventricular nucleus. Fewer CRF neurons were innervated after PHA-L injections in the medial and dorsal parts of the BST. Thus, the BST directly innervates CRF neurons in the lateral and paraventricular hypothalamus. Previous studies have demonstrated that CRF lateral hypothalamic neurons project to the central grey, parabrachial nucleus and dorsal vagal complex. Thus, the BST can alter the activity of CRF neurons that project to the median eminence and to a separate population of CRF cells that innervate autonomic regions of the brainstem. Supported by NIH NS 20041.

THE EFFERENT CONNECTIONS OF THE DORSOMEDIAL NUCLEUS OF THE HYPOTHALAMUS: A PHAL STUDY IN THE RAT. R.H. Thompson, N. S. Canteras, L.W. Swanson.* Dept. Biol. Sci., University of Southern California, Los Angeles, CA 90089.

PHAL was injected stereotaxically into 25 rats to characterize the efferent projections of the DMH. No differences in the pattern of labeled projections were apparent in experiments with injections centered in any of the 3 major parts of the nucleus. DMH projections may be divided into ascending and descending components, with the former divided into periventricular (PVP) and lateral (LP) pathways. The ascending pathways are predominantly intrahypothalamic and contain the vast majority of fibers arising in the DMH. The PVP courses rostrally to end mainly in the parvicellular paraventricular, parastrial, median preoptic, anterodorsal preoptic, preoptic suprachiasmatic (PSCh) nuclei and in the region surrounding the PSCh. Some fibers also innervate the paraventricular nucleus of the thalamus. The LP runs through dorsomedial and ventromedial parts of the medial forebrain bundle. It contributes fibers to the medial preoptic area and nucleus, and to the anteroventral preoptic nucleus; some of these fibers turn medially, joining those from the PVP to innervate the PSCh. LP fibers also project to ventral parts of the bed nuclei of the stria terminalis and lateral septum. Descending fibers from the DMH innervate the posterior hypothalamic nucleus, tuberomammillary and supramammillary nuclei, periaqueductal gray, specific parts of the reticular formation, Barrington's nucleus, parabrachial nucleus, and nucleus of the solitary tract. In summary, DMH projections remain primarily within the hypothalamus, innervating structures that mediate endocrine and autonomic responses. To a lesser extent, they also project to premotor nuclei that may influence voluntary movements.

593.3
DIENCEPHALIC ORIGINS OF MCH-IMMUNOREACTIVE (MCH-ir) PROJECTIONS TO THE PERIAQUEDUCTAL GRAY (PAG). C.F. Elias and J.C. Bittencourt*. Lab. of Immunohistochemistry of Peptides and Neuronal Tracers, Dept. of Anatomy ICB/USP, Sao Paulo - SP 05508 - BRASIL.

The PAG has been implicated in many functions, like: analgesia, vocal expression of emotion, blood pressure control, control of reproductive behavior. For this reason, the afferent projections to this midbrain region are extensive, such as the lateral hypothalamic area, zona incerta, anterior cingulate cortex. Bittencourt et al (1992) described an extended MCH-ir terminals in the CNS of the rat, including the PAG. In order to address the origins of those projections, we have used retrogradely transported fluorescent dye (5% of crystalline deposits of True-Blue in the lateral-ventral portion of the PAG) and immunohistochemical techniques. The results suggest that the MCH-ir cells projecting to the PAG are concentrated in the following regions: medial aspect of the zona incerta, dorsolateral hypothalamic area, dorsomedial aspect of the tuberomammillary nucleus, caudal part of the anterior hypothalamic area an surrounding the fornix.

QUANTIFICATION OF NORADRENERGIC VARICOSITIES IN APPOSITION TO VASOPRESSIN-IMMUNOREACTIVE NEURONS IN THE MONKEY PARAVENTRICULAR NUCLEUS. S.D. Ginsberg[1]*, P.R. Hof[1,2], W.G. Young[3], and J.H. Morrison[1,2]. [1]Fishberg Res Ctr for Neurobiology and [2]Dept of Geriatrics and Adult Development, Mt Sinai School of Medicine, New York, NY 10029, [3]Dept of Neuropharmacology, Scripps Clinic, La Jolla, CA 92037.

Previous investigation of dopamine-ß-hydroxylase-immunoreactive (DßH-ir) innervation of monkey hypothalamus has revealed a high density of noradrenergic varicosities throughout the paraventricular nucleus (PVH). In order to further characterize DßH-ir varicosity density on specific transmitter-identified postsynaptic targets within the primate PVH, double label immunofluorescence combined with confocal laser scanning microscopy was employed. In this study, DßH-ir varicosities and vasopressin-immunoreactive (VP-ir) perikarya were scanned confocally and the resultant images were superimposed. In this double label scheme, DßH-ir varicosities that were in apposition to (less than 1 μm away) VP-ir profiles were counted, whereas varicosities not in apposition to VP-ir profiles were not quantified. This procedure yielded a varicosity to neuron ratio which gave one measure of transmitter innervation. In addition, the distribution of DßH-ir/VP-ir appositions was assessed to determine the cellular structures on which the majority of contacts occur (e.g. dendrites or perikarya). Preliminary observations indicate that the DßH-ir varicosities are distributed primarily on or around VP-ir dendrites, and may be one of the dominant inputs to this subclass of PVH neurons. Supported by the MacArthur Foundation, and NIH MH45212.

GLUTAMATE- AND ASPARTATE-LIKE IMMUNOREACTIVITIES IN CHEMICALLY IDENTIFIED HYPOTHALAMIC NEURONS.

B. Meister*, A.P. Nicholas and T. Hökfelt, *Dept. of Histology and Neurobiology, Karolinska Institute, P.O. Box 60400, 104 01 Stockholm, Sweden.*

Recent evidence suggests that the amino acid glutamate (GLU) may be the dominant excitatory transmitter in neuroendocrine regulation. Both GLU and aspartate (ASP) have been demonstrated in presynaptic hypothalamic axons. In the present study we have by means of indirect immunofluorescence histochemistry examined the distribution of GLU- and ASP-immunoreactive (-IR) cell bodies within the hypothalamus. Of special interest was to explore the presence of GLU- and ASP-like immunoreactivity (-LI) in chemically identified neurons of hypothalamic nuclei. GLU/ASP-LI was demonstrated in cell bodies of the suprachiasmatic (SCN), periventricular (Pe), supraoptic (SON), paraventricular (PVN) and arcuate (Arc) nuclei. In the SCN, GLU/ASP-LI was demonstrated in many vasopressin (VP)-containing cells in the dorsomedial aspect of the nucleus. Few GLU/ASP-IR cells in the SCN were also somatostatin (SOM)-IR. In the Pe, single SOM-IR cells were GLU/ASP-positive. Magnocellular neurons in the SON and PVN contained GLU/ASP-IR and after double-labelling it was shown that there was colocalization with both VP and oxytocin. Within the Arc, GLU/ASP was mainly found in the ventromedial aspect of the nucleus, however, single neurons were also distributed in the ventolateral aspect. Double-labelling revealed that most of the GLU/ASP-IR cells also were neuropeptide Y (NPY)-containing. Few GLU/ASP-IR cells in the ventrolateral aspect of the Arc showed tyrosine hydroxylase (TH)-LI. The TH-containing neurons within the A13 cell group of the zona incerta were to a large extent GLU/ASP-positive. The results suggest that the excitatory amino acids GLU and ASP are colocalized with several peptides and TH in hypothalamic neurons.

IN VITRO DEPOLARIZATION INDUCED CHANGES OF PITUICYTE MORPHOLOGY ARE NOT DEPENDENT ON EXTRACELLULAR CALCIUM. B.-G. Zhao[1] and P. Cobbett, Dept Pharmacol. & Toxicol. and Neuroscience Prog., Michigan State Univ., East Lansing, MI 48824, USA.

Morphological plasticity in the neurohypophysis following certain changes in physiological state is well established. We have used cultures of adult pituicytes (Bicknell et al., Brain Res Bull 22, 379-388, 1989) to examine the involvement of extracellular Ca in the control of pituicyte morphology. Pieces of neurohypophysis were cultured for 14 days, when culture medium was replaced by a balanced salt solution (with 2mM Ca and 2mM Mg) for 90min and the fraction of cells that were stellate was determined. In control medium, this fraction was 0.09±0.01 (mean±SEM, n= 5 dishes); in medium containing 50mM K, it was significantly increased independent of Ca concentration (0.77±0.04, n=8, Ca 2mM and Mg 2mM; 0.72±0.04, n=8, Ca 50μM and Mg 4mM). In medium containing the β-adrenergic receptor agonist isoproterenol (10μM) or isoproterenol (10μM) and reduced Ca (Ca 50μM and Mg 4mM), it was also increased (0.69±0.03, n=5, and 0.78±0.04, n=5, respectively). We conclude that Ca influx is not necessary for changes of pituicyte morphology to occur.

SYNCHRONOUS NEURONAL ACTIVITY IN THE SUPRACHIASMATIC NUCLEUS (SCN) INDEPENDENT OF CHEMICAL SYNAPTIC TRANSMISSION. Y. Bouskila and F. E. Dudek*. Mental Retardation Res. Ctr., UCLA Sch. of Med., Los Angeles, CA 90024

The SCN, which contains the mammalian biological clock, exhibits a circadian rhythm of firing rate. Since these data are derived from neuronal populations they also imply that neuronal activity in the SCN is synchronized. To examine possible mechanisms of synchronization, coronal hypothalamic slices (350-500 μm) were prepared 2 h before the dark phase (12:12 L:D) from male rats. Simultaneous multiple-unit recordings showed that the circadian rhythm of neuronal activity level was correlated between different locations within the SCN ($0.63 \le r \le 0.99$, $p<0.0015$) and thus confirmed the neuronal *synchronization* (n=6). To study mechanisms of synchronization in the SCN, extracellular Ca^{2+} was replaced with Mg^{2+} (+ 0.1 mM BABTA), which blocks chemical synaptic transmission and increases membrane excitability. This treatment produced periodic bursts of action potentials which were synchronized throughout the SCN (n=11), but were not synchronized with similar bursts in the contralateral SCN (n=9). Furthermore, a mixture of NMDA, non-NMDA and $GABA_A$ receptor antagonists (AP-5 - 100 μM, DNQX - 50 μM and bicuculline - 50 μM) had no effect on burst synchrony (n=6). Whole-cell patch-clamp recordings confirmed that the Ca^{2+}-free medium blocked evoked postsynaptic potentials (PSPs) (n=4) and that the mixture of antagonists blocked the remaining spontaneous PSPs (n=6). These results indicate that synchronous neuronal activity can occur in the SCN without active chemical synapses, suggesting that a different mechanism of communication exists; a similar mechanism(s) of neuronal synchronization may coordinate the cellular elements in the SCN responsible for circadian rhythms in mammals. NMDA receptor-linked channels in primary hypothalamic supraoptic punch cultures M.C. Curras,* J.N. Hayward and R.B. Meeker. Department of Pharmacology, Neurology and the Neurobiology Curriculum, University of North Carolina at Chapel Hill, North Carolina

Although glutamate binding to NMDA receptors is low in the hypothalamus (Monaghan et al, 1983), responses to NMDA have recently been reported (Hu and Bourque, 1991; Van den Pol et al., 1991). However, these studies disagree on the abundance of NMDA receptors. To characterize supraoptic (SON) NMDA receptors we used the high resolution of single-channel patch clamp. Timed pulses of NMDA (100 μM) in combination with added glycine (1-10 μM) were applied to outside-out patches from large neurons in embryonic (ED16) SON explant cultures in nominally-free Mg solutions at -60mV. Before excising patches most neurons were filled with 0.4% biocytin for 3-7 minutes. The mean unitary conductance of NMDA-activated channels was 46.7±4.0 pS (n=9) and raising the glycine concentration from 1 to 10 μM increased the frequency of openings (n=2). 1mM Mg^{2+} blocked channel openings at negatve potentials in 4 out of 4 patches. To test for the presence of GluR1-7 non-NMDA receptor phenotypes at this resolution we exposed the same outside-out patches to 300 μM kainic acid (KA) and 100 μM Amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) sequentially. Current responses to KA were much greater than to NMDA/glycine indicating a relative abundance of KA receptors. AMPA currents were rapidly desensitizing (n=2) and KA currents were either desensitizing (n=1) or non-desensitizing (n=1). These findings confirm an earlier report that NMDA, KA, and AMPA channels are present on individual SON neurons (Hu and Bourque, 1991). In addition, these results suggest the presence of GluR1-4 and functional GluR5 (Herb et al., 1992) glutamate receptor subunits in the hypothalamus. Supported, in part, by NIH Grant NS-13411.

Whole-cell patch clamp recordings of spontaneous synaptic currents and their block by amino acid neurotransmitter antagonists in medial preoptic slices from immature male rats. N. W. Hoffman*, J.-P. Wuarin, and F. E. Dudek, Mental Retardation Res. Cetr. UCLA Sch. of Med., Los Angeles, CA. 90024

Inhibitory and excitatory amino acid neurotransmitters mediate fast synaptic potentials in several discrete hypothalamic nuclei (e.g., van Den Pol, A.N., et al., Science, 250: 1276, 1990). In the medial preoptic area, a more diffuse hypothalamic region implicated in diverse biologic functions, electrically evoked IPSPs are due to activation of $GABA_A$ receptors (Hoffman, N.W., et al., Soc. Neurosci. Abstr., 16: 574, 1990). The present investigation used whole-cell patch-clamp recordings in slices (400 μm) from immature rats to examine the pharmacology and development of spontaneous synaptic currents in medial preoptic neurons. These currents, particularly the spontaneous IPSCs, were prominent in recordings (n=12) from animals 8 to 33 days of age. Bath application of the $GABA_A$ receptor antagonist, bicuculline (10 μM, n=6), blocked the spontaneous IPSCs (15-50 pA), and the non-NMDA glutamate receptor antagonist, CNQX (3 μM; n=4), blocked the spontaneous EPSCs (3-10 pA). Tetrodotoxin (0.5 μg/100 ml) abolished most spontaneous postsynaptic currents, indicating their dependence on Na^+ spikes; however, some tetrodotoxin-resistant miniature postsynaptic potentials persisted during this treatment. These results support the hypothesis that amino acid neurotransmitters mediate all fast synaptic events in the medial preoptic area, and these chemical synapses are functional when medial preoptic subregions are undergoing sexual differentiation.

ASYMMETRICAL DIFFERENCES IN THE ELECTROENCEPHALOGRAPHIC (EEG) ACTIVITY OF THE PREOPTIC AREA-ANTERIOR HYPOTHALAMIC AREA (POA-AHA) OF THE FEMALE RATS. **M.A.Sánchez,J.Manjarrez,R.Alvarado,R.Tapia*, and R.Domínguez. Escuela Nacional de Estudios Profesionales Zaragoza, UNAM, Instituto Nacional de Neurología y Neurocirugía, and Instituto de Fisiología Celular, UNAM.**

The hypothalamus presents neurochemical and functional asymmetries. In this report we studied the EEG activity in both sides of POA-AHA during the estrous cycle of the rat. The record was performed with bipolar electrodes, and analized with the Rhythm program (Stellate System). Left and right sides of POA-AHA showed differences both in amplitude and power in the EEG activity. Four rats had more amplitude and power in the right side, and three animals showed an inverse pattern. These differences correlated with the position adopted by the animals when they were anaesthetized and mounted in the stereotaxic apparatus. Neither correlation nor coherence between left and right recordings were observed. These results indicate that differential EEG activity in both sides of the POA-AHA is related with an intrinsic behavioral asymmetry.

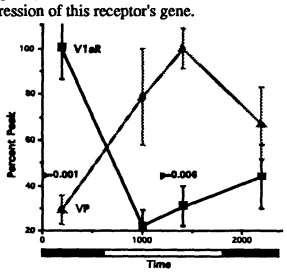
CIRCADIAN RHYTHM OF EXPRESSION OF VASOPRESSIN V1a RECEPTOR GENE IN THE SCN. W.S. Young, III, N.L. Ostrowski*, A-M. O'Carroll, and S.J. Lolait Lab. of Cell Biology, N.I.M.H., Bethesda, MD 20892.

The suprachiasmatic nucleus (SCN) is thought to be the generator of circadian rhythms in mammals. Diurnal variations in the expression of several neuropeptide genes, including the one encoding vasopressin (VP), exist in the SCN, although the roles of these neuropeptides are not understood. VP receptors (of the V1a type that is present in kidney and liver and linked to phosphoinositol turnover) are also present in the SCN. Our cloning of the rat V1a receptor (V1aR; Nature 356 523, 1992) enabled us to look for a diurnal rhythm in the expression of this receptor's gene.

Four groups of adult male Sprague-Dawley rats (4 per group) were entrained for 10 days (lights on 0600-1800) prior to sacrifice at 0200, 1000, 1400, and 2200. 12μ frozen sections through the SCN were processed for hybridization histochemistry for V1aR (Endocrinology 131, 1992) or VP (Mol. Brain Res. 1 231, 1986) mRNA. We confirmed the diurnal rhythm for VP expression with highest levels at 1400. V1aR mRNA had just as large a swing in levels, but peaked at 0200. (statistical comparisons are with respective peak values).



We are currently performing double-labeling experiments to see if the V1aR and VP transcripts are co-localized and are examining Brattleboro rats to see if the rhythm in V1aR expression is maintained.

CONNEXIN 32 mRNA LEVELS IN THE SUPRAOPTIC NUCLEUS PRIOR TO AND DURING LACTATION. G.I. Hatton* and P.E. Micevych, Dept. of Neuroscience, Univ. California, Riverside, CA 92521 and Dept. Anatomy & Cell Biology, Univ. California, Los Angeles, CA 90024

Recent evidence suggests that there is elevated direct intercellular communication in the supraoptic nucleus (SON) during lactation. The major evidence for this is an increase in the incidence of dye-coupling in the SON of nursing mothers compared with virgin rats. Dye-coupling is thought to be mediated by direct intercellular channels of connexin protein, which in neurons has been shown to be connexin 32 (Cx32). To test whether the increased coupling is related to elevated Cx32 mRNA in the SON, virgin rats, mothers sacrificed before the start of lactation and mothers that had been lactating for 14 days were processed for Cx32 *in situ* hybridization histochemistry with a ^{35}S-labeled riboprobe (Micevych and Abelson, *JCN* 305:96-118, '91). The labeling ratio was designated as density of silver grains over a structure ÷ density of silver grains over the background. Cx32 cRNA hybridization was observed over scattered cells throughout the SON in virgin rats (labeling ratio = 3.98 ± 1.20). No distinct dorso-ventral gradient was noted but most of the hybridization was observed in the rostral to middle portions of the nucleus. Mothers that were sacrificed after parturition but before lactation had the highest labeling ratio (10.61 ± 1.51) in the SON. Mothers that had been allowed to lactate for 14 days had a SON labeling ratio (6.62 ± 2.50). These results indicate that the Cx32 mRNA increases prior to lactation and then is reduced during lactation and suckling. Thus, the neural and endocrine events at the time of parturition may be responsible for the elevated levels of Cx32 mRNA which code for gap junction proteins that account for increased dye-coupling between SON neurons. (Supported by NS21220 and NS09140).

EXPRESSION AND REGULATION OF A HUMAN PROENKEPHALIN FUSION GENE IN THE HYPOTHALAMUS OF TRANSGENIC MICE D. Borsook*, A. Dauber, R. Burstein, A. Strassman, K. Herrup, M. Comb, S Hyman Molecular Neurobiology Laboratory, Mass. Gen. Hospital, Boston MA 02114

Proenkephalin (ENK) is expressed in many nuclei of the hypothalamus where it is regulated by a variety of physiological stimuli. For example, estrogen increases ENK expression in the ventromedial nucleus and stress produces increases of ENK expression in the paraventricular nucleus. However, the trans-synaptic regulation of ENK expression in the hypothalamus is not well understood. In order to investigate developmental and physiological influences on enkephalin expression in the hypothalamus, we have produced transgenic mice expressing a human ENK ß-Galactosidase fusion gene containing 3kb of 5' flanking sequences and 1kb of the 3' flanking sequences from the human proenkephalin gene and studied the expression of the fusion gene in both fetal and adult animals under a variety of conditions. This construct confers basal expression of the reporter gene ß-Gal in the adult and fetal hypothalamus. In the adult high levels of expression are observed in the paraventricular, ventromedial, supraoptic and mammillary nuclei, moderate levels in the anterior, perifornical, lateral, periventricular and low levels in the suprachiasmatic nucleus. In In the fetal hypothalamus expression was seen in the periventricular region and in regions destined to become specific nuclei, particularly those with high levels of expression viz. the paraventricular and ventromedial nuclei. ß-Gal expression correlated with the endogenous gene based on *in-situ* hybridization. Regulation of the transgene was produced by (a) Injections (i.p.) of hypertonic saline produced an increase of ß-Gal in the supraoptic and paraventricular nuclei at 3, 6 and 12 hours with no change in controls (max at 6 hrs); (b) A noxious stimulus (electrical stimulation of the maxillary nerve) in urethane anesthetized animals, produced enhanced expression in the lateral nucleus; (c) pregnancy increased levels in the lateral ventromedial nucleus. In order to identify activation of identified enkephalin neurons by such stimuli, we have double-labelled ß-Gal positive cells with the IEG c-fos. These results show that the transgenic model may be useful for investigating mechanisms of proenkephalin regulation in the hypothalamus.

ASSOCIATION CORTEX AND THALAMOCORTICAL RELATIONS

PATTERN AND COLOR ENCODING NEURONS WITH OCULOMOTOR PROPERTIES IN THE MACAQUE PULVINAR. J.D. Port, E. F. Castillo and L. A. Benevento*. Dept. of Anatomy, University of Maryland College of Dental Surgery, Baltimore, MD 21201, and Dept. of Anatomy and Cell Biology Univ. of Illinois, Chicago, IL 60612.

The dorsal portion of the lateral pulvinar and the adjacent portion of the medial pulvinar (PL/PM) are interconnected with cortical and subcortical regions which encode information as to the form or location of visual objects. We recorded from single cells in PL/PM of awake behaving monkeys (Macaca mulatta). We found a class of neurons that responded differentially to 9 different forms or colors. Such cells responded to several of the patterns or colors, but usually they responded best to only one or two of them. These responses were said to be pattern or color preferential if a certain pattern or color gave a response which was statistically different than the responses to the other patterns or colors. Of the 83 cells tested for pattern selectivity to date, 37% responded with excitatory peaks to the presentation of at least one of the pattern stimuli. The 400 visual cells tested had response latencies falling cleanly into three latency classes identical to those found in a previous study with anesthetized animals (Benevento et.al., Exp. Brain Res., 1992). Class A cells had response latencies of < 75 msec; class B cells had latencies of 76 - 140 msec, and class C cells had response latencies > 140 msec. Interestingly pattern/color responsive cells could be found in all latency classes. Visually responsive cells also had a variety of oculomotor properties. Seventy-six percent of the pattern preferential cells possessed some oculomotor property such as presaccadic and postsaccadic discharges to targets placed in diagonally opposed quadrants and a suppression of discharge during the saccade. Eye movements could enhance the response to a pattern or color. The results suggest that the pulvinar contains cells which have sensory and oculomotor properties which are usually segregated in other cortical and subcortical regions.

ASYMMETRIES IN BEHAVIOR FOLLOWING UNILATERAL MEDIODORSAL THALAMIC LESIONS IN RATS. J.M. Vargo*, T.L. Callahan and P.J. Best. Dept. of Psychology, Miami Univ., Oxford, OH 45056.

Bilateral lesions of either the medial precentral prefrontal cortex (AGm) or mediodorsal thalamic nucleus (MD) produce spatial context recognition deficits evidenced by a failure to respond to familiar but out-of-place stimuli (K.A. Stokes & P.J. Best, 1987, Neurosci. Abs., 13:1067; J.M. Vargo & P.J. Best, 1990, Neurosci. Abs., 16:1095). Asymmetries in the behavior of rats with left vs right AGm lesions have been reported (J.M. Vargo et al., 1988, Exp. Neurol., 102, 199). This study investigated the possibility that MD, the primary thalamic input to AGm, may be lateralized. Rats with left MD lesions demonstrated more asymmetrical rotational behavior compared to right MD, bilateral MD, or control animals. Left MD animals also demonstrated greater contralateral spatial context recognition deficits in a unilateral version of the "out-of-place" paradigm. However, neither left nor right MD lesions produced hemi-inattention as is seen following unilateral AGm lesions.

594.3

SEROTONINERGIC, NORADRENERGIC AND DOPAMINERGIC INNERVATION OF THE PRIMATE MEDIODORSAL THALAMIC NUCLEUS M.L. Schwartz* and L. MrzljakSect. of Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510.

Since many of the modulatory transmitter systems originating from the brainstem nuclei have similar actions on the activity of thalamocortical relay cells (McCormick & Pape, 1990, J. Physiol., *431*), we examined the distributions of serotonin (5-HT), noradrenaline (NA) and dopamine (DA) immunoreactive fibers in the mediodorsal (MD) thalamic nucleus of the adult rhesus monkey. Our goal was to determine whether these systems have overlapping or distinct anatomical distributions. Immunoreactive axons of each of these fiber systems exhibited a different pattern of distribution. The densest innervation was found for 5-HT labeled axons. These were present at all levels of the MD, although their density was greatest in caudal portions of the nucleus. The most striking feature of the 5-HT fiber distribution was the irregular mosaic-like arrangement of areas containing higher and lower fiber densities. This mosaic-like organization was evident throughout the nucleus. In contrast to the innervation by 5-HT fibers, both the DA and NA innervations of the MD exhibited striking regional variations in their rostral-caudal and medial-lateral distributions. NA fibers were sparsely distributed throughout the nucleus, but were more dense in the medial magnocellular division. DA immunoreactive fibers were rare in rostral portions of the MD. In caudal portions of the nucleus DA fibers were concentrated and numerous in ventral and lateral regions of the parvicellular division. Comparisons of adjacent DA and 5-HT immunoreacted sections revealed that these two transmitter systems exhibited an interdigitating and complimentary pattern of innervation in the posterior MD. These data indicate that modulatory transmitter systems originating in the brainstem have distinctive regional patterns of innervation in the MD which may contribute to the functional diversity of the subdivisions of this nucleus and its cortical targets. Supported by NS 22807-06 and MH 44866.

GLUTAMATE IS THE THALAMOCORTICAL TRANSMITTER IN PROJECTIONS FROM THE MEDIAL DORSAL THALAMIC NUCLEUS TO THE PREFRONTAL CORTEX IN THE RAT: AN IN VIVO IONTOPHORETIC STUDY. J. Gigg*, A.M. Tan and D.M. Finch. Department of Neurology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Anatomical and physiological studies have shown projections from the medial dorsal thalamus (MD) to anterior cingulate cortex (CG). We used an iontophoretic technique to identify the neurotransmitter used in this thalamic projection. Rats were anesthetized and stimulating and recording electrodes were placed stereotaxically. Extracellular responses from CG neurons were recorded after electrical stimulation of the MD thalamus and vicinity. Recordings were made with 5-30MΩ "piggy-back" electrodes (single recording pipettes attached to seven-barreled iontophoretic assemblies). Twenty-eight percent of all cells showed an excitatory response to MD stimulation. Sixty-five cells that showed no excitation were tested with the $GABA_A$ antagonist bicuculline methiodide (BMI). BMI produced a short latency excitatory response in 37 (57%) of these cells.

Application of the AMPA antagonists CNQX or DNQX selectively decreased the excitatory responses. These data indicate that: (a) the thalamic projection to prefrontal cortex is glutamatergic; and (b) this projection is regulated by GABA. Supported by NIH Grant NS 16721.

CHEMOARCHITECTONIC STUDY OF THE MEDIODORSAL THALAMIC NUCLEUS IN THE MACAQUE MONKEY. C. Cavada*, T. Compañy, A. Hernández-González, and F. Reinoso-Suárez. Dept. Morfología, Fac. Medicina, Univ. Autónoma de Madrid, 28029 Madrid, Spain.

Histochemical and immunohistochemical compartments were uncovered in the mediodorsal (MD) thalamic nucleus of macaques by analyzing the distributions of acetylcholinesterase (AChE) and cytochrome oxidase (CO) activities, and of serotonin (5-HT) and tyrosine hydroxylase (TH) immunoreactive (ir) fibers. Adjacent sections through the thalamus of adult *Macaca nemestrina* were stained to reveal Nissl substance and myelin, and processed for AChE and CO histochemistry, and for 5-HT and TH immunohistochemistry. Two AChE-poor, but CO-rich, sectors were observed along most of the rostro-caudal extent of MD: the medial third, and the ventral rim adjacent to the centromedian nucleus. Within and between these sectors lie patches of moderate AChE staining. The lateral two-thirds of MD show prominent AChE activity, which is unevenly distributed: poor- and very rich-AChE patches are intermingled with larger AChE-rich zones. CO staining in this region is less intense than in the medial third, and is distributed in dark and light zones. Many of the CO-rich zones appear to overlap with zones of AChE-moderate or rich staining. The rostral end of MD is predominantly AChE-poor, whereas the dorsal and caudal ends of the nucleus are predominantly AChE- and CO-rich. The 5-HT innervation of MD is among the densest within the thalamus. The distribution of 5-HT-ir fibers is heterogeneous, with denser aggregates usually coextensive with AChE-moderate or rich zones. TH-ir fibers in MD are relatively sparse, making it difficult to characterize heterogeneities in their distribution.

The present findings show that MD is a mosaic of biochemically diverse zones. This diversity is likely to have a bearing on the functional interactions of MD with the association areas of the frontal, parietal and temporal lobes.

CALCIUM BINDING PROTEIN IMMUNOREACTIVITY IN GABA NEURONS OF CAT ANTERIOR INTRALAMINAR NUCLEI. M.Molinari*, M.E.Dell'Anna, E.Rausell, T.Hashikawa, M.G.Leggio, G.Macchi, E.G.Jones. Exp. Neurology Lab, Catholic University, Rome (Italy) and Neural System Lab, FRP, Riken, Wako (Japan).

Recent data have stressed the importance of certain calcium binding proteins (CBP) as markers for thalamo-cortical neurons. In particular Parvalbumin (PV) and 28 kd-calbindin (CB) have been shown to be expressed in projection neurons in the monkey thalamus, and to distinguish separate classes according to their input-output connections. In the monkey thalamus, relatively few GABA neurons, mainly those of the reticular nucleus, show PV immunoreactivity (IR) (Jones & Hendry, Europ. J. Neurosci., 1, 222-246, 1989). We have observed that PV is more widely distributed in the GABA neurons of cat thalamus, which suggests certain interspecies variability in terms of neuronal specificity of CBPs. Little is known about the distribution of the CBPs in neurons of the intralaminar nuclei (IL). The aim of the present study was the immunocytochemical characterization of GABA-IR neurons of the cat anterior IL nuclei according to the CB and PV-IR. Single-labeling immunoperoxidase and double-labeling immunofluorescence techniques have been used for the localization of the three antigens. GABA, PV and CB-IR was distributed in a patchy fashion within the IL nuclei. In superimposed adjacent sections processed for GABA, PV or CB, some degree of complementarity was observed, i.e., rich CB zones overlap with PV poor zones and viceversa. The distribution of GABA-IR is similar to that of PV-IR although the overlap was not complete. Double labeling experiments demonstrated that the majority of PV-IR neurons within IL (up to 90%) were also GABA-IR, while only a small number of GABA-IR cells (10 to 20%) did not show PV-IR. Less than 30% of the total CB-IR neurons showed GABA-IR, while CB-IR was present in about 70% of the GABA-IR neurons. The present findings demonstrated that the majority of IL GABA cells contain at least one of the two CBPs PV or CB and possibly that CB and PV might coexist in the same GABA cells. Thus, GABA cells of the cat IL form a heterogeneous population in terms of their expression of CBPs, and present significant differences in comparison with monkey thalamic GABA neurons. This diversity may be related to the functional role of the IL nuclei in the two species.

ELECTROPHYSIOLOGICAL PROPERTIES OF CAT ASSOCIATION NEOCORTICAL CELLS. A. Nuñez*, F. Amzica and M. Steriade. Lab. of Neurophysiology, Laval Univ. Sch. of Med., Quebec, Canada G1K 7P4.

Intrinsic properties and synaptic responses of association cortical neurons were studied in vivo, by means of intracellular recordings in areas 5 & 7 of cats under urethane anesthesia. Cells were identified by ortho- and antidromic activation from LP and CL thalamic nuclei and from contralateral cortex. A group of physiologically identified neurons were intracellularly stained with Lucifer Yellow and found to be pyramidal-shaped elements.

Two neuronal types, regular spiking and intrinsically bursting cells, were detected. Regular spiking cells were further differentiated according to the shape of their AHP and to their adaptation properties. High-threshold spike-bursts were rhythmically fired at 4-7 Hz.

A subpopulation of cortical cells displayed oscillations at 20-50 Hz. This rhythmic activity was voltage-dependent: it was triggered by depolarizing pulses, was blocked by hyperpolarization, and was not observed after intracellular injection with QX-314. The cells expressing 20-50 Hz oscillations were antidromically activated from the homotopic contralateral cortex and from the thalamus, thus suggesting that the fast oscillation can be synchronized in corticocortical and corticothalamic networks.

Thalamic as well as cortical stimuli evoked EPSPs with an earlier and a late component. The former increased with hyperpolarization, whereas the latter component decreased and eventually disappeared with membrane hyperpolarization. The late EPSP component was strikingly potentiated at frequencies above 3-4 Hz.

All these intrinsic and synaptic properties may assist cortical neurons in their rhythmic activities during sleepy and alert states.

ANATOMIC ORGANIZATION OF THE HUMAN ORBITOFRONTAL CORTEX. P.R. Hof*[1], E.J. Mufson[2], N. Archin[1], A. Edwards[1], W.G. Janssen[1] and J.H. Morrison[1]. [1]Fishberg Res Ctr for Neurobiology, Mount Sinai Sch of Med, New York, NY 10029, [2]Tech 2000, Rush Presbyterian-St Luke's Med Ctr, Chicago, IL 60612.

The primate orbitofrontal cortex (OFC) is a component the paralimbic belt and consists of several distinct areas. Studies of the monkey OFC indicate that these areas are characterized by a complex array of intrinsic and extrinsic connections. To define the chemoarchitectonic organization of the human OFC, we have used antibodies to nonphosphorylated neurofilament protein (SMI32) and to the calcium-binding protein parvalbumin (PV). Immunohistochemistry revealed complementary labeling patterns corresponding to the cytoarchitecture defined by Nissl preparations. SMI32-immunoreactive (ir) pyramidal neurons were located only in layers V-VI in the dysgranular caudal OFC, whereas they were distributed in both layers III and V-VI in the lateral and polar granular regions. Interestingly, the density of PV-ir neurons and neuropil staining paralleled that of SMI32-ir cells in layer III. Neuropil labeling exhibited a high degree of regional specialization in that a dense plexus of PV-ir fibers was observed in layer I of the lateral OFC, while the medial dysgranular OFC displayed dark fiber patches in layer III. These patches were less densely labeled in areas with low SMI32-ir neuron counts in layer III. PV staining in the polar area of the OFC showed the typical features of granular cortex with labeled neurons predominating in layers III and IV. These region-specific staining patterns may represent a possible anatomical substrate for the distribution of select SMI32-ir corticocortical efferent, and PV-ir thalamocortical and intrinsic systems in the human OFC.

CHEMOARCHITECTURE OF THE MONKEY AND HUMAN CINGULATE CORTEX. B.A. Vogt*[1], E.A. Nimchinsky[2], P.R. Hof[2] and J.H. Morrison[2]. [1]Dept of Physiology and Pharmacology, Bowman-Gray Sch of Med, Winston-Salem, NC 27103, and [2]Fishberg Res Ctr for Neurobiology, Mount Sinai Sch of Med, New York, NY 10029.

Physiological studies have demonstrated that the cingulate cortex contains a variety of subareas involved in the integration of sensorimotor functions. In order to characterize the complex anatomic organization of these regions, we have studied the chemoarchitecture of the monkey and human cingulate cortex in its full rostrocaudal extent. Immunostaining with antibodies to nonphosphorylated neurofilament protein (SMI32) and to the calcium-binding protein parvalbumin (PV) revealed striking regional differences and clear delineation of subareas in both species. For instance, layer III of areas 24b and 24c was practically devoid of SMI32-immunoreactive (ir) pyramidal cells, whereas the posterior areas 23b and 23c displayed an increasing density of these cells in both layers III and V. PV staining showed a bilaminar neuropil pattern anteriorly coinciding with layers III and V, and a more homogeneous labeling posteriorly as layer IV emerges in area 23. Interestingly, an area possibly corresponding to a cingulate motor region (area 24c') appears to be located at the transition zone between typical anterior and posterior staining patterns and is characterized by the presence of numerous large SMI32-ir pyramidal cells in layers III and V. In addition, in the human, large PV-ir pericellular baskets were observed in layer V of area 24c'. Thus, SMI32 and PV exhibit regionally coordinate staining patterns that may represent anatomic equivalents of physiologically defined elements of the cingulate cortex.

SUBDIVISION OF MACAQUE ORBITAL AND MEDIAL PREFRONTAL CORTEX. S. T. Carmichael* and J. L. Price, Dept of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110

To analyze the cortical structure of the orbital and medial prefrontal cortex (OMPFC), we studied immunohisotochemical staining with four antibodies in three macaque species. These can be correlated with histochemistry and axonal connections to provide multiple structural criteria for the recognition of cortical areas. These antibodies included: an antibody directed against a non-phosphorylated neurofilament epitope (SMI-32), an antibody directed against a membrane bound proteoglycan derived from motor cortex extracts [8b3 (Guimaraes et al., *Soc. Neurosci. Abst.* 16:240)] and two antisera directed against the calcium binding proteins parvalbumin and calbindin. Parvalbumin immunoreactivity shows areal variation in the density and laminar position of stained cell bodies and the presence of a horizontal plexus of neurites. Medial prefrontal areas have relatively few parv-ir cells, whereas the orbital areas 13l, 11m and the gustatory cortex have a dense parv-ir plexus. With calbindin immunostaining, areas differ in the relative density of a population of stained cells that forms a band in layers V and VI and in the extent of vertical neurite staining. SMI-32-ir pyramidal cell bodies and proximal dendrites are prominent in specific medial orbital areas (e.g. 13l and lad), but nearly absent in areas on the medial wall (24, 32) and the gyrus rectus (14c, 14r). 8b3 antibody staining within the OMPFC varies in the laminar distribution of reactive cells and the presence of a band of neuropil staining in the deep layers. In particular, area 12l is the only OMPFC area that has a significant population of densely immunoreactive cells in layer II.

In all, 22 areas have been distinguished within the OMPFC. The axonal connections of these areas, examined in a parallel study, indicate that these provide a complex substrate for the integration of limbic and sensory inputs. Supported by NIH grant DC00093 and training grant 5T32NS07057.

STRIPE-LIKE INTRINSIC CONNECTIONS MADE BY PYRAMIDAL NEURONS IN MONKEY PREFRONTAL CORTEX (AREAS 9-46). J.S. Lund*, J.B. Levitt, D.A. Lewis, and T. Yoshioka. Departments of Psychiatry and Neurobiology, Anatomy and Cell Science, University of Pittsburgh, Pittsburgh, PA 15261.

We have used biocytin injections in macaque prefrontal cortex (anterior to the arcuate sulcus between principal sulcus and mid-line) to examine pyramidal neuron intrinsic connectivity as a possible model for prefrontal cortical organization in the normal human. Iontophoretic (core size: 150-300μm) and pressure (300-400μm) injections made into the superficial layers give wide-ranging lateral projections within the same area of cortex. Projections local to a small iontophoretic injection form a narrow band of terminals in layers 1-3 (300-400μm wide, 2-4mm long) centered on the injection site. Collateral fibers spread orthogonally from this terminal band, making frequent bifurcations, to establish a series of parallel bands of terminals with uninervated bands between, spaced fairly regularly across the cortex (center to center 650-800μm). The whole pattern of terminal label is stripe-like, with occasional cross-links between the bands, and insertions of narrow interbands and can reach 7-8mm across the cortex. The projections arise from neurons in layers 2-3 and 5 and terminate in layers 1-3. The stripe-like pattern contrasts with patch-like patterns in other cortical regions (V1, V2, V4, motor, somatosensory) and is smaller in scale than stripe-like zones of corticocortical afferent terminals (300-750μm wide, 1.0-1.5mm apart; Goldman-Rakic and Schwartz, '82). However we find the intrinsic stripe width to match gaps in the distribution of callosal efferent neuron populations: it is therefore possible that the intrinsic system samples inputs from several sources of afferents but relays only to selected efferent destinations from any one point across the region. INTRINSIC CONNECTIONS OF PRIMATE PREFRONTAL AND PARIETAL CORTEX REVEALED BY MICROINJECTIONS OF CHOLERA TOXIN. M.F. Kritzer* and P.S. Goldman-Rakic. Section of Neurobiology, Yale. Univ. Sch. Med, New Haven, CT 06510.

Physiological studies in primates show that neurons in prefrontal and parietal cortices selectively respond in complex ways to visuospatial stimuli and, as a population, represent all portions of the visual field. As in sensory areas, intracortical connections are likely to participate in scultping these responses. In order to gain insight into the layer-by-layer organization of intrinsic connections in these areas, we plotted neurons retrogradely labeled by microinjections (5-15nl) of gold-conjugated cholera toxin (B-subunit) in specific layers of prefrontal and parietal cortex in rhesus monkeys.

The intrinsic circuits were similar in prefrontal and parietal cortices and the laminar location of injections predicted the pattern of labeling in each area. Supragranular injections produced widespread labeling in layers II/III, with labeled neurons extending as far as 3mm laterally and often grouped in clusters some 0.5-0.7mm wide; labeled cells in layers IV-VI mainly occupied narrow columns (~1mm across) directly beneath these same injection sites. Injections in infragranular layers produced nearly inverse patterns; cells in layers II/III formed one or two clusters above injection sites, while more uniform labeling in layers V/VI extended up to 3mm laterally. A striking feature of labeling in deep layers was marked asymmetry, e.g., for some injections, labeled cells extended millimeters in some directions and only a few hundred microns in others. Finally, injections centered in layer IV yielded single columns of labeling (0.5-1mm across) passing through all layers. This layer-by-layer diversity in intracortical connections in prefrontal and parietal cortices may support the varied computational processing carried out in these areas. Supported by MH44866-04.

HEMISPHERIC ASYMMETRY OF DARPP-32 IN RAT CINGULATE CORTEX. C.S. Toomim*[1], P. Greengard[2] & P.S. Goldman-Rakic[1] [1]Section of Neurobiology, Yale Sch. Med., New Haven, CT 06510 & [2]Lab. Molec. Cell. Neurosci., Rockefeller Univ. NY, NY.

Immunohistochemistry of rat rostral forebrain for 32 kdalton-dopamine regulated phosphoprotein (DARPP-32) at sub-maximal staining levels revealed consistent lateral asymmetries in several nuclei and functionally identified cortical areas, with each animal having its own pattern of staining. The most easily discriminable areas were medial frontal (Fr) cortex and striatum. Because of dopamine D1 receptor involvement in memory tasks (Sawaguchi & Goldman-Rakic Sci '91) and the importance of medial frontal cortex in memory tasks (Kolb & Tees Cerebral Cortex of the Rat '90), we analyzed cortical areas cingulate (Cg) 1, 2 & 3 and Fr 2. In Cg1 & 2, DARPP is lateralized in 14 out of 22 rats studied. The laterality is consistent throughout Cg1 & 2, but may show abrupt changes at the Cg 2 - 3 junction, the cingulate - retrosplenial junction, and at the Cg 1 - Fr 2 interface. The pattern is also independent of laterality in the striatum. Staining of adjacent sections for Calbindin and cAMP regulated phosphoprotein (ARPP) shows that any asymmetry of these proteins is not correlated with that of DARPP-32. The lack of correlation between the antigens indicates that the pattern is not due to perfusion artifact. The constancy of the pattern in assays done on different days rules out the possibility of staining artifact as a cause of the laterality. We are currently investigating the relationship between staining asymmetry and behavioral asymmetries.

SPATIAL DEFICITS AND HEMISPHERIC ASYMMETRIES IN THE RAT FOLLOWING UNILATERAL AND BILATERAL LESIONS OF POSTERIOR PARIETAL OR MEDIAL AGRANULAR CORTEX. V. King and J.V. Corwin*. Depts. of Psychology, Univ. of Wisconsin, Madison, WI 53706, and Northern Illinois Univ., DeKalb, IL 60115.

Previous research (Kesner et al., 1989) has indicated that the posterior parietal (PPC) and medial agranular (AGm) cortices play a prominent role in spatial processing in rodents. Bilateral (bi) PPC lesions produce allocentric spatial deficits and biAGm lesions produce egocentric spatial deficits.

To further examine the roles of AGm and PPC in spatial processing in rodents the current study examined the effects of unilateral (uni) PPC or AGm lesions to determine if space is represented in rodents in a hemispatial fashion as is the case in humans. Eight groups of rats received either uni or bi PPC, AGm, or cortical control lesions. The rats were tested in either an adjacent arm (egocentric) task, or a cheeseboard (allocentric) maze

As found in previous studies, biPPC operates were impaired in learning the allocentric task but not the egocentric task, while the AGm operates demonstrated the opposite pattern. The uniPPC operates demonstrated lateralized deficits in the allocentric task. Right hemisphere PPC operates were significantly impaired relative to left hemisphere operates. UniAGm operates demonstrated a deficit in the egocentric task intermediate to the controls and the biAGm operates. Analysis of the pattern of errors in the uni lesion groups indicated no evidence of hemispatial deficits in either the egocentric or allocentric tasks. Thus, unlike humans with PPC lesions rats do not demonstrate hemispatial deficits. The present results do indicate that, as in humans, there is a hemispheric asymmetry for allocentric spatial processing.

594.15

ROSTRAL-CAUDAL TOPOGRAPHY OF SUBCORTICAL EFFERENT PROJECTIONS OF THE MEDIAL AGRANULAR CORTEX IN THE RAT. J.V. Corwin , R.L. Reep*, V.King, and J. Leslie. Depts. of Psychology, Northern Illinois University, DeKalb, IL 60115, and Univ. of Wisconsin, Madison, WI 53706; and Dept. of Physiol. Sciences, Univ. of Florida, Gainesville, FL 32610.

Our previous research has indicated that unilateral destruction of the rostral or caudal medial agranular cortex (AGm) produces dissociable behavioral components of the neglect syndrome. Given the behavioral differences resulting from rostral vs. caudal lesions it is of some interest to examine differences in the anatomical connectivity of these components of the AGm. In the present study we have focused on the rostral-caudal (r-c) topography of the subcortical projections of AGm.

Autoradiography, Fluoro-Ruby, and WGA-HRP were used to make spaced microinjections throughout the r-c extent of AGm. A distinct r-c topography was noted for projections to caudate-putamen (c-p) and thalamus. Rostral injections produced terminal fields in the dorsal central core of the c-p rostral to the anterior commissure, injections in middle AGm at the level of the septum labeled the dorsolateral rim of c-p from the level of the genu to the fornix. Caudal AGm injections produced sparse terminal fields in the dorsal c-p caudal to the genu. In thalamus, rostral AGm projects to the centralis lateralis (CL), ventral lateral (VL), gelatinosis, and ventromedial (VM) nuclei; middle AGm to the dorsal CL, and posterior (PO) nuclei; and caudal AGm to PO and the ventral laterdorsal nucleus. Thus, the trend through r-c AGm is to demonstrate a rostro-ventral to caudo-dorsal pattern of thalamic labeling. The behavioral significance of these r-c differences in the efferents of AGm remain to be determined.

AREAL SUBDIVISIONS AND THALAMIC CONNECTIONS OF THE CAT'S INSULAR CORTEX. F. Clascá, A. Llamas* and F. Reinoso-Suárez. Dept. of Morphology, Autonomous Univ. of Madrid, Sch. of Med., 28029 Madrid, SPAIN.

The thalamic connections of the cortex surrounding the sylvian, ectosylvian, orbital and anterior rhinal sulci of the cat's brain were mapped by making small unilateral injections of WGA-HRP and serial reconstructions of the labeling. These results are part of a study aimed to elucidate the cortical territory of the cat's brain with cytoarchitectonic and connectional characteristics comparable to those reported on the insular areas of the old world monkey.

The main anatomofunctional subdivisions of the insula (Granular -IG-, Dysgranular -IDg-, and Agranular -IA- areas) were recognized in the cat. These newly defined insular areas are situated in the orbital gyrus and the orbital and anterior rhinal sulci. IG thalamic connections are stablished with somatosensory regions, such as the anterior suprageniculate and ventral posteroinferior nuclei. IDg is linked to the visceral, gustatory and premotor thalamus (ventral periphery of the ventral posteromedial nucleus, and the ventral lateral nucleus). IA is connected with the mediodorsal and parafascicular thalamic nuclei.

The connections of the classical cat's "insular" cortex (anterior sylvian gyrus and sylvian sulcus) are not comparable with those of the primate insula. Therefore we propose to name these zones anterior sylvian (SA) and parainsular (Pal) areas. SA is related with the caudal suprageniculate and ventromedial nuclei, and the most medial portion of the lateral posterior-pulvinar complex. Pal is mainly connected with the dorsal division of the medial geniculate complex. The connections of these two areas are reminiscent of the visual-auditory fields of the caudal superior temporal sulcus, and of the the parainsular cortex (Brodmann's area 52) of old world monkeys.

Functional anatomy of matching and discrimination of shape in man. R.Kawashima, P.E.Roland* and B.T.O'Sullivan Lab. for Brain Research and PET, Karolinska Institute, S10401,Stockholm, Sweden

The purpose of this study was to compare the activation patterns in the human brain of 1) discrimination versus matching as psychophysical procedures and 2) intra-modal (i.e. tactile) matching versus cross-modal (i.e. tactile-visual) matching. The regional cerebral blood flow was measured with ^{15}O-butanol and positron emission tomography in 9 normal volunteers during 1) a control state, 2) a tactile discrimination task, 3) a tactile matching task and 4) a tactile visual matching task. The right hand was used for all tasks. The shape stimuli were spherical ellipses (Roland &Mortensen, Brain Res. Rev. 12: 1-42,1987). The contralateral postcentral gyrus and supplementary motor area, ipsilateral anterior lobe of cerebellum and anterior insula were activated in all four tasks. Discrimination exclusively activated the prefrontal cortex and contralateral head of the caudate nucleus. The tactile-visual matching activated visual association areas: the posterior inferior. parietal lobule bilaterally, the ipsilateral inferior temporal cortex and the ipsilateral pulvinar. The tactile-tactile matching task activated the ipsilateral posterior inferior temporal cortex and the contralateral precuneus. The results indicated that the comparison of two stimuli, in contrast to matching, require the participation of the prefrontal cortex. That the remote visual association areas are of importance for the conversion of tactile shape into visual representations and the representation of visual shape.

VISUAL EVOKED MAGNETIC FIELD RESPONSES IN PARIETAL CORTEX IN MAN

S.Murakami*,S.Kuriki°,J.Miyazawa,M.Fujii,R.Fukatsu and N.Takahata Dep. of Neuropsychiatry,Sapporo Medical College and °Res.Ins. of Applied Electricity Hokkaido University, Sapporo 060 Japan

It is well Known that Parietal Cortex(PC) disorder induces a constructive apraxia and other visuo-spatial symptoms in man.Otherhand,in monky,neural responses to visual and other stimuli were recorded in the same neuron of PC. The function of PC seems to be related to integrating and processing visual information.But little is reported about the direct recording PC responses to visual stimuli in man. In the present work,we recorded magnetic field responses to visual stimulation in order to find out where the sources of the responses were in PC.

Four healthy adults were studied in the magnetically shieled room.Stimulation was provided randomly(1-2 sec) using 3 LED(light duration 0.5 or 1 sec fixed) arranged in center or 20°right or left to the subject,50 cm away from the eye.The magnetic field over PC was recorded with a 37-channel SQUID magnetometer system(BTi).128 responses were averaged and from the distribution of field responses a current dipole source was estimated.The spacial locations of the source were mapped on the MRI of each subject brain.

Magnetic field responses were found at latency 100-140, 190-220 and 260-290 msec.The dipole sources of their responses plotted on MRI suggested that they were located in intraparietal sulcus.

ENDOGENOUS POTENTIALS IN THE HUMAN ORBITOFRONTAL CORTEX EVOKED BY RARE AND REPEATED STIMULI. [1,3,4]E. Halgren*, [2]P. Baudena, [1]J. Clarke, [2,5]G. Heit. [1]INSERM CJF90-12, Neurology, CHRU Pontchaillou, 35033 Rennes, France; [2]INSERM U97, Paris; [3]Wadsworth VAMC; [4]Psychiatry and Brain Res., UCLA; [5]Neurosurgery, Stanford.

Evoked potentials were recorded from 15 patients with electrodes chronically implanted into the orbitofrontal cortex in order to localize their epileptogenic zones prior to surgical treatment. Electrodes were positioned perpendicular to the interhemispheric plane, from the inferior frontal g. to the g. rectus. P3-like potentials up to 200μV in amplitude were observed during sensory discrimination and recent memory tasks, with two patterns of response. The first was a triphasic negative-positive-negative waveform evoked at about 200-285-350ms latencies by rare target and distractor visual and especially auditory stimuli, but usually not by repeated words or faces. These peaks resembled the scalp N2/P3a/SW, but occurred up to 100ms earlier than the peaks at the scalp (Pz), and often with equal latency to distractor versus target stimuli. This waveform was widespread in the orbital cortex, with steep voltage gradients and occasional inversions in the most medial lead (g. rectus). The second pattern was a broad positivity with peak latency of about 350ms, approximately equal to that of the scalp P3b. This potential was generally larger and more focal than the triphasic waveform, was not recorded by more dorsal electrodes, and polarity-inverted in the most lateral cortex in one case. It was evoked by rare tones and symbols, and especially by repeated words and faces. In summary, the human orbitofrontal cortex appears to generate cognitive evoked potentials corresponding to the scalp N2/P3a/SW, and P3b. Whether orbital generators propagate significantly to the scalp requires additional study.

ORIGIN AND CHARACTERISTICS OF COHERENT THALAMO-CORTICAL 40-HZ OSCILLATIONS IN THE HUMAN BRAIN.

U.Ribary*, R.Llinás, F.Lado, A.Mogilner, A.Ioannides+, R.Jagow, M.Joliot and J.Volkmann. Center for Neuromagnetism, Dept. of Physiology and Biophysics, New York University Medical Center, New York, N.Y, 10016, USA; +Dept. of Physics, Open University, England.

A 14- and a 37-channel MEG system (BTi) were used, in order to determine the origin and the spatio-temporal dynamic properties of 40-Hz oscillatory activities in the human brain.

MEG data was recorded over an entire hemisphere (from 35-37 positions) before and during auditory processing. Magnetic 40-Hz responses were obtained from adult healthy subjects and from Alzheimer's patients. Magnetic Field Tomography (MFT) localized the underlying distributed activities within the brain (Ribary et al., Proc. Natl. Acad. Sci. 88, 11037-11041, 1991). This technique comprises a mathematically weighted source space which allows the spatial resolution of simultaneous sources localized at different brain depths. The MFT solutions were superimposed onto three-dimensional reconstructed brain images (MRI). Well-defined 40-Hz coherence was found between cortical-subcortical sites with a time shift that is consistent with thalamo-cortical conduction times. Similar data were also found in single recording epochs before and during auditory processing, indicating that the oscillatory avtivity in the 40-Hz range is continuously generated by the central nervous system, and is resetted by the auditory input. In addition, these single epoch recordings confirm the existance of a sweep-like rostro-caudal progression of activity at thalamic and at cortical level. These activities were altered in Alzheimer's patients, where a similar activity pattern was present, but the cortical component was reduced.

Our study indicates the possibility to analyze, non-invasively, the functional properties underlying higher frequency oscillations in the human brain and to evaluate its changes during pathological states.

595.1

EFFECTS OF PERIRHINAL CORTICAL LESIONS ON EXPLORATORY BEHAVIOUR AND SPATIAL MEMORY IN THE RAT. K.A. Wiig and D.K. Bilkey*. Department of Psychology, University of Otago, Dunedin, New Zealand.

The perirhinal cortex, situated between neocortical areas dorsal to the rhinal sulcus and entorhinal areas ventral to the rhinal sulcus, is considered to be a nodal point in the exchange of information between cortical and limbic regions. Behavioural results from primate studies suggest that the perirhinal cortex may play an important role in memory, as lesions of this area result in a severe memory impairment (Zola-Morgan et al *J. Neurosci*, Vol 9(12) 1989). To date, there have been no studies investigating the function of the perirhinal cortex in the rat. In order to determine whether damage to this region produces a memory related deficit, bilaterally lesioned and control rats were tested in two paradigms. The initial procedure investigated the rats' response to novelty and environmental changes. In this experiment, perirhinal lesioned rats spent significantly more time exploring both neutral and novel objects than control animals. In addition, lesioned animals showed an increased rate of rearing relative to control rats. Lesioned rats spent significantly less time grooming than control animals, whereas locomotor activity remained unchanged. Rats were also trained in the Morris Water Maze in order to test for deficits in spatial memory. It was found that rats with bilateral damage to the perirhinal cortex were not impaired at this task. In fact, latencies to find the platform were significantly lower than those of control animals. These results suggest that the perirhinal cortex, unlike other temporal lobe or limbic system structures, is not critically involved in spatial memory. Rather, it appears that this region may play some role in habituation or attentional processes.

595.2

MEDIAL SEPTAL LESIONS IMPAIR SPATIAL REVERSAL LEARNING. J.J. Boitano*, T. Small, M.M. Fiorini, S. Belanger, T. Savinelli and C.P.J. Dokla. Depts. of Psychology, Fairfield Univ., Fairfield, CT 06430 & Saint Anselm College, Manchester, NH 03102.

Reversal learning in F-344 rats that had sustained electrolytic lesions of the medial septal area (MS) was examined using a water task version of a T-maze. Rats had to locate a stable, hidden platform and avoid a collapsable, hidden platform positioned in either the NW or NE quadrants of a 1.5 m pool from a fixed starting position (S). Side preference was determined over 5 adaptation days using two stable, hidden platforms. Acquisition testing followed with 10 trials/day to the preferred side using a criterion of 9 out of 10 correct trials. Finally, 10 reversal problems were conducted using the stable and collapsable platforms. The MS rats were not significantly different from the sham-operated controls (CONT) during acquisition on a days-to-criterion measure. However, MS rats were highly impaired on the reversal problems compared to the CONT rats (5.4 vs. 2.7 days; $p < 0.002$). These results confirm and extend earlier findings on the importance of the MS-cholinergic pathway in spatial reversal learning.

595.3

SPATIAL MEMORY DEFICITS FROM LESIONS OF THE CHOLINERGIC BASAL FOREBRAIN USING IBOTENATE, QUISQUALATE, AND AMPA. J.J. Waite* and L.J. Thal. Dept. of Neuroscience & Neurology, UCSD & VAMC, San Diego, CA 92161.

Rats were lesioned in both the medial septum and bilateral nucleus basalis with 3 excitotoxins which interact with different subsets of glutamate receptors: ibotenic acid (Ibo), quisqualic acid (Quis) and AMPA. Animals were trained in a Morris water maze to escape to a submerged platform. All 3 groups of lesioned animals were deficient in their ability to acquire the spatial memory task in comparison to sham-operated controls. Three weeks later, Ibo and AMPA groups were tested on their ability to learn a new platform location. Neither of the 2 lesioned groups were able to incorporate knowledge of the new platform location as well as the control group, based on the overall latency to escape to the platform and quadrant analysis of individual search strategies. The activity of choline acetyltransferase (expressed as percent of control) was assayed from rats sacrificed 2 months after completion of surgeries:

	Frontal Cortex	Posterior Cortex	Hippocampus	Globus Pallidus
Ibo	62.1%	78.8%	56.0%	98.6%
Quis	52.5%	43.3%	57.9%	99.5%
AMPA	33.5%	16.3%	43.5%	89.1%

Each lesioned group exhibited spatial learning and memory deficits in comparison to controls in the water maze. The behavioral deficits measured did not correlate with the degree of depletion of ChAT activity assessed in regions of cholinergic terminal fields.

595.4

THE EFFECTS OF ENTORHINAL LESIONS ON SPATIAL MEMORY IN TWO VERSIONS OF THE WATER MAZE TASK. A.H. Nagahara*, T.A. Otto, and M. Gallagher. Department of Psychology, University of North Carolina, Chapel Hill, N.C., 27599.

Entorhinal cortex provides a major link between the hippocampus and neocortical systems. The present experiment examined the role of entorhinal cortex in spatial memory, a function that depends on the integrity of the hippocampus.

Long-Evans rats underwent either entorhinal lesion by aspiration or sham operation. Three weeks after surgery, rats were trained to locate a submerged platform in the Morris water maze (6 trials/day for 3 days; ITI 30s) followed by a free swim probe trial. Three weeks later animals received the same protocol for reversal training with the platform placed in the opposite quadrant. Animals were then trained on a single-trial place learning task involving one acquisition trial and a retention trial in a daily session (with the platform randomly relocated each day). After initial training, rats were repeatedly tested at delays of 30 s or 5 min.

Histological analysis showed extensive damage to entorhinal cortex with limited damage to surrounding regions; Timm stain confirmed extensive loss of the entorhinal projection to the outer molecular layer of the dentate gyrus. Entorhinal lesioned animals showed only modest impairment on the multiple-trial place learning task. However, on the single-trial place learning task, there was a pronounced delay-dependent impairment in the lesioned rats. These results suggest that memory demand (delay interval) substantially increases the sensitivity of a spatial task to the effects of entorhinal damage. Spatial Memory Impairment following Adrenalectomy-Induced Dentate Gyrus Volume Reduction in Rats. C.D. Condon* and E.J. Roy. Neuroscience Program and Dept. of Psychology, Univ. of Illinois, Champaign, IL 61820.

Long-term adrenalectomy (ADX) has previously been shown to cause selective cell loss in the hippocampal dentate gyrus of the rat. Using stereological estimates, we quantified the volume of the dentate gyrus and investigated whether damage to the dentate gyrus disrupts learning in two spatial memory tasks (Morris Water maze and 8-arm radial maze).

Rats were trained on the Morris Water Maze and radial maze (4 arms baited) 12 and 21 weeks after ADX respectively. Rats were sacrificed 7.5 months after ADX. Water maze performance was significantly impaired in ADX rats (n=8) relative to SHAM and partial ADX (n=8) rats. However, all rats were able to learn the maze. Radial maze learning (both working and reference memory) and reversal did not differ between groups. Dentate gyrus volume was greatly reduced in ADX rats (10 - 80%, mean 41%). Pyramidal cell regions CA1, CA2, CA3 and CA4 were unchanged. To account for the near-normal performance of ADX rats, we hypothesize that under conditions of long-term ADX (1) the dentate connectivity is redundant (2) the dentate is capable of sprouting and reorganization or (3) another brain region is functioning in place of the dentate gyrus.

595.6

THE EFFECTS OF LESIONS OF THE ENTORHINAL CORTEX AND THE HORIZONTAL NUCLEUS OF THE DIAGONAL BAND OF BROCA ON PERFORMANCE OF A SPATIAL LOCATION ORDER RECOGNITION TASK. D.L. Johnson*, A.A. Chiba and R.P. Kesner. Dept. of Psychology, Univ. of Utah, Salt Lake City, Utah 84112.

Rats were trained on an 8-arm radial maze to perform an order recognition memory task for spatial location information. Each day, rats were given a study phase followed by a test phase. In the study phase, rats were allowed to visit all 8 arms in a predetermined sequence that varied on a daily basis. During the test phase, the rats had to choose which of two arms was visited earlier in the study sequence of 8 arms, in order to receive additional food reinforcement. Temporal distance refers to the number of spatial locations that are visited between test items. In this study, performance for temporal distances of 0,2,4, and 6 served as the dependent variable.

After extensive training, percent correct performance increases as a function of temporal distance with excellent performance for distances of 2, 4, and 6 but chance performance for distance of 0. After rats displayed better than chance performance on tests of the 2,4, and 6 distances, they received electrolytic lesions of the entorhinal cortex (ENTO), ibotenic or quisqualic acid lesions of the horizontal nucleus of the diagonal band of Broca (HNDB), or saline injections into the HNDB or sham operations (CONTROL).

CONTROL rats continued to perform well for the longer temporal distances. However, ENTO and HNDB lesioned groups showed a performance deficit for all temporal distances. The quisqualic acid HNDB lesion group displayed a greater performance deficit than the ibotenic acid HNDB lesion group. These findings suggest that the ENTO and the HNDB play an important role in memory for the sequential ordering of spatial information.

595.7

EFFECTS OF PARIETAL CORTEX AND HIPPOCAMPUS IN MEMORY FOR DISTANCE INFORMATION. J.M. Long*, R.P. Kesner, Dept. of Psychology, Univ. of Utah, Salt Lake City, UT 84112.

It has been postulated that rats form an internal representation of the environment as a spatial cognitive map. Of the many cues (e.g.distance, direction, spatial location) available to an animal in spatial tasks, it is not known which cues are represented in memory. In order to test for the contribution of the hippocampus and parietal cortex to memory for allocentric spatial cues, Long-Evans rats were trained on a go/nogo task which required the animal to remember the distance between two identical objects. After acquisition, rats were given either hippocampal or parietal cortex lesions, which resulted in impaired performance. In a different experiment rats were trained to discriminate the distance between two identical objects. Distance discrimination performance was impaired in rats with parietal cortex, but not hippocampal lesions. It appears that rats can represent allocentric distance information within their spatial cognitive maps. Furthermore, the hippocampus might be involved in temporary representation of allocentric distance information, whereas the parietal cortex might be the site of a more permanent representation of allocentric distance information.

595.8

THE EFFECTS OF LESIONS OF THE DORSAL HIPPOCAMPUS OR THE VENTRAL HIPPOCAMPUS ON PERFORMANCE OF A SPATIAL LOCATION ORDER RECOGNITION TASK. A.A. Chiba*, D.L. Johnson, and R.P. Kesner, Department of Psychology, University of Utah, Salt Lake City, Utah 84112.

Each rat was trained on an eight-arm radial maze task examining memory for the temporal order of spatial location as a function of temporal distance. During the study phase of each trial, rats were allowed to visit each of eight arms once in an order that was randomly selected for that trial. During the test phase of each trial, rats were required to choose which of two arms occurred earlier in the sequence of arms visited during the study phase. The arms presented in the test phase varied according to temporal distance (0,2,4,6), or the number of arms in the running sequence of the study phase that occurred between the two test arms. Once the rats reached a criterion of 75% correct performance for the temporal distances of 2, 4, and 6 (rats continued to display chance performance for the temporal distance of 0), electrolytic brain lesions of the dorsal hippocampus, the ventral hippocampus, or the cortex immediately above the dorsal hippocampus (control lesions) were made.

Following surgery, control lesioned rats continued to perform at chance for the temporal distance of 0, but performed at or above 75% correct for the temporal distances of 2, 4, and 6. The performance of rats with ventral hippocampal lesions did not significantly differ from that of control lesioned rats. The performance of rats with dorsal hippocampal lesions was at chance for both the temporal distances of 0 and 2, but did not significantly differ from that of control animals for the temporal distances of 4 and 6. These data suggest that memory for the temporal order of spatial location across all temporal distances is not dependent on the integrity of the ventral hippocampus, whereas memory for shorter temporal distances is dependent on the integrity of the dorsal hippocampus. However, previously reported data (Chiba & Kesner, 1989) revealed a performance deficit across all temporal distances (0,2,4, and 6) in rats with total hippocampal (dorsal and ventral) lesions. Thus, it appears that the effect of total hippocampal lesions in rats on memory for the temporal order of spatial location is not equivalent to the combined effects of independent dorsal and ventral hippocampal lesions in rats.

595.9

PHTHALIC ACID LESIONS OF THE RAT NUCLEUS BASALIS MAGNOCELLULARIS (NBM) IMPAIR MEMORY IN A DOUBLE Y-MAZE. **P.E. Mallet*, R.J. Beninger, K. Jhamandas and R.J. Boegman. Depts. of Psychol. and Pharmacol. Toxicol., Queen's Univ., Kingston, Canada, K7L 3N6.**

The differential effects of intra-NBM injections of excitotoxins on amygdalar choline acetyltransferase (ChAT) rather than cortical ChAT, may explain the differential mnemonic effects observed. The present study evaluated the mnemonic effects of intra-NBM infusions of phthalic acid (1,2-Benzenedicarboxylic acid), an excitotoxin that strongly decreases amygdalar ChAT activity. Sprague-Dawley rats were trained to traverse a double Y-maze for food reinforcement until performance exceeded 88% correct. Successful performance depended on accuracy in both a working and a reference memory component. Rats were then given either unilateral phthalic acid (300 nM, 0.5 µl) or sham (0.9% saline, 0.5 µl) lesions of the NBM, and were again tested on the maze. Biochemical analysis revealed that phthalic acid lesions produced a large decrease in amygdalar ChAT, but had little effect on cortical ChAT. Behavioral results showed an increase in working but not reference memory errors in the phthalic acid lesioned rats, and no effect in the sham operated controls. These results suggest that the cholinergic projections from the NBM to the basolateral amygdala play an important role in mnemonic functioning.

595.10

Amygdala Lesions Impair and Fornix Lesions Enhance Acquisition of Information about Spatial Locations: Dependence on Method of Reinforcer Presentation. R.J. McDonald* and N.M. White. Department of Psychology, McGill University, Montreal, Québec, Canada.

We have previously shown (McDonald and White, Neuroscience Abs. 17, 54.1) that lesions of the amygdala, but not of the hippocampus or dorsal striatum, impair acquisition/expression of a conditioned *cue* preference using 2 arms of an 8-arm radial maze in which the arms were distinguished from each other by the presence or absence of a light at the entrance. In the present experiment we tested the effects of these lesions on a conditioned *place* preference using 2 randomly chosen arm locations (excluding adjacent locations) for each subject on a radial maze. The maze was physically rotated before each daily trial so the arms were distinguished solely by their spatial locations. Each pairing consisted of a session in which a rat was confined to one arm that contained food and a session in which the rat was confined to the other arm with no food, in a counterbalanced manner. On the test day, each rat was given free access to arms in both locations for 20 min and the amount of time spent on each arm was recorded. Control rats showed a preference for the location associated with food after 3 pairings, but not after 1 or 2 pairings. Rats with bilateral damage to the lateral amygdala showed no significant preference for either location. Rats with damage to the fornix showed significant preferences for the food-associated location after 1, 2 or 3 pairings. These results suggest: 1) the method of reinforcer presentation may be a factor determining which neural substrate mediates acquisition of a memory; 2) when rewards are presented passively, acquisition of information about their relationship to neutral stimuli may be mediated by a memory system that includes the amygdala, 3) when rewards are presented passively, hippocampal processing may interfere with acquisition even when the task involves learning about spatial locations.

595.11

CUE FAMILIARITY REDUCES SPATIAL DISORIENTATION FOLLOWING HIPPOCAMPAL DAMAGE. J.E. Holden* and B. Therrien. The University of Michigan, Ann Arbor, MI 48109

When the hippocampus (HPC) is damaged, place navigation is disrupted and spatial disorientation results. A single cue marking a hidden goal has decreased disorientation in rats. However, they were impaired when compared to controls. We hypothesized that cue familiarity would enhance the ability of rats with HPC damage to locate a cued hidden platform in the Morris water test. After preoperative training with the cue (n = 21) or handling only (n = 17), rats were given electrolytic bilateral HPC (BHPC) lesions or sham surgery for controls. All rats were then tested for four days, six trials per day, with the cue marking the platform location. One way ANOVA showed that rats with BHPC lesions familiar with the cue (FB) were significantly more efficient than rats unfamiliar with the cue (UB) in swim time (X = 10.31 ± 2.20 vs 46.72 ± 7.51 seconds, $p<.05$) and in directional heading error (X = 31.98 ± 3.40 vs 57.92 ± 4.02 degrees, $p<.05$) on Day 1. These differences occurred across the four test days. No significant differences were found between FB animals and controls familiar with the cue (FC). A second experiment tested the effect of cue familiarity when a competing cue was present. Cue familiar animals were tested with a distractor in the testing environment postoperatively. No significant differences were found between FB (n = 7) and FC (n = 4) animals. We conclude that: 1) cue familiarity improves performance on a spatial memory task following HPC damage; and 2) the effect of cue familiarity remains in the presence of an environmental distractor.

595.12

A ROLE FOR THE LATERAL STRIATUM IN THE MEDIATION OF VISUOSPATIAL COGNITION. JCS Furtado* and MF Mazurek McMaster University Medical Centre, Hamilton, Ontario, CANADA

Recent studies have emphasized the importance of parallel pathways in the cortico-striato-pallido-thalamic circuit. In this model, the medial striatum is understood as being involved in "cognitive" processing while the lateral striatum is regarded as selectively mediating "motor" function. We have studied the "cognitive" and "motor" abilities of rats with bilateral quinolinate-induced lesions of the medial (MED) or lateral (LAT) striatum. Compared with saline-injected controls, the experimental groups were significantly impaired in the place task version of the Morris Water Maze. No group differences were found when the platform was visible, suggesting that the observed impairment in the water maze reflects an impairment, on the part of the MED and LAT groups, to use visuospatial cues. By contrast, when the same animals performed two tests of motor behaviour (tongue extension and food manipulation) only the LAT group was impaired. This study confirms the selective role of the lateral striatum in the control of specialized motor behaviours, but suggests that both the medial and lateral striatum are involved in the mediation of visuospatial cognition.

595.13

HEMIDECORTICATION, PRIOR TRAINING AND LEFT-RIGHT RESPONSE LEARNING IN THE RAT: EVIDENCE FOR A LEFT-HEMISPHERE SPECIALIZATION FOR THE LEFT-RIGHT SENSE. M. Noonan* and S. Axelrod, Canisius College and SUNY/Buffalo, Buffalo, New York 14208.

We hypothesized that unilateral cortex removal has two opposite effects pertinent to learning left-right response tasks: (1) provision of a pronounced neural asymmetry which facilitates acquisition, but also (2) induction of a unilateral response bias so strong that the facilitatory effect is masked. We trained hemidecorticated and sham-operated rats on two water-escape T-maze tasks, predicting that, in the hemidecorticates, mastery of the first task should break the induced response bias, thereby allowing the facilitation to appear on the second. The prediction was confirmed, but only for the right operates, who were indeed worse than the shams at learning either task when it was first, but better than the shams at either task when it was second. By contrast, left operates were worse than the shams at both tasks, irrespective of testing order. (Morris-test performance was unaffected by either left or right hemidecortication.) The results confirm the hypothesis that induced neural asymmetry can facilitate left-right learning, and appear to reveal a left-hemisphere specialization in rats, parallel to that in humans, for the ability to tell left from right.

595.14

DISSOCIATING THE EFFECTS OF HIPPOCAMPAL AND AMYGDALAR LESIONS IN RATS WITH A BATTERY OF NONSPATIAL MEMORY TASKS. D.G. Mumby*, J.P.J. Pinel, & T.J. Kornecook. Dept. of Psychology, University of British Columbia, Vancouver, B.C. Canada V6T 1Z4.

We tested normal rats on a battery of nonspatial memory tests that resemble some of those used in studies of brain-damage-produced amnesia in monkeys: (1) Object discrimination and reversal, (2) concurrent object discriminations, (3) delayed nonmatching-to-sample (DNMS) with various retention delays (4, 15, 60, and 120-s) and list lengths (1, 3, 5, and 7 items), and (4) temporal-order recognition. Each task made use of the same apparatus and, like the monkey versions of these tasks, each one used objects as test stimuli. The performance of intact rats on these tasks was compared to that of rats that received either bilateral aspiration lesions of the hippocampal formation and posterior parietal cortex (HF) or posterior parietal cortex alone (PPC), or bilateral electrolytic lesions of the amygdala (AM). All testing was conducted postsurgery.

The results revealed several dissociations. Rats with HF or PPC lesions were impaired in learning the object discrimination; rats with HF lesions were impaired on the reversal. Rats with AM or HF lesions were impaired in learning the concurrent object discriminations, and those with HF lesions were significantly worse than those with AM lesions. Rats with AM lesions were impaired in learning DNMS, but after all of the rats had mastered this task at a 4-s retention delay, those with AM lesions performed as well as the intact rats at longer delays, whereas those with HF or PPC lesions were impaired. There were no significant differences among the groups on the DNMS-with-lists task or on the temporal-order recognition task. The resemblance that the present test battery bears to the nonspatial test batteries that are often used in studies of brain-damage-produced amnesia in monkeys should enable direct comparisons between the present results and those of similar experiments in monkeys.

595.15

THE ROLE OF POSTERIOR CINGULATE CORTEX (AREA 29) IN LEARNING AND MEMORY IN THE RAT. R. J. Sutherland*, J. M. Hoesing, R. Kornelson and J. E. Evanson. Depts. of Psychology and Physiology, Univ. of New Mexico, Albuquerque, NM 87131-1161.

Area 29 is extensively connected with the hippocampal system (HPC), cortical association areas, and dorsal thalamus. Clinical studies and experimental work with animal models suggest that area 29 damage can produce amnesic symptoms. Our experiments were designed to explore the characteristics of the memory disorder and to clarify the anatomical basis for these effects. Prior work (J. Neurosci. 1988, 8(6): 1863-1872) with rats revealed that area 29 aspiration produces a long-lasting impairment of place learning using the Morris water task. We now demonstrate that: 1. destruction of area 29 intrinsic neurons using multiple microinjections of the cytotoxin, quisqualic acid, produces an impairment of place navigation which is indistinguishable from nonspecific aspiration lesions, 2. limiting the neurotoxic damage to either primarily area 29c or 29d produces similar, but less dramatic, impairments than total removal, 3. using a combined lesion strategy including neurotoxic HPC, electrolytic anterior thalamic, and area 29 aspiration lesions, unilateral crossed lesions of area 29 + HPC or area 29 + anterior thalamus produce impairments comparable in magnitude to destruction of these structures bilaterally, 4. increasing the interval between place navigation training and area 29 damage does not affect the impairment, 5. posterior parietal cortex, but not perirhinal, aspirations produce anterograde and retrograde impairments comparable to area 29 damage, and 6. area 29 aspiration impairs the ability to resolve a nonspatial, negative patterning discrimination in a discrete trial bar-pressing task. Thus, area 29 circuitry is important in certain forms of memory, acting in concert with HPC, thalamic, and posterior parietal circuitry.

595.16

SELECTIVE DAMAGE OF FOREBRAIN-CORTICAL PATHWAYS: COMPARATIVE EFFECT ON SPATIAL LEARNING AND CORTICAL CHOLINERGIC RELEASE. M. Ammassari-Teule* G.L. Forloni, D. Amoroso and S. Consolo. Inst. of Psychobiology , C.N.R. 00198 Rome Italy and Mario Negri Inst., 20157 Milan, Italy.

Rats were assigned to one of the following treatments: mechanical deafferentation of the basal forebrain-cortical projections (DEAFF), ibotenic (IBO) or quisqualic (QUIS) acid lesions of the nucleus basalis magnocellularis (NBM) and sham operations (SHAM). They were trained to perform radial eight-arm maze tasks with all the paths or only four paths baited. Cortical cholinergic release measured by microdialysis in vivo and choline acetyltransferase (ChAT) activity were then assessed in the four lesion conditions. The results show that, in the full baited maze task, only the DEAFF group showed severe spatial learning deficits. In the four-baited path task, the deafferented group was still more impaired but some defects emerged in rats with neurotoxic lesions of the NBM. ChAT activity was reduced by 30% after IBO lesions and by more than 50% after DEAFF or QUIS lesions. Cholinergic release, however, was unaffected by IBO lesions but dropped in the same fashion after DEAFF or QUIS lesions. Thus, no correlation between cortical cholinergic depletion and spatial learning impairment was evident. The similar behavioral deficit produced by DEAFF and fornix sections suggests that, among the basal forebrain-cortical pathways, descending fibers projecting towards the septo-hippocampal system could exert a strong control on spatial learning.

595.17

MEMORY FOR OBJECTS, SPATIAL LOCATIONS AND MOTOR RESPONSES: TRIPLE DISSOCIATION AMONG THE HIPPOCAMPUS, CAUDATE NUCLEUS AND MEDIAL EXTRASTRIATE VISUAL CORTEX. R. P. Kesner*, M. Dakis, Dept. of Psychology, Univ. of Utah, Salt Lake City, UT 84112.

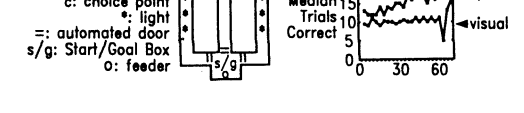
Rats were first trained in a matching or non-matching-to-sample task for spatial location, response and visual object information aimed at measuring working or data-based memory for allocentric spatial, response (egocentric spatial) and sensory-perceptual (visual object) attributes. After training, rats received lesions of either the hippocampus, caudate nucleus or medial extrastriate visual cortex. After recovery from surgery they were retested. Results indicated that there was only a memory deficit for spatial location information even at the shortest delays for rats with hippocampal lesions, only a memory deficit for response information even at the shortest delays for rats with caudate nucleus lesions, and only a memory deficit for visual object information even at the shortest delays for rats with medial extrastriate visual cortex lesions. Thus, there appears to be a triple dissociation among the hippocampus, caudate nucleus and medial extrastriate visual cortex in mediating allocentric spatial, response (egocentric spatial) and sensory-perceptual (visual object) attributes of memory. The results support the neurobiology of an attribute model of memory.

595.18

DIFFERENCES IN SPATIAL AND VISUAL WORKING MEMORY PERFORMANCE OF RATS IN A PHI(ϕ)-MAZE. W. J. Wilson*, N.C. Steinbronn, J.C. Lopshire, P.H. Galloway, S.A. Kellenberger, A.M. Hartman, & R.L. Bennett. Dept. of Psychological Sciences, Indiana University – Purdue University, Fort Wayne, IN 46805, USA.

Working memory in the rat has been studied extensively with tasks that involve spatial cues, often using the radial-arm maze or the T-maze. We compared working memory for spatial cues with that for visual cues in the phi (ϕ)-maze, a maze modeled loosely after the "automated T-maze" designed by Berger (1977), in which the rat is reinforced upon its return to the Start Box for having chosen the correct arm.

Rats were run in one of two reinforcement conditions in the ϕ-maze. In the Spatial task, rats were reinforced for alternately selecting the left and right arms. All 5 rats in this task reached the criterion of 15 or more correct trials on two successive daily 20-trial sessions within 16 sessions. In the Visual task, rats were reinforced for alternating between the lighted and dark arms. None of the 6 rats in this task reached the criterion within 60 sessions; they performed at near chance levels throughout, yet all readily learned a visual discrimination task in the ϕ-maze thereafter. Thus rats were able to perform a task that required working memory of spatial information, but were unable to use visual working memory, despite being able to discriminate based on the same visual cues. Explanations include the possibilities that rats differ in their capacity to encode spatial (proprioceptive, kinesthetic?) and visual information in working memory, or that the omni-present spatial cues interfered with learning of the Visual task.



596.1

RECOVERY OF SPATIAL NAVIGATION AND LEARNING IN THE MORRIS WATER MAZE AFTER BILATERAL TRANSECTION OF THE PERFORANT PATH IN RATS. R.W. Skelton* & R.K. McNamara. Dept. Psychology, Univ. Victoria, Box 3050, Victoria, British Columbia, CANADA, V8W 3P5.

Knife cuts to the perforant path (PP) disrupt acquisition of spatial (place, locale) learning in the Morris water maze (Skelton & McNamara, 1992 Hippocampus, 2, 78). The present study examined retention and recovery of both spatial navigation and place learning.

Rats were trained to locate a submerged platform, then given bilateral knife cuts of the PP, either in the angular bundle (1.7 mm ant. to EBZ) or 2 mm further anterior (to dennervate only the dorsal hippocampus). Starting 48 hrs after surgery, rats were tested with 4 submerged platform trials, 1 probe trial and 1 visible platform trial daily for 14 days, then weekly for 6 weeks. Rats with cuts at either level of PP were initially impaired on submerged platform and probe trials, but not on visible platform trials. Performance on probe trials reached control levels after about 10 test days, and continued to improve over the 6 weekly tests. A residual deficit was revealed when the platform was then moved to a new location: rats with cuts at either level took 3-4 days to reach the level of probe trial performance reached by controls in 1 day. These results suggest that 1) damage to the PP innervation of the dorsal hippocampus may be as debilitating as total PP transection 2) the PP is required for accurate navigation and place recall, 3) substantial recovery or retraining of spatial navigation occurs within 10 days, and 4) recovery of place learning remains incomplete for up to two months. (Supported by research grant from NSERC.)

596.2

PERFORMANCE OF ISCHEMIC RATS ON WIN-STAY AND WIN-SHIFT TASKS. E.R. Wood,* T.J. Bussey and A.G. Phillips. Department of Psychology, University of British Columbia, Vancouver, BC, Canada V6T 1Z4.

The present study was designed to assess in rats the effects of ischemia-induced damage on the performance of two 8-arm radial maze tasks: one (spatial win-shift) sensitive to lesions of the hippocampus, and the other (cued win-stay) sensitive to lesions of the caudate. Male Wistar rats received either sham surgery or 20-min transient forebrain ischemia induced by a combination of bilateral carotid occlusion and hemorrhagic hypotension. Following an 8 week recovery period the rats were tested on one of the two tasks. Each trial of the win-shift task consisted of two phases. In phase 1, 4 target arms were blocked and rats were allowed to enter and retrieve food from the 4 unblocked arms. In phase 2, all arms were unblocked and the previously blocked target arms were baited. Rats were allowed to explore the maze until all 4 target arms had been visited. Each rat received daily trials with a delay of 4-s between phase 1 and phase 2, until they reached the criterion of 4 target-arm entries in the first 5 arm entries during phase 2, for 3 consecutive trials. Rats then received 15 trials with a 5-min delay, and 6 trials with a 2-h delay. A random set of 4 target arms was used on each trial. Ischemic rats were significantly impaired at the 2-h delay, but not at the 4-s or 5-min delays, indicating that ischemia affects performance of this spatial win-shift task only at long delays.

In the cued win-stay task, all 8 arms were accessible, with light cues at the distal ends of 4 target arms. On each daily trial, rats were allowed to explore the maze until they had entered and retrieved food from each lit arm twice (arms were rebaited after the first entry). After a rat retrieved food from a lit arm for the second time, the light was turned off. A random set of 4 target arms was used on each trial. Ischemic rats were not significantly impaired on this cued win-stay task.

These findings of ischemia-induced impairments on a win-shift task at long delays, but not on a cued win-stay task suggest that this model of ischemia causes functional damage to the hippocampus, but not to the striatum.

596.3

AGED C57 MICE DECLINE IN SPATIAL LEARNING PERFORMANCE AND ASSOCIATED HIPPOCAMPAL PROTEIN KINASE C ACTIVITY. J.M. Wehner* and D.E. Fordyce. Institute for Behavioral Genetics, The University of Colorado at Boulder, Boulder, CO. 80309-0447

C57BL/6 (Ibg and Nia) mice were tested on the Morris water maze task for 6 days followed by 12 days of testing on the place learning-set task (8 trials/day with each task). Mice were tested at 3, 14, and 25 months of age. A decline in learning performance was observed in mice 15 and 25 months of age compared to mice 3 months of age. Mice 25 months of age were significantly impaired in both the Morris and place learning-set task probe trial performance compared to 3 months of age mice ($p<.02$) with no significant alteration in swim speed. These aged mice also demonstrated a significant reduction in membrane-bound hippocampal protein kinase C activity ($p<.05$) with no significant change in cytosolic or loosely-bound protein kinase C activity. The effects of aging in C57 mice on spatial learning performance and hippocampal protein kinase C activity were found in both the Ibg and Nia substrains. These data, therefore, indicate that the age-induced decline in spatial learning performance in C57 mice may be associated with an age-induced alteration in hippocampal protein kinase C activity.

PHYSICAL ACTIVITY ENHANCES SPATIAL LEARNING PERFORMANCE WITH AN ASSOCIATED ALTERATION IN HIPPOCAMPAL PROTEIN KINASE C ACTIVITY IN C57 AND DBA MICE. D.E. Fordyce* and J.M. Wehner. Institute for Behavioral Genetics, The University of Colorado at Boulder, Boulder, CO. 80309-0447

The effects of physical activity on spatial learning performance and associated hippocampal functioning were examined in C57BL/6 and DBA/2 (Ibg) mice. Previously, we observed a marked enhancement in spatial learning performance and associated alterations in hippocampal cholinergic function of rats exposed to physical activity (Fordyce and Farrar, 1991, Beh. Brain Res.46:123-133). Because of genetic analyses afforded by using inbred strains of mice, it was of interest to examine if this physical activity effect could be achieved in two strains of mice differing in learning performance (Wehner et al., 1987, Brain Res. 523:181-187). C57 and DBA mice (3 months of age) were subjected to an eight week physical activity protocol consisting of moderate pace (0.4 mph) treadmill running 5 days/week and 60 min/day. Mice were then tested on the Morris water task for 6 days followed by the place learning-set task for 12 days (8 trials/day with each task). Hippocampal protein kinase C activity was measured in cytosolic, loosely-bound and membrane-bound homogenate fractions. Mice subjected to the physical activity protocol were compared to age-matched sedentary controls from the same set of litters. Physical activity enhanced performance on both the Morris and place learning-set task probe trials ($p<.02$). DBA mice, which characteristically perform poorly in comparison to C57 mice, were enhanced to perform similarly to C57 mice. These alterations in performance were accompanied by alterations in membrane-bound protein kinase C activity ($p<.05$). The data from this study, therefore, indicate that the protein kinase C second messenger system, as well as cholinergic function, in the hippocampus may be involved in the physical activity-induced enhancement of spatial learning performance.

MOUSE STRAIN DIFFERENCES IN LEARNING SET SPATIAL NAVIGATION PERFORMANCE

B.F. Petrie* Dept of Psychology, Red Deer College Red Deer, Alberta, Canada T4N 5H5

Swiss Webster (SW); DBA; and Deer Mice (DM) were tested for acquisition and retention of a learning set place task in the Morris water maze. The learning set consisted of daily placing the hidden platform sequentially at 1 of 4 separate locations in the pool. All animals were swum for 63 days in this version of the water task. SW mice were unable to reliably find the platform. The time taken by DBA and DM in escaping the pool declined rapidly, reaching asymptote within 21 days, with DM showing the ability, throughout the study, to reach the platform significantly faster than either SW or DBA. Analyses of swim path selection used by the 3 strains clearly indicated that DM were the most systematic in the selecting and sequencing, from a variety of potential strategies, the appropriate methods necessary for the most efficient solution of the problem. The present results suggest, that in light of the strain differences observed in swimming behaviors investigation of strain differences in the neuroanatomic structures believed to be related to the solving of spatial problems, might be a fruitful area of investigation.

SPATIAL LEARNING IN DEER MICE: EFFECTS OF SEX AND REPRODUCTIVE STATUS. M. Kavaliers,* L. A. M. Galea, E. L. Hargreaves, D. L. Innes and K. -P. Ossenkopp. Neuroscience Prog., Univ. Western Ontario, London, ON, Canada.

Sex difference in spatial ability have been proposed to be related to mating systems, space use, and reproductive condition. Deer mice, Peromyscus maniculatus, are polygynous rodents with reproductive males displaying greater range sizes than females. The present study considered the effects of reproductive status on spatial learning by males and females of two different populations of deer mice. The performance of the two populations of adult breeding and non-breeding deer mice was examined in a Morris water maze. Latency of the animals to reach a hidden platform was measured over 6 blocks of 4 trials. All groups of mice were able to learn the spatial task, with the mice derived from a population originally present in an arid interior region acquiring the task more slowly than mice that were descendants of a population inhabiting a small island. In both populations, breeding males showed significantly faster acquisition and better retention of the spatial task than did breeding females. In contrast, non-breeding mice of both populations displayed no significant sex differences in their spatial performance. These findings indicate that reproductive and hormonal condition have significant effects on the display of sex differences in spatial learning.

ACQUISITION, LEARNING-SET, AND LONG-TERM RETENTION DEFICITS OF SPATIAL INFORMATIONS IN AGED MICE. C. Lebrun, I.Koenig*, and R.Jaffard. Laboratoire de Neurosciences Comportementales et Cognitives, URA 339 and *Laboratoire de Neurobiologie Cellulaires, Univ. Bordeaux I et II, Avenue des Facultés, 33405 Talence, France.

Ability in learning and memory during aging in mice has been investigated using two-choice discrimination tasks in a 8-arm radial maze. Each discrimination consisted of presenting two adjacent arms (pairs) with only one always the same, baited across trials. On the first phase, animals were concurrently trained on two pairs (Acquisition 1) until they reached a criterion of 13 correct responses out of 16 successive trials. On the second phase (Acquisition 2), animals learned to discriminate the two other pairs. To acquire the task, the animals had the possibility to use either extra-maze (place) or intra-maze cues (black and white visual cues constantly placed on each arm across the trials).

Results showed that, as compared to young mice (4-5 months), aged animals (24-25 months) exhibit i) slower acquisition on the first two pairs (Acquisition 1), ii) weacker positive transfer from Acquisition 1 to Acquisition 2, iii) a long-term retention deficit (over 20 and 40 days) of previously acquired informations (Acquisition 1 and 2).

An additional experiment was conducted in order to verify the contribution of intra-maze cues to discrimination performance in young and aged mice. Results showed that young mice use preferentially extra-maze cues, whereas old animals learn by using both intra- and extra-maze cues. Supported by CNRS, URA 339, and Fondation "France Alzheimer".

MEMORY DEFICITS AND ASSOCIATED DECREASES OF CEREBRAL 2-DG LABELLING INDUCED BY CHRONIC ALCOHOL CONSUMPTION IN MICE: REVERSAL BY METHYL β-CARBOLINE-3-CARBOXYLATE ADMINISTRATION. B. Bontempi, D.J. Beracochea, C. Destrade* and R. Jaffard. Lab. Neurosci. Comportementales et Cognitives, URA CNRS 339, Univ. Bordeaux 1, Av. Facultés, 33405 Talence, France.

We previously showed that long term (17 months) chronic alcohol consumption by mice produced significant reduction in cerebral energy metabolism as measured by 2-DG labelling in the diencephalon, in particular the mammillary body (MB) (Soc. Neurosci., 1991, Abs. 17, 481). Here, we investigated the effects of two shorter durations (6 and 12 months) of alcohol consumption by Balb/c mice on 2-DG uptake patterns observed following a memory test in a T-maze. 2-DG was injected into the jugular vein immediately before a 35 min period of testing for sequential alternation in a T-maze and the subjects were sacrificed for autoradiographic analysis using the relative 2-DG method. Although no significant effects on either 2-DG labelling or memory performance were observed after 6 months of alcohol consumption in comparison to controls, mice of the 12 month group showed significantly increased susceptibility to interference in the alternation task. This mnesic deficit was associated with a concomitant decrease in testing-induced 2-DG labelling intensity of the MB. Administration of β-CCM (0.5 mg/Kg s.c.) to subjects of the 12 month alcohol group reversed the memory impairment of these mice as compared to saline-injected controls. Parallel studies of the effect of β-CCM on 2-DG labelling patterns in these mice are being conducted in an attempt to establish an eventual correlation between memory performance in the alternation task and MB metabolic activity.

596.9

LITTER SEX-RATIOS AFFECTS ADULT PERFORMANCE IN A SPATIAL TASK. L.A. M. Galea*, K.-P. Ossenkopp, & M. Kavaliers. Neuroscience Prog., Univ. of Western Ontario, CANADA.

Previous research in this laboratory has shown that breeding adult meadow voles *Microtus pennsylvanicus* acquire a spatial task in a sexually-dimorphic manner, favoring males, and that no sex differences are shown in performance in immature voles. The present study addressed the question of whether there would be sex differences in performance on a spatial task in breeding adult voles which had previously not demonstrated a sex difference when tested as juveniles. Sixteen litters of adults were re-tested in a hidden platform Morris water-maze six weeks after being initally tested at either day 10, 15, 20, or 25 after birth. (Juvenile voles tested at days 20 or 25 acquired the task faster than voles tested at days 10 or 15). Adult voles that had previously learned the task at day 20 or 25 retained the task and showed no sex differences in performance. However, adult breeding voles previously tested at days 10 or 15 did demonstrate a sex difference in performance favoring males but **only** in litters with a female-biased sex-ratio (♀ > ♂). Thus, females in male-biased litters acquired the task as rapidly as males. This suggests that meadow voles retained the spatial task better if they had initially showed faster acquisition or learned the task at an older age, and that the relative amount of androgens *in utero* may influence the development of spatial ability.

EFFECTS ON SIMPLE ASSOCIATION AND SPATIAL MEMORY OF NEUROTOXIN LESIONS TO THE AVIAN HIPPOCAMPUS. H.N. Rice and D.F. Sherry*. University of Western Ontario, London, Ont., N6A 5C2, Canada.

Black-capped chickadees (*Parus atricapillus*) (n=11) were trained on a simple cue association and a spatial task in an indoor aviary with 6 artificial trees, each with 10 food sites. The spatial task required birds to find 6 seeds placed in the same sites from trial to trial. The cue task required birds to find 6 seeds at cued sites randomly assigned to locations on each trial. After reaching a criterion of 3 correct choices in the first 6 attempts, birds were randomly assigned to one of three groups: kanic acid (0.2μg/μl) lesion, colchicine (4.0μg/μl) lesion, or control. Two min infusions of 0.25 μl of solution were made at four sites in the hippocampus through a stereotaxically placed 10 gauge cannula. Following recovery, birds were tested on acquisition of novel simple association and spatial tasks. Both lesion groups were impaired on the spatial task, regardless of the neurotoxin. Preliminary results suggest no impairment on the simple cue task. Previous findings showed, in contrast, that black-capped chickadees with bilateral aspirations of the entire hippocampus do not re-acquire this spatial task.

596.11

EFFECTS OF HIPPOCAMPAL LESIONS ON VISUAL SPATIAL ATTENTION IN PIGEONS. T. Fremouw,* P. Jackson-Smith, C. P. Shimp, and R. P. Kesner. Dept. of Psychology., Univ. of Utah, Salt Lake, UT 84112.

We explored the role of the hippocampus in determining reaction times of pigeons (Columba livia) in a task somewhat analogous to the classic Posner spatial attention paradigm. Brief cues preceded targets to which pigeons responded for food. Most cues were valid in the sense that the cue appeared in the same location as the subsequent target. On some trials, however, cues were invalid and appeared in the opposite location as the target. Hippocampal lesions do not affect location specific attention as reflected in the "validity effect." In other words, reaction times were faster after valid than invalid cues. Hippocampal lesions may, however, affect the length of time over which pigeons can sustain non-location specific attention to the task, as reflected in an increase in overall reaction times on both valid and invalid trials in contrast to corresponding results from control animals. Thus, the hippocampus may be required for sustained global attention, but not spatial specific att ntion.

596.12

CALLOSOTOMY BUT NOT EARLY EXPERIENCE INFLUENCES SPATIAL LEARNING IN THE RAT. S.E. Maier* & D.P. Crowne, Dept. Psychology, Univ. Waterloo, Waterloo, ON, Canada, N2L 3G1

For a number of years, research on the effects of early experience in the form of infantile 'handling' revealed propitious treatment effects on measures of spatial directionality and avoidance learning. In this experiment, we wondered whether handling would facilitate spatial learning and safeguard against the disruptive effects of corpus callosum transection on spatial learning. Rats were given or denied 'handling' between birth and weaning. As adults they underwent complete section of the corpus callosum and were tested in the Morris water maze and open field. Handled rats were not different from non-handled rats at learning the spatial task. Cutting the corpus callosum interfered with spatial learning even though it had no adverse effect on open field ambulation, thus ruling out a motor impairment to explain the spatial outcome. The results suggest that the early experience manipulation may be specific to certain types of spatial behaviors and learning tasks.

CONTINGENCIES CONTROLLING WIN-SHIFT ALTERNATION IN A SPATIAL TASK.

A.G. Gittis* and M. McHaddon, Psychology Department, Westminster College, New Wilmington, PA 16172.

Two choice spatial alternation procedures have been variously called "win-shift" tasks or delayed non-match to sample. Variants of this procedure are used to assess functioning of subcortical memory mechanisms under the assumption that working memory is needed to remember a prior response and that shifting is an acquired habit. Lesion (Chudik and Gittis, *SN Abstr.*, 1991) and ontogenetic studies (Gittis, et.al., *AL&B*, 1988) question these assumptions. This experiment investigates the task by evaluating the role contingencies play in maintaining performance.

Hooded rats were trained to an 80% acquisition criterion on a win-shift task in a Y-maze. "Winning" is a forced component of a trial in which one arm of the Y is blocked with the rat finding food at the end of the open arm. By choosing the alternative arm, "shifting", the rat is subsequently rewarded. After acquisition, subjects were assigned to groups in which, for an additional 100 trials, reward for winning, shifting or both was withheld. Results showed that presence or absence of reward on the forced component plays little role in task performance, whereas removal of reward for shifting is highly disruptive. These results place in doubt that memory for reward at the prior response (the foraging model) plays any role in alternation. The fact that reward for shifting is of critical importance makes the results enigmatic in light of observations that alternation requires little prodding when it appears ontogenetically. A resolution is offered by interpreting alternation through the "dead reckoning" model proposed by Gallistel, (*Organization of Learning*, 1990).

NEONATAL HANDLING: EFFECTS ON SPATIAL MEMORY, BASAL CORTICOSTERONE LEVELS, AND HIPPOCAMPAL FUNCTION. D.M. Hayden-Hixson*[1], N. White[2], J.C. Ritchie[2], and C. B. Nemeroff[3]. [1]Toxicology Progr. and [2]Psychobiology Res. Lab, Duke University Medical Center, Durham, NC 27710, [3] Dept. Psychiatry, Emory University School of Medicine, Atlanta, GA 30322.

Accumulated data indicate the neurobiological concommittants of neonatal handling include increased resistance to the deleterious consequences of chronic stress and normal aging on brain function. This study examined the effects of neonatal handling on spatial memory/ learning and basal plasma corticosterone levels in male and female Long Evans rats. Animals were either handled 5min/day (days 1-21: H1; days 5-21: H5) or left undisturbed. At $2^{1/2}$ months of age, animals were trained on an 8-arm radial arm maze (RAM) for 21 days. All manipulations were performed during the first 4 hrs of the dark phase of the light:dark cycle. Food access was not restricted at any time.

Overall, handled males were significantly (P<.05) more accurate (higher first arm to repeat scores, and fewer total errors to complete task scores) and more efficient (lower total time and arms to complete task scores) than both nonhandled males and nonhandled females. Handled females were also significantly more accurate and efficient than nonhandled males, but not nonhandled females. Plasma corticosterone levels were significantly lower in handled compared to nonhandled males. Handled and nonhandled females had comparable corticosterone levels. Hippocampal glucocorticoid receptor autoradiography and 11-hydroxysteroid dehydrogenase bioactivity studies on the brains of these animals and their appropriate controls are ongoing at this time.

EFFECTS OF LEARNING PLACE SIGNIFICANCE IN RAT HIPPOCAMPAL PLACE CELLS

M. FUKUDA*, T. KOBAYASHI, T. ONO AND R. TAMURA
Department of Physiology, Toyama Medical and Pharmaceutical University, Toyama 930-01, Japan

Rats implanted with lateral hypothalamic electrodes for rewarding intracranial self-stimulation (ICSS) were trained to explore a circular open-field, in which ICSS was delivered whenever the animals' exploration behavior met certain experimenter defined criteria. Complex spike activity from the dorsal hippocampus CA1 was recorded during the task. The following three conditions were examined for naive and well-trained animals. (1) ICSS was delivered after the animal entered a randomly located circular area in the field. (2) ICSS was delivered when the animal entered a circular area corresponding to the place field, or remained in it for 2s; after a previous visit to a similar area outside the place field. (3) ICSS was delivered only when the animal entered a circular area outside of the place field, after a previous visit to a circular area corresponding to the place field. Some hippocampal cells have place field responses during homogeneous exploration. These place fields could be moved, after several trials, to other positions where reward was newly delivered. This change was gradual in successive trials. The naive rats could learn task (2) after several trials. Some hippocampal cells acquired clear place fields during learning. The results suggest plasticity of place cells in the hippocampus, and their importance in learning and memory of place.

596.16

SPATIAL MEMORY PERFORMANCE OF RATS ON A WORKING MEMORY TASK DOES NOT REQUIRE THE PRESENCE OF VISUAL DISTAL CUES. L.S. Janis*, C.W. Weaver, M.A. Kocot, T.L. Mosher, & G.L. Dunbar. Institute of Animal Behavior, Rutgers University, Newark, N.J. 07102*& Central Michigan University, Mt. Pleasant, Mi. 48859.

A popular construct in recent theories of spatial performance is that rats use visual distal cues to create a "cognitive map" of the maze surroundings. Previous research has indicated that rats will either use a distal-cue (spatial) strategy or a pattern-response (non-spatial) strategy to solve a working memory task in the radial arm maze. In the present experiment we used a novel testing paradigm to test the hypothesis that rats which use the spatial strategy require the presence of distal cues. Sixteen male rats were first trained on a working memory task on an eight-arm radial maze with all visual distal cues present. Following the attainment of an 85% accuracy criterion for 5 consecutive days, the rats were then retested on the maze with all the visual distal cues blocked by a black curtain. Results indicated that of the 7 rats that used a spatial strategy during the initial training phase, 4 of these rats continued to use an apparent spatial strategy during the retest phase although no visual cues were present. Our results indicate that spatial strategy need not be derived exclusively from distal cues. Additionally, one of the rats who initially used a response strategy during the training switched strategy in the retest phase. These results suggest that rats probably use complex response strategies to solve difficult spatial tasks and that distal visual cues may not be critical.

PROBE TESTS TO ASSESS SPATIAL MEMORY IN THE WATER TANK. A.L.Markowska*, J.Long, C.Johnson, and D.S.Olton, Department of Psychology, The Johns Hopkins University, Baltimore, MD 21218.

The present experiment introduces a variable interval (VI) probe trial to assess spatial memory in the water maze, and demonstrates a substantial influence of the response/reinforcement contingencies during probe trials on performance. For platform trials, a platform was in its raised position, accessible to the rat. Three groups differed in their probe trials. Two groups had the standard no-platform probe (NP) trials in which the platform was unavailable for the entire trial: NP6,12 had the NP probe trial in Sessions 6 and 12, NP1-12 had the NP probe trial once each session for all 12 sessions. The third group, VI1-12, had the VI probe trial once each session for all 12 sessions. During the VI probe trial, the platform was in its lowered position, unavailable to the rat, for a variable interval of time, and then raised so that the rat could escape from the water, maintaining the same response/reinforcement contingencies on probe trials that were present on platform trials. On platform trials, VI1-12 had more accurate memory of the platform location than NP6,12 or NP1-12, as indicated by heading angle. On probe trials, VI1-12 showed better and more stable performance as indicated by time in the platform location, and number of times the platform location was crossed. These effects were due to the lack of extinction produced by the VI probe trial as compared to the NP probe trial, and to the acceleration of spatial learning induced by the VI probe trial. Because the VI procedure produced better performance than the NP procedure in both platform trials and probe trials, it can be used for repeated measurements of spatial memory, a characteristic that is not readily attainable with the NP probe trial.

LONG-TERM EFFECTS OF NEONATAL LIMBIC LESIONS ON SPATIAL RECOGNITION IN RHESUS MONKEYS. L. Malkova*, J. Bachevalier and M. Mishkin. Lab. of Neuropsychology, NIMH, Bethesda, MD 20892.

Three monkeys with neonatal amygdalo-hippocampal lesions (AH), 3 with neonatal cortical area TE lesions (TE), and 5 normal controls (N) were trained between 4-9 years of age in a series of cognitive tests to assess the long-term effects of neonatal lesions on memory. Earlier we reported that monkeys with neonatal limbic lesions were severely impaired in both visual and tactile recognition (Bachevalier et al., Soc. Neurosci. 14:1, 1988, Malkova et al., Soc. Neurosci. 17:338, 1991). Here, we report the results of additional behavioral testing of the same monkeys on delayed nonmatching-to-sample for location (DNMS). The animals in group TE were unimpaired, reaching criterion on 10-sec DNMS in 360 trials and averaging 77% across 30-120 sec delays, as compared to scores of 286 and 81%, respectively, in the normal controls. By contrast, none of the animals in group AH reached the criterion in 1000 trials, though two attained 90% and 86% with additional correction training. On 30-120 sec delays, the performance scores of these two animals dropped sharply, averaging 66%. The results confirm and extend our previous findings indicating that early damage to the limbic system (i.e. amygdala, hippocampus, and adjacent cortical areas) yields a permanent and global memory loss.

FOURTH VENTRICLE BOMBESIN INJECTIONS SUPPRESS SUCROSE INTAKE IN DECEREBRATE RATS. F.W. Flynn.* Dept. of Psychology and Neuroscience Program, Univ. of Wyoming, Laramie, WY.

Systemic injections of bombesin (BN) suppress sucrose intake in decerebrate rats. Also, 4th ventricle injections of BN in intact rats inhibit feeding. These studies do not *simultaneously* demonstrate that BN-produced afferent signals are both detected and integrated by caudal brainstem (CBS) neural circuitry to control intake. To evaluate whether the CBS, in isolation of the forebrain, contains the requisite neural systems to mediate the effects of 4th ventricle BN injection on ingestive behavior, intraoral sucrose (0.1 M) intake was measured in control and decerebrate rats (n=11/group) following 4th ventricle injections of 1, 5, 10, 20, and 50 ng BN. Fourth ventricle BN injections produced the same reliable dose-dependent reductions of sucrose intake in both groups. This result, taken with a previous report that systemic injections of BN suppress ingestive behavior in decerebrate rats, provides compelling evidence that local CBS neural circuitry mediates the sensory-motor integrative aspects that underlie bombesin's effects on ingestive behavior. MICROINJECTION OF BOMBESIN INTO MIDLINE THALAMIC NUCLEI ELEVATES BLOOD GLUCOSE, FREE FATTY ACIDS, AND CORTICOSTERONE IN RATS. M.W. Gunion,* M.J. Rosenthal, S. Miller, M. Hoyt, and D. Yonson. Research Service, Sepulveda VAMC, Sepulveda, CA 91343; Dept. Medicine, U.C.L.A. Los Angeles, CA 90024.

Several midline thalamic nuclei are implicated in autonomic, particularly cardiovascular, regulation. They have not been evaluated for roles in metabolic fuel or glucocorticoid regulation. Some of these nuclei strongly bind bombesin; bombesin microinjections into other autonomic nuclei cause elevated blood levels of glucose, free fatty acids, and corticosterone. Under methoxyflurane anesthesia, male Sprague-Dawley rats (300–350) received chronic guide cannula aimed at various midline thalamic nuclei. After a minimum of 7 days recovery, microinjections of bombesin (15, 50, 150 ng/300nl, in 0.9% NaCl+0.1% BSA) were made. Blood samples (120 ul) taken from the tail tip 0, 15, 30, 60, 90, and 120 min postmicroinjection were assayed for serum glucose, free fatty acids, and corticosterone. Positive sites were found in these thalamic nuclei: interanteromedial, paraventricular, rhomboid, centromedian. In the thalamic paraventricular nucleus, positive sites were clustered in the anterior subdivision of the nucleus. In the centromedian nucleus, positive sites were grouped on the midline, and not found in the lateral extensions of the nucleus. This pattern of active sites corresponds well with the previously demonstrated midline distribution of bombesin-binding sites. [Supported by PHS NS20660 (MWG), AG04793 (MJR), and Veterans Administration funds (MWG, MJR).]

GALANIN ANTAGONISTS M40, C7, AND M32, MICROINJECTED INTO THE PVN OF THE HYPOTHALAMUS, BLOCK GALANIN-INDUCED FEEDING IN RATS. R.L. Corwin*, J.K. Robinson, U. Langel+, T. Bartfai+, and J.N. Crawley. NIMH, Building 10, Room 4N214, Bethesda, MD 20892, + Dept. of Neurochemistry and Neurotoxicology, Stockholm Univ., Sweden.

Exogenous galanin (GAL) microinjected into the paraventricular nucleus of the hypothalamus (PVN), increases consumption of high fat foods in nondeprived rats. Potent galanin receptor antagonists have recently been developed which are chimeric peptides with GAL 1-13 at the N-terminus and another peptide sequence at the C-terminus. We tested three of these antagonists (M40, C7, and M32) in a feeding paradigm previously used to assay GAL-induced feeding. Male Sprague-Dawley rats were surgically implanted with bilateral stainless steel cannulae, aimed just dorsal to the PVN. Approximately 1 week after surgery, free-feeding rats were trained to consume a mash consisting of 2 vanilla wafers soaked in 10 ml deionized water during a 30-min test. On test days, Ringer's vehicle or antagonists, and GAL 1-29 or vehicle were injected separately and bilaterally into the PVN. GAL 1-29 (0.5 nM) significantly increased mash consumption. M40 (0.5 nM), C7 (0.1 nM) and M32 (0.25 nM) significantly blocked GAL-induced feeding. None of the antagonists had a significant effect on mash consumption when given alone. These new receptor antagonists appear to be effective blockers of feeding stimulated by exogenous galanin microinjected into the PVN, indicating their potential usefulness in investigating the behavioral actions of endogenous galanin.

597.4

HYPOTHALAMIC GALANIN GENE EXPRESSION IS ASSOCIATED WITH PREFERENTIAL FAT INTAKE, INSULIN LEVELS AND BODY WEIGHT. S.J. Tucker, M. Jhanwar-Uniyal, S.C. Chua Jr, J. Grinker* and S.F. Leibowitz. The Rockefeller Univ., New York, NY 10021, Univ Michigan, Ann Arbor, Michigan.

The self-selection feeding paradigm enables rats to select the macronutrients of choice. Studies conducted with neuropeptide galanin (GAL) show that GAL selectively induces ingestion of fat when injected into the hypothalamus. In this study, Sprague-Dawley rats (n=13) were given pure macronutrient diets (carbohydrate, protein and fat). Using quantitative Northern blot analysis, we have measured the levels of hypothalamic GAL messenger RNA (GAL mRNA). Circulating levels of insulin (INS) were assessed by RIA, and glucose (GLU) levels were estimated by YSI glucose analyzer. Body mass index (BMI) and 3 different fat pad weights, namely, retroperitoneal, inguinal and epididymal, were also recorded. The results, in rats consuming a minimum of 20 Kcal/24 hrs of fat, displayed that: 1) a significant positive correlation exists between daily fat ingestion and hypothalamic GAL mRNA ($r=0.61$; $p<0.05$); 2) GAL gene expression is significantly correlated with INS levels ($r=0.58$; $p<0.05$) and INS/GLU ratio ($r=0.60$; $p<0.05$); 3) GAL mRNA is positively correlated with body weight ($r=0.66$; $p<0.05$) and BMI ($r=0.63$; $p<0.05$), but not correlated with any of the individual fat pad weights. The results of this study demonstrate that increased hypothalamic GAL synthesis may be related to greater fat ingestion, INS secretion, as well as body weight.

[Leu^{31}-Pro^{34}] Neuropeptide Y (NPY), but not NPY 20-36, has discriminative stimulus effects similar to NPY and induces food intake. D. C. Jewett*, J. Cleary, D. W. Schaal, T. Thompson & A. S. Levine University of Minnesota and VA Medical Center Minneapolis, MN 55455 and 55417

Previously we demonstrated that the stimuli associated with NPY can be discriminated from those stimuli associated with an injection of vehicle. In the present study, we compared the discriminative stimulus effects of a Y1 [Leu^{31}-Pro^{34}] (LP-NPY) and Y2 agonist [NPY 20-36] to those of NPY. Five rats were maintained at 80% of their free-feeding weights and trained to discriminate a 1.2 nmol intracerebroventricular (icv) NPY injection from no injection. Responses on one lever following injection with NPY were reinforced, while responses on the other lever following no injection were reinforced. Responses prior to the first reinforcer or timeout were a measure of the discriminative stimulus effects of the agent. Following acquisition of the discrimination, rats were administered icv saline, and 1.2, 2.4, 3.5 nmol LP-NPY and NPY 20-36. Our findings suggest LP-NPY has stimulus effects similar to NPY. 3.5 nmol LP-NPY completely generalized to 1.2 nmol NPY. Lower doses of LP-NPY partially generalized to the training dose. Approximately 50% of the responses following 1.2 nmol and about 75% of the responses following 2.4 nmol were made on the NPY-appropriate lever. No NPY 20-36 doses tested resulted in NPY-appropriate responding. Saline administration also did not engender NPY-appropriate responding. LP-NPY also increased food intake. Rats were injected with the same agents and doses as above, and food intake was measured over 2 hours. All doses of LP-NPY significantly increased food intake relative to saline controls ($p<.0001$). Rats ate 4.7, 6.7 and 5.2 g after 1.2, 2.4, 3.5 nmol LP-NPY. No significant increases in food intake were observed following NPY 20-36 administration relative to saline control.

INCREASED FOOD INTAKE FOLLOWING MORPHINE OR NPY ADMINISTRATION INTO THE VENTRAL TEGMENTAL AREA OF RATS. J. M. Rudski*, M. K. Grace, C.J. Billington and A.S. Levine. University of Minnesota, Minneapolis MN 55455 and VA Medical Center, Minneapolis MN 55417

Previous studies in our laboratory indicate that administration of Neuropeptide Y (NPY) or *mu* opioid agonists into the lateral ventrical in rats produces naloxone reversible increases in food intake at times of day when feeding is usually not observed. Feeding following opiate administration typically requires repeated injections, suggesting that tolerance to sedation produced by opiates must develop before feeding can occur. It has been suggested that morphine applied to the VTA produces motivational without motoric effects (Noel & Wise, *Society for Neuroscience Abstracts* 1990). In the present studies, morphine (0.1, 1.0 or 10.0 n mol), NPY (1 µg), or NPY and naloxone (50µg) were administered into the VTA 2 hours into the light cycle and 4 hour cumulative food intake was recorded. Increases in food intake were not evident following the first injection and required repeated administration. Feeding was not increased over the first 2 hours following morphine injections, and casual observation of the rats indicated some motor impairment. However, 4 hour cumulative food intake was positively related to dose ($F_{(3,25)}=8.14$, $p<0.001$). NPY administered into the VTA produced feeding at 1 ($F_{(2,15)}=16.17$, $p<0.005$), 2 ($F_{(2,15)}=13.93$, $p<0.005$) and 4 ($F_{(2,15)}=7.77$, $p<0.005$) hours after injections. NPY's effect was blocked by naloxone (50µg). These results demonstrate that morphine and NPY administered into the VTA increase food intake.

597.7

NALOXONE AND FLUOXETINE BLOCK EATING IN A PYY-MODEL OF BULIMIA NERVOSA. M. M. Hagan and D. E. Moss*. Laboratory of Psychobiochemistry, University of Texas at El Paso, Texas 79968.

Peptide YY (PYY) has been implicated in the neurobiology of bulimia (Kaye et al., 1990; Morley et al., 1987). Naloxone (NAL) and fluoxetine (FLU) have been proposed as anti-bulimic agents (Enas, 1989; Mitchell, 1989). Little is known about the effect of NAL and FLU on PYY-induced eating.

Female rats with cannulae in the fourth ventricle were pretreated with NAL 100ug/3ul i.c.v., NAL 10mg/kg sc, FLU 3-30ug/3ul i.c.v., FLU 5-10mg/kg ip, clomipramine (CLO) 3-30ug/3ul i.c.v., CLO 5-10mg/kg ip, or vehicle (VEH). At least 13 rats served in each condition. Twenty minutes after pretreatment, all rats received 5ug/5ul PYY i.c.v. every hour for a total of 15 ug PYY. Cumulative 4h food intake for PYY alone was 8.02g. VEH intake was 3.22g. Both central and peripheral injections of NAL blocked PYY-induced eating (2.58g and 3.21g, respectively). FLU ip also suppressed PYY-induced eating (3.29g). Central injection of FLU, however, did not affect PYY-induced eating (6.30g). Both central and peripheral CLO also had no effect on PYY-induced eating (8.35g).

Our results with NAL suggest opioids mediate PYY-induced eating. The resuls with FLU and CLO indicated that a serotonergic mechanism may be involved but at a site distant from the fourth ventricle and via FLU-sensitive 5-HT receptors. Further research is being directed at other neurochemical locations.

THE MU AND KAPPA OPIOID ANTAGONISTS, ß-FUNALTREXAMINE (ß-FNA) AND NOR-BINALTORPHIMINE (nor-BNI), REDUCE NEUROPEPTIDE Y-INDUCED FEEDING. C.M. Kotz, M. K. Grace, C.J. Billington and A.S. Levine*, VA Medical Center, Minneapolis MN 55417 and University of Minnesota, Minneapolis MN 55455.

Intracerebroventricular (ICV) injection of naloxone has been reported to decrease the robust feeding observed after ICV injection of Neuropeptide Y (NPY). In the present study we evaluated the effects of ß-FNA and nor-BNI, two opioid antagonists selective for the mu and kappa opioid receptors, on NPY-induced feeding. In the first study we pre-injected (ICV) male Sprague Dawley rats with 50 nmol of nor-BNI 60 min before ICV administration of NPY (5µg). Nor-BNI reduced NPY-induced feeding 2 and 4 hours after NPY injection (table). ß-FNA acts as a kappa opioid agonist immediately after injection and as a mu antagonist 20-24 hours after injection. We found that when 50 nmol of ß-FNA was injected (ICV) 22 hours before NPY (5 µg ICV) injection, food intake (g) was decreased.

	0-1 Hour	0-2 Hour	0-4 Hour
Vehicle	0.1 ± 0.1	0.1 ± 0.1	0.7 ± 0.3
NPY	0.9 ± 0.3	1.9 ± 0.5	3.6 ± 0.7
NPY + nor-BNI	0.3 ± 0.3	0.6 ± 0.5	1.1 ± 0.5
Vehicle	0.6 ± 0.3	1.2 ± 0.4	1.7 ± 0.4
NPY	3.4 ± 0.5	4.5 ± 0.8	5.5 ± 0.8
NPY + ß-FNA	1.1 ± 0.4	2.3 ± 0.6	3.7 ± 0.8

These data indicate that blockade of the mu or kappa opioid receptors decreases NPY-induced feeding. This suggests that NPY's ability to increase food intake is dependent upon opioid action.

597.9

PEPTIDE CCK RECEPTOR ANTAGONIST INCREASES REAL FEEDING AND ATTENUATES SUPPRESSION OF SHAM FEEDING BY EXOGENOUS CCK-8 IN RATS. Brenner*, L.A. & Ritter, R.C. Dept. of VCAPP, Washington State University, Pullman, WA 99164

Non-peptide CCK receptor antagonists abolish suppression of real and sham feeding by exogenous CCK and some intestinal nutrients. They also increase real feeding when administered in the absence of exogenous CCK. t-Boc-Tyr(SO_3H)-Nle-Gly-D-Trp-Nle-Asp-2-phenylethylester (D-Trp-JMV) is a potent, heptapeptide, CCK receptor antagonist. Since this antagonist is similar in size, molecular form and weight to CCK-8, we reasoned that it should reach receptors accessible to exogenous CCK-8 and not receptors protected by blood-neural barriers. Therefore, we have examined the ability of D-Trp-JMV to increase real feeding and to attenuate suppression of sham feeding by exogenous CCK-8 or intraintestinal oleate. Intraperitoneal injection of 500 ug/kg of this compound abolished CCK-8 (2ug/kg) induced suppression of sham feeding or real feeding. A 1.0 mg/kg dose of D-Trp-JMV significantly increased real feeding. Suppression of sham feeding by intraintestinal oleate was not reliably attenuated by D-Trp-JMV at doses up to 4.0 mg/kg. The fact that oleate-induced suppression of sham feeding was not abolished by D-Trp-JMV may indicate that this effect is mediated at a different receptor site than that mediating suppression of feeding by exogenous CCK-8. Alternatively, levels of CCK released by oleate during sham feeding may have been too high to permit effective competition by the doses of D-Trp-JMV administered. Finally, our results indicate that both exogenous CCK-8 and endogenous CCK, released during real feeding, reduce food intake by acting at a site(s) accessible to peripherally administered peptides. Supported by NIH NS20561.

STUDIES ON THE DEVELOPMENT OF TOLERANCE TO THE ANORECTIC ACTIONS OF CCK-8 IN RATS. L. Bednarz, K.E. Asin and A.M. Nadzan*, Neuroscience Research Div., Pharmaceutical Discovery, Abbott Labs, D-47U, Bldg-AP10, Abbott Park, IL 60064.

Although acute injections of CCK-8 suppress food intakes in rats, when the compound is administered on a daily basis, progressively higher doses are required to affect intakes as animals become tolerant to its anorectic actions. We examined in more detail the development of this tolerance.

Four groups of male rats were placed on a restricted feeding schedule where they were allowed access to a liquid diet for 60min in the AM and for 30min in the PM until intakes had stabilized. During the subsequent **training period,** rats were injected (ip) daily with either vehicle (V) or CCK-8 (10nmol/kg) 10min prior to the AM feeding period and again 2h after it. Administration of CCK-8 prior to feeding suppressed ($p<.05$) 60 min intakes about 25% on the first injection day but had no effect by Day 3. Ten min prior to feeding on Day 4 **(test day),** one group of rats was administered V, while the other 3 were given CCK-8. Analysis of 60min intakes indicated that CCK-8 on the **test** day suppressed feeding in rats that had received it **after** the feeding period during training, but not in those that had received it **prior to** the feeding period during training. Thus, although these 2 groups had received CCK-8 the same number of times, "tolerance" to its anorectic effects developed only in the group which had had the drug injected prior to the feeding period. These results suggest that alterations in drug metabolism or receptor mechanisms cannot fully account for the development of tolerance to CCK-8. In other studies, we found that the development of tolerance was slower in 4h deprived rats than in rats maintained on the feeding schedule described above.

Our results suggest that learning mechanisms and the animal's motivational state may be involved in the development of tolerance to the anorectic effects of CCK-8.

EFFECTS OF CCK-8 AND VARIOUS ANORECTIC DRUGS ON THE LICKING BEHAVIOR OF RATS. K.E. Asin[1]*, J.D. Davis[2] and L. Bednarz[1], Neuroscience Res. Div., Pharmaceutical Discovery, Abbott Labs, D-47U Bldg-AP10, Abbott Park, IL 60064 and [2]Univ. IL-Chicago, Dept. Psychol., Chicago, IL 60680.

The licking behavior of rats can be reduced to its component parts which can then be described qualitatively and quantitatively. Detailed analysis of these behaviors may prove to be useful for comparing how different classes of anorectic drugs act to suppress intakes. In the present studies we examined the licking behavior of rats drinking sucrose following the injection of various clinically used anorectic drugs and CCK-8.

Male, Sprague-Dawley rats were trained to consume a 0.4M sucrose solution over a 30 min period in cages equipped with lickometers. On test days, rats were injected (ip) with various doses of either the catecholamine (CA) agonists d-amphetamine sulfate (AMPH)(0-1 mg/kg) or phenylpropanolamine (PPA)(0-16 mg/kg), or with the indirect serotonergic (5HT) agonists d-fenfluramine (FEN)(0-5 mg/kg) or fluoxetine (FLU) (0-10 mg/kg) 30 min prior to drinking. Other rats were treated with CCK-8 (0-10 nm/kg) 10 min prior to the drinking session.

AMPH and PPA suppressed intakes primarily by reducing the number of bursts of licking, perhaps reflecting the stimulant properties of these drugs. In contrast, FEN and FLU reduced intakes by reducing the size of the burst and by increasing the number of licks/ml (ie: reducing lick efficiency). Burst size was also reduced by CCK-8. Reductions in burst size have been reported to occur in response to decreases in the palatability of the solution being consumed (Davis 1989). Thus, as a class, the CA anorectics reduced intakes by affecting mechanisms distinct from those altered by the 5HT drugs. The effects of CCK-8 were most similar to those of FLU and FEN; more detailed analyses will be presented.

These studies demonstrate that the microstructural analysis of licking behaviors better characterizes how anorectic drugs act to suppress intakes than does simple measurement of volume consumed.

597.12

CIS-FLUPENTHIXOL DOES NOT REVERSE THE INHIBITION OF FOOD INTAKE PRODUCED BY CCK-8 L.H. Schneider*, J. Dokko, J. Gibbs and G.P. Smith. Dept. of Psychiatry, NY Hospital-Cornell Medical Center, Bourne Laboratory, White Plains, NY 10605

PURPOSE We wanted to investigate the report that a dose of the dopamine (DA) antagonist cis-flupenthixol (FLU) reversed the inhibition of food intake produced by CCK-8 (Linden, *Acta Physiol. Scand.*, 137, 1989).

METHODS Male S-D rats (n=7) had 30-min access to a 10% sucrose solution following a 6 h pellet deprivation and ip injections at -15 min (saline or FLU) and -5 min (saline or CCK-8), using a crossover design.

RESULTS Baseline test intake (ml/30 min) was 11.4 (± 0.8) [mean (± SE)]. CCK-8 (4 ug/kg) decreased intake significantly [5.1. ± 0.8; $p < .001$)]. Pretreatment with FLU (0.1 mg/kg) did not change the inhibitory effect of CCK-8 [5.7 (± 0.7)]. This dose of FLU did not inhibit test intake [12.3 (± 1.6)].

CONCLUSION Under our conditions, FLU did not reverse the inhibition of food intake produced by CCK-8. Thus, we did not find the effect reported by Linden. Possible reasons for this disparity include the test diet and period she used (1 h access to rat chow pellets). Further work is required to demonstrate that the satiating effect of CCK-8 on food intake may be modulated by dopaminergic mechanisms.

EFFECTS OF ISLET AMYLOID POLYPEPTIDE (IAPP) ON FOOD INTAKE IN RATS. J.E. Blevins*, T.E. Adrian, R.D. Reidelberger. Veterans Administration Medical Center and Department of Biomedical Sciences, Creighton University School of Medicine, Omaha, NE 68105.

IAPP (also called amylin) inhibits feeding when injected intrahypothalamically in rats and intraperitoneally in mice. Because amylin is secreted from pancreatic islets into the circulation in response to feeding, we examined the effects of intravenous administration of IAPP on food intake. Rats (n=9-14) with chronic jugular vein catheters received bolus injections of vehicle and either rat or human IAPP (5 and 10 nmol/kg) or continuous infusion of vehicle and rat IAPP (2 nmol/kg-h for 2 h) at the beginning of the dark period after a 5-h fast. Ingestion of ground chow was measured 1, 2, 4, and 24 h later. ***Results***: Human IAPP did not inhibit feeding. Rat IAPP suppressed feeding at each dose. Cumulative food intake was inhibited by 5 nmol/kg at 1 h (50%, $P<0.001$) and 2 h (35%, $P<0.01$); by 10 nmol/kg at 1 h (42%, $P<0.05$), 2 h (49%, $P<0.01$), and 4 h (20%, $P<0.05$); and by 2 nmol/kg-h at 2 h (24%, $P<0.001$) and 4 h (17%, $P<0.01$). ***Conclusions***: 1) Circulating IAPP may play an important physiological and/or pathophysiological role in control of food intake. 2) The differences in amino acid sequence between rat and human IAPP (6 of 37 amino acids) may be sufficient to impair binding of human IAPP to the receptor involved in the feeding response.

597.14

C-FOS IMMUNOHISTOCHEMICAL LOCALIZATION OF CENTRAL SITES RESPONSIVE TO PERIPHERAL ENTEROSTATIN. Q. Tian, L. Lin, D.A. York* and G.A. Bray. Pennington Biomedical Research Center, Baton Rouge, LA 70808.

Enterostatin is the aminoterminal pentapeptide of pancreatic procolipase which is released by tryptic cleavage. We have shown that enterostatin is a potent inhibitor of food intake and that this anorectic effect is specific to fat when rats are given a choice of macronutrients. The peptide is effective after peripheral or central administration. To gain insight into the possible sites of action in the CNS, we have compared the effects of peripherally administered enterostatin and the lipoprivic feeding agent, 2-mercaptoacetate (2MA) on induction of the immediate-early gene c-fos. Rats were adapted to a high fat diet for 10 days and then injected with either 80 μg enterostatin, 2MA (800 μMol/kg) or saline vehicle immediately prior to providing access to food. After two hours, the rats were perfused intracardially with 4% paraformaldehyde, the brain removed, fixed and subsequently 50 μM sections were cut. Sections were incubated with c-fos antisera and antibody-antigen complexes detected by a biotinylated IgG-Steptavidin/peroxidase procedure. The distribution of c-fos immunoreactivity induced by enterostatin and 2MA was different. Enterostatin induced c-fos appearance in the Supraoptic, Arcuate and Pons nuclei, nucleus tractus solitarius, periaqueductal grey and the hippocampus. In contrast, the 2MA induced c-fos immunoreactivity predominated in the Area Postrema, Dorsomotor Nucleus, Parabrachial nucleus, Central nucleus of amygdala and the locus coruleus. The data suggest enterostatin and 2MA may act at different sites to regulate fat feeding.

597.15

CHRONIC RESTRAINT STRESS ENHANCES THE PROPHAGIC EFFECT OF THE κ-AGONIST U-50,488H . A. Badiani * and J. Stewart. Center for Studies in Behavioral Neurobiology, Psychology, Concordia University, Montréal, Québec, Canada, H3G 1M8.

Chronic treatment with amphetamine enhances the prophagic effect of the kappa-opioid agonist U-50,488H (U50). Since, cross-sensitization between stress and amphetamine has been reported, we studied the effect of chronic stress on the feeding response to U50.

An automatized apparatus was used for the continuous monitoring of feeding, drinking, and locomotor activity. Eight male Wistar rats underwent ten daily (6 h after the onset of the light phase) stress sessions (20 min of restraint) whereas 8 control animals were only briefly handled. All rats had food and water *ad libitum*. There was a slight increase in food intake in stressed animals in the 30 min following stress. After the last stress session the rats were left undisturbed for 120 hours and then tested for two consecutive days in a counterbalanced order, each animal being injected i.p. with saline on one day and with 3 mg/kg of U50 on the other day. U50 increased feeding and reduced drinking in the following two hours; more rats ate (100% vs. 62.5% after saline) and ate a larger first meal. The prophagic effect of U50 was greater in stressed rats. Food intake in the first hour was 2.81±0.37 g in group Stress-U50 vs. 1.77±0.41 g in group Control-U50. The size of the first meal (intermeal interval ≥ 30 min) was 3.19±0.46 g in group Stress-U50 vs. 1.79±0.35 g in group Control-U50. The antidipsic effects of U50 was unchanged.

These results demonstrate that chronic exposure to a relatively mild and non-anorectic stress can sensitize the rat to the prophagic effect of the highly selective kappa-opioid agonist U-50,488H.

DECREASED FOOD-INTAKE AND MORPHINE ANALGESIA FOLLOWING CENTRAL GYLBENCLAMIDE. D.S. Roane*, and N.E. Boyd. Div. Pharmacology and Toxicology, School of Pharmacy, NE La. Univ., Monroe, LA 71209-0470

Previous research has indicated the presence of a reciprocal relationship between food-intake and opioid mediated analgesia. We believe the most likely cellular candidate common to both ingestive and nociceptive behaviors is the ATP-sensitive K^+ channel (K_{ATP}). This ion channel appears to be opened by mu and delta-1 opioid receptor agonists in the service of analgesia and closed as cellular ATP rises -- potentially providing an explanation for why some feeding paradigms and alterations in glucose metabolism affect morphine analgesia.

To further examine the role of the K_{ATP} in the relationship between feeding and opioid function we administered 80 nmol of glybenclamide (an K_{ATP} antagonist) into male S.D. rats via the lateral ventricle. Chow consumption in the treated animals was significantly reduced over the following 48 hours ($F=2.62$, $p<0.013$) with the peak effect (78% of control) occurring at 6 h. In the tail-flick test, 4 mg/kg morphine sulfate provided analgesia of 42.38 ± 8.4% and 18.89 ± 7.67% in vehicle and treated animals, respectively, ($p<0.05$, n=8/group, one-tailed t-test). These results support the hypothesis that food-intake and analgesia are reciprocally modulated through activity at the K_{ATP}.

597.17

GRF-INDUCED FEEDING IS AN OPIOID-DEPENDENT AND PROTEIN SELECTIVE EFFECT. P.R.Dickson*[1] and F. J. Vaccarino[2]. 1. Dept Psychology, Northeastern University, Boston, Ma. 02115 2. Dept Psychology, University of Toronto, Toronto, Canada, M5S 1A1

Work in our lab has shown that growth hormone-releasing factor (GRF) acts centrally (in the suprachiasmatic nucleus/medial preoptic area, SCN/MPOA) to stimulate food intake in rats, independent of its endocrine effects. Injection of GRF into the SCN/MPOA during the middle of the light cycle stimulates protein (P) intake, while carbohydrate (C) and fat (F) intake is unaffected. This feeding effect is dependent on opiate actions in the paraventricular nucleus of the hypothalamus (PVN), since opiate blockade in this site blocks expression of GRF-induced feeding. The present experiments further explored the effects of GRF on macronutrient selection, and the role of opiates in expression of this behavior.

In all experiments, animals were given two macronutrient choices (P/10% F; C/10% F). The first study determined the effect of PVN morphine (MOR) on macronutrient selection. Animals were injected in counterbalanced order with 0, 1, 10, 17 ug MOR, and intake measured at 1, 2, and 4 hours. MOR selectively stimulated P intake up to 4 hours post-injection; the effects on C intake were inconsistent. The next study examined the ability of selective deprivation to alter the feeding effects of either SCN/MPOA GRF (1 pmol) or 2 mg/kg MOR. Rats were tested in ad lib feeding conditions, and when they had been 24 h deprived of either P or C (indep. groups). GRF increased P intake in ad lib and P deprivation conditions. C deprivation was not able to switch the GRF effect from augmentation of P intake. Systemic MOR showed variable effects, increasing P intake following P deprivation, and C intake following C deprivation. A final study examined involvement of GRF in expression of circadian patterns of macronutrient selection. Injection of GRF antibodies into the SCN/MPOA resulted in a selective, dose-dependent suppression of nomally elevated P intake at dark onset. Conclusions of these studies are that SCN/MPOA GRF is involved in feeding behavior and nutrient regulation mediated by PVN opioids, and this effect is P selective. NSERC grant #35036 to FJV.

597.18

MORPHINE-INDUCED FEEDING: A COMPARISON OF THE LEWIS AND FISCHER 344 INBRED RAT STRAINS. D.D. Krahn and B.A. Gosnell, Dept. of Psychiatry, University of Michigan, Ann Arbor, MI 48109.

Rats of the Lewis inbred strain have been shown to self-administer more morphine than rats of the inbred Fischer 344 (F344) strain (Suzuki et al., *Japan. J. Pharmacol.* 47:425, 1988). We therefore measured whether these stains also differ in their feeding response to morphine. In Exp. 1, rats were maintained on powdered rat chow and given s.c. injections of morphine sulfate (1, 3 or 10 mg/kg) or saline. Food intake was measured 2, 4 and 6 hrs after injection. This procedure was repeated 3 additional times (2 days apart), such that all rats were tested with all doses of morphine and with saline. In Exp. 2, rats were given a choice of 2 diets: a fat/protein diet and a carbohydrate/protein diet. Feeding responses to morphine were measured in a manner identical to that in Exp. 1. In both experiments, the feeding response to morphine was greater in Lewis rats than in F344 rats. To determine whether these responses might be explained by differences in the levels of morphine achieved in blood or brain, rats of each strain were given s.c. injections of morphine sulfate (3 mg/kg) and sacrificed either 30 min (n=6/strain) or 3 hrs (n=6/strain) after injection. Serum and brain morphine levels were determined by RIA. Lewis rats had significantly less brain morphine than F344 rats at 30 min (61±2 vs. 42±1 ng/g, $p<.05$); they did not differ in morphine content at 3 hrs. Serum levels were similar at 30 min and at 3 hrs. Thus, differences in tissue levels cannot readily explain the differences in feeding responses to morphine. These results indicate a strain difference in the feeding response to morphine which complements previously observed differences between Lewis and Fischer 344 rats in the self-administration of morphine. Supported by NIDA Grants DA05471 and DA06827.

THE EFFECTS OF CONTINUOUS MORPHINE INFUSIONS ON DIET SELECTION AND FOOD INTAKE. B.A. Gosnell and D.D. Krahn. Dept. of Psychiatry, University of Michigan, Ann Arbor, MI 48109.

The administration of morphine causes a short-term increase in food intake, and repeated administration of morphine has been shown to cause progressively larger increases in intake and/or the relative intake of dietary fat. In this experiment, we measured the effects of continuous morphine infusions on diet choice and total intake. Male rats were given ad lib access to two diets: a high-carbohydrate diet (CHO; 80% carb., 20% protein) and a high-fat diet (FAT; 80% fat, 20% protein). Diet intakes were measured daily for 21 days. Via the implantation of osmotic minipumps, one group (n=11) received continuous infusions of morphine sulfate (approx. 2.8 mg/kg/hr) for days 1-7 and of saline for days 8-14. A second group (n=11) was infused with saline for days 1-7 and with morphine for days 8-14. A third group (n=12) received sham surgery but no minipumps. Regardless of whether morphine was infused when the diets were introduced or after 7 days of adaptation to the diets, morphine caused a significant decrease in CHO intake for the first 5 days of the 7 day infusion period (compared to the sham group). Intake of the FAT diet was generally elevated at the beginning of the drug infusion period and depressed toward the end of this period. Total caloric intake was significantly decreased on final 6 days of morphine infusions. Percentage of total caloric intake consumed from the FAT diet was significantly increased for only the first 2 days of the infusion periods. Termination of morphine infusions caused a decrease in the intake of both diets, with no change in relative diet preference; intakes generally returned to control (sham) levels within 1-3 days. These effects (a sustained decrease in total intake with only an initial increase in fat preference) differ from those reported after repeated intermittent administration of morphine in short-term trials. Supported by NIDA Grants DA05471 and DA06827.

DIFFERENTIAL INVOLVEMENT OF CENTRAL OPIOID RECEPTOR SUBTYPES IN SACCHARIN INTAKE IN RATS. I.W. Beczkowska*, J.E. Koch and R.J. Bodnar. Dept. of Psychology, Queens Col., CUNY, Flushing, NY 11367.

Saccharin intake in rats is decreased following naltrexone (NTX) and increased following mu and delta agonists. Our laboratory recently evaluated the central roles of general (NTX), mu (beta-funaltrexamine, B-FNA), kappa (nor-binaltorphamine, Nor-BNI), mu_1 (naloxonazine), $delta_1$ (DALCE) and $delta_2$ (naltrindole, NTI) opioid antagonists upon intake of sucrose which possesses palatable and nutritive qualities. Sucrose intake was reduced by NTX, B-FNA and Nor-BNI, implicating mu_2 and kappa receptors. The present study evaluated over 1 h central antagonist effects upon intake of saccharin which possesses palatable qualities without postingestive consequences. NTX (20-50 ug) significantly reduced saccharin intake (25-60 min, 60-67%) confirming opioid involvement. In contrast, neither B-FNA nor Nor-BNI affected saccharin intake, suggesting that mu and kappa effects upon sucrose intake altered postingestive factors. Saccharin intake was significantly reduced by DALCE (5-15 min, 51-60%) and NTI (5-60 min, 65-80%), implicating delta receptor mediation. Since sucrose and saccharin differ in their postingestive consequences, any opioid involvement in palatability should consider post-ingestive factors in assessing receptor mediation. (Supported by DA04194).

DIFFERENTIAL INVOLVEMENT OF CENTRAL OPIOID RECEPTOR SUBTYPES IN TAIL-PINCH FEEDING IN RATS. J.E. Koch* and R.J. Bodnar. Dept. of Psychology, Queens Col., CUNY, Flushing, NY 11367.

Hyperphagia during tail-pinch stress is decreased following general (e.g., Science 209: 1259-1261, 1980; Life Sci. 26: 2113-2118, 1980) and mu (CTOP, Soc. Neurosci. Abstr. 17: 491, 1991), but not by kappa (nor-binaltorphamine, Nor-BNI) or delta (naltrindole, NTI) opioid antagonists. Since there are multiple mu (mu_1 & mu_2) and delta ($delta_1$ & $delta_2$) opioid receptor subtypes, the present study evaluated whether tail-pinch feeding was differentially altered following central administration of mu (beta-funaltrexamine, B-FNA), mu_1 (naloxonazine, NAZ), kappa (Nor-BNI), $delta_1$ (DALCE) and $delta_2$ (NTI) antagonists. Like CTOP, B-FNA significantly and dose-dependently (1-20 ug, icv) reduced tail-pinch eating by 30%. In contrast, NAZ (50 ug) failed to alter tail-pinch feeding, implicating the mu_2 opioid receptor subtype. Neither Nor-BNI (1-20 ug), DALCE (40 ug) nor NTI (20 ug) altered tail-pinch eating, indicating that kappa, $delta_1$ and $delta_2$ binding sites are involved. Since no antagonist altered the latency or duration of food contact during tail-pinch, opioids appear to modulate ingestive rather than activational mechanisms. The selective influence of the mu_2 binding site in tail-pinch feeding is similar to its effects on glucoprivic, high-fat and sucrose intake. (Supported by DA04194 and DA07135).

DRUGS OF ABUSE: ETHANOL AND MONOAMINES

598.1

SEROTONIN POTENTIATES ETHANOL-INDUCED EXCITATION OF VTA NEURONS *IN VITRO*, M.S. Brodie* and S.A. Shefner, Dept. Physiology and Biophysics, University of Illinois, College of Medicine, Chicago, IL 60680.

Dopamine neurons of the ventral tegmental area (VTA) are important components of brain pathways which mediate drug-induced reward. Ethanol (EtOH) increases the firing rate of VTA neurons *in vivo* (Gessa, et al., 1985), and *in vitro* (Brodie, et al., 1990). The EtOH-induced increase in firing rate of VTA neurons may underlie the rewarding effects of ethanol. It has been shown that serotonin reuptake blockers reduce alcohol intake in human alcoholics and in animal studies. We have begun studies to assess the effects of serotonin (5-HT) on ethanol-induced excitation of VTA neurons.

Coronal brain slices containing the VTA were prepared from young adult rats (100 to 200 gm), and the slice was superfused in a recording chamber maintained at 35-36° C. Twenty-one neurons from 17 rats were studied. All drugs were administered in the superfusate. Concentrations of ethanol (40 - 160 mM) were tested in the absence and presence of 5-HT (1 - 50 μM). All neurons studied were excited by EtOH, and had electrophysiological characteristics typical of putative dopamine-containing neurons. In most cases, serotonin alone had a small, transient excitatory effect on these neurons; this excitation subsided within 15 minutes. In 15 of 21 neurons (71%), the excitatory effect of ethanol was increased in the presence of 5-HT by more than 10%. Increases in EtOH-induced excitation of 100% over pre-5-HT controls were seen typically, while the largest increase in EtOH excitation observed was 821%.

These studies suggest that serotonergic agents may be useful in altering the potency of EtOH in reward areas of the brain and may provide an opportunity for the development of pharmacotherapeutic agents useful in the treatment of alcoholism. Supported by P.H.S. grant #AA-05846-09.

EVALUATION OF m-CHLOROPHENYLPIPERAZINE (mCPP) EFFECTS ON ETHANOL (E) INTAKE AND BEHAVIOUR IN WISTAR RATS. D.M. Tomkins, Y. Buczek and E.M. Sellers*. Departments of Pharmacology, Medicine and Psychiatry, University of Toronto and Clinical Research and Treatment Institute, Addiction Research Foundation, Toronto, Ontario M5S 2S1, Canada.

The 5-HT_1 agonist, mCPP, has been reported to produce subjective effects similar to those following alcohol intake and increase desire for alcohol in chronic alcoholics. The aim of the present study was to assess the effects of mCPP on E intake and the behavioural profile exhibited by the rats prior to and during an E limited access procedure. Following an acquisition phase, rats were placed in individual drinking cages at 1630 h each day and 15 mins later were given 40 mins access to 12% E solution and water. The rats' behaviour was scored every 15 secs as: drinking, active, grooming or resting. In E consuming rats (0.55 ± 0.06 g/kg), mCPP (0.1-1 mg/kg s.c.) significantly reduced E intake by 33% to 85% ($p < 0.05$) compared to vehicle treatment days. Water intake was unaffected. On vehicle-treated days, rats exhibited a consistent behavioural profile. Following 1 mg/kg mCPP, prior to E access, rats rested more and exhibited fewer tube directed behaviours ($p < 0.05$). Rats with no E preference (0.07 ± 0.01 g/kg) also exhibited a similar shift in their behavioural profile. Thus, mCPP caused a marked attenuation in E intake in E-preferring rats. At the lower doses investigated this reduction was selective and not due to behavioural disruption. The effect on preparatory behaviour at 1 mg/kg may reflect a reduced anticipation for E. Alternatively, the anxiogenic properties of mCPP may underlie this profile as is supported by our observations in the low drinking rats.

ETHANOL PRODUCES NALOXONE-BLOCKABLE ENHANCEMENT OF EXTRACELLULAR DOPAMINE IN NUCLEUS ACCUMBENS OF LEWIS RATS. E.L. Gardner* and J. Chen, Departments of Psychiatry and Neuroscience, Albert Einstein College of Medicine, New York, NY 10461

Activation of brain reward mechanisms is hypothesized to constitute the essential reinforcement produced by abusable substances (Wise, *Pharmacol. Biochem. Behav.* 13[suppl.1]:213-223, 1980), and brain dopamine (DA) systems projecting to the nucleus accumbens (Acc) are hypothesized to constitute a crucial substrate for brain reward (Wise & Bozarth, *Brain Res. Bull.* 12:203-208, 1984). However, the action of ethanol on these brain systems has been less clear than for other abusable drugs. We now report that acute ethanol challenge (0.5-2.5 g/kg, i.p.) induces a dose-dependent increase in basal extracellular levels of DA and its main metabolites, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), in Acc of freely moving Lewis rats as measured by *in vivo* brain microdialysis. Naloxone at 0.1 mg/kg i.p. produced 50% blockade of this effect, and naloxone at 0.5 mg/kg i.p. produced 100% blockade. These data confirm previous microdialysis findings of ethanol-induced activation of forebrain DA systems (Di Chiara & Imperato, *Proc. Nat. Acad. Sci. U.S.A.* 85:5274-5278, 1988), but additionally implicate endogenous opioid peptide mechanisms in ethanol's activation of brain reward substrates. Thus, the present data may help to explain previous findings that naloxone blocks ethanol's enhancing effects on electrical brain-stimulation reward (Lorens & Sainati, *Life Sci.* 23:1359-1364, 1978). (Supported by NIH grant RR 05397, NIDA grant DA 03622, and a research grant from the Aaron Diamond Foundation).

QUINPIROLE MICROINJECTED INTO THE VENTRAL TEGMENTAL AREA, DECREASES ETHANOL REINFORCED RESPONDING IN THE RAT. H.H. Samson*, C.W. Hodge, M. Haraguchi, R.S. Lewis and H.L. Erickson. Alcohol and Drug Abuse Institute, University of Washington, Seattle, WA 98195.

The role of the mesolimbic dopamine system in drug reinforcement processes has received wide attention over the last several years. However, the role this system may play in ethanol reinforcement remains to be elucidated. In this study, rats were trained to lever press for oral ethanol (10% v/v) reinforcement using a sucrose-substitution procedure. They were neither food nor water restricted during the experiment. When stable responding was achieved, bilateral cannula guides were implanted 1mm above the ventral tegmental area (VTA). Following recovery, quinpirole at doses of 0.001, 0.01, 0.1 and 1.0 ug/brain injected into the VTA were tested at weekly intervals.

At doses of 0.1 and 1.0, responding was significantly decreased compared to both saline and sham control sessions. The decrease in responding was primarily a result of an early termination of the normal response pattern. This effect was identical to that observed in prior research on the response pattern following microinjection of the D2 DA antagonist raclopride into the n. accumbens. The results suggest that a blockage of DA transmission in the mesolimbic dopamine system at either the VTA or the n. accumbens reduces ethanol reinforced behavior. This supports the hypothesis that ethanol reinforcement involves this mesolimbic DA pathway as implicated for reinforcement with other drugs of abuse.

SENSITIZATION TO THE DOPAMINE RELEASE-ENHANCING EFFECTS OF ETHANOL DEMONSTRATED IN MALE LONG-EVANS RATS. D. Benjamin*, E.R. Grant, K.R. Goldstein, and L.A. Pohorecky. Center of Alcohol Studies, Rutgers University, Piscataway, NJ 08855.

In contrast to Wistar and Sprague-Dawley rats, dopamine (DA) release in the n. accumbens (NA) of male Long Evans rats does not increase in response to an initial exposure to ethanol (ET). The present study characterized the effect of repeated exposures to ET on the release of DA, serotonin (5-HT), and their metabolites using intracerebral microdialysis coupled with HPLC-EC. ET-naive male Long-Evans rats were implanted with guide cannulae over the NA and the ventral tegmental area (VTA). One week after surgery, microdialysis probes with active membrane lengths of 2.5 mm in the NA and 2 mm in the VTA were lowered. The probes were perfused with Ringer's solution at a rate of 1 μl/min. On the first day of dialysis, baseline amounts of neurochemicals were determined over 3-5 samples taken at 20 min intervals, after which saline was injected IP. Following one or more post-saline samples, ET (1.0 g/kg, IP) was injected and 4 samples were collected, then a second 1 g/kg injection was given. This procedure was then repeated 24, 48, or 72 h later. We have found that, in Long-Evans rats, DA release in the NA does not increase in response to the initial exposure to ET. Subsequent exposure to 1 g/kg caused 303$\pm$11% ($p < 0.05$, n=6) increments in DA release in the NA 24 h later. Substantial increments were found at the later timepoints. These results demonstrate increases in the response of the mesolimbic DA system to ET with repeated exposures, and suggest that increases in DA release in the NA might underlie sensitization to the reinforcing/rewarding effects of ET in Long-Evans rats (see Goldstein *et al.*, this volume). Further characterization of the mesolimbic DA sensitization to ET is in progress. (Supported by Smithers Prevention and NIAAA grants AA05306 and AA08499).

598.6

EFFECT OF ETHANOL ON THE RELEASE OF MONOAMINES IN THE NUCLEUS ACCUMBENS OF THE ALCOHOL PREFERRING AA AND ALCOHOL AVOIDING ANA RATS. K. Kiianmaa*, J. Kokkonen, M. Nurmi and I. Nykänen. Biomedical Research Center, Alko Ltd, Helsinki, Finland.

The importance of central monoamines, with the emphasis on the dopaminergic neurons, in the control of voluntary ethanol consumption was examined by studying the effect of ethanol on the extracellular levels of monoamines in the nucleus accumbens of the alcohol preferring AA (Alko Alcohol) and alcohol avoiding ANA (Alko Nonalcohol) rats with *in vivo* microdialysis. Samples were collected from freely moving animals every 15 minutes, and concentrations of the monoamines and their metabolites were determined in the dialysate with smallbore HPLC. Ethanol (0.5, 1, or 2 g/kg, IP) significantly increased the extracellular levels of DOPAC and HVA in a dose dependent manner suggesting stimulation of dopamine release by ethanol. A similar trend was found with dopamine itself although the results from the present material did not reach significance. The extracellular levels of 5-HT, 5-HIAA or noradrenaline were not affected.

598.7

ETHANOL AND SEROTONIN (5-HT)-MEDIATED MEMBRANE RESPONSES IN RAT HIPPOCAMPAL CA1 NEURONS. Alex. H.L.Lau* and Gerald.D. Frye. Dept. of Med. Pharmacol. & Toxicol., Texas A&M Univ., Coll. of Med., College Station, TX 77843-1114.

Increasing evidence suggests that 5-HT plays an important role in ethanol tolerance and reinforcement. Intracellular recordings in hippocampal brain slices were used to evaluate the effects of ethanol on 5-HT mediated membrane hyperpolarization and spike afterhyperpolarizations (AHPs) block in CA1 pyramidal neurons. Neither acute ethanol (30 mM) treatment in vitro nor in vivo ethanol dependence affected 5HT-mediated (1-100μM) membrane hyperpolarization. Acute ethanol (30mM) increased AHPs during the 40 min superfusion making its apparent biphasic effect on 5-HT-mediated (1-100μM) inhibition of AHPs difficult to interpret. Most striking was the complete block of ethanol-induced enhancement of the AHP by 5-HT (100μM). In vivo ethanol dependence did not alter 5-HT inhibition of the AHP. These results suggest that ethanol may interact with presumed 5-HT_4 receptors thought to mediate AHP block in the hippocampus, while 5-HT_{1A} receptors appear relatively resistant to ethanol. Supported in part by AA06322 & RSDA, AA00101 to GDF.

BEHAVIORAL EVIDENCE FOR DOWN-REGULATION OF 5HT3 RECEPTORS PRODUCED BY CHRONIC ETHANOL. C.J. Wallis, S.M. Rezazadeh , and H. Lal* Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX, 76107.

Ethanol treatment increases the efficacy of ligand gated ion channels; thus it may result in down regulation of such receptors. In the 5HT receptor family, only 5HT3 receptors are located on ligand gated ion channels. MDL72222 (MDL, a 5HT3 receptor antagonist, 10 mg/Kg,1h) produced no effect on the time spent in the open arms of an elevated plus maze (EPM, Lal et al., Alcohol 8:467-471, 1991) in naive rats, but significantly reduced the total arm entries. In these rats, MDL (10 mg/Kg) given 1h prior to an injection of ETOH (1.5 g/Kg, ip) resulted in a reduction of ETOH-induced incoordination (rotorod) without changing the rate of recovery (additive with ETOH tolerance). After chronic ETOH treatment (7 d in liquid diet, 4.5%), open arm and total arm activity was reduced in animals tested 12 h after a final dose of ETOH, 3 g/Kg. Animals given MDL (5,10, or 20 mg/Kg, 1h) showed a further reduction in open arm and total arm activity, demonstrating exacerbation of these symptoms of ETOH withdrawal. MDL (10mg/Kg) given to naive animals trained to discriminate pentylenetetrazol (PTZ) from saline (Lal et al., JPET 247:508-518, 1988) resulted in a reduction of the threshold dose for PTZ discrimination. ETOH withdrawal also reduced the threshold dose for PTZ discrimination and this effect was additive with that of MDL. It is hypothesized that ETOH treatment results in down regulation of 5HT3 receptors as part of the development of tolerance and/or dependence. Supported by NIAAA Grant AA06890

EXTRACELLULAR CONCENTRATIONS OF DOPAC, HVA AND 5HIAA IN NUCLEUS ACCUMBENS ARE CORRELATED WITH MEASURES OF ETHANOL-SEEKING BEHAVIOR IN RATS. B.A. Blanchard*, S. Wang, S. Steindorf & S.D. Glick, Dept. of Pharmacology & Toxicology, Albany Medical College, Albany, NY 12208

The mesolimbic dopamine (DA) system has been proposed as a neurochemical substrate for the reinforcing effects of drugs of abuse such as stimulants, opiates and ethanol (EtOH). Rats with high EtOH preference, as a group, have been reported to have lower levels of DA and 5HT in nucleus accumbens (NAC) relative to non-preferring rats. We examined the role of individual differences in DA, DOPAC, HVA and 5HIAA in NAC and striatum (STR) in individual differences in EtOH consumption. Levels of these compounds were assessed in freely moving adult male and female Long-Evans rats by in vivo microdialysis and HPLC. Rats were then trained to bar press for oral EtOH reinforcement. Intake of and preference for 10% (v/v) EtOH were significantly correlated with several neurochemical measures in NAC: DOPAC, HVA and 5HIAA, but not DA, were inversely correlated to measures of EtOH-seeking behavior. There were no significant correlations of STR metabolites with EtOH intake. These findings indicate that individual differences in EtOH intake are related to differences in neurotransmitter function in a terminal region of the mesolimbic system, providing further support for its role in the reinforcing properties of EtOH.

EFFECTS OF CHRONIC ETHANOL IN NMDA-EVOKED RELEASE OF ^{3}H-NORADRENALINE IN THE RAT HIPPOCAMPUS. R.Labarca[1], C.Sepúlveda[1], M.Seguel[1], K.Gysling[2], G.Bustos*.[1]Faculties of Medicine and [2]Biological Sciences, Catholic University, Santiago, Chile.

Recent findings support the notion that ethanol-induced behavior is mediated, at least in part, by the NMDA/ionophore complex. For this reason, we decided to study the effects of chronic ethanol administration on the function of NMDA receptor using NMDA-evoked release of ^{3}H-Noradrenaline from hippocampal slices as a functional model.

In CA1-CA3, ethanol in vitro, at contrations of 10, 20,50 and 100 mM, evoked the release of aspartate (ASP), the highest concentrations (50 and 100 mM) being less potent; omission of Ca++ ions from the superfusion media completely abolished the ethanol-induced effect. The evoked release of GLU was much weaker, and only observed at higher concentrations of ethanol (20,50 and 100 mM). At 20 mM, ethanol enhanced K+-evoked release of ASP but not that of GLU.

Twenty four hours after a chronic liquid ethanol diet for 3 months, NMDA-evoked release of ^{3}H-Noradrenaline was marginally augmented in the dentate girus (DG) but not in CA1-CA3. After 30 days of withdrawal, however, the NMDA-evoked release of ^{3}H-Noradrenaline in the DG was Markedly inhibited, whereas in CA1-CA3 a trend of this phenomenon was observed, without reaching statistical significance.

These results suggest that chronic ethanol consumption produces changes in NMDA/ionophore complex that may be related, at least in part, to the pharmacological effects of ethanol. (Supported by Fondecyt Nº 0739/91).

DRUGS OF ABUSE: COCAINE AND BIOCHEMISTRY

599.1

ACUTE AND CHRONIC COCAINE ADMINISTRATION: DOSE RESPONSE EFFECTS ON ZIF268, C-FOS, PREPROENKEPHALIN, AND PREPRODYNORPHIN mRNAs IN RAT BRAIN. J.B. Daunais*, W.T. Bohler, and J.F. McGinty Dept. of Anatomy and Cell Biology, East Carolina University School of Medicine, Greenville, N.C. 27858.

Wistar rats were administered saline or cocaine HCl (NIDA) i.p. at 10, 20, or 30 mg/kg once daily for 1 or 10 days. One hour following the last injection, the rats were anesthetized and decapitated. Brains were removed and frozen until 12µm sections were cut on a cryostat. Sections were fixed, defatted, pretreated, and hybridized with a 48mer oligonucleotide probe to preprodynorphin (PPD) or preproenkephalin (PPE), or a 40mer oligo probe to c-fos or zif268 at 37°C for 20hr. After stringent washing, the slides were dried and apposed to Kodak X-OMAT film for 2 wk (PPD) or 1 wk (PPE, c-fos, zif).

Zif268 mRNA increased in a dose-dependent fashion after acute and chronic cocaine in layers IV and VI of frontal and parietal cortex, layer II of piriform cortex, olfactory tubercle, dorsal striatum including the fundus striati, islands of Calleja, and tenia tecta. Acute cocaine induced a far more robust signal than chronic cocaine in these areas. Minimal induction of Zif268 hybridization signal was present in the nucleus accumbens, particularly in the core of cocaine-treated animals after acute or chronic administration.

In the acutely treated rats, c-fos mRNA increased dose dependently in piriform cortex, olfactory tubercle, and dorsal striatum, whereas signal was lacking in the chronic cocaine groups, except in the piriform cortex, indicating a downregulation of c-fos.

PPE and PPD signal hybridization were robust in the dorsal and ventral striatum of all groups. Digital image analysis is currently under way to determine if there are any appreciable differences in signal between the cocaine-treated animals and their respective controls after acute or chronic administration.. These data suggest that widespread changes occurring at the molecular level after acute cocaine may differ from those following chronic cocaine. Supported by DA 03982.

599.2

AP-1 AND CRE-BINDING ACTIVITY ARE REGULATED IN THE RAT LOCUS COERULEUS AND NUCLEUS ACCUMBENS FOLLOWING CHRONIC MORPHINE OR COCAINE. B.T. Hope*, H. Nye, and E.J. Nestler, Lab. of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale School of Medicine, New Haven, CT 06508.

We have studied changes associated with transcription factors, which control gene expression, in two model systems of drug addiction in the rat: chronic morphine in the locus coeruleus (LC) and chronic cocaine in the nucleus accumbens (NAc). Correlating with increases in c-fos and c-jun in the LC during morphine withdrawal (*Brain Res.*, 525:256), AP-1 binding in gel shift assays has now also been shown to increase. A decrease in CREB phosphorylation with acute morphine, and an increase during morphine withdrawal has been shown recently in the LC (*J. Neurochem.*, 58:1168). We now report that although there is no change in CRE-binding during acute morphine, there is an increase following chronic morphine. This suggests the possibility that chronic morphine increases the total amount of some CRE-binding protein(s) in this brain region. In the NAc, in addition to the previously shown desensitization in c-fos and c-jun expression and persistent increase in AP-1 binding following chronic cocaine (Hope et al., *PNAS*, 1992), there is also an increase in CRE-binding, which increases even further following 1 week of withdrawal. There are also striking regional differences in CRE-binding patterns in gel shift assays, further indicating regional heterogeneity of transcription factors in the brain. The results indicate that levels of transcription factors are altered in the brain following chronic drug treatment, and that such alterations may underlie functional changes associated with addiction.

599.3

ACTIVATION OF TRANSCRIPTION FACTOR GENES IN STRIATUM BY COCAINE IS MEDIATED BY BLOCKADE OF BOTH 5-HT AND DA UPTAKE. **R.V. BHAT* AND J.M. BARABAN. Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.**

Cocaine elicits robust increases in the expression of several transcription factors in striatum. As this response is abolished by D_1 receptor blockade, it has been assumed that blockade of DA uptake mediates the striatal activation of transcription factors. However, we have found that the selective 5-HT uptake inhibitors, fluoxetine (5-10 mg/kg) and citalopram (2 mg/kg) which do not induce c-Fos or *zif268* by themselves, markedly potentiate the ability of mazindol, an inhibitor of DA uptake, to activate c-*fos* or *zif268* in striatum. These findings suggest that cocaine's blockade of 5-HT uptake contributes to its activation of these genes. To assess the role of the 5-HT system, rats were treated with p-chloroamphetamine to lesion the 5-HT system selectively. This treatment markedly reduces activation of *zif268* and c-*fos* by cocaine in the striatum. In contrast, lesioning of the NE system with DSP-4 does not. These results indicate that, along with the DA system, the 5-HT system plays a key role in mediating cocaine's activation of transcription factor genes in the striatum. The involvement of both these systems may help explain several anomalous features of the pharmacology of this response.

599.4

REGULATION OF PREPROTRH mRNA LEVELS IN RAT BRAIN BY CHRONIC COCAINE. K.A. Sevarino* and R.J. Primus, Div. of Molecular Psych., Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06508.

Short-term and long-term consequences of chronic cocaine exposure on levels of preproTRH (ppTRH) mRNA were examined in adult male rats. Rats received i.p. injections of cocaine hydrochloride (15 mg/kg, b.i.d.) for fourteen days, and were then sacrificed 45 min, 18 hr, 72 hr, or one week following the last cocaine injection. RNA was extracted from the amygdala (AMY), hippocampus (HIPPO), hypothalamus (HYPO), and nucleus accumbens (NAc), and levels of ppTRH mRNA were measured by solution hybridization assay. PpTRH mRNA was decreased by 30-40% in HYPO and NAc at 45 min and 18 hr following the last chronic cocaine injection. While levels of ppTRH mRNA returned to control levels by 72 hr post-injection in the NAc, levels remained significantly decreased in the HYPO after one week of cocaine withdrawal. In the AMY, ppTRH mRNA was decreased by 45% at 45 min post-injection. PpTRH mRNA levels in the AMY returned to control levels by 18 hr post-injection and then increased significantly both 72 hr and one week following cocaine withdrawal. PpTRH mRNA in the HIPPO increased slightly at 45 min post-injection, increased by 40-50% at both 18 hr and 72 hr post-injection, and remained increased, by 20%, one week following cocaine withdrawal.

This study shows that levels of ppTRH mRNA are regulated by chronic cocaine exposure in a time-dependent and region-specific manner. The long-term changes in ppTRH mRNA may suggest a role for this peptide in drug craving and addiction.

599.5

THE USE OF SUBTRACTION HYBRIDIZATION TO DETECT COCAINE UP-REGULATED MESSENGER RNAs IN RAT NUCLEUS ACCUMBENS. J.R. Walker*, E.J. Nestler, and K.A. Sevarino. Division of Molecular Psychiatry, Departments of Psychiatry and Pharmacology, Yale Univ. School of Medicine, New Haven, CT 06508.

Cocaine is one of the most reinforcing substances known. Further, chronic use results in sensitization to the drug, a phenomenon which may be related to its powerful addictive effects. Behavioral, electrophysiological, and biochemical evidence indicates that the nucleus accumbens (NAc) is part of the neural pathway mediating the reinforcing and sensitizing properties of cocaine. To identify protein alterations in the NAc that underlie cocaine's effects, we have developed a subtraction hybridization procedure to detect cocaine-regulated mRNAs. Subtraction enrichment was performed by hybridizing cDNA synthesized from cocaine-treated NAc mRNA with mRNA from untreated rat NAc. The subtracted cDNA was used as a probe to screen a rat NAc cDNA library, and sequences representing mRNAs up-regulated by chronic cocaine were isolated. The mRNAs detected to date fall into three groups: several novel proteins, mitochondrially-encoded proteins, and artifactually-isolated ribosomal RNAs. We are currently characterizing the cocaine-regulated proteins, both known and novel, for their pharmacological specificity to cocaine, the time course of their regulation, and the anatomical pattern of their regulation. We are also improving the subtraction hybridization protocol to eliminate the artifactual detection of ribosomal RNAs.

599.6

DOPAMINE TRANSPORTER: SPECIES DIFFERENCES IN MOLECULAR WEIGHT. A. Patel, L. Markham+, R. Lew*, G. Uhl+ and M.J. Kuhar. Labs. of Mol. Pharmacology & +Mol. Neurobiology, ARC/NIDA, Box 5180, Baltimore, MD 21224.

The dopamine transporter (DAT) is glycosylated in a brain-region-species fashion, but species differences in these post-translational modifications have not been described. Four potential N-linked glycosylation sites are found in the rat DAT 2nd extracellular loop and only 3 sites in the human DAT cDNA although it encodes an almost-identical number of amino acids (see abstract by D. Vandenbergh et.al.). We now report use of the DAT photoaffinity label ^{125}I-DEEP {[^{125}I]1-[2-(diphenyl methoxy) ethyl]-4-[2-(4-azido-3-iodophenyl) piperazine} and SDS-polyacrylamide gel electrophoresis to estimate the sizes of the mature DAT protein in striatal membranes from the dog, rat, and human and its size in primate kidney COS cells expressing the rat DAT cDNA. Prestained standards were used to estimate molecular mass and 30 μM (-) cocaine was used to define nonspecific labelling. Canine, rat, human and COS cell membranes displayed transporter sizes ranging from 76 to 110 kDa. Initial results using endo- and exo-glycosidases indicated that in the striatum and nucleus accumbens, the differences in apparent transporter size largely resulted from differential glycosylation.

599.7

CHARGE ISOFORMS OF DOPAMINE TRANSPORTERS. R.A. Vaughan, M.T. McCoy and M.J. Kuhar*. NIDA Addiction Research Center, P.O. Box 1580, Baltimore, MD 21224

Dopamine transporters from rat striatum and nucleus accumbens membranes were photoaffinity labeled with either ^{125}I-DEEP, (a GBR analog) or ^{125}I-RTI-82 (a cocaine analog) (Brain Res. 1992, 596:173). Radiolabel-pure preparations were subjected to isoelectric focusing in one dimensional urea-polyacrylamide slab gels in order to investigate sample heterogeneity. Following electrofocusing, radioactivity corresponding to dopamine transporters was distributed into several sharp bands of approximate pI 5.6-6.6. Very similar patterns were obtained using tissue from either region and either photoaffinity probe. Since the predicted isoelectric point of the protein based on cDNA sequence is 7.05, the multiple acidic forms observed may be a consequence of heterogenous post-translational modifications. Enzymatic deglycosylation and dephosphorylation of dopamine transporter samples are being used to test this hypothesis.

599.8

[^{3}H]GBR12935 AND [^{3}H]BTCP LABEL MULTIPLE BINDING SITES IN RAT STRIATAL MEMBRANES. H.C. Akunne[1]*, C. Dersch[1], G.U. Char[1], J.S. Partilla[1], B.R. de Costa[2], K.C. Rice[2] and R.B. Rothman[1]. [1]LCP, NIDA Addiction Research Center, Baltimore, MD 21224 and [2]LMC, NIDDK, NIH, Bethesda, MD 20892. *Neurosciences Section, Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

The present study addressed the hypothesis that there exist multiple sites/states associated with the dopamine (DA) transporter. We used [^{3}H]GBR12935 AND [^{3}H]BTCP to label the DA transporter present in striatal membranes, and conducted the assays under identical assay conditions : 18-24 hr incubations at 4^0 C in 55.2 mM sodium phosphate buffer, pH 7.4, with a protease inhibitor cocktail. In order to obtain data suitable for quantitative curve fitting, it was necessary to periodically repurify the [^{3}H]ligands by HPLC. Under these conditions, we observed greater than 90% specific binding. The method of binding surface analysis was used to characterize the interaction of GBR12935, BTCP, mazindol, and CFT with binding sites labeled by the [^{3}H]ligands. Fitting of the data to one and two site binding models, using MLAB-PC, demonstrated that for both [^{3}H]ligands, the two site model fit the data far better than did the one site model. Structure-activity studies suggested that while each radioligand labeled a site common to both, each also labeled a distinct site. These results support the hypothesis of multiple binding sites/states associated with the DA transporter. Identification of selective agents for these sites may be valuable tools for further studies of the DA transporter.

599.9

COCAINE RECEPTORS SOLUBILIZED FROM RHESUS STRIATUM ARE HETEROGENEOUS ON THE BASIS OF CHARGE. L.M. Gracz* and B.K. Madras. Harvard Medical School, New England Regional Primate Research Center, Southborough, MA 01772.

High- and low-affinity binding components for [^{3}H]cocaine and [^{3}H]CFT (2β-carbomethoxy-3β-(4-fluorophenyl)tropane) associated with the dopamine transporter have been identified in monkey caudate-putamen. The heterogeneity of binding sites for [^{3}H]CFT was not an artifact produced by the freezing and thawing of tissue as both sites were observed in freshly prepared and in frozen striatal homogenates from squirrel monkey. Futhermore, both components of [^{3}H]CFT binding were preserved in solubilized striatal membranes (1% digitonin in Tris-HCl buffer; 25% yield) from rhesus monkey. Size-exclusion gel chromatography of the solubilized preparation failed to resolve two distinct binding components and instead yielded a single, broad peak of [^{3}H]CFT binding centered about an apparent molecular weight of 200,000. In contrast, DEAE chromatography yielded three distinct peaks of [^{3}H]CFT binding. The pharmacological profiles of the peaks were determined in competition experiments with [^{3}H]CFT and other drugs (n = 2). [^{3}H]CFT binding was fully inhibited by cocaine cogeners, monoamine uptake inhibitors, and dopamine in each peak. Additionally, the peaks exhibited different high- and low-affinity binding profiles for cocaine, GBR 12909, and dopamine. However, the individual DEAE peaks could not be resolved by size-exclusion gel chromatography. The results suggest that cocaine binding site heterogeneity may be a function of the charge state of the dopamine transporter. Supported by USPHS grants DA00499, DA06303, MH14275, and RR00168.

CATIONIC AND ANIONIC REQUIREMENTS FOR THE BINDING OF [^{3}H]CFT TO THE DOPAMINE UPTAKE CARRIER. M.E.A. Reith* and L.L. Coffey. Dept. of Basic Sci., University of Illinois College of Medicine, Peoria, IL 61656.

[^{3}H]CFT binds to the dopamine transporter with a higher affinity than its parent molecule [^{3}H]cocaine. In the present study with freshly prepared Sprague-Dawley striatal P_2 membranes, [^{3}H]CFT binding occurred to a single site. When Na^+ was the only cation present at 1-200 mM and phosphate the only anion, optimal binding was observed at 30-50 mM Na^+ with a profound reduction in binding at higher [Na^+]. Similar binding values were observed when [Na^+] was varied with Cl^-, NO_3^-, or $S_2O_4^{2-}$ as the co-varying anion in the presence of a fixed concentration of 10 mM sodium phosphate as the buffer; much lower binding, over the entire sodium concentration range, occurred when the fixed sodium phosphate concentration was reduced to 1 mM. Curves describing binding at varying [NaI] with 1 or 10 mM sodium phosphate were above those for varying [NaCl], [$NaNO_3$], or [Na_2SO_4] at the respective [sodium phosphate]; again phosphate anion had a stimulatory effect. With I^-, maximal binding occurred at a higher [Na^+] (150 mM or more) than with any other anion tested. With 1 mM sodium phosphate, substitution of 10 mM KCl or LiCl for NaCl virtually abolished binding. At 10, 30, and 200 mM sodium phosphate the K_d of binding was 22, 9, and 32 nM, respectively; with 50 mM sodium phosphate, substitution of 49 mM NaCl increased the K_d from 9 to 30 nM; with 130 mM sodium phosphate, substitution of 120 mM NaI reduced the K_d value by one-half; there was little or no change in the B_{max} (214 pmol/g fresh tissue). These results are compatible with the notion that [^{3}H]CFT binding requires low concentrations of Na^+, is stimulated by phosphate anion or I^-, but is unaffected by Cl^-, NO_3^-, or SO_4^{2-}. Concentrations of Na^+ above 50 mM become inhibitory, an effect counteracted by I^-.

MERCURIC CHLORIDE HAS A BIPHASIC EFFECT ON [^{3}H]METHYLPHENIDATE BINDING TO THE DOPAMINE TRANSPORTER. M.M.Schweri* Mercer Univ.Sch. of Med., Macon,GA 30207.

In previous work, we have shown that one or more Cys residues are present in or near the cocaine-sensitive domain on the dopamine transport complex recognized by the radiolabeled stimulant, [^{3}H]methylphenidate ([^{3}H]MP) [*Neuropharmacology* 29:901, 1990]. Because Hg^{+2} is known to form a strong complex with sulfhydryl groups, the present work was undertaken to determine the effect of $HgCl_2$ on binding to this site in striatal tissue preparations of male Sprague-Dawley rats. In the presence of 0.05-1000 μM $HgCl_2$, a biphasic dose-response curve was obtained. Binding was enhanced below 5 μM $HgCl_2$ (maximum = 160% of control at 2.5 μM), but was completely inhibited at higher concentrations (IC_{50} = 8.5 μM). Scatchard analyses of [^{3}H]MP binding in the presence of 1 and 10 μM $HgCl_2$ gave the following results (3 experiments were conducted in each series):

SERIES	[$HgCl_2$]	K_D (M)	B_{max} (pmols/mg protein)
I	0	84 ± 4	7.5 ± 0.2
	1 μM	58 ± 4*	8.5 ± 0.5
II	0	93 ± 10	9.8 ± 0.5
	10 μM	220 ± 41**	6.6 ± 0.1*

*p<.01, **p<.05 compared to paired value at 0 $HgCl_2$, one-tailed paired t-test. $HgCl_2$ may differentially affect stimulant binding via interaction with specific Cys residues in the transporter macromolecule.

CHARACTERIZATION OF FETAL RAT BRAIN COCAINE RECEPTORS LABELED WITH [^{3}H]COCAINE OR THE POTENT COCAINE ANALOG [^{125}I]RTI-55. L.P. Shearman*, R.L. Maguire, and J.S. Meyer. Dept. of Psychology, Neuroscience and Behavior Program, Univ. of Massachusetts, Amherst, MA 01003.

[^{3}H]cocaine binding sites are present in the fetal rat brain (Meyer and Collins, Soc. Neurosci. Abs. 15:255, 1989). To characterize these sites, we assessed the potency of various monoamine uptake blockers to inhibit [^{3}H]cocaine (10 nM) binding to gestational day (GD) 20 whole-brain membranes. The following rank order of potency (IC_{50}) was obtained: cocaine > GBR 12909 ~ zimelidine ≥ desipramine ~ mazindol ≥ clomipramine ~ nisoxetine (all drugs yielded pseudo-Hill coefficients less than 0.7). Thus, cocaine appears to bind primarily to the dopamine and serotonin transporters in the fetal brain. In subsequent experiments, we studied the binding of the potent cocaine analog [^{125}I]RTI-55. GD20 whole-brain membranes were incubated with 10 pM [^{125}I]RTI-55 along with increasing concentrations of unlabeled RTI (0.1 pM to 100 nM). 50 μM cocaine was used to define nonspecific binding. A 2-site model was preferred statistically over a 1-site model by non-linear computerized curve fitting. Kinetic constants were as follows: K_D=0.13 nM, B_{Max}=0.18 pmol/mg protein for the high-affinity site, and K_D=11.56 nM, B_{Max}=0.59 pmol/mg protein for the low-affinity site. The K_D of the high-affinity site closely parallels that reported for adult rat striatum (Boja et al., Eur. J. Pharmacol. 194:133, 1991), whereas the K_D of the low-affinity site is somewhat higher. [^{125}I]RTI should be a useful ligand for studying the effects of prenatal cocaine on the subsequent development of cocaine binding sites. Supported by DA-06495.

EFFECTS OF INJECTION OF KINASE INHIBITORS INTO THE A10 DOPAMINE REGION ON COCAINE-INDUCED MOTOR ACTIVITY. J.D. Steketee*. Department of Pharmacology and Therapeutics, Louisiana State University Medical Center, Shreveport, LA 71130-3932.

Acute peripheral injection of cocaine stimulates motor activity in parallel with an increase of extracellular dopamine in the nucleus accumbens, as measured by in vivo microdialysis. The augmented behavioral and neurochemical responses which occur with repeated, intermittent treatment are termed sensitization. In other neuronal models, an increase in protein kinase C (PKC) activity has been associated with sensitization. Before examining the role of PKC in sensitization, it was necessary to examine the effects of different kinase inhibitors on the acute motor-stimulant response to cocaine. Cannulae were bilaterally implanted above the ventral tegmental area (A10 region), a region proposed to be critically involved the sensitized behavioral response to cocaine, for intra-cranial injections. One week after surgery animals received intra-A10 injections of saline or a kinase inhibitor 5 min before receiving peripheral injections of saline or cocaine (15 mg/kg). Animals received each of the 4 possible treatment combinations with a minimum 72 hr inter-trial interval. The kinase inhibitors used in these studies included polymyxin B (PMB), a calmodulin kinase and PKC inhibitor, H7 hydrochloride, a PKC and protein kinase A (PKA) inhibitor and H8 hydrochloride, a PKA and cGMP-dependent protein kinase inhibitor. Preliminary data demonstrated that H7 dose-dependently inhibits, while PMB does not alter cocaine-stimulated motor activity. The most effective dose of H7 (30 nmol/side) did not significantly alter baseline motor activity. These data suggest that PKA may play a role in the acute motor-stimulant response to cocaine and will be verified with intra-A10 injections of H8. In vivo microdialysis studies are currently being conducted to determine whether the H7-induced inhibition of cocaine-stimulated motor activity, is associated with an inhibition of cocaine-induced dopamine release in the nucleus accumbens.

EFFECTS OF CHOLERA TOXIN INFUSION INTO THE NUCLEUS ACCUMBENS ON LOCOMOTOR BEHAVIOR. S. T. Cunningham[1]* and A. E. Kelley[2]. [1]Dept. of Psychology, Harvard University, Cambridge, MA 02138, [2]Dept. of Psychology, Northeastern Univ., Boston, MA 02115.

Intracellular signal transduction mechanisms are currently the focus of much research. Although manipulation of second messenger systems is widespread in cell biology, there are very few experiments examining the consequences of such manipulation on behavior. In three separate experiments, we investigated the effects of microinfusion of cholera toxin (CTX, a bacterial toxin that stimulates production of cyclic AMP) into the nucleus accumbens (N. Acc.) on locomotor activity in rats (N=30). For Experiment I, three groups of rats received either saline or CTX (50 or 500 ng/µl) into the N. Acc. Locomotor activity (horizontal and vertical activity) was measured for 4 h following a single CTX infusion and subsequently for 4 h on 6 consecutive days. No acute effects on motor activity were observed. However, the 500-ng dose of CTX induced long-lasting hyperactivity that was apparent 24 h later and that lasted 4 days. A smaller but significant hypermotility occurred on days 4 and 5 following infusion of the 50-ng dose. Site-specificity of this behavioral phenomenon was investigated in Experiment II by infusion of CTX (250 ng/µl) into either the N. Acc. or the posterior dorsal striatum (PDS). CTX treatment of the PDS had no behavioral effects, while the long-lasting hyperactivity following treatment of the N. Acc. was replicated. In Experiment III, the effect of intra-accumbens pretreatment with saline or CTX (10 ng/µl) on *d*-amphetamine (0.5 mg/kg)-induced motor activity was investigated. This low dose of CTX did not increase baseline motor activity one day later; however CTX did induce a sensitized locomotor response to amphetamine. These data suggest that CTX induces long-lasting upregulation of the cyclic AMP system which is reflected by enhanced motor responses normally mediated by the N. Acc. Further, the results may have important implications for mechanisms underlying drug-induced sensitization.

AGING AND BEHAVIOR II

SEROTONIN UPTAKE IN THE BRAINS OF AGING RATS: PAROXETINE BINDING AND THE EFFECTS OF IMIPRAMINE AND TETRAHYDROACRIDINE. R.C.Arora,* J.W.Crayton, and A. Gulati. Section on Biol. Psychiatry, Hines VA Hospital, Dept. of Pharmacology and Psychiatry, Loyola Stritch Sch. of Med., and Dept. of Pharmacodynamics, Univ. of IL., Chicago, IL.

To examine the relationship between aging and serotonin (5-HT) metabolism, we studied 5-HT uptake in the frontal cortex (FC) and hippocampus (H) of young (4mos.), adult (15 mos.) and old (24 mos.) Fischer 344 rats. 5-HT uptake was studied by measuring binding of the specific 5-HT uptake site ligand, ^{3}H-paroxetine (PA). Bmax of PA binding was significantly higher in the H of adult rats compared with either young or old rats. The difference in Bmax between young and old rats was not significant. Kd of PA binding did not change significantly with age. In contrast to the findings in H, FC showed no difference in Kd or Bmax in PA binding. Imipramine inhibited PA binding in FC and H but there was no difference in IC_{50} values between the three groups. Tetrahydroacridine (THA) inhibited PA binding in FC and H but was 2000 times less potent than imipramine. IC_{50} values for THA did not change with age in either brain region. These findings suggest that the number of 5-HT transporter sites in the hippocampus increase with brain maturity but then drops significantly during old age, and may have implications for the normal and pathological age-related decrements in learning and memory thought to be mediated by hippocampal structures.

C-FOS mRNA RESPONSE TO ACUTE HALOPERIDOL IS BLUNTED IN THE STRIATUM OF AGED RATS. D.J. Doble*, K.M.Merchant and D.M. Dorsa. Dept. of Psychiatry, Univ. of WA, Seattle WA 98195 and GRECC, VAMC, Seatttle WA 98108

Previous studies demonstrated that administration of the dopamine D2 receptor antagonist haloperidol (H) induces transcription of the neurotensin/neuromedin N (NT/N) gene in neurons of the dorsolateral striatum (DLSt). This effect may be mediated in part by the proto-oncogene c-fos. The administration of H results in a rapid increase in transcription of the c-fos gene in the DLSt; this precedes the induction of the NT/N mRNA response to H in this region.

We have observed a blunting of the striatal NT/N mRNA response to H in aged animals. To further characterize the subcellular mechanisms underlying this blunted NT/N response, 3 month old and 24 month old Fischer 344 rats were treated acutely with saline or H (1 mg/kg i.p.). Animals were sacrificed after 1/2 or 1 hour and blood was collected for H levels. In situ hybridization for c-fos was performed using a ^{35}S labelled oligonucleotide probe. Densitometric analysis of film autoradiograms revealed a significant increase in striatal c-fos mRNA in both of the H treated groups compared with controls ($p<0.001$). However, the c-fos mRNA response was decreased in the old H-treated animals when compared with the young H-treated animals ($p<0.01$). These data suggest that the age-related blunting of the NT/N mRNA response to H may result in part from decreased transcription of the c-fos gene. We will explore the possibility that this alteration in post-synaptic response reflects the senescent decline in D2 receptors. The effect of diminished c-fos transcription on the expression of primary transcripts of the NT/N gene in these animals will also be discussed.

LOCALIZATION OF AGING-RELATED CHANGES IN α_2-ADRENERGIC RECEPTORS TO SPECIFIC BRAIN REGIONS OF FISCHER 344 RATS D.R. Wallace* and N.R. Zahniser. Dept. of Pharmacology, Univ. of Colorado Hlth. Sci. Ctr., Denver, CO 80262.

Aging-related regulation of central α_2-adrenergic receptors was examined in specific brain regions of 8- and 27-month-old Fischer 344 rats. For these studies, saturation isotherms were generated with the partial α_2-adrenergic receptor agonist p-^{125}I-iodoclonidine (^{125}I-PIC) and quantitative autoradiographic analysis. Assays were carried out with ^{125}I-PIC (0.05 - 3 nM) and 50 mM Tris-HCl buffer (pH 7.4) containing 10 mM $MgCl_2$ and 1 mM EGTA for 90 min at 21°C. In the three brain regions investigated -- cerebral cortex, hypothalamus and locus coeruleus -- ^{125}I-PIC bound to a single class of noninteracting sites. The affinity of the receptor for ^{125}I-PIC did not differ among the three brain regions or between the two age-groups; the Kd values ranged from 0.4 - 1.5 nM. The rank order of the density of α_2-adrenergic receptors was hypothalamus > locus coeruleus > cerebral cortex. The density of receptors in the hypothalamus of the aged rats was reduced by approximately 60% (adult: 1350 ± 162 fmol/mg; aged: 561 ± 155). In contrast, no significant aging-related reductions were observed in either locus coeruleus (adult: 482 ± 144; aged: 350 ± 59) or cerebral cortex (adult: 246 ± 17; aged: 212 ± 21). These results demonstrate that there is a marked loss of α_2-adrenergic receptors in the hypothalamus of aged Fischer 344 rats, which is not observed in either locus coeruleus or cerebral cortex. The receptor down-regulation in the hypothalamus may contribute to altered behaviors in aged animals. Further, in locus coeruleus and cerebral cortex, functional changes, rather than changes in receptor affinity or density, would be expected to mediate aging-related changes which involve α_2-adrenergic receptors. P CHANNEL AND CALBINDIN ARE DIFFERENTIALLY AFFECTED FOLLOWING CORTICOSTERONE TREATMENT IN AGING. D. Hillman*, S. Chen, T.T. Aung, B. Cherksey, M. Sugimori, and R. Llinas, Department of Physiology and Biophysics, New York University Medical Center, New York, NY 10016

A polyclonal antibody (Cherksey et al. 1991 Soc. Neurosci.) against P type calcium channels (Llinas et al. 1989 *Proc. Natl. Acad. Sci. USA* **86**:1689-1693) was used to localize these channels in the mammalian CNS (Hillman et al. 1991 *Proc. Natl. Acad. Sci. USA* **88**:7076-7080). Electron microscopic examination revealed intensely labeled patches on the plasma membrane and ER of Purkinje cell dendrites and spines. Immunoreactions for calbindin protein produced the highest levels of reaction in the same types of neurons as the P channel. In the dentate gyrus of Fischer 344 aged rats (23 mo.), densitometric analysis showed a marked reduction in calbindin (as compared to 3 mo. of age); where as, P channel protein was moderately reduced. Corticosterone treatment of young rats, for one week, increased calbindin by 40% above normal, but P channel levels were unaffected. Aged rats treated with corticosterone, however, had about a 50% recovery of the calbindin aging-effect, while P channels were unaffected by the treatment. This study shows that steroid levels in aging may be a critical factor in controlling the level of calcium sequestration through calcium binding proteins. Supported by NIH-NINCDS: NS-13742 and NIH-NIA: AG-09480

BEHAVIORAL ANALYSIS OF CHRONIC NIMODIPINE TREATMENT IN AGED RATS. J. Hengemihle, E.L. Spangler, J.A. Joseph, D. Roberts, P. Garofalo, E. Bresnahan*, and D.K. Ingram, Gerontology Research Center, Natl. Inst. Aging, NIH, Baltimore, MD 21224.

Nimodipine is a calcium channel antagonist reported to have beneficial effects on treatment of ischemic damage as well as the potential for retarding aspects of brain and behavioral aging when provided chronically to rats (A. Scriabine *et al., FASEB J.* 3:1799, 1989). We treated aged male F-344 rats (22-24 mo) with nimodipine in subcutaneous pellets in the following doses: 0 (controls), 20 mg (low-dose) or 40 mg (high-dose) replenished after 6 wk. After 3 mo of treatment, surviving rats and a group of young controls (6 mo) were tested in a behavioral battery involving exploratory activity in an open field and in a runwheel cage as well as motor abilities required for remaining on an inclined screen, suspended from a wire, and balanced on a rotorod. Rats were also pretrained for one-way active avoidance in a straight runway before being trained in a 14-unit T-maze. During 20 trials rats were required to negotiate each of 5 maze segments within 10 sec to avoid footshock (0.8 mA). According to analysis of variance (ANOVA), nimodipine treatment produced no significant effects ($ps>0.05$) on body weight, food intake, or survival of aged rats. ANOVA of behavioral results indicated significant ($ps< 0.05$) age-related decline in performance of all tasks except in open-field behavior. Nimodipine treatment had no significant effects on performance of aged rats except in maze learning. Rats on the high-dose regimen performed significantly ($p<0.05$) better than aged controls in the maze. The results indicate that chronic nimodipine treatment of aged rats had no toxic effects and might be beneficial for preventing age-related decline in learning performance.

[^{3}H]CGS 19755 BINDING TO NMDA RECEPTORS IN RAT HIPPOCAMPUS: EFFECTS OF AGE AND CHRONIC NIMODIPINE. R.D. Kusztos[1], D.K. Ingram[2], J.A. Joseph[2], E.L. Spangler[2] and E.D. London[1]*. Addiction Res. Ctr., NIDA[1]; Gerontology Res. Ctr. NIA[2], Balto., MD 21224.

Previous reports have indicated marked age-related declines in hippocampal NMDA receptor concentrations in rats (e.g. M Tamaru et al., *Brain Res.*, **542**: 83, 1991). Nimodipine is a Ca^{2+} channel antagonist, reported to offer protection against cerebral ischemia, and to retard behavioral and brain aging in rats (A Scriabine et al., *FASEB J.*, **3**:1799, 1989). We have examined binding of [^{3}H]CGS 19755, a radioligand for NMDA receptors (DE Murphy et al., *Br. J. Pharmacol.*, **95**:932, 1988), in hippocampi of naive male F-344 rats of different ages, and of aged male F-344 rats treated chronically (3 mo) with nimodipine and provided with extensive behavioral testing (3 wk). Nimodipine was delivered via s.c. pellets of 20 mg (low dose) or 40 mg (high dose), which were replaced once after 6 wk. Assays were performed on well-washed, Triton-treated crude membranes.

In naive and untreated rats, marked age-related declines (42%) in [^{3}H]CGS 19755 binding were observed (23-25 mo vs. 7 mo). There was no significant age difference in protein content of the hippocampi. In contrast, hippocampi of rats receiving extensive training did not show an age-related decline in [^{3}H]CGS 19755 binding. Furthermore, compared to corresponding control rats, aged rats treated with low (but not high) doses of nimodipine revealed significantly higher hippocampal [^{3}H]CGS 19755 binding ($p < 0.05$). Thus, our findings suggest that age-related decline in hippocampal NMDA receptor binding appears only in naive rats, while chronic treatment with nimodipine may up-regulate NMDA receptor binding in highly trained, aged rats.

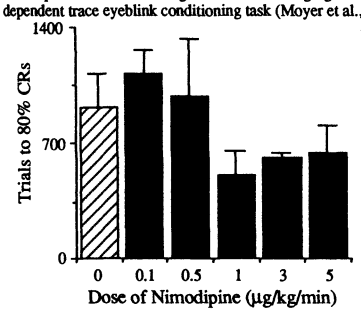
DOSE DEPENDENT EFFECT OF NIMODIPINE ON LEARNING RATE IN AGING RABBITS. M. Kowalska and J.F. Disterhoft*. Department of CMS Biology, Northwestern University Medical School, Chicago, IL 6061

Nimodipine, a dihydropyridine calcium entry blocker, facilitates learning in aging rabbits (Deyo *et al.*1989). The present study is determining the relation between i.v. nimodipine dose and learning enhancement of aging rabbits in the hippocampally - dependent trace eyeblink conditioning task (Moyer et al.,1990).



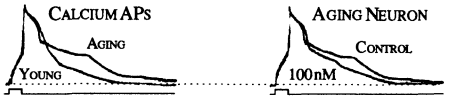
20 aging female rabbits (mean age=38.5 mo) have been trained using a 500 msec trace eyeblink (nictitating membrane) task to a behavioral criterion of 80% conditioned responses (CRs) or for a maximum of 25 days (2000 trials). Groups of animals were given either various doses of nimodipine or vehicle.

There were no differences in latencies or amplitudes of CRs or UCRs between the groups. The results suggest that a 1ug/kg/min nimodipine is the most effective in enhancing learning rate. It facilitates aquisition approximatelly two-fold in comparison to vehicle. Determining the optimal dose of nimodipine is important for further system and cellular studies on nimodipine actions in aging brain. (Supported by NIH 1 ROI AG08796 and The Miles Institute).

600.8

NIMODIPINE DECREASES CALCIUM ACTION POTENTIALS IN AGING AND YOUNG RABBIT CA1 NEURONS. J.R. Moyer, Jr.* and J.F. Disterhoft. CMS Biology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

The dihydropyridine calcium antagonist, nimodipine, facilitates learning in aging rabbits (Deyo *et al.*, 1989) and increases spontaneous firing of CA1 neurons *in vivo* (Thompson *et al.*, 1990). We previously reported that 100 nM nimodipine reduced the post-burst afterhyperpolarization (AHP) of aging but not young CA1 neurons and that aging neurons had larger AHPs (Moyer *et al.*, 1991). Since the AHP is primarily a Ca^{2+}–activated K^+ current, we studied the effects of nimodipine on calcium action potentials (APs) in aging and young CA1 neurons.



Intracellular recordings were made from 18 CA1 neurons (11 young, 7 aging) using current-clamp. 2M CsCl electrodes were used to block voltage-dependent K^+ currents and 4 µM TTX was added to the aCSF to block Na^+ currents. Cells were exposed to bath applied vehicle followed by increasing concentrations of nimodipine (100 nM to 10 µM). Aging neurons had prolonged calcium APs. 100 nM nimodipine decreased the calcium AP in aging neurons; 1 µM had little additional effect. In young neurons, 1 µM nimodipine had little or no effect on the calcium action potential, but 10 µM reduced it slightly. Nimodipine acted on the plateau phase of the calcium AP, which had a time course similar to the AHP and may underlie the enhanced AHP seen in those neurons. These data support the hypothesis that aging neurons have increased calcium influx that may contribute to their larger AHPs. Nimodipine reduced the calcium AP in an age- and concentration-dependent manner and may underlie it's learning enhancement in aging animals. (Supported by 1 RO1 AG08796 & The Miles Institute).

REDUCED CONTROL OF MOTOR OUTPUT IN A HUMAN HAND MUSCLE OF OLDER SUBJECTS DURING SUBMAXIMAL CONTRACTIONS.

M. Galganski, A.J. Fuglevand, and R.M. Enoka*. Depts. Exercise & Sport Sciences and Physiology, Univ. Arizona, Tucson, AZ 85721.

Aging is associated with a reduction in the number of motor units innervating a muscle but with an increase in the innervation ratio of surviving motor units. The purpose of the study was to determine the effect of these age-related changes on the capability of subjects to control force during isometric contractions at submaximal targets. Twenty-three healthy, neurologically normal human subjects (young: ages 20-37 years; old: ages 60-75 years) participated in the study. Motor unit activity was recorded from first dorsal interosseous muscle while the left index finger exerted an abduction force. The maximum voluntary contraction force (MVC) was not different among subjects (29 vs 24 N for the young and old subjects, respectively). Subjects were required to hold the isometric force at four different levels (5%, 20%, 35% and 50% MVC) for 20 seconds. Elderly subjects displayed greater force fluctuations about each force level. The coefficient of variation about each force level (6.6%, 3.7%, 2.9%, 2.9% vs 11.0%, 5.0%, 4.2%, 3.9% for the young and old subjects, respectively) was statistically greater for the older subjects. Moreover, the force exerted by single motor units (young: n=102; old: n=88) was found to be statistically greater in elderly subjects (29.1 vs 16.2 mN). However, the motor unit discharge characteristics were similar for the two groups of subjects. The presence of motor units with larger force amplitudes in elderly subjects may account for their decreased ability to control force.

AGE DIFFERENCES IN VISUOMOTOR CONTROL.

E.A. Roy[1]*, T. Winchester[1] and S. Black[2]. [1]Department of Kinesiology, University of Waterloo, Waterloo and [2]Sunnybrook Health Sciences Centre, Toronto, CANADA.

The movement characteristics of a simple aiming task were examined in two groups of right-handed subjects involving either younger (20-35 years) or older (60-75 years) adults. A WATSMART system was used to record positional coordinates of a marker placed on a stylus which was grasped in the right hand. Discrete pointing movements were made to a target of two different widths (12 mm or 57 mm) over two different amplitudes (150 mm or 300 mm) giving rise to indices of difficulty ranging from 2.4 to 5.65 bits. Subjects were instructed to move as quickly and accurately as possible. The results revealed that the overall movement time was greater for the older subjects for all conditions and reflected the relative difficulty of the task condition. Peak velocities achieved were considerably larger for the longer movements for both groups, with the younger subjects reaching higher peak velocities in all conditions. While th2e time to peak velocity was similar between the groups, time after peak velocity differed significantly with the older subjects spending more time decelerating toward the target. The significance of these findings for understanding the effects of age on reaching is discussed with reference to current theories of motor control.

AGE-RELATED SHRINKAGE OF THE MAMILLARY BODIES: *IN VIVO* **MRI EVIDENCE.**

I. Torres, N. Raz, J. Acker#, C.J. Long*. Dept. Psychology, Memphis State Univ., Memphis, TN 38152 and Baptist Memorial Hospital, Memphis, TN 38119.

Mamillary bodies (MB) are hypothesized to play a critical role in declarative memory - a cognitive function that declines with age. In this study, age-related differences in the size of MB were examined using magnetic resonance (MR) imaging. The cross-sectional area of the MB was estimated from MR images of the brain in healthy volunteers and neurologically intact patients (N=82, age 18-78). The cross-sectional area of the tectum was used as a control region of interest (ROI). The area of the MB declined with age ($r = -.51$, $p < .001$); the area of the tectum did not ($r = -.08$, ns). Covarying skull size and sex did not alter the results. Supported by MSU Center for Applied Psychological Research.

SELECTIVE AGING OF HUMAN CEREBRAL CORTEX: EVIDENCE FROM IN VIVO MRI MORPHOMETRY.

N. Raz*, I. Torres, W. Spencer, J. Acker. Dept. Psychology, Memphis State Univ., Memphis, TN 38152 and Baptist Memorial Hospital, Memphis, TN 38119.

The effects of aging on the size of selected cortical regions in 29 healthy volunteers and 54 patients with negative radiological findings were examined using magnetic resonance imaging (MRI) scans. In both samples, similar patterns of cortical aging emerged. The size of sampled regions of association cortices (dorsolateral prefrontal and inferior parietal) correlated negatively with age, whereas no significant correlations between the size of primary somatosensory and visual cortices and age were found. In the first but not in the second sample, some of the correlations were attenuated after controlling statistically for skull size and sex. Overall, there were small but consistent trends for leftward asymmetry of the white matter, and rightward asymmetry of the grey matter. The results support the notion of pathoclysis (selective aging) of association areas accompanied by relative sparing of sensory cortices. Supported by MSU Center for Applied Psychological Research.

AGE-RELATED COGNITIVE DECLINE AND EEG SLOWING IN DOWN'S SYNDROME AS A MODEL OF ALZHEIMER'S DISEASE.

H. Soininen*, J. Partanen, V. Jousmäki, E.-L. Helkala, M. Vanhanen and P.J. Riekkinen Sr. Dept. of Neurology and Clinical Neurophysiology, University of Kuopio, 70211 Kuopio, Finland.

The patients with Down's syndrome (DS) invariably develop Alzheimer-type neuropathological changes at 40 years of age and older and display deficits in the ascending cholinergic and monoaminergic projections as do patients with Alzheimer's disease (AD). To address whether studying DS patients of different ages could serve as a model for progression of AD, we studied quantitative EEG and neurophysiological performance in an aging series of 31 DS patients, 36 patients with probable AD and age-matched controls. We found an age-related decline of cortical functions and slowing of the EEG in DS patients aged from 20 to 60 years. EEG slowing, decrease of the peak frequency, was significantly related to Mini-Mental status scores, and visual, praxic and speech functions, and memory in the DS patients similarly as in the AD patients. Such correlations were not demonstrated for young or elderly controls. This study provides neuropsychological and electrophysiological data to suggest that studying DS patients of different ages can serve as a model for progression of AD.

ENHANCED CORTISOL AND ACTH RESPONSES TO HYPERTONIC SALINE INFUSION IN OLDER HUMANS.

E.R. Peskind*, M.A. Raskind, D. Wingerson, M. Pascualy, D.J. Dobie, R.C. Veith, D.M. Dorsa, and C.W. Wilkinson. Dept. of Psychiatry, Univ. of Washington School of Medicine, and Seattle and American Lake VA GRECC, Seattle, WA 98195

Hypertonic saline administration is a physiologic stimulus of the hypothalamic-pituitary-adrenal (HPA) axis. It increases plasma ACTH and cortisol in young normal humans and elevates CRH mRNA in the paraventricular nucleus of rats. This study addressed the hypothesis that the enhanced HPA axis responsivity demonstrated in old rats also occurs in normal older humans and, if so, whether it is altered in Alzheimer's disease (AD). We administered a 90 minute hypertonic saline infusion (5% sodium chloride at 0.06 ml/kg/min) and a 90 minute placebo infusion (0.9% sodium chloride at 0.06 ml/kg/min) to normal young men (n=11, age=29 ± 2 yrs), normal older men (n=7, age=63 ± 3 yrs), and otherwise healthy older men with AD (n=17, age=67 ± 2 yrs). Hypertonic saline produced substantial and equivalent increases in serum osmolality, serum sodium, plasma vasopressin, and plasma norepinephrine among groups. In contrast, the responses of plasma ACTH and plasma cortisol to hypertonic saline infusion as compared to placebo infusion were significantly greater in older normal and AD subjects than in young subjects. Cortisol and ACTH responses did not differ between older normal and AD subjects. These results suggest increased responsivity of the HPA axis in human aging. Supported by AGO5136, AGO8419, and the Dept. of Veterans Affairs.

ADHESIVE PROPERTIES OF CELLS OVEREXPRESSING ß/A4 AMYLOID DNA. G.E. Maestre*, B. A. Tate, R.E. Majocha, C.A. Marotta. Massachusetts General Hospital and Harvard Medical School, Boston 02114 USA and University of Zulia Apdo 526 Maracaibo, Venezuela.

Several clones of PC12 cell overexpressing ß/A4-C terminal region of amyloid precursor protein (APP) have been examined for alterations in adhesive properties. The rate of attachment to substrate of transfected and control cells was assessed. Following plating in uncoated plastic petri dishes, unattached cells were collected and counted at several time intervals for up 24 to hours. At 30 minutes, approximately half of control cells while none of the transfected cells adhered to the dish. By six hours both transfected and control showed 100% attachment. The strength of adhesion to substrate was also assessed. After 48 hours of incubation, under similar disruptive forces, about 65% of transfected cells and only 25% of the control cells remain attached. Transfected cells at the light microscopy level showed increased cell clumping. These data suggest that overexpression of the ß/A4-C terminal region of APP may alter both cell-substrate and cell-cell adhesion.

Evidence for Altered APP Processing Following Acute Head Trauma in The Rodent. D. Games, K. M. Khan, F.G. Soriano, J. Lieberburg* and S. Sinha. Athena Neurosciences, South San Francisco, CA. 94080.

The epidemiological association between traumatic head injury and Alzheimer's Disease, the detection of beta amyloid (βAP) deposition in the brains of professional boxers and reports of βAP deposits following acute head injury in the human prompted us to ask if altered amyloid precursor protein (APP) localization and expression resulted after head injury in the rodent. The injury was delivered by a 10 gram weight dropped on the exposed dural surface overlying the parietal cortex from a height of 10 cm. After 24 hours dystrophic cells, neurites and fiber tracks confined to the injured area were intensely stained with N- and C- terminal APP antibodies, as well as with an antibody raised to a synthetic peptide containing the amino terminal portion of βAP. Specific staining was evident 4 hours after injury and persisted for up to one week. This aberrant APP staining correlated with the appearance of amino terminally truncated APP fragments on Western blots, clustered at ~22 Kd and ~70-80 Kd, also confined to the injured and penumbral regions. Gross alterations in total APP levels were not evident. The coincidence of increased APP staining in dystrophic cells and axons and the appearance of aberrant carboxyl terminal fragments confined to the injured regions suggest that altered APP processing, perhaps as a consequence of localized up regulation, occurs as an acute response to head trauma.

601.3

A 17-MER PEPTIDE SEGMENT OF THE AMYLOID β/A4-PROTEIN (APP) REDUCES NEUROLOGIC DAMAGE IN A RABBIT SPINAL CORD ISCHEMIA MODEL. M.P. Bowes, T. Saitoh, J.A. Zivin, J.-M. Roch, and K. Ueda*, Univ. California, San Diego, Dept. of Neurosciences, La Jolla, CA 92093-0624, USA.

A synthetic 17-mer peptide corresponding to Ala319-Met335 of β/A4-protein precursor (APP) has a neurotrophic effect on rat neuroblastoma cells (L.W. Jin et al., reported at this meeting). We evaluated the ability of this peptide to reduce CNS damage in a rabbit spinal cord reversible ischemia model (Zivin et al., Arch. Neurol. 39:408-412, 1982). Ischemia of the caudal lumbar cord is produced by temporary occulsion of the abdominal aorta. Saline or peptide (200, 500 or 1000 nM) was administered i.t. 20 minutes prior to ischemia and once daily for three days thereafter. Neurologic outcome was evaluated after four days. Durations of ischemia encompassing all grades of neurologic function were included. The 500 nM dose significantly reduced neurologic damage. The average ischemia duration necessary to produce permanent neurologic damage increased from 30.1±1.77 min in controls to 41.4±4.7 min in the 500 nM group. The 200 nM dose produced a nonsignificant trend toward reduced neurologic damage. Our results demonstrate that this 17-mer peptide is capable of reducing neurologic damage in vivo in a model of CNS ischemia, a finding consistent with a neurotrophic effect of APP.

601.4

LOCALIZATION OF ß-AMYLOID PRECURSOR PROTEIN (ß-APP) IN THE RAT CENTRAL NERVOUS SYSTEM (CNS). A.C.Y. Lo*, D.L. Price and S.S. Sisodia. Neuropathology Lab., The Johns Hopkins University Sch. of Medicine, Balto., MD 21205.

Previous studies have documented that ß-APP undergoes fast anterograde axonal transport in the rat peripheral nervous system and is present at nerve terminals in the CNS. Using sucrose gradient fractionation of cortical membranes and immunoisolation with antisynaptophysin beads, we showed that a small fraction of APP colocalizes with synaptophysin, a small synaptic vesicle (SSV) marker. However, the vast majority of APP fractionates with vesicle populations that are immunopositive for transferrin receptor, an endosomal marker, suggesting colocalization in endosomes. Current studies are directed towards further characterization of APP localization in nerve terminals at the ultrastructural level by subcellular fractionation and immunoelectron microscopy techniques using synaptosomes as an experimental model.

MICE TRANSGENIC FOR HUMAN β-AMYLOID PROTEIN ARE IMPAIRED IN SPATIAL, BUT NOT CUED LEARNING. G. Tirado-Santiago*[1], J. Nalbantoglu[2], J.P. Julien[2], & M.L. Shapiro[1], Depts. of [1]Psychology and [2]Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada.

Brain deposition of β-amyloid is an early marker of Alzheimer's disease. Mice (B6C3, 8 months old) transgenic for a human β-amyloid fragment were compared to normal litter mates in spatial and nonspatial learning tasks in the Morris water maze. A cDNA fragment including amino acids 591-695, spanning the amyloid-forming and C-terminus portion of the β-amyloid precursor protein, was cloned into the first exon of the human neurofilament NF-L gene, under the transcriptional control of the NF-L promoter. Northern analysis showed 3 of 7 transgenic lines expressed human β-amyloid transcripts in brain tissue. Spatial and non-spatial learning were tested using standard procedures in the Morris water maze task (n: transgenic = 4, control=7). Behavior was tested blind to the genetic history of the mice. Three probe tests were given: (1) the water temperature was reduced from 25° to 20° C, (2) the platform was moved to the opposite quadrant to distinguish spatial from procedural learning, and (3) the platform was made visible. Two measures of learning and performance have been analyzed statistically thus far: escape latency and the number of trials correct [reaching the platform before the end of a trial]. Transgenic mice were impaired relative to their litter mates in spatial learning in both measures and each probe test (e.g. number correct: $F(1,9) = 9.2$, $p < 0.02$) except when the platform was visible, when the two groups of mice performed similarly ($F(1,9) = 0.01$, $p = 0.9$). Eighteen month old mice are now being tested. The results suggest that expression of human β-amyloid protein may produce a selective learning deficit in 8 month old mice.

HISTOLOGICAL DEMONSTRATION of AMYLOID-IMMUNOREACTIVE DEPOSITS IN THE BRAINS OF APP-TRANSGENIC MICE. Rudy Krause II, Robert W. Manning, J. Patrick Card, Darlise DiMatteo, Leonard G. Davis*. CNS Research, The Dupont Merck Pharmaceutical Co., Wilmington DE 19880.

The creation of transgenic mice expressing the human form of the amyloid precursor protein (APP, 751 amino acid form) allows an investigation of the relationship between APP expression and AD. Immunohistological analysis of such transgenic mice (founders) at 15-26 months of age with antibodies (previously characterized and used to identify plaques in AD tissue) allowed us to observe an increase of antibody reactive elements in the brains of transgenic founder animals (n=13) when compared to non-transgenic littermates (n=10), and an older (ca. 30 months of age) control group (n=4). Three major brain regions of differential staining were evident: cortex, hippocampus, and cerebellum. The antibody reactive bodies were demonstrated in several forms: a group of localized "laminar-like dispersed spots" in the hippocampus similar to that described [M. Jucker et al., Science 255, p. 1443, 1992], these were also present in some controls; vascular staining similar to cerebro-vascular plaques; and intense cellular and some extracellular staining. The differences between the transgenic and control groups demonstrate that expression in mice of the human form of APP751 results in an increase in the amyloid-immunoreactivity. It is worth noting that although the mouse APP is >90% homologous to the human APP, potentially significant differences occur in the first fifteen amino acids in the β-amyloid sequence which could contribute to the inability of the mice to appropriately process the transgene (human APP-751). Further evaluation of these animals will be necessary before their usefulness as an AD model can be determined.

CREATION OF TRANSGENIC MICE POSSESSING NORMAL AND MUTATED HUMAN APP. Robert W. Manning*, Christian Reid, Rudy Krause II, Geneva Barkley, Leslie Smith, Leonard G. Davis. CNS Disease Research, The Dupont Merck Pharmaceutical Co., Wilmington DE 19880-0328.

One of the characteristic features of Alzheimer's Disease (AD) is the deposition of β-amyloid into neuritic- and cerebrovascular-plaques. This pathology has been implicated in the manifestation of the clinical symptoms. β-amyloid is a 4200 dalton peptide which is derived from a larger precursor protein (APP). Alternate exon usage results in the generation of at least three APP forms (695, 751, and 770 amino acids) that contain the sequence for β-amyloid. It has been suggested that either overexpression of APP, disruption of the tissue specific balance of the APP forms, or abnormal processing of the precursor protein may result in the deposition. More recently, single nucleotide mutations in APP have been reported in some Familial AD pedigrees and in Hereditary (Dutch) Cerebral Hemorrhage with Amyloidosis (HCHWA-D). In order to test the causal relationship of the above hypotheses on plaque formation as part of the etiology in AD, we have used transgene based expression of the human APP751 and APP695 cDNAs in transgenic mice under the control of the mouse thy-1.2 promoter. The thy-1.2 promoter has been shown to direct neuronal expression in transgenic mice. Additionally, site specific mutagenesis was used to generate single nucleotide changes that result in the amino acid substitutions previously reported in the inherited disorders. Transgenic mice possessing the two mutated forms in APP751 and in APP695 have also been created. The construction of the vectors and preliminary molecular biological analysis will be presented.

SECRETED FORMS OF AMYLOID PRECURSOR PROTEIN (APP^S) REGULATE INTRANEURONAL CALCIUM LEVELS: ROLES FOR APP^S IN NEURONAL PLASTICITY. M. P. Mattson[1]*, I. Lieberburg[2] and R. E. Rydel[2]. [1]Sanders-Brown Center on Aging and Dept. of Anatomy and Neurobiology, University of Kentucky, Lexington, KY 40536; [2]Athena Neurosciences, South SanFrancisco, CA 94080.

Amyloid precursor proteins (APP) are membrane-associated proteins produced in neurons and axonally transported. Normal enzymatic processing of APP results in the release of secreted forms of APP (APP^S), whereas in Alzheimer's disease (AD) aberrant processing results in the liberation of intact ß-amyloid peptide which forms aggregates that can destabilize calcium homeostasis and increase neuronal vulnerability to excitotoxicity (*J. Neurosci.*, 12:376, 1992). The normal function(s) of APP^S are unknown. We now report that APP^S695 and APP^S751 cause a potent dose-dependent (10 pM - 1 nM) and rapid (sec to min) reduction in intraneuronal free calcium levels (measured using fura-2) in cultured human cortical and rat hippocampal neurons. The reductions in calcium levels were reversible and were blocked by antibodies that recognize a region common to both APP^S695 and APP^S751 (aas. 444-592 of APP695). APP^S-induced reductions in calcium levels occurred in cell bodies, neurites and growth cones; preliminary data indicate that APP^S may influence growth cone motility. We are currently exploring the mechanism whereby APP^S lower calcium levels. We propose that by influencing neuronal calcium homeostasis APP^S play roles in regulating neurite outgrowth and modulating synaptic plasticity (LTP). Abnormal processing of APP in AD may result in a loss of calcium homeostasis and neurofibrillary degeneration as the result of disruption of normal APP^S functions, and the accumulation of ß-amyloid peptide. (supported by: NIH, Alzheimer's Association, Eli Lilly & Co., and Athena Neurosciences).

EVIDENCE THAT BRAIN SYNAPTIC MEMBRANES CONTAIN A RECEPTOR FOR THE ALZHEIMER AMYLOID βA4 PEPTIDE. B.A. Bahr*, B. Abai, S. Shahrestani, S. Viteri, and G. Lynch. Center for the Neurobiology of Learning and Memory, University of California, Irvine, California 92717-3800

Alzheimer's disease neurodegeneration is associated with deposition of the 39- to 43-amino acid amyloid βA4 polypeptide in neuritic plaques and the cerebral vasculature. The precursor protein for βA4 (APP) has been suggested to be a specialized adhesion molecule necessary for synapse formation and function (Breen *et al., J. Neurosci. Res.* 28:90, 1991; Schubert *et al., Brain Res.* 563:184, 1991); other such proteins have been identified (Bahr & Lynch, *Biochem. J.* 281:137, 1992). Furthermore, symptoms of Alzheimers have been shown to be strongly linked to the development of synapse pathology and synaptic loss (Masliah *et al., Neurosci. Lett.* 103:234, 1989). Accordingly, rat synaptosomal membranes (SPMs) were seeded onto microtitre wells coated with portions of APP or extracellular matrix proteins in order to test for homotypic and/or heterotypic receptors that recognize synaptic matrices. Subsequent assays using antibodies to the nerve terminal marker synaptophysin determined that neocortical SPMs bound to merosin, fibronectin, entactin, and to a lesser extent laminin, fibrinogen, and collagen. In comparison, it appears that the greatest amount of SPM attachment was directed to neurotoxic carboxyterminal fragments of APP including *i)* βAPP-C104 which spans the βA4 and cytoplasmic domains of APP, *ii)* amino acids 25 to 35 of βA4 (βA25-35), and to a degree *iii)* βA1-40. No SPMs bound to βA1-16, BSA, or substance P which has a similar amino acid sequence as βA25-35. The βA25-35 binding had the following regional selectivity: hippocampus ≈ neocortex » striatum > cerebellum ≥ thalamus ≈ brain stem > olfactory bulb. The binding was inhibited by 100 μM βA1-40 and by the adhesion blocker GRGDSP (EC_{50}=2.8 ± 0.1 mM), but not by 1 mM βA1-16, 100 μM substance P, 100 μM physalaemin, 10 mM GRADSP, or 3 mM REDV. Merosin-SPM attachment, however, was blocked by REDV (EC_{50}=230 ± 10 μM) but not by βA1-40 or βA25-35. This data suggest that at least two receptor types are involved in synaptic matrix recognition, perhaps one of which plays an active role in synaptic pathogenesis (Supported by the HFSP).

601.10

DISTRIBUTION OF BINDING SITES FOR THE NEUROTOXIC PEPTIDE, βAPP-C104, IN RAT BRAIN. M.R. Kozlowski*, E. Hall, R.L. Neve[2]. Department of Screening and Biochemical Research, Bristol-Myers Squibb Pharmaceutical Research Institute, Wallingford, CT 06492-7660, and [2]Molecular Neurogenetics Laboratory, McClean Hospital, Belmont, MA 02178.

We have reported the existence of a binding site for a naturally occurring, neurotoxic fragment of the amyloid precursor protein (APP): βAPP-C104 (Kozlowski et al., J. Neurosci., in press). The binding characteristics of this site suggest that it may be involved in the production of βAPP-C104 neurotoxicity. In the present study, we report the regional distribution of this binding site in rat brain, determined autoradiographically. Structures showing the greatest amount of binding included cerebellum and related areas, superior and inferior colliculi, and hypothalamus. Moderately high amounts of binding were observed in cortex, hippocampus, caudate nucleus, and most thalamic nuclei. Only small amounts of binding were found in globus pallidus, ventroposteromedial thalamic nucleus, and in white matter.

The finding of moderately high levels of βAPP-C104 binding in cortex and hippocampus, two structures that are particularly affected in Alzheimer's disease, supports the idea that βAPP-C104-induced toxicity may be an etiological factor in this disorder. It is curious, however, that the greatest amount of binding was found in the cerebellum, a structure not damaged in Alzheimer's disease. The apparent mismatch between binding site density and putative toxic response to the peptide may be due to a higher concentration of the toxic peptide in susceptible regions or particular sensitivity of certain areas to the events that follow binding.

601.11

A DIRECT ROLE FOR PROTEIN KINASE C AND THE TRANSCRIPTION FACTOR JUN/AP-1 IN THE REGULATION OF THE β-AMYLOID PRECURSOR PROTEIN GENE. J. Trejo, N.N. Dewji, R.M. Bayney, and J.H. Brown*, Department of Pharmacology, U.C. San Diego, La Jolla, CA 92093.

The mechanisms involved in β-amyloid deposition in Alzheimer's disease are largely unknown but might in part involve overexpression of the β-amyloid precursor protein (β-APP) gene. The promoter region of this gene contains two upstream sequences homologous to the transcription factor activator protein-1 (AP-1) recognition site. Activation of protein kinase C (PKC) leads to the induction Fos and Jun (major constituents of AP-1), increased AP-1 DNA binding activity, and transcriptional activation of AP-1 responsive genes. To determine whether PKC activation also regulates β-APP gene expression we measured β-APP mRNA levels and transcriptional activation of a 593 bp β-APP promoter-luciferase reporter gene construct (β-APP-LUC) in a human glial (1321N1) cell line. Activation of PKC with the phorbol ester PMA results in a 4-fold increase in β-APP mRNA levels. In transient transfection experiments the β-APP-LUC is transcriptionally activated by PMA as well as by co-expression of a constitutively activated PKC. We used gel mobility shift assays to determine if PMA induces protein DNA binding to either of two oligonucleotides corresponding to the putative AP-1 sites. The upstream AP-1 site effectively binds factors in nuclear extracts from PMA stimulated cells while the downstream AP-1 site fails to exhibit binding activity. To directly establish a role for Fos and Jun in transcriptional regulation of the β-APP gene, cells were co-transfected with β-APP-LUC reporter together with Fos and Jun expression plasmids. Surprisingly the β-APP promoter is transactivated by co-expression of Jun while Fos appears to repress transcriptional activation. We conclude that β-APP gene transcription is regulated through the activation of PKC and induction of Jun/AP-1 which binds to the upstream AP-1 site to activate transcription.

601.12

NICOTINE EFFECTS ON REGULATION OF APP SPLICING AND NEUROTROPHIN LEVELS IN SH-SY5Y CELLS. L. Monteggia*, S. P. Arneric, and T. Giordano. Neuroscience Research, Abbott Laboratories, Abbott Park, IL 60064-3500.

It has been reported that an inverse relationship exists between nicotine intake and incidence of Alzheimer's Disease (AD). Altered splicing patterns of APP and changes in neurotrophin expression have been implicated in AD and behavioral deficits in rats. In this study we sought to determine if the beneficial nicotinic effects observed in AD are related to changes in APP splicing and/or neurotrophin levels by studying differentiated SH-SY5Y cells. Cultured SH-SY5Y cells were differentiated with 10μM retinoic acid (RA) for eight days; nicotine (100nM or 1 μM) was added on the eighth day, 24hrs prior to RNA isolation. We used rtPCR to measure the splicing ratio of APP, along with the levels of NGF, BDNF and NT3 transcripts relative to cyclophilin RNA. Although there were no differences in the APP splicing ratio (APP 695 transcript represented 65% of the total APP RNA at each condition) there was a statistically significant increase (1.6X; $p<0.05$) in total APP RNA relative to cyclophilin RNA with 1 μM nicotine. Changes in the levels of NGF, NT3 and BDNF transcripts relative to cyclophilin RNA following nicotine administration were also observed although not statistically significant. Thus, in this in vitro model, the effects of nicotine can not be attributed to altered APP splicing or induction of neurotrophins.

601.13

RELEASE OF THE AMYLOID PRECURSOR PROTEIN IN FIBROBLASTS TRANSFECTED WITH PROTEIN KINASE C-α. B.E. Slack*[1], R.M. Nitsch[1], G.M. Kunz Jr.[1], E. Livneh[2], AND R.J. Wurtman[1], [1]Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge MA 02139, USA and [2]Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot 76100, Israel.

Protein kinase C (PKC) has been implicated in the proteolytic processing of the Alzheimer amyloid precursor protein (APP) (Buxbaum et al., PNAS 87: 6003, 1990) and concomitant release of an N-terminal fragment (Caporaso et al., PNAS 89: 3055, 1992). The effect of the PKC activator phorbol 12-myristate 13-acetate (PMA) on APP release was compared in Swiss 3T3 fibroblasts transfected with PKC-α and the gene for neomycin (neo) resistance, and in control (neo resistant) cells. Basal APP release from cells transfected with PKC-α was significantly increased (to 177 ± 24% of control, n=11), while levels of cell-associated APP were unchanged. PMA (100 nM) increased APP release from control fibroblasts by approximately 2.4-fold within 1 hr. The effect was dose-dependent (from 1 nM to 1 μM) and was inhibited by the PKC antagonist H-7 (100 μM). In fibroblasts transfected with PKC-α, the maximum response to PMA (expressed as fold increase over basal release) was reduced by more than 50% relative to controls. This reflected an increase in basal APP release in the transfected cells rather than a reduction in the absolute amount of APP released by PMA treatment. The EC50 for PMA was reduced from 60 nM (in controls) to 8 nM (in PKC-α transfected cells). These results show that APP release is regulated by PKC-α in Swiss 3T3 fibroblasts. Possibly, altered function of one or more subspecies of PKC may contribute to abnormal APP processing and subsequent amyloid deposition in Alzheimer's disease brain. (Supported by NIMH)

Neuronal activity driven expression of amyloid precursor protein (beta-APP) in glial cells

R.B. Banati[1]*, J. Gehrmann[1], C. Czech[2], U. Mönning[2], G. König[2], K. Beyreuther[2] and G.W. Kreutzberg[1]
[1]Department of Neuromorphology, Max-Planck-Institute for Psychiatry, 8023 Martinsried, F.R.G., [2]Center for Molecular Biology, University of Heidelberg (ZMBH), Heidelberg, F.R.G.

There is conflicting evidence concerning the pathophysiologically relevant source of the amyloid precursor protein (beta-APP) and the mechanisms that lead to its deposition in the amyloid plaques in Alzheimer's disease. The *in vivo* expression of the amyloid precursor protein was investigated in lesions models of the the rat central nervous system. By means of immunocytochemistry, Western and Northern blot analysis we found the amyloid precursor protein constitutively expressed in glial and other non-neuronal cell types. Under normal conditions amyloid precursor protein expression showed regional differences in different brain regions. In the experimental lesion models the expression of amyloid precursor protein was not only near the site of lesion but also in projection areas remote to the sites of primary neuronal de/regeneration. An increase in the expression of the amyloid precursor protein occurred in distinct glial elements within hours after the experimental lesions. The swiftness by which the amyloid precursor protein is expressed suggests a fast signal from neuron to glia.

NEURODEGENERATION INDUCED BY β-AMYLOID PEPTIDES *IN VITRO* MAY FOLLOW AN APOPTOTIC PATHWAY. A. Copani*, D.T. Loo, C.J. Pike, A.J. Walencewicz, and C.W. Cotman, Irvine Research Unit in Brain Aging, *University of California, Irvine, CA 92717 USA.*

In the nervous system cell death may occur through two distinct processes: necrosis and apoptosis. Necrotic cell death, resulting from acute injury, is characterized by cell swelling and lysis; conversely, apoptotic cell death is characterized by cell shrinkage and release of membrane-bound bodies. The factors that trigger apoptosis in the nervous system have been proposed to activate an endogenous program of cellular self-destruction, yet they remain poorly defined.

In Alzheimer's disease, β-amyloid is hypothesized to contribute to neuronal loss. We have reported that aggregated β-amyloid peptides (βAPs) can be neurotoxic *in vitro*. Here, we analyze morphological and biochemical events associated with βAP-induced neurodegeneration to understand the mechanism by which treated neurons die. Degenerating neurons, observed under phase-contrast microscopy during a 24h exposure to βAPs, exhibited condensed cell bodies with dystrophic neurites. The degenerative events proceeded asynchronously and affected a significant portion of the neuronal population. At 24h a disparity between the number of degenerating neurons and the release of lactate dehydrogenase was observed, suggesting that cell lysis is not the initial event in the degenerative process. A breakdown of cellular DNA into oligonucleosome-length fragments is often associated with apoptosis. Using agarose gel electrophoresis, we found that βAP-treated cultures exhibited a regularly spaced "ladder" of DNA fragments. Aurintricarboxylic acid, an inhibitor of nucleases *in vitro*, suppressed the DNA fragmentation and delayed neuronal lysis when added to the cultures simultaneously with the peptide. Untreated cultures exhibited measurable DNA fragmentation, likely resulting from normally occurring cell death *in vitro*, but it was significantly less than in βAP- treated cultures.

Our study suggests that neurons exposed to βAPs degenerate in a manner consistent with morphological and biochemical changes characteristic of apoptosis, perhaps as a result of accelerated normal cell death *in vitro*.

601.16

NEUROTOXICITY INDUCED BY CHRONIC APPLICATION OF ß AMYLOID FRAGMENT 25-35: INVOLVEMENT OF APOPTOSIS. G.Forloni*, R. Chiesa, N. Angeretti and S. Smiroldo. Istituto di Ricerche Farmacologiche "Mario Negri", 20157 Milano, Italy.

The ß amyloid protein (ß-AP) is the major component of the senile plaques and cerebral vascular deposits characteristic of Alzheimer's Disease (AD). Recently, it has been shown a neurotoxic activity of ß-AP and its fragments. Other authors have reported that ß-AP itself is not neurotoxic, but it renders neurons more sensitive to excitotoxic damage. In this study, we investigated the neurotoxic effect of chronic exposure of rat cultured hippocampal neurons to ß amyloid fragment 25-35 (ß-25-35). Moreover, we tested, in the cells exposed to ß-25-35, the presence of the cascade of events characteristic of programmed cell death, defined apoptosis. Primary hippocampal neurons were derived from fetal rat brain at embryonic day 17,plated at a concentration of $5x10^5$/ml and cultured in the presence of fetal calf serum (10%). The neuronal death was determined visually and quantified by spectrophotometric method. The cells were exposed to micromolar concentrations of ß-25-35. A single application of ß-25-35 did not induce any neuronal alteration even at the highest concentration (100 μM). When the exposure to ß-25-35 (25-100μM) was repeated every two days for 10 days, a significant reduction of cell survival was evident. Furthermore, the morphological analysis and the DNA fragmentation indicated that the neuronal death induced by ß-25-35 involved also the mechanism of apoptosis. These results confirm the potential pathogenetic role played by ß-AP in AD and indicate that ß-AP may induce neuronal death through a specific programmed process.

Nimodipine-sensitive, β-amyloid(25-35)-induced $[Ca^{2+}]_i$ responses in single cultured rat hippocampal neurons. J.C.Chisholm*, J.N.Davis, and E.J.Hunnicutt, Jr., Miles Inst. Preclin. Pharmacol. West Haven, CT 06516.

Fragments of β-amyloid (βAP), a protein deposited in plaques characteristic of Alzheimer's disease, enhance delayed, Ca^{2+}-dependent excitotoxicity in CNS neurons. Exposure to various fragments of peptide for 1-4 days increases toxicity of glutamate, kainate, and NMDA measured in human and murine neurons in culture (Koh, Brain Res. 533:315;'90; Mattson, J.Neurosci. 12:376;92). Using calibrated fura2 measurements of $[Ca^{2+}]_i$ in single neonatal rat hippocampal neurons, cultured for 8-10 days, we report dose-dependent increases in $[Ca^{2+}]_i$ during acute application (10 - 100 μM) of a toxic βAP(25-35) fragment. Within 1 min of application, βAP increased $[Ca^{2+}]_i$ (n=20 of 20) to well over 3 μM in some cells. Response included transient and sustained components. It persisted for up to 40 min, the longest time tested, in the absence of Mg^{2+} and presence of the glutamate potentiator, glycine (100 nM). Nimodipine (10 - 100 nM) blocked these responses dose-dependently when applied before βAP. In conclusion, finding of an acute, dose-dependent effect of βAP(25-35) suggests the possibility of interaction with a specific binding site. Furthermore, nimodipine block of $[Ca^{2+}]_i$ responses induced by βAP(25-35) suggests a possible role for nimodipine in attenuating effects of βAP mediated by increases in $[Ca^{2+}]_i$.

MOLECULAR MODELING OF THE FAMILIAL ALZHEIMER'S DISEASE MUTATIONS IN AMYLOID PRECURSOR PROTEIN. R.V. Fishleigh, R.P. Mee, B. Robson and B.A. Yankner* - Proteus Molecular Design Limited, Marple, UK, Harvard Medical School and The Children's Hospital, Boston, MA 02115.

Point mutations in the transmembrane domain of amyloid precursor protein (APP) have been identified in some families with the early-onset form of Alzheimer's disease. Molecular dynamics simulations, which model the motions of a molecule as it changes over time by calculating interatomic forces, have been used to explore the conformational effects of the APP mutations. The Prometheus™ software (Proteus Molecular Design Ltd.) was used in combination with supercomputing capability for this study. The native Val-717 form of APP formed a stable transmembrane α-helix with some unwinding in the region of Gly(708)-Gly(709). The transmembrane α-helix was markedly destabilized in the Gly-717 APP mutation, with helix breakdown at the substitution site and frequent propagation of irregularity to Gly(708)-Gly(709) in the β amyloid domain. Helix instability also occurred in the Ile-717 and Phe-717 APP mutants. The predicted altered conformation of the transmembrane domain of the mutants may play a role in modifying the balance between alternative APP processing pathways to promote the formation of β-amyloid. Further studies on the APP transmembrane domain using explicit molecular models of the lipid bilayer are currently underway.

602.1

SYNTHESIS AND SECRETION OF ACTIVE α1-ANTICHYMOTRYPSIN BY MURINE ASTROCYTES. K. Kanemaru and C. R. Abraham*. Arthritis Ctr. Boston Univ. Sch. of Med., Boston, MA 02118.

α1-antichymotrypsin (ACT), a serine protease inhibitor, was found to be one of the components of senile plaque amyloid (Abraham et al., Cell 52:487, 1988). In situ hybridization studies showed that ACT mRNA was expressed in reactive astrocytes around senile plaques, indicating that reactive astrocytes were the origin of ACT (Pasternack et al., Am. J. Pathol. 135:827, 1989; Koo et al., Neurobiol. Aging 12:495, 1991). To confirm this possibility, we studied the synthesis and secretion of ACT using primary murine astrocyte cultures obtained from one day old neonatal brains. We stained cultured astrocytes with a polyclonal antibody to human ACT (Dako) which revealed cytoplasmic granular labeling consistent with compartmentalization in secretory granules. This staining was completely abolished by preincubation of the antibodies with human ACT. The presence of ACT in the conditioned medium was examined by Western blotting. A 60kDa protein was detected in the culture medium with ACT antibodies. Secretion of the ACT-like protein was stimulated by fetal calf serum. In addition, the ACT-like molecule from the culture medium of murine astrocytes could form SDS-insoluble complexes with iodinated human cathepsin G. A complex of approximately 90kDa was detected by autoradiography. These results suggest that reactive astrocytes synthesize and secrete an active ACT-like protein. ACT, secreted by reactive astrocytes, may disturb the protease-antiprotease balance, resulting in abberant processing of the ß amyloid precursor protein. (Supported by NIH AG-09905).

602.2

BINDING OF SECRETED HUMAN NEUROBLASTOMA PROTEOGLYCANS TO THE ALZHEIMER'S AMYLOID A4 PEPTIDE. Howard Fillit[1,2*], Luc Buee[1,3], Wanhong Ding[1], and Andre Delacourte[3] 1Ritter department of Geriatrics and Adult Development, [2]Fishberg Center for Neurobiology, The Mount Sinai Medical Center, New York, NY, 10029-6574, U.S.A. and [3]INSERM U156, Place de Verdun 59045 Lille Cedex FRANCE. Proteoglycans (PGs) may play a fundamental role in amyloid deposition. PGs were purified from conditioned medium of human neuroblastoma cells (SKNSH-SY 5Y). A heparan sulfate PG (HSPG) and a dermatan sulfate PG were identified by enzyme susceptibility. A monoclonal antibody to the protein core of a vascular HSPG found in senile plaques in Alzheimer's disease also reacted with HSPG protein core secreted by human neuroblastoma cells. High affinity binding between $^{35}SO_4$ labelled neuroblastoma PGs and the Alzheimer amyloid (A4) peptide was demonstrated by affinity chromatography. Specificity studies demonstrated that binding of human neuroblastoma PGs to the amyloid peptide was primarily mediated by a heparan sulfate glycosaminoglycan. No significant binding of neuroblastoma PGs was found to two other basic peptides also containing a putative heparin-binding domain derived from the beta-amyloid precursor. Human neuroblastoma PGs may bind to the Alzheimer amyloid peptide in a region with a heparin binding consensus sequence which also contains the cleavage site of the beta amyloid precusor protein. Neuronal HSPG may either regulate the secretion of the amyloid protein precursor or modify the binding of the amyloid protein precursor to other cellular adhesion molecules. Alterations in HSPG-A4 binding may be related to the pathogenesis of amyloid deposition in Alzheimer's disease.

602.3

BETA AMYLOID DEPOSITION AND NEURONAL DEGENERATION IN CULTURED HUMAN CORTICAL NEURONS. J. Busciglio* and B.A. Yankner. Dept. of Neurology, Harvard Medical School and The Children's Hospital, Boston, MA 02115.

We have established a method for long-term culture of human cortical neurons. Chronic administration of 4 μM of the β amyloid peptide β1-40 resulted in progressive neuronal degeneration. Immunocytochemical analysis showed that β1-40 gradually accumulated specifically on the neuronal soma as the incubation time increased, forming compacted deposits that contain the cell bodies of degenerating neurons and are surrounded by dystrophic neurites. Amyloid deposition was not observed in the absence of cells or after incubation with a control peptide. Immunocytochemical analysis with an antibody to a phosphorylated tau isoform showed marked induction of this antigen which preceded and accompanied neuronal degeneration caused by β1-40. Western blot analysis with this antibody showed the induction of a 57 kD band after treatment with β1-40. Increased immunoreactivity with Alz-50 but not with antibodies to MAP-2 or MAP-5 was also observed after treatment with β1-40. These results suggest that the formation of neuronal β amyloid deposits causes neuronal degeneration and alteration of the neuronal cytoskeleton. Compact amyloid plaques in Alzheimer's disease may form around degenerating neurons.

602.4

SUBSTRATE-BOUND BETA-AMYLOID PEPTIDE: NEUROTROPHIC EFFECT ON PRIMARY CEREBRAL CORTICAL NEURONS IN VITRO. **J.R. Wujek*, M.D. Dority, J. Silver, and R.C.A. Frederickson. Gliatech, Inc., Cleveland, OH 44122 & Case Western Reserve Univ., Cleveland, OH 44106.**

Beta-amyloid peptide (βAP), when dissolved in culture medium, has been reported to be neurotoxic to primary neurons (Yankner et al., 1989, Science 245:417). However, β-Amyloid in Alzheimers diseased brain is found primarily as insoluble plaques. Therefore, we have examined the effect of substrate-bound βAP on primary cerebral cortical neurons in vitro. A small volume of βAP_{1-40}, βAP_{1-28} or βAP_{25-35} was applied to culture dishes coated with a layer of poly-L-lysine over a layer of nitrocellulose. Each βAP solution dried and formed a dot approximately 1mm in diameter. A cell suspension of enriched primary embryonic cortical neurons (E15) was then seeded onto the dish. The supernatant was removed twenty minutes later and replaced with fresh culture medium. The cells adhered preferentially to the βAP_{1-40} dot and the βAP_{25-35}. No preferential adhesion was seen on the βAP_{1-28} dot. Over a period of 30 days, the neurons extended many neurites. Neurons off the dots also extended neurites, but were observed to degenerate at 3 weeks in culture. In contrast, neurons on the βAP dots, survived beyond 4 weeks in culture. These results indicate that βAP, in its insoluble form, exhibits adhesive and neurotrophic properties for primary cortical neurons in vitro.

SECRETED FORMS OF APP INCREASE NEURONAL SURVIVAL AND PROTECT CULTURED RAT AND HUMAN CNS NEURONS AGAINST HYPOGLYCEMIC DAMAGE. B. Cheng[1]*, V. L. Smith-Swintosky[1], I. Lieberburg[2], R. E. Rydel[2] and M. P. Mattson[1]. [1]Sanders-Brown Center on Aging and Dept. of Anatomy & Neurobiol., Univ. of Kentucky, Lexington, KY 40536; [2]Athena Neurosciences, S. San Francisco, CA 94080.

In the accompanying abstract (Mattson et al.) we reported that secreted forms of amyloid precursor protein (APP^S) exert a potent calcium-lowering effect in cultured rat hippocampal and human cortical neurons. We now report APP^S695 and APP^S751 dose-dependently (100 pM - 100 nM) promote neuronal survival and protect these same neuronal populations (as well as rat septal neurons) from hypoglycemic damage. Neuroprotection was observed when the APP^S were added before or up to 12 hr following the onset of hypoglycemia. APP^S695 and APP^S751 each reduced resting levels of intraneuronal calcium and prevented the hypoglycemia-induced elevation in intraneuronal calcium levels. Antibodies that recognize a region common to both APP^S695 and APP^S751 (aas. 444-592 of APP695) abolished the neuroprotective effect of APP^Ss in glucose deprived cultures, whereas antibodies directed against other regions of the APPs were ineffective. APP^Ss also prevented neurofibrillary tangle-like antigenic changes in tau and ubiquitin normally caused by a hypoglycemic insult. Since hypoglycemic damage involves NMDA receptor activation, these data suggest that APP^S might also modify neuronal responses to glutamate, a possibility now being explored. APP^S may normally play a neurotrophic/neuromodulatory role and aberrant processing of APPs may contribute to a loss of calcium homeostasis in AD by: (1) disrupting a normally trophic/neuroprotective function of APP^S and (2) liberating ß-amyloid peptide which may enhance neuronal vulnerability to ischemic/excitotoxic insults. (supported by: NIH, Alzheimer's Association, ILSI, Athena Neurosciences and Eli Lilly & Co.).

INTRACELLULAR APPLICATION OF β-AMYLOID PEPTIDE INDUCES EXCITATORY CURRENTS IN RAT HIPPOCAMPAL NEURONS. L.K.Simmons*, M.O. Chaney, S.P. Little, and R.L. Berry. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285.

The accumulation of extracellular deposits of β - amyloid peptide (A4P) in senile plaques is believed to be a primary event in the pathogenesis of Alzheimer's Disease. Several groups have shown that A4P is neurotoxic and potentiates other forms of neurotoxicity *in vitro*. Since there is increasing evidence that A4P can also accumulate inside neurons, we used electrophysiological protocols to investigate the intracellular effects of the peptide.

Pyramidal neurons from primary cultures of rat hippocampal cells were voltage-clamped using the whole-cell clamp configuration. Patch pipettes contained either A4P (1-40) or a control scrambled sequence 1-40 peptide in an "internal" salt solution. A4P (0.5 - 20 nM) elicited large, spontaneous inward currents. Occassionally the currents exhibited seizure-like activity, with periods of high frequency bursting interspersed with periods of low activity. These currents were never observed with the control peptide (up to 1 mM concentrations), had a reversal potential near 0 mV, and were voltage-dependent -- increasing in frequency when the cell membrane was clamped above -40 mV. These inward currents were not blocked by extracellular application of TTX or TEA, but were reversibly blocked with Cd^{2+}.

Mattson et al. (1992; J. Neurosci., 12:376) reported that prolonged exposure to μM concentrations of extracellular A4P potentiates neurotoxicity by disrupting cellular Ca^{2+} homeostasis. We show that a Ca^{2+}-dependendent excitatory current is activated with intracellular dialysis of nM concentrations of A4P, suggesting that at least part of the toxicity observed *in vitro* could be due to small amounts of A4P entering the cell.

N-TERMINAL CLEAVAGE OF B-AMYLOID BY CATHEPSIN G IS DEPENDENT ON PH AND IONIC CONDITIONS. J.L., Sonnenberg, S.R., Sahasrabudhe, J. Hulmes, A.J.Blume and M.P Vitek* Departof Molec. Pharmacology, Lederle Laboratories, American Cyanamid Company, Pearl River, N.Y., 10965.

BAP formation depends on its extraction from APP. The peptide HSEVKMDAEF spans the precursor site where ami**No-BetA-endoPeptidase (N-BAPase)** should cleave between Met and Asp (M/D cut) to generate the amino-terminus of BAP. When a putative N-BAPase like activity, Cathepsin-G, is incubated with the HSEVKMDAEF substrate, we observe several products that are separated by HPLC and identified by amino-acid sequencing. With the suggestion that APP processing (Golde and Greengard) and Cathepsin G localization occurs in the lysosomal compartment of the cell, we wished to test the effect of pH, with a focus on acidic pH, on our peptide/Cat-G system. We find 2 dominant cleavage patterns where the levels of the product pairs HSEVK plus MDAEF (K/M cut) and HSEVKM plus DAEF (M/D cut) are dependent on the pH and ionic strength of the reaction. At alkaline pH the K/M cut is favored while acidic pH favors the M/D cut which is more sensitive to high ionic strength.

	0 mM NaCl			150mM NaCl			500mM NaCl		
pH	K/M	M/D	Uncut	K/M	M/D	Uncut	K/M	M/D	Uncut
4.8	0%	65	35	0	40	60	0	19	81
5.3	5	70	25	3	39	58	0	27	7
6.2	57	42	0	42	59	5	4	47	48
7.3	70	30	0	79	21	0	75	24	0
8.3	94	5	0	92	8	0	81	19	0
9.2	100	0	0	94	6	0	75	25	0

These results suggest that chymotrypsin-like proteases and compartmental environment may play a role in directly generating the N-terminus of BAP or if we hypothesize an additional amino-exo-peptidase activity, that Cathepsin-G may also play an indirect role in BAP formation.

602.8

"CALPAIN INHIBITORS SIGNIFICANTLY DECREASE THE CATALYTIC ACTIVITIES OF A MAJOR EXTRA-LYSOSOMAL PROTEINASE, THE MULTICATALYTIC PROTEINASE COMPLEX." M.E. Pereira and S. Wilk*, Department of Pharmacology, Mount Sinai School of Medicine, C.U.N.Y., New York, N.Y. 10029

The calcium activated proteinases calpain I and II have been the focus of many recent studies addressing protein degradation in neurodegenerative diseases. In addition to calpains, brain contains another major extra-lysosomal proteinase known as the multicatalytic proteinase complex (MPC) (Wilk, and Orlowski, J. Neurochem. 40: 842:1983). MPC has unique catalytic properties, splitting peptide bonds on the carboxyl side of hydrophobic (chymotrypsinlike activity), basic (trypsinlike activity) and acidic amino acids (peptidyl glutamyl peptide activity; PGP) . A fourth catalytic site appears to be responsible for the initial breakdown of proteins such as ß-casein (caseinolytic activity). MPC has been suggested to be the "catalytic core" of the Ubiquitin/ATP-dependent protein degradation pathway. The neuropathological finding of ubiquitinated proteins in neurofibrillary tangles in Alzheimer's disease and in other neuronal inclusion bodies may implicate MPC-malfunction in neurodegenerative disorders, resulting in abnormal accumulation of ubiquitin-protein conjugates. Two recently synthesized peptide aldehydes, N-acetyl-Leu-Leu-norleucinal or calpain inhibitor I (CPI_1) and N-acetyl-Leu-Leu-methioninal or calpain inhibitor II (CPI_2), have been proposed as selective calpain inhibitors. Since MPC is also inhibited by some peptide aldehydes, we determined the effect of calpain inhibitors I and II on the catalytic activities of an apparently homogeneous preparation of bovine pituitary MPC. All four catalytic activities were inhibited by CPI_1 and CPI_2 with the caseinolytic activity being the most sensitive (IC_{50}'s of 7.2 μM and 11.9 μM respectively). Chymotrypsinlike activity (hydrolysis of Cbz-Gly-Gly-Leu-pNA) was markedly decreased in the presence of CPI_1 and CPI_2 with approximate IC_{50}'s of 9.9 μM and 24.9 μM res, ectively. The trypsinlike (Cbz-D-Ala-Leu-Arg-2NA) and PGP (Cbz-Leu-Leu-Glu-2NA) activities declined moderately with increasing inhibitor concentrations, up to 100 μM. Caution must therefore be exercised when these inhibitors are used to infer calpain function. (Supported by the Alzheimer's Association/New York City Chapter Pilot Research Grant PRG-90-114 to M.E.P.; NIH grant NS-17392 and an ADAMHA Research Scientist Award MH-00350 to S.W.)

ß-AMYLOID CONTAINING PEPTIDES PRODUCED IN NEWBORN RAT CEREBRAL CORTEX PRIMARY CULTURES. Xue R, LeBlanc AC, LaSala D, Gambetti, P*. Inst. Pathol. Case Western Reserve U. Cleveland, OH 44106

Combined morphological, immunocytochemical and biochemical studies have shown that the changes in cell composition and organization undergone by primary cultures of rat cerebral cortex between 7 and 32 days in vitro (DIV) are associated with changes in expression and processing of the amyloid precursor protein (APP). Cultures at 7 DIV which are composed mostly of evenly distributed astrocytes, microglia and neurons express full-length forms of APP and a series of five smaller C-terminal peptides, the largest of which appears to contain the entire ß-amyloid peptide (ßAP). Between 14-32 DIV, clusters of small cells, closely associated with neurons and immunocytochemically identified as immature oligodendrocytes, increase significantly in the cultures. These cultures simultaneously show an increase in the larger ßAP-containing peptide while the four smaller C-terminal APP peptides decrease significantly . Moreover, an additional ßAP reactive peptide which migrates at a slightly slower rate than synthetic ß-amyloid (1-40) peptide is also detected. Immunocytochemistry has revealed cell surface immunoreactivity to ßAP and APP C-terminal antibodies around these clusters. Preliminary results of pulse-chase experiments indicate active synthesis of APP by oligodendrocytes.

These results suggest that immature cells of the CNS cerebral cortex are producing and extruding relatively large amounts of ßAP-containing peptides.Supported by NIH NIA RO1 AGNS 08155, Britton fund and NIH NIA AGO8992-01.

602.10

EFFECT OF AGGREGATED AMYLOID ON CULTURED HIPPOCAMPAL NEURONS. R.K. Lartius* and E. Uemura. Neuroscience Program, Iowa State University, Ames, IA 50011.

β-amyloid protein (β-AP) is a peptide that abnormally deposits in diseases such as Alzheimer's disease (AD). Recent evidence has suggested that the accumulation of this peptide may result in neuronal death and the formation of neurofibrillary tangles. Toxic effects have been reported when cultured neurons were exposed to synthetic amyloid peptides. Further, it has been suggested that peptide aggregation alters toxicity. In this study, we examined effects of aggregated amyloid fragments on cultured hippocampal neurons. Synthetic peptides homologous to amino acids 1-40 (β 1-40) and 25-35 (β 25-35) of β-AP were dissolved in ultrapure water (10 mg/ml) and allowed to aggregate for at least 2 days. At this time, the aggregated peptide was removed by centrifugation. Small amyloid islands approximately 1 mm in diameter were formed by precipitating the aggregate onto polylysine-treated or untreated 35 mm^2 culture dishes. Control dishes with no amyloid were prepared in an identical manner. Hippocampal neurons isolated from E18 rat pups were then seeded onto the dishes. By 4 h, neurons had attached to both the β 25-35 and the β 1-40 islands. By 24 h, the majority of these cells had extended neurites and were largely multipolar. Attachment and outgrowth to the islands were independent of polylysine treatment. After 7 days, the cultures were fixed and processed for MAP 2 and Tau-1 immunohistochemistry. There were no significant differences in cell survival or somal MAP 2 or Tau-1 staining compared to control following exposure to either amyloid peptides. These finding suggests that, by itself, amyloid in the aggregated form is not neurotoxic. Further, since neurons attached and elaborated processes on these peptides, amyloid has apparent substrate properties. The latter may explain the abnormal neurite sprouting that has been observed in the plaque regions of AD. (Supported by Hoechst-Roussel Pharmaceuticals, Inc.)

ENHANCED EXPRESSION OF AMYLOID PRECURSOR PROTEIN AFTER MIDDLE CEREBRAL ARTERY OCCLUSION. J. A. Clemens*, D.T. Stephenson and K. Rash. The Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285.

Induction of amyloid precursor protein mRNA after persistent focal ischemia in rat cerebral cortex has recently been reported (Abe et al., *J. Cereb. Blood Flow Met.*, 11: 1991). In order to determine if expression of APP itself is enhanced after cerebral ischemia and its cellular origin, we performed immunocytochemistry using antibodies to various epitopes of APP on tissue from rats subjected to permanent middle cerebral artery occlusion (MCAO). Male spontaneously hypertensive rats were anesthetized with isoflurane and the middle cerebral artery was occluded at the level of the rhinal fissure. This treatment produces an infarct restricted to the cerebral cortex. At 4 and 7 days following MCAO the rats were deeply anesthetized and the brains were perfusion fixed with periodate lysine paraformaldehyde. Ten micron thick frozen coronal sections were made through the infarct and immunostained with different polyclonal antibodies directed to C-terminal epitopes of APP (kindly provided by D. Selkoe). Pathological structures including dystrophic neurites and axonal spheroids were strongly labeled at the border of the infarct zone. In addition, many neuronal cell bodies were stained intracellularly in this region. Modified bielschowsky silver staining of near-adjacent sections demonstrated argyrophilic neurons and axons in this same border zone. This finding complements the recent reports of APP accumulation following stab lesion and kainic acid injection. These data suggest APP accumulates in regions of neurodegeneration/regeneration following focal ischemia and implicates that APP may play a role in the reaction of the CNS to injury.

602.12

β-AMYLOID PEPTIDES INDUCE MORPHOLOGICAL CHANGES IN CULTURED RAT MICROGLIA. A.R. Korotzer*, C.J. Pike, and C.W. Cotman. Irvine Research Unit in Brain Aging, *University of California, Irvine, CA 92717 USA.*

Microglia are often associated with senile plaques, a pathological hallmark of Alzheimer's disease. The insoluble core of plaques consists largely of aggregated β-amyloid protein. Synthetic β-amyloid peptides (βAPs) can induce neurodegeneration in vitro, an effect reported to be influenced by the state of peptide aggregation. We have examined the effects of synthetic βAPs on rat microglia in culture.

Two different βAPs were used: β1-42, a full-length homolog of the β-amyloid protein deposited into senile plaques, and β25-35, an active fragment of β-amyloid protein that exhibits both aggregative and neurodegenerative properties. Cultures treated with both β25-35 and β1-42 contained visible precipitate, indicating the presence of aggregated peptide.

Within hours after addition to purified cultures of ramified microglia, β25-35 had induced severe beading of processes; often processes appeared discontinuous under light microscopy. β1-42 also induced this morphological effect, although often with less intensity than β25-35.

These observations indicate that aggregated βAPs, in addition to their reported neurodegenerative properties, also induce morphological changes in microglia in vitro.

602.13

AMYLOID P COMPONENT AND ALZHEIMER AMYLOID LESIONS. L.S. Perlmutter*, M.A. Myers, E. Barrón, D. Saperia, H.C. Chui. Dept. of Neurology, University of Southern Calif. Sch. Med., Los Angeles, CA 90033.

Amyloid P component (APC) is a globular glycoprotein associated with the amyloid proteins that accumulate in virtually all amyloidoses, including Alzheimer disease (AD). This study continues our analyses of APC's association with the lesions of AD, particularly "preamyloid" and neurofibrillary tangles (NFT). Autopsy samples from AD and non-AD cases were fixed in mixed aldehydes and immunocytochemically labeled with a polyclonal antibody against APC (DAKO-Patts). Reaction product was visualized with the avidin-biotin-peroxidase technique (Vectastain), using diaminobenzidine as chromagen. In all cases, regional foci of labeled neurons, astrocytes, microglia, and/or oligodendrocytes were seen; thus APC accumulation is not specific to AD. In AD, the cytosol of intracellular-NFT-laden neurons was labeled, while the extracellular- (E-) NFT themselves were darkly stained. Some plaques resembling "preamyloid" deposits were dispersed through the neuropil. More classical-appearing accumulations contained immunolabeled knob-like structures that, at the light microscopic level, appeared to be dystrophic neurites . However, ultrastructural analyses revealed that dystrophic neurites were never immunolabeled. Hence, these accumulations may not be classic plaques, but rather diffuse accumulations of APC around E-NFT.

An acute phase reactant in rodents, APC's function in humans is unknown. Recently, APC immunostaining has been shown to parallel that of complement proteins, suggesting an association with complement activation and the initiation of phagocytosis (Akiyama et al, Brain Res, 1991, 548:349). APC's localization to "preamyloid," and its association with biochemically diverse types of amyloids, further suggests a central role in amyloid processing. (CA AD Prog., AG07127, AG05142, AG07624)

602.14

ALZHEIMER AMYLOID PRECURSOR PROTEIN OCCURS AS A CHONDROITIN SULFATE PROTEOGLYCAN IN GLIOMA CELLS, **J.Shioi*, J.P.Anderson, J.A.Ripellino, S.Efthimiopoulos, L.M.Refolo, and N.K.Robakis. Dept. of Psychiatry and Fishberg Res. Ctr. for Neurobiol., Mount Sinai Med. Ctr., New York, N.Y. 10029**

Amyloid ß-protein is a major component of senile plaques found in brains of patients with Alzheimer's disease. It is hypothesized that this small protein is a pathological degradation product of the amyloid precursor (APP). We have found that both full length and truncated, secreted APP exist as the core protein of a chondroitin sulfate proteoglycan (CSPG). The secreted APP CSPG in C6 cell culture medium was partially purified by ion-exchange and gel filtration chromatography. Western blot analysis revealed a diffuse band (ca 140k-250kD). This material was detected by several antibodies which specifically recognize different regions of APP. Chondroitinase AC- or ABC-treatment completely eliminated this high molecular weight band with a concomitant increase in the APP band (120kD). The digested product reacted with an anti-stub monoclonal antibody which recognizes 4-sulfated disaccharide. Heparinase or heparitinase did not have any effect on this PG. The N-terminal sequence of this CSPG core protein matched with that of APP. Densitometric analysis showed that about 90% of the secreted APP can occur in the CSPG form. CSPG form of full length APP was also detected on the cell surface. The close proximity of two consensus CS attachment sites to both the N-terminus of the amyloid ß-protein and the secretase cleavage site, suggests that the CS chains may affect the APP processing and/or production of the amyloid ß-protein.

PHOSPHORYLATION OF β/A_4 AMYLOID PRECURSOR PROTEIN (APP) *IN VIVO*. I.P. Shapiro*,[1,2], L. McConologue[3], K.E. Eidman, T.R. Soderling[2]. [1]Department of Pathology and [2]Vollum Institute, Oregon Health Sciences University, Portland, OR 97201 and [3]Athena Neurosciences, South San Francisco, CA 94080.

We wanted to determine the protein kinase(s) which phosphorylate APP, the site(s) of APP phosphorylation, and whether changes in the biochemistry of APP might be associated with APP phosphorylation. Cultured Sf9 insect cells, infected for 48h with recombinant APP_{695}-baculovirus, were labeled with ^{32}P-orthophosphate and immunoprecipitated with a polyclonal anti-$APP_{590-695}$ antibody (C-terminal-immunoreactive). Under basal conditions, APP was phosphorylated on Ser only.

PKC(α) stimulated the ^{32}P-phosphorylation of full-length APP (≥2-fold) and of a ~10 kDa C-terminal APP fragment (≥10-fold) in Sf9 cells co-expressing PKC and APP. The same site in the cytoplasmic domain of APP was phosphorylated by PKC in full-length APP and in the *in situ*-generated C-terminal fragment, as indicated by the presence of the same PKC-stimulated tryptic phosphopeptide in both APP species. PKC stimulated ^{32}P incorporation into PSer only. One possibile explanation for the large relative increase in ^{32}P labeling of the C-terminal fragment is that PKC stimulates the accumulation of this fragment. Experiments to characterize the C-terminal fragment, the precise PKC phosphorylation site, and the mechanism of increased ^{32}P incoporation into this APP C-terminal fragment are ongoing.

These studies demonstrate that PKC phosphorylates APP and that APP phosphorylation may regulate the processing of APP *in vivo*.

Solvent effects on rat and human β-protein toxicity and amyloid formation in vivo. S.A. Frautschy[1]*, Waite, J.[2,3] G.M. Cole[2], A. Baird[1], J. Pitha[4] Thal, L.J.[2,3] [1]Dept. MCGB Whittier Institute, 9894 Genesee, La Jolla, Ca. 92037, [2]Dept. of Neurosciences, UCSD, La Jolla, Ca. 92093 [3]Dept. Neurology, Veterans Admin., San Diego, 92161, [4] Gerontology Res. Cent., Baltimore, MD 21224

Evidence for mutations in and around the β-protein coding region of the amyloid precursor protein (APP) gene in families with early onset Alzheimer's disease (AD) suggests that altered APP metabolism may play a role in AD. Although some studies have reported β-protein toxicity, this subject is controversial. Our purpose was to determine the effects of various solvents on β-protein toxicity and amyloid formation. Fifteen μg of human β(1-40) or rat β(1-42) were dissolved in 35% acetonitrile, water, or a 35% 2-hydroxypropyl-β-cyclodextrin (cyclodextrin) solution in PBS. A 1 μl volume was infused into 16 male Fischer 344 rats into the CA1 region of the hippocampus. Solvent alone or solvent plus reverse sequence peptide was infused on the control side. Rats were sacrificed at 7 d and analysis of necrosis was performed on frozen sections using Nissl stain, β-protein distribution using immunocytochemistry and amyloid formation using Thioflavin-S or Congo Red staining. Results demonstrated that acetonitrile caused gross toxicity which was markedly enhanced by β-protein. β-protein in water was also toxic. However, with cyclodextrin/PBS, the toxic effects were almost negligible. There was intensive staining for β-protein around the tip of β-protein needle injections. On the contralateral side light staining of glial cells was associated with the needle track. The CA3 pyramidal neurons, distal to injury stained for β-protein on both sides. Intriguingly, staining for amyloid patterns was similar to anti-β-protein except that the cyclodextrin/PBS treatment showed no Congo Red birefringence and weak Thioflavin-S fluorescence. We conclude that solvent effects play a major role in acute β-protein neurotoxicity, and that cyclodextrin may inhibit amyloid formation and amyloid toxicity.

β-AMYLOID-INDUCED NEURODEGENERATION IN VITRO: RELATIONSHIP TO PEPTIDE AGGREGATION. C.J. Pike[1]*, D. Burdick[2], A.J. Walencewicz[1], C.G. Glabe[2] and C.W. Cotman[1]. [1]Irvine Research Unit in Brain Aging and [2]Department of Molecular Biology and Biochemistry, *University of California, Irvine, CA 92717 USA.*

The β-amyloid protein is present as an insoluble aggregate within senile plaques, the definitive lesions of Alzheimer's disease (AD). We have demonstrated previously that β1-42, a full-length synthetic β-amyloid peptide (βAP), readily forms aggregates in vitro and is neurotoxic to cultured hippocampal neurons when in an aggregated state. Here we have examined an overlapping series of βAPs to investigate further the structure-function relationship between the neurodegenerative and aggregative properties of β-amyloid protein. βAPs were studied both after initial solubilization in water and after a 7-day incubation of these solutions. Aggregation of βAP solutions was assessed by light microscopy, electrophoresis, and ultracentrifugation studies. We found that only βAPs containing a substantial portion of the hydrophobic transmembrane region formed aggregates that were stable under tissue culture conditions. Following addition to cultures of E-18 rat hippocampal neurons, only those βAPs that exhibited aggregation were observed to cause significant neurodegeneration. Partial reversal of βAP aggregation by solvent treatment resulted in a corresponding attenuation in toxicity. These data suggest not only that hydrophobic sequences may affect the stabilization of βAP aggregation, but also that the state of aggregation of βAPs may be relevant to their biological activities. Together these observations support the theory that β-amyloid protein contributes to AD pathology either directly as a neurotoxin and/or indirectly by increasing neuronal vulnerability to other forms of injury.

CULTURE OF POSTNATAL MESENCEPHALIC DOPAMINE-CONTAINING NEURONS FROM WILD-TYPE AND WEAVER MICE. B.B. Ligon and S. Roffler-Tarlov*, Program in Neuroscience, Tufts Univ. Sch. Med., Boston, MA

Weaver is an autosomal recessive mutation in mice that affects the differentiation and vitality of several classes of neurons. In the midbrain, many of the dopamine-containing cells of the substantia nigra fail to differentiate normally and die after the first postnatal week. This is a report of our preliminary results of the fate of these neurons placed in culture.

For these experiments, the ventral mesencephalon and the striatum were removed from the brains of 7 day-old pups that were identified as being either homozygous weaver or homozygous normal mice by the appearance of the cerebellum. Disassociated cells from midbrain and striatum of the same mouse were plated together at high density on cover slips coated with polylysine, laminin and fibronectin. The coverslips were placed in 24-well plates with modified DMEM and serum.

After 4 days in culture, the cells were fixed and stained for the presence of tyrosine hydroxylase (TH) to identify the dopamine-containing populations. Both weaver and wild-type TH-positive neurons displayed both fusiform and polygonal morphology. In cultures of weaver, the TH-positive fusiform cells outnumbered the polygonal types by a ratio of 4 to 1; whereas polygonal forms outnumbered fusiform by a ratio of approximately 3 to 1 in the wild-type. Pyknotic nuclei were abundant in the weaver cultures and scarce in the wild-type indicating that cell death took place in the weaver cultures during this period at a greater rate than in the wild-type cultures.

This culture system appears to reflect the early cell death of the weaver's dopamine-containing neurons that takes place *in vivo*. These cultures may serve as a useful assay for conditions that influence the development and long-term survival of dopamine-containing neurons. NIH NS20181

MECHANISMS OF CELL DEATH PRODUCED BY CALCIUM INTOXICATION IN DIFFERENTIATED PC12 CELLS. P.P. Michel, S. Vyas, M. Ruberg, P. Anglade, F. Javoy-Agid* and Y. Agid, INSERM U289, Hôpital de la Salpêtrière, 75013 Paris, France.

Normal neuronal cell death either in vivo, during embryonic development or in vitro in cell culture models has been reported to be an active process, dependent on gene expression and protein synthesis (Ellis et al., Annu. Rev. Cell Biol., 7, 663, 1991, Martin et al., J. Neurosci., 10, 184, 1990). The question is whether there is a comparable activation of a cell death program in Parkinson's disease, a neurodegenerative state that is characterized by a selective and progressive loss of dopaminergic neurons. Since disruption of calcium homeostasis is a feature common to most models of cell degeneration, we studied the effects on gene expression of the ionophore A23187 in differentiated PC12 cells, i.e., a type of cells which exhibits properties similar to dopaminergic neurons.

In PC12 cells grown for 8-12 days in presence of NGF2.5S (25ng/ml) and serum proteins, treatment with low concentrations of the calcium ionophore A23187 (3-10μM) for 24hrs produced selective neurite disruption with limited loss of the number of cell bodies as characterized by the trypan blue exclusion criterion. Accordingly, [3H]-dopamine uptake, an index of neurite integrity was impaired in this range of concentrations. Neuronal differentiation could be resumed upon withdrawal of A23187 in the presence of NGF. Widespread cell degeneration occured at higher concentrations only (>30μM). Electron microscopical studies revealed morphological changes in the cytoplasm (formation of lipid droplets; mitochondrial shrinkage; reticulum vacuolation) but no obvious nuclear alterations such as chromatin segregation. In addition, DNA fragmentation could not be detected on agarose gels suggesting that in this culture model, nuclease activation is not a prerequisite for cell death. Other factors such as Ca^{2+} activated proteases or deregulation of certain genes that lead to irreversible damage are being studied.

603.3

NMDA-MEDIATED GLUTAMATE NEUROTOXICITY IN MESENCEPHALIC DOPAMINE NEURONS IN CULTURE. S. Kikuchi and S.U. Kim* Dept. of Neurology, Univ. of British Columbia, Vancouver, Canada.

Neurotoxic action of excitatory amino acids has been considered as one of the causes for the neuronal loss in neurodegenerative diseases that include Parkinson disease. In this study, we investigated the neurotoxic effect of glutamate in dopaminergic neurons grown in culture. Dissociated cell cultures were prepared from 13 day fetal mouse mesencephalon, while 10-14 day old cultures were exposed to glutamate for 10 minutes, and 24 hours later cultures were evaluated for glutamate neurotoxicity by tyrosine hydroxylase (TH) and MAP2 immunostaining and by dopamine uptake assay. In the glutamate-exposed cultures, the number of TH-positive and MAP2-positive neurons and the level of dopamine uptake were decreased to 30-50% of the control. Glutamate neurotoxicity was completely blocked by MK801, an NMDA receptor antagonist, and was reduced by magnesium ion. Phorbol ester and gangliosdies (GM1 and GT1b) were also found to block glutamte neurotoxicity, suggesting that protein kinase C translocation and activation might be important steps in the pathomechanism of glutamate neurotoxicity.

603.4

MK-801 DOES NOT PREVENT DOPAMINERGIC CELL DEATH INDUCED BY MPP+ IN RAT MESENCEPHALIC CULTURES. Y. Agid, B. Zalc*‡ and P.P. Michel, INSERM U289 et ‡U134, Hôpital de la Salpêtrière, 75013 Paris, France.

Neuroprotective effects of MK-801 were tested in a culture model reproducing the selective degeneration of dopaminergic neurons in parkinsonian brains (Michel et al., J. Neurochem., 54, 1102, 1990). Dissociated mesencephalic cells derived from embryonic rat brains were exposed to the 1-methyl-4-phenylpyridinium ion (MPP+), the active metabolite of the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). MPP+ at low concentrations (3 and 10μM) produced selective and dose-dependent toxic effects towards dopaminergic neurons as quantified by the loss of tyrosine hydroxylase positive (TH+) neurons and the loss of [3H]-DA uptake whereas non dopaminergic cell types remained unaffected. MK-801 at 3 and 10μM did not rescue degenerative neurons. At 50μM, i.e., the highest concentration that is not toxic by itself in this culture system, MK-801 was also ineffective. Additionally, degree of dopaminergic damage was not reduced when repeated additions of the glutamate antagonist were performed during exposure to MPP+ or when mesencephalic cultures were left after intoxication for several days in a culture medium still supplemented with MK-801 but lacking the toxin. Furthermore, in control cultures, MK-801 did not affect the uptake of [3H]-DA significantly, thereby suggesting that this compound does not interfere with the accumulation of MPP+ into dopaminergic nerve terminals. At higher concentrations tested (100μM), MPP+ produced a non selective destruction of all cultured cells as characterized by the loss of the number of trypan blue excluding cells and the loss of [3H]-GABA uptake. In these conditions, MK-801 was also found ineffective. Altogether these results indicate that MPP+ neurotoxic effects are not related to an excitotoxic process and/or that MK-801 does not interfere with MPP+ toxic scenario. Therefore antiglutamates may prove not to be effective in preventing dopaminergic cell degeneration in Parkinson's disease.

DEPRENYL AND CLORGYLINE SUPPRESS HYDROXYL RADICAL GENERATION DURING DOPAMINE OVERFLOW ELICITED BY 2'-METHYL-MPTP. S.-J. Huang, C.C. Chiueh*, and D.L. Murphy, Lab. of Clinical Science, NIMH, Bethesda, MD 20892.

We have recently reported the use of *in vivo* intracranial microdialysis perfusion of salicylate to assess hydroxyl radicals (•OH) formation in the brain. The •OH adducts of salicylate were measured by HPLC-EC. Intrastriatal infusion of 2'-methyl analog of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (2'-methyl-MPTP, 1 nmol/min, for 60 min) but not MPTP caused a sustained increase in dopamine (DA) efflux lasting for more than 4 hours. In addition, increased •OH generation was also detected during the sustained DA overflow.

Pretreatment with deprenyl and clorgyline (5 mg/kg, i.p.) suppressed not only the DA overflow but also the •OH generation elicited by 2'-methyl-MPTP. Our ongoing *in vitro* results indicate that 2'-methyl-MPTP can potentiate iron-catalyzed DA autoxidation which leads to formation of •OH and neuromelanin. Thus enhanced •OH formation may be due to autoxidation of the released DA in the basal ganglia where high levels of iron are present. •OH may also be formed during the deamination of released DA and the oxidation of 2'-methyl-MPTP by A and B type monoamine oxidase. This data leads to a new working hypothesis that monoamine oxidase inhibitors may protect against MPTP-induced selective DA neurotoxicity by suppressing the generation of cytotoxic •OH radicals in the iron-enriched basal ganglia.

A METHOD FOR MEASURING DOPAMINE-PROTEIN CONJUGATES AS AN INDEX OF DOPAMINE OXIDATION. M.J. Zigmond* and T.G. Hastings, Dept. of Cellular and Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Dopamine (DA) and free radicals are implicated in the induction of striatal damage associated with certain neurotoxic events. In the presence of oxygen, DA oxidizes to free radical species and DA quinones. The quinones may attack and bind to nucleophilic groups on proteins resulting in potentially cytotoxic alterations in cellular function. To establish a method for measuring DA-protein conjugates as an index of DA oxidation, we incubated striatal slices with ^{3}H-DA under various buffer conditions and determined the amount of radioactivity bound to acid-precipitated protein. The amount of tritium bound to protein was greatly influenced by the concentration of reducing agent (ascorbate or glutathione) present in the incubation buffer. After a 1 h incubation with 60 nM ^{3}H-DA, there was a 3.4-fold increase in the amount of tritium bound to protein in a Krebs-bicarbonate buffer without ascorbate, as compared with the same buffer containing 0.85 mM ascorbate (2.52 ± 0.43 pmol/mg prot and 0.74 ± 0.04 pmol/mg prot, respectively). The difference increased to 6.6-fold after 120 min. The amount of tritium bound to protein was reduced by 90% in the presence of 10 µM glutathione. To characterize the DA-protein conjugate, striatal slices were incubated with 100 µM ^{3}H-DA and the labeled protein was hydrolyzed in 6 N HCl. Two major electroactive peaks containing radioactivity and corresponding to the elution positions of cysteinyl-DOPAC and cysteinyl-DA were isolated by HPLC in a 1 to 2.5 ratio. These findings suggest that: 1) the oxidation products of DA and DA metabolites are binding to protein; 2) binding occurs by covalent interactions with protein sulfhydryl groups; and 3) DA oxidation associated with cytotoxicity would be strongly influenced by cellular maintenance of antioxidant capacities. (Supported in part by USPHS grants NS19608, MH00058, and NS09076.)

PROSTAGLANDIN SYNTHASE-CATALYZED OXIDATION OF DOPAMINE. T.G. Hastings* and M.J. Zigmond. Dept. of Cellular and Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

The oxidation of dopamine (DA) is implicated in neuromelanin formation and cytotoxicity, and is a likely contributor to the selective vulnerability of dopaminergic neurons. Although the oxidation of DA will occur nonenzymatically, examples of enzymatic activity mediating the toxicity of DA and related compounds have been reported. Numerous peroxidase-type enzymes are capable of catalyzing the oxidation of DA to reactive quinones, however, these enzymes are not found in brain. Prostaglandin (PG) synthase, an arachidonic acid metabolizing enzyme, is prominent in brain and has peroxidase activity that requires reducing cosubstrates such as catechol-containing compounds. As a result of this reaction, DA may be co-oxidized to DA quinones and free radical semiquinones. To investigate this possibility, we examined whether purified PG synthase would catalyze the oxidation of DA in vitro. Utilizing spectrophotometric analysis, we measured the formation of the DA oxidation product, dopachrome. We observed that PG synthase oxidized DA, using either arachidonic acid or hydrogen peroxide as a substrate, at an initial rate of 12.0 nmol/min, 44-fold faster than DA autoxidation. The rate of the catalyzed reaction began to plateau within 2 min, indicative of the enzyme's self-inactivation. In the presence of bovine serum albumin, the PG synthase-catalyzed oxidation of DA resulted in the binding of DA to protein which was identified as cysteinyl-DA conjugates. The amount of cysteinyl-DA isolated from protein was increased 2-4 fold in the presence of PG synthase, using either substrate. The identification of cysteinyl-DA indicates that the enzyme catalyzes the co-oxidation of DA to quinones which are capable of reacting with nucleophilic thiol groups on proteins. DA oxidation catalyzed by PG synthase represents potential mechanisms for neuromelanin formation and cytotoxicity. (Supported in part by USPHS grants NS19608, MH00058, and NS09076.)

USE OF SALICYLATE TO TRAP HYDROXYL RADICALS IN RAT BRAIN: A METHODOLOGICAL STUDY L.P. Liang*, T.G. Hastings, M.J. Zigmond and A. Giovanni. Dept. Cellular and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Formation of free radicals in brain has been implicated in many neuro-degenerative processes, including those induced by ischemia, excitatory amino acids, and amphetamines. It has been reported that salicylate can react with hydroxyl radicals to form the stable adducts 2,3- and 2,5-dihydroxybenzonic acid (DHBA) (Floyd et al., J. Free Rad. Biol. Med., 1986). Tissue levels of these adducts can be determined by HPLC with electrochemical detection. We assessed the practicality of this method and determined a paradigm for estimating the content of hydroxyl radicals in rat brain. Following its systemic administration (100 mg/kg, i.p.), salicylate levels peaked at approximately 150 nmol/g tissue at 2 hrs and then declined with a t½ of 4 hr in several brain areas, including striatum, frontal cortex, and hippocampus. The major adduct of salicylate formed in vivo was 2,5-DHBA, which reached a peak of approximately 250 pmol/g tissue (2 hr) in the different areas. DHBA levels were not affected by the addition of the reducing agent ascorbate (0.5 mM) and/or the iron chelator DETAPAC (1 mM) during tissue homogenization (sonication at 100 mg/ml in 0.2 M perchlorate). Freezing the tissue (-70°C) also had no effect. We are using this method to examine formation of free radicals in vivo under several conditions associated with an increase in DA availability, such as methamphetamine exposure (see Giovanni, Soc. Neurosci. Abs., 1992) and L-DOPA-treatment. Our data demonstrate the usefulness of this technique to trap free radicals in vivo to quantify these highly reactive and short lived oxygen species. (Supported in part by NS19608, MH18273, and MH00058.)

METHAMPHETAMINE INCREASES HYDROXYL RADICALS IN RAT STRIATUM: ROLE OF DOPAMINE. A. Giovanni*, T.G. Hastings, L.P. Liang, and M.J. Zigmond. Department of Cellular and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

The role of dopamine (DA) in the induction of dopaminergic neurotoxicity resulting from methamphetamine (METH) treatment supports the hypothesis that DA may be involved in the etiology of Parkinson's disease. DA can autoxidize to form a variety of potentially neurotoxic compounds, including free radicals such as the hydroxyl radical (OH•). To assess the role of free radicals in the toxic effects of METH, we used salicylate to trap OH• in vivo. We then used HPLC with electrochemical detection to measure the striatal content of 2,3-dihydroxybenzonic acid (2,3-DHBA) and 2,5-DHBA, stable adducts resulting from OH• attack upon salicylate (see Liang et al., Soc. Neurosci. Abs., 1992). Adult male rats (325-375 g) were given a neurotoxic regimen of METH (12.5 mg/kg, s.c., 4x, at 2 hr intervals) and neurotoxicity was assessed by examining striatal DA content for long-term depletion. Some rats received salicylate 1 hr after the last dose of METH and the animals sacrificed 2 hr later. Under these conditions, METH caused an increase in the level of 2,5-DHBA in striatum, from 107 ± 13 to 237 ± 34 pmol/g tissue (mean ± SEM, n=8 and 9, respectively). This increase, as well as the decrements in striatal DA, was blocked by pre-treatment with α-methyl-*p*-tyrosine (2 x 50 mg/kg, i.p.), an inhibitor of catecholamine biosynthesis. These results indicate that: 1) the concentration of free radicals in striatum increases in response to neurotoxic doses of METH; and 2) DA plays an essential role in this METH-induced increase in free radicals. These findings also suggest that under other conditions of increased availability, endogenous DA may play a role in neurodegeneration through the formation of free radicals. (Supported in part by NS19608, MH18273, and MH00058.)

603.10

THE EFFECT OF FREE RADICALS ON DOPAMINE METABOLISM, IMPLICATIONS FOR PARKINSON'S DISEASE.

F.F. Oldfield* Department of Pharmacology, University of Missouri, Columbia MO-65212

The mechanism for the accelerated loss of dopaminergic neurons in Parkinson's Disease is unknown. One hypotheses focuses on the oxidative stress associated with the natural metabolism of dopamine (DA). We have used ESR spin trapping to study the kinetics of free radical production from DA metabolism by serum or mitochondrial MAO. The spin adduct observed is the hydroxyl (OH) adduct of the spin trap 5,5-dimethyl-1-pyrroline N-oxide. A quantitative comparison of the ESR with simultaneous enzyme assays shows that the number of OH radicals trapped is a substantial fraction (>10%) of the number of DA metabolized. Surprisingly, kinetic analysis of the ESR data shows that adventitious copper is responsible for the OH production in the serum MAO system. When Gamma irradiation was used as an alternative source for free radical production we detected altered mitochondrial MAO ability to metabolise DA. The role of protective agents and transition metals is under study. These results support the oxidative stress hypothesis associated with DA which plays a role in Parkinson's Disease. (Supported in part by a grant to F.F.Oldfield from the Parkinson's Disease Foundation.)

MPP$^+$ INDUCED OXIDATIVE STRESS - NEW INSIGHTS INTO THE HYDRIDE TRANSFER MECHANISM. J. D. Adams* and L. K. Klaidman. Dept. Molecular Pharmacology and Toxicology, Univ. Southern Calif., Los Angeles, CA 90033.

We recently proposed a new mechanism for MPP$^+$ induced oxidative stress, involving a two electron transfer, called hydride transfer. This process is mediated by a number of enzymes, especially flavin enzymes. Hydride tranfer to MPP$^+$ results in the formation of 1-methyl-4-phenyl-1,4-dihydropyridine (DHP) which is quickly oxidized by $O_2^{\cdot-}$ in one electron steps. The first product is MPP$^{\cdot}$ which can reduce oxygen to form $O_2^{\cdot-}$ or cleave hydrogen peroxide to form OH$^{\cdot}$, and regenerate MPP$^+$. We now report the quantitation of $O_2^{\cdot-}$, H_2O_2 and OH$^{\cdot}$ during incubations of MPP$^+$ or MPDP$^+$ with enzymes including monoamine oxidase, lipoamide dehydrogenase, aldehyde dehydrogenase and xanthine oxidase. These experiments in addition to oxygen uptake experiments are demonstrating the ability of MPP$^+$ to redox cycle and form radicals that could be damaging to cells. Most of the enzymes examined are found in mitochondria, and perhaps the cytosol, which may indicate the importance of oxygen radical formation by MPP$^+$ in mitochondria. This redox cycling can complement the formation of $O_2^{\cdot-}$ during inhibition of NADH dehydrogenase by MPP$^+$. Mitochondrial and cytosolic generation of oxygen radicals are critical components of the toxicity induced by MPP$^+$.

SHORT TERM ALTERATIONS OF NIGRAL MALONDIALDEHYDE (MDA) LEVELS AND STRIATAL DOPAMINERGIC MARKERS INDUCED BY INTRANIGRAL IRON INFUSION. G.J. Sengstock[1]*, N. Zawia[3], C.W. Olanow[2], A.J. Dunn[4], G.W. Arendash[1]. Depts. of Biology[1], Neurology[2], Univ. of South Florida, Tampa, FL 33620; NIEHS[3], Research Triangle Park, NC 27709; Dept. of Pharmacology[4], LSU Medical Ctr., Shreveport, LA 71130.

In Parkinson's disease (PD), iron content and lipid peroxidation are increased within the substantia nigra (SN). We recently reported that iron infusions into the rat SN induce localized neurodegeneration as well as dose-dependent reductions in striatal dopaminergic markers (*Brain Res Bull* 28:645, 1992). To test whether iron-catalyzed lipid peroxidation may be associated with the resultant degenerative changes, 0.63nmol of iron or vehicle was infused unilaterally into the SN of adult male rats. Animals were decapitated at several time points through 1 month. Striatal tissue was assayed for biogenic amines by HPLC. To record only **basal** MDA levels in the SN and prevent further MDA formation beyond decapitation, desferrioxamine and BHT were incorporated in our spectrophotometric MDA microassay. Vehicle infusion had no effect on MDA or striatal dopaminergic markers. In contrast, MDA values from iron-infused animals were significantly elevated (72%, $p<0.05$) 1 hour post-infusion compared to nonoperated control animals and returned to control levels by 1 day. Successive to the SN alterations, striatal DOPAC and HVA (catabolites of dopamine metabolism) were significantly increased ($p<0.05$) at 1 day, as was calculated dopamine turnover ($p<0.001$). By one week, all neurochemical values returned to control levels. These data are supportive of the hypothesis that lipid peroxidation, as determined by MDA levels, is acutely increased following iron infusion into the SN This suggests that iron-induced lipid peroxidation may be involved in the degeneration of nigrostriatal dopaminergic neurons in PD.

SEASONAL VARIATION IN THE INCIDENCE OF NEURODEVELOPMENTAL DISORDERS. J. Liederman * and K. Flannery, Psych. Dept., Boston Univ., Boston, MA 02215.

Neurodevelopmental disorders (NDs) such as learning disabilities, articulation disturbances, attention deficit disorder, cerebral palsy, and mental retardation may sometimes be triggered by events that occur during gestation. One important intrauterine factor may be endocrinological; it has been suggested that imbalances of sex hormones during gestation may be associated with neurodevelopmental disorder. Since hormone levels are known to vary seasonally, the relationship between hormonal variation in utero and ND was indirectly assessed by measuring the incidence of NDs for children conceived during different seasons (defined in terms of length of daylight). This was was examined in a subsample of The National Collaborative Perinatal Project (N = 21,833). There were seasonal variations in the rate of NDs with the highest prevalence for winter/fall conceptions as compared to spring or summer. These findings were robust since they remained unchanged when considering seasonal variations in other risk factors such as maternal weight gain, maternal anemia, and maternal infections.

SELECTIVE COGNITIVE DEFICITS LINKED TO GENE SIZE AND PARENTAL INHERITANCE IN NONRETARDED CARRIERS OF FRAGILE X SYNDROME. V.J.Hinton*, J.M.Halperin, C.S.Dobkin, X.H.Ding, W.T.Brown and C.M.Miezejeski. CSI/IBR Center for Developmental Neuroscience, Staten Island, NY 10314.

The relationship between inheritance, the size of the FMR-1 gene, and cognitive function was evaluated in nonretarded adult female carriers of the Fragile X Syndrome. The goals were to determine whether 1) parental inheritance of FMR-1 affects cognitive and genomic expression; 2) mild cognitive impairments are associated with expansion of an unstable CGG region in the FMR-1 gene; and 3) specific cognitive domains are affected by this expansion. Sixteen women with paternally inherited FMR-1 (PI), 11 women with maternally inherited FMR-1 (MI) and 16 controls were compared with regard to DNA fragment size probed with StB 12.3 and neuropsychological measures. The PI group did not differ from controls on IQ, with all being within 1 SD of the mean, and none showed large CGG expansion in the FMR-1 gene. In contrast, five (45%) subjects in the MI group had IQ scores more than 1 SD below the mean and large (>500 bp) CGG expansion in the FMR-1 gene. All other MI subjects were indistinguishable from the PI subjects on both cognitive and molecular measures. The MI group was then subdivided into two groups based on size of CGG expansion. After controlling for IQ, MI subjects with large expansions were found to be selectively impaired ($p < .05$) on measures of perceptual and attentional function, but not verbal skills. Thus, molecular status of FMR-1 appears to be linked to parental inheritance and may selectively affect specific cognitive skills in nonretarded women.

604.3

SPECT EVIDENCE OF DELAYED FRONTAL CORTEX MATURATION IN CHILDHOOD AUTISM M. Zilbovicius*, B. Garreau, Y. Samson, Ph. Remy, B. Bruck, C. Barthélémy, A. Syrota, G. Lelord. SHFJ, CEA, Orsay and INSERM U316, Tours, France.

Neurobiological causes of childhood autism, a severe developmental disorder, are still unknown. Clinical and cognitive data have suggested that the maturation of the cerebral cortex may be delayed in this disorder, particularly involving the frontal lobes. Maturational changes in cerebral function can currently be assessed by measures of regional metabolism (Chugani and Phelps, 1986) or cerebral blood flow (Tzourio et al., 1988). We used SPECT to compare the regional distribution of cerebral blood flow (rCBF) in five young children with primary autism (age: 41 ± 7.8 months) and in five age-matched non-autistic children (33.4 ± 6.8 months). All studies were performed under sedation with the Xenon 133 iv injection method. The normalized frontal rCBF was markedly lower in the autistic group (0.86 ± 0.07) than in controls (0.96 ± 0.08, $p < .0008$). The normalized posterior cortical rCBF was slightly higher in autistic than in control children (1.1 ± 0.1 vs 1.07 ± 0.25, $p < .04$). The mean cerebral cortical blood flow was similar in both groups (autistic: 73.2 ± 10.1 ml/min/100g; control: 72.4 ± 8.5 ml/min/100g, ns). We believe that the marked frontal hypoperfusion found in these young autistic children (2-4 years) may indicate a delayed frontal lobe maturation rather than a permanent frontal abnormality since: 1) such frontal hypoperfusion is found in normal but younger children (1-2 years old), and 2) frontal perfusion is normal in older (5-11 years old) autistic children (Zilbovicius et al., 1992).

CHRONIC ABERRANT BEHAVIOR IN THE MENTALLY RETARDED: ANIMAL MODELS, RISK FACTORS, AND ADJUNCTIVE BEHAVIOR. P. S. Loupe, C. J. Stodgell, & R. E. Tessel.* Dept of Pharmacol. & Toxicol., Univ. of Kansas, Lawrence, KS 66045

Spontaneously hypertensive (SHR), Sprague-Dawley (SD) rats neonatally depleted of brain catecholamines by 6-hydroxydopamine injection (6HD; 100 ug/rat) or made microencephalic by prenatal methylazoxymethanol (MAM; 25mg/kg) injection to pregnant dams, and post-weaning social isolation (SI) and prior environmental stress may respectively model genetic,organic and environmental risk factors for self-injurious behavior (SIB), stereotypies, aggression and hyperactivity (Chronic Aberrant Behaviors; CAB) seen in the mentally retarded. It may be that CAB are induced and maintained at high frequencies in the mentally retarded because the risk factors increase susceptibility to the adjunctive (schedule-induced) consequences of intermittent reinforcement. In an attempt to evaluate this hypothesis, group-housed and SI MAM, SHR, 6HD and SD rats with prior histories of repeated exposure to electric foot-shock were magazine trained under a VI 45" schedule of food-pellet presentation to a 5-sec latency criterion for removal of food from a hopper; MAM rats required significantly more sessions to reach criterion than any other group ($p < .01$). The schedule was then changed to an FT 60" and the proportion of inter-pellet intervals in which specified behaviors occurred (behavioral frequency) were determined. Locomotor activity and rearing frequencies during FT session 1 were similar among each of the non-environmental risk factor groups except those in MAM which were significantly greater ($p < .05$). These frequencies increased significantly ($p < .05$) across subsequent sessions in SHR but not in 6HD, MAM or SD. Grooming frequency increased significantly across sessions ($p < .01$) to essentially to the same extent in all groups. No biting (an index of aggression), SIB or effect of housing was observed during training. The relationship of these findings to CAB will be discussed. (Supported by NICHHD grant 1 PO 1HD26927)

EFFECTS OF METHYLAZOXYMETHANOL (MAM) TREATMENT ON GESTATIONAL DAY 14 (GD14) ON NEUROCHEMISTRY, REGIONAL BRAIN WEIGHT, AND BEHAVIOR. S. A. Ferguson*, R. R. Holson, M. G. Paule and J. F. Bowyer. Divisions of Neurotoxicology and Reproductive & Developmental Toxicology, National Center for Toxicological Research, Jefferson, AR 72079.

Sprague-Dawley rats were injected sc with either MAM (20 mg/kg) or saline on GD14 (plug date=GD 0). Beginning prior to weaning and continuing through adulthood, offspring were assessed on a variety of behavioral tests, including activity measures. Regional brain weights were obtained and DA and 5-HT concentrations in caudate nucleus (CN) were measured. Contrary to what is typically reported, MAM-treated rats exhibited either hypoactivity or normal activity levels; no consistent indications of hyperactivity were noted. Frontal cortex, hippocampus, and CN of MAM-treated rats were most reduced in weight (cortex weight was 50% of control) while brainstem, olfactory bulbs, thalamus, cerebellum, and body weight were relatively unaffected. MAM treatment increased 5-HT concentration in CN two-fold, with little effect on DA concentration. Regional brain weight reductions and increased CN 5-HT concentrations in MAM-treated rats were consistent with previous findings; however, neither activity nor DA levels were consistent with literature reports. The possibility that these data may reflect a strain difference cannot be excluded.

AN INBRED EPILEPSY-PRONE SUBSTRAIN OF BALB/c MICE SHOWS AN ABSENCE OR REDUCTION OF CORPUS CALLOSUM AND AN ABNORMAL PROJECTION TO BASAL FOREBRAIN. S. Dolina*, C. Morin, C.E. Ribak and R.T. Robertson. Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Epilepsy-prone (EP) and epilepsy-resistant (ER) substrains of mice derived from the BALB/c strain have been developed through 19 generations of close breeding and subsequent inbreeding. The BALB/c strain shows the acallosal phenotype in about 15% of the population. In this study, we determined the presence or absence of a corpus callosum and patterns of efferent projections from motor cortex in EP and ER mice. Data were collected from juvenile (postnatal age 13-14 days) and adult mice. Animals from the 8th and 9th inbred generations were used. Aldehyde fixed tissue was prepared for Nissl stains and DiI for the tracing of cortical efferents.

ER animals had normal corpora callosa (101 of 101 cases). Twenty of 26 EP animals were acallosal and the remaining 6 EP animals displayed a corpus callosum markedly reduced in size. Placements of small crystals of DiI in motor cortex of ER animals revealed the presence of a normal corpus callosum, with anterograde labeling of terminals and retrograde labeling of pyramidal neurons in the contralateral cortex. In acallosal EP animals, DiI labeled axons extended toward the midline, but turned ventrally to course through the medial septum. These fibers appeared to terminate in the basal forebrain in the region of the nucleus of the diagonal band. EP animals with a rudimentary corpus callosum showed some labeled fibers crossing the midline to terminate in the contralateral cortex, but many fibers also coursed ventrally to the basal forebrain.

These results show that aberrant cortical projections to the basal forebrain occur in mice that lack a complete corpus callosum. Further, in this model a strong linkage between acallosal brains and inherited epilepsy is demonstrated.

Supported by NIH grants NS 15669 and NS 25674.

DISTRIBUTION AND MORPHOLOGY OF THE CORTICOSPINAL TRACT NEURONS IN PRENATALY X-RAY IRRADIATED RATS. RETROGRADE TRACING AND INTRACELLULAR LUCIFER YELLOW STAINING STUDIES.

H. Ochiai, S. Miyahara, S. Wakisaka, and M. Inoue*. Dept. of Neurosurgery, Miyazaki Med. College Miyazaki 889-16 and Dept. of Physiology, Fukuoka Univ., Fukuoka 812, Japan.

X ray irradiation to foetus is a potent teratogenic procedure, and such it is the prime cause of mental retardation and behavioral abnormality. In order to clearify the effect of X ray irradiation on development of the corticospinal (CS) tract neurons, fetal rats were irradiated with X ray (1.5 Gy, 140 kV, 4 mA) at pregnant day 12. At the day 30 of postnatal, FAST BLUE or HRP was injected into cervical cord at C3-4 level to identify CS neurons. Three days after the injection, the animals were sacrificed, brain was removed and sectioned at a thickness of 100 micrometer, and the CS neurons were stained intracellulary with Lucifer Yellow, photo-oxydated and analyzed. Most of retrogradely labeled neurons distributed layer V, their row formation was poor and vertical disposition was remarkable. Clustering of ectopic neurons were sometimes seen at layer VI. Most of the CS neurons distributed in layer V was typical pyramidal cell, but the neurons distributed in the deep of layer V had relatively round somata and the apical dendrites were thinning, shortened and sometimes wavy, indicating that the development and differentiation were poor. The ectopic neurons had small and round somata, and it had slender and spokewise dendrites, which had rich dendritic trees. The heterogeneity of the population and variety of shape of the CS neurons in X ray irradiated rats results from the effects of irradiation on early events in neuronal development such as neuronal generation and migration.

604.8

THE HISTOPATHOLOGICAL RESPONSE OF THE FETAL SHEEP BRAIN TO MID-GESTATIONAL HYPOXIA.

D.H. Penning[1], M.R. Grafe[2]*, Y. Matsuda[3], R. Hammond[3], B. Richardson[3]. Queen's Univ., Kingston, Ontario[1]; Univ. of Calif. San Diego[2]; Univ. of Western Ontario[3].

Intrauterine hypoxic/ischemic injury is the cause of significant morbidity and mortality in newborns and children and may produce injuries ranging from learning disorders to severe neurologic impairment. We examined the physiologic and neuropathologic effects of midgestation hypoxia in chronically instrumented fetal sheep. The results of the physiologic studies have been reported (Matsuda et al, Am J Obstet Gynecol, in press). Fetal sheep were catheterized in utero 5 days prior to hypoxia. At 87-99 days gestational age (term=147 days) the ewes inspired a hypoxic gas mixture (9% O2) for 8 hours; maternal and fetal blood gases were monitored throughout the experiment. Fetuses became hypoxic (PaO2=14.8 mmHg vs. controls=29.0), but only mildly acidotic (pH=7.23 vs. controls=7.36). Three days after hypoxia the ewes were euthanized and fetuses removed and immediately perfused with formalin. The brains were routinely prepared for histology and sections were taken to include cerebral cortex with white matter, hippocampus, thalamus, basal ganglia, cerebellum, and brain stem. Control animals included animals subjected to the same surgical procedures, but without hypoxia as well as normal, uninstrumented animals. One hypoxic animal was excluded from further analysis due to acute meningitis. Three of the 4 remaining hypoxic animals had moderate to severe white matter necrosis in the cerebral hemispheres. In the most severely injured regions adjacent cortex was also infarcted, but selective neuronal injury was not seen. One hypoxic animal showed no significant changes. Mild, focal white matter injury was seen in one of the two instrumented controls. Uninstrumented controls (n=3) had no significant pathologic changes. The results of these studies correlate well with the white matter necrosis seen in some premature infants. Similar studies in near-term (>129 days) fetal sheep are underway.

EARLY POSTNATAL OXYGEN DEFICIENCY AND NEURAL-BEHAVIORAL DEVELOPMENT IN RATS.

M.Dyer*, E.A. Montgomery, M.E. Bargett, J.G. Csernansky, and C.R. Almli. Develop. Neuropsychobiol. Lab., Dept. of Psychiatry, Wash. Univ. Sch. Med., St. Louis, MO, 93110.

Perinatal oxygen deficiency decreases motor activity and alters its cyclicity immediately after the treatment. In the present study, behavior, neuropathology and neurochemistry of pups deprived of oxygen were studied until postnatal day 21.

Pups at P0 or P1 were deprived of oxygen (placement in airtight chambers until a gasping criterion; 3 identical treatments + rest periods). Pups were housed with the dam. Behavior (open field activity, sensory-motor reflex testing), HPLC biochemistry (dopamine, serotonin of accumbens, striatum, and hippocampus), and histopathology were studied at P1, P7, P14 and P21.

Oxygen deprived and control pups showed no differences in body weights at any age. Preliminary analyses indicate relationships between behavioral, neurochemical and histopathological measures. (Conducted under NIH Guide for Care and Use of Laboratory Animals).

604.10

BIRTHDATES OF NEURONS IN NEOCORTICAL ECTOPIAS OF NEW ZEALAND BLACK MICE.

G.F. Sherman*, L.V. Stone, N.R. Walthour, G.W. Boehm, V.H. Denenberg, G.D. Rosen, and A.M. Galaburda. Department of Neurology, Harvard Medical School, and Beth Israel Hospital, Boston, MA 02215 and Biobehavioral Sciences Program, University of Connecticut, Storrs, CT 06269.

Previous studies have shown that 40-50% of New Zealand Black (NZB/B1NJ) mice, a strain which spontaneously develops severe autoimmune disease, have ectopic collections of neurons in layer I of the cortex (Sherman et al., Acta Neuropathol., 74:239-242, 1985). Usually one ectopia is seen in affected brains, although multiple ectopias are sometimes present. Ectopias contain as few as 10 or as many as 100 or more neurons, and have been seen as early as E13-14. The birthdates of neurons in the ectopias has not been determined and therefore in the present study we examined ectopias in adulthood after BrdU (an S-phase marker) injections of pregnant NZB mice.

NZB mice were time-mated (E0 was the day a vaginal plug was found) and the pregnant females were given an injection of BrdU (Becton-Dickinson; 50 µg per gram of body weight) on one day from the range covering the birth of most neurons in the cerebral cortex (E10-E18). Over 100 offspring were anesthetized in adulthood and perfused with 0.9% saline followed by 4% paraformaldehyde. The brains were removed form the crania and placed into 10% buffered sucrose overnight, followed by 30% buffered sucrose for 24 hours, after which they were frozen and cut coronally at 30 µm on a sliding microtome. Every fifth section was stained with thionin to reveal neocortical ectopias and BrdU immunohistochemistry was performed on adjacent sections.

BrdU staining of neurons was similar to that reported by other authors: after early injections BrdU-positive neurons were present mostly in infragranular layers of the cortex, whereas the supragranular layers were positively-stained after later prenatal injections. However, the layer I ectopias showed a different pattern. Cells born as early as E12-13 and as late as E15 were present in the adult ectopias. The morphology of these cells was neuronal in appearance, however, double-labeling experiments are necessary to make any definitive statements. The older ages (E16-18) are presently being examined. We conclude that the ectopias originate early during the prenatal period and may consist of neurons generated over a wide range of prenatal days. (Supported in part by NIH grant HD 20806.)

BIRTHDATES OF NEOCORTICAL NEURONS IN INDUCED MICROGYRIA IN THE RAT.

G.D. Rosen*, J.M. Richman, G.F. Sherman, and A.M.Galaburda. Beth Israel Hospital and Harvard Med. School, Boston, MA 02215.

A freezing probe placed on the skulls of newborn rats acutely damages the cortical plate underlying the probe. Within one week of the lesion, the cortex reorganizes forming an area resembling focal microgyria. This four-layered structure consists of an outer molecular layer (i); a second layer (ii) which is contiguous with layer II and III of the adjacent, intact cortex; a *lamina dissecans* (iii); and a fourth layer (iv) which is contiguous with layer VIb. The current experiment was designed to determine the birthdates of neurons comprising this induced neocortical malformation.

Time-mated pregnant Wistar rats were injected with either [^{3}H]thymidine or BrdU on embryonic day (E) 15, E17, E19, or E21. At postnatal day (P) 0 or P1, the pups from these litters were anesthetized by hypothermia and a freezing probe (≈ -70°C) placed on the skull overlying the cortical plate. Animals were sacrificed on either P1, P3, P4, P5, P7, P10, and P60 by transcardial perfusion with saline followed by 4% paraformaldehyde. The brains were post-fixed for 28-96 hours, sectioned coronally, and either immunohistochemically stained for BrdU or prepared for autoradiography.

Neurons born on E15, which are seen in the infragranular layers of the undamaged cortex, were rarely found in the microgyric cortex. When present they could be seen only in microgyric layer iv. Neurons generated on E17 and E19 were found scattered throughout microgyric layer ii, whereas in the undamaged cortex E17 neurons were generally found in inferior laminar locations to those born on E19. A few E21 neurons were seen in the most superficial portions of microgyric layer ii. These results suggest that the majority of neurons comprising the microgyric cortex are generated later in neuronogenesis.

SELECTIVE LAMINAR AND AREAL DELETION OF CORTICAL NEURONS BY PRENATAL X-IRRADIATION IN THE MACAQUE MONKEY.

O. Algan*, P.S. Goldman-Rakic, P. Rakic Section of Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510

Ionizing irradiation was used to separately diminish or delete cells in infragranular, granular and supragranular layers of the neocortex in fetal monkeys. X-irradiation was performed on specific embryonic (E) days to disturb mitotic division and migration of neurons destined to form particular layers (Rakic, '74-'88). Macaque fetuses were irradiated at E33-40, E39, E70-73, E70-80, E80-90 with individual doses among 40-264 rads (R) and cumulative doses of 100-600R. Pregnant monkeys were anesthetized, and an X-Ray tube was focused on the fetal head, localized with ultrasound. Offspring were tested behaviorally in a separate study and/or sacrificed between P60 and 2 yrs. The brains were cut at 35µm from celloidin blocks and stained with cresyl violet. The density per unit volume, the size and the distribution of neurons in each layer of areas (A) 17 and 24 were examined using an unbiased 3D cell counting method (Williams & Rakic, '88). The effects of doses and schedules of irradiation were evaluated by ANOVA. We found first, that the density of cortical cells was lower in irradiated offspring, who also had larger cerebral ventricles than age matched controls. Second, our initial results indicate that irradiation had different effects at different ages: e.g., at E70-80, irradiation with >400R decreased cell density substantially in layers II-V of A17, while irradiation with similar doses (250-300R) at E80-90, depleted more superficial layers preferentially. Irradiation at E70-80 with 100-400R depleted predominantly middle layers IV and V. Third, different dose response effects were obtained in different areas of the same specimens in accord with the timing of cell origin of these areas. For example, irradiation at E80-90 did not alter cell density in A24, while irradiation at E70-80 affected only layer II which is generated at that time. The preferential depletion of specific layers of primate neocortex by X-irradiation provides an opportunity to analyze the effect of individual laminar loss in selected areas on the local synaptic organization and the pattern of extrinsic connectivity of the cerebral cortex as well as the consequent effects on behavior. Pyramidal Cells in the Sensory-motor Cortex of the H-Tx rat with infantile hydrocephalus. H.C. Jones* and N.G. Harris#. Dept of Pharmacology, Univ. of Florida, Gainesville, Fl 32610 and # Dept of Physiology, King's College, London W8 7AH, UK.

The H-Tx rat has congenital hydrocephalus caused by obstruction of the aqueduct at 18-days gestation. The lateral ventricles expand rapidly after birth and the cortical grey matter becomes severely attenuated, particularly in the posterior cortex where there is disruption of the laminar structure in the deeper layers. Layer V pyramidal cells have been studied at 21 days after birth by quantitative analysis of Golgi-stained sections from the sensory-motor (anterior) cortex. The basal dendrites of cells in the most severely affected rats were significantly reduced by 40 -60 % in total length and also in vertical and horizontal extent when compared to control rats. This was confirmed by concentric circle analysis which showed a reduction in the number of dendrite-ring intersections with increasing distance from the soma. The angle of the apical dendrite to the pial surface was between 0 and 17° in control rats but around 40% of the cells from hydrocephalic rats were abnormally orientated with angles greater than 17°. The apical dendrites, although variable, were not significantly altered in cells from hydrocephalics in either vertical or horizontal extent. The results are consistent with ventricular expansion resulting in compression of the deep layers of the cortex and also with tangential forces causing disorientation of pyramidal cells.

EFFECTS OF HYDROCEPHALUS AND DECOMPRESSION ON RETINAL CELL DEVELOPMENT. E.C. Williamson, H.E. Pearson, T.J.Shickley and J.P.McAllister II. Temple University School of Medicine, Philadelphia, PA 19140.

Even after surgical decompression, infantile hydrocephalus often results in permanent neurological symptoms, including visual deficits. However, little is known about the cellular changes that may be responsible for these problems. The present study was designed to analyze the retinae of normal, severely hydrocephalic, and decompressed kittens to determine the density and size of retinal ganglion cells. Hydrocephalus was induced in 10 day old kittens by intra-cisternal injection of kaolin. Kittens were allowed to survive from 7-28 days and then sacrificed and perfused with mixed aldehydes. Animals that received ventriculoperitoneal shunts were shunted 10-15 days after the induction of hydrocephalus and then sacrificed 10-14 days after shunt placement. Retinae were flat-mounted onto glass slides and stained with cresyl violet. A 750 x 750 micron sample area was chosen 1 cm along the horizontal meridian in nasal retina, and cells were drawn using a drawing tube under 40X magnification. Cell density and cell area were determined using the Bioquant image analysis system. Total cell density was significantly increased in severely hydrocephalic animals but returned to within normal levels following decompression. On the basis of cell size, however, the glial population was significantly increased and there was a significant loss of ganglion cells in both the hydrocephalic and the shunted groups. Based on the results, we conclude that gliosis occurs as a result of cell death in the retina following hydrocephalus, and decompression is unable to reverse these effects. Supported by NS25196 and HD21527.

604.15

DYSPLASIA OF THE OLFACTORY BULB IN A RABBIT MODEL OF HYDROCEPHALUS. M. J. De Rosa, Ch. E. Olmstead#, W. J. Peacock, C. P. E. Outram, R. Gayek, H. V. Vinters, and R. S. Fisher. Departments of Pathology, Surgery/Neurosurgery, Anatomy, Laboratory Animal Medicine and Brain Research Institute. Univ. Calif. Sch. of Med., Los Angeles CA 90024

In a paradigm designed for the induction of hydrocephalus in the rabbit by the intracisternal injection of kaolin, we have demonstrated a dyslamination of the cerebral cortex, cell loss and alterations in the cytostructural composition of cortical neurons. These findings are being extended to an analysis of the olfactory bulbs, a major drainage route for cerebrospinal fluid and an area markedly affected by this manipulation. We have demonstrated a deviation from the normal layering pattern of the olfactory bulb with the most severe effects occurring in the granule cell layer. Rather than the "shingled" appearance of the granule cell layer seen in the littermate control animals, this layer in the hydrocephalic animals appears as a solid sheet of cells with no separation into the overlapping laminae commonly seen. Mitral cell and glomerular layers also appear affected by this insult. As the major developmental landmarks appear later in the olfactory bulb than in the cerebral cortex, the olfactory bulb of the kaolin induced hydrocephalic rabbit may be an interesting system for the study of neurodevelopment and developmental neuropathology.

EXPRESSION OF N-CAM IN THE REELER MOUSE CEREBELLUM. E.M. Sajdel-Sulkowska* and M. Lee Dept. Psychiatry,Harvard Medical School and Mailman Research Center, McLean Hospital, Belmont, MA 02178

During the development of CNS in rodents, the neural cell adhesion molecule (N-CAM) mRNA form containing a 30 bp VASE exon replaces RNA that lacks this exon. The resulting structural modification of N-CAM may affect neuronal interaction and migration. The objective of these studies was to compare the expression of the alternative splicing forms of N-CAM in the cerebellum of the control and reeler mice; the cerebellum of this neurological mutant is characterized by the inside-out cell layering as a result of the abnormal neuronal migration. We have used a reverse transcriptase-polymerase chain reaction (RT-PCR) method to examine the expression of the N-CAM mRNA. Both splicing forms were expressed in the control and mutant mouse cerebellum; the embryonic mouse brain tissue showed predominantly the form lacking VASE exon. Preliminary data suggests the presence of an additional form of N-CAM expressed in the mutant but not the control cerebellum. Further experiments are in progress to verify the existence of the additional splicing form and to identify the novel sequence.

EXPRESSION OF ALTERNATIVELY SPLICED FORMS OF NEUROFIBROMIN mRNA IN THE CHICK EMBRYO L. Baizer,*G.S. Ciment, K.M. Stocker, and G.L. Schafer RS Dow Neurological Sciences Institute, Good Samaritan Hospital and Medical Center and Department of Cell Biology and Anatomy, OHSU, Portland, Oregon 97209

Neurofibromatosis type 1 (NF-1) is among the most common inherited disorders. Identification and characterization of the NF-1 gene product (now known as 'neurofibromin') has revealed that it is similar in structure and function to the ras-GTPase Activator Protein (GAP). Further nucleotide sequence analysis of human neurofibromin cDNAs has indicated the existence of an alternatively spliced form of the mRNA which contains 63 additional nucleotides in the GAP-Related Domain.

To analyze the possible role(s) of the alternatively spliced forms of neurofibromin mRNA in embryonic development we have isolated the corresponding chicken cDNAs. The predicted amino acid sequence of the chicken insert, as well as the actual site of insertion, is identical to that for human neurofibromin. RNAse protection and RNA-PCR analyses were used to assess levels of expression of the alternatively spliced forms of neurofibromin in the chick embryo. Most tissues express predominantly the higher molecular weight form ('type II') throughout development. In contrast, relative amounts of the two forms are modulated dramatically in the brain between e3 and e12, with type II the major form early in development and type I later. We are currently performing in situ hybridization analysis to determine the precise localization of the two forms of mRNA. Supported by the Oregon MRF.

SYMPOSIUM. $GABA_B$ RECEPTORS AND THEIR ROLE IN NEUROTRANSMISSION, NEUROMODULATION AND NEUROPATHOLOGY. N.G. Bowery (Chairperson), Univ. London, U.K.; R.A. Nicoll, Univ. California; H-R. Olpe, *CIBA-Geigy, Switzerland; J. Sarvey, Uniformed Services Health Science, Washington; H. Bittiger* and K. Kuriyama, Univ. Kyoto, Japan.

Many physiological and pathological events have been attributed to $GABA_B$ receptor activation in the mammalian brain. The symposium will attempt to cover most aspects of these phenomena. N.G. Bowery will provide an overview of past and present concepts of the characteristics of $GABA_B$ receptors and will consider their role in diseased states. R.A. Nicoll will discuss the significance of $GABA_B$ receptors in the hippocampus, the brain region from which much of our knowledge of their function derives. H-R. Olpe will consider the role of $GABA_B$ site activation in neuronal excitability and plasticity within the cerebral cortex. This will be complemented by the presentation of J. Sarvey who will examine the mechanisms of long-term potentiation. H. Bittiger will introduce new $GABA_B$ receptor antagonists and will provide substantial evidence for a role for $GABA_B$ receptors in the genesis of absence seizures. Finally, K. Kuriyama will provide information about recent progress in the purification and structural analysis of the $GABA_B$ receptor.

606

SYMPOSIUM. NEUROBEHAVIORAL MECHANISMS OF SALT INTAKE BEHAVIOR. E.Stellar, Univ. of Pennsylvania. (Chairperson); B.S. McEwen, Rockefeller Univ. (Chairperson); J. Schulkin, Univ. of Penn.; R.E. Norgren, Penn. State Univ. Col. of Med., S. Nicolaidis, Col. de France; and S.J. Fluharty, Univ. of Pennsylvania.

Sodium is the major electrolyte of extracellular fluid importantly involved in virtually all aspects of nervous system function. The appetite that develops for salt during sodium deficiency is an excellent example of an innately organized, motivated behavior. This symposium will review exciting new advances in the neurobiology of this behavior. **Drs. E. Stellar and J. Schulkin** will introduce the symposium by reviewing briefly the behavioral evidence in support of the neurohormonal synergy of adrenal steroids and peptides that regulates sodium ingestion. **Dr. R.E. Norgren** will describe recent studies on the complexity of gustatory coding in the nucleus of the solitary tract and parabrachial nucleus and their modification during sodium deficiency. **Dr. S. Nicolaidis** will discuss the neurophysiological analysis of diencephalic neurons whose integrative properties are regulated both by steroids and angiotensin during sodium deficiency. **Dr. B.S. McEwen's** presentation will focus on the biochemistry and molecular biology of Type I and Type II corticosteroid receptors, as well as neuropeptide gene expression involved in the control of sodium appetite. Lastly, **Dr. S.J. Fluharty** will discuss the intracellular and behavioral functions of neuronal angiotensin receptors and the molecular mechanisms by which adrenal steroids regulate the brain's responsiveness to the peptide.

GLIA AND OTHER NON-NEURONAL CELLS VI

608.1

APOLIPOPROTEIN E IN GLIAL CELLS OF THE RAT OLFACTORY BULB: POSTNATAL DEVELOPMENT AND RESPONSE TO DEAFFERENTATION. G.E. Handelmann * and M.J. Russell. Dept. of Pharmacology, Univ. of Utah, Salt Lake City, UT 84112 and Dept. of Anesthesiology, Univ. of California-Davis, Sacramento, CA 95817.

Apolipoprotein (apo)-E, a lipid transport protein, has been proposed to play a role in nerve regeneration. We therefore studied apo-E's distribution, development, and response to injury in the olfactory system, the only region of the mammalian CNS in which true nerve regeneration is known to occur. Using single and double label immunocytochemistry, we found apo-E immunoreactivity (IR) in astrocytes in all layers of the adult olfactory bulb. Apo-E-IR was extensively colocalized with GFAP. In the olfactory nerve, apo-E was present in cell bodies and occasional fibers, possibly those of the ensheathing cells, a type of astroglia. In rat pups, apo-E was present in the olfactory nerve as early as 2 days postnatal, although very little GFAP was present. The adult pattern of apo-E distribution was reached by 3 months of age. In aged rats (1 and 2 years old), the distribution of the astrocytes was unchanged, but they contained more GFAP- and apo-E- IR and had the morphological appearance of reactive astrocytes. Similarly, deafferentation of the bulb in younger adults, induced by zinc sulfate irrigation of the nasal epithelium, also increased apo-E- and GFAP- IR in all layers. The effects were most pronounced in the glomerular layer, the site of the olfactory nerve terminals, and within the olfactory nerve. These results indicate that apo-E is synthesized by glia of the olfactory nerve and bulb, and that its synthesis is increased in response to aging and nerve injury. The increased synthesis may be elicited by a factor associated with axonal degeneration.

608.2

EXPRESSION OF β4 INTEGRIN IN RAT PERIPHERAL NERVE IS DEVELOPMENTALLY REGULATED AND AXONALLY MODULATED DURING REGENERATION. ML. Feltri[1], S. Scherer[2], L.Wrabetz[2], H. Vogelbacker [2], P. Bannerman[3*], M.Shy[4], J Kamholz[2]. [1]S.Raffaele Hospital, Milano, Italy; [2]University of Pennsylvania, [3]Children's Hospital of Philadelphia and [4]Thomas Jefferson University, Philadelphia, PA, 19104.

Integrins are a family of receptors implicated in cell adhesion and cell signaling whose ligands include extracellular matrix proteins. Myelinating Schwann cells (SC) require various basement membrane components to initiate myelination. Since expression of the β4 integrin subunit has been shown to be restricted to epithelial cells and SC, we chose to study expression of β4 integrin in postnatal sciatic nerve development and after crush injury. Using a β4 integrin cDNA from a rat peripheral nerve library, Northern blot analysis demonstrated that β4 integrin mRNA is present at low levels at postnatal day 1 and steadily increases from day 15 to at least day 90. After a crush injury, which results in Wallerian degeneration followed by prompt axonal regeneration, β4 integrin mRNA expression falls markedly by 4 days post-transection and reappears by 8 days and peaks by 12 days, paralleling the time course of axonal regeneration. Furthermore, β4 integrin mRNA expression is induced in forskolin-stimulated SC in culture, an *in vitro* model of SC-axonal signaling. We conclude that in sciatic nerve β4 integrin expression is axonally modulated, suggesting that β4 integrin may function in axon-SC interactions during myelination.

608.3

GLIAL SURFACE MOLECULES IN LESIONS AND REGENERATION: GENERATION OF A PANEL OF MONOCLONAL ANTIBODIES.
J. R. Madsen,* Dept. of Neurosurgery, Children's Hospital, Boston, MA 02115.

Several known molecular species, and probably many not yet identified, mediate neuronal-glial interactions and promote or inhibit regeneration of axonal processes. Differential interactions of primary rat central nervous system (CNS) neurons with a panel of cell lines exhibiting glial properties therefore may reveal molecular cues which affect neurite growth in the CNS. Of a panel of glial-like cell lines generated by transformation of CNS progenitor cells by retroviral infection [Snyder et al., Cell 68:33-51, 1992], two particular subclones (C27 and C17) vary significantly in their ability to support neuronal outgrowth (C17 >> C27). To look for cell surface determinants responsible for the differences in neurite growth, panels of monoclonal antibodies have been generated using protocols of "subtractive immunization."

Thus far, at least fourteen different monoclonal antibodies have been generated which recognize epitopic differences between the surfaces of the neurite-promoting C17 cell line and the neurite-inhibiting C27 cell line. Western blot analysis shows that these antibodies bind a variety of proteins in the 30 kD to 120 kD range. Immunohistological screening has revealed that several of the epitopes recognized by the antibodies increase in concentration after injury of the rat sciatic nerve or the goldfish optic nerve, two systems known to support neuronal regeneration *in vivo*. Striking histological differences between the two optic tecta of the goldfish are also observed three weeks after unilateral optic nerve crush. Less striking, but still regionally specific, changes in immunoreactivity are seen in the superior colliculus of the rat after unilateral optic nerve injury. Western blot analysis of the lesioned tissues shows up- and down-regulation of specific proteins as a result of lesioning. Two of the antibodies bind different proteins which are up- and down-regulated in the same tissue after lesioning.

These antibodies are being evaluated in neurite outgrowth assays, and may yield insight into both neurite-promoting and neurite-blocking activities of CNS glia. . Modification of these biological activities may become a therapeutic intervention for CNS injury in the future.

PERIPHERAL NERVE INJURY INDUCES SCHWANN CELLS TO EXPRESS TWO MACROPHAGE PHENOTYPES: PHAGOCYTOSIS AND THE GALACTOSE SPECIFIC LECTIN MAC-2. S. Rotshenker*, A. Saada, S. Aamar, and F. Reichert. Dept. of Anatomy & Embryology, Hebrew University-Hadassah Medical School, Jerusalem, Israel.

There is a long standing debate whether Schwann cells (SC) play a role as phagocytes during the course of Wallerian degeneration. We examined, electron microscopically, the phagocytic activity of SC and macrophages (MO) in 3 different preparations of injured mouse peripheral nerves. One, cultures of intact nerve explants which are rich in SC but devoid of MO. Two, nerve segments undergoing degeneration in-situ, thus containig both SC and MO. Three, frozen nerves that were put back in-situ and thus became rich in MO but devoid of SC. Both MO and SC displayed phagocytic activities. This observation suggests that injury induces SC to acquire MO phenotypes. We studied, therefore, by immunocytochemistry and immmunoblot analysis, the expression of the molecules MAC-1, MAC-2, F4/80 and Fc, which characteristically are displayed by mature inflammatory murine MO. Of these, only the expression of MAC-2 was induced in the SC rich and MO poor intact nerve explants. Immunocytochemistry of dissociated nonneuronal cells further revealed that both SC and MO express MAC-2. Thus nerve injury induces SC to express two MO phenotypes: phagocytosis and MAC-2. The two may be related in that MAC-2, as a galactose specific lectin, could be instrumental in lectinophagocytosis.

EFFECT OF ANTI-GalC ON CNS MYELIN FORMATION. J. Rosenbluth*, Z. Liu, D. Guo and R. Schiff. Depts. Physiology & Rehab. Medicine, N.Y.U. School of Medicine, New York, NY 10016.

Anti-GalC hybridoma cells (Ranscht et al. PNAS 79:2709) were implanted into spinal cord dorsal columns (DC) of Cyclosporine(Cs)-treated suckling or weanling rats. Fixation after 1 wk showed numerous hybridoma cells in the DC. In the older group, whose DC were myelinated at the time of implantation, fascicles of myelinated fibers interspersed among hybridoma cells appeared largely intact, though in some cases they showed "unraveling" of outer myelin lamellae. In the younger group, the medial portion of the DC was only partially myelinated at the time of implantation, but would normally have become almost fully myelinated by the time of fixation. Here, comparable fascicles of nerve fibers interspersed among hybridoma cells remained completely devoid of myelin. The observations suggest that the Ig produced by this hybridoma has little effect on existing myelin sheaths in Cs-treated rats, after 1 wk, but interferes significantly with formation of new CNS myelin in vivo, as it does with formation of PNS myelin in vitro (Ranscht et al., J. Neurosci. 7:2936). A similar Ig-mediated mechanism could contribute to failure of remyelination in MS plaques. Supported by NIH & NMSS.

REGULATION OF A NOVEL CYCLOOXYGENASE (PROSTAGLANDIN G/H SYNTHETASE) GENE BY DEXAMETHASONE AND CALCIUM IONOPHORE IN ASTROCYTES. M. K. O'Banion*, J. C. Dusel, D. K. Miller, and P. D. Coleman. Departments of Neurology and of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, NY 14642.

Prostaglandins are important mediators of many physiologic processes. Within the CNS, they may play roles in fever, the sleep/wake cycle, proprioception, and response to injury. In astrocytes, prostaglandin production is profoundly increased by calcium ionophore and decreased by glucocorticoid hormones; however the mechanisms underlying these changes are poorly understood. We have recently cloned a novel 4.1 kb cDNA encoding a cyclooxygenase that arises from a gene distinct from that for the previously cloned 2.8 kb cyclooxygenase mRNA (O'Banion *et al.* 1991. J. Biol. Chem. 266:23261; O'Banion *et al.* 1992. Proc. Natl. Acad. Sci. USA, in press). We find that both genes are expressed in primary rat astrocyte cultures and have used Northern blot analyses to characterize their regulation by calcium ionophore and glucocorticoid hormones.

In astrocytes, dexamethasone (1 μM, 4 h) reduces the level of 4.1 kb mRNA by 2-3 fold without altering the 2.8 kb mRNA level. This inhibition occurs in the presence of cycloheximide which alone increases 4.1 kb mRNA levels by nearly 10-fold without super-induction of the 2.8 kb mRNA. Calcium ionophore (A23187; 5 μM) markedly induces (>10 fold) the level of 4.1 kb mRNA within 3 h. Preliminary results suggest that the induction of 4.1 kb mRNA by ionophore is transient.

These observations are consistent with our previous studies in mouse fibroblasts and human monocytes and suggest that the 4.1 kb mRNA encodes the predominant regulated cyclooxygenase in astrocytes. [Supported by LEAD award AG09016 and RO1 AG01121 to P.D.C].

REGULATION OF TRANSFORMING GROWTH FACTOR ALPHA (TGFα) mRNA EXPRESSION IN RAT HYPOTHALAMIC ASTROCYTES BY TGFα AND ESTRADIOL (E_2). Y.J. Ma*, M. Moholt-Siebert, D.F. Hill and S.R. Ojeda. Div. Neurosci., Oregon Regional Primate Research Center, Beaverton, OR 97006

TGFα, a mitogenic polypeptide that acts via activation of epidermal growth factor receptors (EGFR), has been implicated in the neuropathological mechanism by which hypothalamic lesions induce sexual precocity and the neuroendocrine process that underlies the initiation of normal female puberty. TGFα appears to exert these effects via stimulation of luteinizing hormone releasing hormone (LHRH) secretion. Since both TGFα and EGFR expression in the hypothalamus are predominantly astroglial, and LHRH neurons are devoid of EGFR, we have postulated that TGFα facilitates LHRH release indirectly via an autocrine/paracrine-mediated activation of glial function. To begin examining this hypothesis, hypothalamic astrocytes cultured in defined medium were exposed to either TGFα (50 ng/ml) or a phorbol ester (TPA, 10 ng/ml) for various lengths of time. The effect of these agents on TGFα mRNA was assessed by RNase protection assay. TGFα mRNA was readily detected in untreated astrocytes; both TGFα and TPA increased TGFα mRNA levels to maximal values (3-4-fold increase) by 8h. Additional experiments were performed to determine if glial TGFα mRNA levels are regulated by E_2. RNase protection assays revealed the presence of E_2 receptor mRNA in cultured hypothalamic astrocytes; E_2-17β (1 nM), but not E_2-17α, induced a two-fold increase in TGFα mRNA within 8h of treatment. These results suggest that: a) TGFα can act in an autocrine fashion on hypothalamic astrocytes to enhance expression of its own gene, and b) hypothalamic astrocytes express E_2 receptors which mediate a facilitatory effect of E_2 on TGFα gene expression. (Supported by NIH Grants HD25123, HD18185 and RR00163)

DIFFERENTIAL GLIAL GENE EXPRESSION IN THE RAT BRAIN. D. G. Schaar, A. C. Sherwood, B. A. Sieber, C. F. Dreyfus and I. B. Black*. Dept. of Neuroscience and Cell Biology, Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey, 675 Hoes Lane, Piscataway, NJ 08854.

Studies conducted by this laboratory have established that in culture, local substantia nigra (SN) support cells contribute to the survival of the dopaminergic neurons selectively lost in Parkinson's Disease. Fractionation of embryonic SN glia into enriched oligodendrocyte, type I or type II astrocyte subpopulations identified the type I astrocytes as the source of the soluble neurotrophic factor(s) for SN dopaminergic neurons. These well-characterized SN glial populations have been utilized in subtractive cloning methodologies to identify genes specifically expressed by type I astrocytes.

The support cell fractionation generated 70-95% homogeneous glial subpopulations, from which total RNA was harvested. The limiting amount of RNA obtained necessitated development of a subtractive cloning technique using the polymerase chain reaction (PCR). In the library described, sequences in common between type I and II astrocytes were removed by stringent hybridization and hydroxyapatite (HAP) chromatography. Ten cDNA clones have been isolated from the type I cells which are not expressed or expressed at relatively low levels in type II astrocytes.

Nucleotide sequence analysis of the type I specific cDNA's have indicated the isolation of novel open reading frames with no significant homology to existing Genebank or EMBL sequences. In addition, two cDNA's contain novel sequences with the exception of their 3' untranslated regions which contain a 50 base pair stretch identified as a rat repetitive element (SINE). Further analysis of these type I astrocyte specific cDNA clones will give insight into the molecular basis of the type I astrocyte neurotrophic effect on SN dopaminergic neurons. In addition, subtractive cloning approaches reported here may be used to analyze other glial populations from discrete brain regions.

A SUBPOPULATION OF HIPPOCAMPAL ASTROCYTES SPECIFIC FOR THE ZINC-CONTAINING MOSSY FIBRE ZONE E. Jung, A. Schnecko, E. Braak* and T.G. Ohm. Zentrum der Morphologie, J.W.Goethe-Universität, W-6000 Frankfurt/Main 70, Germany

The projection of the zinc-containing axons of granule cells of the fascia dentata, e.g. the mossy fibres, is restricted to sectors CA3 and CA4 of the hippocampus. Serial sections of hippocampi of adult man were stained for zinc-containing fibres with a non-perfusion Timm method, while adjacent ones were stained with Darrow-red and aldehydefuchsin. In contrast to the common opinion that there is no astrocytic subtype specific for any of the hippocampal sectors, the Timm-stained areas correlate with the zone of aldehydefuchsin-positive astrocytes. The demonstration of astrocytes by means of a Gallyas-silver-stain or GFAP-immunocytochemistry reveals no morphological differences between astrocytes of CA3 and CA4 and those of CA2, CA1. Since astrocytes regulate axonal outgrowth in a region-specific manner, it is temptative to speculate that the aldehydefuchsin-positive astrocyte of sectors CA4 and CA3 might be a candidate for a specific neuron-glia interaction which restricts the outgrowth of the mossy fibres to sectors CA3 and CA4.

IMMUNOCYTOCHEMICAL EVIDENCE FOR NERVE GROWTH FACTOR ACCUMULATION IN MICROGLIA. G.M. Gilad* and V.H. Gilad. NPB, NIMH Neuroscience Center at St. Elizabeths, Washington, DC 20032.

Nerve growth factor (NGF) can be produced by a variety of cell types, including neurons, astrocytes, Schwann cells and fibroblasts. While macrophages may produce only small amounts, their CNS counterparts, the microglia, may be stimulated to produce significant amounts of NGF. Not surprisingly, being a secretory product, immunocytochemical localization is evident only in cells that accumulate NGF. In the present study, using antibodies to NGF and to a variety of cell-specific markers, we found that accumulation of NGF immunoreactivity occurs selectively in cultured microglia, and in macrophages and microglia at the site of brain injury, but not in other cell types. It is implied that microglia and macrophages may sequester their own newly synthesized NGF or, by pinocytosis, extracellular NGF. Sequestration of NGF by these cells may assume importance after CNS injury.

MICROGLIAL PLASTICITY IN VIVO: EVIDENCE FOR THEIR RAPID AND REMOTE ACTIVATION IN EXPERIMENTAL NEUROPATHOLOGY

JOCHEN GEHRMANN* AND GEORG W.KREUTZBERG
DEPARTMENT OF NEUROMORPHOLOGY, MAX-PLANCK-INSTITUTE OF PSYCHIATRY, 8033 MARTINSRIED NEAR MUNICH, GERMANY

Resting microglial cells form a network of regularly spaced, ramified cells throughout the CNS. Studies on their reactions after facial nerve axotomy have suggested that they function as an intrinsic immune defense system within the CNS. To further examine this hypothesis in vivo, we have studied the microglial reactions in several experimental neuropathologies. These include retrograde reactions of motoneurons, anterograde reactions, combined anterograde and retrograde reactions and recently neurotoxin models. In addition, we have studied global ischemia and T cell-mediated autoimmune inflammation of the central and peripheral nervous system. From these results it has become evident that microglial cells (but not astrocytes) rapidly proliferate and increase the expression of several immunologically relevant molecules, such as MHC class I and II antigens. Their activation is further observed rapidly if the site of the microglial activation is quite remote from the site of the primary lesion. At the ultrastructural level, two phenomena among several other things were observed: a distinct activation of perivascular microglial cells and an involvement of activated, perineuronal microglial cells in the deafferentation (synaptic stripping) of afferent synaptic terminals from the surface of motoneurons. The latter observation in particular could be relevant for better evaluating neurological deficits in patients suffering e.g. from nerve trauma. In summary, microglial cells thus appear to be the main immuneffector cell population of the CNS.

Interleukin 6 is elevated in Human Brain Tumor Cyst Fluid.

J. H. Neal* and C. W. Cotman *Departments of Neurosurgery and Psychobiology, University of California, Irvine 92717*

Radioimmunoassay for several cytokines including Tumor Necrosis Factor-alpha (TNF-α), Interleukin 1-alpha (IL-1α), Interleukin 1-Beta (IL-1β), Interleukin 2 (IL-2) and Interleukin 6 (IL-6) was carried out on tumor cyst fluid (TCF) from patients with malignant astrocytic brain tumors (n=8), serum from normal controls (n=5), serum from patients with malignant brain tumors (n=5), and cerebrospinal fluid (CSF) from 3 patients with malignant brain tumors. CSF levels of all cytokines were less than 0.1 ng/ml. TNFα, IL1α, IL1-β, and IL-2 levels were higher in serum and TCF than in CSF and were in the range between 0.2 and 1.5 ng/ml. There was no significant difference in levels of these individual cytokines between TCF and serum, suggesting an equilibrium in these factors between serum and tumor cyst fluid. In contrast, IL-6 levels were elevated an average of 50-100 fold in TCF compared to serum. These results indicate that IL-6 is enriched in TCF, suggesting a possible role of the cytokine in the pathophysiology of malignant brain tumors and/or brain response to tumor invasion.

GAP JUNCTIONS DISAPPEAR IN CULTURED ASTROCYTES AND LEPTOMENINGIAL CELLS FOLLOWING PROTOZOAN INFECTION. A.C. Campos de Carvalho, C. Roy, E.L. Hertzberg, R.A. Corpina, H.B. Tanowitz, J.A. Kessler', L. Weiss, M. Wittner and D.C. Spray. Depts. Neuroscience, Neurology and Medicine, A. Einstein Coll. Med., Bronx, N.Y. & Fed. Univ. Rio de Janeiro, Brazil.

American trypanosomiasis [Chagas' disease caused by *Trypanosmoa cruzi* (T.c.)] and toxoplasmosis [caused by *Toxoplasma gondii* (T.g.)] are two protozoan diseases where nervous system involvement is increasingly widespread in immunosuppressed individuals. Infection of myocardial cells with T.c. results in asynchronous conduction and gap junction loss [Circ. Res (92)70:733]. To examine whether similar changes occured in cells of brain, pure cultures of leptomeningial cells or astrocytes were infected with T.c. or T.g. and junctional communication and connexin abundance and intercellular distribution were examined. For either type of cell infected with either parasite, intercellular coupling (injected Lucifer Yellow) was reduced, and was often altogether absent. Immunocytochemical studies using antibodies specific for connexin43 (in the case of astrocytes) or both connexin43 and connexin26 (for leptomeningeal cells) demonstrated that the punctate staining indicative of gap junctions was much reduced in the individual infected cells, although uninfected neighbors could display normal staining. Western blots indicated that abundance of connexin43 in infected cells was slightly increased compared to uninfected control cells. Phosphorylation state of connexin43 (inferred from electrophoretic mobility of connexin43 isoforms) was little affected. We conclude that both protozoan parasites infect both types of brain cells, resulting in a loss of intercellular communication and organized gap junctions without affecting expression or post-translational processing of the gap junction protein. Presumably, these changes result from altered targeting or assembly of the junctional protein.

PEPTIDES: RECEPTORS VI

609.1

A MELANOPHORE BASED BIOASSAY SYSTEM DESIGNED TO ANALYZE LIGAND EFFECTS ON G-PROTEIN LINKED RECEPTORS COUPLED TO PHOSPHOLIPASE C. G.F. Graminski, C.K. Jayawickreme, M.N. Potenza and M.R. Lerner*, Depts. of Cell Bio., Int. Med., & Pharm., & HHMI, Yale Univ. Sch. of Med., New Haven, CT 06510.

A melanophore based bioassay system has been developed for rapidly evaluating ligand effects on recombinant receptors coupled to the phospholipase C second-messenger pathway. The assay is based on agonist induced darkening of *Xenopus laevis* melanophores resulting from pigment dispersion. Both TPA and the Ca^{2+} ionophore A23187 are potent stimulators of pigment dispersion in *Xenopus* melanophores, suggesting that pigment dispersion is mediated via phospholipase C activation. To test this hypothesis, pigment cells were transiently transfected with the phospholipase C activating murine GRP\bombesin receptor. Treatment with bombesin and other agonists induced pigment dispersion in cells expressing the bombesin receptor but not in wild type cells. The responses were dose dependent. EC_{50} values for bombesin (0.12 nM) and other agonists such as litorin (0.15 nM) and neuromedin B (1.3 nM) were comparable to the literature values. The bombesin receptor antagonist, [D-Phe^6]Bomb$_{6-13}$ methyl ester, inhibited pigment dispersion with an IC_{50} value of 15 nM. Bombesin stimulation provoked a substantial increase of 1,4,5-IP_3 production over basal levels while no rise in cAMP was observed. This bioassay system potentially offers great utility and speed for analyzing the pharmacological potencies of agonists and antagonists associated with receptors linked to phospholipase C.

609.2

A COMPUTER-ENHANCED VIDEO ASSAY FOR THE FUNCTIONAL EXPRESSION OF RECEPTORS COUPLED TO G_s, G_i AND PHOSPHOLIPASE C. T.S. McClintock*, G.F. Graminski, M.N. Potenza, C.K. Jayawickreme, A. Roby-Shemkovitz and M.R. Lerner. Boyer Center for Molecular Medicine and Dept. of Internal Medicine, Yale Univ. Sch. Med., New Haven, CT 06510.

We have created a versatile and sensitive visual assay for the expression of receptors linked to G-proteins. Transient transfection of Xenopus melanophores with plasmids containing cDNAs for either the β_2 adrenergic (G_s), the substance P (phospholipase C), or the D_2 dopamine receptor (G_i) at dilutions of 1 plasmid in 10,000 were detectable. Computerized subtraction of video images taken pre- and poststimulation allowed the detection of individual responses in fields of 10,000 cells. Activation of phospholipase C and adenylate cyclase caused dispersion of melanosomes (organelles containing melanin) while inhibition of adenylate cyclase caused melanosome aggregation. Responding cells appear to require only a single copy of a plasmid containing a receptor cDNA. This assay is capable of conveniently screening several hundred thousand cDNA clones per day.

609.3

INDUCTION OF PKC BY ANP RECEPTOR ACTIVATION AND INVOLVEMENT OF G PROTEINS IN RAT BRAIN SLICES. A. Rathinavelu, P. Sun, G. Pavlakovic and G.E. Isom*, Dept. of Pharmacol. & Toxicol., Sch. of Pharmacy & Pharmacal Sci., Purdue Univ., W. Lafayette, IN 47907.

Atrial natriuretic peptides (ANP) are synthesized and localized in different brain areas. Natriuretic peptides bind to specific receptors and generate cGMP as the second messenger. When ANP receptors were stimulated excessively with 5 and 10 μM ANP (99-126) a marked increase in activity of protein kinase C (PKC) in the cytosolic fraction of the diencephalon occurred. The membrane PKC level was not altered significantly with treatments up to 5 μM ANP, whereas 10 μM ANP produced a slight increase. The increase in cytosolic PKC was 80% above control with 5 μM ANP treatment of the diencephalon slices and maximal induction was observed following 60 min treatment. Incubation of ANP (5 μM) with actinomycin D (10 μg/ml) or cycloheximide (20 μg/ml) blocked the induction of PKC to 90% and 84%, respectively. This indicated the increase in cytosolic PKC resulted from de novo protein synthesis. Pertusis toxin (5 ng/ml) attenuated the induction of PKC by 30% suggesting Gi proteins are involved in the ANP mediated PKC induction. cGMP levels in 0.001 and 0.01 μM ANP treated diencephalon slices increased 5.4 fold and 3.8 fold respectively compared to controls. Incubation of slices with 0.5, 1.0 and 5 μM ANP showed a non-significant increase in cGMP levels. These results suggest increases in cytosolic PKC levels alter the guanylate cyclase-coupled receptor function.

609.4

MATCHING LOCALIZATION OF IMMUNOREACTIVE VIP AND VIP RECEPTOR IN THE VISUAL CORTEX. A.Csillag[1], K.Zilles[2*], A.Schleicher[2] and F.Hajós[3]. [1]1st Dept.Anat.,Semmelweis Univ. of Med., Budapest, Hungary; [2]C.& O.Vogt Inst. for Brain Res., Univ. of Düsseldorf, Germany; [3]Univ. of Vet. Sci. Budapest, Hungary.

Vasoactive intestinal polypeptide (VIP) is present in cortical non-pyramidal neurons. The density and position of VIP immunoreactive (VIP-IR) terminals suggest a powerful regulatory role of VIP in the cortex. In the present study, the localization of VIP receptor immunoreactivity (VR-IR) was studied simultaneously with VIP-IR using double label immunocytochemistry supplemented with a quantitative analysis of distribution. A considerable spatial overlap was found between VIP-IR particles (axonal boutons) and some VR-IR cell bodies. Quantitative analysis revealed a preferential accumulation of VIP+ boutons over the cytoplasm, rather than the nuclear or pericellular region, of VR-IR cells. Ultrastructurally, VR-IR was detected in postsynaptic target structures of VIP+ boutons, including the endoplasmic reticulum and subsynaptic specialization. Thus, the neuroanatomical relations favour the existence of a functional VIP - VIP receptor interaction in the occipital cortex of the mouse.

Supported by DFG grant Zi 192/6-3.

SR 48692, A NON-PEPTIDE ANTAGONIST OF NEUROTENSIN RECEPTORS IN HUMAN TISSUES. **W. Rostène*[1], S. Equilbey[1], D. Gully[2], C. Labbé-Jullié[3], D. Pelaprat[1], G. Le Fur[2] and P. Kitabgi[3]. [1]INSERM U.339 Hôpital St Antoine 75012 Paris, France; [2]SANOFI RECHERCHE 31036 Toulouse, France; [3]IPMC-CNRS 06560 Valbonne, France.**

SR 48692 was reported to be a potent non-peptide antagonist of Neurotensin (NT) receptors and effects in both guinea-pig and murine species (D. Gully et al.;P.Kitabgi et al.,this volume). In order to test whether this compound also had some activity in humans, homogenates from newborn or adult human cortices were prepared. Binding studies demonstrated that SR 48692 competitively inhibited specific binding of 125INT with an IC50 of around 12 nM. Autoradiographic data obtained at the level of the substantia nigra and nucleus paranigralis of normal human tissue sections demonstrated a dose-dependent inhibition of 125INT labeling with increasing concentrations of SR 48692. Similar data were obtained on 125INT binding in primary cultures of human mesencephalic neurons. In a cell line rich in NT receptors, derived from a colon carcinoma (HT29),SR 48692 competitively antagonized NT-induced intracellular calcium mobilization obtained by means of flow cytometry using indo-1 fluorescence. The observed pA2 values (mean 8.1 nM) were consistant with results obtained in binding studies (Ki 20 nM). Moreover, in this model, SR 48692 was devoid of any intrinsic agonist activity. In conclusion, this potent non-peptide antagonist of NT receptors may help to understand the putative pathological roles of NT.

609.6

REGULATION OF GALANIN BINDING SITES IN THE BED NUCLEUS OF THE STRIA TERMINALIS AND SEPTUM ACROSS PUBERTY. B. Planas*, P.E. Kolb, M.A. Raskind, and M.A. Miller. Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA 98195.

Galanin-like immunoreactivity in the brain increases across development in male and female rats (Gabriel et al., Peptides 10: 369-374, 1989). The increase in GAL-LI may be due to an increase in GAL gene expression induced by the pubertal rise in gonadal hormones as estrogen has been found to increase GAL-LI and GAL mRNA levels (Gabriel et al., Neuroendocrinology 51: 168-173, 1990). In order to determine whether the developmental increase in GAL-LI influences GAL binding, we have used slice binding techniques and quantitative autoradiography to compare the distribution and density of GAL binding sites in the bed nucleus of the stria terminalis (BST) and septum (S) of prepubertal and adult male rats.

^{125}I-GAL binding sites were studied in slide-mounted coronal brain sections of 24 d (n=6) and 90 d (n=6) old male rats. Slides were incubated in 0.25 nM ^{125}I-GAL at room temperature for 60 min. Specific binding was determined by the addition of 0.25 µM unlabeled GAL.

Data analysis of 8 atlas matched film autoradiograms revealed a differential distribution of ^{125}I-GAL binding with age ($p<0.0001$). The optical density of specific binding in the BSTL was significantly greater ($p<0.01$) in adult rats compared to prepubertal rats (0.42±0.01 vs. 0.34±0.02). However, many brain regions revealed a pattern of increased binding densities in prepubertal animals: BSTM (0.33±0.01 vs. 0.14±0.01), BSTV (0.33±0.02 vs. 0.15±0.02), MS (0.33±0.01 vs. 0.12±0.01), LSV (0.34±0.01 vs. 0.10±0.01), LSI (0.33±0.01 vs. 0.08±0.01). No apparent differences in GAL binding were observed in the LSD or dorsal region of the LSI.

These results indicate that the density of GAL binding sites in portions of the BST and septum changes across puberty. These differences may result from changes in GAL innervation within these brain regions.

609.7

EVIDENCE FOR SPECIFIC N-TERMINAL GALANIN FRAGMENT BINDING SITES IN THE RAT BRAIN. P.B. Hedlund*, U.-B. Finnman, N. Yanaihara and K. Fuxe. Dept. of Histology and Neurobiol., Karolinska Institutet, Box 60400, S-10401 Stockholm, Sweden.

Galanin$_{1\text{-}29}$ (GAL) is a neuropeptide with several biological activities in the brain, such as stimulation of feeding behavior and interactions with 5-HT$_{1A}$ and acetylcholine receptors. In most cases N-terminal fragments such as GAL$_{1\text{-}15}$, but not C-terminal fragments, have been shown to retain the biological activities of the native GAL$_{1\text{-}29}$ molecule.

We have analyzed the distribution of [^{125}I]GAL$_{1\text{-}15}$ (specific activity 2000 Ci/mmol) binding sites in the rat brain using quantitative receptor autoradiography. The distribution was different from [^{125}I]GAL$_{1\text{-}29}$ binding sites, but also with several overlapping regions. Most notably [^{125}I]GAL$_{1\text{-}15}$ binding sites were present in the dorsal hippocampus, the neostriatum and the neocortex, areas almost lacking [^{125}I]GAL$_{1\text{-}29}$ binding sites in the rat brain. The [^{125}I]GAL$_{1\text{-}15}$ binding was more readily displaced with GAL$_{1\text{-}15}$ than with GAL$_{1\text{-}29}$ indicating the presence of a binding site with higher affinity for the fragment. The fragment binding site was saturable with a K_d of 0.63 ± 0.02 nM and a B_{max} of 15.3 ± 1.7 fmol/mg protein in the dorsal hippocampus and a K_d of 0.44 ± 0.09 nM and a B_{max} of 15.8 ± 0.5 fmol/mg protein in the ventral limbic cortex. Non-specific binding was determined as the binding in the presence of 10 µM of GAL$_{1\text{-}15}$. The specific binding was approximately 80% at B_{max}. The present study gives evidence for the existence of specific binding sites for the GAL$_{1\text{-}15}$ fragment different from the GAL$_{1\text{-}29}$ receptor which may represent a unique GAL fragment receptor.

609.8

EVIDENCE FOR DELTA OPIOID RECEPTOR SUBTYPES L. Fang*, R. J. Knapp, M. A. Jarosinski†, V. J. Hruby† and H. I. Yamamura Dept's of Pharmacology and Chemistry†, University of Arizona, Tucson, AZ 85724.

The existence of δ opioid receptor subtypes was suggested previously in comparisons of δ agonist activity in mouse brain and mouse vas deferens (MVD); the different binding affinities in rat brain and MVD measured for [D-Ala^2, (2R, 3S)-γ^{E}Phe^4, Leu^5]enkephalin methyl ester (CP-OMe); and the differential antagonism of δ antinociception by selective irreversible antagonists *in vivo*. We have produced additional evidence for the existence of δ opioid receptor subtypes in mouse brain and vas deferens using a new δ opioid receptor selective antagonist: H$_2$N-Tyr-L-Tic-Phe-Phe-OH (TIPP). The ability of naltrindole (NTI), a selective δ antagonist, and TIPP to inhibit 100 pM [^{3}H]naltrindole binding in mouse brain and MVD were determined using a one site model. NTI has equal affinity for the sites labeled by [^{3}H]naltrindole in both tissues, whereas TIPP has 12 fold lower affinity in MVD compared to brain. These observation support the presence of different δ opioid receptor subtypes having different anatomical distributions. Supported in part by NIDA grants.

REGIONAL DISTRIBUTION OF CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS IN THE TREE SHREW BRAIN. E. Fuchs*, M. Weinrich and G. Flügge. German Primate Center, Göttingen, FRG.

CRF is the predominant messenger in the control of the activity of the pituitary-adrenal axis and is therefore ultimately responsible for triggering the endocrine responses to stress. In the present project we are investigating the influences of chronic stress on central nervous CRF receptors. For our studies we used tree shrews (*Tupaia belangeri*), a species which provides a useful model for studying the outcome of psychosocial stress on the central nervous system. In the first part of the study we localized and quantified the receptors in the brains of control animals by autoradiography with ^{125}I-labeled ovine CRF. It revealed the presence of receptors with a high and a low affinity component. High densities of specific CRF receptors were localized in the tractus olfactorius, the dentate gyrus, the outer layers of cortex and superior colliculi, the cerebellum, the vagal nucleus, and the pituitary (anterior part, intermediate zone). Moderate concentrations were present in the amygdala and the lateral septum. Lower densities were found in the caudate nucleus and the locus coeruleus. These results indicate species differences with respect to distribution and densities of CRF receptors. In the second part of the study we are currently investigating whether chronic psychosocial stress induces changes of CRF receptor affinities and/ or densities of these receptors.

LHRH NEURONS IN THE MEDIAL SEPTAL-DIAGONAL BAND OF BROCA-PREOPTIC AREA (mS-dbB-PO) DO NOT PROJECT DIRECTLY TO THE HIPPOCAMPUS. C.A. Dudley*, S.B. Sudderth, and R.L. Moss, Department of Physiology, UT Southwestern Medical Center, Dallas, TX, 75235-9040

Neurons containing immunoreactive LHRH are located primarily in the mS-dbB-PO complex, while autoradiographic studies have demonstrated dense concentrations of LHRH receptors in the hippocampus. The route by which LHRH reaches its receptors in the hippocampus is unknown. The present study was designed to determine if LHRH neurons in the mS-dbB-PO project directly to the hippocampal formation. The fluorescent retrograde tracer, fluorogold (FG) was injected unilaterally into 4 separate hippocampal locations in 5 ovariectomized female rats. Six additional females received similar injections of a different retrograde tracer, wheat germ agglutinin (WGA). After a 5-day survival period, the animals were sacrificed and their brains processed immunohistochemically for detection of cells containing both LHRH and FG or LHRH and WGA. As a positive control, some sections containing retrogradely labeled neurons were processed for choline acetyltransferase (CHAT) immunoreactivity. The WGA and FG injections covered targeted hippocampal sites and many retrogradely labeled cells were found in the mS-dbB-PO complex. Approximately 10% of the retrogradely labeled cells were found to contain CHAT; however, no neurons were found to co-localize LHRH and either WGA or FG. The results indicate that LHRH receptors in the hippocampus are not directly innervated by LHRH neurons in the mS-dbB-PO area and suggest that LHRH reaches its hippocampal receptors via a non-synaptic route. Supported by MH47418.

ISCHEMIA II

610.1

"THERAPEUTIC WINDOW" FOR NMDA ANTAGONIST PROTECTION AGAINST FOCAL CEREBRAL ISCHEMIA MAY BE NARROW. G.K. Steinberg*, N.M. Panahian, G.H. Sun. Dept. of Neurosurgery, Stanford University Medical Center, Stanford, CA 94305.

While NMDA antagonists have been shown to protect against focal cerebral ischemia, it is not clear how long drug therapy can be delayed and still achieve neuroprotection. Under halothane anesthesia, 55 rabbits underwent 2 hour occlusion of the left internal carotid, anterior cerebral and middle cerebral arteries followed by 4 hours of reperfusion. Rabbits were treated with either i.v normal saline (n=10) or the NMDA antagonist dextrorphan (DX) as follows (n=5/group) - 1 hour delay: 5, 10 or 15 mg/kg/hr; 2 hour delay: 7.5, 12.5, 17.5 mg/kg/hr; 4 hour delay: 10, 15 or 20 mg/kg/hr. Injury was assessed using magnetic resonance imaging for ischemic edema and histopathology for ischemic neuronal damage (IND). Protection against cortical ischemic damage was demonstrated only when DX administration was delayed 2 hours (17.5 mg/kg group: 27 ± 7% IND, 29 ± 8% edema; 12.5 mg/kg group: 28 ± 9% edema compared with normal saline control: 45 ± 7% IND, 47 ± 3% edema, p<.05). Protection against striatal IND was found only with 2 hour DX delay (7.5 mg/kg group: 37 ± 17%; 12.5 mg/kg group: 50 ± 15% vs. control: 83 ± 6%). DX treatment delayed 4 hours worsened the ischemic edema (15 mg/kg group: 70 ± 5%; 10 mg/kg group: 71 ± 9%, p<.05). DX treatment with one hour delay failed to demonstrate neuroprotection at any dose. These results suggest that NMDA antagonists may have to be given within 2-3 hours of ischemia onset to be of benefit. Lack of protection when drug was started during the ischemic period (before reperfusion) may reflect poor delivery to ischemic tissues. The "therapeutic window" for NMDA antagonist protection against focal ischemia may be relatively narrow.

610.2

NEUROPATHOLOGIC END POINTS IN EXPERIMENTAL STROKE THERAPY (MK-801): THE IMPORTANCE OF BOTH EARLY AND LATE EVALUATION. L. Persson, J. Valtysson, P. Andiné, H. Hagberg and L. Hillered*. Departments of Neurosurgery and Clinical Chemistry, University Hospital, Uppsala, Sweden.

The effect of the NMDA receptor blocker MK-801 (dizocilpine maleate) was evaluated both early (3 days) and late (28 days) after middle cerebral artery (MCA) occlusion. The aim was to determine whether or not the previously reported protective effect of MK-801 found in acute experiments remained after 28 days, i.e. when the ischemic lesion has reached its final appearance.[1]

MK-801 (0.5 mg/kg, i.v.) or isotonic saline was randomly given to rats 30 min after MCA occlusion. Infarct size was estimated from 8 histological sections of defined levels of the brain.

A 40% ($p < 0.05$) reduction of infarct size was found in MK-801 treated rats studied after 3 days. This effect was not found 28 days after MCA occlusion, where no difference in infarct size or final tissue loss (infarct volume + ipsilateral hemisphere atrophy) was seen between the MK-801 and placebo-treated rats. There was no significant effect of MK-801 on the ipsilateral hemisphere volume (reflecting edema) at 3 days.

Thus, MK-801 seemed to have a transient attenuating effect on the ischemic process itself with no apparent influence on the edema component. This study underlines the importance of including a late end point when evaluating the efficacy of neuroprotective stroke therapy. It remains to be shown whether or not multiple dose treatment with NMDA receptor blockers attenuate the final neuropathologic outcome after experimental stroke.

610.3

DIFFERENTIAL EFFECT OF MK-801 AND SEMISYNTHETIC GANGLIOSIDES ON PROTEIN KINASE C (PKC) ACTIVATION AND IMMEDIATE EARLY GENES EXPRESSION IN A PHOTOCHEMICALLY-INDUCED STROKE IN RATS. A. N. Kharlamov*, R.C. Hayes, R. Sheffield, A. Guidotti, E. Costa, and D. M. Armstrong. FGIN, Georgetown Univ. Med. School, Washington, DC 20007

In culture the protracted and abusive stimulation of glutamate (GLU) receptors results in neuronal death through a mechanism involving the persistent translocation of PKC and the destabilization of $[Ca^{2+}]_i$ homeostasis. In contrast, intermittent GLU receptor use elicits the coordinated expression of immediate early genes (IEG) acting as nuclear third messengers. In the present study the in vivo mechanism of action of GLU receptor stimulation was examined using the photochemically induced model of stroke in the rodent. Following i.v. injection of Rose Bengal, injury of the sensory/motor cortex ensues and the binding of the phorbol ester [^{3}H]PDBu as well as mRNA contents for c-*fos*, c-*jun*, *zif*268, *nur*/77 and FOS and JUN proteins were increased. [^{3}H]PDBu binding was employed as an index of PKC translocation and was observed maximally increased (i.e., 4-5 fold) in the cortex adjacent to the infarcted area 1 to 12 hours following stroke. In contrast, IEG expression extended throughout much of the cortex ipsilateral to the lesion. Importantly, the increase in [^{3}H]PDBu binding could be substantially reduced following treatment of rat with the semisynthetic gangliosides, LIGA4 and LIGA20 (35 μmol/kg, i.v., one hour before lesion). Both drugs have been shown to be blockers of PKC translocation. In addition, pretreatment with the NMDA antagonist, MK-801 (6 μmol/kg, i.v., 1 hour before lesion) nearly abolished the rise in [^{3}H]PDBu binding. MK-801 also blocked the rise in IEG although treatment with the semisynthetic gangliosides failed to affect the expression of these genes and gene products. These results *in vivo* differentiate the mode of action of MK-801 from that of semisynthetic gangliosides. Moreover, they confirm that semisynthetic gangliosides prevent the Ca^{2+}-dependent destabilization of PKC homeostasis that is also blocked by MK-801 without interfering with the Ca^{2+} mediated IEG response that is blocked by the NMDA receptor antagonist MK-801.

610.4

REVERSIBLE INACTIVATION OF CALCIUM/CALMODULIN KINASE II INDUCED BY SPINAL CORD ISCHEMIA. D.A. Shackelford, R.Y. Yeh, and J.A. Zivin*. Dept. of Neurosciences, Univ. of Calif. at San Diego, La Jolla, CA 92093-0624.

It has been proposed that ischemia-induced neuronal damage is caused by an accumulation of extracellular glutamate leading to an influx of extracellular Ca^{2+} through membrane channels disrupting Ca^{2+} homeostasis. The activity of Ca^{2+}/calmodulin-dependent protein kinase II, which is involved in regulation of neurotransmitter synthesis and release and neuronal plasticity, has been shown to decrease after ischemia in several models. In the present study, the kinetics of inactivation and fate of the protein in the rabbit spinal cord ischemia model were analyzed. The Ca^{2+}/calmodulin-dependent activity of CaM kinase II, measured by incorporation of phosphate into exogenous peptide substrates, decreased rapidly such that after 10 min of ischemia, which precedes irreveresible paraplegia, 65% and 40% of the actvity was lost from the cytosol and particulate fractions, respectively. However, analyses of CaM kinase II autophosphorylation activity by renaturation of spinal cord homogenates after Western transfer to filters, showed a decrease in autophosphorylation of the β, β' isoforms of CaM kinase in the cytosol but an increase in autophosphorylation of β, β' and α isoforms in the particulate fraction after 5-10 min of ischemia. Immunoblotting with monoclonal antibodies to the α and β subunits of CaM kinase II indicated that the subunits decreased in the cytosol and increased in the particulate fraction due to ischemia. Thus inactivation of CaM kinase II induced by ischemia correlates with loss of protein in the cytosol. However, in the particulate fraction, loss of activity is probably due to a reversible conformational change. The role of phosphorylation in inactivation and changing the subcellular distribution of the enzyme is being investigated.

610.5

ENADOLINE AFFORDS NEUROPROTECTION IN A RAT MODEL OF FOCAL ISCHEMIA.

N.J. Hayward, A.T. McKnight and G.N. Woodruff*.
Parke-Davis Neuroscience Research Centre, Addenbrookes Hospital Site, Hills Road, Cambridge, CB2 2QB, England.

Various kappa opioid agonists have been shown to be neuroprotective in both global and focal models of cerebral ischemia. The present study evaluated the efficacy of the potent and selective kappa agonist enadoline (CI-977) in a rat model of chronic focal ischemia following continuous subcutaneous administration.

Under gaseous anesthesia the left middle cerebral artery of male Sprague Dawley rats was occluded proximal to its lenticulostriate branches by microbipolar coagulation. Enadoline or vehicle (saline) was administered subcutaneously 30min pre occlusion and by continuous administration starting 5min post occlusion via an osmotic minipump implanted subcutaneously in the back of the animal. Animals were sacrificed 24h post occlusion and the brains removed and rapidly frozen. 20μm sections were taken at 9 pre-selected coronal levels and stained with haematoxylin-eosin. Areas of infarction were assessed using computer-assisted image analysis and the volume of infarction derived by integration of the known stereotaxic co-ordinates of the 9 planes.

Enadoline at 0.1, 0.3, 1mg/kg plus 0.4, 1.2, 4mg/kg/day respectively, dose-dependently decreased the volume of infarction in the cerebral cortex compared to saline control animals. The greatest reduction in infarction (52%) was observed at 1mg/kg plus 4mg/kg/day. The study emphasizes the potent neuroprotective effect of enadoline in animal models of cerebral ischemia.

610.6

PEPTIDE GROWTH FACTORS ARE NEUROPROTECTIVE DURING ISCHEMIC INDUCED NITRIC OXIDE TOXICITY IN PRIMARY HIPPOCAMPAL CELL CULTURES.

K. Maiese*, J. Boniece, and J. A. Wagner. Dept. of Neurol. and Neuroscience, Cornell Univ. Med. Coll., NY, NY 10021.

Nitric oxide synthase inhibitors prevent cell death in primary cortical cell cultures during glutamate toxicity (Dawson, V.L. et . al., Proc. Natl. Acad. Sci., 88:6368-6371, 1991). We sought to determine (a) whether nitric oxide (NO) mediates hippocampal cell death during ischemia, i.e. during anoxia and glucose deprivation; and (b) whether the peptide growth factors, basic fibroblast growth factor (bFGF) and epidermal growth factor (EGF), can prevent hippocampal cell death during NO exposure. In a dose dependent manner, inhibition of nitric oxide synthase by N-methyl arginine rescued between 10%-50% of the cells that would normally die during an eight hour anoxic incubation . In addition, L-arginine, a precursor for NO, reversed the neuroprotective effects of N-methyl arginine during anoxia. Likewise, N-methyl arginine increased cell survival during an eight hour period of glucose deprivation, but to a lesser extent. Nitroprusside, an agent that decomposes to NO, was toxic to hippocampal cells and pretreatment of cultures with either bFGF (10ng/ml) or EGF (10ng/ml) for 24-48 hours prior to nitroprusside exposure increased survival by 28%-37%. Control experiments demonstrated that addition of equivalent concentrations of cyanide for the same time were not toxic, supporting the idea that NO was the toxic agent. This data strongly suggests that NO is necessary and sufficient to mediate hippocampal cell death during ischemia and that both bFGF and EGF are neuroprotective against NO toxicity. These insights into the mechanisms of ischemic cell death may direct future therapeutic modalities for cerebrovascular disease.

610.7

EFFECTS OF INHIBITION OF NITRIC OXIDE BIOSYNTHESIS ON FOCAL CEREBRAL INFARCTION IN RATS.

S. Yamamoto*, E.V. Golanov, S.B. Berger, and D.J. Reis. Div. of Neurobiol, Dept. Neurol. & Neurosci., Cornell Univ. Med. Coll., New York, NY 10021.

It has been proposed that nitric oxide (NO) synthesized *in situ* by the constitutive (Ca^{++}-dependent) form of nitric oxide synthase (NOS) may contribute to neurotoxicity associated with cerebral ischemia. We investigated whether acute or chronic inhibition of NOS by N-nitro-arginine (NNA) would modify the volume or distribution of infarctions produced by occlusion of the middle cerebral artery (MCA) in spontaneously hypertensive rats. Comparison was made with neuroprotection afforded by electrical stimulation of the cerebellar fastigial nucleus (FN) (Reis et al. *JCBFM* 11:810, 1991) or treatment with the oxazoline rilmenidine (RIL) (Maiese et al. *JCBFM* 12:53, 1992). Rats were anesthetized with halothane (2.0%) and the MCA occluded while either the FN was stimulated or RIL (0.75 mg/kg) or NNA (0.04 mg/kg/min, i.v.) administered for 1h. Rats were killed 24h later and infarct volume determined. FN stimulation and RIL reduced infarct volume by 52% ($p<0.001$; n=4) and 27% ($p<0.05$; n=4). However, NNA increased volume by 32% ($p<0.001$; n=6) unrelated to associated hypertension. Repeated administration of NNA (2.4 mg/kg, i.p.) every 4h from 4-23h after MCA occlusion had no effect on lesion size. We conclude that NO generated from constitutive NOS of neurons, glia, endothelium and/or macrophages nor the inducible form of NOS in glia (Galea et al., *Soc. Neurosci. Abstr.*, 1992) or macrophages does not contribute to cell death in focal ischemic infarction.

610.8

L-ARGININE (L-ARG) DECREASES INFARCT VOLUME AFTER MIDDLE CEREBRAL ARTERY OCCLUSION (MCAO) IN SPONTANEOUSLY HYPERTENSIVE RATS (SHR).

E. Morikawa, Z. Huang, R.H. Price*, M.A. Moskowitz. Neurosurgery and Neurology Depts., Massachusetts General Hospital, Boston, MA 02114.

Nitric oxide (NO), a potent dilator produced by vascular endothelium is synthesized from l-Arg by NO synthase. We explored the possibility that administering l-Arg (and possibly generating NO) before and after focal ischemia might influence stroke outcome.

SHRs were subjected to distal MCAO + ipsilateral common carotid artery occlusion. L-Arg HCl (300 mg/kg) was injected i.p. 16 and 3 h before, and 5 and 120 min after right MCAO (n=9). Control rats (n=10) received saline. After 24h the resultant injury was evaluated after staining with 2,3,5-triphenyltetrazolium chloride.

Mean infarct volumes (mm^3)±SE for control and l-Arg treated rats were 147±12 and 92±17, respectively ($p<0.03$). There were no sign group differences in core and temporalis temp, MABP, brain volume and body wt or other parameters. Additional studies will be needed to determine the importance of NO to this effect.

610.9

ANTIOXIDANTS ATTENUATE DAMAGE TO CULTURED CORTICAL NEURONS INDUCED BY EXCITOTOXINS OR COMBINED OXYGEN-GLUCOSE DEPRIVATION.

J.J. Lynch III*, K. Rose and D.W. Choi. Dept. Neurol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Antioxidant compounds can reduce CNS damage in both in vitro and in vivo models of hypoxia-ischemia. We have found that 21-aminosteroid antioxidants can reduce neuronal death induced by exposure to glutamate agonists or combined oxygen-glucose deprivation in murine cortical cell cultures.

The water soluble analog of alpha-tocopherol, trolox, produced a concentration-dependent reduction in murine cortical neuronal loss induced by a 24-hr exposure to NMDA (20 μM) or AMPA (10 μM plus 10 μM MK-801 to block NMDA receptor activation). Furthermore, trolox, vitamin C, vitamin E, and the 21-aminosteroid U74500A also augmented the neuroprotective effect of 10 μM MK801 plus 100 μM CNQX in cultures exposed to prolonged oxygen-glucose deprivation. These results support the idea that free radicals mediate some of the injury triggered by glutamate receptor overstimulation. In addition, free radicals may mediate damage induced by oxygen-glucose deprivation that is unrelated to glutamate receptor activation (at least, of ionotropic glutamate receptors).

610.10

PREVENTION OF POST-ISCHEMIC MOLECULAR ALTERATIONS AND NEUROLOGICAL INJURY BY ACETYL-L-CARNITINE.

G. Fiskum*, Y. Liu, K.M. Myers, N.N. Kazerouni, Y.E. Bogaert, and R.E. Rosenthal. Depts. of Biochemistry and Molecular Biology and Emergency Medicine, George Washington University School of Medicine, Washington, DC 20037.

This study tested the hypothesis that post-ischemic IV administration of acetyl-L-carnitine (ALCAR) can improve cerebral energy metabolism, inhibit free radical-mediated molecular alterations and improve neurological outcome in a clinically relevant model of cardiac arrest (CA) and restoration of spontaneous circulation (ROSC). Seventy adult female beagles were anesthetized with chloralose and divided among 11 experimental groups including those where dogs were subjected to 10 min of CA followed by 30 min, 2 hr and 24 hr of ROSC in the absence and presence of post-ischemic administration of either ALCAR or acetate + carnitine at a concentration of 100 mg/kg immediately following defibrillation and 50 mg/kg q 6 hr. Although the level of total free plus esterified carnitine in the frontal cortex increased by > 100 % within 30 min following the initiation of either drug treatment relative to vehicle-treated controls only ALCAR-treated animals exhibited a significant amelioration of the abnormally elevated cortical lactate levels and lactate/pyruvate ratios present following 2 hr of ROSC. Free radical-dependent protein oxidation, as measured by the presence of dinitrophenlhydrazine-reactive carbonyl groups, is significantly elevated following 2 and 24 hr of ROSC in the absence or presence of carnitine + acetate but is not different from non-arrested controls during 24 hr reperfusion in the presence of ALCAR. These findings may help explain why ALCAR-treated, 24 hr ROSC animals exhibited significantly lower neurological deficit scores (NDS = 22.3 ± 5.2 S.E.) than those of vehicle treated controls (NDS = 48.4 ± 5.4) or than those exhibited by animals treated with carnitine + acetate (NDS = 41.0 ± 3.1) (NDS of 0 - normal; NDS of 100 = brain death).

610.11

FELBAMATE REDUCES NEURONAL NECROSIS AND BEHAVIORAL DEFICITS INDUCED BY CARDIAC ARREST IN THE RAT. L.M. Adams, P.H. Schwartz, T.P. Palos, A.M. Morin* and C.G. Wasterlain. Epil. Res. Lab., VAMC Sepulveda, and Brain Res. Inst., UCLA, Los Angeles, CA. 90027

Felbamate, a novel anticonvulsant and putative NMDA receptor antagonist, has been shown to ameliorate hypoxic injury to the *in vitro* hippocampal slice and neuronal necrosis and infarction after hypoxia/ischemia in the neonatal rat. We tested its neuroprotective properties in an adult rat model of transient complete global cerebral ischemia induced by cardiac arrest. This model gives rise to severe neurological sequelae including myoclonus, hindlimb extensor hypertonus and severe necrosis to the hippocampus, cortex and Purkinje cell layer of the cerebellum. Rats were subjected to reversible cardiac arrest. Felbamate (1000 mg/kg p.o.) or vehicle (10 ml/kg H_2O) was administered one hour prior to cardiac arrest. Six days later the animals were given a qualitative neurological examination and were perfusion fixed for quantitative histological analysis. Felbamate reduced neurological deficits in every neurological category examined. Statistical significance was reached in the total neurological deficit score from 46.6 ± 7.4 to 67.3 ± 7.1 ($p<0.05$) (the lower the score, the more severe the deficit), facial myoclonus from 1.40 ± 0.31 to 4.14 ± 0.55 ($p<0.05$) and acoustic startle from 2.50 ± 0.60 to 4.14 ± 0.55 ($p<0.05$). In addition, Felbamate reduced the damage score in the Cortex from 2.92 ± 0.42 to 1.57 ± 0.43 ($p<0.05$) increased the number of live neurons in the CA_1 sector of the hippocampus from 154 ± 44 to 413 ± 127 ($p<0.05$). No protection was observed in the cerebellum. In conclusion Felbamate appears promising as a neuroprotective agent in global forebrain ischemia.

610.12

DELAYED INCREASES IN QUINOLINIC ACID AND SELECTIVE INDUCTION OF KYNURENINE PATHWAY ENZYMES AFTER TRANSIENT CEREBRAL ISCHEMIA. K. Saito,[1] T. S. Nowak Jr,[2] S. P. Markey,[1] and M. P. Heyes[1]* Section on Analytical Biochemistry[1], NIMH, and Stroke Branch[2], NINDS, Bethesda, MD 20892.

Accumulation of the excitotoxin and kynurenine pathway metabolite, quinolinic acid (QUIN), has been demonstrated in several brain regions following transient cerebral ischemia in the gerbil *(J. Cerebral Blood Flow Metabol.* 10: 660,1990). In the present study, proportional increases in brain indoleamine-2,3-dioxygenase (IDO) activity and QUIN levels occurred 4 d after 10 min ischemia, particularly in hippocampus and, to a lesser extent in striatum, cerebral cortex and thalamus, but not in cerebellum. Notably, these metabolic changes paralleled the degree of neuronal injury, local inflammation and macrophage infiltrates. In addition, the activities of kynureninase, kynurenine 3-hydroxylase and 3-hydroxyanthranilate-3,4-dioxygenase were also increased in hippocampus but not cerebellum. No changes kynurenic acid levels in brain and CSF, or alterations in brain kynurenine aminotransferase activity occurred. Synthesis of [$^{13}C_6$]-QUIN was demonstrated in hippocampus but not cerebellum 1 h after intracisternal administration of [$^{13}C_6$]-L-tryptophan. Increased activities of kynurenine pathway enzymes provide a mechanism to accelerate formation of QUIN from L-tryptophan within the brain. We hypothesize that these responses reflect immune stimulation within macrophage infiltrates, as well as other reactive cells, at the site of injury. Studies of the neuropathologic consequences of this delayed QUIN accumulation are warranted.

VISUAL DEVELOPMENT: CRITICAL PERIOD AND DEPRIVATION

611.1

INCREASED NGF SYNTHESIS IN RAT VISUAL CORTEX IN RESPONSE TO LIGHT-DEPRIVATION. A.A. Schoups*, R.C. Elliott, W.J. Friedman and I.B. Black. Dept. Neuroscience & Cell Biology, UMDNJ, Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Beside their well-described role in the peripheral nervous system, neurotrophins have been shown to be crucial for the development and maintenance of central neurons. To begin investigating their role in activity-dependent plasticity, we measured mRNA's for nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF) in the rat visual system during normal postnatal development and after dark-rearing. Northern blots as well as a fast and highly sensitive solution hybridization technique were used to determine mRNA levels.

In occipital cortex, both NGF mRNA and BDNF mRNA increased during ontogeny. Levels were low at 1 week postnatally, and increased exponentially during the second and third week after birth. Dark-rearing for three weeks following birth resulted in a marked increase in NGF mRNA, confirming recent data on a possible role of NGF in experience-dependent plasticity in the visual system. Current experiments involve: 1. Combining immunocytochemistry and in situ hybridization studies, to localize synthesis of neurotrophins and their receptors, and 2. Probing a potential role of glutamate receptors in this experience-dependent modulation of NGF synthesis.

We conclude that occipital cortex responds to light-deprivation by increased synthesis of NGF. Supported by NIH grant # HD 23315 and NS 10259.

611.2

NEUROCHEMICAL DIFFERENTIATION OF CORTICAL NEURONS IN VITRO. M.Götz* and J.Bolz, Friedrich-Miescher Labor der Max-Planck Gesellschaft, Spemannstr. 37-39, 7400 Tübingen, Germany

Neurons in the adult cerebral cortex exhibit a high degree of neurochemical diversity. At birth, however, most cortical neurons are immature and they begin to express their specific transmitters only postnatally. Which factors are involved in the determination of neurochemical phenotypes in the cortex? We studied transmitter expression of cortical neurons in slice cultures, and in dissociated cell cultures kept in medium with or without serum, from rat cortices at different developmental stages. Cells were stained after different days *in vitro* (DIV) with antisera against glutamate, GABA, or the neuropeptide VIP. Double-immunofluorescence with the neuronal marker MAP2 was used to evaluate the percentage of neurons expressing one transmitter. When slice cultures were prepared from postnatal cortices, neurons continued their neurochemical differentiation similar to the development *in vivo*. In contrast, in slice cultures prepared from E19 cortices, cells that did not complete their migration *in vitro* did not express their proper transmitter phenotypes, whereas cells that had already reached their final position differentiated properly, indicating that influences during migration of cortical neurons are crucial for neurochemical differentiation. To elucidate the time period during which these influences are required, cortical cells were dissociated either 3 days, 1 day or 1 hour after their birthdate *in vivo*. Whereas neurons labelled with BrdU 1-3 days before dissociation were found to contain glutamate or GABA after 7-10 DIV, no neurons labelled with BrdU 1 hour prior to dissociation could be double-labelled with the neurotransmitter antisera even after 14 DIV. Cells labelled with BrdU 1 day before dissociation in an acute slice preparation were also able to express their transmitters properly. These results indicate that factors in the local environment are important for the specification of neurochemical properties of cortical neurons, and that the expression of their transmitter is determined within 24 hours after their birthdate.

611.3

DEVELOPMENT OF GABA-ERGIC SUBPOPULATIONS MARKED BY NEUROPEPTIDES AND CALCIUM-BINDING PROTEINS IN KITTEN VISUAL CORTICAL AREAS. D. Hogan*, E.R. Terwilleger and N.E.J. Berman. Dept. of Anatomy and Cell Biology, Univ. of Kansas Medical Center, Kansas City, KS, 66160-7400.

The development of GABA-ergic interneurons in feline striate cortex (area 17) and extrastriate cortex (medial and lateral banks of the lateral suprasylvian sulcus; MLS and LLS) was tracked by avidin-biotin immunohistochemistry and immunofluorescent- double labelling using antibodies to GABA and to molecular markers which identify subpopulations of GABA-ergic neurons in adult mammalian primary visual cortex; i.e., neuropeptide Y (NPY), somatostatin (SOM), and the calcium-binding proteins parvalbumin (PV) and calbindin (CalD). The density of GABA-ir neurons was relatively constant during development and among visual areas. By contrast, most of the GABA-subpopulations increased in the cortex of all visual areas during development, and thus the proportion of GABA-ir neurons which were also SOM-ir, NPY-ir, PV-ir and CalD-ir rose during development. All SOM-ir cells were GABA-ergic at all ages. NPY-ir cells, though much less numerous than SOM-ir cells, were both GABA-ir and SOM -ir. Most (>98%) of the PV-ir and CalD-ir interneurons were observed to be GABA-ergic. Though SOM and CalD were not colocalized in neurons of the cortex perinatally, SOM-ir was observed in about two-thirds of the CalD-ir neurons in the subplate under MLS and LLS. In mature animals, SOM and CalD were occasionally observed to be co-expressed in neurons of supragranular cortical layers of all areas. In general, though GABA is expressed by interneurons in the cortex early during visual cortical development, their secondary molecular phenotype is not expressed until later. Supported by MH38399, BNS881997 and RCD8954894.

611.4

GROWTH-INHIBITION IN CAT VISUAL CORTEX AT THE END OF THE CRITICAL PERIOD FOR EXPERIENCE-DEPENDENT PLASTICITY, STUDIED IN VITRO C. M. Müller* and V. Schoop, Max-Planck-Institut f. Entwicklungsbiologie, 7400 Tübingen, Germany

During a restricted period of postnatal development the cat visual cortex undergoes an experience dependent modification of its circuitry including the elimination of ineffective thalamo-cortical synapses whereas effective projections can form additional contacts. We investigated whether the termination of the critical period for cortical malleability is paralleled by changes of the growth permissiveness of the cortical tissue.

Cryostat sections of unfixed visual cortex from kittens and cats aged from 2 weeks to one year were used as substrate for cultured embryonic neurons from E16-E18 rat or E6 chick cortex. After a culturing period of 1 to 3 days viable neurons were labeled with the carboxyfluoresceine-ester CFDA-AM and immediately observed with epifluorescence. Neurons readily adhere and grow on white and gray matter of visual cortex from kittens younger than 6 weeks. Thereafter neurons gradually fail to adhere on white matter and growth of neurites is significantly reduced on gray matter. This change in growth behaviour occurs between the sixth and tenth postnatal week, i.e. coincident with the termination of the critical period for cortical malleability.

It is concluded that changes in the growth permissiveness of cortical tissue contribute significantly to the termination of the critical period for cortical plasticity. As the end of the critical period coincides with the time of cortical myelination it is suggested that myelin-associated growth inhibitors (Caroni & Schwab, J.Cell Biol. 106:1281, 1988) may underly the change in growth permissiveness.

THE EMERGENCE OF PINWHEEL-LIKE ORIENTATION DOMAINS IN THE VISUAL CORTEX OF KITTENS DURING THE CRITICAL PERIOD. Tobias Bonhoeffer*, Dae-Shik Kim and Wolf Singer. Max-Planck Institut für Hirnforschung, Deutschordenstrasse 46, 6000 Frankfurt 71, FRG.

It has been shown previously that iso-orientation domains in cat visual cortex are arranged in pinwheel like patterns (Bonhoeffer and Grinvald, Nature 353, 429-431). In the present study we attempted to investigate how these structures develop in the cortex of young kittens. We used optical imaging of intrinsic signals to explore the structure of iso-orientation domains in kitten visual cortex. We developed a technique which allowed us to chronically record intrinsic signals from one animal over the course of 4-8 weeks. Since the intrinsic signals recorded from kitten visual cortex proved to be much stronger than in the adult brain we attempted to record activity maps through the intact dura of the animals to minimize the risk of infection. Using this technique we found that in kittens of 4½ weeks of age pinwheels are already clearly present. Moreover, we also observed strong ocular-dominance maps, allowing us to assess the relationship between ocular-dominance and orientation maps in kittens. The orientation maps changed remarkably little between weeks four and eight postnatally. In the structures from which we were able to acquire optical data (i.e. the parts of area 17/18 on the lateral gyrus) we could not observe any new iso-orientation domains or pinwheels being formed during this period of time. This suggests that in normal kittens the basic structure of the orientation maps is formed before the age of 4-5 weeks. We are currently trying to image from the cortex of younger cats, hopefully back to the age of two weeks postnatally.

611.6

A CRITICAL PERIOD FOR THE DEVELOPMENT OF CLUSTERED HORIZONTAL CONNECTIONS IN CAT STRIATE CORTEX. M.B. Dalva, E.M. Callaway, and L.C. Katz.* Dept. of Neurobiology, Duke University Med. Center, Durham, NC 27710.

The clustered horizontal connections of layer 2/3 pyramidal neurons in cat striate cortex specifically link iso-orientation columns. The highly specific pattern of clusters emerges during the first 6 weeks of postnatal development by the selective elimination of unbranched axon collaterals to inappropriate regions and the differential growth of appropriately situated collaterals. Axon rearrangements depend on visual activity: incorrect projections are maintained in animals binocularly deprived for 6 weeks (Callaway & Katz, PNAS 88:745, 1991), and strabismic rearing alters the pattern of clusters (Lowel & Singer, Science 255:209, 1992). To determine when the development of these intrinsic connections is sensitive to activity cues, animals were deprived of patterned visual experience by binocular lid suture prior to natural eye opening. Eyes were reopened at after 6-14 weeks of deprivation to determine whether normal visual experience could restore the normal pattern of clustered connections. Small injections of red fluorescent latex microspheres were made to define patterns of horizontal connections in the deprived state; after 8-12 weeks of normal visual experience a second injection of green microspheres was made. Comparisons of the two patterns demonstrated that the crudely clustered pattern seen after six weeks of deprivation could still be refined to the normal pattern by visual experience. Preliminary results indicate that this ability to recover has disappeared by 14 weeks of deprivation. Thus, intrinsic cortical connections related to orientation, like LGN afferents related to ocular dominance, are sensitive to visual activity during a restricted period of early postnatal life. 611.7

POSTNATAL DEVELOPMENT OF IPSILATERAL CORTICOCORTICAL CONNECTIONS IN THE CAT'S VISUAL CORTEX. D.J.Price*. Dept. of Physiology, Univ. Med. Sch., Edinburgh, U.K.

During the postnatal development of connections from area 17 to 18 of the cat's visual cortex, an initially highly exuberant pathway is refined mainly by axonal retraction. Previous studies suggested that the topographic organization of the early immature projection is very crude, and there is no clustering of the association neurones in area 17 as in the mature pathway.

Retrogradely transported fluorescent tracers were injected in area 18 in kittens aged 0-20 days. In some animals, axonal bifurcation in the area 17-to-18 projection was examined by co-injecting a different dye either at an adjacent point in area 18 itself, or at a topographically related point in another extrastriate cortical area. Labelling of area 17 was studied.

The results reveal a finer organization of the immature area 17-to-18 pathway than was previously suspected. Even at the earliest postnatal ages, while axons from area 17 are just penetrating area 18, there is evidence of rudimentary clusters of association neurones in area 17. Computer-modelling of the distributions of these cells suggests that the majority do send axons to topographically related regions of area 18, while a smaller number project extremely divergently. Few double-labelled cells were seen, indicating a low incidence of bifurcation in kittens, as in adults.

611.8

DEVELOPMENT OF CONNECTIONS IN VISUAL CORTICAL AREAS OF MACAQUE MONKEYS. T.A. Coogan and D.C. Van Essen* Div. Biology, Caltech, Pasadena CA 91125

The development of connections within and between areas V1 and V2 was studied by placing crystals of Di-I in fixed tissue taken from animals at two stages of development: the day of birth and embryonic day 133 (E133), 30 days after the latest generated neurons in V1 are born (Rakic, '74). At E133 labeled axons from V1 are confined to white matter below V2, where they ramify to some degree, but by birth the V1-V2 projection has reached layer 4. No labeled subplate neurons were seen after dye injections at either age. Intrinsic V1 connections are quite extensive at E133; the same layers are involved at this stage as at maturity, and extend approximately the same distances, with the exception of layer 1, where fibers extend over 10mm from the injection site, even crossing the V1/V2 border. However, at E133 there is no evidence of clustering of connections in superficial layers of V1, whereas these connections are clearly clustered at birth. In the feedback direction, the V2 to V1 projection has entered the grey matter by E133. At this stage the projection arises principally from deep layer cells, each of which has a dendrite which extends into layer 1. At birth the V2 to V1 projection comes predominantly from superficial layer cells. These observations suggest that the modular arrangement of connections in superficial layers of V1 is sculpted from a more uniform state; and that the feedback projection begins to innervate its target before the forward projection does so.

611.9

NATURALLY-STRABISMIC PRIMATE LACKS INTRINSIC HORIZONTAL CONNECTIONS FOR BINOCULAR VISION IN STRIATE CORTEX. L. Tychsen*[1] and A. Burkhalter[2]. Depts. Ophthalmology[1] and Neurosurgery[2], Washington Univ. Sch. of Med., St.Louis, MO 63110.

Although it has been postulated that strabismus in human infants is associated with maldevelopment of connections in the visual cortex, no anatomic data from naturally-strabismic primates has been reported. We have now shown abnormalities of horizontal connections in visual area V1 in a macaque monkey with infantile-onset strabismus. The monkey developed esotropia 6 weeks after birth and showed ocular motor behaviors that characterize early-onset esotropia in human infants.

In V1 of normal primates blobs and interblobs of left eye columns connect to blobs and interblobs of left and right eye columns (Livingstone and Hubel, 1984). To examine whether this organization is present also in naturally-strabismic animals, we injected biotinylated dextran amine (BDA) into left or right eye columns of V1. Ocular dominance columns were made visible by laserablating the left optic nerve head 5 days before the injection. After 3 more days the animal was sacrificed and alternating sections were stained for BDA and cytochrome oxidase (CO). Injections confined to columns driven by the left eye revealed connections only to left eye columns and skipped right eye columns (and vice versa). Connections along the horizontal axis of the visuotopic map were longer than connections along to the vertical axis. The total extent along the long axis was ~16 columns (~5° of the central visual field) and ~8 columns along the short axis.

These results show that anatomic alterations in strabismic primate correspond to behavioral deficits in binocularity, and suggest that as in cat (Löwel and Singer, 1992), correlated input from the 2 eyes is important for the normal development of intracortical connections.

LABELING OF OCULAR DOMINANCE COLUMNS IN AMBLYOPIC MACAQUE MONKEYS USING CYTOCHROME OXIDASE HISTOCHEMISTRY. M.P. Stryker* & J.C. Horton. Departments of Physiology & Ophthalmology, UCSF, San Francisco, CA 94143-0444.

Two monkeys underwent suture of the right eyelids at 1 week of age. A year later, ^{3}[H]-proline was injected into single geniculate lamina. Autoradiographs revealed shrunken ocular dominance columns belonging to the amblyopic eye, but remarkably, cytochrome oxidase (CO) activity in layer IVC appeared completely homogeneous. In layers II,III alternating dark and light rows of blobs were visible. The light rows fit in register with deprived eye dominance columns in IVC. To label the eye dominance columns in IVC using CO, a third monkey was raised with the right eyelids sutured. At 21 months the left occipital lobe was excised. No CO columns were visible in layer IVC, confirming the two prior experiments. Next ^{3}[H]-proline was injected into the left eye. A week later the left eye was enucleated and the right eye was re-opened; 2 weeks later sections from the remaining occipital lobe were processed for either CO or autoradiography. In sections reacted for CO we observed thin, dark columns alternating with wide, pale columns. Comparison with adjacent autoradiographs established that the thin, dark columns belong to the deprived, right eye. These findings indicate that early monocular suture in macaques produces uniform CO activity in layer IVC of striate cortex, but visual deprivation combined with subsequent enucleation causes a pattern to emerge of shrunken (amblyopic eye) columns alternating with expanded (normal eye) columns. (Supported by grants from NEI & National Children's Eye Care Foundation)

611.11

ANISOMETROPIA INDUCES AMBLYOPIA WITHOUT SHRINKAGE OF OCULAR DOMINANCE COLUMNS IN HUMAN STRIATE CORTEX. J.C. Horton* & M.P. Stryker. Departments of Ophthalmology & Physiology, UCSF, San Francisco, CA 94143-0350.

In macaques raised with unilateral eyelid suture, cytochrome oxidase activity is homogeneous in layer IVC of striate cortex (Stryker & Horton, 1992). Subsequent enucleation of the normal eye causes thin, dark columns alternating with wide, pale columns to appear in layer IVC. The thin, dark columns are the ocular dominance columns of the amblyopic eye. In an analogous clinical case, we examined the pattern of cytochrome oxidase activity in a 53-year-old man with amblyopia in the left eye (20/400 acuity), who became blind in his normal right eye 3 months before death. The amblyopia was due to a difference of 6 diopters in the refractive power of the two eyes (anisometropia), first detected at age 5.

The mosaic of ocular dominance columns in each striate cortex was reconstructed from serial flattened sections reacted for cytochrome oxidase activity. Surprisingly, no shrinkage of the ocular dominance columns serving the amblyopic eye was observed. Dark stripes occupied 48% of the column area in the left cortex and 54% of the column area in the right cortex. Slightly more cortex was filled in each side by the contralateral eye, reflecting the normal attenuation of ipsilateral eye columns in peripheral binocular cortex. We conclude that ocular dominance columns in layer IVC of human striate cortex do not shrink in anisometropia, implying a different cortical basis for this form of amblyopia.

EFFECTS OF ARTIFICIAL STRABISMUS ON MACAQUE MT.

J. Anthony Movshon* and Lynne Kiorpes.
Howard Hughes Medical Institute and Center for Neural Science, New York University, New York 10003.

Tyschen and Lisberger (1986, *J. Neurosci.*) observed a nasal-ward bias in smooth pursuit eye movements and visual motion judgements in humans with esotropic (convergent) strabismus, suggesting that these individuals had abnormal visual motion processing. Subsequently Walton and Lisberger (1989, *ARVO*) found similar oculomotor abnormalities in monkeys raised with artificial strabismus, and raised the possibility that abnormal mechanisms of pursuit initiation might underlie these changes.

Motion signals in cortical area MT support pursuit eye movements. We therefore used suitable targets to assess the direction and speed preferences of MT neurons in anesthetized adult macaque monkeys given surgical esotropia in infancy. We found no unusual asymmetries in the motion-related responses of these cells. We did observe a sharp reduction in binocular interaction in MT cells, similar to that seen in V1. Because MT cells receive a convergent input from large areas of V1 and V2, this suggests that the functional organization of cortico-cortical connections can be altered by abnormal experience in a manner reminiscent of the well-known changes seen in thalamocortical connections. These changes do not seem to affect visual motion signals, so we conclude that pursuit anomalies in strabismus reflect changes in the generation of oculomotor commands rather than in the visual processing of motion information.

DRUGS OF ABUSE: COCAINE AND OTHER STIMULANTS

612.1

PRENATAL COCAINE EXPOSURE ALTERS DOPAMINE TRANSPORTER BINDING IN ADULT MICE. G.A. Pritchard*, J.J. Byrnes, L.G. Miller. Dept. of Pharmacology and Experimental Therapeutics and Neuroscience Program, Tufts Univ. School of Medicine, Boston, MA 02111.

Prenatal cocaine administration is associated with persistent behavioral effects, but the neurochemical basis for these effects is uncertain. We exposed pregnant mice to cocaine, 10 mg/kg, during days 14-21 of gestation. At 6 weeks of age, offspring were evaluated for motor activity and dopamine transporter binding in striatum in vivo using WIN 35,428. No differences in motor activity were observed among untreated, vehicle-exposed, or cocaine-exposed mice. Similarly, no change in activity was noted in response to chronic cocaine among the exposure groups. However, total dopamine transporter binding in striatum was significantly reduced by approximately 20% in cocaine-exposed mice compared to the other groups. No change was observed in nonspecific binding evaluated in cerebellum. Specific binding in striatum was thus reduced significantly by approximately 25%. These data indicate that prenatal cocaine exposure is not associated with changes in motor activity untreated or in response to chronic cocaine, but is associated with alterations in dopamine transporter binding in mature offspring.

612.2

REGULATION OF DOPAMINE RECEPTORS mRNA EXPRESSION IN THE RAT BRAIN BY COCAINE. C.Spyraki(1,3), A. Prikhozhan(1), G.W.Huntley(1) and S.C.Sealfon*(1,2) 1.Fishberg Center for Research for Neurobiology and 2.Department of Neurology,The Mount Sinai School of Medicine, NY, NY 10029, 3. Lab.of Pharmacology,Medical School,University of Crete, GR.

The mesolimbic/mesocortical DAergic pathways and the DA receptor subtypes, pharmacologically defined as D1/D2, appear to mediate the reinforcing properties of cocaine, on both behavioural and biochemical grounds. The present study focuses on possible regulation of D1 and D2 receptor gene expression in rat brain by cocaine treatment, using in situ hybridization (ISH). Adult male Wistar rats were treated with intraperitoneal cocaine administered either for one (0; 5.0; 10.0; 20.0; 40.0 mg/kg) or for 15 days (0; 10.0; 20 mg/kg). Twenty four hrs after the last injection, the animals were deeply anaesthetized and perfused. The brains were frozen and 25μm thick sections were taken through the accumbens,striatum and midbrain with a sliding microtome. The floating sections were processed for ISH with 35S-radiolabeled rat D1 and D2 cRNA probes. Quantitative ISH, performed on film autoradiograms with a computer assisted densitometer, was used to examine changes in the levels of D1 and D2 mRNA in nucleus accumbens (ACC), olfactory tubercle (TO), caudate nucleus (CP), ventral tegmental area (VTA) and substantia nigra(SN). The results show that D1 mRNA expression was affected by neither acute nor chronic cocaine treatment at the ACC, TO and CP. Similarly no changes were revealed in the D2 mRNA levels at the ACC, CP, and SN. An average of 25% decrease(statistical significance 95%) in D2 mRNA density was measured at TO in animals treated with single injections of cocaine at the high doses(20 and 40 mg/kg). A tendency for decrease with the same regimen was observed in VTA. Within the limitations of the experimental paradigm used in this study, the data suggest that the regulation of DA receptor gene expression by cocaine is not robust and manifests dose, receptor subtype and anatomical specificity. (supported by the Aaron Diamond Foundation)

612.3

COCAINE INCREASES ACCUMBENS SEROTONIN RELEASE CONCURRENTLY WITH DOPAMINE RELEASE IN PSYCHOSTIMULANT REINFORCEMENT. P.A. Broderick*, R.T. Wechsler, F.T. Phelan, and F. Eng. Dept. Pharmacol., CUNY Med. Sch. (J-910) & CUNY Grad. Sch., Convent Ave, W. 138th St, NY, 10031,USA.

Ultrastructural evidence from light and electron microscopic studies shows that serotonin (5-HT) plays an important role in the regulation of dopaminergic (DA-ergic) ventral tegmental (VTA) neuronal circuitry (Herve *et al, Brain Res.* 435:71; 1987). *In vivo* neurochemical studies show that a colocalized, DA-ergic and 5-HT-ergic response to cocaine occurs in VTA, suggesting that 5-HT may be a relay or a gating mechanism for DA (Broderick, P.A., *Pharmacol. Biochem. & Behav.* 42[4]; 1992). This paper assesses the concurrent effects of intraperitoneal (IP) cocaine (10 mg/kg) on DA and 5-HT release in nucleus accumbens (NAcc) of freely moving and behaving, male, Sprague-Dawley rats with *in vivo* electrochemistry (voltammetry). DA and 5-HT were detected separately and sequentially within 10-15 seconds with stearate microelectrodes (cf. Broderick P.A., *Brain Res.* 495:115; 1989, for microelectrode preparation). Activity patterns were studied with infrared photocell beam detection. The results show that (IP) cocaine increased DA and 5-HT release. Concomitantly, the cocaine-induced psychostimulant behaviors, hyperactivity, rearing and stereotypy were increased. Agoraphobic behavior (the tendency to avoid the center of the cage) was inhibited; thus, an acute anxiolytic effect was seen. Cocaine-induced DA and 5-HT release highly correlated with behavior. The data show that cocaine comodulates 5-HT with DA in NAcc, the terminal neurons of the VTA-DA-ergic pathway. [Supp: NIDA R01 DA 04755-01 and PSC-CUNY Awards RF 6-69201 and RF 6-61188].

612.4

AJ76, DOPAMINE AUTORECEPTOR ANTAGONIST, MODULATES ACCUMBENS DOPAMINE AND SEROTONIN IN COCAINE-INDUCED PSYCHOSTIMULANT BEHAVIOR. F.T. Phelan*, R.T. Wechsler, F. Eng, M.F. Piercey[1] and P.A. Broderick. Dept. Pharmacol., CUNY Med. Sch., Convent Ave. & W. 138th St., NY, 10031, USA, CNS Res., Upjohn Co.[1], Kalamazoo, MI 49007, USA.

AJ76 is a centrally acting dopamine (DA) receptor antagonist which produces weak behavioral stimulation via inhibition of presynaptic DA autoreceptors (Svensson *et al, Naunyn-Schmeid. Arch. Pharmacol.* 334:234; 1986). AJ76 reversed the electrophysiological effects of cocaine (Hoffman *et al. Neurosci. Abstr.* 17:681; 1991) and is itself not self-administered (Roberts, D.C., pers. comm.). The present paper assesses the neurochemical and behavioral profiles of AJ76 in combination with cocaine, using *in vivo* electrochemistry and activity pattern analysis. Specific details for *in vivo* electrochemistry (voltammetry) are published (Broderick, P.A., *Brain Res.* 495:115; 1989). Stearate indicator microelectrodes were stereotaxically implanted in nucleus accumbens of male, Sprague Dawley rats under Na pentobarbital anesthesia; 9-15 days of recovery were allowed. Time course studies show that, although AJ76 significantly increased DA and 5-HT release *per se* (Eng *et al*, this meeting), AJ76 pretreatment down-modulates cocaine-induced DA and 5-HT release concurrently with down-modulating locomotor activity, rearing and stereotypy. Cocaine's acute anxiolytic activity was not down-modulated. The unusual behavioral profile of AJ76, involving biogenic amines subserving cocaine reinforcement, offers a new approach to cocaine pharmacotherapeutics. [Supp: NIDA R01 DA 04755-01, The Upjohn Co. RF 7-76207 & PSC/CUNY RF 6-69201 & RF 6-61188 Awards to P.A. Broderick].

612.5

MESENCEPHALIC NEURONAL CELL CULTURE AS A MODEL OF DOPAMINE TRANSPORTER ONTOGENESIS. M. Valchár and I. Hanbauer*. Lab. of Chem. Pharmacol., NHLBI, Bethesda, MD 20892.

In primary cultures of ventral mesencephalon (CVMN) from 14 day old rat embryos, [^{3}H]DA uptake, sensitive to nanomolar concentrations of cocaine and its congeners, is expressed as soon as neurites are formed. Using [^{3}H]WIN 35,428 as a ligand, we found no specific binding sites for [^{3}H]WIN 35,428 in the absence or presence of Na^+ in membrane preparations of cells cultured 5-6 days. However, in intact cells low affinity binding sites of [^{3}H]WIN 35,428] (K_D=336,000nM) were found in the cytosol of CVMN. The cytosolic [^{3}H]WIN 35,428 binding was sodium-independent, and was displaced by micromolar concentrations of DA uptake inhibitors. When CVMN were cultured for 12-20 days both high (K_D=57 nM) and low affinity binding sites (K_D=105,776 nM) were expressed in intact cells. The high affinity binding site of [^{3}H]WIN 35,428 was sodium-dependent, and was displaced by nanomolar concentrations of cocaine or mazindol. Membrane preparations from CVMN, cultured for 12-20 days, also contained sodium-dependent, high affinity binding sites of [^{3}H]WIN 35,428. Pharmacological studies indicate a relationship between the high affinity [^{3}H]WIN 35,428 binding sites and the DA transporter complex, whereas the cytosolic [^{3}H]WIN 35,428 binding sites were functionally unrelated.

612.6

THE COCAINE BINDING SITE: MODULATION BY VARIOUS IONS AND CHANNEL BLOCKERS. J.W. Boja* and T.A. Kopajtic. NIDA Addiction Research Center, P.O. Box 5180, Baltimore, MD 21224

Several studies have suggested that certain calcium channel modulators may affect the behavioral effects of cocaine. However, no study has examined the effects of various ion channel modulators directly upon the binding of cocaine to the dopamine transporter. The effects of NaCl, KCl and Ca_2Cl and their respective channel modulators had upon the striatal cocaine binding site were determined using the cocaine analog [^{3}H]WIN 35,428. The addition of NaCl had no effect upon specific binding however, Ca_2Cl and to a lesser extent KCl decreased binding. Various Na^+, K^+, Cl^- and Ca^{2+} channel blockers were also tested for their ability to inhibit specific [^{3}H]WIN 35,428 binding. Most of the Na^+ channel blockers tested were of moderate potency, the exceptions being benzamil and flunarizine which displayed higher potency. Both of these agents are also reported to have activity at the Ca^{2+} channel. The K^+ channel blockers were of low and moderate potency while the Cl^- channel blockers had no effect. Of the Ca^{2+} channel blockers tested only pimozide demonstrated high potency. This was postulated to be due to its ability to act upon both L and T-type channels. These results suggest that the Ca^{2+} channel blockers deserve further study as useful therapeutic potential in the treatment of cocaine addiction.

612.7

NEUROANATOMIC AND MOLECULAR SPECIFICITY OF C-FOS INDUCTION BY COCAINE IN DEVELOPING RAT BRAIN. Barry E. Kosofsky*, and Steven E. Hyman. Molecular Neurobiology Laboratory, Massachusetts General Hospital, Harvard Medical School, Boston, MA 02114.

A class of immediate early genes (eg., the IEG c-fos) that act as transcription factors, may subserve one mechanism by which substances of abuse alter programs of neural gene expression. We have injected saline (vehicle control) or cocaine (30 mg/kg, ip) in to rat pups (P8, P15, P28) and adults and sacrificed animals acutely (@45 minutes for mRNA (northern) and in situ hybridization histochemistry analyses, and @120 minutes for immunohistochemical analysis) to determine the ontogeny and spatial distribution of cocaine induced IEG activation. On P8, cocaine induces c-Fos in striatal patches, in a few scattered globus pallidus neurons, in layer VI neocortical neurons, but not in anterior cingulate cortex. On P15, cocaine induced striatal c-Fos is more diffuse, with a lateral predominance. In globus pallidus there is a high density of c-Fos immunoreactive (IR) neurons. In neocortex there is augmentation of significant basal c-Fos expression after cocaine treatment, particularly evident in infragranular layers. Anterior cingulate cortex, which is minimally activated on P8 or P15, has a high density of c-Fos IR neurons in cocaine exposed P28 and adult animals. In globus pallidus of P28 and adult rats exposed to cocaine there are no c-Fos IR neurons. Striatal induction of c-Fos by cocaine on P28 and in the adult is densest medially. Both basal and cocaine induced c-Fos IR in neocortex is markedly decreased in P28 and adults when compared to P15 animals. Analysis of adjacent sections in cocaine treated animals at each age suggests that neither presynaptic markers (dopamine innervation), nor post-synaptic markers (D1 and D2 dopamine receptor mRNA distribution) nor intrinsic neuronal markers (DARP-32, Substance P) are entirely predictive of the spatial and temporal specificity of cocaine induction of c-Fos IR described. We conclude that cocaine induces c-fos mRNA and c-Fos protein with a significant degree of spatial selectivity, and temporal specificity. We suggest that cocaine induced alterations in gene expression during critical developmental periods may irrevocably alter CNS form and function, with differential regional, temporal, and cellular vulnerabilities.

612.8

EFFECTS OF REPEATED COCAINE ADMINISTRATION ON 5-HT_{1A} RECEPTORS IN RAT BRAIN. J. I. Javaid*, S. K. Sahni, S. C. Pandey and J. M. Davis. Illinois State Psychiatric Institute, University of Illinois at Chicago, Chicago, IL 60612.

Repeated administration of cocaine causes augmentation in behavioral effects (behavioral sensitization) induced by acute administration. However, the specific adaptive neurochemical mechanisms underlying this behavioral sensitization are not well-understood. Electrophysiological studies have suggested that the effects of cocaine on serotonergic function may be modulated by 5-HT_{1A} receptor subtype. In the present studies we examined the changes in the binding of [^{3}H]-8-hydroxy-2-(di-N-propylamino) tetralin (8-OH-DPAT, 5-HT_{1A} selective ligand) in rat cortex and hippocampus after repeated cocaine administration. Cocaine (10 mg/Kg) was administered once daily by intraperitoneal injection for a total of 9 injections over 11 days (5 injections with 2 days off, followed by 4 injections). Four groups [saline (S)/S; cocaine (C)/S; S/C; C/C] of animals were pretreated with 8 injections of S or C followed by the 9th injection as S or C "challenge". The animals were sacrificed by decapitation 24 hours after the last injection, brains removed immediately and dissected into cortices and hippocampi for [^{3}H]-8-OH-DPAT binding. There were no statistically significant differences in either the number of binding sites (B_{MAX}) or the affinity (K_D) of DPAT binding in cortex and hippocampus from various groups. These results suggest that behavioral sensitization with repeated cocaine administration is not associated with changes in either pre- or postsynaptic 5-HT_{1A} receptors.

612.9

THE ROLE OF DA, NE, AND 5-HT NEURONAL SYSTEMS IN THE DISCRIMINATIVE STIMULUS EFFECTS OF COCAINE. A. K. Singha* and J. B. Appel. Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, S.C. 29208.

To elucidate the role of dopaminergic, adrenergic, and serotonergic neuronal systems in the stimulus effects of cocaine, rats (n = 32) were trained to discriminate i.p. injections of cocaine (10 mg/kg) from saline (1 ml/kg) in a two-lever, drug discrimination paradigm. Various doses of compounds which have been reported to act selectively at DA, NE, or 5-HT receptor sites were then given in combination with the training drug. The results indicated that the DA (D_1) antagonist SCH 39166 (0.01-0.2 mg/kg) blocked the effects of cocaine in a dose-dependent manner. Neither the α_1 NE antagonist prazosin (0.05-0.2 mg/kg), the α_2 antagonist idazoxan (1.25-5.0 mg/kg), the non-selective 5-HT antagonist metergoline (5.0-20.0 mg/kg), nor the 5-HT_2 antagonist ketanserin (0.06-0.2 mg/kg) had significant effects on the cocaine cue. These data support the hypothesis that DA, particularly D_1 receptors, are involved in the discriminable and, perhaps, other subjective effects of cocaine.

Supported by **USPHS Research Grant R01 DA02543**, from the National Institute on Drug Abuse.

612.10

IN VITRO AND IN VIVO LABELING OF DOPAMINE AND SEROTONIN TRANSPORTERS WITH β-CIT. R.B. Innis*, M. Laruelle, Y. Zea-Ponce, S.S. Zoghbi, R.T. Malison, M.S. Al-Tikriti, G. Wisniewski, E.H. Sybirska, E.O. Smith, J.L. Neumeyer, R.A. Milius, D.S. Charney, P.B. Hoffer, R.M. Baldwin. Yale University. /VA Medical Center, West Haven, CT 06516 and Research Biochemicals, Inc., Natick, MA 01760

Methyl 3ß-(4-iodophenyl)tropane-2ß-carboxylate (β-CIT or RTI-55) displayed high affinity for both dopamine (DA) uptake sites labeled with [^{3}H]CFT (IC50 = 1.6 nM) in monkey striatum homogenates and serotonin (5-HT) uptake sites labeled with [^{3}H]paroxetine in rat cortical membranes (3.8 nM). Saturation studies performed with [^{125}I]β-CIT showed the presence of high and low affinity sites (K_{high} = 0.74 nM, K_{low} = 34 nM, $Bmax_{high}$ = 140 pmol/g tissue, $Bmax_{low}$ = 760 pmol/g tissue) in rat striatum, while binding in cortex was best fit with a one-site model (Kd=1.7 nM, Bmax=67 pmol/g tissue). *In vivo* [^{123}I]β-CIT binding was studied in baboons with SPECT scanning (n=39). Striatal activity increased slowly, reached a plateau level at 140 ± 10 min and remained constant until the end of the experiment (330 ± 8 min). Midbrain activity peaked at 47 ± 2 min and declined with a rate of 14 ± 1% /hr. At 300 min, the striatal to cerebellar ratio was 7.3 ± 1 and the midbrain to cerebellar ratio was 2.3 ± 0.4, with cortical activity similar to that in cerebellum. *In vivo* displacement studies with selective monoamine inhibitors GBR12909, citalopram, and maprotiline showed that striatal activity was associated with DA transporters, and midbrain activity with 5-HT transporters. Since DA and 5-HT uptake sites displayed different uptake kinetics and anatomical localization, [^{123}I]β-CIT is a potentially useful SPECT ligand to visualize both sites.

AMPHETAMINE-INDUCED DOPAMINE RELEASE: A CELL CULTURE MODEL. K. F. Farrell, D.L. Conant and S. P. Berger*. Dept. of Psychiatry, Univ. California San Francisco and Veterans Affairs Medical Center, San Francisco, CA 94121.

Amphetamine derivatives and other substrates of the catecholamine transporter such as tyramine are believed to induce release of dopamine by a carrier mediated "exchange diffusion". Uptake of amphetamine derivatives by the catecholamine transporter is thought to be coupled with a nonexocytic release of dopamine. An important assumption in this "exchange diffusion model" is that specificity of these agents is derived from their ability to act as substrates of the dopamine transporter. Therefore, a good correlation is expected between the competitive inhibition of dopamine uptake and dopamine release. Pheochromocytoma (PC12) cells have been used extensively to characterize the exocytic release of dopamine and we have begun to study PC12 cells as a model of nonexocytic dopamine release.

Our findings on the stereospecific release of dopamine from PC12 cells by amphetamine derivatives is supported by earlier reports that tyramine is believed to release dopamine via a carrier mediated mechanism. Likewise, consistent with the nonexocytic exchange diffusion model, the ability of amphetamine derivatives to release dopamine is calcium independent . However, there appears to be a poor correlation between the inhibition of dopamine reuptake and the ability to induce release. We have observed a rank order of fenfluramine > d-amphetamine > l-amphetamine > tyramine in the ability to release dopamine and d-amphetamine = l-amphetamine > tyramine > fenfluramine for inhibition of uptake. Inasmuch as tyramine has also been reported to bind to and be a substrate of the vesicular dopamine transporter, we examined whether the transport of catecholamines into storage vesicles is a potential source of specificity for dopamine release. An identical rank order was observed in the ability of amphetamine derivatives to inhibit [^{3}H]ketanserin binding to vesicles as was earlier found to release dopamine. These results suggest that the vesicular transporter may play a critical role in the mechanism of amphetamine-induced dopamine release from PC12 cells.

612.12

DAILY POST-SESSION COCAINE ADMINISTRATION IMPAIRS ACQUISITION OF A POSITIVELY-MOTIVATED AUTOSHAPED LEVER-TOUCH RESPONSE IN RATS. P.H. Janak*, W.A. Rodriguez and J.L. Martinez, Jr. Dept. of Psychology, Univ. of California, Berkeley, CA 94720.

The effects of daily peripheral (IP) post-session injection of cocaine (COC) on the development of an autoshaped lever-touch response were investigated. Male Sprague-Dawley rats received 10 daily pairings of a retractable lever (CS) and food delivery (US). Reinforcement delivery was not contingent upon a response; however, if the subjects contacted the lever during CS presentation, then reinforcement was delivered immediately. COC, at a dose of 5.55 mg/kg [$F(1,30)=5.21$, $p<.03$], but not 2.75 mg/kg [$F(1,30)=0.18$, $p>.5$], impaired acquisition of the lever-touch response. COC's effect on lever-touch acquisition depended upon the time of drug administration relative to the conditioning session, as injection of COC 3 hrs after each session did not affect response acquisition. In addition, COC's effect depended on explicit CS-US pairing as post-session COC administration did not alter responding when the presentation of both the CS and the US were uncorrelated. These results indicate that the post-session administration of COC can alter the retention of a positively-motivated conditioned response, as seen by impaired acquisition of the lever-touch response. (Supported by DA06192 and DA05375.)

EXCITATORY AMINO ACIDS: PHARMACOLOGY VI

613.1

POLYAMINE AGONISTS, ANTAGONISTS AND INVERSE AGONISTS REDUCE NMDA RECEPTOR SINGLE-CHANNEL CURRENTS. D. M. Rock* and R. L. Macdonald#. Neuroscience Program* and Depts. of Neurology and Physiology#, University of Michigan, Ann Arbor, MI 48104.

Polyamines modulate the binding of open channel blockers to the NMDA receptor subtype of postsynaptic glutamate receptor. Using voltage-clamp and single-channel recording techniques, we previously have shown that spermine (SP) has multiple actions on NMDA receptor currents. At low concentrations SP increased opening frequency to enhance NMDA receptor current, but at higher concentrations SP produced a voltage-dependent reduction in the amplitude and average open time of NMDA receptor single-channel openings.

The related polyamines, arcaine (ARC), spermidine (SD), diethylenetriamine (DET), putrescine (PUT) and diaminodecane (DA-10), all produced a voltage-dependent reduction in NMDA receptor current. Reduction in amplitude of NMDA receptor single channel openings by SD, DET and PUT was similar to SP and the concentration dependence of the reduction was related to charge at physiological pH. The highly charged polyamine SP (+4) reduced the amplitude of single channel openings at concentrations lower than PUT (+2). Reduction of NMDA receptor currents by ARC and DA-10 however was different. The reduction of NMDA receptor single-channel currents by ARC was associated with increased open channel noise and DA-10 produced a flickery block of single-channel currents. Reductions of NMDA currents by SP and DA-10 were not reversed by the polyamine antagonist DET.

These data suggest that polyamines may reduce NMDA receptor current by voltage-dependent effects on NMDA single-channel amplitude and average open time and that the polyamine reduction of NMDA receptor current appears to have a pharmacological profile different from that described for polyamines in receptor binding assays.

613.2

POSITIVE ALLOSTERIC MODULATION OF NON-NMDA RECEPTORS IN HIPPOCAMPAL RAT BRAIN SLICES. M. Bertolino*, M. DiBella', M.Baraldi', S. Vicini and E. Costa. FGIN, Georgetown University, Washington, DC, 'School of Pharmacy, Modena University, Italy.

Excitatory synaptic transmission in the mammalian brain is due to the activation of non-NMDA agonist-sensitive glutamate receptors, and the termination of the synaptic currents may be related to the fast desensitization of these receptors (Trussel, L. and Fischbach, G. Neuron 3:209-218, 1989; Vyklicky, L. et al. Neuron 7:971-984, 1991). Therefore, drugs that potentiate the action of non-NMDA receptors can potentiate synaptic transmission and related functions (such as long term potentiation, etc.). We investigated whole-cell currents elicited by bath application of L-glutamate in CA1 pyramidal neurons in thin (250 μM) slices of adult rat hippocampus using the patch-clamp technique. L-glutamate (50 μM) was applied in the presence of TTX (0.5 μM) in order to block action potentials and evoked synaptic activity and Dizolcipine (MK-801, 5 μM) to block non-competitively NMDA-sensitive glutamate receptor activation. Combined application of L-glutamate with the "nootropic" compound aniracetam (1 mM) produced ionic current 144 ± 15% greater than L-glutamate alone (mean ± SE, n= 5 neurons). Similarly, the benzothiadiazide Diazoxide (1 mM) potentiated the L-glutamate current by 145 ± 31% (n= 5), while cyclothiazide (a potent thiazide derivative) at 50 μM enhanced the L-glutamate current by 288 ± 80% (n= 4). We were interested in characterizing the potency and efficacy of other diazoxide derivatives to identify more potent and selective compounds. To this aim we synthesized diazoxide derivatives by various groups substitution. Cyclothiazide is not the only derivative that is more potent than diazoxide. In fact, ring halogenation in position six and seven also plays an important role in the positive modulation of hippocampal glutamate receptors.

613.3

2-PHOSPHONOETHYLPHENYLALANINE DERIVATIVES AS NOVEL ANTAGONISTS OF KAINIC ACID/AMPA RECEPTORS. E.W. Karbon*, D.L. Bednar, M.A. Bailey, S. A. Borosky, R.A. Zubrowski, J.W. Ferkany, Z. Huang and G.S. Hamilton. Nova Pharmaceutical Corporation, Baltimore, MD 21224.

A series of substituted 2-phosphonoethylphenylalanines were synthesized and tested for their ability to interact with kainic acid (KA)/AMPA receptors in rat brain poly (A$^+$) RNA-injected *Xenopus* oocytes and excitatory amino acid receptor binding sites in rat brain membranes. Of the four monomethyl substituted derivatives tested, only the 5-methyl compound potently inhibited KA-induced currents (K_i = 13 μM). 5-Trifluoromethyl (K_i = 10 μm) and 5-ethyl (K_i = 17 μM) derivatives had potencies comparable to 5-methyl, whereas 5-*t*-butyl (K_i = 29 μM), 5-methoxy (K_i = 67 μM) and 5-phenyl (K_i = 139 μM) were less potent. 3,5-Dimethyl (K_i = 12 μM) was substantially more potent than 3,6-dimethyl (K_i = 220 μM). Within the 5-halo series, the rank order of potency was 5-I (K_i = 3 μM) > 5-Br (K_i = 10 μM) > 5-Cl (K_i = 15 μM) > 5-F (K_i = 68 μM) >> 5-H (K_i > 200 μM). Reduction of the aromatic ring resulted in a complete loss of activity for the 5-methyl compound.

Test compounds exhibited comparable potency in inhibiting KA-induced currents and [^{3}H]CNQX binding in rat brain membranes, but were weak inhibitors of [^{3}H]glutamate binding. Some compounds exhibited moderate (K_i = 40-100 μM) affinity for strychnine-insensitive [^{3}H]glycine binding sites. The 5-methyl compound blocked the KA-induced reduction in striatal choline acetyltransferase activity, and both the 5-methyl and 5-I compounds inhibited KA-induced cytotoxicity in cultured rat cortical neurons.

The findings demonstrate that selected 2-phosphonoethyl-phenylalanine derivatives are antagonists of KA/AMPA receptors. As representatives of a new chemical class of KA/AMPA antagonist, these compounds should be useful in further defining the physiological roles of KA/AMPA receptors.

613.4

RECEPTOR BINDING AND ELECTROPHYSIOLOGICAL PROPERTIES OF KAINIC ACID/AMPA RECEPTOR AGONISTS AND ANTAGONISTS. D.L. Bednar*, R.A. Zubrowski, M.A. Bailey and E.W. Karbon, Nova Pharmaceutical Corporation, Baltimore, MD 21224.

[^{3}H]CNQX binding assays and rat brain poly (A$^+$) RNA-injected *Xenopus* oocytes were used to characterize the biochemical and electrophysiological properties of several kainic acid (KA)/AMPA receptor agonists and antagonists. The rank order of potency for inhibition of [^{3}H]CNQX binding in rat cerebral cortical membranes was NBQX > CNQX > (S)-5-nitrowillardiine (NW) > (S)-5-fluorowillardiine (FW) > KA = (RS)-AMPA = (S)-5-iodowillardiine (IW) > L-BOAA. Inclusion of KSCN (100 mM) resulted in 80-, 20- and 2-fold increases in the potency of the agonist ligands AMPA, L-BOAA and KA, respectively, whereas the potency of the antagonists, NBQX and CNQX, was reduced. Amongst the agonist willardiines, the greatest increase in potency was observed with FW (20-fold), followed by IW (6-fold) and NW (4-fold). Aniracetam (1 mM), a compound which reduces KA/AMPA receptor desensitization, had no effect on AMPA potency either in the absence or presence of KSCN.

In *Xenopus* oocytes, KA produced large, non-desensitizing inward currents which were similar to those elicited by IW. In contrast, AMPA, L-BOAA and FW produced small, desensitizing responses. In the presence of either AMPA, L-BOAA or FW, KA-induced currents were markedly reduced. Likewise, responses to IW were attenuated by 50% in the presence of either AMPA or FW.

These findings suggest that in the presence of KSCN, KA/AMPA receptors adopt a conformation with greatly increased affinity for desensitizing, but not non-desensitizing agonists. Furthermore, an inverse relationship was observed between the magnitude of the KSCN-induced increase in agonist potency and the magnitude of agonist-induced steady-state currents.

613.5

THE 2,3-BENZODIAZEPINE GYKI 52466 SELECTIVELY BLOCKS AMPA/KAINATE RECEPTORS BY A NOVEL NON-COMPETITIVE MECHANISM.

S.D. Donevan* and M.A. Rogawski, Epilepsy Research Branch, NINDS, NIH, Bethesda MD 20892.

Excessive activation of non-NMDA (AMPA/kainate) excitatory amino acid receptors may play a role in the pathogenesis of epilepsy and various neurodegenerative disorders. Recent studies have demonstrated that the 2,3-benzodiazepine GYKI 52466 antagonizes non-NMDA excitatory amino acid receptor responses (Tarnawa et al., 1990; Ourdouz & Durand, 1991). In the present study we compared the effects of GYKI 52466 with that of the quinoxaline NBQX on currents evoked by AMPA and kainate in whole cell recordings from cultured rat hippocampal neurons. GYKI 52466 caused a concentration-dependent block of inward currents evoked by AMPA (IC_{50}=7.5±0.4 μM) and kainate (11±1 μM), but was inactive against currents evoked by NMDA or GABA. The EC_{50} values for kainate in the presence of 10 and 30 μM GYKI 52466 (169±2 μM and 202±18 μM, respectively) were similar to control (173±16 μM), whereas GYKI 52466 produced a concentration-dependent reduction in the maximal current evoked by kainate. In contrast, NBQX caused a concentration-dependent rightward shift in the kainate concentration-response curve with no change in the maximal response to kainate. Thus GYKI 52466 is a non-competitive antagonist, whereas NBQX acts in a competitive fashion at the glutamate recognition site. GYKI 52466 did not appear to block via an open channel mechanism as there was no voltage- or use-dependence to its actions. These results demonstrate that GYKI 52466 selectively inhibits AMPA/kainate responses by a novel noncompetitive mechanism. Noncompetitive non-NMDA antagonists such as GYKI 52466 could offer advantages over competitive blockers in the treatment of neurological disorders, particularly in situations where high levels of glutamate would render the competitive antagonists relatively ineffective.

613.6

STEREOSELECTIVE EFFECTS OF AMOA ON NON-NMDA RECEPTORS EXPRESSED IN XENOPUS OOCYTES

P.Wahl*, B. Nielsen, P.Krogsgaard-Larsen, J.J.Hansen A.Schousboe & R. Miledi PharmaBiotec Research Center, The Royal Danish School of Pharmacy, Copenhagen, Denmark, and Laboratory of Cellular and Molecular Neurobiology, UC Irvine CA 92717, USA.

There are pharmacological and therapeutic interests in compounds capable of blocking subtypes of central glutamate receptors. Pharmacological charaterization of the action of the novel non-N-methyl-D-aspartate (non-NMDA) antagonist AMOA (2-amino-3-[3-(carboxymethoxy)-5-methylisoxazol-4-yl]propionate) on glutamate receptors was investigated in Xenopus oocytes injected with mouse brain mRNA. AMOA (150 uM) produced a nearly parallel shift to the right of the dose-response curve for kainate induced currents. AMOA was found to have two different effects on AMPA receptors: (1) currents elicited by low concentrations of AMPA (6 uM) were inhibited by AMOA with an IC_{50} value of 160 +/- 19 uM; (2) currents elicited by high concentrations of AMPA (100 uM) were potentiated with an IC_{50} value of 88 +/- 22 uM. The maximal potentiating effect of AMOA on AMPA currents was around 170%. Quantitative analysis showed that the apparent K_d value of AMOA with respect to its potentiation of AMPA responses was about 15-fold lower that its K_i value for inhibition of AMPA responses. This suggests that the ability of AMOA to potentiate or inhibit AMPA responses may be mediated by different sites. Nonetheless, the two opposing effects of AMOA on AMPA responses are specific for the L-configuration of AMOA. This unusual antagonistic/agonistic property of AMOA may explain its unusual properties with regard to antagonism of non-NMDA receptor mediated events previously described.

613.7

NMDA RECEPTOR SPLICE VARIANTS DIFFER IN THEIR RESPONSE TO ETHANOL. S.N. Treistman*, H. Bayley, V.V. Koltchin, and V. Anantharam. Dept. of Pharmacology, Univ. of Mass. Medical School, Worcester, MA 01655 and Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

A number of laboratories have reported the NMDA receptor to be very sensitive to ethanol, and the reduction of current through this receptor/channel may underlie some of the behavioral effects of ethanol. Using RT-PCR, we have isolated four splice variants of the NMDA receptor from rat brain (see V. Anantharam abstract, this meeting). The variants, in which each of two cassettes (21 and 37 amino acids) are present or absent, have been expressed in *Xenopus* oocytes, and their response to ethanol has been examined. In all of the splice variants 25-100 mM ethanol reduces the inward current evoked by 100 μM NMDA. However, the magnitude of this reduction differs among the different variants. The rank-ordering of the variants according to the reduction of NMDA-evoked current in the presence of ethanol, with the most sensitive first, is: NMDAR1-LL > NMDAR1-LS > NMDAR1-SL > NMDAR1-SS. In addition to differences in their ethanol sensitivity, we find that the apparent desensitization of the variants differs, with NMDAR1-LL showing significantly greater desensitization than NMDAR1-SS. We are currently determining the relationship between the apparent desensitization of the receptor and its response to ethanol. Work supported by ADAMHA grant AA05542.

613.8

NON-SELECTIVE ACTIONS OF ETHANOL AS AN EXCITATORY AMINO ACID (EAA) ANTAGONIST ON RAT SPINAL NEURONES IN VIVO. D. Lodge*, S.N. Davies and M.G. Jones. Royal Veterinary College, London NW1, UK.

Recent reports have indicated that ethanol selectively reduces N-methyl-D-aspartate (NMDA) induced excitation in several neuronal preparations. To examine this action of ethanol in vivo, we studied the effects of both local pressure ejection and systemic administration of ethanol on responses of spinal and brainstem neurones in anaesthetised rats to iontophoretic administration of NMDA, quisqualate, kainate and AMPA.

Pressure ejection of ethanol produced variable effects on responses to EAAs, sometimes with reductions in spike height, but selective antagonism of NMDA was not observed. Intravenous ethanol up to 4g/kg reduced effects of all EAAs on some neurones and the higher doses were sometimes accompanied by respiratory and/or cardiovascular effects but no preferential reduction of responses to NMDA were observed.

In the same protocol, LY274614 (1mg/kg), ketamine (5mg/kg) and (-)-b-cyclazocine (0.25mg/kg) blocked responses to NMDA whereas GYKI52466 (10mg/kg) and NBQX (5mg/kg) blocked those to AMPA/kainate.

In conclusion, no evidence was found to support the view that ethanol is a selective NMDA antagonist in vivo.

613.9

AGENTS WHICH ANTAGONIZE THE NMDA RECEPTOR-CHANNEL COMPLEX IN VIVO ALSO CAUSE DISTURBANCES OF MOTOR COORDINATION. A. J. Carter* and R. E. Miller, Dept. of Pharmacology, Boehringer Ingelheim KG, W-6507 Ingelheim, Germany.

We have investigated the relationship between functional antagonism of the NMDA receptor-channel complex in vivo and disturbances of motor coordination. Antagonism of the NMDA receptor-channel complex was assessed by measuring the ability of various compounds to inhibit NMDA-induced lethality in mice. Disturbances of motor coordination were measured by the rotarod technique. Noncompetitive NMDA antagonists of both arylcyclohexamine (PCP, (+)MK-801, (-)MK-801, ketamine) and benzamorphan (dextrorphan, N-allylnormetazocine) structure, competitive antagonists (CGP 37849, CGP 39551) and a glycine site antagonist (L-687,414) inhibited NMDA-induced lethality after subcutaneous administration. These compounds also interfered with motor coordination. There was an excellent correlation (r=0.8) between the two tests. Several other antagonists of the glycine site (7-chlorokynurenic acid, 5,7-dichlorokynurenic acid, ACPC and (+)HA-966) did not inhibit NMDA-induced lethality after systemic administration of doses up to 100 mg/kg and did not interfere with motor coordination. We conclude that any compound which antagonizes the NMDA receptor in vivo, irrespective of whether it is a noncompetitive, competitive or glycine site antagonist, will disturb motor coordination.

613.10

EFFECTS OF THE NMDA ANTAGONIST, KETAMINE, IN HEALTHY HUMAN SUBJECTS. J.H. Krystal*, L.P. Karper, J.P. Seibyl, R. Delaney, G. Freeman, G.R. Heninger, M.B. Bowers, J.D. Bremner, D.S. Charney. Schizophrenia Biological Research Center West Haven VA Med. Cntr., West Haven, CT 06516.

Non-competitive NMDA antagonists, such as PCP, are thought to produce a schizophrenia-like syndrome in humans. This hypothesis was formally evaluated in humans using ketamine. METHODS: Healthy subjects (n=18) completed 3 test days in a randomized order, under double-blind conditions: placebo, ketamine 0.1 mg/kg, ketamine 0.5 mg/kg. All drugs were infused i.v. over 40 minutes. RESULTS: The Mini-Mental Status Examination was not effected by either ketamine dose. Positive and negative symptoms of schizophrenia assessed by the BPRS, perceptual changes assessed by the Perceptual Aberration subscale of the Psychosis Proneness scale, and dissociative symptoms assessed by the Clinician Administered Dissociation Scale, all showed dose-related increases. Frontal lobe function assessed by Wisconsin Card Sort perseverative errors and by assessment of verbal fluency showed dose-related impairment. Ketamine also produced dose-dependent impairment in delayed but not immediate recall of object names. Ketamine also dose-dependently increased plasma cortisol and prolactin and suppressed plasma HVA. IMPLICATIONS: Ketamine transiently produced a broad range of the symptoms and neuropsychological deficits characteristic of schizophrenic patients. These data place further emphasis of evaluations of excitatory amino acid function in schizophrenia.

613.11

SOMATOSTATIN CONTAINING DENTATE HILAR NEURONS IN PRIMARY CULTURE EXPRESS Ca^{2+} PERMEABLE KAINATE RECEPTORS. Simon J. Gibbons* and Richard J. Miller. Dept Pharmacol. and Physiol. Sci., University of Chicago, 947 E. 58th Street, Chicago, IL 60637. USA.

We have studied the excitatory amino acid receptor pharmacology in a population of hippocampal GABA-containing neurons in primary culture. Neurons were dissociated from the dentate gyrus of 5 day old rats and cultured in a defined serum free medium over a feeding layer of astrocytes. These cultures are highly enriched (>85%) in neurons which express immunoreactivity for somatostatin-14 and GABA but not the Ca^{2+} binding proteins parvalbumin or calbindin D28K. Together with the morphological appearance of the cells, this information suggests that they represent a population of neurons which are particularly sensitive to ischaemic insults in vivo and are exceptionally vulnerable in human limbic epilepsy (Freund et al. (1992) Brain Res. Bull. 28 27, deLanerolle et al. (1987) Epilepsia 28 600).

Using fura-2 based microfluorimetry non-NMDA glutamate receptor-mediated rises in $[Ca^{2+}]_i$ were observed (EC50 values for AMPA = 11.5μM and Kainate = 55.8μM, n=6 to 8). In the absence of extracellular Mg^{2+}, with 10μM glycine added to the perfusate, responses to 10μM NMDA were also observed (mean $\Delta[Ca^{2+}]_i$ = 172nM, n = 5). Although some cells have caffeine sensitive intracellular stores, no metabotropic glutamate receptor-activated $[Ca^{2+}]_i$ rises have been detected. In Na^+ free medium, kainate caused concentration dependent rises in $[Ca^{2+}]_i$ (EC50 = 373μM). This effect was reduced by CNQX. In addition, kainate mediated uptake of Co^{2+} was observed in these cells using a silver staining technique. Thus it appears that dentate gyrus hilar neurons have Ca^{2+} permeable kainate receptors which may contribute to the selective vulnerability of these cells in vivo.

SJG is supported by a long term fellowship from the Human Frontier Science Program.

NMDA DIFFERENTIALLY STIMULATES SOMATOSTATIN (SS) BUT NOT NEUROPEPTIDE Y (NPY) GENE EXPRESSION IN CORTICAL SS/NPY PRODUCING NEURONS. Y.C. Patel, A. Warszynska, G. Kent, J.-L. Liu, D.N. Papachristou, and S.C. Patel*. Fraser Labs, McGill University, Montreal, Quebec, and Newington VAMC, CT.

SS and NPY are coproduced in a subpopulation of neurons that are selectively resistant to NMDA neurotoxicity. We have previously reported that quinolinic acid (QA) and NMDA augment SS-mRNA in cultured fetal rat cortical neurons. Here we have examined coregulation of SS and NPY gene expression by these 2 agents in this system and compared their effects with those of forskolin (F) and PMA known to activate SS and NPY gene transcription by cAMP or protein kinase-C (PKC)-dependent mechanisms. Cultures were treated with different agents for up to 24 h. mRNA for SS and NPY was determined by Northern analysis with cRNA probes.

	SS-mRNA (fold increase)		NPY mRNA (fold increase)
QA 5 mM	3.9^+		1.1
NMDA 5 mM	5.0^+	$^+p < 0.05$	0.65
forskolin 10 uM	4.5^+	vs control	1.6^+
PMA 0.4 uM	1.5^+		2.9^+

QA and NMDA stimulated mRNA for SS but not for NPY. In contrast, F and PMA augmented both SS and NPY mRNA. In time-course studies NMDA/QA induction of SS-mRNA occurred after a delay of 16 h. Transcriptional regulation of the SS gene was examined by acute transfection of cortical cultures with an SS promoter-CAT construct. CAT activity was stimulated 3-4 fold with F but not by NMDA or QA. These data show differential NMDA stimulation of SS but not NPY mRNA. NMDA stimulation of SS gene expression does not require activation of the cAMP or PKC signalling pathways. It is not transcriptionally mediated and is likely posttranscriptional as also suggested by the delay in SS-mRNA induction.

PROCESS OUTGROWTH, GROWTH CONES AND SPROUTING VIII

614.1

MAPPING OF CYTOSOLIC CALCIUM CONCENTRATION IN GROWING AXONS OF RAT SENSORY NEURONES. S.R. Bolsover, M.R. Duchen* and A. Amato. Physiology Department, University College London.

Previous work using the calcium indicator Fura-2 has suggested the presence of steady-state gradients of cytosolic free calcium concentration ($[Ca^{++}]_i$) in various types of nerve cells that are extending axons or dendrites. These measurements were subject to possible errors caused by uptake of Fura-2 into intracellular organelles. We have therefore used dextran-conjugated Fura-2, which is not taken up into organelles, to measure $[Ca^{++}]_i$ in the axons and growth cones of sensory neurons in culture.

After injection with Fura-2 dextran (MW ≈10,000, Molecular Probes) dorsal root ganglion cells from adult rats were incubated in Hams F14 medium supplemented with 4% Ultraser G (Gibco) in an atmosphere of 5% CO_2 and 95% air. $[Ca^{++}]_i$ was imaged in 31 growth cones which were displaying a full repertoire of behaviours including active forward growth. Mean growth cone $[Ca^{++}]_i$ was 225±44nM, n=31. No steady-state gradients of $[Ca^{++}]_i$ were observed, either within the growth cone (leading edge $[Ca^{++}]_i$ minus mean growth cone $[Ca^{++}]_i$ = 29±32nM, n=30) or along the axon (soma $[Ca^{++}]_i$ minus growth cone $[Ca^{++}]_i$ = 88±87nM, n=30). Taken together with similar findings in mouse neuroblastoma cells (Silver *et al.*, 1989) these data strongly refute the model that steady-state $[Ca^{++}]_i$ gradients are a general feature of growing neurites.

Goldberg and Burmeister (1989) described three stages in the advance of axons of *Aplysia* neurons: protrusion, engorgement and consolidation. In rat sensory neurones $[Ca^{++}]_i$ was identical in regions of the growth cone undergoing each of these behaviours. Thus spontaneous changes in $[Ca^{++}]_i$ do not appear to trigger these behaviours in isolated neurones. However, an increase of $[Ca^{++}]_i$ to >400nM, whether spontaneous or induced by A23187, caused growth cone retraction.

614.2

SPATIAL GRADIENTS OF CYTOSOLIC CALCIUM DURING DEPOLARIZATION OF DEVELOPING SENSORY NEURONES. F.A. Al-Mohanna, A. Amato and S.R. Bolsover*. Physiology Department, University College London

Previous work using mouse neuroblastoma cells (Silver *et al.*, 1990) has shown that depolarization produces marked spatial gradients of cytosolic free calcium concentration ($[Ca^{++}]_i$). Little or no $[Ca^{++}]_i$ change was seen in the neurite, while $[Ca^{++}]_i$ changes in the growth cone were restricted to a small number of spatially restricted hotspots. We have now examined whether similar $[Ca^{++}]_i$ gradients are set up by depolarization of primary sensory neurones. As before, we used the fall of Fura-2 fluorescence during steady illumination with 380nm light to measure $[Ca^{++}]_i$ changes with a time resolution of 60msec.

During the first day after plating on a laminin substrate, dorsal root ganglion cells isolated from adult rats extend large (up to 40µm across) growth cones connected to the cell body by broad, short neurites. When cells at this early stage of axon outgrowth were whole-cell patch clamped and depolarized, $[Ca^{++}]_i$ increased in all regions of the cell, so that no spatial gradients of $[Ca^{++}]_i$ developed in the neurites and growth cones.

After two or more days in culture, cells exhibited the more familiar appearance of long narrow axons terminated by small (up to 20µm across) growth cones. Since these cells are not suitable for voltage clamp, we examined $[Ca^{++}]_i$ changes during a train of five action potentials delivered during a 50msec period. Unlike the situation in the early growth cones, depolarization produced a clear $[Ca^{++}]_i$ gradient in the growth cones, with the leading edge of the growth cone showing a greater $[Ca^{++}]_i$ increase than the more proximal region of the growth cone. These results raise the possibility that electrical activity could selectively activate calcium-dependent processes at the growth cone leading edge.

GROWTH CONE COLLAPSE, A DETERMINANT OF SYNAPSE SPECIFICITY. N.I. Syed*, K. Lukowiak and A.G.M. Bulloch. Departments of Physiology and Anatomy, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

A model system for examining synaptogenesis is provided by the large, identified dopamine neuron (RPeD1) of the adult mollusc *Lymnaea stagnalis*. This interneuron exhibits robust sprouting and synaptogenesis with appropriate targets *in vitro*. Behavioral analysis of the growth cones from both RPeD1 and the appropriate targets indicates mutual attraction. We present evidence that this attraction of target cell growth cones towards RPeD1 growth cones prior to synaptogenesis is mediated via transmitter/receptor interaction. We also demonstrate that RPeD1 cell growth cones contain and release dopamine and that the target cell growth cones respond appropriately to the exogenous application of dopamine. However, when cultured with inappropriate target cells RPeD1 does not form synapses, rather its growth cone induces the collapse of approaching target growth cones either upon contact or even before filopodial contact is made. Utilizing time-lapse video microscopy we present evidence that this contact and non-contact mediated collapse of inappropriate target cell growth cones by RPeD1 is mediated via transmitter receptor interaction involving second messenger pathways other than Ca^{2+}. Our experiments suggest that the release of dopamine from RPeD1 growth cones and the presence of appropriate receptor on the target may provide the basis for cell-cell recognition during synaptogenesis in this system.

DEPOLARIZATION TRIGGERED NEURITE RETRACTION OF LEECH CELLS IN CULTURE IS SUBSTRATE AND CALCIUM DEPENDENT. M.D. Neely* and M. Gesemann, Biocenter Univ. Basel, 4056 Basel, Switzerland

The substrate upon which a leech neuron is placed influences not only its pattern of growth and the distribution of Ca^{2+} channels on its surface, but also the degree of retraction following electrical stimulation (S. Grumbacher-Reinert and J. Nicholls, 1992, J.Exp.Biol. 167:1-14). To investigate how substrates regulate neurite outgrowth, the effects of depolarization (by raised extracellular K^+) were analyzed in cells grown on leech extracellular matrix (ECM) and the plant lectin Concavalin A (Con A). In cells on ECM, K^+ depolarization, like electrical stimulation, led to neurite retraction. This retraction was inhibited by Mg^{2+} and therefore appeared to be a Ca^{2+} mediated effect. Cells grown on Con A did not respond with retraction of their neurites after depolarization. Scanning electron microscopy of growth cones on ECM revealed filopodial and lamellipodial retraction following high K^+ exposure, while growth cones on Con A showed no change after the same treatment. Analysis of the effect of depolarization on the cytoskeleton revealed changes in the microfilaments in cells on ECM. No alteration in microfilamental organization after high K^+ application was observed in cells on Con A. These results demonstrate the key role of substrate molecules in defining the final form of a neuron.

SERUM LYSOPHOSPHATIDATES CAUSE RECEPTOR MEDIATED NEURITE RETRACTION IN PC12 CELLS. G. Tigyi, D. L. Dyer & R. Miledi*. Lab. of Cellular and Molecular Neurobiology, Dept. of Psychobiology, University of California, Irvine, CA 92717 Lysophosphatidic acids (LPA's), produced during blood coagulation and bound to serum albumin were found to be the principal serum component causing neurite retraction in NGF differentiated PC12 cells. LPA's purified from albumin, or of synthetic origin, elicited neurite retraction with an ED_{50} in the micromolar range. Application of LPA's caused the intracellular level of IP3 to increase ~10 fold within 7.5 min. Monitoring intracellular free [Ca^{2+}] levels with Fura2 ratio-imaging revealed a concomitant transient increase from the resting level (<100nM) to 300 nM. Neurite retraction was abolished in the absence of extracellular Ca^{2+}. Divalent cation blockers of Ca^{2+} channels had a similar effect; however, organic blockers of the different classes of voltage gated Ca^{2+}-channels were ineffective. This suggests the involvement of a non-voltage activated Ca^{2+}-influx mechanism. Bradykinin and carbachol activated similar second messenger events without causing neurite retraction. Thus, increased PIP2 turnover and a transient rise in Ca^{2+} are not sufficient for neurite retraction by LPA. Neurite retraction was also prevented by pretreatment with cholera toxin, suggesting the involvement of a G_s-mediated, cAMP-dependent pathway. It is concluded that LPA-induced neurite retraction is not due to an increase in [Ca^{2+}] alone, but depends on interactions of different second messenger pathways. SINGLE CELL LASER INACTIVATION OF FASCICLIN II PERTURBS AXONOGENESIS IN THE GRASSHOPPER LIMB BUD. J.L. Schnipper, M.S. Shankland* and D.G. Jay. Dept. Cell. & Dev. Biol., Harvard Univ., Cambridge, MA 02138 and Dept. Anat. & Cell Biol., Harvard Med. Sch. Boston, MA 02115.

Fasciclin II is a neural cell adhesion molecule that is structurally similar to NCAM and is expressed by the Til pioneer neurons during axonogenesis. Previously, we showed that chromophore assisted laser inactivation (CALI) directed against fasciclin II results in a perturbation of axonogenesis but not axon adhesion of the Til neurons (Booth et al., Neurosci. Abstr. 17: 14, 1991). Recently, single cell CALI has been developed, in which the laser is focused on one cell (Sydor et al., Neurosci Abstr. 17: 14, 1991). We now show that single cell CALI against fasciclin II on the Til neurons perturbs axonogenesis with high efficacy and reveals a three-hour time period during which CALI will cause this perturbation.

Laser irradiation of Til neurons in whole-mounted grasshopper embryos at the 30% stage of development incubated with malachite green-labeled anti-fasciclin II blocked axon initiation (15/18). No significant disruption in axonogenesis was seen in non-irradiated contralateral limbs (n=47), or in embryos incubated with dye-labeled anti-fasciclin I regardless of laser irradiation (n=15). Single-cell CALI against fasciclin II had no effect on axon adhesion (n=20), in contrast with CALI against fasciclin I. Also, single cell CALI against fasciclin II was only effective between complete Til cell emergence from the epithelium and these cells becoming tear-shaped. This stage is coincident with the localization of cytoskeletal elements and organelles to the proximal pole from which the growth cone will emerge (Lefcort and Bentley, J. Cell Biol. 108: 1737, 1989). The higher efficacy of single cell CALI over large scale CALI in perturbing axonogenesis may be due to greater antibody accessibility, more precise aiming of the laser, and the ability to perform CALI at precise stages based on Til cell morphology. This last feature also enabled us to pinpoint the narrow time window during which CALI is effective in perturbing axonogenesis.

GLYCOSAMINOGLYCANS AS MEDIATORS OF RETINAL GANGLION CELL BODY AND AXON POLARITY. P. A. Brittis* and J. Silver. Dept. of Neurosciences, CWRU, Cleveland, OH 44106

In the developing vertebrate retina differentiating retinal ganglion cells retain a radial configuration while maintaining primitive endfeet attachments at both the ventricular and vitreal surfaces of the retinal neuroepithelium. We have previously shown that early in retinal development, only the vitreal endfeet are emersed in a dense matrix of chondroitin sulfate (CS).The perturbation of the glycosaminoglycan (GAG) side chains with chondroitinase ABC in whole developing retinas disrupts several stages of retinal ganglion cell differentiation such as the temporal control of gangliogenesis, cell soma polarization, and the control over the invariance of axonal direction (Brittis et al. *Science*, 1992).

After whole rat retinas at E.13 were cultured and exposed to free chondroitin-6-sulfate GAG chains for 48 hours, the exogenous CS was distributed in high concentrations around the ventricular endfeet. In direct contrast to control retinas and retinas treated with a chondroitin sulfate proteoglycan in solution, all of the retinal ganglion cell bodies and axons in the GAG treated eyes were found within this novel layer of CS matrix. This repolarization was concentration dependent and was marked by the retraction of the vitreal end feet followed by the relocation of the retinal ganglion cell bodies to the ventricular surface of the neuroepithelium. This newly polarized optic fiber layer was anatomically indistinguishable from a normal nerve fiber layer except that the individual axons were not oriented in any particular direction.

We show that the ability of immature retinal ganglion cells to initiate axons is not restricted to the vitreal endfoot and that the ventricular endfoot also has this potential. We have also found that cell body and axon polarity in intact retinas can be induced by the location and concentration of the GAG component of the extracellular milieu.

NCAM, L1 AND N-CADHERIN INFLUENCE NEURITE OUTGROWTH FROM RETINAL NON-PROJECTION NEURONS. I. Kljavin*, Neurosci. Res. Group, U. Calgary; C. Lagenaur, Dept. Neurobio. Anat. and Cell Sci, U. Pittsburgh, J. Bixby, Dept Pharmacology, U. Miami Sch. Med, T. Reh, Dept. Bio. Structure, U. Washington.

NCAM, N-cadherin and L1 are cell adhesion molecules now known to be important for promoting axon growth from projection neurons, eg. retinal ganglion cells. However, the CAMs important for regulating axon outgrowth from non-projection neurons, like amacrine and photoreceptor cells, are not known. Such local circuit neurons extend their neurites on cellular surfaces not normally encountered by the ganglion cell axons, to terminate on neighboring cells. Therefore, we compared neurite outgrowth from rat ganglion cells, amacrine cells and rods in vitro on immunopurified forms of NCAM, L1 and N-cadherin. Single isolated early postnatal ganglion cells grow neurites on all three cell adhesion molecules. NCAM and N-cadherin strongly promote neurite outgrowth from either early (P3) or late (P10) postnatal amacrine cells, while L1, promotes neurite outgrowth from only a small percentage of the amacrine cells. None of these cell adhesion molecules support neurite outgrowth from early postnatal rods, but, surprisingly, NCAM stimulated vigorous neurite extension from rods isolated from postnatal day 10. These results show that NCAM, N-cadherin, and L1 can promote neurite outgrowth from local circuit neurons, but the use of any particular CAM is dependent on the cell type and the developmental period. PATTERNS OF GROWTH CONE CONTACT WITH DIFFERENT ADHESIVE SUBSTRATES AS DETERMINED BY INTERFERENCE REFLECTION MICROSCOPY J.A. Drazba*, C.L. Smith, and V. Lemmon, Laboratory of Neurobiology, Laboratory of Neural Control, NINDS, NIH, Bethesda, MD 20892 and Dept. of Neurosciences, Case Western Reserve University School of Medicine, Cleveland, OH, 44106

We examined dynamic changes in the closeness of growth cone contacts with laminin, L1/8D9, or N-cadherin substrates by measuring reflection intensities in images obtained with time-lapse interference reflection microscopy (IRM). Growth cones from both chick retinal ganglion cells and sympathetic neurons were observed. The closeness of contact of individual growth cone membrane patches on each substrate modulated rapidly. However, there were marked differences in the overall extent of growth cone contacts to different substrates. Growth cones on laminin had the fewest areas of close contact, growth cones on L1 had the most, and those on N-Cadherin were intermediate between these two. Measurements of growth cones were compared to those of fibroblasts, which exhibited a much broader range of reflection intensities. The focal contacts of fibroblasts were closer than any of the contacts of growth cones. The IRM profiles of growth cones observed in these studies reveal quantitative differences in the closeness of growth cone adhesion to different substrate molecules and correlate with reported differences in growth rate and morphology observed on these substrates.

GROWTH CONES ARE ACTIVELY INFLUENCED BY SUBSTRATE-BOUND ADHESION MOLECULES.
S.M. Burden*, H.R. Payne, and V. Lemmon, Dept. of Neurosciences, Case Western Reserve University School of Medicine, Cleveland, OH, 44106

As axons advance to appropriate target tissues during development, their growth cones encounter a variety of cell adhesion molecules (CAMs) and extracellular matrix molecules (ECMs). Purified CAMs and ECMs influence neurite outgrowth *in vitro* and are thought to have a similar function *in vivo*. We previously utilized scanning electron microscopy to compare morphological characteristics of retinal ganglion cell (RGC) growth cones on several substrates. We found that growth cone lamellipodial area and number of filopodia per growth cone are affected by the substrate bound adhesion molecule (Payne, et.al.,(1992) Cell Motil. and Cytoskel. 21:65-73). In this report, we use timelapse videomicroscopy to examine dynamic transformations of RGC growth cones as they progress from L1/8D9, N-cadherin, or laminin onto a different substrate. Contact made by the leading edge of a growth cone with a new substrate causes a rapid and dramatic alteration in growth cone morphology. Frequently, the changes encompass the entire growth cone including those regions not in direct contact with the new substrate. These studies demonstrate that growth cones are actively affected by the substrate, probably through a transmembrane signalling mechanism.

INTERFERENCE REFLECTION MICROSCOPIC (IRM) STUDY OF CHANGES IN GROWTH CONE-SUBSTRATUM CLOSE CONTACTS AT BOUNDARIES BETWEEN LAMININ AND FIBRONECTIN. T. M. Gomez* and P. C. Letourneau, The University of Minnesota, Minneapolis, Minnesota 55455.

Growth cones of chick dorsal root ganglia (DRG) neurons exhibit a variety of behaviors in culture at a boundary between glass-adsorbed laminin (LMN) and fibronectin (FN) (Gomez et al., Soc. Neurosci. Abst. 17:738, 1991). Growth cones that encounter LMN while migrating on FN usually cross onto LMN, often with an increased rate of neurite elongation and altered morphology. Reciprocally, growth cones that encounter FN while migrating on LMN often reorient their direction of migration and maintain association with LMN. It is not known whether differences in substratum adhesion contribute to the behavior of DRG growth cones at LMN-FN boundaries.

To address this question, growth cone contact with LMN and FN treated substrata was assessed using IRM. Our results confirm a previous report that DRG growth cones express closer contacts when growing on FN than on LMN (Gundersen, J. Neurosci. Res. 21:298-306, 1988). A new finding, however, using time-lapse IRM, was that the nature of contacts of a single growth cone changes rapidly as it passes from one substratum onto another, such that a growth cone in contact with both substrata can show two patterns of attachment. Growth cones accelerate and expand their lammelipodia as they migrate onto LMN from FN and simultaneously lose many close contacts, acquiring an IRM pattern typical for migration on LMN alone. Alternatively, growth cones that extend onto FN from LMN increase their total area of close contact and acquire an IRM pattern typical of migration on FN alone.

These data suggest that: 1) the extent of adherence of a growth cone to LMN or FN does not necessarily predict the choice of substratum and; 2) the pattern of close contacts expressed by a growth cone, as revealed by IRM, can change locally as a growth cone extends from LMN onto FN or from FN onto LMN. EXPRESSION OF L2/HNK-1 IN REINNERVATED PERIPHERAL NERVE. T.M.Brushart*, R.Martini, and M.Schachner. Depts. of Orthopaedics & Neurology, Johns Hopkins, Balt., MD, and Swiss Federal Institute, Zurich, Switz.

The cell adhesion molecule-associated carbohydrate epitope L2/HNK-1 is abundant in peripheral motor nerve, but scarce in sensory nerve (Martini et al'92). These experiments evaluate the expression of L2 by denervated motor and sensory pathways after reinnervation by motor or sensory axons. Surgeries were performed on the femoral nerves of adult C57Bl6 mice, in which motor and sensory axons intermingle proximally, but are segregated distally into sensory and motor branches. Six groups were prepared: 1) distal sensory and motor branch repair 2) crossed distal repair, sensory to motor, motor to sensory 3) proximal trunk repair 4) correct intercalated graft-sensory graft in sensory branch, motor graft in motor branch 5) incorrect intercalated graft-sensory in motor, motor in sensory. Sensory axons did not induce L2 expression in sensory or motor pathways. Motor axons induced L2 in some sensory pathways, but correctly reinnervated motor pathways expressed L2 more vigorously. Regenerating axons thus alter pathway characteristics, yet pathways retain evidence of their previous axonal associations. The strong interaction of motor axons with old motor pathways suggests that L2 expression is associated with preferential reinnervation of motor pathways by regenerating motor axons (Brushart '88,'90).

615.2

EXPRESSION OF mRNAs FOR NGF, BDNF, NT-3, *trk*, *trk*B, AND *trk*C IN SPINAL CORD SCAR TISSUE IN THE ADULT RAT AND CAT. Frisén, J., Verge, V.M.K., Cullheim*, S., Fried, K., Hökfelt, T., and Risling, M. Departments of Anatomy, and Histology and Neurobiology, Karolinska Institute, S-104 01 Stockholm, Sweden.

Lesioned CNS axons sprout into scar tissue formed at the injury, but fail to regrow for any significant distance. It is not fully understod by which mechanisms the scar tissue assists sprouting. We have examined expression of neurotrophins and their receptors in two different types of spinal cord lesions, with in situ hybridization and immunohistochemical techniques. In adult rats the dorsal funiculus was cut at the mid-thoracic level and a longitudinal incision was made rostral to the transection in order to extend the lesion. In adult cats a longitudinal incision was made in the lumbar ventral funiculus which results in intramedullary axotomy of motoneurons. The scar tissue that forms after these lesions is known to assist and sustain longterm axonal sprouting and lack blood-brain barrier function. Elevated expression of mRNA for nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), and neurotrophin-3 (NT-3) was seen predominantly around the border of the scar and in surrounding neuropil and white matter, after both types of lesions, with some expression within the dorsal funiculus scar tissue. In the ventral funiculus lesioned animals labelled cells were also seen in the motor nucleus neuropil. Low affinity NGF-receptor (LNGFr) mRNA was increased in the scar tissue after both types of lesions, and immunoelectron microscopy localized LNGFr-immunoreactivity mainly to axons and perivascular cells. Preliminary results regarding localization of mRNAs for the *trk*-family show all three *trk*s (*trk*, *trk*B, and *trk*C) to be increased in the scar border, neuropil and white matter ipsilateral to the lesion. In addition, both full-length and truncated forms of *trk*B were also abundantly expressed within the scar tissue. The expression of mRNA for these trophic factors and receptors could be of importance for the permissiveness to axonal sprouting in spinal cord scar tissue. Macrophages which have admittance to the scar tissue, in the absence of blood-brain barrier, may be involved in the regulation of the studied mRNAs.

615.3

CNS SCARRING IN DEVELOPING AND MATURE ANIMALS EXAMINED WITH ANTIBODIES TO GFAP, G-CAM, NCAM AND THE 11-59 AND TED15 ANTIGENS. J.D. Peduzzi*, T.B. Grayson, and E.E. Geisert, Jr. Department of Physiological Optics (J.D.P.) and Department of Cell Biology, University of Alabama at Birmingham, Birmingham, Alabama 35294.

A major barrier to CNS regeneration is the glial scar that forms following injury. Astrocyte maturation correlates with the lack of axonal regeneration. We used several antibodies to examine scar formation in developing rat brain.

Cortical lesions were made on postnatal day 2 (P2), P9, P18 and adult rat. The animals were deeply anesthetized and sacrificed 10 days later. Brains were processed for immunohistochemistry using antibodies to GFAP; NCAM; G-CAM (a recently identified adhesion molecule - Geisert,E.E., T.P. Murphy, M.H. Irwin & H. Larjava, NS Lett. 133:262, 1991); 11-59 antigen (involved in neuron-glia interactions); and TED15 antigen (a brain-specific keratan sulfate proteoglycan - Geisert, E.E., R.C. Williams & D.J. Bidanset, Brain Res. 571:165, 1992).

A scar was consistently observed following a stab wound at P9 or older. Injuries at P2 gave variable results: some animals formed scars and others had no reactive gliosis. Intense G-CAM and TED15 but little NCAM or 11-59 staining was found at the scar's edge. This suggests that G-CAM and TED15 are involved in CNS response to injury. Supported by Spinal Cord Society & Whitehall Foundation.

615.4

NGF RECEPTOR EXPRESSION ALONG THE PNS/CNS DORSAL ROOT AXON PATHWAY. A.M. Avellino, K. C. Andrus, and M. Kliot*. Dept. of Neurological Surgery, Univ. of WA. and Seattle VAMC, Seattle, WA. 98108.

Expression of NGF and its low affinity receptor (NGFr) by Schwann cells increases dramatically in peripheral nerve distal to an axonal injury and then decreases back to negligible baseline levels following successful axonal regeneration (Johnson & Taniuchi, 1987). In contrast, oligodendrocytes and astrocytes do not express NGFr and also either inhibit or do not support comparable axonal growth (Snider & Johnson, 1989). These findings suggest that the expression and distribution of NGFr may explain, at least in part, the preferential ability of the adult mammalian PNS to promote axonal growth as compared to the CNS. To test this hypothesis, we have studied the expression of NGFr along the PNS/CNS pathway traversed by dorsal root sensory fibers.

Using a polyclonal antibody to the NGFr (provided by M. Bothwell), we have studied its expression both normally and following dorsal root transection. Tissue was cut in the parasaggittal plane so as to visualize the dorsal root and its entry zone (DREZ) as well as the spinal cord in the same section. Immunohistochemical staining has demonstrated the following findings: 1) NGFr is normally present, at low levels, in the PNS but not the CNS portion of the dorsal root pathway with an abrupt transition occuring at the DREZ, 2) ventral roots demonstrate very little if any NGFr staining normally, and 3) following dorsal root transection, NGFr staining increases dramatically in its PNS but not CNS portion. These results suggest that the absence of NGFr expression within the CNS portion of the dorsal root pathway following axonal injury may contribute to the regenerative failure observed following a dorsal root crush injury (Liuzzi & Lasek,1987/Stensaas et al.,1987/Kliot et al.,1990).

615.5

CHANGES IN EXPRESSION OF JUN AND KROX PROTEINS AND IN NITRIC OXIDE METABOLISM FOLLOWING TRANSECTION OF THE MEDIAL FOREBRAIN BUNDLE IN THE RAT CNS. T. Herdegen , S. Brecht, R. Bravo[1] and M. Zimmermann, II. Physiol. Institut, D-6900 Heidelberg; [1]Bristol-Myers Squibb Pharm. Inst, Princeton, USA.

In anaesthetized SD rats, the medial forebrain bundle (MFB) was unilaterally transected by a 1 mm blade via craniotomy in a stereotaxic frame at Bregma -2.0 and expression of JUN, FOS and KROX nuclear proteins was assessed by immunocytochemistry. This resulted in axotomy of neurons located in the medial thalamus, ncl. parafascicularis of thalamus, ncl. mammilaris, ventral tegmentum and substantia nigra. Neuronal cell nuclei in these areas showed an ipsilateral expression of c-JUN, JUN D and KROX-24 (syn. Zif/268, EGR-1, NGFI-A). The proteins appeared within 12-24 h and had a maximal expression after 48 h. JUN D and KROX-24 declined after 30 days whereas c-JUN still persisted on a submaximal level for up to 60 days (the longest investigated period). c-FOS, FOS B, JUN B and KROX-20 (syn. EGR-2) proteins were not induced. Further investigations will elucidate dependence of expression on period of survival, age and length of the proximal nerve stumps. MFB lesion also induced changes in the nitric-oxide metabolism in axotomized neurons such as increase of activity of nitric-oxide synthase. Supp. by DFG.

615.6

ACETYLCHOLINESTERASE IN DENERVATED AND REGENERATING FROG MUSCLES. B. Haesaert and L. Anglister*. Anatomy Dept., Hebrew Univ. Med. Sch., Jerusalem 91010, Israel.

Acetylcholinesterase (AChE) in muscle appears as globular (G) and asymmetric (A) molecular forms, differing in structure, solubility and location. The enzyme is highly concentrated at neuromuscular junctions. Our studies, carried out on frog muscles, were aimed to determine the effect of denervation on AChE produced by myofibers. In cutaneus pectoris muscles the major globular forms, distinguished by their sedimentation coefficients, are 4-6S AChE (G_1, G_2, 50-60%) and 10.8S (G_4, 10-15%). The major asymmetric form is a 17.5S AChE (A_{12}, 15-20%). Following denervation and irreversible inactivation of all original AChE in the muscles, the myofibers have newly produced AChE at junctional areas, that was predominantly G_4-AChE. The A_{12} form was still produced at 2 wks, but was practically undetectable at 4 wks after denervation. Histochemical examination showed no appearance of active AChE on the myofiber surface at the denervated synaptic sites. However, in contrast, regenerating myofibers showed production of high concentrations of A-AChE at 4 wks after denervation combined with muscle damage. Moreover, active newly made AChE accumulated on the surface at the denervated synaptic sites. The results show that denervation causes inhibition of the production and/or assembly of A-AChE and of the appearance of the synaptic AChE. This inhibition does not occur if muscles are regenerating. In all cases the level of intacellular G4-AChE is elevated, suggesting its possible role as precurser or degradation product. (Supported by grants from BSF and Bruno Goldberg Foundation).

CHRONIC NERVE LIGATION LEADS TO ENHANCED $GABA_A$ RECEPTOR-INDUCED CONDUCTANCES IN A SUBCLASS OF RAT DORSAL ROOT GANGLION NEURONS. D.L. Eng*, G.B. Richerson, J.D. Kocsis, Dept. Neurology, Yale Med. Sch., New Haven, CT. 06510; and VAMC, W. Haven, CT. 06516.

Chronic ligation of the rat sciatic nerve elicits both a reduction in primary afferent depolarization and a decrement in GABA-induced depolarization of the L4 and L5 dorsal roots. The aim of the present study was to examine electrophysiological properties of $GABA_A$ receptors on dorsal root ganglion (DRG) neurons following chronic axonal injury. Sciatic nerves were disconnected from their targets by ligation and transection. L4 and L5 DRG neurons were cultured in 2-4 wks. Whole cell patch clamp recordings were obtained from 20-42 μm neurons within a day after plating. Patch electrodes (1-3 Mohm) were made from borosilicate glass and filled with 140 mM KCl-based solution. GABA (100 μM) was applied to the entire cell body by rapid pressure microinjection to capture the peak response prior to desensitization. GABA-induced current was measured from voltage clamp experiments using test potentials of -60, -80, -100 mV (>80% series resistance comp.) to calculate slope conductances. In neurons with diameters of 34-42 μm, whole cell conductances of 116 ± 111 nS(n=31) and 446 ± 295 nS(n=26) ($p < 0.005$) were recorded from control and ligated groups, respectively. Muscimol elicited a similar response as GABA, and the responses were blocked by bicuculline. There was no difference in GABA-mediated conductance between control and ligated groups in the 20-32 μm neurons. All injured neurons with large GABA conductances had short duration action potentials with no notable inflections. Control neurons had a variety of action potential types. These data indicate that peripheral nerve ligation leads to a substantial increase in $GABA_A$ induced inward current in a subset of DRG neurons (34-42 μm dia). Given that dorsal root axonal GABA-sensitivity is reduced following a similar nerve injury, it is suggested that GABA receptor synthesis may continue after chronic nerve injury, but that receptor transport is impaired to the central terminals. Supported by the VA and NIH.

NEURONAL INDUCTION OF A PC12 NEURITE PROMOTING ACTIVITY. L.M. Bolin* and E.M. Shooter, Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Peripheral nerve Schwann cells provide trophic support to regenerating neurons in injured sciatic nerve. An *in vitro* paradigm in which cells could interact through diffusible substances but not through cell contact was designed to study the neuron-Schwann cell trophic milieu. Adult rat Schwann cells isolated 30hr post-crush were cocultured with chick E8 dorsal root ganglion neurons. Neurons respond to this coculture by neurite extention. The neurite promoting activity present in the coculture conditioned medium (CM) can be transferred to naive DRG cells and elicit a similar neurite extension. This was true for E8 retina and PC12 cells but did not occur when conditioned media (CM) from cocultures with E8 liver or L cells was transferred. The same results were obtained when iSC cells (a spontaneously immortal Schwann cell clone) were cocultured. CM from primary Schwann cells or iSC grown alone has no effect on PC12 cells. The fact that this activity results from neuron-Schwann cell coculture suggests a neuronal induction. Antisera raised against NGF did not inhibit the PC12 neurite extension in response to 20% iSC-PC12 coculture CM. Incubation of the coculture CM with heparin sepharose resulted in a loss of activity that could be restored by elution in 1M NaCl. This heparin binding is characteristic of FGF-1 (acidic FGF) which promotes neurite extension in PC12 cells. It is tempting to speculate that it is the neuron-stimulated Schwann cells which produce this heparin-binding neurite promoting activity, because these Schwann cells were isolated from the injured sciatic nerve and may be maximally responsive to neuronal signals.

RAPID AND EXTENSIVE GROWTH OF NEURITES ACROSS LESIONS OF IMMATURE MAMMALIAN SPINAL CORD IN CULTURE. J.M. Treherne*, G. Knott, J.G. Nicholls and N.R. Saunders Biocenter, University of Basel, CH-4056 Basel, Switzerland

The isolated central nervous systems of newly born opossums and 15-day rat embryos survive in culture for 7 days or longer. Our earlier work has shown that lesions to the spinal cord *in vitro* are followed, after 3-5 days, by restoration of conduction and by profuse fiber outgrowth. Experiments have now been made in which we follow with video microscopy the trajectories of axons stained by the carbocyanine dye (DiI) in living preparations. By 2 days after injury, neurites entered and traversed the lesion; by 4-days, neurites were observed several mm beyond the crush. These morphological measurements correlate well with the restoration of conduction measured by recording electrically from injured preparations. With the CNS *in vitro* it is possible to analyze how the rate and the pattern of growth are influenced by such factors as: the age of the animal, the extent of myelination, the level of electrical activity and the chemical environment. Our results demonstrate the dramatic repair of CNS that can be accomplished at early stages of development, compared with that seen in older animals. Supported by a grant from the Swiss National Fund No. 31-30047-90.

THE INFLUENCE OF SCHWANN CELLS ON EARLY PERIPHERAL NERVE REGENERATION STUDIED BY CHRONICALLY IMPLANTED ELECTRODES IN THE CAT. K. Fugleholm*, C. Krarup, Dept. of Neurophysiology, Inst. of Med. Physiology, Panum Inst., Univ. of Copenhagen, Copenhagen, Denmark, DK 2200 N.

I 21 cats, implanted silicone cuff and patch electrodes with multiple contacts were used to examine the influence of Schwann cells on the rate of elongation after Wallerian degeneration. The right tibial nerve was crushed or cut and resutured and in the other leg in addition frozen for 20 mm distal to the lesion. Regeneration was followed by weekly recordings of electrically evoked responses from the axonal sprouts until reinnervation of the plantar muscles occurred after 42-84 days. The action potentials from single regenerating fibers which had conduction velocities and amplitudes of 0.5-3 m/s and 0.15-0.5 μV respectively. The spatial relation of the regenerating axons to the stimulation electrodes was examined by electron microscopy showing the presence of axons when an action potential was recordable. The serial electrophysiological observations suggested that the rate of elongation was 3-4 mm/day after crush alone and similar after crush+freezing. However after section and resuture, freezing caused an initial phase of very slow regeneration suggesting that the presence of Schwann cells was critical when the continuity of bands of Büngner had been disrupted. After the initial slow phase, the elongation rate seemed to be independent of freezing.

615.11

ABDUCENS INTERNUCLEAR NEURONS SURVIVE AND REGAIN NORMAL DISCHARGE CHARACTERISTICS FOLLOWING LOSS OF THEIR TARGET MOTONEURONS. R.R. de la Cruz, A.M. Pastor and J.M. Delgado-García* Lab. de Neurociencia. Univ. de Sevilla, 41012-Sevilla, Spain.

The highly specific projection of abducens internuclear neurons (ABD Ints) onto the contralateral medial rectus motoneurons (MR Mns) offers a good model to evaluate the morpho-physiological consequences of target removal on adult CNS neurons. MR Mns were killed by the injection of a cytotoxin into the MR muscle. Following target removal, the overall firing activity of ABD Ints appeared markedly reduced. The neuronal sensitivity to both eye position and velocity showed values significantly lower than controls. ABD Ints also showed a significant reduction in the amplitude of their excitatory and inhibitory synaptic potentials of vestibular origin. However, after this initial period, ABD Ints exhibited, from one month up to one year, discharge properties and synaptic potentials that did not differ from controls. A morphological study demonstrated the absence of cell death in the ABD Ints population, but a progressive decrease in the density of their axonal terminals within their normal area of distribution. Therefore, these adult CNS neurons survive long-term target removal with the maintenance of appropriate physiological signals.

TOWARDS PULSE PROCESSING NEURAL COMPUTERS FOR BIDIRECTIONAL COMMUNICATION WITH THE NERVOUS SYSTEM.
R. Eckmiller* and M. Jansen. Dept. Biophysics, University of Düsseldorf (FRG)

Monitoring and control of signal time courses of the human nervous system becomes increasingly important for diagnostic and functional repair purposes (e.g.: cochlear implants, EEG, FES). However, recording from or stimulation of nervous tissue currently does not allow for an adequate communication with the nervous system as an information processing structure by means of multiple spike trains at the single neuron level.

Neurotechnology is gradually emerging for development of multicontact neural interfaces (MNI) and adaptive neural computers (ANC) as the two key components for communication with the nervous system by means of asynchronous spike trains via a multi-channel (with 10^2-10^3 single neuron contacts) neural interface.

This paper reports on the development and test of an ANC prototype consisting of 32 electronic neuron analogs and 64 synapse analogs with adaptive weights and adaptive delays (Jansen et al. In: 2nd Int. Conf. Microel. of Neural Netw. Munich, Oct. 91). In brief, each of the biology-inspired neuron analogs generates single impulses (1 ms) once its membrane potential (as definded by the asynchronous input of EPSPs and IPSPs from corresponding synapses) reaches the adjustable threshold. In conjunction with a PC to monitor neural parameters in real time and to specify various initial network topologies (via electronic switch arrays), a number of selected applications for pattern recognition, adaptive filtering, and motor control in real time have been successfully tested. With these experiments, some main features of weight- and/or delay adaptation with embedded learning rules (using 'training neurons' and presynaptic synapses) were studied.

DEGENERATIVE DISEASE: ALZHEIMER'S—β-AMYLOID VII

616.1

IDENTIFICATION AND ANALYSIS OF AN AMYLOID PRECURSOR-LIKE PROTEIN LOCALIZED ON CHROMOSOME 19 W.Wasco, B.T.Hyman*, and R.E.Tanzi, Dept. of Neurology, MGH, Boston, MA.

We have isolated a cDNA from a mouse brain library that encodes a protein whose predicted amino acid sequence is 42% identical to the amyloid β protein precursor (APP). This 653 amino acid amyloid precursor-like protein (APLP) is similar to the APP and the *Drosophila* APPL genes in overall structure and amino acid sequence. The strongest homology occurs in the cysteine-rich, acidic-rich, glycosylated, and cytoplasmic domains. These data suggest that APP is part of a highly conserved gene family. The APLP cDNA hybridizes to two messages of approximately 2.4 and 1.6 kb that are present in mouse brain and neuroblastoma cells. APLP has been mapped to human chromosome 19q13.2-cen, the same region in which a late-onset familial Alzheimer disease (FAD) locus has been provisionally assigned. In situ hybridization and immunohistochemical studies show APP and APLP to be expressed in similar human brain regions and cell subpopulations. We are currently testing APLP as a candidate gene for late-onset FAD by standard genetic linkage and mutation analysis. Additionally, we are screening the human genome for other spliced forms of APLP and additional members of the APP gene family.

616.2

TRANSMITTER DEPENDENT INDUCTION OF β-APP mRNA. V. Haroutunian*, S.T. Ahlers[1], P.A. Shea[1], N. Girenkova, K.L. Davis, and W.C. Wallace. The Mount Sinai School of Medicine, NY and [1]Naval Medical Research Institute, Bethesda, MD.

Previous studies have indicated that lesions of the nucleus basalis of Meynert (nbM) induce β-APP synthesis and β-APP mRNA in the ipsilateral cortex. The induction is rapid (within 1hr) and long-lasting (at least 45 days). We now report on the nature of the stimulus which triggers the β-APP response. Anesthetized rats were implanted with cannulae directed at the nbM and received an infusion of 20% lidocaine. In some of the rats cortical acetylcholine (ACh) release was measured by **in vivo** microdialysis prior to, during, and for 90 minutes following lidocaine infusion. These rats were then sacrificed. The remaining rats were re-anesthetized one week later and recovery of ACh release was measured without further lidocaine infusions. Infusion of lidocaine into the nbM led to a rapid reduction (approximately 50%) in cortical ACh release. ACh release had returned to pre-lidocaine infusion levels when measured one week later. Analysis of cortical β-APP mRNA by Northern blot indicated that β-APP was induced immediately after lidocaine infusion when cortical ACh release was reduced by approximately 50%, but not one week after lidocaine infusion when cortical ACh release had normalized. These results indicate that β-APP mRNA is reversibly induced when cortical transmitter levels drop below a certain threshold and provide a possible mechanism for β-APP induction in neurodegenerative disease.

616.3

TWO AP-1 SITES ARE NECESSARY FOR THE PROMOTER ACTIVITY OF APP GENE IN ASTROCYTE CELLS. D. K. Lahiri* and C.Nall. Lab of Molecular Neurogenetics, Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN-46202

Beta-protein (4.2kDa molecular weight) is generated by proteolytic cleavage of larger amyloid precursor proteins (APP) encoded by a gene on chromosome 21. The apparent over expression of the APP gene in certain areas of the brain in Alzheimer disease indicate that abnormalities in gene regulation might be an important factor in the neuropathology. The control of transcription is mediated by different DNA regulatory elements (*cis-acting*) present in the promoter of the gene. There are about 26 DNA motifs, present in the 5'-flanking region of the APP gene, through which various cell-type specific factors (*trans-acting*) can exert their influence on transcription. Recombinant plasmids containing different parts of the promoter region of the APP gene linked to a reporter gene were constructed. Sequences derived from the 5'-flanking region were tested for their effects on the promoter activity by transient expression in PC12 (chromaffin), IMR-32 (neuronal) and C6 (astrocyte) cells. The amyloid gene promoter has two sites, one at -345 and one at -38, which contain a consensus sequence recognized by transcription factor AP-1/*fos*. Since this factor is induced by phorbol esters and retinoic acids, their effects on the activity of the APP gene promoter were examined. A differential stimulation in the basal activity of the promoter was observed in the cell extracts prepared from the phorbol-ester treated astrocyte and neuronal cells. The deletion plasmids were used to determine if the two AP-1 sites act independently or cooperatively. Results of three separate transfections, one using a plasmid containing both AP-1 sites and two others using deletion plasmids containing either of the two sites, suggest that both AP-1 sites are essential for the stimulation in C6 cells. Gel shift and DNase I foot printing assays are being employed to characterize the trans-acting factors in C6 and IMR cells. Thanks to Drs. B. Ghetti, H. Hendrie, J. Nurnberger and N. Robakis.

616.4

CHARACTERIZATION OF A NUCLEAR FACTOR BINDING DOMAIN WITHIN A REGION OF THE APP PROMOTER THAT IS ESSENTIAL FOR ITS ACTIVITY.
W.W. Quitschke* and D.Y. Goldgaber, *Department of Psychiatry, State University of New York at Stony Brook, Stony Brook, NY 11794-8101.*

The major component of amyloid depositions is the amyloid beta protein, which is a truncated form of the larger amyloid precursor proteins (APP). The promoter of the APP gene was analyzed for its ability to direct cell type specific expression. The APP promoter and selected deletions were placed 5' to the reporter gene chloramphenicol acetyl transferase. The promoter deletions were transfected into different cell lines that showed variant levels of endogenous APP transcripts. Transient transfection assays showed that 96 base pairs 5' to the transcriptional start site are sufficient for full cell type specific promoter activity.

A nuclear factor that binds to this region in a sequence specific manner was identified by mobility shift electrophoresis, DNase footprinting, and methylation interference. The DNase protected domain extends from position -31 to -51 upstream from the main transcriptional start site (+1). Mutations within this domain revealed a sequence of twelve base pairs that is crucial for factor binding. This sequence overlaps with the consensus sequences for transcription factors AP-1 and AP-4. However, competition experiments suggest that the nuclear factor that binds to the APP promoter is distinct from both AP-1 and AP-4. In addition, factor binding to the characterized recognition sequence is observed in nuclear extracts originating from human, mouse, and rat cells, suggesting a high degree of conservation.

REGULATION OF APP SPLICING AND NEUROTROPHIN LEVELS IN THE ADULT RAT HIPPOCAMPUS BY RETINOIC ACID. T. Giordano*, J. B. Pan, L. Monteggia, and S. Watanabe. Neuroscience Research, Abbott Laboratories, Abbott Park, IL 60064.

It has recently been reported that retinoic acid (RA) is capable of increasing the levels and altering the splicing ratio of APP in cultured SH-SY5Y cells. We have observed a similar effect in these cells. To determine whether this effect is present in vivo, aged (20-22 month old) male Wistar rats were injected (i.p. at 1 ml/kg body weight, q.d.) with saline, vehicle (DMSO), or low (64 µg/kg body weight) or high (640 µg/kg body weight) dosages of RA in DMSO for 2 weeks. The abundance of each of the three major APP species and a control RNA, cyclophilin, were measured by rtPCR. In the saline injected rats, APP-695 represented approximately 90% of the total APP measured. DMSO treated rats exhibited a 10X increase in total APP ($p<0.005$) relative to cyclophilin and an increase in the level of APP-695 to 94% of the total APP. Treatment of RA in DMSO decreased the accumulation of total APP relative to cyclophilin at both the low (4X; $p<0.01$) and high (5X; $p<0.05$) dosages when compared to DMSO treated rats. Furthermore, the level of APP-695 decreased to 82% with low dosage of RA and 75% at high dosage of the total APP transcripts. In addition we did not detect a significant change in either NGF, NT-3, or BDNF transcripts following low or high dosage RA administration relative to cyclophilin RNA nor did we observe a change in ChAT activity at either of the dosages tested. In conclusion, the effects of RA on APP RNA observed in vivo cells are not indicative of changes in cultured SH-SY5Y.

616.6

A RAT MODEL TO STUDY THE EFFECTS OF BAP-CONTAINING AMYLOID IN BRAIN. A.D. Snow, R. Sekiguchi, D. Nochlin*, K. Kimata, W.A. Schreier and D.G. Morgan. Dept. of Neuropath., Univ. of Washington, Seattle, WA 98195; Inst. for Molecular Science of Medicine, Aichi Med. Univ., Japan & Div. of Neurogerontology, USC-Los Angeles, CA 90089.

Accumulation of amyloid containing beta-amyloid protein (BAP) in the brain is a diagnostic feature of patients with Alzheimer's disease. An animal model is needed to study the formation and subsequent consequences of amyloid deposition in the brain. In the present study, 3 month old Sprague-Dawley rats (4 animals/group) received continuous infusion (for 1 week) directly into hippocampus of 1) saline, 2) BAP (residues 1-40), 3) different amyloid plaque co-components, or 4) BAP (1-40) plus different amyloid plaque co-components. Congo red and thioflavin S positive extracellular amyloid deposits were observed only in the group given BAP (1-40) plus a specific amyloid plaque co-component. This study therefore provides a rapid in vivo animal model to study amyloid accumulation in brain, and further indicates that a specific co-component in necessary for amyloid accumulation and its persistence in brain. TRANSGENIC MOUSE STUDIES OF ALZHEIMER AMYLOID PRECURSOR (AAP) PROTEINS AND DERIVATIVES. B.D.Greenberg[1]*, S.M.Ali[1], S.Siedlak[2], P.A.Gonzalez-DeWhitt[1], S.Kuentzel[1], R.A.Altman[1], H.G.Polites[1], J.M.Glendening[1], D.E.Lowery[1], P.Cras[3], T.J.Raub[1] and G.Perry[2]. [1]The Upjohn Company, Kalamazoo, MI 49001; [2]Institute of Pathology, Case Western Reserve University, Cleveland, OH 44106; [3]Born-Bunge Foundation, University of Antwerp, Belgium.

We are attempting to generate transgenic mouse models for Alzheimer-type amyloidogenesis based on overexpression of AAP protein derivatives in appropriate brain regions. A C-terminal AAP-695 segment containing the entire β protein domain (Glu593-Asn695) has been expressed under the control of a chimeric metallothionein-growth hormone promoter system (Swanson et al. Nature **317**:363 [1985]), with AAP sequences replacing the growth hormone coding sequence described in that paper. This transgene is abundantly expressed in transfected HeLa cells, producing novel dense inclusions associated with the endoplasmic reticulum. In extracts of whole brain, Northern analyses reveal that transgene mRNA levels exceed those of the endogenous mRNA up to six-fold. *In situ* hybridization indicates that the transgene is expressed in pyramidal neurons within cortex and hippocampus. Immunocytochemical analyses with several antibodies to AAP epitopes N-terminal to Glu593, reveal elevated intraneuronal accumulation of endogenous AAP protein in these brain regions in the transgenic mice. In cortex, this immunostaining is significantly more abundant than in control mice and nontransgenic littermates, with p values ranging from <.05 to <.0001 depending upon the antibody used. These mice may therefore provide useful models to study the effects of chronic AAP overexpression on brain pathology and amyloid formation.

616.8

MORE TRANSGENIC MOUSE STUDIES OF ALZHEIMER AMYLOID PRECURSOR (AAP) PROTEINS AND DERIVATIVES. S.M.Ali, P.A.Gonzalez-DeWhitt, R.A.Altman*, T.M.Pohlad, H.G.Polites, S.Kuentzel, T.J.Raub and B.D.Greenberg. The Upjohn Company, Kalamazoo, MI 49001.

We are attempting to generate transgenic mouse models for Alzheimer-type amyloidogenesis based on overexpression of AAP protein derivatives in appropriate brain regions. The mouse AAP gene promoter has been used to direct the expression of the full length human AAP-695 cDNA, and the region encoding the N-terminal 639 residues. The latter contains the complete β-protein domain at its C-terminus. One set of constructs (MP-SAR) utilizes the 3'-untranslated region of rat growth hormone, and another (LBM-SAR) utilizes approximately 1500 bases of the mouse AAP gene 3'-untranslated region. Both sets of transgenes are abundantly expressed in transfected HeLa and mouse LTK- cells. Media conditioned by HeLa cells expressing the MP-SAR constructs contain in excess of 200 ug AAP protein per liter. AAP production by LBM-SAR transfectants has not yet been quantitated. Transgene expression has been revealed by Northern blot analysis of whole-brain homogenates from MP-SAR mice in several independent founder lines. *In situ* hybridization analyses are underway. Microinjections of LBM-SAR constructs into fertilized mouse oocytes have just begun. The current status of these studies will be reviewed.

616.9

EFFECTS OF ALZHEIMER-ASSOCIATED MUTATIONS ON A HUMAN BRAIN APP RNA-BINDING PROTEIN: . R.E.Tanzi*, W.H.Pettingill, W.Wasco, and B.T.Hyman. Dept. of Neurology, Mass. General Hospital, Boston, MA 02114.

Three single basepair substitutions in exon 17 of the APP gene have been reported in affected individuals of ten families with familial Alzheimer's disease. All three mutations are predicted to destabilize a stem-loop structure in the APP mRNA which occurs in the 3' end of the sequence encoding the amyloidogenic βA4 domain (nucleotides 1906 and 1924; APP695 sequence). The stem-loop resembles iron-responsive elements (IREs) present in the 5' and 3' untranslated regions of the mRNAs for ferritin and transferrin receptor, respectively. The stem-loops in these messages control translation in response to iron concentration via RNA-binding proteins. We have shown that the IRE-like stem-loop in APP message binds a novel human brain RNA-binding protein. Preliminary studies indicate that this binding is abolished when the APP717(V->I) is introduced into the stem. We are also testing the effects of the other two mutations on the RNA-protein interaction. Data will be presented on our attempts to isolate and clone the APP RNA-binding protein. Additionally, the effects of the Alzheimer disease mutations on APP mRNA stability and translation are being assessed.

616.10

BIOLOGICAL ACTIVITY OF THE AMYLOID β/A4-PROTEIN PRECURSOR I: FUNCTIONAL MAPPING OF GROWTH PROMOTING ACTIVITY. J.-M. Roch*, H. Ninomya, D. Otero and T. Saitoh. Dept. of Neurosciences, University of California San Diego, La Jolla, CA 92093, USA.

The secreted form of the amyloid β/A4-protein precursor (APP) is involved in the growth regulation of fibroblasts (Saitoh et al., Cell 58:615-622, 1989). Recently, we have shown that the region of the secreted form of APP-695 necessary for this growth regulation is contained within a 40 amino acid domain which is adjacent and C-terminal to the KPI insertion site of APP-751. This active site begins at Thr296 and extends to Met335 (Roch et al., J. Biol. Chem. 267:2214-2221, 1992). To define more precisely the site of activity, we synthesized several peptides spanning the 40 amino acid domain. In addition, we also prepared bacteria-made APP-751 (secreted form), as well as mutant forms of APP-695 and -751 (secreted forms) . These deletion mutants were lacking the majority of the 40 amino acid domain. Each of the peptides, as well as the bacteria-made APP variants were tested in our biological assay on A-1 fibroblasts (a cell line that produces very low APP levels and is dependent on exogenous APP in the medium for normal growth). Our results narrow down the active site of the secreted form of APP-695 from the domain of 40 amino acids to a region of 17 residues starting at Ala319 and extending to Met335.

616.11

BIOLOGICAL ACTIVITY OF THE AMYLOID β/A4 PROTEIN PRECURSOR. II: NEUROTROPHIC EFFECT OF AN APP PEPTIDE ON A RAT BRAIN NEUROBLASTOMA CELL LINE.

L.-W. Jin*, E. Masliah, H. Ninomiya, J.-M. Roch, D. A. Otero, D. Schubert+, and T. Saitoh. Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093 and+ The Salk Institute for Biological Studies, San Diego, CA92138.

We previously demonstrated that secreted forms of amyloid β/A4 protein precursor (APP) promote growth of fibroblasts (Cell, 58:615, 1989), and adhesion of PC12 cells to substratum (Neuron, 3:689, 1989). The growth promoting activity of APP is fully represented by a synthetic 17-mer peptide corresponding to Ala319-Met335 of APP-695 (Roch et al., reported in this meeting). In order to investigate the effect of the 17-mer APP peptid on neuronal cells, we have chosen B103, a neuronal cell line derived from rat brain that does not express APP. The neuronal phenotype of B103 has been documented (Nature, 249:224, 1974). We found that the rat CNS neuroblastoma cultures treated with 17-mer APP peptide for 20 hours had longer neurites and more neurite-bearing cells. The significant effect was seen at 10 nM to 200 nM, with maximal effect at 100 nM. The peptide with sequence reverse to that of 17-mer did not have any effect at the same concentration range. This result demonstrates that a small stretch of sequence in the secreted form of APP-695 has both growth promoting and neurotrophic activities.

616.12

BIOLOGICAL ACTIVITY OF THE AMYLOID β/A4-PROTEIN PRECURSOR. III: BINDING OF IODINATED 17-MER PEPTIDE (ALA319-MET335 OF APP-695) TO RAT NEUROBLASTOMA (B103) CELL MONOLAYER.

H. Ninomiya, L.-W. Jin, J.-M. Roch, D. Otero and T. Saitoh.* Dept. of Neurosciences, University of California San Diego, La Jolla, CA 92093, USA.

A synthetic 17-mer peptide corresponding to Ala319-Met335 of APP-695 has a neurotrophic effect on rat neuroblastoma (B103) cells (L.-W. Jin et al., reported in this meeting). As an initial attempt to find out a possible mechanism for this effect, we employed the binding assay of ^{125}I-17-mer on B103 cell monolayer. (1) The binding was time-dependent and saturable with Kd values of 20±5 nM and Bmax values of 80±8 fmole/10^6 cells (mean±SEM, n=4). (2) Both unlabeled 17-mer and secreted form of APP-695 fully displaced the binding while reverse-sequence 17-mer did not. (3) C-terminal 11 amino acid-long peptide of the 17-mer fully displaced the binding while N-terminal 8 amino acid-long peptide did not. (4) Neither the addition of heparin nor heparan sulfate in the assay medium had any effect on the binding. These results suggest the presence of novel binding sites on B103 cell monolayer recognized by a specific domain of the secreted form of APP.

REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS

617.1

DISTRIBUTION OF MELATONIN RECEPTORS IN THE BRAIN AND RETINA OF THE LIZARD.

A.F. Wiechmann* and C.R. Wirsig-Wiechmann. Depts. of Neurobiology & Anatomy and Ophthalmology, Bowman Gray School of Medicine, Winston-Salem, NC 27157.

Melatonin binding sites were identified in the brain and retina of the lizard *Anolis carolinensis* using *in vitro* autoradiography and computer-generated color imaging. Radioactive labelling was observed in areas which receive primary, secondary, and tertiary visual input: the superficial layers of the optic tectum, lateral geniculate nucleus, nucleus rotundus, dorsal ventricular ridge, striatum, and interpeduncular nucleus. Other areas that demonstrated binding included the medial habenular nucleus, medial cortex, dorsal cortex, mammillary nucleus, and septum. In the retina, melatonin binding was localized in the inner plexiform layer.

An asymmetry of melatonin binding was seen in the diencephalon: a high degree of melatonin binding was present in the left medial habenular nucleus, and no binding was observed in the habenulum on the right side of the brain.

This study demonstrates that melatonin receptor binding sites are widely distributed in the forebrain and midbrain of the lizard, and are very prominent in areas of the nervous system which are associated with visual processing. Since the light-sensitive parietal eye projects to the left medial habenulum in the lizard but not to the right habenulum, these observations suggest that the left habenulum is under dual control (neuronal and hormonal) of the parietal eye/pineal complex, and that melatonin may play a significant role in neural processing of visual information. *(Supported by NIH grants EY08006 and NS27586)*

617.2

EXPRESSION OF THE GLUCOCORTICOID RECEPTOR (GR) IN THE TREE SHREW BRAIN BY *IN SITU* HYBRIDIZATION.

O. Jöhren[1], H. Haack[2], G. Flügge[1], F.W. Schürmann[3]* and E. Fuchs[1]. [1]German Primate Center, [2]Max-Planck-Inst. Biophys. Chem. and [3]Zool. Inst. University, 3400 Göttingen, FRG.

In the brain, glucocorticoids act via two types of intracellular receptors, the mineralocorticoid and the glucocorticoid receptor (GR). Among other processes, hippocampal GRs are involved in the regulation of the HPA-axis activity. Studying the neurophysiological consequenses of psychosocial stress in tree shrews (*Tupaia belangeri*), we recently demonstrated degeneration of hippocampal pyramidal neurons in chronically stressed males probably due to elevated glucocorticoids (1). To better understand these processes on the cellular level, we cloned the tree shrew GR for constructing a probe for *in situ* hybridization histochemistry (ISHH). Tree shrew genomic DNA was amplified by polymerase chain reaction and DNA fragments were subsequently cloned. Dideoxy sequence analysis of the cloned DNA fragment revealed 92% (human) and 88% (rat, mouse) homology compared to the corresponding cDNA sequences. Linearized vectors containing the tree shrew GR DNA fragment were used to generate ^{35}S-labeled sense and antisense RNA probes. ISHH experiments with this specific probe showed high levels of GR-mRNA in the hippocampal formation. Currently we are investigating the regional distribution of GR-mRNA in the three shrew brain. These data will be the basis for further studies on regulation GR-numbers under chronic psychosocial stress.

617.3

STRATEGIES FOR THE PRODUCTION OF EXTREMELY HIGH TITRE ANTISERA AGAINST SMALL NEUROTRANSMITTER MOLECULES.

D.V. Pow, D. K. Crook, I.C. Gynther* and D.I. Vaney. Vision, Touch and Hearing Research Centre, University of Queensland, Brisbane 4072, Australia.

We have devised a simple new technique which permits the rapid production in 1-2 months of extremely high titre polyclonal antisera against a wide variety of small molecules including the transmitters glycine, glutamate, and GABA. These antibodies are used routinely for post-embedding immunocytochemistry of resin-embedded sections at dilutions of 1 in a million, rather than a typical dilution of 1 in a thousand for conventionally prepared antisera, indicating that we have achieved a 100- to 1000-fold increase in titre. The high titres of these antisera, which are due to the dramatic expansion of lymphocyte clones secreting high affinity antibodies, have a number of distinct advantages, principally the dramatic reduction of non-specific background labelling. To achieve this result we made use of the observation that particulate antigens, of a size likely to be encountered by the immune system (such as viruses), are very effective antigens. We have coupled antigens to suitably sized gold particles, along with a non-specific stimulator of the immune system, muramyl dipeptide. This combination, when injected, elicits massive and rapid immune responses in all animals we have studied to date. We suggest that our methodology may have much more widespread application than indicated here; it should facilitate greater efficiency of monoclonal antibody production by virtue of expanding the lymphocyte clones of interest prior to fusion and may well, with appropriate modifications, represent a potent alternative modality for human immunisations.

617.4

DISTRIBUTION OF THE KAINATE CLASS GLUTAMATE RECEPTOR SUBUNITS (GluR5-GluR7) IN THE TEMPORAL CORTEX OF THE MACAQUE: LOCALIZATION TO IDENTIFIED PROJECTION NEURONS OF THE ENTORHINAL CORTEX.

P.F. Good[1]*, T. Moran[2], S.W. Rogers[3], S. Heinemann[4], and J.H. Morrison[1]; [1]Fishberg Rsrch. Ctr. for Neurobiology, and [2]Hybridoma Facility, Mt. Sinai Med. Ctr., NY, NY 10029, [3]University of Colorado Med. Ctr., Denver, CO. 80262, and [4]Salk Institute for Biological Studies, La Jolla CA 92037

Glutamate is considered to be the predominant excitatory neurotransmitter in the central nervous system. Specificity of synaptic circuitry and physiological response to this ubiquitous neurotransmitter is conferred by receptor diversity. We have generated monoclonal antibodies to the kainate (K) class (GluR5-GluR7) glutamate receptor subunits. Analysis of the distribution of the K class subunits in the temporal cortex of the cynomolgus monkey demonstrates that it is heavily concentrated in the hippocampus and entorhinal cortex. Antibodies to the K class subunits label the soma and dendrites of pyramidal neurons within all CA fields and subiculum, as well as the dendrites of the granule cells of the hippocampus. The soma of the granule cells are conspicuous by their absence of immunoreaction for the K subunits. In the entorhinal cortex, soma and apical dendrites of neurons within layers V and VI extending to superficial layers were prominently labeled while only the soma and sparse proximal dendrites of layer II and III cells exhibited labeling. This dense pattern of labelling was also present in the perirhinal region while the predominantly unimodal visual region of the inferior temporal cortex was sparsely labeled. The polymodal region within the superior temporal sulcus was heavily labeled as was the insula.

Neurons of layer V of the entorhinal cortex identified by retrograde labeling with fast blue as projecting to STS were filled with lucifer yellow. Double labelling with antibodies to the K class subunits has demonstrated that these neurons express these subunits. Immunoreactivity is present on the soma and primary dendritic shaft of these neurons but is excluded from distal dendrites. Supported by NIH grant AG06647 and American Health Assistance Foundation (AHAF).

DISTRIBUTION OF GLUTAMATE RECEPTOR SUBUNIT PROTEINS IN MONKEY NEOCORTEX. J.H. Morrison[1]*, J.C. Vickers[1], G.W. Huntley[1], P.F. Good[1], W.G. Janssen[1], N. Archin[1], T. Moran[2], S.W. Rogers[3], and S.F. Heinemann[4]; [1]The Fishberg Research Center for Neurobiology, and [2]Hybridoma Facility, Mount Sinai School of Medicine, New York, NY 10029, [3]University of Colorado Medical Center, [4]The Salk Institute for Biological Studies.

The non-NMDA glutamate receptor subunits have been classified into an AMPA/kainate (A/K) class (GluR1-GluR4) and a kainate (K) class (GluR5-GluR7). We recently developed monoclonal antibodies (MAb) to several of these subunits, and have used them in combination with polyclonal antibodies (PAb, provided by R.J. Wenthold) to characterize glutamate receptor profiles of specific regions, layers and cell types in primate neocortex. Neurons containing the K class subunits are widely distributed in primate neocortex, yet exhibit a high degree of regional and laminar specificity. MAbs to K class subunits used in combination with PAbs to A/K class subunits suggest that K class subunits are present in pyramidal cells that represent a subclass of the neocortical cells immunoreactive for A/K subunits GluR1 and GluR2/3. In addition, K subunits are present in some pyramidal cell soma, but are particularly abundant in primary apical dendrites of pyramidal cells. Often the labeled apical dendrites coalesce into dendritic bundles, and appear to originate primarily from layer V. Double labeling studies with antibodies to various cytoskeletal proteins demonstrate that the K subunits are often localized to a particular portion of the primary dendrite, suggesting that K class subunits may exhibit preferential laminar localization along a given apical dendrite, allowing for association with particular afferents with preferred laminar targets. Electron microscopic studies confirm the dendritic localization of K subunits, and suggest that these subunits may be preferentially distributed in primary dendritic shafts as opposed to spines. In summary, a high degree of specificity exists in respect to the glutamate receptor profile of neocortical neurons, and complex colocalization patterns exist suggesting that individual neurons may contain K/A and K subunits with differential somatodendritic distribution. Supported by NIH Grant AGO6647 and the American Health Assistance Foundation (AHAF).

DETECTION OF Y1-NEUROPEPTIDE Y BINDING SITES IN RAT BASILAR ARTERY BY QUANTITATIVE RECEPTOR AUTORADIOGRAPHY. E.S. Corp* and J.A. McQuade. Bourne Laboratory, New York Hospital-Cornell Medical Center, White Plains, N.Y. 10605.

We employed *in vitro* quantitative autoradiography to measure parameters of binding over the basilar artery (BA) visualized in slide-mounted sections of rat medulla labeled with ^{125}I-peptide YY (PYY, 0.05 nM). Affinity, capacity and specificity of the labeled sites were determined using NPY, PYY and subtype-selective ligands.

Assuming a single site fit, nonlinear regression analysis (LIGAND) resolved NPY and PYY binding with equal affinity and capacity: (NPY-K_i = 0.8 nM, B_{max} = 10 fmol/mg; PYY-K_d = 1.3 nM, B_{max} = 14 fmol/mg). The occupied sites were predominately (> 75%) **Y1** (Pro^{34} NPY K_i = 4.4 nM). Based on the inhibitory potency of NPY$^{13-36}$, **Y2** occupancy was < 25% (KD_i = 141).

Vasoconstrictive effects of NPY are well known and these data suggest that cerebral vascular NPY receptors are type-**Y1**, like their counterpart in peripheral vascular smooth muscle.

This rank order of potency is similar to the rank order of potency for these same agonists to stimulate feeding following fourth icv administration. Although it is unlikely that NPY acts at the BA to induce food intake, an action on cerebral arterioles can't be ruled out. Alternatively, NPY and PYY may act at vascular-type receptors expressed in neural elements as yet undetected by current methods.

DYNAMIC AND EQUILIBRIUM SPECT MEASUREMENT OF HUMAN BENZODIAZEPINE RECEPTOR BINDING POTENTIAL A. Abi-Dargham, J.P. Seibyl, M. Laruelle, Z. Rattner, S. Zoghbi, R.M. Baldwin, G. Wiesnewski, Y. Zea Ponce, E. O. Smith, D.S. Charney*, P.B. Hoffer and R.B. Innis. Yale University/VA Medical Center, West Haven, CT 06516.

SPECT imaging with [^{123}I]iomazenil was performed in healthy volunteers under dynamic and equilibrium conditions to measure the benzodiazepine binding potential (BP = B_{max}/K_d). In the dynamic paradigm, four subjects were injected with 10 to 16 mCi of [^{123}I]iomazenil (SA ~180000 Ci/mmol) in a single iv bolus. Continuous blood sampling was performed and free parent compound measured. Brain acquisitions were obtained every 2 min on the ASPECT device, reconstructed with the photopeak window, attenuation corrected, and resliced to a standard orientation using external fiducial markers. Brain and blood data were fit to a three compartment model to estimate transfer rate constants, K1 to k4. BP was calculated as $K_1*k_3/k_2*k_4*f_1$, with f_1 = the measured free fraction in the blood. In the equilibrium paradigm, a continuous i.v. infusion after an initial bolus of the radiotracer lead to a steady state concentration in the plasma which was sustained for 8 hours allowing equilibrium to occur at the receptor site. Under equilibrium conditions with negligible receptor occupancy, $B_{max}/K_d = B/F$, where B is the specific binding at equilibrium and F is the free radioligand concentration in the blood. Two subjects were given 10 mCi with a bolus to hourly infusion ratio of 3 to 4. The BP values for the occipital pole obtained with equilibrium (184±29; n=2) and dynamic (151±39; n=5) approaches were in relative good agreement supporting the validity of both methods.

IN VITRO AND EX VIVO AUTORADIOGRAPHY OF α_2 ADRENOCEPTORS WITH [^{3}H]ATIPAMEZOLE. T. F. Budinger, C. A. Mathis* and A. Biegon. Lawrence Berkeley Laboratory, Univ. of California, Berkeley, CA 94720.

The feasibility of using [^{3}H]atipamezole as an in vitro and in vivo imaging agent for brain a_2 adrenoceptors was examined with ex vivo autoradiography in the rat and in vitro autoradiography in rat and human brain postmortem. In vitro auotradiography was performed by applying 0.5nM radioligand to 20μ rat or 40μ human brain sections for 1 hour at room temperature, followed by 2 X 10 min wash in ice cold incubation buffer. Nonspecific binding was determined in the presence of 10μM unlabeled clonidine. Sections were dried and apposed to tritium sensitive film for 4 weeks. A computerized image analysis system was employed to measure standards and regions of interest and to compute regional specific binding. Distribution of specific [^{3}H]atipamezole binding in rat and human brain was compatible with the known distribution of a_2 adrenoceptors as demonstrated by in vitro autoradiographic studies using agonists and the antagonist idazoxan but not rauwolscine. Following the tail vein injection of 100μCi [^{3}H]atipamezole (60 Ci/mmole), the ligand readily crossed the blood-brain-barrier and accumulated in the rat brain, with a brain:blood ratio of 5:1 and 0.6% injected dose/gr brain at 5 min. The distribution of activity at 1 h following injection was similar to the distribution of a_2 adrenocepotrs observed in vitro. Coinjection of Idazoxan 2mg/kg produced a significant reduction in brain activity in vivo. Thus, appropriately labeled atipamezole shows promise as an imaging agent for human a_2 adrenoceptors with high resolution positron emission tomography (PET).

MOUSE BRAIN LOCALIZATION OF NEW [F-18]BENZO-VESAMICOL TRACER IS NOT CHANGED BY PRE-TREATMENT WITH SIGMA LIGANDS HALDOL, 3-PPP, OR E2020. GK Mulholland*, PS Sherman, MR Kilbourn, Y-W Jung, KA Frey, DM Wieland and DE Kuhl. Division of Nuclear Medicine, Department of Internal Medicine, University of Michigan School of Medicine, Ann Arbor, MI 48109.

Radiolabeled benzovesamicol analogs studied in these laboratories as potential tracers for Alzheimers disease (AD) show a localization pattern *in vivo* consistent with cholinergic density in the normal rodent or monkey brain. However, recent reports that vesamicol (VES) itself binds to non-cholinergic sites in addition to the ACh vesicular transporter (Hicks *J Neurochem.* 57:509, 1991), and a lack of correlation between [3H]VES binding and ChAT levels in postmortem AD brains (Kish *Neurosci Let.* 117:347,1990 Ruberg, *Neurosci.* 35:327, 1990) raise questions about the cholinergic specificity of benzovesamicols. The potent inhibition of [3H]VES binding *in vitro* by haldol (IC_{50} 43 nM, Altar, *Synapse* 2:486,1988) points to possible interactions of VES and sigma sites. We wanted to know if brain localization of a promising new F-18 labeled benzovesamicol FEOBV ((-)-fluoroethoxybenzovesamicol) would be affected by pretreatment with CNS drugs reported to have high affinity for the sigma receptor (Koe, Soc Neurosci Abs 17:, S133.3, 1991). Haldol (5 μmol/kg), (+)-3-PPP (20 μmol/kg), or E-2020 (10 μmol/kg) were administered intraperitoneally 60 min prior to IV injection of high specific activity FEOBV (30 μCi, 15 pmol). Animals (n=3 per data point) were sacrificed 5, 45 and 240 min post tracer. Brain regions were dissected and counted for radioactivity. Control animals showed total brain uptake of 1.5% of injected dose, and a striatum: cortex: hippocampus: cerebellum ratio of 9:3:3:1, at 240 min. In spite of the large doses, none of the pretreatments produced significant change in regional distribution from control values at the time points examined. In terms of total brain uptake only the haldol group showed a slight depression in early global FEOBV levels that can be ascribed to reduced blood flow and tracer delivery. Thus it is concluded that, unlike vesamicol, FEOBV and possibly similar benzovesamicol analogs do not interact at sigma binding sites *in vivo*.

EXPRESSION OF AN ALTERNATIVELY SPLICED VARIANT OF THE DOPAMINE D3 RECEPTOR IN HUMAN BRAIN. C. Schmauss, H. Haroutunian & L.M. Refolo*. Dept. Psychiatry, Mount Sinai Medical School, New York, NY 10029.

The amplification of the human dopamine D_3-encoded cDNAs (D_{3A}) by reverse transcriptase/polymerase-chain reaction resulted in the additional amplification of a dopamine D_3-like mRNA sequence (D_{3B}). A comparison of the nucleotide sequences of both D_{3A}- and D_{3B}-encoded cDNAs revealed that they are identical, with the exeption of 98 nuclotides that are found in the third cytoplasmic domain of cDNA that encodes D_{3A}, but not in cDNA that encodes D_{3B}. This results in a differently predicted amino acid sequence of the carboxyl terminal region of the putative D_{3B} receptor. Inclusion or exclusion of the 98 nucleotide-long sequence is apparently regulated by alternative splicing. In postmortem brains obtained from schizophrenic patients, D_{3A}- and D_{3B}-encoded mRNAs are co-expressed in the olfactory bulb, prefrontal and temporal cortex, hypothalamus and nucleus accumbens, while in the parietal cortex, hippocampus, substantia nigra, pons, cerebellum and pituitary only D_{3B}-encoded mRNA is expressed. D_{3A}-encoded mRNA is the predominant form found in the caudate.

We have began to examine the distribution of D_{3A}- and D_{3B}-encoded mRNAs in postmortem brains of patients with Alzheimer's disease (AD) (age and postmortem interval matched). These preliminary data indicate that the expression of D_{3B}-encoded mRNA is similar in AD and schizophrenia, but, in contrast to schizophrenia, the expression of D_{3A}-encoded mRNA could also be detected in the parietal cortex and the hippocampus of AD brains. Whether these results reflect individual variations in the ability to process D_{3A}-encoded mRNA in different brain regions or are disease-related is currently under investigation. Furthermore, we will present results of experiments that aim at characterizing the pharmacological characteristics of the putative D_{3B} receptor.

NEURITE OUTGROWTH IN PRIMARY CULTURES OF *DROSOPHILA* PHOTORECEPTOR AND OPTIC LOBE CELLS. Chinglu Li* and I.A. Meinertzhagen. Life Sciences Centre, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

The visual system of *Drosophila melanogaster* has been widely used in developmental neurobiology, for which successful *in vitro* cultures of eye imaginal discs and optic lobe neurons offer a powerful prospective tool. We have established a primary culture system, with which, for the first time, we have obtained constant neuronal differentiation from both optic lobe and eye imaginal discs. Late third-instar larval or white prepupal wild-type *Drosophila melanogaster* raised at 25°C were surface sterilized, and the eye imaginal discs and the lateral poles of the supraesophageal hemispheres (containing the optic lobes) dissected out under sterile conditions. Eye discs were partially dissociated by mechanical trituration, while optic lobe cells were dissociated by trituration after 10min in 0.25% trypsin. Preparations were culured in Nunc dishes coated with poly-L-lysine at 25°C in a humid chamber using the bicarbonate-free Leibovitz L-15 medium supplemented with 10% fetal bovine serum. Neurite outgrowth was observed in both cultures within a few hours of initiating the culture. The cells are immunoreactive to anti-HRP, which recognizes an epitope on insect neurons. Optic lobe cells differentiated as single cells with bifurcated fibers, or as clusters with neurites that faciculate together. Sometimes ganglion cells about 5μm in diameter clustered around a larger round cell (diameter ~10μm), presumed to be their stem cell neuroblast. Some processes from these neurons had clear growth cones and varicosities. Cultures have been maintained up to 30d. For successful culture of eye imaginal discs it is important to dissociate the discs only partially. Disc fragments usually reseal into vesicles of various sizes. Healthy neurite outgrowth is usually observed from those vesicles or clusters, although single cells with long fibers are also seen; growth cones can be seen in some cells. Anti-HRP indicates that neuronal differentiation occurs in these eye disc fragments, which also give rise to non-neuronal cells.

ELECTRICAL PROPERTIES OF PEPTIDERGIC NEURONS ARE UNCHANGED WITH TIME IN CULTURE. D.E.R. Meyers and I.M. Cooke*, Békésy Lab. of Neurobiol., Univ. of Hawaii, Honolulu, HI 96822, USA.

After 1 d in defined culture, regenerating crustacean (*Cardisoma Carnifex*) peptidergic neurons show veiling or branching morphologies. Veiling cells are routinely immunopositive for crustacean hyperglycemic hormone (CHH), fire over-shooting spikes and express Na, Ca and K currents. Branching neurons having spherical somata <25 μm diam. and fine processes that are often varicose are CHH negative, do not fire over-shooting spikes; under voltage clamp (VC) they are dominated by K current (Cooke et al., PNAS **86**:402, 1989; Meyers et al., J. Neurophysiol. **67**:1301, 1992). We have now recorded from these types and larger branching neurons after 5 - 6 d in culture. Using whole-cell patch recording (pipette, 300 mM K^+; bath, crab saline), 3 of 4 veiling but only 1 of 5 branching cells fired over-shooting spikes. Under VC, all 6 veiling cells tested showed inward (max. 0.3 - 1.9 nA) and outward (1.1 - 3.9 nA, V_c 0 mV, V_h -40 mV) current, while only 3 of 12 branching cells did so (<0.5 nA). The mean soma diam. of these cells (44 ± 6, $\bar{x}\pm$SD, μm) was significantly larger ($F(1,7) = 17.6$, $P = .004$) than that of the others (25 ± 6 μm). Max. outward current at 0 mV (V_h -40 mV) in the 12 cells was 0.6 - 3.5 nA. Sixteen branching cells were examined in solutions designed to isolate I_{Ca}. Ten generated I_{Ca} (max. 334 ± 328 pA). The mean soma diam. of these cells (37 ± 9 μm) was significantly larger ($F(1,15)$, $P = .02$) than that of cells devoid of I_{Ca} (26 ± 7 μm). We conclude that the electrical properties of the cells previously studied at 24 h do not change substantially over the following 5 d. The large-diam. branching cells which generate I_{Ca} were not targeted in our earlier study as they could not be distinguished from veiling cells that had not produced a lamellipodium by 24 h.

CALCIUM TRANSIENTS IN RESPONSE TO CONDITIONING FACTORS IN REGENERATING *HELISOMA* NEURONS. D.L. Kania* and C.S. Cohan Dept. of Anatomical Sciences, SUNY at Buffalo, Buffalo, N.Y. 14214

Previous studies have shown a correlation between neurite elongation and intracellular calcium levels in *Helisoma* neurons (Cohan and Kater, 1987). This study examined whether the initiation of outgrowth from a cut axon stump was associated with changes in intracellular calcium levels in response to the presence of conditioning factors.

Identified neuron, B19, was removed from the buccal ganglia with an attached piece of axon and plated into defined culture medium. Cells were injected with Fura-2 and calcium levels were monitored at the distal axon before and at various times after the addition of conditioning factors. In the absence of conditioning factors, no regenerative outgrowth was observed and calcium levels remained constant. However, the addition of conditioning factors resulted in the extension of new neurites from the distal axon together with cyclical elevations in intracellular calcium that were first detected at 8-12 hours. Approximately 50% of the cells exhibited calcium transients. These transient elevations had peak amplitudes that were 20-30% above basal calcium levels and had a period of about 10 minutes. Transients were blocked by lanthanum indicating that the calcium originated from influx across the plasma membrane. Blocking calcium transients with lanthanum did not inhibit the initiation of outgrowth. However, the rate and extent of outgrowth was significantly lower.

These data indicate that application of conditioning factors to *Helisoma* neurons induces calcium transients. While the calcium transients do not appear to be directly related to the initiation of outgrowth, they do appear to have some affect on the rate and extent of outgrowth in these neurons.

RAPID REGULATION OF $[Ca^{2+}]_i$ CHARACTERIZES NEURONS SHOWING OUTGROWTH IN DEFINED CULTURE. R. A. Graf*, Békésy Lab. of Neurobiol. and Dept. of Zool., U. of Hawaii, Honolulu, HI 96822.

There are conflicting observations on the relations between $[Ca^{2+}]_i$ and outgrowth from cultured neurons. This report provides observations pointing to the capability for Ca^{2+} homeostasis as an important attribute of neurons showing outgrowth. Peptidergic neurons from the X-organ - sinus gland neurosecretory system of land crabs (*Cardisoma carnifex*) when cultured in defined medium show immediate outgrowth having several characteristic patterns including veiling (associated with immunoreactivity to crustacean hyperglycemic hormone antisera) and various types of branching (Cooke, et al. 1989, PNAS **86**:402). A few neurons show little regeneration. Here I compare the $[Ca^{2+}]_i$ responses of cells lacking outgrowth with extensively-regenerated cells (from same culture) after application of depolarizing $[K^+]_o$ (5X normal; 1-7 min). $[Ca^{2+}]_i$ was determined by imaging with fura-2/AM using the ratiometric equation with $R_{min}=0.4$, $R_{max}=6.0$, and $K_d=800$ nM. In both morphological classes, basal $[Ca^{2+}]_i$ ranged from 50-200 nM and increased at least 200 nM in response to $[K^+]_o$, in processes as well as somata. Time courses of $[Ca^{2+}]_i$ increases of neurons with and without outgrowth were similar (peak within 1-2 min), but $[Ca^{2+}]_i$ declined to within 100 nM of basal levels only in cells exhibiting outgrowth. In non-growing neurons it remained high. New $[Ca^{2+}]_i$ steady state levels were established within 20 min. The cell's ability to regulate perturbations of $[Ca^{2+}]_i$ may be critical to neuronal outgrowth.

THE ROLE OF EXTRACELLULAR MATRIX MOLECULES AND MICROGLIA IN REGENERATION OF THE LEECH CNS. L. M. Masuda-Nakagawa, D. Brodbeck and J.G. Nicholls* Biocenter, University of Basel, Basel, Switzerland, 4056

The aim of our experiments is to investigate how substrate molecules of the extracellular matrix (ECM) influence the growth and regeneration of nerve cells. Earlier work has shown that the growth of leech neurons in culture depends on substrate molecules, each substrate producing a characteristic growth pattern. In particular a laminin-like molecule induces slender, straight and relatively unbranched processes. *In vivo*, laminin appears in the regenerating CNS closely associated with regenerating fibers. One question is whether the laminin is newly synthesized or displaced from other sites. Metabolic labeling of regenerating CNS in culture with ^{35}S-methionine indicates that laminin synthesis increases one week after a lesion. Tests have been made to identify the cellular components that make the laminin. Two findings implicate microglial cells: (1) the accumulation of laminin correlates with the migration of microglial cells to the crush site. (ii) microglial cells in culture show immunoreactivity to laminin by immunofluorescence staining. To clarify further the association of laminin with microglial cells immunolabeling is being studied by electronmicroscopy. Our evidence suggests that these wandering macrophage like cells may play a key role in regeneration of the leech CNS in vivo. Supported by Swiss National Fund Grant No. 31-27 814.89.

MODULATION OF BOTH AN NCAM-LIKE ADHESION MOLECULE ON THE SURFACE OF *APLYSIA* NEURONS AND NEURITE FASCICULATION BY 5-HT AND FMRFAMIDE. N. Peter, B. Aranoff, F. Wu and S. Schacher*. Ctr. Neurobiol. & Behav., Columbia Univ. Coll. of P & S, NYSPI, N.Y., N.Y. 10032.

A group of neuron-specific membrane glycoproteins in *Aplysia*, apCAM, was characterized recently and belongs to the same family of cell adhesion molecules as NCAM. Mabs recognizing apCAM can alter the degree of neurite fasciculation of most cells, including sensory and motor cells mediating the gill-withdrawal reflex. The level of expression of these molecules on the surface of the sensory cells, but not the motor cell L7, is down-regulated by applications of 5-HT that evoke long-term synaptic facilitation and structural changes in sensorimotor synapses in-vitro. We therefore examined 1) whether the transmitter FMRFamide, that produces long-lasting changes in sensorimotor connections accompanied by structural changes in the sensory cells, can modulate the level of apCAM, and 2) whether the modulation of apCAM is correlated with transmitter-induced changes in neurite-neurite interaction. Applications of FMRFamide that evoke long-term structural and functional plasticity modulate the level of apCAM on the surface of target cell L7, but not presynaptic sensory cells. As reported for 5-HT effects on sensory cells, the down-regulation of apCAM on L7 by FMRFamide may involve its internalization. Cell-specific changes in the pattern of neurite interactions are evoked by the transmitters and parallel the growth pattern of cells treated with Mabs to apCAM. 5-HT produces a significant reduction in the frequency of fasciculation of sensory cell growth cones with neurites of other sensory cells compared to control or FMRFamide applications. In parallel, FMRFamide reduces significantly the frequency of fasciculation by L7 growth cones on other neurites of L7 compared to control or 5-HT applications. These results suggest that the down-regulation of apCAM on the surface of sensory or motor cells by the respective neurotransmitters may contribute to the transmitter-induced changes in the interactions between homologous cells. These cell-specific changes may participate in the structural modulations accompanying long-term facilitation or inhibition of the sensorimotor synapse evoked by 5-HT or FMRFamide, respectively.

618.7

EVIDENCE FOR A ROLE FOR TYROSINE PHOSPHORYLATION IN REGULATING THE PERIPHERAL ACTIN NETWORK OF THE GROWTH CONE. D.-Y. Wu* and D. J. Goldberg, Center for Neurobiology and Behavior, Columbia University College of Physicians and Surgeons, New York, NY 10032

The network of actin filaments in the periphery of the growth cone is specialized in its organization and activities and plays a critical role in the formation and movement of protrusive structures (filopodia, veils and lamellipodia). The facts that 1) binding of growth factors (such as NGF) to receptor protein-tyrosine kinases apparently rapidly and locally initiates the generation of at least some aspects of this specialized actin system and 2) several actin-associated proteins are substrates for tyrosine phosphorylation suggest that protein tyrosine phosphorylation is important in regulating the assembly or activity of the peripheral actin system. We have investegated this possibility in *Aplysia* neurons.

Axotomized *Aplysia* neurons placed in culture form growth cones with well developed peripheral actin systems even in the absence of growth factor. Immunofluorescence microscopy with a monoclonal antibody to phosphotyrosine reveals staining throughout the growth cone but especially bright staining at the tips of most filopodia. Treatment with an inhibitor of protein-tyrosine kinase (PTK), genistein, eliminates the tip staining from most filopodia. VEC-DIC microscopy reveals that genistein and another PTK inhibitor, lavendustin A, rapidly cause a temporary elongation of filopodia as well as a disappearance of ribs (bundles of actin filaments) in lamellipodia. In addition, either inhibitor completely prevents the formation of filopodia and veils that normally occurs massively along an *Aplysia* axon when it is transected in culture. These results suggest that protein tyrosine phosphorylation, even in the absence of growth factors, is important in regulating the peripheral actin network of the growth cone. One important site of interaction of tyrosine phosphorylated proteins and the actin network may be the tips of filopodia.

618.8

DEVELOPMENTAL EXPRESSION OF G PROTEINS IN MIGRATORY NEURONS OF THE INSECT ENTERIC NERVOUS SYSTEM. P.F. Copenhaver*, M. LaGrange, and A. Horgan, Cell Biol. & Anat. L215, Oregon Health Sci. Univ., Portland, OR 97201.

The formation of the enteric nervous system (ENS) in the moth, *Manduca sexta*, involves the migration of about 400 neurons, the EP cells, along a series of pre-formed pathways on the gut musculature. We are using this system to investigate the mechanisms regulating the onset, duration, and directionality of the cell migratory process. Specifically, we have examined the developmental expression and possible function of the heterotrimeric guanyl nucleotide binding proteins (G proteins) in the course of neuronal migration. Antibodies against the α-subunits of G proteins cloned from *Drosophila* (Wolfgang et al., Devt. **113**, 527) were used to map the patterns of G protein expression during embryonic development. While none of the G proteins could be detected in the premigratory EP cells, all of the cells began to express detectable levels of Goα as they began to migrate. The intensity of staining gradually increased during the migratory period, with immunoreactive material distributed throughout the axonal processes of the EP cells as well as their somata. When preparations were exposed to 10 uM aluminum fluoride for 30 min just prior to the onset of migration, we found that cell migration was completely blocked, although subsequent axonal outgrowth still occurred. To test the possible role of Goα in regulating the extent of neuronal migration, we are using intracellular injections of GTP analogues and purified fragments of the G protein-specific antibodies to characterize the sensitive period and specificity of this putative novel function for G proteins in development. Supported by NSF # BNS 9010538 and by the American Heart Association.

618.9

ACTIN DISPOSITION IN, AND SUBSTRATE ADHESION BY, FILOPODIA EXTENDED FROM PIONEER GROWTH CONES *IN SITU*. T.P. O'Connor* and D. Bentley, Dept. Molecular and Cell Biology, University of California, Berkeley, CA 94720

Filopodia previously have been shown to be essential for correct steering by the Ti1 peripheral pioneer neuron growth cones migrating *in situ* in embryonic grasshopper limb buds. Contact between an extending filopodium and a guidepost neuron can result in selective extension of microtubules into the branch forming from that filopodium. F-actin disposition may be important in controlling microtubule access to filopodia, and in regulating the stability of filopodia. Here, we examined actin disposition in filopodia and the consequences of F-actin depolymerization by cytochalasin.

In an embryonic limb bud fillet preparation, the spatial arrangement of F-actin in pioneer growth cones was observed by injecting rhodamine-labeled phalloidin (2.5U/ul) into Ti 1 cell bodies and allowing it to diffuse throughout the cell. Dense F-actin labeling was observed in filopodia and small branches that extended from the growth cone, and in the peripheral cortical actin network of the axon; little staining was observed in the central region of the growth cone or the axon. Within approximately 2-4 minutes of the addition of cytochalasin D (0.01 - 10 ug/ml), phalloidin labeled F-actin collapsed. If cytochalasin was washed out within 30 min. of initial application, the original pattern of phalloidin labeling was rapidly reconstituted.

Following application of cytochalasin to DiO labeled growth cones, some (predominently short) filopodia retract into the growth cone. However, in every growth cone tested many lengthy filopodia remained extended for periods up to two hours (after 10-20 hr they eventually were withdrawn). Video imaging of DiO labeled growth cones double-labeled with phalloidin confirmed that F-actin did depolymerize following cytochalasin application.

These results suggest that individual filopodia form periodic substrate adhesions; these adhesions may maintain filopodia for several hours in the absence of F-actin. If this is the case, it may account for both the unusual length of filopodia *in situ*, and the ability of individual filopodia to steer along favored guidance substrates.

VIDEO MICROSCOPY OF VACUOLES WHICH FORM FOLLOWING OSMOTIC PERTURBATION OF MOLLUSCAN GROWTH CONES. J.A. Harris, K.E. Smith* and C.E. Morris, Loeb Institute (and Biology Dept.) University of Ottawa, OCH, Ottawa, Ontario, Canada K1Y 4E9

Molluscan neurons regenerating in culture (usually unidentified *Lymnaea* neurons, occasionally *Aplysia* bag cells) were subjected to a variety of acute (minutes) and longer term (hours) osmotic shocks. Cells were monitored on video. Within minutes of return to isosmotic medium, vacuoles (post hyposmotic vacuoles: pHOSvac) formed in the growth cones and at adhesion sites; surprisingly, they disappeared within minutes when neurons were re-shocked. The process was repeatable and the pHOSvacs characteristically reappeared in their previous locations. Isolated growth cones were competent to form pHOSvacs.

pHOSvac formation did not represent irreversible damage to the neurons. Time lapse video of neurons exposed to a distilled water pulse (<2 min) followed by return to isomotic solution (inducing pHOSvacs) demonstrated that over 24 h most of the pHOSvacs disappeared and neuronal arborization processes (eg. lamellipodial searching, axonal transport, retrograde ruffling) continued.

Both pHOSvac formation and their rapid disappearance during a second HOS seem counterintuitive; by pursuing the phenomenon we hope to learn something about processing of cytoplasmic lipid pools. Supported by NSERC, Canada.

IDENTIFICATION OF AN OCTOPUS PROTEIN RELATED TO A HELISOMA ECM NEURITE OUTGROWTH-PROMOTING PROTEIN. J. D. Robertson*, R. D. Hadley and C. E. Hammond, Dept. Neurobiol., Duke Univ., and Dept. Cell Biol. and Anat., Med. Univ. of SC.

We have evidence that tactile learning in *Octopus* is mediated in part by extension of filopodia within neuropils; it can be blocked by treatments that block actin-based filopodial extension (cytochalasin D) and is stimulated by nerve growth factor. To block filopodial extension independently, we plan to interfere with neurite outgrowth-promoting molecules in *Octopus* brain using Fabs and examine the effect on learning.

A ~300 kD *Helisoma* ECM protein has neurite outgrowth-promoting activity for cultured *Helisoma* neurons (i.e., anti~300 kDa Fabs block growth cone initiation, or cause collapse and retraction of active growth cones). We have identified an Mr ~300 kD protein in *Octopus* brain that comigrates with the *Helisoma* protein, and shows a similar Mr shift under reducing vs. nonreducing conditions on SDS PAGE. Antibodies against the *Helisoma* ~300 kD protein also recognize the octopus protein on immunoblots. Antibody Fab fragments against the octopus protein will provide an important tool to address the question of whether neurite outgrowth (i.e. filopodial extension) is crucial to octopus learning. Supp. by NIH 1RO1-NS-26853-01A2.

INTERACTIONS BETWEEN DIFFERENT BRANCHES IN A SINGLE LEECH NEURON W.B. Gan, E.R. Macagno* Dept. of Biol. Sciences, Columbia Univ., New York, N.Y. 10027

In a developing nervous system, a neuron usually sends many axonal branches to interact with different environments. The outgrowth of one branch may only depend on its own environment or, alternatively, different branches may influence each other's growth. Here we choose AP neurons in *Hirudo medicinalis* as our model system to test these two possibilities. During embryogenesis (before embryonic day 10), AP neurons extend lateral projections through two roots to peripheral targets and longitudinal projections through the connective towards neighboring ganglia. Only the lateral projections are found in the adult; the longitudinal projections are eliminated through the inhibition by adjacent segmental homologues during development. Previous studies have shown that either killing the adjacent AP homologues or cutting both roots with scissors at E11-E15 induces the longitudinal projections to grow into the adjacent ganglia and out of their roots to the periphery. (W.Q. Gao & E.R. Macagno, 1987, 1988).

In this report, we studied the relationship between lateral and longitudinal branch outgrowth. DiI staining revealed that there is an enormous amount of AP process outgrowth in the periphery during the time that the longitudinal projections stop growing (E11-E15). After killing its adjacent homologues at E9-E10 and examining the cell three days later, we found that the lateral projections slowed down their outgrowth in the periphery when the longitudinal projections extended ectopically into the periphery through the adjacent ganglia.

Since in the pervious experiments all the nerves in the roots were severed, we tested whether cutting only the AP's lateral projections can induce the longitudinal projection to grow and to overcome the inhibition. To do this, an individual AP cell was stained at E12-E13 with DiI and cut its two lateral projections with a laser microbeam. It was found that the longitudinal projections grew into the periphery within two days via the adjacent ganglia. Cutting only one projection within the root induced the longitudinal projections to grow close to or into the adjacent ganglion but not to the periphery.

Taken together, these results suggest that in the intact nervous system, in which a neuron has many axonal branches, outgrowth state of one branch can influence the outgrowth of the others.

IN VITRO GROWTH OF CRAYFISH AXONS FROM TONIC AND PHASIC MOTONEURONS. K. Egid* and G. A. Lnenicka Depart. of Biol. Sci., State Univ. of New York, Albany, N.Y. 12222

Tonically and phasically active crayfish axons and motor terminals have well-characterized differences in physiology and morphology (Lnenicka, *N.Y. Aca. Sci. 627*:197-211, 1991). To investigate the ontogeny of these differences, we have developed a culture system in which we can observe the regenerative growth of crayfish tonic and phasic motor axons. Abdominal nerve cords, including ganglia one through five, were dissected from juvenile crayfish and plated onto coverslips in culture medium. Within three days, growth was observed from the cut ends of the phasic and tonic branches of the third root. Using standard electrophysiological techniques, we determined that tonic and phasic neurons in culture for one week, retain their different electrical activity patterns. Many tonic cells were spontaneously active, while phasic cells showed no spontaneous impulse activity but responded to stimulation of their cell bodies.

In our initial studies, we have examined the growth patterns of the tonic and phasic motor axons. Cultures were photographed, and the negatives projected and traced. Either length or area of growth was calculated and branching patterns described. Axonal growth was observed as early as 24 hrs after plating and continued for an additional 7 to 10 days. Three patterns of growth repeatedly occurred within a single culture dish: 1) slender with little or no branching, 2) bush-like with extensive branching, 3) extremely wide and flat with little branching. Growth rates and branching pattern of axons differed between the two populations of cells. Growth from tonic axons was almost exclusively type 1, while the growth of the phasic cells consisted of all three types. (Supported by NSF grant BNS-9121757)

COLCHICINE BLOCKS AXONAL REGENERATION IN AN IDENTIFIED NEURON OF *HELISOMA*. **P. J. Kruk* and A. G. M. Bulloch. Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.**

Colchicine is known to bind to microtubules and block axonal transport in many animal classes, including mammals and gastropods, it also blocks neurite elongation in mouse neuroblastoma and PC12 cells. We tested the effect of colchicine on adult *Helisoma* buccal neuron 4 (B4) regenerating after axotomy. This neuron has two axons, one in the ipsilateral and one in the contralateral esophageal nerve trunks, which together innervate the paired salivary glands. The experiments were performed on semi-intact preparations that consisted of the buccal mass, the salivary glands, and all the central ganglia, including the buccal ganglia. Axotomy was performed by crushing both esophageal nerve trunks at a distance of 200-400 μm from the buccal ganglia (20-40% of the nerve length). These semi-intact preparations were cultured separately in medium with various concentrations of colchicine. After culturing for 6-7 days, one of the two neurons B4 in each semi-intact preparation was injected with Lucifer yellow to test its morphology. In control experiments (no colchicine in medium), both axons of the neurons B4 showed extensive regenerative neurite outgrowth. However, neurite outgrowth was blocked in the presence of micromolar or millimolar concentrations of colchicine. It is concluded that colchicine prevents axonal regeneration in *Helisoma* neuron B4, presumably by blocking axonal transport.

SEROTONIN INHIBITS LESION INDUCED SPROUTING IN THE SNAIL CNS: AN *IN VIVO* STUDY. M.W.Baker* and R.P.Croll. Dept. of Physiol. & Biophys., Dalhousie Univ. Halifax, N.S. Canada.

The bilaterally symmetric, serotonergic metacerebral giant (MCG) cell projects to the buccal ganglia of *Achatina fulica* via the ipsilateral cerebrobuccal connective (CBC). This innervation is predominately unilateral providing the only 5-HT in the buccal ganglia. Serotonin-like immunoreactivity (SLIR) in the buccal ganglia 3-7 days after a cut to the CBC, reveals a unilateral loss of 5-HT immunoreactivity in the lesioned ganglion, suggesting the degeneration of severed fibers from the MCG. While ipsilateral regeneration is prevented by a cut to the CBC, SLIR nevertheless returns to the lesioned ganglion 3-4 wks after the lesion. Dye fills and electrophysiological measures reveal that this serotonergic innervation is the result of neuritic sprouting from the contralateral, uninjured MCG (cMCG) into the denervated ganglion. We have previously shown that pharmacological depletion of 5-HT in *Achatina* results in the supernumerary labeling of neuronal elements in the CNS (Baker & Croll, Soc. Neurosci. Abstr: 17,295), thus suggesting that lesion induced depletion might also act to trigger neuronal sprouting. This possibility was tested by administering exogenous 5-HT in conjunction with a cut to the CBC. Sprouting by the cMCG after injection of 5-HT (0.5 mg every second day), was considerably retarded when compared with the normal sprouting response seen 3-4 wks following lesion with vehicle control, DA and 5-HTP injections. These results support a previously suggested role for 5-HT as a neuritogenic modulator in the central nervous system of the snail.

DEVELOPMENT OF NEUROTRANSMITTER SYSTEMS: ACETYLCHOLINE AND SEROTONIN

619.1

NICOTINIC ACETYLCHOLINE RECEPTORS ARE DECREASED IN RAT DENTATE GYRUS FOLLOWING ENTORHINAL CORTEX LESIONS. J. Aubert*, J. Poirier, A. Baccichet, S.Gauthier and R. Quirion. Douglas Hospital Research Center, Departments of Psychiatry and Neurology & Neurosurgery, Center for Studies in Aging, McGill University, Montreal, Quebec, Canada, H4H 1R3.

It has been shown that lesions of the entorhinal cortex (EC) in rat promote the sprouting of acetylcholinesterase (AChE) positive fibers in the dentate gyrus (DG) of the hippocampus. It was suggested that these fibers were cholinergic in nature and originate from the septum nucleus. In our model, lesions of the EC in adult Fisher-344 rats were performed and the status of various cholinergic markers was assessed using receptor autoradiography at various days post-lesions (DPL) (2, 4, 8, 14, and 30). As reported by others, (AChE) staining was significantly *increased* in the ipsilateral DG from 8 to 30 DPL. In contrast, [^{3}H]AF-DX 384 (2nM) and [^{3}H]acetylcholine (20nM)/muscarinic-M2, [^{3}H]pirenzepine (15nM)/muscarinic-M1, [^{3}H]hemicholinium-3 (10nM)/high affinity choline uptake blocker, [^{3}H]AH-5183 (20nM)/blocker of acetylcholine vesicular storage binding sites and choline acetyltransferase (ChAT) activity remained *unchanged* throughout the whole time course. Interestingly, [^{3}H]*N*-methylcarbamylcholine (20nM)/nicotinic binding sites are significantly *decreased* in the ipsilateral molecular and granular layers of the DG from 8 to 30 DPL. Taken together these findings reveal that sprouting AChE-positive fibers of the DG in the EC lesions model are unlikely to be of functional cholinergic nature. The *decrease* in nicotinic binding sites further support this contention on the basis of their likely presynaptic localization in the septo-hippocampal pathway. Supported by the Alzheimer Society of Canada, the American Health Assistance Foundation and MRCC.

NICOTINIC ACETYLCHOLINE RECEPTOR ALPHA-3 SUBUNIT mRNA IN RAT VISUAL CORTEX: ONTOGENY AND EFFECTS OF NEONATAL ENUCLEATION. T.A. Austin*, S.M. Grady and J.L. Fuchs. Dept. Biological Sciences, University of North Texas, Denton, TX 76203.

The present study examines the role of the alpha-3 nicotinic AChR subunits in developing rat visual cortex. Brain sections from hooded rats were used for in situ hybridization. Slide-mounted sections hybridized with antisense or sense (control) mRNA were exposed to film and were later dipped in emulsion. In autoradiographs from P0-P2 rats, alpha-3 mRNA was not yet evident in the visual cortex, but by P5, dense label in layer IV distinguished area 17 from other neocortical areas. During the second postnatal week, alpha-3 levels increased in layer IV throughout the neocortex, but remained highest in area 17. The developmental time course resembles that of geniculocortical innervation, suggesting that nicotinic receptors may be associated with postsynaptic targets for ingrowing LGN axons. We therefore tested whether normal expression of alpha-3 depends upon LGN input. In rats monocularly enucleated at birth and examined on P10-11, alpha-3 mRNA declined in deprived cortex, particularly in layer IV of the monocular region of area 17. In other rats, excitotoxic lesions of LGN made on P9-10 resulted in decreased labeling in ipsilateral area 17. Excitotoxic cortical lesions appeared to eliminate hybridization within the lesioned area, supporting the hypothesis that the alpha-3 mRNA was primarily in neurons, rather than in glia. The observation that neonatal enucleation affected levels of alpha-3 mRNA in area 17 suggests that neural input may influence the differentiation of postsynaptic neurons by altering gene expression governing neurotransmission.

ACETYLCHOLINE RECEPTOR EXPRESSION IN LONG TERM PRIMARY CULTURES OF MAMMALIAN MYOTUBES. C.G. Carlson*, A.M. Bode, M.J. Blake, Y. Feng, J. Faber, B.I. Milavetz. Depts. of Physiology; Pharmacology and Toxicology; Biochemistry and Molecular Biology; Univ. N. Dak., School of Medicine, Grand Forks, ND 58202.

In order to examine synapse-independent mechanisms for regulating the expression of mammalian embryonic (E-) and adult acetylcholine receptors (A-AChRs), a protocol has been developed for preparing and maintaining long term primary cultures of mammalian myotubes. Single channel studies of AChR activity from 9 culture runs revealed both E-AChR (γ_E = 43.4 ± 1.05 pS, SEM, N=55) and A-AChR (γ_A = 65.8 ± 3.2 pS, N=14) activity with a common pipette reversal potential of -67.7 ± 1.8 mV (N=59). The ratio of arithmetic mean burst durations (5 μsec minimum gap duration) for the two event classes (A-AChR/E-AChR) was 0.53 ± 0.03 (N=21). E-AChRs accumulated to maximum levels (minimum channels/patch) between culture days (CD) 10 and 19 and then declined (by about 90%) to a minimum between CD 25 and 29. Northern blot determinations show a corresponding reduction in α, γ, and δ subunit mRNA levels between early (CD13) and late (CD21) culture periods. Evidence for synapse-independent A-AChR expression is based on patch clamp data showing developmental increases in A-AChR activity. Although this expression was lower and more variable than that at intact endplates, up to 40% A-AChR events were observed in individual patches over a 3 day period of expression. The relationship between this expression and that of the subunit mRNAs is under investigation (We thank J.P. Merlie and P. Gardner for kindly providing AChR subunit cDNAs; NSF-EPSCOR 90).

SEGMENT-SPECIFIC ACETYLCHOLINE RESPONSES OF RETZIUS NEURONS IN THE MEDICINAL LEECH. Lidia Szczupak, Sheryl Jordan, Kathleen A. French*, and William. B. Kristan Jr. Department of Biology., University of California, San Diego, La Jolla, CA, 92093-0322.

Acquisition of the mature phenotype of neurons depends on both intrinsic and extrinsic signals. As part of a study of how these two signal sources interact during neuronal maturation in the medicinal leech, we have studied how Retzius neurons from segments containing the male and female reproductive ducts [Rz(5,6)] and from standard segments [Rz(X)] respond to acetylcholine (ACh) applied to the soma. Single ganglia were isolated and desheathed, Rz neurons were voltage clamped with a single microelectrode and the ionic currents elicited by pressure pulses of ACh were studied. In addition, both types of Rz cells were studied in isolation in a cell culture system.

All Rz cells responded to ACh with an anionic outward current, and Rz(X) in addition developed a rapidly desensitizing cationic inward current. This inward current had a physiological and pharmacological profile typical of neuronal nicotinic receptors. In contrast, the outward current possessed features some of which are typical of nicotinic cholinergic receptors and others of which are typical of muscarinic receptors.

These distinctive responses to the application of ACh mimic how each type of Rz cell responds when pressure-sensitive mechanoreceptor neurons (P cells) are stimulated. Therefore, we will determine whether the P cell to Rz neuron synaptic interaction is mediated by a cholinergic synapse, as a model for the development of postsynaptic responses in segmentally homologous, but physiologically distinct, neurons that derive from the same cell lineage.

AN ULTRASTRUCTURAL STUDY OF SEROTONERGIC CELLS IN THE CNS OF EMBRYONIC AND LARVAL *APLYSIA*. R. Marois*, G. M. Kelly, S. Hockfield & T. J. Carew. Interdepart. Neurosci. Prog., Section of Neurobiol., Depts of Biol. and Psychol., Yale University, New Haven, CT 06520

In adult *Aplysia*, identified serotonergic (5HT) neurons in the cerebral ganglion (CG) contribute importantly to synaptic plasticity (Mackey et al., 1989). Some of these 5HT cells have been identified in embryonic and larval *Aplysia* using whole-mount immunocytochemistry (Marois & Carew, 1990). As an initial analysis of the roles that these cells may exert during the development of the nervous system, we have examined the fine structure and projections of the 5HT neurons of the CG using immunocytochemistry at the LM and EM level.

Our results confirmed the presence and fate of 5 serotonin-like immunoreactive (SLIR) cells in the CG at the onset of the larval period: two bilateral pairs of cells apparently belonging to the ACC cluster of adult *Aplysia* (Nolen & Carew, 1986) and a median unpaired cell that is lost at metamorphosis. These cells have four main projection trajectories. 1) All project centrally to a dense neuritic plexus in the CG, where large SLIR fibers associate with non-serotonergic neurites. 2) One of the bilateral pairs of cells and the unpaired median cell send forward projections to the velum, where they appear to contact both myocytes and velar ciliated cells, supporting a role for 5HT in ciliary beating. 3) SLIR fibers also seem to interact with myocytes of the body wall and internal muscle bundles. 4) Another SLIR fiber, apparently from the second bilateral pair of cells, appears to follow the pleuroabdominal tract of the CNS. This fiber extends posteriorly and ventrally from the CG through an ensheathed nerve bundle to a cluster of cells located dorsal to the statocysts. There it joins a neuropil, and then continues more caudally at the latero-ventral margin of the esophagus. The course of this fiber, together with the known ontogenetic position of the other central ganglia, suggests that it travels through the anlage of the pleural and possibly the abdominal ganglia. Thus it will be of interest to determine the anatomical connections and possible functional roles of this identified serotonergic projection.

TRYPTOPHAN HYDROXYLASE-IMMUNOREACTIVE NEURONS OCCUR IN THE HYPOTHALAMUS OF THE CHICK EMBRYO. A.M. Gabaldon, J.K. Lobner, S.L. Saavedra and J.A. Wallace*. Dept. of Anatomy, Univ. of New Mexico Sch. of Med., Albuquerque, NM 87131.

Numerous tyrosine hydroxylase-immunoreactive (TH+) cells occur in the chick hypothalamus in patterns observed for dopamine (DA)-containing neurons in mammals. However, the majority of these cells cannot be demonstrated to synthesize DA. In chick embryos near hatching, we have now examined the hypothalamus for the presence of cells immunoreactive for tryptophan hydroxylase (TPOH+), the first enzyme in the synthesis of serotonin (5-HT). Large numbers of intensely stained TPOH+ neurons are found in locations contiguous with sites containing TH+ cells. However, TPOH+ cells occur in the paraventricular organ (PVO) where no TH+ neurons are seen. While 5-HT-immunoreactive cells are detected in the PVO, no other 5-HT containing perikarya are observed in the hypothalamus corresponding to sites of TPOH+ neurons. This is in contrast to the lower brainstem where TPOH+ and 5-HT-immunostained cells co-localize in all nuclei examined. Therefore, most hypothalamic TPOH+ neurons may lack amino acid decarboxylase or the isoform of the TPOH enzyme in these cells is inactive. Supported by MBRS grant GM-08139-18.

THE DEGREE OF NEUROTOXIC INSULT ELICITED BY METHYLENEDIOXY-METHAMPHETAMINE (MDMA) IS MODIFIED BY POSTNATAL AGE. H.W. Broening*, G.D. Newport, S.F. Ali, W. Slikker, Jr. Division of Neurotoxicology, NCTR, Jefferson, AR 72079.

MDMA has been demonstrated to be a potent and selective neurotoxicant to the serotonergic neurotransmitter system. Persistent depletions in serotonin (5-HT) and 5-hydroxy-indoleacetic acid (5-HIAA) levels as well as long-term loss of 5-HT uptake sites and tryptophan hydroxylase activity are observed following administration of MDMA to experimental animals. Sprague Dawley rats, males and females, were given a single p.o. dose of MDMA at various postnatal ages and 5-HT and 5-HIAA levels were measured by HPLC/EC one week after MDMA exposure. MDMA administration at or prior to postnatal day (PND) 10 did not result in deficits in 5-HT or 5-HIAA levels one week after MDMA exposure. Administration of 40 mg/kg of MDMA on PND 15 or PND 20 resulted in an 11 or 13 % depletion respectively, in 5-HT levels in the hippocampus, but had no significant effect on levels of 5-HIAA one week after MDMA exposure. This is in contrast to administration of 40 mg/kg of MDMA to 150 day old rats, wherein 5-HT and 5-HIAA levels where decreased by 50 and 49 % respectively, in the hippocampus one week after MDMA exposure. These results indicate that sensitivity to the long-term 5-HT depleting effects of MDMA develops as the rat CNS begins to mature. Further study of this phenomenon may provide a greater understanding of the underlying mechanisms responsible for the neurotoxic effects of MDMA.

619.8

THE ROLE OF SEROTONERGIC REUPTAKE BLOCKADE IN PRODUCING COCAINE'S EFFECTS ON CEREBRAL FUNCTION IN PERIWEANLING RATS. G.S. Frick, H.E. Hughes, E.A. Grose, L.A. Freed*, D.L. Dow-Edwards Laboratory of Cerebral Metabolism, Department of Pharmacology, SUNY-Health Science Center at Brooklyn, Bklyn, NY 11203.

Previous studies from our laboratory have shown permanent neurochemical changes in rats administered cocaine during postnatal days 11-20 (Dow-Edwards, Annals NY Acad Sci 562:280-289, 1989). By comparing the effects of fluoxetine, a serotonin reuptake inhibitor, to cocaine, the contribution of this pharmacologic property of cocaine to the long-term neurochemical effects can be determined. Sprague-Dawley rats were mated in our animal facility and on day of parturition, pups were assigned to receive sc injections of cocaine or fluoxetine at 25mg/kg or equivalent volume of vehicle each day during days 11-20. Local rates of glucose utilization were determined when the animals were 21 days old using the deoxyglucose method of Sokoloff. The final dose of drug or vehicle was administered 20 min prior to deoxyglucose administration. ANOVA revealed a significant main effect of treatment in each of the 18 brain structures selected for analysis. Post hoc analysis indicated that cocaine but not fluoxetine administration resulted in altered patterns of brain glucose utilization. We therefore suggest that the effects of developmental cocaine exposure on adult brain function are not due primarily to inhibition of serotonin reuptake.

DEVELOPMENT OF NEUROTRANSMITTER METABOLISM IN THE BRAIN OF THE CHICK, GALLUS DOMESTICUS. Naokuni Takeda *. Dept. of Biotechnology, COSMO Research Institute, Satte, Saitama, 340 - 01, JAPAN.

The dynamics of neurotransmitters including precursor amino acids,biogenic monoamines and their metabolites were examined with the progress of embryonic development. These 30 compounds were analysed simultaneously by coulometric three dimension HPLC system (CEAS: ESA Inc., USA).

In the early stege (St. 5*), primitive pathways were TYR-4 ➡ TYRA ➡ HPAC-4 and TYR-4 ➡ L-DOPA ➡ 3OMD. In the middle stege (St. 10*), TRP ➡ 5HT ➡ 5HIAA pathway appeared. In the late stage (St. 25*), NE was detected, in particular in the hindbrain. Just before hatching (St.44), DA ➡ DOPAC pathway appeared. Levels of 5HT, NE and DA increased with the progress of development. These main pathways are shown below. These results will be discussed from the view point of ontogeny and phylogeny.

IMMUNOHISTOCHEMICAL EVIDENCE OF INDOLAMINE AND CATECHOLAMINE CONTAINING CELLS IN CULTURES OF HUMAN CENTRAL NERVOUS SYSTEM. M.C.Calvet* and C.Levallois. INSERM U336, USTL, 34095 Montpellier, France.

Embryonic neurons from monoaminergic nuclei of the brainstem are used for neural transplantation; the knowledge of the localization and of the development of those embryonic cells has to be investigated. As previously described, serotonergic cells are mainly located in the rhombencephalon; catecholamine containing cells are located in the rhombencephalon and an extensive system is described in the mesencephalon. The living dissociated cells isolated from 6-10 week old human fetuses were immunostained for serotonin (5HT) and dopamine (DA) at different ages in vitro. Numerous 5HT-stained neurons in the rhombencephalon and DA-stained neurons in the mesencephalon were observed which developed numerous processes with well individualized growth cones. These results show that monoaminergic cells are characterized in the CNS at the early stages of the human development.

RESULTS FROM A RAPID SCREENING TECHNIQUE FOR ASSAY OF NEURONAL DIFFERENTIATION FACTORS. M.-J. Fann*, and P. H. Patterson. Division of Biology, 216-76, Caltech, Pasadena, CA91125.

We have developed a relatively rapid assay for simultaneously screening multiple neuronal differentiation activities. Sympathetic superior cervical ganglia are dissociated from neonatal rats and grown in 96-well plates in the presence of candidate factors. After 7 days, total RNA is extracted and expression of mRNAs for 14 different neuropeptides and neurotransmitter synthetic enzymes is analyzed in parallel by the RT-PCR method. Among the 21 cytokines and growth factors tested so far (IL-1α, IL-2, IL-3, IL-4, IL-5, IL-6, INF-γ, TNF-α, GM-CSF, G-CSF, TGF-α, TGF-β, IGF-I, EGF, SCF, oncostatin M (ONC), cholinergic neuronal differentiation factor (CDF), ciliary neurotrophic factor (CNTF), PDGF, aFGF, bFGF), only CDF and CNTF alter neuronal gene expression in this assay. A new finding is that both of these factors induce cholecystokinin and preproenkephalin mRNA. Interestingly, although CDF, IL-6, and ONC are structurally related, and IL-6, CDF and ONC have receptor subunits in common, we are thus far unable to observe an induction of neuropeptide or neurotransmitter synthetic enzyme mRNAs by IL-6 or ONC in the sympathetic neurons.

620.2

QUANTIFICATION OF mRNA LEVELS ENCODING NEUROTROPHIC FACTORS DURING POSTNATAL DEVELOPMENT OF MOUSE NIGROSTRIATAL DOPAMINE NEURONS Cynthia L. Shannon and Mariann Blum * Fishberg Research Center for Neurobiology , Mount Sinai School of Medicine, New York, NY 10029

Neurotrophic factors in the EGF, FGF and neurotrophin family have been shown to increase the survival of midbrain dopamine neurons in vitro. Conventionally, trophic molecules are thought to be provided by targets to support projection neurons. Not only is there evidence for the expression of growth factors in the striatum, a target for dopamine neurons, but growth factor mRNA is also found in the substantia nigra and even in the dopamine neurons themselves. These trophic substances may be acting as target derived factors and/or serve as paracrine or autocrine factors to promote growth and support survival. In order to substantiate the role of neurotrophic factors in the development and maintenance of dopaminergic neurons, we have begun a postnatal developmental study on the expression of EGF, TGF-α, BDNF, bFGF and aFGF mRNA in the dorsal striatum and ventral mesencephalon. Brain tissue from mice was collected at fourteen postnatal time points ranging from two days to twenty weeks. The quantitative nuclease protection assay was employed to determine the levels of growth factor mRNA in total cytoplasmic RNA. The specific mRNA for aFGF, bFGF, TGF-α , and BDNF were detected at every time point assayed and were compared after normalization to total RNA. During postnatal development TGF-α mRNA levels were consistently higher in the dorsal striatum than in the ventral mesencephalon; whereas BDNF mRNA levels were always higher in the ventral mesencephalon. The expression level of aFGF increases in both areas as the animal matures. The advantage to this approach is that within a defined region, at a given time in development, growth factor levels can be compared and relationships between growth factor family members can be identified. Correlating the changes in expression of these neurotrophic factors and known developmental events will give clues to the function of these important molecules in normal brain development.

MODEL NEURONAL CULTURES TO STUDY THE EFFECTS OF DRUGS ON NEURONAL FUNCTION. W. Chen, P. Coates and S.E. Poduslo*. Depts. of Neurology, Cell Biology and Biochemistry, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

Model primary cultures of neurons were prepared from midbrain and striatal areas of embryonic rats. The specific brain areas were dissected and subjected to a brief trypsinization step in isolation medium. The softened tissue was passed through nylon screens and the cell suspension plated onto polyethyleneamine coated flasks. After one hour the medium (Dulbecco's high glucose with insulin, 1% BSA and 10% fetal calf serum) was changed to remove cell fragments. Over the next 24-48 hours the cultures consisted primarily of neurons which extended long processes. Choline acetyltransferase and tyrosine hydroxylase enzyme activities were measured in the cultures after 2 days in vitro. The choline acetyltransferase assay measured the production of ^{14}C acetylcholine while the tyrosine hydroxylase assay measured the nonenzymatic decarboxylation of DOPA. The tyrosine hydroxylase assay was modified in that neurons in T_{25} flasks were scraped and homogenized in a buffer containing 0.1% Triton and then concentrated in an Amicon Centricon 10 filter. The pH of the substrate mixture was adjusted to obtain the optimal pH of 6.1 for this assay. The assay was conducted in microfuge tubes in a final volume of 20μl. After the reaction the samples were transferred to glass vials for decarboxylation and subsequent $^{14}CO_2$ absorption. After 2 days in culture, neurons from midbrain had an activity of 20pmol/min/mg soluble protein for tyrosine hydroxylase and 313pmol/min/mg protein for choline acetyltransferase. In addition, mRNA levels for the dopamine receptors and c-fos and c-jun will be assessed. This neuronal culture system will be used to measure the effects of cocaine and methamphetamine on neuronal function. Supported by NIH grant DA07366.

620.4

ANALYSIS OF SERUM ANTI-GM1 ANTIBODY TITER IN PATIENTS RECEIVING GM1 THERAPY. R.K.Yu*, M.Saito, Y.Zhang, R.Fiorentini, F.Khin-Maung-Gyi, Gary H. Friday. Med. Coll. VA, VCU, Richmond, VA 23298 and Fidia Pharmac. Corp., Washington DC 20006

It is well known that gangliosides, particularly GM1, possess neuritogenic and neuronotrophic properties in vitro and in vivo. Gangliosides have also been shown to exert protective effects in certain neurodegenerative conditions, including strokes, spinal cord injury, and neuropathies. Thus, ganglioside GM1 has been used as a therapeutic agent for a variety of neurological diseases. To examine the safety of GM1 therapy, we carried out double blind, placebo-controlled studies in normal subjects and patients with acute ischemic cerebral infarction. Serum samples removed at different time intervals (day 0 to 84) were assayed for anti-GM1 titers using a solid-phase ELISA. Of the 418 samples assayed, only 7 were judged to have a marginal anti-GM1 response at 1:800 dilution. Among the 7 positive samples, 1 was from a subject who received a single dose (1,200 mg) of GM1, 2 were from a subject before and after receiving 400 mg of GM1, and the other 4 were from 3 subjects receiving no GM1. We conclude that there is no clear association between GM1 therapy and the development of anti-GM1 titers.

COMBINED BUT NOT INDIVIDUAL GROWTH SUBSTANCES MIMIC THE REPARATIVE EFFECT OF GM1 GANGLIOSIDE ON CULTURED DOPAMINE NEURONS DAMAGED BY MPP+. N. Stull* and L. Iacovitti, Dept. of Neurology, Hahnemann Univ. Phila. PA 19102

We have previously demonstrated that, in culture, GM1 ganglioside can increase the number of dopamine neurons surviving MPP+ toxin treatment as well as enhance their biochemical function (Stull, et al. 1991). Cytokines and neuronal growth factors are also thought to play a role in the survival and biochemical development of these neurons. Therefore, we sought to examine whether growth substances either individually or together could mimic and/or enhance the reparative effects of GM1 on MPP+ damaged dopamine neurons. The ventral mesencephalon was dissected, plated, and maintained on standard media. On day 4, some cultures were fed media containing 2.5 μM MPP+. One day later, cultures were refed media supplemented with one or all of the following: NGF, bFGF, aFGF, EGF, IGF, CNTF, TGFβ, IL1, LIF, and Insulin (1-100ng/ml). To test whether growth substances could further enhance the GM1 effect, in some cases, media was simultaneously supplemented with 100μM GM1. After 7 days in vitro, cultures were processed for assay of tyrosine hydroxylase (TH) activity and TH-immmunostaining. Exposure to MPP+ for 24hrs produced a 23-30% decline in the number of surviving TH+ neurons. The addition of individual growth substances had no effect on cell loss due to MPP+. However, the addition of a mixture of all growth substances to MPP+-treated cultures restored the number of TH+ neurons to nearly control levels (93%), and simultaneously induced the level of TH activity/TH+ neuron (33%). Incubation with TGFβ alone resulted in a comparable degree of biochemical induction(35%) but had no effect on dopamine cell survival. Addition of GM1 to individual growth substances or the mixture did not further enhance survival or dopamine biochemistry. These data suggest that while individual factors like TGFβ may influence transmitter biochemistry, it is the combination of growth substances which may be important for improving dopamine cell survival after MPP+ damage. Since GM1 does not act synergistically with these substances, it is possible that growth substances and GM1 both work through a common pathway to achieve their beneficial response in injured dopamine neurons.

GM1 REGULATES THE MORPHOLOGY OF NEURO-2a NEUROBLASTOMA CELLS BY ALTERING THE DISTRIBUTION OF MAP-2. L-J. Wang, G. Yorke* and F. Roisen. Department of Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, KY 40292.

Our laboratory has demonstrated that exposure of either primary sensory neurons or established neuroblastoma lines to the ganglioside GM1 enhances microtubule (MT)-dependent neurite formation. Taxol (MT stabilization) potentiates GM1-mediated neuritogenesis, whereas Colcemid (MT disassembly) blocks ganglioside-induced neurite elongation. Several reports indicate that GM1 increases tubulin mRNA in neuroblastoma cells. Therefore, the mechanism underlying GM1's neuritogenic action appears MT-related. Since developing neurons contain microtubule associated proteins (MAPs) and Tau proteins, which have the capacity to regulate neuronal morphology, this study examined immunocytochemically the effect of GM1 exposure on the level and distribution of MAP-2, tubulin, MAPs and Tau proteins in Neuro-2a murine neuroblastoma cells. Cells were plated in the presence and absence of GM1 (150 μg/ml) for 24 hr prior to immunolocalization with monoclonal antibody (mAb) specific for MAP-2 and a polyclonal antibody (pAb) against MAPs and Tau protein. Further studies employed mAb and pAb against tubulin. GM1 increased MAP-2 reactivity of the distal neuritic regions but did not alter the distribution or reactivity of MAPs or Tau-positive material. Simultaneous exposure of Neuro-2a to GM1 and taxol (2 hr) resulted in intense label of MAP-2 over all distal neuritic regions. Western blot analysis of cells exposed to GM1 for 24 hr revealed levels of MAP-2 equivalent to that found in the untreated controls. Further studies employing immunoelectron microscopy are in progress. Our results are consistent with the belief that gangliosides facilitate neuronal development by producing a redistribution of existing intracellular structural and regulatory protein pools. Furthermore, they suggest that GM1 changes neuronal morphology by altering the distribution of MAP-2 which regulates MT assembly. Supported by a grant from the Alliant Community Trust Fund.

DEVELOPMENTAL EXPRESSION OF G41, A NOVEL LAMININ-LIKE CDNA CLONE IN NORMAL AND MUTANT MOUSE BRAIN T.T.Quach*, A.M.Duchemin, B.K.Schrier[1]. Dept of Pharmacology,OSU,Col.of Med.,Columbus,OH,[1] Technology Unlimited,Wooster,OH.

We have designed a 30 mer oligonucleotide representing a common and conservative amino-acid sequence of NGF and BDNF to screen a cDNA library constructed in plasmid pGEM, from poly(A+)RNA extracted from lesioned rat brain. More than 30 clones with a positive signal were sequenced with T7DNA polymerase from both ends. One of the above clones appears to be potentially interesting in light of the trophic and/or adhesive activity of the gene product(s). Sequence comparison of partially sequenced insert (1000bp on 1.3Kb) revealed homology from both ends, of 53% and 55% with B2 laminin chain, and of 67% with IGF over 170 bp in the middle of the insert. In addition, G41 has a motif representing 100% homology to N-CAM. We have previously shown that in the rat, the unique hybridizing band was detected at a position corresponding to approximately 3.8Kb and that G41 gene is regulated during brain injury.

A unique band with an apparent similar size was observed in mouse brain. In the present study, we examined the developmental pattern of G41 expression in normal and mutant mouse brain -staggerer, weaver, and purkinje deleted mutant- to identify whether this gene is similarly regulated or whether there is some abnormal expression in mutants during development. Experiments designed for this purpose are currently underway.

EFFECT OF CONCANAVALIN A (Con A) ON GROWTH OF CULTURED NEURONS FROM MAMMALIAN CENTRAL NERVOUS SYSTEM (CNS). P.W. Coates* and T. L. McKee. Cell Biology & Anatomy, Texas Tech Univ. HSC - School of Medicine, Lubbock, TX 79430.

The lectin Con A is a useful tool for inducing alterations in properties of some cultured neurons. Besides changing membrane properties (ion channel activity, neurotransmitter responses and synaptic connectivity), Con A promotes nerve fiber outgrowth in *Aplysia*, leech and chick dorsal root ganglia. To determine whether neurons from mammalian CNS grow more in response to Con A, neurons from fetal rat brain (striatum) were cultured at low cell density in three-dimensional (3D) collagen lattices or polyethylenimine (PE) coated dishes in the presence or absence of Con A (0.5 or 5.0 μg/ml). Nerve fiber length of single neurons was measured using image analysis. Morphological indicators of complex growth were also assessed. Data from three experiments were pooled and analyzed using analysis of variance. Total nerve fiber length per neuron increased significantly for neurons cultured at low dose Con A on 3D. Fiber outgrowth of neurons on PE showed a similar pattern. At higher Con A concentration, there was an increase in mean number of primary processes for neurons on both substrates, and in average number of terminals of neurons on PE. Observations suggest that neurons from mammalian CNS can grow longer nerve fibers and express somewhat more complex growth patterns under the influence of Con A. The precise molecular mechanism by which Con A induces alterations in neuronal growth (or membrane properties) is not known, but it has been suggested that different mechanisms might be involved rather than a single receptor and transduction mechanism. It is also conceivable that under these culture conditions Con A could affect mechanisms for fiber elongation differently than mechanisms influencing complex growth. Supported by SITRF.

TROPHIC ACTIONS OF MIDKINE (MK), A HEPARIN-BINDING PROTEIN, ON MOUSE SPINAL CORD AND SENSORY GANGLION NEURONS IN CULTURE. M. Michikawa*, H. Muramatsu, T. Muramatsu and S.U. Kim. Dept. of Neurology, Univ. of British Columbia, Vancouver, Canada; and Dept. of Biochemistry, Kagoshima Univ., Kagoshima, Japan.

Midkine (MK) is a 14 kDa protein product of a retinoic acid responsive gene, MK, and is a member of a new family of heparin-binding growth factors structurally unrelated to FGF (J. Cell Biol, 110, 607, 1990). It has a 50% sequence homology with pleiotrophin and has been found to promote neurite extension in embryonic rat CNS neurons. Trophic effects of MK were studied in dissociated cell cultures of fetal mouse spinal cord and dorsal root ganglion (DRG). There was a 3-4 fold increase in the number of MAP-2 immunoreactive neurons and a 2-4 fold increase in choline acetyltransferase activity (ChAT) in MK-treated spinal cord (13-14 day fetal) cultures. The number of surviving neurons following MK treatment was 3-4 fold over controls in 13-14 day fetal and 17 day fetal DRG cultures, while there was no apparent difference in neuronal survival in neonatal DRG cultures. These results suggest that MK has definite trophic effects on mouse spinal cord and DRG neurons such as neuronal survival and ChAT induction activities.

MENINGES RELEASE A DIFFUSIBLE ACTIVITY THAT PROMOTES CORTICAL VIABILITY AND NEURITE EXTENSION.

Makoto Sato* and D.D.M. O'Leary. The Salk Institute, La Jolla, CA 92037.

At very early stages of development, the influence of the mesoderm on the ectoderm is crucial for the establishment of the nervous system. However, mesodermal influences on the later development of the central nervous system have received little attention. Here we demonstrate that the meninges, which are of mesodermal origin and cover the brain and spinal cord, substantially influence cortical development in vitro. The viability of dissociated cortical neurons cultured in the presence of meninges, but at a distance, is enhanced 3-fold when grown in a collagen matrix and more than 10-fold when grown on polylysine. Meninges co-cultured at a distance with cortical explants or dissociated cortical cells in 3-D collagen matrices also greatly enhance neurite outgrowth and the rate of axon extension. Meninges-conditioned medium (MCM) shows the same effects. Axons cultured with meninges or MCM have a more deviated growth behavior and are much less fasciculated than those grown in control medium. In addition, the effect of MCM is farily acute. Use of time-lapse video imaging shows that the growth rate of cortical axons is dramatically enhanced about 40 min. after exposure to MCM. These facts imply that the meninges-derived factor(s) may have an adhesive-nature and act directly on the tips of growing neurites (i.e. growth cones). The extracllelular matrix components laminin and fibronection, which have adhesive properties and increase the rate of axon growth of the peripheral neurons, do not mimic the effects of MCM in these cortical cultures. When we treat MCM with centricon (Amicon, molecular weight cut off device), we observe the neurite extension activity in the fraction under 30kD. These findings show that meninges release a diffusible factor(s) that promotes in vitro cortical viability and neurite extension. The meninges may play a crucial role in promoting multiple aspects of cortical development. We are pursuing the precise nature and identity of the responsible molecule(s).

AMNIOTIC BASEMENT MEMBRANE REGULATES SMOOTH MUSCLE RESPONSES TO SUBSTANCE P. C.W. Bowers* and L.M. Dahm. Beckman Res. Inst., Div. Neurosci., Duarte, CA 91010.

Using a novel smooth muscle (SM) preparation, the avian amnion, we have examined the extracellular factors that determine the responsiveness of SM cells to specific neurotransmitters. The avian amnion is an anatomically simple tissue, neither innervated nor vascularized, containing only a single layer of epithelium, and 1-2 layers of SM. While responsive to many types of neurotransmitter, the amniotic muscle is normally unresponsive to the neuropeptide substance P. This is unusual, because most non-vascular SMs contract vigorously in response to nanomolar substance P. Culturing the intact amnion in a defined medium for 1 wk did not induce the appearance of substance P responses, as assessed by contractility measurements. However, when the amniotic SM was dissociated from the rest of the tissue and cultured in the same defined medium as used for the intact cultures, SM cells became responsive to substance P within 24 hr, with 90% of the SM cells contracting in response to nanomolar substance P by 4 days in culture. These results were not associated with proliferation and were specific for substance P. When amniotic SM cells were dissociated and plated onto basement membrane purified from amnion, the induction of substance P responsiveness was completely suppressed. Smooth muscle cells plated onto the same coverslip, but not in direct contact with the purified basement membrane, showed the usual induction of substance P responsiveness. The data suggest that molecules in the basement membrane normally suppress the amnion's response to substance P. We hypothesize that other tissues expressing diverse pharmacological phenotypes may also be regulated by molecules in the extracellular matrix.

CHEMICAL LESION INDUCED 5-HT SPROUTING CO-OCCURS WITH INCREASES IN LAMININ, S100, AND 30-45KD PROTEINS, BUT NOT 5-HT1 RECEPTOR IN THE STRIATUM. D. Beversdorf●*, C. F. Pu●, B. A. Al-Seikhan●, E. C. Azmitia○, and F. C. Zhou•. Indiana Univ. Sch. Med.●, Dept. Anatomy, Indianapolis, IN 46202 and Dept. Biology, New York Univ.○, NYC, NY 10003.

Excitotoxic lesion in striatum induced intense sprouting of 5-HT fibers (Zhou et al., 1991). We report here that lesions altered the trophic state of brain profoundly. Ibotenic acid (IB) injected into striatum of Sprague-Dawley rats induced four levels of changes post-lesion: (a) removal of intrinsic neurons at injection site at 3 days; (b) accumulation of reactive astrocytes at 3, 8 and 21 days; (c) hyperexpression of laminin and S-100; (d) stimulation of expression of 45KD protein and increases in levels of 49, 35, 30 KD proteins. Area of 5-HT innervation coincides with that of hyperexpression of trophic substance S100 and laminin, which is at injection site, but not reactive GFAP-positive astrocytes. 5-HT receptor binding with [3H]-5-HT did not show an increase in autoradiograph density within area of lesion. The hyperexpressed S100 and laminin marked a subpopulation of astrocytes which is smaller than population of GFAP-positive reactive astrocytes. These reactive, hyperexpressed astrocytes may be responsible for hyperinnervation. Similar 5-HT hyperinnervation was seen in hippocampus after IB/ kainic acid lesioning. (supported by NIH grant NS23027 to FCZ)

REGULATION OF VASOACTIVE INTESTINAL PEPTIDE (VIP) AND SUBSTANCE P (SP) EXPRESSION IN SUPERIOR CERVICAL GANGLION (SCG) AFTER AXOTOMY AND IN CULTURE. M. S. Rao *, Y. Sun, U. Vaidyanathan, S. C. Landis, and R. E. Zigmond. Dept. of Neuroscience, Case Western Reserve University, School of Medicine, Cleveland, OH 44106

The expression of VIP- and SP- immunoreactivity (IR) increase in sympathetic neurons of the neonatal and adult SCG when the ganglion is maintained in organ culture for 48 hrs. In addition, VIP-IR increases in SCG in situ within 48 hr of postganglionic axotomy (Soc. Neurosci. Abstr. 17:400,1991). We have examined the time course of VIP induction after axotomy and found that levels of VIP-IR increased significantly by 24 hr, reached a peak by 6 days, and remained elevated for at least 2 weeks. To determine whether SP is also increased by axotomy, we measured SP-IR 48hr and 2 weeks after surgery, using a radioimmunoassay. Consistent with a previous report (Brain Res. 234:182,1982), there was no difference in the level of SP-IR between axotomized and sham-operated ganglia 2 weeks after surgery; however, 48 hr after axotomy, SP-IR was increased 12-fold. Immunohistochemical studies revealed an increase in SP-IR in principal neurons in the SCG 48 hr after axotomy. Previous studies have indicated that the increase in substance P that occurs in organ-cultured SCG can be reduced by the synthetic glucocorticoid dexamethasone. We have compared the effects of dexamethasone (0.1 μM) on SP and VIP expression in organ culture and in cell culture. Dexamethasone blocked the increases in SP-IR normally seen in both types of culture almost completely and reduced the increases in VIP-IR by about half. Thus, qualitatively there are marked similarities in the regulation of VIP and SP in the SCG, though there appear to be quantitative differences. 620.14

A SOLUBLE FACTOR SECRETED BY GANGLIONIC NON-NEURONAL CELLS INCREASES VIP LEVELS IN DISSOCIATED CELL CULTURE AND EXPLANTS OF RAT SUPERIOR CERVICAL GANGLION (SCG) . Y. Sun*, M. S. Rao, R. E. Zigmond and S. C. Landis. Department of Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

Explantation causes an increase in VIP levels in both adult and neonatal rat SCG. A similar increase is seen in dissociated cultures of SCG, in both defined and serum-containing medium. To investigate whether ganglionic non-neuronal cells play a role in VIP induction, cultures were preplated to reduce the non-neuronal cell population by an estimated 80-90%. Compared to control cultures, cultures that had been preplated showed a 60% reduction in VIP per neuron after 2 days. To determine if the effect of the non-neuronal cells is mediated by cell contact or the release of a soluble factor, we examined the ability of non-neuronal cell conditioned medium (NNCM) to alter VIP levels. The NNCM increased VIP levels in dissociated cell cultures by 2-3 fold. Medium conditioned by neuronal cultures that had been preplated had no effect. The NNCM also caused a 2-3 fold increase in VIP content in SCG explants. Two previously described factors, CDF/LIF and CNTF, have an effect in culture similar to that of NNCM and thus might be responsible for the alterations in VIP levels produced by NNCM. To determine whether the NNCM contains CNTF, we performed ciliary neuron survival assays. The NNCM did not have any detectable trophic activity, suggesting that the factor in NNCM is not CNTF. Whether the NNCM contains CDF/LIF remains to be determined. (Supported by NS12651, MH00162, HD25681 and a AHA fellowship to MSR)

620.15

REGULATION OF VASOACTIVE INTESTINAL PEPTIDE (VIP) EXPRESSION IN RAT SUPERIOR CERVICAL GANGLION (SCG) IN ORGAN CULTURE BY AGENTS THAT ELEVATE cAMP. R. P. Mohney and R. E. Zigmond*. Dept. of Neuroscience., Case Western Reserve University, School of Medicine, Cleveland, OH 44106 ,

VIP expression increases in sympathetic neurons in adult rat SCG in organ culture. The VIP gene contains a cAMP response element that is required for cAMP-regulated transcription of the gene. VIP itself and secretin, another member of the same peptide family, have been shown to act in many tissues via stimulation of adenylate cyclase. Therefore, we examined whether these peptides can increase VIP expression in the SCG. Adult rat SCG explants were cultured for 30 min in medium containing 500 μM IBMX alone or IBMX together with 10 μM forskolin or 3 μM secretin. Both forskolin and secretin significantly increased cAMP levels in the ganglia. After 24 or 48 hr in culture, explants treated with forskolin or secretin also showed a significant (1.5-fold) increase in VIP-like immunoreactivity (IR). In contrast, 10 μM isoproterenol increased cAMP levels without altering VIP-IR. This apparent discrepancy may be due to isoproterenol causing changes in cAMP levels in non-neuronal cells, but not in neurons, in the ganglion. Peptide histidine isoleucine amide (PHI) is coded for by the same mRNA that codes for VIP. Preliminary data indicate that 10 μM VIP increases the level of PHI-IR. The data raise the possibility of a positive feedback loop in which VIP could stimulate its own synthesis.

620.16

VASOACTIVE INTESTINAL PEPTIDE (VIP) REGULATES DEVELOPMENT OF MULTIPLE NEURONAL POPULATIONS: SENSORY AND CEREBELLAR GRANULE CELLS E. DiCicco-Bloom,* K. Emsbo and I.B. Black, Dep't. Neurosci. & Cell Biol., UMDNJ/Robert Wood Johnson Medical School, Piscataway, NJ, 08854

Previous studies indicated that VIP is a multifunctional regulator of sympathetic development, stimulating neuroblast mitosis, neuritogenesis, and survival during a critical embryonic period in the rat (Pincus *et al*, Nature 343:564). Moreover, the local production of VIP in sympathetic ganglia in vivo suggested that the peptide acts via autocrine mechanisms (Pincus *et al*, Soc. Neurosci. XVII:908; A. Davidson *et al*, this vol.). To define the spectrum of populations responsive to VIP mitogenic and trophic activity, we examined effects in developing sensory and cerebellar granule neurons in culture.

Dissociated embryonic day 14.5 dorsal root ganglion cells were preplated to reduce non-neurons and cultured in serum-free media with NGF for 48hrs. The major neuronal population (>95%) consisted of small round or oval cells exhibiting mono- or bipolar neurites. VIP elicited a two-fold increase in neuron number. Neurons cultured in the presence of VIP, however, did not incorporate [3H]thymidine, a marker for DNA synthesis, suggesting that the peptide was not mitogenic. To the contrary, cell counting indicated that VIP elicited increased neuronal survival. VIP trophic activity was specific, since several related peptides were without effect. While NGF was permissive for VIP effects, peptide trophic activity did not depend on the presence of the neurotrophin or non-neurons.

In contrast to sensory neurons, VIP exhibited only mitogenic activity in cultures of postnatal day 7 cerebellar granule neurons and precursors. VIP stimulated a two-fold rise in the percentage of neuroblasts entering the mitotic cycle without affecting cell survival. Our observations suggest that the multifunctional peptide, VIP, exerts different ontogenetic actions in different neuronal populations. (Dysautonomia Fdn, NIH:HD23315, UMDNJ Fdn)

620.17

THE NEUROTROPHIC ACTIONS OF PACAP27 ON PC12 CELLS. C.L. Weill*, M. Treuil and A. Arimura. Depts. of Neurol. & Anat., Louisiana State Univ. Med. Ctr, New Orleans, LA 70112 and U.S.-Japan Biomed. Res. Labs., Tulane Univ. Hebert Ctr., Belle Chasse, LA 70037.

Pituitary Adenylate Cyclase-Activating Peptide (PACAP) is a new member of the vasoactive intestinal peptide/glucagon/secretin peptide family. PACAP binds with high affinity to cells of the pheochromocytoma cell line PC12h and stimulates adenylate cyclase (Watanabe et al., BBRC 173:252, 1990). In the present study we examined some of the neurotrophic properties of PACAP27 on PC12 cells including: metabolism, cell survival and neurite outgrowth. PC12 cells were maintained in RPMI medium plus heat inactivated serum, 10% horse and 5% fetal bovine. At 10 nM PACAP caused a 1.5-fold and 1.3-fold increase in cell diameter and cell protein respectively. Cell survival was determined in serum free medium in the absence and presence of PACAP27 from 0.01 to 100 nM and NGF at 2 nM. After 5 days the following levels of survival were determined relative to the initial number of cells plated: serum free control, <20%; NGF, 88%; PACAP 0.3 to 3 nM, 60% and 10 to 300 nM 100%. In the presence of 1% horse serum, 10 nM PACAP27 supported neurite outgrowth from 70% of the cells at a nearly linear rate of 7.3 µm/day. Neurites possessed varicosities and terminal growth cone-like structures and were stable for up to two weeks. Thus, the hypothesis that PACAP is a new neurotrophic factor is supported by virtue of the localization of PACAP and its receptor to both the central and peripheral nervous systems and the data presented here demonstrating PACAP's capacity to regulate the metabolism, survival, and morphological differentiation of PC12 cells.

PACAP27 INDUCES TRANSCRIPTION OF IMMEDIATE EARLY GENES IN PC12 CELLS. J.M. Lyles,* C.L. Weill and A. Arimura. Depts of Neurol. & Anat., Louisiana State Univ. Med. Ctr, New Orleans, LA 70112 & U.S.-Japan Biomed. Res. Labs., Tulane Univ., Belle Chasse, LA 70037.

Pituitary Adenylate Cyclase-Activating Peptide (PACAP) is a new member of the vasoactive intestinal peptide/glucagon/secretin family of peptides which binds with high affinity to pheochromocytoma cells (PC12h) and stimulates adenylate cyclase (Watanabe et al., BBRC 173:252, 1990). PACAP27 was recently shown to act as a neurotrophic factor: it increased PC12 cell diameter and total protein, enhanced cell survival in low serum medium and promoted neurite outgrowth (see Weill et al., 1992 Soc for Neurosci Abstr.). We have examined the induction of several immediate early genes in cultured PC12 cells treated with PACAP27 and with nerve growth factor (NGF) by employing a modified nuclear run-on procedure involving the rapid extraction and column purification of hnRNA. PACAP induced a different pattern of gene expression than did NGF: whereas 2nM NGF enhanced the level of expression of several genes (c-fos>b-actin>c-jun>c-myc), 10nM PACAP most noticeably enhanced c-fos, but had little effect on c-myc, c-jun or b-actin expression at 30 min. A dose response study over 0.1-100nM showed that PACAP effectively stimulated gene induction at physiological (nM) concentrations. A time response study showed maximal c-fos and c-jun induction at 10 min, while b-actin was slightly induced later at 1-2h. Thus, PACAP was shown to regulate the transcription of immediate early genes in PC12 cells which further supports the hypothesis that PACAP is a new neurotrophic factor.

620.19

INNERVATION DEPENDENT PRODUCTION OF CHOLINERGIC DIFFERENTIATION FACTOR BY SWEAT GLAND CELLS S. J. Tresser, M. S. Rao, and S. C. Landis*. Depts. of Neurological Surgery and Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

During normal development the sympathetic innervation of rat sweat glands undergoes a switch from a noradrenergic to cholinergic phenotype. Transplantation experiments indicate that the switch is induced by the target tissue. Previous studies have shown that cholinergic inducing activity that could be responsible for directing the switch is present in extracts of developing and adult rat footpads. In the present studies we have examined whether this activity is due to sweat gland cells and begun to study its regulation. First, homogenates of footpads of tabby mutant mice which lack sweat glands were tested for their ability to induce choline acetyltransferase (ChAT) activity in cultured sympathetic neurons. Levels were significantly reduced, suggesting that most of the activity in normal footpads is associated with the glands. Second, primary cultures of rat sweat gland cells were established. Like sweat gland cells *in situ*, the cultured cells possessed immunoreactivity (IR) for G-protein and cytokeratin but lacked IR for vimentin. In contrast, primary cultures of fibroblasts were IR for vimentin but not G-protein or cytokeratin. Low levels of differentiation factor, measured by induction of ChAT activity in cultured sympathetic neurons, were released by sweat gland cells grown in the absence of neurons. Co-culture with neurons, however, resulted in a twelve-fold increase in the amount of sympathetic cholinergic activity. In addition, vasoactive intestinal (VIP) levels increased significantly, similar to the increase in VIP which accompanies the transition from noradrenergic to cholinergic phenotype *in vivo*. Our results suggest that cell-cell interactions between neurons and sweat gland cells are necessary to induce the latter to produce cholinergic differentiation factor.

OTHER FACTORS AND TROPHIC AGENTS: GENERAL III

621.1

CHANGES IN TAURINE-LIKE IMMUNOREACTIVITY DURING DEVELOPMENT OF THE HIPPOCAMPUS AND CEREBELLUM OF THE RAT. Kathy R. Magnusson.* Dept. of Anatomy & Neurobiology, Colorado State University, Fort Collins, CO 80523

Taurine is believed to play an important role in the development of the central nervous system, but the function(s) are not yet clear. The goal of this study was to determine whether there are changes in anatomical localization of taurine during development of the cerebellum and/or hippocampus of the rat, which could indicate the function(s) of taurine during the developmental process. Rats were perfused transcardially with 4% paraformaldehyde - 2% glutaraldehyde and vibratome sections were labeled with a monoclonal antibody raised against fixative-modified taurine. Taurine-like immunoreactivity (Tau-LI) appeared to be homogeneous in the layers of the hippocampus and dentate gyrus (DG) in 7 and 14 day old animals and differentiation of stained structures in the molecular layers was not possible. By 28 days of age, the labeled dendrites of pyramidal cells were identifiable in CA1 and CA3. By 56 days of age, pyramidal dendrites and cell bodies and granule cells all stained more intensely than the surrounding neuropil. In the cerebellum of 7 day old rats, there is a narrow band of Tau-LI in the molecular layer adjacent to the Purkinje cell layer. This band broadens toward the surface by post-natal day 14 and, by day 28, the entire molecular layer is stained with Tau-LI. Purkinje cell and dendrite staining increases relative to neuropil staining from 14 to 56 days of age. These results show that the anatomical localization of taurine does change during development to young adulthood in the rat in two different brain regions. The identification of these changes should help elucidate the role(s) that taurine plays in development.

621.2

CHANGES IN TAURINE- AND GLUTAMATE-LIKE IMMUNOREACTIVITY DURING REGENERATION IN THE DENTATE GYRUS OF THE RAT. Catherine Tannert, Tim D. Hassinger* and Kathy R. Magnusson. Dept. of Anatomy & Neurobiology, Colorado State University, Fort Collins, CO 80523

Glutamate has been suggested to act as a stop signal for axons, prior to synapse formation. Taurine, which is known to be involved in development of the nervous system, is protective against glutamate toxicity. Our goal was to determine whether these neuroactive amino acids are linked during regeneration by examining changes in immunohistochemical staining in the dentate gyrus following unilateral electrolytic lesions of the entorhinal cortex. With the use of monoclonal antibodies, changes in immunoreactivity were determined by comparing lesioned to sham-operated animals. We have observed an increase in taurine-like immunoreactivity (Tau-LI) in the outer molecular layer of the dentate gyrus, ipsilateral to the lesioned entorhinal cortex in 2 month-old rats. These changes were present at 3, 7, 14, 28 and 56 days post lesion. The increase in Tau-LI within the molecular layer appeared to be associated with the region of increased ACHE staining. Increases in Tau-LI were also seen in the ipsilateral stratum lacunosum/moleculare of CA1, which is another terminal zone for the perforant pathway. Increases in glutamate-like immunoreactivity (Glu-LI) were observed in the outer molecular layer of the dentate gyrus ipsilateral to the lesion in some animals. No changes were observed in Glu-LI in the stratum lacunosum/moleculare. These results suggest that taurine may play a role(s) in the process of regeneration in the young adult rat brain, but these roles are not always linked with changes in glutamate.

621.3

SEROTONIN, TAURINE AND REGENERATION OF GOLDFISH RETINA. L Lima*, P. Matus, M. Urbina. Lab. Neuroquímica, Centro de Biofísica y Bioquímica, Instituto Venezolano de Investigaciones Científicas, Apartado 1827, Caracas, Venezuela.

Post-crush goldfish retinal explants have been used to study the regulation of the outgrowth by neuroactive agents Taurine has a trophic effect on this retina in culture and in vivo, partially mediated by the entrance of calcium (Lima et al., 1988,1991). The serotonergic receptors, the transporter and the modulation of the serotonergic system by light stimulus has been also studied in this retina (Lima et al., 1992; Schmeer et al., 1991). Serotonin (5HT) has a selective effect on the development of neurons of invertebrates and vertebrates (Murrain et al., 1990; Sikich et al. 1990). The nerve growth index of retinal explants was evaluated as the product of fiber length and density. Monoamines and metabolites were determined by HPLC with EC. Serotonin (5HT) at nM concentrations completely blocked the regeneration and antagonized the stimulatory effect of taurine. 8-OH-Dipropyl-aminotretalin DPAT, a $5HT_{1A}$ receptor agonist had a similar effect. The $5HT_2$ receptor agonist, (+) -1-2,5dimethoxy-4-iodophenil-2-aminopropane DOI, and serotonin uptake blockers, such as imipramine and fluoxetine were less potent in the impairment of outgrowth. The concentration of 5HT decreased 3 and 5 days after the crush of the optic nerve, 5HT and taurine play a role in the regeneration of the post-crush retina.

PRELIMINARY DATA ON NEUROCHEMICAL AND BEHAVIOURAL CONSEQUENCES OF NEONATAL CHRONIC BLOCKADE OF NMDA RECEPTOR IN THE RAT. A. Contestabile,F. Facchinetti,E. Ciani,M. Virgili and R. Dall'Olio. Depts. of Biology and Pharmacology,University of Bologna,Italy. (Spon: ENA)

Recent evidence suggests that NMDA receptor may be involved in survival and differentiation of neurons and synapses. We report data on chronic blockade of this receptor during the critical period of postnatal brain maturation. Neonatal rats were injected dayly with increasing s.c. doses of a non competitive (MK-801) or a competitive (CGP 39551) antagonist of the NMDA receptor from postnatal day 1 to 22. At 24 days of age,body weight was decreased by more than 50% and brain weight by about 25% in treated rats. D-(3H) aspartate uptake and choline acetyltransferase were significantly increased in the cerebellum of treated rats,while markers for GABAergic neurons,astrocytes and myelination were at the same levels of controls. No significant neurochemical differences were noticed in the cortex and hippocampus,except for delayed maturation of the myelination marker. The treated rats,tested with actometric cages,showed a marked hypermotility which lasted for at least 2 weeks after the end of the treatment. Data on adult rats treated in the same way,will be presented.

621.5

Chronic neonatal NMDA receptor blockade with MK-801 alters monoamine metabolism and affects spatial learning in the adult rat. J.A. Gorter*, G.J. Boer, M.G.P. Feenstra, M.H.A. Botterblom and J.P.C. de Bruin. Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam, The Netherlands (Spon: ENA)

We examined the question whether chronic MK-801 treatment in neonatal rats (0.25 mg/kg injected s.c.; twice per day, from postnatal day 8 through 19), which previously had been shown to alter NMDA receptor function, would also affect spatial learning in the adult rat. MK-801 treated rats were able to learn the spatial (watermaze) task as well as control rats but at a significantly slower rate. Visual cue learning was not affected by the neonatal treatment, indicating that the slower spatial learning is not caused by either locomotor or sensory deficits. Although MK-801 injections induced increased motor activity throughout the treatment period, in adulthood there were no longer differences apparent. At the same time, however, monoamine metabolism of the frontal cortex and striatum as detected by high pressure liquid chromotography with electrochemical detection, was higher in the MK-801 treated group than in the control group. Dihydroxyphenylacetic acid (DOPAC) concentrations were elevated (>40%) in both regions tested, while 5-hydroxyindol-acetic acid (5-HIAA) was significantly elevated only in the cortex (19%), and 3-methoxy-4-hydroxyphenylglycol (MHPG) was elevated only in the striatum (47%). The increase in the concentration of monoamine metabolites along with the previous demonstrated alterations in NMDA receptor function, could contribute to the impairment in spatial learning in adult rats neonatally treated with MK-801.

STIMULATION OF SOMATOSTATIN EXPRESSION IN CULTURED CILIARY GANGLION NEURONS BY ACTIVIN IN CHOROID CELL CONDITIONED MEDIUM. J. N. Coulombe[1], R. Schwall[2], A.S. Parent[3], F.P. Eckenstein[3], and R. Nishi*[3]. [1]Dept. of Anatomy, Uniformed Services University of the Health Sciences, Bethesda MD 20814; [2]Dept. of Endocrinology, Genentech Inc., So. San Francisco CA 94080; [3]Dept. of Cell Biology & Anatomy, Oregon Health Sciences University, Portland OR 97201.

We are interested in testing the hypothesis that neurotransmitter phenotype can be regulated by interactions between neurons and the target tissues that they innervate. The chicken ciliary ganglion (CG) contains two populations of neurons: ciliary neurons that innervate striated muscle in the iris and ciliary body and choroid neurons that innervate vascular smooth muscle in the choroid layer of the eye. Ciliary and choroid neurons differ in their transmitter phenotype in that choroid neurons use the neuropeptide somatostatin as a co-modulator with acetylcholine. We have previously shown that CG neurons are induced to express somatostatin-like immunoreactivity (SOM-IR) by co-culture with choroid cells. This interaction is mediated by a macromolecule in choroid conditioned medium *(Coulombe & Nishi, J. Neurosci. 11: 553).* Here we present evidence that this somatostatin stimulating activity is likely to be activin A, a molecule that has been implicated in a variety of other developmentally important phenomena. Our results are the following: 1) human recombinant activin A induces SOM-IR in cultured CG neurons; 2) ChCM mimics activin by inducing hemoglobin synthesis in K562 cells; 3) hemoglobin synthesis induced in K562 cells by ChCM is inhibited by inhibin; 4) western blot analysis of ChCM with activin A specific antibodies reveals one band that co-migrates with human activin A; 5) northern blot analysis of poly-A+ RNA from cultured choroid cells reveals a band that hybridizes at high stringency with an activin A (inhibin) β subunit riboprobe; 6) follistatin, an activin-binding and inactivating molecule, abolishes the ability of ChCM to induce hemoglobin in K562 as well as its ability to induce SOM-IR in CG neurons. These results suggest that activin may serve as a target-derived factor controlling somatostatin in vivo. Supported by NS25767 (RN), AG07424 (FPE), EY06178 (JNC), and EY06352 (ASP).

SOMATOSTATIN ENHANCES NEURITE OUTGROWTH IN PC 12 CELLS

Donna Ferriero*, R. Ann Sheldon, Robert Messing

Somatostatin (SS) is present in selective regions of the developing central nervous system in very high quantities suggesting a role for the peptide in neuronal differentiation. SS is in growth cones of the human cat retina and can stimulate neurite outgrowth in molluscan neurons. We have studied the effect of SS on neurite outgrowth in a well defined model of neuronal differentiation, PC12 cells after Nerve Growth Factor (NGF) induction. Using this model we have found that SS can enhance the NGF induced neurite outgrowth. We plated PC12 cells at a density of 10×10^3 cells/well and examined cells every 24 hours for neurite formation after incubation with SS (100nM-10uM) alone and in combination with NGF. A neurite was defined as a process greater than one cell body in diameter in length possessing a terminal growth cone. The percentage cells bearing neurites were calculated by counting 100 cells/well in quadriplicate wells. Cells plated on polyomithine coated dishes grown in defined medium containing 50ng/ml NGF began to develop distinct neurites on day 4. Simultaneous treatment with 1uM SS increased the percentage of neurite-bearing cells significantly (NGF 70± 10% v. SS ± NGF 84±6%; $p \leq 0.03$). On day 2 using variable concentrations of NGF (1-4nM), a marked increase in the number of cells bearing neurites was seen in the presence of 1uM SS (70% v. 7%). On inspection of the cells, those treated with SS + NGF had significantly longer neurites than the NGF treated cells (23.4 ± 12.9 v. 18.6 ± 9.3um; $p<0.01$). In addition, the complexity of neuritic networks was greater in the SS + NGF treated cultures. These preliminary data suggest that SS may function as a trophic factor in early neuronal differentiation, promoting neurite outgrowth.

THYROID HORMONE ALTERS CHOLINERGIC SOMAL ENLARGEMENT AND RECOVERY OF CHAT+ NEURON NUMBER AFTER AXOTOMY OF PROJECTIONS FROM BASAL FOREBRAIN TO MEDIAL CORTEX. T.W. Farris* and L.L. Butcher. Laboratory of Chemical Neuroanatomy and Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563.

To examine the regenerative morphologic effects of putative growth-promoting factors on cholinergic neurons, we administered thyroxine (T4, 2.5 mg/kg, ip) or saline daily for 7, 15, 30 or 60 days to 8 week-old female rats following unilateral knife-cut axotomies of the cholinergic medial pathway which projects from the cholinergic basal nuclear complex (CBNC) to cingulate and occipital medial cortices. Brain tissue was processed immunohistochemically for choline acetyltransferase (ChAT) and for Nissl substance. In the saline groups, computerized morphometry using light microscopy showed surprisingly that ChAT+ medial septum (MS) somata—which do not project appreciably to medial cortex and, thus, were not axotomized—underwent mild transient enlargement at 30 days compared to 7 and 60 days ($p < .05$). Yet, no effect was seen in somata of the vertical limb of the diagonal band (VDB) which do project to cortex and were axotomized. Concommittantly, maximal loss of ChAT+ somal number on postlesion days 7 (for MS) and 15 (VDB) recovered by day 60 ($p < .05$ each). No change in somal number was seen in Nissl-stained sections possibly indicating only altered ChAT expression. T4 advanced the peak MS somal enlargement from day 30 to 15, and peak VDB ChAT+ neuronal number from day 60 to 15. These data imply that adult CBNC neurons, taxed metabolically by a sublethal axotomy, appear to undergo augmented recovery in response to thyroid hormones. [Support: NIH NS 10928 to L.L.B.]

K252a POTENTIATES EPIDERMAL GROWTH FACTOR-INDUCED DIFFERENTIATION OF PC12 CELLS. C-F. Wu, J. Umbach * & B.D. Howard. Dept. of Biol. Chem. UCLA Sch. of Med. Los Angeles, CA 90024

Epidermal growth factor(EGF) induces the neuronal differentiation of PC12 cells in that it causes the extension of short neurites. The protein kinase inhibitor k252a blocks NGF-induced neurite outgrowth, but it potentiates the EGF effect, resulting in long branched neurites comparable to those induced by NGF. The related compound, K252b which cannot permeate cell membranes, inhibits NGF-induced differentiation, but it neither inhibits nor potentiates EGF-induced neurite outgrowth suggesting that k252a produces its potentiating effect on EGF by acting at an intracellular site. RNA synthesis and activity of the ras proto-oncogene product are required for neurite outgrowth induced by EGF or by a combination of EGF and k252a. EGF increases the mRNA levels of two late response genes (SCG10 and 63) that had previously been found to be induced in PC12 cells only by NGF and FGF. K252a increases the EGF-induced expression of these two genes. These results suggest that EGF and NGF trigger similar but not identical signal transduction pathways.

EGF INCREASES THE NUMBER OF PROLACTIN CELLS IN NEONATAL RAT PITUITARY CULTURES. R. Felix, A. Navarrete, A. Marin and G. Cota*. Department of Neurosciences, Cinvestav, Mexico, DF 07000.

It is known that chronic treatment of rat pituitary tumor cells with EGF stimulates prolactin production. We investigate here the action of EGF on the prolactin cell population of neonatal (10-day old) male rats. Anterior pituitary cells were cultured for 2 days, in the absence or presence of 5 nM EGF in the culture medium. The relative number and basal secretory activity (prolactin plaque area) of the lactotropes was then determined by using the reverse hemolytic plaque assay. In control conditions, 8.0 ± 0.2% (mean ± SE, n = 3) of all pituitary cells induced plaque formation and plaque area was 1980 ± 230 μm^2. EGF induced a 50-60% increase in both the proportion of plaque-forming cells and mean plaque area. Frequency distributions of prolactin plaque sizes indicated the existence of two lactotropes subpopulations in both experimental conditions: small- and large-plaque formers. The additional prolactin cells induced by EGF all formed large plaques. Thus, EGF seems to stimulate prolactin secretion in pituitary cultures by promoting the differentiation of a lactotrope subtype.

SEROTONIN AND ALTERED BEHAVIOR IN THE MODELS OF DEPRESSION AND AGGRESSION IN MALE TRANSGENIC TGFα MICE. Hilakivi-Clarke L.A.*, T. Taira, Goldberg, R. and Clarke R. LCRC, and Dept. Psychiatry, Georgetown Univ., Washington, DC; and Dept. Physiol., Univ. Helsinki, Helsinki, Finland

Transgenic MT42 male mice overexpress the human transforming growth factor α (TGFα) in multiple tissues, including the brain. These animals exhibit increased depressive tendencies in the swim test and increased aggressive behavior in the resident-intruder paradigm, when compared with appropriate CD-1 control mice. Brain monoamine analyses revealed that the levels of norepinephrine, dopamine and serotonin (5-HT) were not significantly altered in the hypothalamus, frontal cortex, or brain stem in the male TGFα mice. However, these animals showed reduced 5-HT turnover in the brain stem ($p<.05$). To elevate the 5-HT turnover, the male TGFα and control mice were treated intraperitoneally with 100 mg/kg tryptophan, a precursor of 5-HT, or with 5-HT uptake inhibitors zimeldine (12.5 mg/kg) or clomipramine (10 mg/kg) 30 min prior to the behavioral tests. Tryptophan did not influence the immobility of the CD-1 mice, but significantly reduced immobility in the swim test in the male TGFα mice ($p<.01$) ($F(2,22)=7.4$, $p<.006$). Similarly, zimeldine reversed the elevated immobility in the male transgenics ($p<.05$), while it increased the immobility time in the controls ($p<.05$) ($F(2,31)=6.9$, $p<.003$). In the resident-intruder paradigm, the TGFα exhibited highly elevated levels of aggression. Tryptophan did not alter the time spent in aggression, but clomipramine significantly reduced aggressive behavior both in the controls and TGFα mice ($F(1,24)=15.3$, $p<.004$).

These results indicate that the increased depressive and aggressive tendencies noted in the male TGFα mice appear to be reversed by 5-HT uptake inhibitors. Thus, TGFα may interact with 5-HTergic systems in the brain.

621.12

PRENATAL HALOPERIDOL (HAL) OR RESERPINE (RES) STUNTING OF RAT BODY AND BRAIN WEIGHT: IN VIVO AND IN VITRO EXAMINATION OF SENSITIVE PERIODS AND DOPAMINERGIC MECHANISMS. P.J. Webb, R.R. Holson*, S.F. Ali, T.F. Grafton, and D.K. Hansen, NCTR/FDA, Jefferson, AR 72079-9502.

Pregnant albino rats were exposed to vehicle, HAL (5 mg/kg twice daily) or RES (0.2 mg/kg twice daily) over mid gestation (gestation days [GD] 12-16) or late gestation (GD 16-20). Another control group was pair-fed both to HAL and RES dams. Offspring body weight, regional brain weight, DNA and protein were evaluated in youth (28-30 days age) or adulthood (90-112 days age). Mid-gestational HAL or RES permanently reduced offspring body weight, regional and whole brain weight and regional brain DNA and protein content at both ages. HAL and RES had comparable effects on whole brain weights (reduction to 90% of control) while RES exposure produced a greater stunting of body weight than did HAL. Comparisons to pair-fed controls revealed that this growth stunting was not due to reduced maternal food intake. Late gestational RES exposure was highly feto-lethal, unlike late HAL exposure. Late gestational exposure to either drug had no effects on offspring body or brain weight that were different from pair-fed controls, with the exception of a permanent and specific HAL not RES stunting of caudate weight, DNA and protein content. In a second experiment, cultured GD 9 embryos were grown for 48 hr in medium containing a range of concentrations of HAL, RES, sulpiride (a specific D_2 antagonist) or SCH23390 (a specific D_1 antagonist). HAL substantially reduced embryonic growth at much lower concentrations than did any of the other compounds. We conclude that prenatal HAL reduces offspring body and brain weight after mid- but not late- gestational exposure, through a mechanism which is probably not dopaminergic.

621.13

MECHANISM OF A HEPATOCYTE SECRETED FACTOR AS AN ACTIVATOR OF NERVE REGENERATION. H.HORIE[1]*, T.KADOYA [2] AND M.TAKANO [3]. Dept. of Physiol.[1] and Ophthalmol.[3],Sch. of Med., Yokohama City Univ., Yokohama 236 and Pharmaceut.,Lab., Kirin Brewery Co.[2], Maebashi 371, JAPAN.

Hepatocyte-conditioned media enhanced neurite regeneration and their survival from nerve-transected terminals of adult dorsal root ganglia with nerve fibers(Horie et al.,NeuroReport, 1991). But this media did not promote neurite regeneration of dissociated adult DRG neurons. Application of a hepatocyte secreted factor to adult rat retina explants showed that this factor enhanced neural regeneration not only in matured peripheral nervous tissues but also in adult central nervous tissues. In comparison with other known neurotrophic factors, NGF, IGF-I and II, EGF, aFGF, bFGF, Insulin, Interleukins(1 to 8) were applied to the peripheral explants. NGF, IGF-I and II, Interleukin 3 and 6 enhanced neurite regeneration, but not survival. NGF did not affect neurite regeneration in adult retina explants. These results indicate that the factor secreted from hepatocytes was different from the other known neurotrophic factors. To analyze mechanism of the factor anti-NGF was administered to the peripheral tissues. This antibody inhibited neurite regeneration from nerve-transected terminals under treatment with hepatocyte conditioned medium. After 5 days in culture the addition of this antibody did not inhibit neurite survival. This result suggests that the factor secreted from hepatocytes may stimulate Schwann cells to release NGF and a survival factor.

DO NIGRAL NEURONS PRODUCE A TROPHIC FACTOR THAT SUPPORTS THE GROWTH OF OTHER NIGRAL NEURONS? C. M. Buhrfiend*, L.R Ptak, D.K. Sierens, S.J. Yu, and P.M. Carvey. Rush-Presbyterian St. Lukes MC, Chicago IL, 60612

The growth of mesencephalic cultures is density dependent, i.e. with a linear increase in cell number, the number of viable cells with processes increases geometrically. This is often referred to as the "autoconditioning" effect. We performed two series of experiments to determine whether or not this autoconditioning effect was due to a soluble factor. Primary, dissociated, E15.5 rostral mesencephalic tegmentum (RMT) cultures were plated out at a density of 250,000 cells/well and were grown in defined media. Media from these cultures was collected at weekly intervals (1-4 weeks) and stored at -70C. 50 uL of this conditioned media was added to freshly plated low cell density (3,500 cells/well) RMT cultures growing in defined media. 40 hours later, the cultures were scored for the number of viable cells with processes. Cultures incubated with conditioned media from 3 and 4 week old RMT cultures had more viable neurons with processes than cultures incubated with conditoned media from 1-2 week old cultures ($p < 0.01$). In a second experiment extracts of the substantia nigra from adult rats stimulated the growth of low cell density RMT cultures relative to the effects of extracts of the cerebellum ($F = 7.15$). Moreover, the growth promoting effect of extracts of the substantia nigra decreased linearly with age (2-24 months, $r = -0.663$). These data suggest that cells of the substantia nigra produce a soluble factor capable of stimulating the growth of other cells within the nigra. It is possible that the nigral cell loss that accompanies aging and Parkinson's disease may facilitate further neuron loss due to the reduction of this nigral-derived "autoconditioning" factor.

DIFFERENCE IN THE ELECTROPHORETIC MOBILITY OF RAS PROTEIN FROM DIFFERENTIATING AND PROLIFERATING PC12 SUBCLONES. Y. Y. Rozenberg, A. Grinnell* and B.D. Howard. Dept. of Biol Chem. UCLA Sch. of Med. Los Angeles, CA 90024

Oncogenic ras causes differentiation of PC12 and proliferation of other cells. A PC12 flat cell variant was transfected with inducible oncogenic ras and subclones were selected. Ras expression caused differentiation of one subclone, 6B3, but it caused proliferation of another subclone, 3A4. Ras protein (p-ras) from 6B3 and 3A4 migrated as 22 kd and 21 kd forms, respectively. After phosphatase treatment, p-ras from 6B3 cells migrated as a 21 kd protein, but the mobility of p-ras from 3A4 cells did not change. This suggests that phosphorylated ras may be involved in differentiation. After treatment of the cells with mevenolin, which inhibits the synthesis of cholesterol precursors and thus protein farnesylation, p-ras from either cell migrates as a 23 kd protein indicating that each is farnesylated. Mevinolin causes PC12 to extend precess that look like neurites. This morphological change is inhibited by introduction into the cells of anti-ras antibody suggesting that ras is involved in this morphological change.

621.16

INFUSION OF MONOCLONAL ANTIBODIES AGAINST AN ENDOGENOUS DA-RELEASING PROTEIN (DARP) INTO THE SUBSTANTIA NIGRA (SN) OF FREELY MOVING MALE RATS DIMINISHES STRIATAL DA AND DOPAC CONCENTRATIONS. H. Cardenas, V. D. Ramirez*. Department of Physiology & Biophysics, University of Illinois at Urbana-Champaign, IL 61801.

The presence of an endogenous DARP has been reported in extracts from adrenal, striatum and cerebellum. DARP has a potent DA-releasing activity and neonatal administration of monoclonal anti-DARP antibodies arrest fetal development and decrease brain catecholamines (Moll. Cell. Neurosci. 2:410-417, 1991). To disclose a possible role for DARP during adulthood we administered monoclonal anti-DARP antibodies (IgM) into the SN of male Sprague-Dawley rats (300-400g B.W.). The antibody was infused at a dose of 10µg/10µl/10 min during 5 consecutive days through a stereotaxically implanted cannula made with a 23 g syringe fixed to the skull. Controls were infused with an IgM anti-fluorescein antibody. On the sixth day, the rats were submitted to an amphetamine test (1 mg/kg i.p.) and their behavior quantified by a computerized activity monitor (OMNITECH) during 30 min. Striatal DA and DOPAC levels were determined by HPLC with electrochemical detection after the amphetamine test. The antibody treatment did not change the ipsilateral DA (controls: 11.6 ± 1; Exps = 12.2 ± 0.6, n=7) nor DOPAC* (Controls: 5.9 ± 0.3; Exps = 6.2 ± 0.5) levels. But decreased ($p<0.01$, n=7) DA (from 13.7 ± 0.4 to 8.5 ± 0.8) and DOPAC (from 6.1 ± 0.4 to 4.7 ± 0.3) levels in the contralateral striatum. There was no difference in the behavioral response to amphetamine. Our results suggest that the blockade of endogenous DARP interfered with the uptake of DARP by terminals in the SN arising from the contralateral SN. This would then lead to a decrease in the catecholamine levels in the contralateral striatum.

*values are in ng/mg of wet tissue.

A NEUROTROPHIC FACTOR OPERATIVE IN THE GENICULOCORTICAL PATHWAY OF RATS: ISOLATION, PURIFICATION AND *IN VITRO* TESTING. K.L. Eagleson*, P. Levitt, I. Fischer and T.J. Cunningham. Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, Pa. 19129.

We have previously identified neuron survival promoting activity present in medium (CM) conditioned by explants of the embryonic primordia of the geniculocortical pathway. The active fraction of the CM promotes the survival of drosal lateral geniculate nucleus (dLGN) neurons following visual cortex lesions in both the neonate and the adult rat. To identify the molecule(s) responsible for this activity, we raised monoclonal antibodies to proteins present in the active fraction. One antibody, 8G6, recognises a 55kD molecule on Western blots. Following immunoaffinity purification and silver staining of gels, we have detected an additional minor band at 110kD which is diminished upon incubation with DTT, indicating the native protein may be present as a dimer. To assess the neurotrophic effects of this molecule *in vitro*, dissociated embryonic day 17 lateral thalamic neurons (which include those of the dLGN) were grown with different concentrations of the afinity-pure 8G6 antigen in defined, serum-free medium. Neurons and dendrites were identified immunocytochemically using an antibody against microtubule-associated protein 2 (MAP 2). Neurite outgrowth is enhanced at 0.05-5ug/ml of the 8G6 antigen and inhibited at 50ug/ml. The same effect is seen at 2 and 4 days in culture. Interestingly, the higher concentration of 8G6 antigen also caused decreased neuron survival. We suggest that the 8G6 antigen is a neurotrophic component of the CM fraction, which we have shown previously to act in a similar concentration-dependent manner *in vivo* (see Eagleson *et al*, 1990). Supported by NS16487 from NINCDS and TRG-89-014 from Alzheimer's Association.

621.18

A NEUROTROPHIC FACTOR OPERATIVE IN THE GENICULOCORTICAL PATHWAY OF RATS: LOCALIZATION AND NEURON SURVIVAL *IN VIVO*. T.J. Cunningham*, F.A. Haun, S.E. Kennedy, P. Levitt and K.L. Eagleson. Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, Pa. 19129.

Previous studies have shown that a fraction of culture medium(CM) conditioned by the embryonic primordia of the geniculocortical pathway will prolong survival of dorsal lateral geniculate nucleus (dLGN) neurons when delivered to the cavity of a large posterior cortex lesion in newborn rats. A molecule that provides neurotrophic support *in vitro* to posterior thalamic neurons (including those of the dLGN) has been isolated and purified from this CM fraction using a monoclonal antibody (8G6). In this study, we tested the neuron survival-promoting activity of this molecule *in vivo*, and examined its distribution in the cerebral cortex and thalamus of neonatal rats. The entire posterior neocortex was ablated from newborn rats and calcium-alginate gel beads, loaded with the affinity-pure 8G6 protein, were placed in the lesion cavity. Five days later, when the dLGN in untreated animals has virtually disappeared, operates with implants of the 8G6 antigen show a significant increase in dLGN neuron survival. Immunostaining of normal neonatal rats reveals patchy 8G6 labeling in several cortical regions with dense staining in parietal and occipital areas. Within these patches, stained cells can be found in all cortical layers but the most consistent labeling is in the soma and dendrites of pyramidal cells in layers III and V. In addition, labeled cells are particularly prominent in neurons of layer VIB. The cortical white matter and resident glial cells are not stained. Surprisingly, immunopositive cells are rare in thalamo-cortical projection nuclei (including the dLGN) which may reflect rapid processing of the factor by responsive neurons. The results suggest that the 8G6 antigen is an endogenous neurotrophic factor in the neonatal rat. Supported by NS16487 from NINCDS and TRG-89-014 from Alzheimer's Association.

NEUROTROPHIC ACTIVITY OF OTOCYST-DERIVED FACTOR: COMPARISON WITH OTHER GROWTH FACTORS AND GANGLIA IN CHICK. L.M. Bianchi* and C.S. Cohan Dept. of Anatomical Sciences, SUNY at Buffalo, Buffalo, N.Y. 14214

During early stages of auditory development, the otocyst releases a factor which promotes outgrowth from the associated statoacoustic ganglia (SAG). Although the release of this factor decreases at later stages of development, the SAG maintain an ability to respond to the otocyst-dervied factor (ODF). We compared the neurotrophic activity of the ODF to other growth factors by 1.) placing ODF on ganglia known to respond to specific growth factors and 2.) testing the ability of specific growth factors to influence SAG. Application of ODF promoted outgrowth from explants and disscoiated cell cultures of chick DRG and sympathetic ganlglia, but not from ciliary or trigeminal ganglia (DM or VL). Outgrowth from DRG and sympathetic ganglia may indicate an NGF-like molecule is released by the otocyst. However, addition of mouse anti NGF antibodies did not block the ability of ODF to promote outgrowth from DRG, sympathetic ganglia or SAG. Experiments were then done to compare whether other growth factors mimic the response of the ODF. At early stages of development (E4-E6), both NGF and CNTF produced outgrowth from explant and dissociated cell cultures of SAG. However, compared to ODF, the length of outgrowth and the number of surviving cells was less in the presence of these growth factors. Additionally, NGF and CNTF were unable to promote outgrowth from older stage SAG (E7-E13). Thus, NGF and CNTF did not mimic the neurotrophic effects of the ODF. These experiments suggest that the ODF has neurotrophic activity which is different from NGF and CNTF.

EXPRESSION OF THE PLEIOTROPHIN GENE IN DEVELOPING MOUSE CENTRAL NERVOUS SYSTEM. H.-J. Yeh, I. Silos-Santiago, R.P. Guillerman, Y.-S. Li, W.D. Snider, and T.F. Deuel*. Dept. of Medicine, Biochemistry, and Neurology, Washington Univ. and the Jewish Hospital, St. Louis, MO 63110.

Expression of the pleiotrophin (ptn) gene was analyzed within the developing mouse central nervous system (CNS) by in situ hybridization. Ptn mRNA was first detected at embryonic day 12 (E12). At E15 and E18 in spinal cord, ptn transcripts were primarily localized in neurons of the dorsal horn of the intermediate gray and of the region surrounding the central canal. Levels of the ptn transcripts decreased progressively postnatally and were absent in adults. In the brain at E15 and E18, ptn mRNA was highly expressed in cells of the ventricular zone and ependymal layer bordering the ventricles. Levels increased progressively in cortical neurons during the postnatal period and were also detected in the dienceph-alon, midbrain, and brainstem. In adults, prominant expression of ptn mRNA was seen among Purkinje cells and Golgi-epithelial cells of the cerebellum, pyramidal cells of hippocampal field CA1, and neurons of cortical layers II and III. Cortical glial cells and cells in the hippocampal white matter also expressed ptn during adulthood. These results indicate that the ptn gene is expressed in a highly spacially and temporally restricted manner in the developing CNS and support a unique role of the ptn gene during embryogenesis and in maturity.

Cells Genetically Modified to Secrete NGF Induce Dense Growth of Sensory Fibers after Transplantation to the Spinal Cord.

M.H. Tuszynski*, J. Ray, F.H. Gage, D. A. Peterson,
Dept. of Neurosciences, Univ. of California-San Diego, La Jolla, CA. 92093-0627.

In the brain, grafts of cells genetically modified to produce trophic factors or other substances improve neuronal survival and promote morphological and functional recovery after injury in the adult. We sought to determine whether neurites of the adult rat spinal cord are also responsive to trophic factors, and if grafts of nerve growth factor (NGF)-secreting genetically modified cells to the spinal cord could promote neuronal recovery. Primary fibroblasts of adult Fischer 344 rats were genetically modified to produce NGF or ß-galactosidase (as controls), and grafted to the intact spinal cord. Fibroblasts naturally secrete collagen and fibronectin, which could produce a "bridge" over which neurites might grow.

32 subjects (16 NGF, 16 ß-gal) underwent T7 laminectomy and received suspension grafts of $6x10^5$cells in 5 ul into the center of the cord. The large graft volumes caused local cord damage and transient motor deficits in the legs. Two weeks later, graft survival was evident in all subjects examined; however, NGF-secreting grafts showed a very dense ingrowth of fibers, indicated by NGF receptor and neurofilament immunocytochemistry. These fibers appeared to be of sensory origin, since they labeled robustly for calcitonin gene-related peptide (CGRP), but not choline acetyltransferase, acetylcholinesterase, or tyrosine hydroxylase. After two months, control grafts were substantially smaller than NGF-secreting grafts; again, fibers grew only into the NGF-secreting grafts. Thus, sensory neurites respond vigorously to intraspinal grafts of NGF-secreting cells. Grafts of fibroblasts genetically modified to secrete NGF or other trophic factors may provide an environment that promotes neuronal recovery after spinal cord injury.

622.2

AXONAL PROJECTIONS BETWEEN THE ADULT RAT SPINAL CORD AND EMBRYONIC NEURAL TISSUE TRANSPLANTS: ORIGIN and DISTRIBUTION Prashant Rai*, Jane Brasko and Gopal D. Das Purdue University, Dept. of Biological Sciences, W. Lafayette, IN 47907 and Univ. of Pennsylvania School of Medicine, Dvn. of Neurosurgery, Philadelphia, PA 19104.

The pattern of afferent connectivity achieved by transplantation of 15-days old embryonic neocortex (n=12), spinal cord (n=12) & brainstem (n=12) into a central hemorrhagic (CH) lesion in the spinal cord of the adult rat was examined in this study. The animals were allowed to survive for 2-3 months post-operatively, and towards the end of this period, a second lesion (right hemisection or CH) was made 2-3 segments rostral or caudal to the site of transplantation to induce degeneration in any long descending or ascending fibers that might have sprouted & given off afferents to the transplants. The animals were perfused & the spinal cords were processed for the Fink-Heimer technique, to permit visualization of degenerating afferents, and for Cresyl violet staining, to permit accurate assessment of host/graft interface regions. Consistent with other transplantation paradigms, afferents were observed to cross the interface and enter the transplants from the host parenchyma. These were collaterals derived from host fibers in the immediate vicinity of the interface, most often from the gray matter. The afferents did not demonstrate any specificity or pattern of distribution. In general, the distribution of these collaterals was somewhat random within the transplant neuropil, & was restricted to the borders of the transplants. There was no evidence to indicate that these afferents extended into the middle of the transplant or that they traversed the length of the transplant to end in the spinal cord on the opposite side. Their distribution was also quite independent of the location of the second lesion in the host spinal cord. The amount of afferent ingrowth in general could be classified as low to moderate in all the transplants, regardless of tissue type. These results indicate that axons of the traumatized adult spinal cord are capable of sprouting into different kinds of embryonic neural tissue transplants, & this capacity is rather limited & restricted to axons near the lesion site only.

622.3

INFLUENCE OF FETAL NEURAL TISSUE TRANSPLANTS ON HISTOPATHOLOGICAL REACTIONS OBSERVED IN THE TRAUMATIZED ADULT SPINAL CORD Jane Brasko*, Prashant Rai and Gopal D. Das Univ. of Pennsylvania School of Medicine, Dvn. of Neurosurgery, Philadelphia, PA 19104 & Purdue Univ., Dept. of Biological Sciences, W. Lafayette, IN 47907.

Embryonic neural tissues transplanted into the traumatized spinal cord of the adult rat have been shown to influence the expression of various histopathological reactions, e.g., glial cell & fibroblast proliferation, spinal cord necrosis & cyst/cavity formation (Das 1986). In the present study, we analyzed the extent of these host histopathological reactions following the transplantation of 1 of 3 different donor tissue types-- 15-days old embryonic neocortex (n=12), brainstem (n=12) or spinal cord (n=12), into a central hemorrhagic (CH) cavity at T-10/T-11 or L-2/L-3 of the adult rat. Lesioned animals that did not receive transplants served as controls (n=7). Histological observations of the spinal cords of these animals after 2-3 months post-operative survival revealed the following: glial cell proliferation and host spinal cord necrosis was very pronounced in the spinal cords of the control animals. However, cyst/cavity formation in these animals was negligible, observed in only 2 of the 7 cases. The expression of these histopathological entities was likewise highly exaggerated in spinal cords that received brainstem or spinal cord transplants. Due to the limited growth of these transplants, there was often space left between them and the walls of the cavity, which permitted excessive proliferation of glial & connective tissue cells, as well as the degeneration of adjacent host tissue. Conversely, the expression of such a response was very limited in spinal cords receiving neocortical transplants. This was due, in general to the great volumetric growth of these transplants, which partially suppressed the development of the host pathological response. These results indicate that the presence of a neural transplant may ameliorate the histopathological sequelae of a CH lesion in the adult spinal cord. However, this effect is not uniform but directly related to the type of tissue transplanted into the site of injury.

622.4

AXONAL GROWTH INTO SCHWANN CELL-SEEDED GUIDANCE CHANNELS GRAFTED INTO TRANSECTED ADULT RAT SPINAL CORD.

X.M.Xu, V. Guénard, N. Kleitman, and M.B. Bunge*. The Miami Project, Univ. of Miami Sch. of Med., Miami, FL 33136.

Schwann cells (SCs) have been shown to effectively promote axonal regeneration in both PNS and CNS. We are testing the ability of SCs to enhance regeneration in adult rat spinal cord when they are present in guidance channels grafted into transected cords. SCs were purified in culture from adult rat sciatic nerves, suspended in a 30:70 solution of Matrigel:DMEM (M/D), and seeded into PAN/PVC permselective channels (2.6 mm ID x 10 mm long; MWCO, 50K Da) at a final density of 80 or 120 x 10^6 cells/ml. Some SCs were labeled with Hoechst 33342 nuclear dye before implantation. Empty and M/D channels served as controls. The spinal cord was transected at T-8, and 3 segments caudal to this level were removed. The rostral cut end was inserted approximately 1 mm into the channel and the distal end of the channel was capped. One month after grafting, a blood vessel-rich cable had formed within the channel in all animals studied. Numerous Hoechst labeled SCs were observed in the cable, many in close association with ingrowing axons, indicating that cultured SCs had survived in the channel. In SC-seeded channels, numerous myelinated axons existed within the cables and some of them extended the whole length of the channels (9-10 mm). Electron microscopy revealed that many unmyelinated axons had grown into the cables as well. A subset of axons entering the graft stained for CGRP. More axons were observed in SC-seeded channels than in the empty channel. In conclusion, when SCs are placed in permselective channels grafted into transected adult rat spinal cord, they stimulate the ingrowth of both myelinated and unmyelinated axons. REDUCTION IN ADJUVANT ARTHRITIS-INDUCED HYPERVENTILATION IN RATS WITH ADRENAL MEDULLARY TRANSPLANTS IN THE SPINAL SUBARACHNOID SPACE. H. Wang* and J. Sagen. Department of Anatomy & Cell Biology, University of Illinois at Chicago, Chicago, IL 60612

Our previous studies have shown that transplanted adrenal chromaffin cells into the CNS pain modulatory regions can reduce acute pain sensitivity. We have extended this work to the reduction of chronic pain by the implants. The adjuvant-induced arthritis model in rats was chosen in the present study since behavioral features of this model, such as a retardation of weight gain and hyperventilation are similar to those seen in human chronic pain conditions. The purpose of these studies was to assess whether adrenal medullary transplants could reduce chronic arthritis pain. To assess this, two groups of adult rats were implanted with either rat adrenal medullary tissue or striated muscle tissue into the spinal cord subarachnoid space, and were injected with Mycobacterium butyricum intradermally into the their tail bases. Body weight, tibio-tarsal joint circumferences and ventilatory responses were measured at weekly intervals. Results showed that spinal adrenal medullary implants in arthritic rats could attenuate the severe retardation of body weight gain seen in control implanted animals. In addition, chronic hyperventilation, associated with chronic pain, was markedly reduced in arthritic rats with adrenal medullary implants, but not control implants. These effects of adrenal medullary implants were attenuated by opiate antagonist naloxone and alpha-adrenergic antagonist phentolamine. Together, these results indicate that transplanted adrenal medullary tissue reduces chronic arthritic pain by releasing catecholamine and opioid peptides into the spinal subarachnoid space. (Supported by NIH grant NS25054)

622.6

PAIN-RELATED BEHAVIOR IN RATS WITH PERIPHERAL NEUROPATHY IS REDUCED WITH BOVINE CHROMAFFIN CELLS TRANSPLANTED INTO THE SPINAL SUBARACHNOID SPACE. A. T. Hama* and J. Sagen. Dept. of Anat. and Cell Biol., Univ. of IL at Chicago, Chicago, IL 60612.

Adrenal medullary tissue allografts transplanted into subarachnoid space, by releasing catacholamines and opioid peptides, may be a clinically useful procedure in reducing pain. Previous work has shown that adrenal medullary tissue transplanted into animals with unilaterally-induced peripheral neuropathy reduced allodynia and hyperalgesia for up to two months. Bovine adrenal chromaffin cells have also been shown to be effective in reducing nociception and may be used as an alternative to human adrenal tissue. The long-term effectiveness of bovine chromaffin cells in reducing pain was evaluated in an animal model of painful peripheral neuropathy, induced by loosely ligating the right sciatic nerve. Various pain syndromes are observed including thermal allodynia and thermal and mechanical hyperalgesia. To quantify thermal allodynia, animals were placed on an innocuous cold (5° C) metal plate for 20 min. and the number of hindpaw lifts and duration of lifting were recorded. To assess mechanical hyperalgesia, hindpaw withdrawal thresholds were measured using the Randall-Selitto test. Finally, to quantify thermal hyperalgesia, hindpaw withdrawal latencies to a noxious radiant heat source were measured. After baseline behavioral evaluation, isolated bovine chromaffin cells were transplanted in subarachnoid space at the level of the lumbar enlargement. Animals were tested weekly for 9 weeks. Animals that received chromaffin cell transplants showed increased withdrawal latencies and thresholds to noxious heat and pressure, respectively, compared to control animals. Also, transplanted animals showed decreased reaction to an innocuous thermal stimulus compared to control animals. Chromaffin cells revealed immunostaining for tyrosine hydroxylase two months after transplantation. These findings indicate that bovine chromaffin cell transplants may be effective therapy in reducing neuropathic pain. Aided by a grant from the Paralyzed Veterans of America Spinal Cord Research Foundation.

622.7

SODIUM BUTYRATE-TREATED PC12 CELLS AS AN ALTERNATIVE GRAFT SOURCE FOR PAIN REDUCTION. P.H. Kim and J. Sagen*. Dept. of Anat. and Cell Biol., Univ. of Il at Chicago, Chicago, Il 60612.

Our lab has previously demonstrated that chromaffin cells transplanted into the spinal cord and periaqueductal gray can reduce pain by providing a basal source of opioid peptides and catecholamines. However, large scale application of this approach is limited by the availability of these postmitotic cells. PC12 cells have the added advantages of ready availability, reproducibility, and uniformity. PC12 cells, unlike mature adrenomedullary chromaffin cells, contain very low levels of opioid peptides. The goal of these studies was to produce PC12 cells with increased opioid peptide production for pain reduction. Preliminary *in vitro* studies are in agreement with previous studies showing that sodium butyrate treatment can increase Met-enkephalin levels 2 to 3 fold in PC 12 cells (Byrd et al., 1987). However, the Met-enkephalin levels return to baseline after butyrate treatment is stopped. In order to permanently increase Met-enkephalin production, butyrate stimulated PC12 cells were treated with antimitotics Mitomycin C and Bromo-2'-deoxyuridine (BrDU), either immediately after butyrate stimulation or four days following withdrawal of butyrate. Both groups were treated with the antimitotics for two days, and were then prepared for neurochemical analysis on the eleventh day of the experiment. Preliminary data revealed a 15 to 25 fold increase in Met-enkephalin levels in the first group compared to controls, while the second group only showed a 2 to 3 fold increase compared to controls. In addition, the antimitotic treatments were success- ful in inhibiting PC12 cell proliferation. The data suggests both synergistic and perhaps independent action of antimitotic agents with butyrate on increasing Met-enkephalin production. Preliminary findings have revealed that treated PC12 cells transplanted into the PAG showed inhibited tumor growth and good survivability. These results suggest that butyrate-treated PC12 cells may provide an alternative donor source for pain reduction (Supported by NIH grant NS25054).

THE PRESENCE OF FETAL SPINAL CORD TRANSPLANTS ALTERS THE RESPONSE OF MACROPHAGES AND MICROGLIA AFTER SPINAL CORD INJURY. E. KUNKEL-BAGDEN*. Dept. of Anatomy and Cell Biology, Georgetown Univ., Washington, DC 20007.

Although fetal spinal cord transplants support the growth of axons and promote the recovery of function in both the neonate and the adult after spinal cord injury, the growth and recovery is more limited in the adult than in the neonate. The influence of macrophages and microglia on axonal growth is unclear; both inhibitory and supportive roles have been suggested for these cells. In order to begin to understand the role of macrophages and microglia in regeneration and plasticity, we sought to determine whether 1) the response of these cells to injury is similar in the neonate and the adult and 2) the presence of fetal transplants alters the response of the macrophages and microglia after injury. Newborn (25) and adult (20) rats received a mid-thoracic hemisection and spinal cord (E14) or hippocampus (E18) transplants were placed into the lesion site. At one week (acute response) or 4-8 weeks (chronic response) after surgery the presence of macrophages and microglia in the lesion/transplant area was examined immunocytochemically with the monoclonal antibodies ED1 and OX-42. After hemisection, at chronic survival times, only a few scattered cells were labeled with the ED1 antibody in the neonatal operates, but ED1 labeled cells were present throughout the lesion area in the adult operates. The adult operates with transplants, however, had fewer ED1 labeled cells present in the host, and no labeled cells were present in the transplants. ED1 labeled cells also were not present in the transplants of the neonatal operates. The macrophage/microglia response after injury is very different in the neonate and the adult, and the presence of fetal spinal cord transplants alters this response. (Supported by NS19259 to B.S. Bregman)

NIMODIPINE ENHANCES VASCULARITY OF INTRASPINAL FETAL GRAFTS AND ALTERS INJURY INDUCED BEHAVIORAL OUTCOMES. P.J. Horner,B.T. Stokes*, Dept. Physiol., The Ohio State Univ., Columbus, Ohio and P.J. Reier, Dept. Neurosci., Univ. Florida., Gainesville, FL.

Fetal transplants have been reported to promote at least partial recovery of a variety of motor behaviors after intraspinal grafting procedures in injured adult animals (Stokes et.al.,1992). In spite of these lasting improvements, certain spontaneous behavioral paradigms (open-field, inclined plane and grid-walking analysis) often reveal early deficits in transplanted animals when compared to injured-controls. We have also previously associated graft integration and potential behavioral effects with neovascularization of the graft segment. In the present experiments, we have investigated whether suspension transplants placed concomitantly with a potent angiogenic agent (nimodipine) can improve these early alterations and diminish the differences in final outcome scores.

Rats were pretested behaviorally, anesthetized and injured with an electro-mechanical impactor device. Ten days later they received an intraspinal transplant of dissociated E_{14} spinal cord cells. In addition, 2 (10 mg) slow-release tablets impregnated with nimodipine were placed (S.Q.) in order to enhance the angiogenic process. Behavioral testing was conducted weekly for 2 months and the success of angiogenic procedures estimated from stereological analysis of semi-thin plastic sections of areas in and around the graft site. Graft capillarity (33% increase in surface fraction), mean vascular diameter and graft size were all enhanced by nimodipine. Integration of graft tissue with the adjacent host was excellent and grafts often included large fascicles of preserved myelinated fibers. Previously described differences in behavioral outcomes after grafting were not seen in the nimodipine treated animals. Angiogenesis may therefore be an important factor in graft development and behavioral outcomes. Supported by NS-10165 and NS-27511.

STRATEGIES IN TRANSPLANT THERAPY FOR SPINAL CORD INJURY. Claire E. Hulsebosch* and John Dorman. Dept. Anatomy and Neurosciences, University of Texas Medical Branch, Galveston, TX 77055

Spinal cord injury results in a devastating loss of behavior below the level of the lesion. In a typical lesion, several tracts are severed, grey matter is destroyed and nearby mildly injured and uninjured neurons may be able to grow neurites a few mm. but no further. In the presence of exogenous therapy, the abortive growth may be encouraged. Examples of therapy to encourage growth include the use of one or more of the following: peripheral nerve transplants, antibodies against inhibitory substances, antibodies to neurotrophins, neurotrophins, and the use of transplanted cells (both embryonic and adult tissue and cultured cell lines). These therapies are used to provide a permissive environment which may encourage neuronal growth. We will present data which coorborates and extends previous work on the ability of an autologous transplant of a peripheral nerve to support neurite growth within the spinal cord after lesions which include the cortical spinal tract. Technical issues will be presented to insure success. In addition, progress in our laboratory on other strategies for spinal cord repair will be presented. SEX DIFFERENCES AND LIFE-SPAN CHANGES IN THE VISUAL ACUITY OF QUAIL. **W. Hodos*, A. L. Holden, J.-Y. Lee, M. A. B. Diamgoz and V. Porciatti. Dept. of Psychology, Univ. of Maryland, College Park, MD 20742, USA; Dept. of Biology, Imperial College, London, SW& 2BB, UK; Instituto di Neurofisiologia del CNR, 56217 Pisa, Italy.**

Male (n=52) and female (n=60) quail were maintained on long days (16L/8D) from 0.5 - 19 months. Their visual acuity was determined by recording spatial-frequency tuning curves of the pattern electroretinogram that was generated in response to grating stimuli. The long-day lengths resulted in continuous ovulation by the females from sexual maturity until death. Both males and females showed systematic changes in acuity throughout the life span. Male acuity is highest at 0.5-3.0 month; thereafter it declined slowly. Female acuity was not significantly different from that of the males at the youngest ages. In contrast to the slow, steady decline of the males, female acuity rapidly rose to a peak at 9-12 months; thereafter it declined rapidly and reached the male level at 18-19 months. Preliminary findings with female quail maintained under short day length (8L/16D), which inhibits ovulation, indicated an improvement in acuity. The biphasic age-acuity curve of female quail is similar to the human age-acuity curve, which also is biphasic. Both of these curves reach a peak at approximately 20% of life span. These results suggest that in females, the endocrine system plays a role in visual aging and that female quail are a useful model for some aspects of human visual aging.

623.2

PERIPHERAL RETINAL DEGENERATION IN THE FISCHER 344 RAT: GENDER, REGIONAL, AND AGE EFFECTS. J. Ison, D. DiLoreto, Jr., D. Grover, E. Lazar, C. del Cerro*, P. Bowen, and M. del Cerro. Departments of Psychology, Ophthalmology, and Neurobiology, University of Rochester, Rochester, NY, 14642.

Fischer 344 (F344) rats are reported to suffer from an age-related retinal degeneration, but little data are available on the exact gender, regional, and age effects on peripheral degeneration. Given the importance of this strain for visual and aging studies, we undertook a longitudinal analysis of its retina from age 1 to 24 months. Outer retinal thickness was measured from sagittal sections at six positions in each eye: superior peripheral (SP), equatorial (SE), and central (SC), and inferior central (IC), equatorial (IE), and peripheral (IP). At least 8 eyes, per sex, per age were analyzed. Histological studies, fundus examinations, ERG recordings, and behavioral tests were performed. Morphometric analysis revealed a significantly thicker female outer retina from 1 to 12 months of age. A significantly increased rate of peripheral degeneration was found in males after 12 months in the SP which was total and complete by 18 months. The IP did not show an increased rate of degeneration until after 18 months. Paving-stone degeneration was seen in both sexes in various loci as early as 3 months. Significant decline in ERG activity was noted as early as 8 months. Functionally, changes in visual kinetics were seen after 18 months that are characteristic of both light-blinded and RCS rats. We found that the pattern of retinal degeneration in the F344 rat is affected by the combination of gender, regional, and age-related factors. (Supported by NEI-05262, and the Rochester Eye Bank)

623.3

EFFECTS OF SIZE OF ATTENTIONAL FOCUS ON VISUAL SEARCH IN AGED ADULTS. P.M. Greenwood, Raja Parasuraman*, Sangeeta Panicker and J.V. Haxby, Catholic University of America, Washington,DC and NIA, Bethesda, MD, 20064.

Feature-integration theory (Treisman & Gelade, 1980) claims that conjunction search requires focal attention directed serially over the display, while feature search depends on parallel processing. Plude & Doussard-Roosevelt (1989) reported that older adults are disproportionately slowed on conjunction but not feature search. Greenwood, Parasuraman and May (1992) reported that engaging visuospatial attention in response to valid cues is unimpaired in normal aging, while disengaging attention from invalidly cued locations is slowed with age. Now we ask whether (a) age alters the ability to adjust the size of the attentional focus and (b) varying the precision of location cues counteracts the effects of age on conjunction search. Forty old and young Ss searched for both features and conjunctions of features over 10 or 15 display elements comprised of three colors and three letters. Cues preceded targets by 500 msec and were rectangles drawn around either the target letter, column containing the target or side of the screen containing the target (valid) or another letter, column or side (invalid). Increasing display size slowed the old more than the young in conjunction search but not in feature search. Cue size also had little effect on feature search. In conjunction search RT decreased linearly with decreases in cue size but similarly in young and old. Cue validity effects were largest in conjunction search at the smallest cue size with old Ss showing greatest effects. Results indicate (a) old Ss are as adept as young in manipulating size of attentional focus, (b) old Ss are slower than young to shift attention during serial search even with valid cues, and (c) serial but not parallel search is dependent on attentional focus.

623.4

Effects of age on motor and cognitive performance in three rat strains. E. L. Spangler*, B. Hess, J. Hengemihle, D. M. Roberts, and D. K. Ingram. Gerontology Res. Ctr., (NIA), Baltimore, MD 21224; Essex Comm. College Essex, MD 21237; Towson State Univ. Towson, MD 21204

Representative groups of the adult life span of male Fischer 344 (F344; 7,13,23 mo), Brown Norway (BN; 7,13,23 mo) and F344/BN F1 (F1; 7,13,23,30 mo) rats were tested in a battery of behavioral tests including 15-min and 24-hr spontaneous activity (SA), inclined screen (IS), wire hang (WH), rotorod (RR), shock-motivated one-way active avoidance (AA) and shock-motivated 14-unit T-maze (TM) performance. ANOVA's and subsequent Bonferroni (BON) post-hoc tests ($p's < 0.05$) revealed age-related declines in all strains for tests of spontaneous activity (24-hr SA), agility and coordination (RR), strength and mobility (TR, IS) and to some extent in learning ability (AA,TM), although the 30-mo old F1 rats made significantly fewer errors than their 23-mo old counterparts in the TM. Evaluation of strain effects with BON indicated that BN and F1 compared to F344 rats were less active in 24-hr SA, were more agile (RR), and were more efficient at learning (AA,TM). Thus, these tests appear to be sensitive to both age-related changes in performance and genetic analysis. Hybrid vigor as well as selection bias may explain the superior performance of the 30-mo old F1 rats in maze learning.

623.5

SEVERITY OF SPATIAL LEARNING IMPAIRMENT IN AGING ASSESSED BY THE DEVELOPMENT OF A LEARNING INDEX Rebecca D. Burwell*, Margaret Burchinal, and Michela Gallagher. Dept. of Psychology, Univ. North Carolina, Chapel Hill, NC 27599.

The Morris spatial learning task has become widely used in neurobiological studies and in the characterization of cognitive decline in the aged rat. An important insight in the study of aging is that individual differences in spatial learning impairment are often good predictors of neurobiological aging. Thus behavioral characterization can provide an important background for studies of brain aging.

This report describes new methods for analyzing performance in the Morris task. For the development of a learning index that reflects the accuracy of spatial learning, the animal's proximity to the target location of the escape platform was used. This proximity measure was integrated over the course of training using a set of weights based on the learning curve for young rats (N=70). Data from aged rats (N=98) indicated that learning index scores differed significantly from young rats, overall. More importantly, the index scores differed for subpopulations of aged rats (impaired and unimpaired) that were formed on the basis of a criterion employed previously in our research. In addition, the index scores for the unimpaired aged subgroup did not differ from those of the young rats. This learning index score now provides a graded measure of learning performance for individual rats that can be used to characterize the severity of age-related cognitive impairment in neurobiological studies. MEASURING CHANGES IN TRANSCRIPT LEVELS FOR VARIOUS GENES IN THE MEDIAL SEPTUM AND HIPPOCAMPUS OF RATS DUE TO AGE AND MEMORY IMPAIRMENT. Rhonda M. Greene, Michael D. Robbins, Michela Gallagher, and Michael McKinney*. Mayo Clinic, Jacksonville, Jacksonville, FL 32224 and University of North Carolina at Chapel Hill, Chapel Hill, NC 27599.

Thirty-six rats were grouped according to age and spatial learning impairment (young, unimpaired aged, and impaired aged) based on performance in a Morris water maze. Total RNA was isolated from the medial septum and hippocampus and reverse transcribed. Specific mRNAs were assessed by quantitative polymerase chain reaction (PCR). In the medial septum, we studied mRNAs for the 695-amino acid ß-amyloid precursor protein (BAPP), growth associated protein (GAP-43), cholineacetyltransferase (ChAT), and the nerve growth factor receptor. BAPP and GAP-43 were also quantitated in the hippocampus, along with the m1 muscarinic acetylcholine receptor. All data was normalized against the level of glyceraldehyde phosphate dehydrogenase mRNA. GAP-43 and ChAT decreased significantly in the medial septum with age. Furthermore, the mRNA for BAPP increased in the hippocampus of impaired aged rats but remained unchanged in the medial septum. Supported by NIA Grant PO1 AG09973 and a NIMH RSDA to MG (KO2-MH00406).

623.7

EFFECTS OF AGING IN BEHAVIORALLY CHARACTERIZED RATS ON MUSCARINIC RECEPTOR SITES USING *IN VITRO* AUTORADIOGRAPHY. T. M. Gill*, M. McKinney†, and M. Gallagher. Department of Psychology, University of North Carolina, Chapel Hill, NC 27599 and †Mayo Clinic, Jacksonville, FL 32224.

Young (4 mo, N=8) and aged (25 mo, N=15) male Long-Evans rats were behaviorally characterized for spatial learning in the Morris water maze. These same subjects were then used to study hippocampal muscarinic binding with quantitative *in vitro* autoradiographic techniques. Tritiated quinuclidinyl benzilate (QNB) alone and [^{3}H] QNB in the presence of the M1 receptor antagonist, pirenzepine, were used to determine total muscarinic, M1, and non-M1 binding.

No age differences in total, non-M1, or M1 binding were found throughout the hippocampus. However, analysis of covariance for M1 sites in ventral dentate gyrus revealed that subgroups differed significantly when binding was assessed in relation to learning: high binding was associated with better learning in aged rats with preserved spatial abilities (r values range from -.70 to -.80), but opposite correlations were found for the young and aged impaired subgroups (r values range from .50 to .60). Further examination of these autoradiograms will indicate whether age-related changes in muscarinic sites are evident in other areas (i.e. frontal cortex and medial septum).

Supported by NIA grant PO1 AG09973 and a NIMH RSDA to MG (KO2-MH00406).

623.8

AGE-RELATED CHANGES IN MUSCARINIC CHOLINERGIC SUBTYPES IN RAT BASAL FOREBRAIN AND FRONTAL CORTEX. Robert P. Yasuda*, Sean A. Satkus, Jason S. Weisstein, and Barry B. Wolfe. Department of Pharmacology, Georgetown University School of Medicine, 3900 Reservoir Road, Washington, D.C. 20007

Muscarinic cholinergic receptor subtypes were examined in young (4-5 months) and aged (24-25 months) Long-Evans rats. The aged rats were further divided into two groups: 1) Aged Unimpaired rats that had similar Morris water maze performance to that of young rats, and 2) Aged Impaired rats that did not perform as well as young rats in the Morris water maze. Antisera selective for the m1-m4 receptor subtypes were used to examine differences in receptor density in these three groups of rats in the basal forebrain and frontal cortex (Mol. Pharmacol., 39: 643-649, 1991; Mol. Pharmacol., 40: 28-35, 1991; Mol. Pharmacol. 40: 783-789, 1991; Soc. Neurosci. Abstr., 17:, 1532, 1991). There were no differences in any receptor subtypes between the aged impaired and the aged unimpaired rats in either brain region. However, there was significant decreases in at least the m4 receptor subtype in aged animals compared to young in the basal forebrain (young, 0.819 ± 0.047; aged unimpaired, 0.599 ± 0.048, $p < 0.01$; aged impaired, 0.583 ± 0.041 pmoles/mg protein, $p < 0.01$; N=8). These decreases in m4 receptor were not observed in the frontal cortex (young, 0.380 ± 0.027; aged unimpaired, 0.417 ± 0.007, $p>0.05$; aged impaired 0.382 ± 0.036 pmoles/mg protein, $p>0.05$; N=5). NORTHERN ANALYSIS OF MUSCARINIC RECEPTOR mRNA IN THE BRAIN OF 3, 18, AND 33 MONTH OLD RATS. H.-J. Lee, M. Clagett-Dame, W. Heideman, and M. Weiler*. School of Pharmacy, University of Wisconsin-Madison and Hazleton Wisconsin, Madison, WI 53706.

The purpose of this investigation was to examine the expression of the five muscarinic receptor mRNAs in three rat brain regions and to determine if there are age-related differences in the expression of these transcripts. Poly $(A)^+$ RNAs of neostriatum, hippocampus and cortex from Fischer 344 X Brown Norway hybrid rats (3, 18 and 33 months) were analyzed by Northern blotting with ^{32}P-labeled oligonucleotide probes of m1, m2, m3, m4 and m5 receptors. Messenger RNA levels were quantitated by densitometry. All five muscarinic receptor mRNAs were detected in blots from the neostriatum and hippocampus, and all but m5 mRNA were detected in cortex. This study revealed the presence of a 6.0 kb m5 mRNA in the neostriatum and hippocampus.

The relative regional abundance of each of the five mRNAs was similar in all the age-groups. The m1, m2 and m3 mRNAs were more abundant in cortex and hippocampus than in neostriatum, the difference being more pronounced with m3 mRNA. The m4 mRNA was most abundant in the neostriatum. The m5 mRNA was most prominent in the hippocampus, weakly detected in neostriatum, and not detected in cortex. With age the expression of m3 mRNA in the neostriatum decreased. No significant age-related changes in the expression of other receptor mRNAs were observed. How this finding relates to other well documented changes in neostriatum with aging remains to be determined. (Supported by a grant from American Federation for Aging Research).

AGING DIFFERENCES IN THE CYCLIC AMP MODULATION OF L-TYPE CALCIUM CURRENTS IN HIPPOCAMPAL SLICE NEURONS. O. Thibault*, L.W. Campbell and P.W. Landfield. Dept. Pharmacol., Univ. Kentucky Col. of Med., Lexington, KY, 40536.

A number of studies have shown that cyclic AMP can modulate calcium (Ca) channels in several preparations. Last year we reported that L-type Ca currents in the rat hippocampal slice neurons were greatly enhanced by the intracellular application of dibutyryl cyclic AMP (dcAMP) (Thibault *et. al.*, Soc. Neurosci. Abstr., 91). Using single electrode voltage clamp, several types of voltage-activated Ca currents are seen in this preparation, including an L-type current that is associated with a prolonged, dihydropyridine-sensitive Ca *aftercurrent*.

Hippocampal CA1 neurons from aged rats also exhibit increased voltage-sensitive Ca spikes and Ca currents. This aging-dependent enhancement of Ca current resembles the dcAMP effect in young neurons. In this study, therefore, we tested the response of aged neurons to intracellular application of dcAMP. We recorded Ca currents from young (3-5 months) and aged (25-27 months) rat neurons treated with TTX and TEA and impaled with pipettes filled with 0.5 M CsCl, 1 mM Mg-ATP, and $\pm$ 1 mM dcAMP.

In young neurons dcAMP again significantly increased the Ca aftercurrent, whereas this treatment did not influence the aftercurrent in aged neurons (which already show an increased aftercurrent). Neither activation/inactivation ranges, nor calcium-dependent inactivation were affected by administration of dcAMP in young or aged neurons.

Since the effects of aging and dcAMP were not additive, the results suggest that these two processes may operate on a common pathway, and that the effects of aging on increased Ca currents may be mediated at least, in part, by increased cAMP-dependent phosphorylation. ATTENUATION OF TYROSINE HYDROXYLASE ACTIVATION FOLLOWING NEUROTOXIC INSULT TO THE HIPPOCAMPUS OF AGING RATS. J.R. Unnerstall*. Dept. of Anatomy and Cell Biology, Unv. of Ill. at Chicago, Chicago, IL 60680.

The locus coeruleus (LC) loses up to 50% of its neurons during normal aging. However, no differences, or possibly, increases in static measures of synaptic integrity, such as norepinephrine content or tyrosine hydroxylase (TH) activity, have been reported in brain regions innervated by LC neurons in aged vs young animals. Yet, behavioral deficits associated with attenuation of LC function seen in aging animals suggest that this neural system has lost its ability to rapidly respond to stimuli or insult. In these preliminary studies, the neurochemical adaptability of LC neurons in aging rats has been assessed using a paradigm originally reported by Acheson and Zigmond (*J. Neurosci.* **1**:493, 1981). Using this model, TH activity was assessed in the hippocampus of young (2 month) and old (24 month) Fisher-344 male rats 72 hours following the infusion of 200 µg of the neurotoxin 6-hydroxydopamine or vehicle into the lateral ventricle. Interestingly, it was noted that baseline TH activity measured under optimal conditions (pH6.2, 3.0 mM 6-MPH_4, 30 µM tyrosine) was two-fold higher in unlesioned old animals compared to the young animals (~12 vs 6 pmoles/min/mg protein). The lesion resulted in a 55-59% decrease of TH activity measured under optimal conditions. When measured under suboptimal conditions (pH6.6, 0.7 mM 6-MPH_4, 30 µM tyrosine), TH activity in young lesioned animals was 83% of that measured in young vehicle treated animals. However, in the old lesioned animals, TH activity measured under suboptimal conditions was only 40% of that measured in age-matched control animals. These data suggest that the ability of LC neurons to rapidly respond and compensate to this insult is attenuated in the old animals due to a deficit in this system's capacity to activate TH. *(NIA grant AG09587.)*

AGE-RELATED IMPAIRMENT OF SYNAPTIC CONNECTIVITY IN THE RAT DENTATE GYRUS REVEALED BY THE UNBIASED DISECTOR TECHNIQUE. F. Morrell*, Y. Geinisman, L. deToledo-Morrell, I.S. Persina and M. Rossi. Depts. of Neurol. Sci. and Psychol., Rush Med. Coll. and Dept. of CMS Biol., Northwestern Univ. Med. Sch., Chicago, IL 60612.

Previous attempts to elucidate whether a loss of hippocampal synapses occurs during normal aging provided conflicting results, possibly, due to the unavailability, at the time, of unbiased methods for synapse quantitation. This study was designed to reexamine the issue by means of modern technical approaches which provide unbiased estimates of synaptic numbers. Groups of 14 young adult (5 months old) and 14 aged (28 months old) male F-344 rats were compared. Synapses were analyzed in the middle (MML) and inner (IML) zones of the molecular layer of the hippocampal dentate gyrus where synaptic contacts are mainly formed by the entorhinal or commissural-associational fibers, respectively. The number of synapses per postsynaptic neuron was estimated using the disector method. The results showed that the total number of synaptic contacts per neuron was significantly diminished in the MML (by 23.6%) and IML (by 22.7%) of aged rats relative to young adults ($p < 0.005$ in both cases, two-tailed randomization test for two independent samples). This age-related synaptic loss involved axospinous, but not axodendritic, junctions of the MML (-24.4%) and IML (-24.0%). Both perforated and nonperforated axospinous synapses (distinguished by a discontinuous or continuous postsynaptic density, respectively) exhibited a comparable age-dependent decrease in numbers, though this decrease did not reach statistical significance in the case of perforated junctions of the IML. The observed loss of axospinous synapses, which are formed by two afferent systems on neurons that survive in senescence, may underlie a reduction in the amplitude of excitatory postsynaptic potentials and a decline in functional synaptic plasticity detected in the dentate gyrus of aged rats.

STRUCTURAL SYNAPTIC REMODELLING FOLLOWING THE INDUCTION OF LONG-TERM POTENTIATION (LTP) IN AGED RATS. Y. Geinisman*, L. deToledo-Morrell, F. Morrell, I.S. Persina and M. Rossi. Dept. of CMS Biol., Northwestern Univ. Med. Sch. and Depts. of Neurol. Sci. and Psychol., Rush Med. Coll., Chicago, IL 60611.

Although aged animals are deficient in the retention of LTP, they potentiate to the same extent as young ones (Barnes, *J. Comp. Physiol. Psychol.*, 1979, *93:* 74; deToledo-Morrell et al., *Neurobiol. Aging.*, 1988, *9:* 581). We showed earlier (Geinisman et al., *Brain Res.*, 1991, *566:* 77) that the induction of LTP in young rats is followed by a selective increase in the number of axospinous synapses with a segmented postsynaptic density (PSD). The aim of the present study was to determine if old potentiated animals exhibit the same structural synaptic modification. Aged F344 rats (27 mo. old) were implanted with stimulating electrodes in the medial perforant path and recording electrodes in the hilus of the ipsilateral dentate gyrus. Potentiated animals were stimulated (with fifteen 20 ms bursts of 400 Hz delivered at 0.2 Hz) on each of 4 consecutive days and sacrificed 1 h after the fourth stimulation. The number of synapses per neuron was differentially estimated for various synaptic subtypes in the middle (MML) and inner molecular layer of the dentate gyrus using the disector technique. Only axospinous synapses with segmented PSDs were significantly increased in numbers in the MML of potentiated aged rats relative to their stimulated (at a frequency of 0.2 Hz) or implanted controls. The magnitude of this increase in old rats was comparable to that found in young adults suggesting that such a modification might account for the equal extent of potentiation observed in the two age groups. However, the absolute number of synapses with segmented PSDs was significantly lower in aged potentiated rats than in young ones. The age-related diminution in a synaptic subtype, which may be essential for plasticity associated with LTP, might result in a deficient retention of LTP.

DENDRITIC GROWTH IN ADULT GRANULE NEURONS IN THE RAT DENTATE GYRUS. N. Blake, S. Seay-Lowe, and B. Claiborne*. Division of Life Sciences, University of Texas, San Antonio, TX 78249.

During late postnatal development (14 to 60 days of age), granule cells in the dentate gyrus lose dendritic branches while their remaining branches continue to elongate as the molecular layer expands. These simultaneous processes of growth and regression lead to a conservation of total dendritic length (Rihn & Claiborne, 1990, Dev. Br. Res. 54: 115). Because the dentate gyrus continues to enlarge throughout the rat's life, we wanted to determine whether the processes of dendritic growth or regression continue as the animal matures.

Granule neurons in the dorsal blade were injected with horseradish peroxidase in in vitro slices from 1-year-old Sprague-Dawley rats. Their dendritic trees were analyzed in three-dimensions using a computer-microscope system. Strict criteria were applied to ensure that only well-filled neurons with a minimum of cut branches were analyzed. Results showed that granule neurons (n=17) had 29 $\pm$ 1 branches (mean $\pm$ S.E.), with 63 $\pm$ 4% of branch points located in the inner third of the molecular layer, 30 $\pm$ 3% in the middle third and 7 $\pm$ 3% in the outer. Total dendritic length per neuron was 4201 $\pm$ 167 um.

When compared to our previous data on granule neurons (n=19) from 40- to 60-day-old rats, these results show that branch number (29 in young rats) remains constant during the first year, while the percentage of branch points in the outer third of the layer decreases (17% vs. 7%). In contrast, total dendritic length increases (3457 vs. 4201 um) as the animals mature. From these data we conclude that dendritic regression does not occur after 60 days-of-age and that dendrites continue to elongate as the hippocampal formation enlarges. Thus there is an overall increase in the size of the granule cell dendritic tree in rats between the ages of 60 days and 1 year. (Supported by NIA and MARC.)

AGE-RELATED INCREASE OF ANDROGEN RECEPTOR mRNA IN THE RAT HIPPOCAMPUS. J.E.Kerr*, L.H.Burgess, S.G.Beck and R.J.Handa. Depts. of Pharmacol. and Exp. Ther. and Cell Biol., Neurobiol., and Anat. Loyola Univ. Chicago, Stritch School of Medicine, Maywood, IL 60153.

Previous studies have revealed age-related losses of glucocorticoid receptor and mineralocorticoid receptor in the rat hippocampus. To determine whether androgen receptor (AR) levels, which are normally found to be relatively high in the rat hippocampus, are similarly altered, we examined the AR mRNA content in various brain regions of young (5 mos) and old (22 mos) intact male Fischer 344 rats (Harlan Inc., Indianapolis IN). Animals were sacrificed and their brains were frozen for later dissection and homogenization in GITC to obtain total RNA for analysis by RNase protection assay. The AR mRNA RNase protection assay used a 141 nucleotide long ^{32}P-labeled rat antisense RNA probe. This probe hybridizes to the N-terminal end of the coding region of both the 9.5 Kb and 11 Kb forms of rat brain AR mRNA. These forms seem to be divergent primarily in their 5' untranslated regions. Dilutions of *in vitro* transcribed sense strand RNA ranging from 2.0 to 50 amol were used to generate standard curves which were linear and had correlation coefficients consistently greater than 0.995. The lower limit of sensitivity of this assay is approximately 2 amol/total input RNA. The hippocampal AR mRNA concentration was 539 ± 54 amol (protected probe) mRNA/mg input RNA in the young animals (n=7) as compared to 729 ± 46 amol/mg RNA in the older rats (n=5) which represents a 35% age-related increase ($p<0.05$). No significant differences due to age were found in either the cortex or hypothalamus. These data suggest that there are age-related and tissue-specific changes in AR regulation in the rat hippocampus which is different from other hippocampal steroid hormone receptors previously studied.

ENTORHINAL CORTEX LESIONS PRODUCE CHANGES IN GLUCOCORTICOID BUT NOT MINERALOCORTICOID RECEPTOR GENE EXPRESSION IN THE RAT HIPPOCAMPUS. D. O'Donnell*[1], N. Aumont[1], A. Baccichet[1], J.R. Seckl[2], J.Poirier[1,3], and M.J. Meaney[1,3]. [1]Douglas Hosp. Res. Ctr, Depts. of Psychiatry and Neurology & Neurosurgery, McGill Univ., Montreal, Canada H4H 1R3; [2]Dept. of Med., West. Gen. Hosp., Univ. of Edinburgh, Scotland EH4 2XU; and, [3]Center for Studies in Aging, McGill Univ.

Entorhinal cortex lesioning (ECL) destroys a major hippocampal input and leads to axonal sprouting in the dentate gyrus. Glucocorticoids are known to inhibit this reinnervation process. In the present study, we examined hippocampal glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) mRNA expression using *in situ* hybridization following unilateral ECL in the rat. Film autoradiography showed that as early as one day post lesion, a dramatic bilateral *decrease* in GR mRNA was observed in the granular dentate gyrus. By contrast, in the CA1 region, a moderate *increase* in GR mRNA was detected. GR mRNA levels in both regions returned to those of control animals 2 days post lesion indicating that these effects were transient. Adjacent sections hybridized with probes to MR mRNA revealed no apparent changes in expression in any hippocampal sub-regions as a result of ECL. Western blots from total hippocampus homogenates, using the BuGR2 antibody (Affinity Bioreagents), confirmed an overall decrease in GR protein in the hippocampus. This decrease was also transient with maximal effect being observed 2 days post lesion and levels returning to control values 4 days post surgery. These results suggest that the regulation of GR but not of MR is associated with synaptic reorganization. Interestingly, the opposing changes in GR mRNA expression seen in the dentate gyrus and CA1 following ECL may be related to the pronounced vulnerability of the CA1 cell field and relative resistance of the dentate gyrus to a number of conditions that threaten neuron survival.

INCREASED DENSITY AND SENSITIVITY TO GABA OF HIPPOCAMPAL ω_1 (Bz_1) MODULATORY SITES IN THE AGED RAT. **J.Vitorica#, D.Ruano#, S. Feldblum@, B. Scatton*§ and J.Benavides§. #Department of Biochemistry, School of Pharmacy, Sevilla (Spain). §Department of Biology, Synthélabo Recherche, 31,Av.P.Vaillant-Couturier, 92220 Bagneux. @INSERM U336, Montpellier (France)**

We have recently reported that the enhancement by GABA of (^{3}H)-flunitrazepam binding to hippocampal ω modulatory sites was much larger in 22-24 month-old than in 3 month-old rats (Ruano et al. J.Pharmacol.Exp.Ther 256, 902-908, 1991). Displacement studies with selective ω_1 ligands suggested that this increased sensitivity to GABA was due to changes ocurring at the level of ω_1 modulatory sites. To further characterize these changes we have now compared the properties of hippocampal ω_1 sites of 3 and 22 month-old Fischer 344 rats.

Saturation curves of (^{3}H)-zolpidem binding to hippocampal membranes demonstrated a 60% increase (n=5, P< 0.05) in the B_{max} for this ligand in the aged rats with no change in affinity.Moreover, 100 µM GABA increased the binding of 3 nM (^{3}H)-zolpidem to well washed hippocampal membranes by 107 ± 10% and by 170 ± 25% in 3 and 22 month-old rats, respectively. Similar changes were observed in rats of the Wistar strain. In sections incubated in the presence of 5 nM (^{3}H)-zolpidem and a saturating (100 µM) concentration of GABA, and processed for autoradiography it was observed that at the hippocampal levels the largest increases in ω_1 binding site density occured in the CA_2 (+90%) and CA_3 (+70%) fields whereas smaller changes were quantified in the CA_1 field (+60% in the ventral part and +20% in the dorsal part) and in the dentate gyrus (+55%). No significant increases were observed in other areas. Detection by in situ hybridization of mRNAs encoding for the two isoforms of Glutamic Acid Decarboxylase (GAD_{65} and GAD_{67}) revealed lower levels of GAD_{65} mRNA in individual hippocampal cells of aged rats but no evident neuronal loss.

Taken together these results demonstrate an increase in the density and sensitivity to GABA of ω_1 sites in the aged rat hippocampus. These alterations probably represent the mechanism whereby hippocampal neurons cope with a decreased GABAergic input.

EFFECT OF AGE ON THE ACTIVITY OF MOLECULAR FORMS OF AChE. C.G. Triplett and K.A. Skau*. Div. of Pharmacol/Med Chem, Coll. of Pharmacy, U Cincinnati, Cincinnati, OH 45267-0004.

Changes in cholinergic transmission have been associated with the decline of memory in the aging human brain. We have studied the effect of age on the activity of AChE in rat brain and several peripheral tissues. Activity of the different molecular forms of AChE in 6 areas of the brain and 7 peripheral tissues were compared between 3- and 24-month old F344 rats by standard AChE assay methods. Significant decreases in activity were seen in G4 forms in olfactory bulb (49% decrease), striatum (39% decrease) and medulla/pons areas (43% decrease). Nonsignificant reductions were seen in fore brain, parietal cortex and cerebellum. Nonsignificant reductions were seen in the G1 forms of the brain areas studied. Significant decreases were seen in total AChE of parietal cortex (36% decrease), striatum (54% decrease), cerebellum (36% decrease), and medulla/pons (26% decrease). Nonsignificant reductions in total AChE were seen in olfactory bulb and fore brain. The decrease in activity of the G4 forms and not the G1 forms suggests a change due to the aging process of the synthesis or degradation of the G4 molecular form. (Supported by an Alzheimer's Association/United Airlines Foundation pilot research grant.)

SPECIES DIFFERENCES IN CALBINDIN-D_{28K} IMMUNOREACTIVITY WITHIN THE BASAL FOREBRAIN. M.L. Smith*, K.G. Baimbridge[1] and R.M. Booze. Dept. of Pharmacology, University of Kentucky Medical Center, Lexington, KY, [1]Dept. of Physiology, University of British Columbia, Vancouver, B.C.

Calbindin-D_{28k} is a calcium binding protein reported to be localized within the cholinergic projection neurons of the human nucleus basalis of Meynert. These neurons malfunction with age and in Alzheimer's disease and may contribute to the cognitive deficits present in both situations. Calbindin-D_{28k}-IR neurons are present within the rat basal forebrain; however, they do not appear to be co-localized with the cholinergic projection neurons. In this study we examined 1) co-localization of calbindin-D_{28k} with GABAergic neurons within the basal forebrain and 2) localization of calbindin-D_{28k} within basal forebrain neurons which project to the cortex .

Fischer-344 male rats were perfused and the brains sectioned on a Vibratome (40µm). Serial sections were collected through the nucleus basalis to be used for double-labeling immunocytochemistry. Sections were incubated in a solution containing primary antibodies against either 1) ChAT and calbindin-D_{28k} or 2) GAD and calbindin-D_{28k}. Primary antibodies were detected using FITC and Rhodamine labeled fluorescent secondary antibodies. Neurons containing both calbindin-D_{28k} and GAD were identified throughout the nucleus basalis of the rat. Numerous neurons were identified in the basal forebrain containing only GAD or calbindin-D_{28k}. As previously reported, no co-localization was detected between ChAT and calbindin-D_{28k}-IR neurons in the basal forebrain of the Fischer-344 male rat. Injection of fluorescent-tagged latex microspheres into the cortex suggests that co-labeled GAD/calbindin-D_{28k}-IR neurons may project cortically. Our results indicate that alternative animal models are needed to more accurately represent the human nucleus basalis of Meynert in which cholinergic neurons contain calbindin-D_{28k}. ALTERATIONS IN MUSCARINIC STIMULATED LOW K_M GTPase ACTIVITY IN AGING AND ALZHEIMER'S DISEASE: IMPLICATIONS FOR ALTERED SIGNAL TRANSDUCTION. R. Cutler, J.A. Joseph*, K. Yamagami, R. Villalobos-Molina and G.S. Roth. Gerontology Res. Ctr./NIA, Baltimore, MD.

Previous reports have shown that there are age-related reductions in muscarinic receptor (mAChR) sensitivity to agonist stimulation, and that these alterations are the result of specific changes in mAChR-G protein interactions [expressed as reduced carbachol-stimulated low K_M (C-SLK_M) GTPase activity (an indicator of receptor/G protein coupling/uncoupling) in hippocampus (HIP) and caudate-putamen (CPU)] and subsequent reductions in phosphoinositide (PI)-mediated signal transduction (ST). Present experiments assessed putative age- and disease-related reductions in C-SLK_M GTPase activity in young (Y), Alzheimer's disease (AD), and age-matched control (AMC) HIP and basal ganglia (BG). Results showed that while there were age- and disease- related reductions in C-SLK_M GTPase activity in BG [$F(4,40) = 7.05$ $p < 0.01$), (e.g., 10^3 carb. df = 40 t's =: Y vs AM 2.71, $p < 0.01$; AM vs AD 2.22, $p < 0.05$; Y vs AD 4.93, $p < 0.001$), only age- and not AD-related deficits were observed in HIP (e.g., t (6) Y vs AD = 1.08, $p > 0.05$; t (7) Y vs AM = 2.58 $p < 0.05$). Results suggest that there are age-and disease-related changes in mAChR-G protein interactions that could contribute to reduced PI-mediated ST. Moreover, there could also be some compensatory alterations in AD HIP in C-SLK_M GTPase activity. Additional experiments examining C-SLK_M GTPase activity in HIP and CPU from irradiated rats have shown reductions in this parameter as well as ST deficits, suggesting free radical involvement in these deficits.

624.4

AGE-RELATED CHANGES IN THE RAT STRIATUM: A MICRODIALYSIS STUDY. R.E. Maloney* and G.A. Gerhardt. Depts. of Psychiatry & Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262.

In vivo electrochemical studies have shown that extracellular dopamine (DA) in the rat striatum following K^+ stimulation is reduced in aged rats as compared to young rats. In this study, the technique of *in vivo* microdialysis was used to further investigate both basal and K^+-evoked overflow of DA in the young and aged rat striatum. Eleven Fischer 344 rats were used(n = 5: 24-26 mos, n = 6: 2-5 mos). Four mm long, 300 μm diameter dialysis probes were stereotaxically implanted into the rat striatum (+1.65 mm A.P., ±1.65 mm Lat. with respect to bregma, Paxinos & Watson). Probes were perfused with artificial CSF at a flow rate of 1.2 μl/min. Samples were taken every 10 mins and analyzed by HPLC with electrochemical detection. When the variability of 5 consecutive DA sample peak heights was < 10%, the perfusion medium was changed to 100 mM K^+ CSF for 10 mins. The K^+ stimulation produced a significant difference in the percent increase for DA, 4119.27% in aged rats and 1509.33% in young rats. Aged rats had significantly lower baseline amounts of DA, DOPAC and HVA. In addition aged animals had significantly lower levels of DOPAC following K^+-evoked DA release. (Supported by USPHS Grants AG06434, AG00441 and NS-09199)

624.5

AGE-RELATED CHANGES IN GLUTAMATE EVOKED DOPAMINE OVERFLOW IN THE STRIATUM OF THE FISCHER 344 RAT. M.N. Friedemann* and G.A. Gerhardt. Depts. of Pharmacology and Psychiatry, University of Colorado Health Sciences Center, Denver, CO 80262.

Glutamate and other excitatory amino acid agonists can elicit dopamine (DA) release from nerve terminals in the striatum. Age-related alterations in this interaction between corticostriatal and nigrostriatal inputs may contribute to motor deficits commonly seen during aging in mammals. The purpose of this study was to examine the effects of aging on glutamate-evoked overflow of DA in the striatum of the rat brain. Male F344 rats that were 6- or 24-months old, were anesthetized with urethane and placed in a stereotaxic apparatus. L-glutamate (0.5 to 3 nmol) was ejected *in situ* from glass micropipettes 300 μm away from a Nafion-coated carbon fiber electrode. DA concentrations were measured in real time using an electrochemical recording system (IVEC-5; Medical Systems, Inc.). The results show that the average amplitude of DA signals was significantly lower in the old rats (0.67 ± 0.09 μM vs. 1.35 ± 0.14 μM; $p < .01$). However, the doses of glutamate applied were significantly greater in the aged rats (1.2 ± 0.1 nmol vs. 0.9 ± 0.1 nmol; $p < .01$). Although this finding may be explained by an increase in uptake of glutamate from the extracellular space, these results suggest that there may be age-related changes in sensitivity to the effects of glutamate on DA nerve endings, in that higher doses of glutamate produced lower amplitude signals in 24-month compared to 6-month old rats. (Supported by USPHS grants AG06434 and AG00441 to GAG and PMAF fellowship to MNF).

SYNTHESIS RATES OF DOPAMINE D_2 RECEPTOR mRNA IN YOUNG AND OLD WISTAR RAT NEOSTRIATA

E.R.Mesco*, J.A.Joseph, G.S.Roth
NIH/NIA, Gerontology Res. Ctr., Baltimore, Md. 21224 USA

Previous work established significant decreases in receptors for dopamine in the striatum of aged animals, relative to young controls. This phenomena is seen in lower animals, as well as humans. The decrease is more pronounced for the D_2 dopamine receptor subtype (40%). In addition, we have noted a 50% decrease in the levels of mRNA for the D_2 receptor in the old striata. The decrease in mRNA levels in aged striata is greater than the cell loss, and prompts the question of whether the surviving neurons are synthesizing less D_2 receptor mRNA.

Present studies were directed toward determining the relative rates of synthesis for dopamine D_2 receptor synthesis in young and aged striatal nuclei, isolated by sucrose gradients. RNA synthesis was done using alpha-[^{32}P] uridine triphosphate. The isolated RNA was hybridized to cDNA sequences cross-linked to a membrane. The sequence used for the D_2 mRNA was from a double stranded insert in a pBR vector which is homologous to bases 25 to 582. cDNA sequences for actin and tubulin were used as controls for the synthesis. Following hybridization, membranes were analyzed using a Betagen to detect total incorporation.

The D_2 mRNA was synthesized at a decreased rate in the aged nuclei (57%, $p<0.01$). There was no significant difference between young and aged nuclei in tubulin or actin mRNA as detected on the blots. The decrease in D_2 mRNA synthesis is partly attributed to the loss of D_2 cells, but also seems to reflect an age-dependent effect on surviving D_2 neurons.

624.7

AGE-RELATED VARIATIONS IN THE STEADY STATE LEVELS OF ALTERNATIVELY SPLICED D2 RECEPTOR mRNAs IN BRAIN AREAS OF DIFFERENT RAT STRAINS. N. Brunello, F. Fumagalli, F. Della Vedova§ and G. Racagni*, Center of Neuropharmacology, Institute of Pharmacological Sciences, University of Milan, Via Balzaretti 9, 20133 Milan and Farmitalia-Carlo Erba, CNS Division, Nerviano, Italy.

Dopamine D2 receptor gene produces two receptor isoforms by alternative messenger RNA splicing, the so called D2-415 and D2-444 subtypes. Age-related reduction of D2 receptor density in various brain areas, particularly in the striatum, have been reported by means of radioligand binding and autoradiographic techniques. Using the highly sensitive reverse transcription-polymerase chain reaction analysis we have investigated possible changes in the relative abundance of the mRNAs encoding the dopamine receptor subtypes D2-415 and D2-444 in brain areas of aged rats. We have observed age-related decrease in the D2-444/D2-415 mRNA ratio in the striatum and in the hippocampus of aged rats, whereas no significant differences were observed in the nucleus accumbens and in the frontal cortex. Steady state mRNA levels for both D2 receptor isoforms were decreased in striatum of aged Wistar as well as aged Sprague Dawley rats. In both rat strains the greater decrease regarded the long form D2 mRNA. In Wistar rats this mRNA form reached only 30% of the corresponding value in young adult rats. The reduction in D2 mRNA ratio and in particular in the long form might have functional significance since it could play an important role in the responses to dopaminergic receptor activation.

TYROSINE HYDROXYLASE EXPRESSION IN THE AGING RODENT OLFACTORY BULB. H. Baker*, K. Morel, J.-Y. Cho and D.M. Stone. Cornell Univ. Med. Coll. at Burke Med. Res. Inst., White Plains, NY 10605.

Olfactory function is compromised in humans as a result of normal aging and in neurodegenerative disorders. To begin a biochemical characterization of the aging process in a rodent olfactory model, we tested the hypothesis that age-related alterations occur in the expression of tyrosine hydroxylase (TH), the first enzyme in the dopamine biosynthetic pathway. Previous experiments in young animals demonstrated that TH expression in periglomerular cells of the main olfactory bulb is significantly reduced following either olfactory deprivation or peripheral deafferentation. The current experiments compared TH activity in young (6 month, mo.), middle-aged (18 mo.) and old (>25 mo.) animals. TH activity did not differ between 6 and 18 mo.-old Fischer (F) 344 rats, but was reduced to 77% of 6 mo. levels in 27-29 mo.-old rats. Similarly, TH protein, demonstrated by immunocytochemistry, and mRNA, as indicated by *in situ* hybridization, were reduced in old as compared to 6 and 18 mo.-old rats. The age-related alterations were not uniform, that is, in some F344 rats, TH activity was normal and in others up to 50% decreases occurred. Immunocytochemical and *in situ* hybridization analyses supported the between animal disparity. In contrast, TH activity in adrenal glands from F344 rats exhibited an age-related increase. Surprisingly, TH expression was not reduced in olfactory bulbs of either a second strain of aged (28 mo.) rats, Fischer 344-Brown Norway F1 hybrids, or C57Bl/6 mice (25-26 mo.) as compared to levels in 6 and 18 mo.-old animals. These data demonstrate that during aging, alterations in TH expression are species, strain and region specific. Supported by AG09686.

ROLE OF CYCLIC ADENOSINE 3',5'-MONOPHOSPHATE-DEPENDENT PROTEIN KINASE IN THE REGULATION OF TYROSINE HYDROXYLASE ACTIVITY IN THE AGED RAT BRAIN. N. Aguila-Mansilla, W. Kedzierski and J.C. Porter*. Dept. OB/Gyn, U.T. Southwestern Med. Ctr., Dallas, TX 75235-9032.

During aging, dopaminergic neurons synthesize and secrete less dopamine (DA) as demonstrated by the observation that the rate of secretion of DA into hypophysial portal blood is significantly less in aged rats than in young rats. The *in situ* activity of tyrosine hydroxylase (TH), the rate-limiting enzyme of catecholamine (CA) synthesis, is regulated by a variety of factors, such as hormones and various protein kinases, including cyclic adenosine 3',5'-monophosphate (cAMP)-dependent protein kinase (PKA). This study was conducted to examine the role of the PKA pathway in the regulation of the *in situ* molar activity of TH in the brains of aged and young castrated female rats. For this purpose, we made use of an *in vitro* incubation system. Hypothalamus and corpus striatum (CS) were incubated for 60 min with various agents that modify the PKA pathway. The incubation mixture contained 10^{-2} M NSD 1015 [dihydroxyphenylalanine (DOPA) decarboxylase inhibitor]. At the end of incubation, the tissue was homogenized and DOPA was measured by HPLC with electrochemical detection and TH by immunoblot electrophoresis analysis. Forskolin, an activator of adenylyl cyclase, at concentrations of 1, 5, and 25 μM significantly ($P<0.01$) stimulated the TH activity in the hypothalamus and CS of young and aged rats. In addition, specific cAMP agonist, (Sp)-cyclic adenosine 3',5'-monophosphothioate, significantly ($P<0.001$) increased the TH activity in tissues from both age groups. Theophylline (1 mM, phosphodiesterase inhibitor) did not affect TH activity in the hypothalamus of aged rats, but did significantly ($P<0.001$) increase TH activity in young rats. In the CS, the TH activity was significantly ($P<0.001$) increased in both groups. These results indicate that the PKA pathway modulates TH activity in the hypothalamus of young and aged rats. Impairment of hypothalamic dopaminergic neurons in aged rats may involve reduced synthesis of cAMP.

BRAIN SENSITIVITY TO KIANIC ACID EXCITOTOXICITY IS ENHANCED IN AGED RATS. D.L. Yuan*, J.P. Kesslak, and C.W. Cotman. Irvine Research Unit in Brain Aging, University of California, Irvine, CA 92717

It has been reported that kianic acid (KA) injection into the adult rat brain causes a severe neurodegenerative response while the same dose into the infant rat brain produces very little damage. A recent study indicated that subcutaneous injection of KA caused significant behavioral and brain damage to aged rats, less response in middle-aged rats and the least in young rats. The current study was designed to compare the histopathology between the young and old rats after directly administrated of KA into the hippocampus.

Young (110 days old) and old (410 days old) male Sprague-Dawley rats were anesthetized with sodium pentobarbital (50 mg/kg) and placed into a stereotaxic apparatus. KA (0.5 ug in 0.5 ul PBS) was administrated into the CA3 region of the dorsal hippocampus using a 10 ul Hamilton microsyringe. Rats were sacrificed 14 days following the KA administration, perfused, the brains removed, sectioned and stained with cresyl violet. KA injections in aged rats resulted in a much more extensive neuronal damage in dorsal hippocampus and adjacent area, compared to young rats. Quantitative analysis of the lesion size indicated an approximately four-time larger lesion volume in old than in young rats and the t-test revealed a significant difference. The result indicates that aged brain is more vulnerable to the excitotoxicity of KA after an intracerebral injection.

624.11

DECREASED NUMBER OF AMPA RECEPTORS WITH AGE. S. Standley, G. Tocco, J.K. Thompson*, M. Baudry & R.F. Thompson., University of Southern California, HEDCO Neurosciences Bldg., Los Angeles, CA 90089-2520.

Activity-dependent modifications of glutamatergic synapses are likely to be involved in learning processes. Learning deficits are particularly frequent with age and have been postulated to be due to a decrease in NMDA receptor responsiveness. We investigated possible changes in glutamate receptors with ageing using quantitative ligand binding autoradiography. Tritiated AMPA and CNQX on one hand and TCP on the other hand were used to label the AMPA and NMDA receptors respectively.

Two groups of Fisher (F344) rats, 2-3 and 29 months old were sacrificed, their brains rapidly removed and frozen. Ligand binding autoradiography was then performed on 10 um thick sections.

The aged animals exhibited a reduced binding for both AMPA and CNQX throughout the brain while TCP binding remained unchanged. The decreased binding was particularly marked in the hippocampus.

These results suggest that the number of AMPA receptors is decreased with age while the number of NMDA receptors remains unchanged. As AMPA receptor properties have been implicated in learning-induced synaptic plasticity, a decreased number of receptors might account for learning deficits observed with aging.

REGULATION OF HYPOTHALAMIC NEUROPEPTIDE Y (NPY) mRNA BY FASTING DURING AGING IN MALE RATS. C.V. Mobbs* and S.P. Kleopoulos.

Regulation of glucose metabolism is impaired during aging, elevated glucose can accelerate some age-correlated impairments, and dietary restriction delays some impairments. NPY mRNA in the arcuate nucleus appears to play a role in regulating glucose metabolism and is induced by fasting. We therefore examined if the induction of NPY mRNA by fasting is impaired during aging. 6-month-old, 12-month-old, and 18-month-old male Sprague-Dawley rats (n=6/group) were fasted for 72 hours, then sacrificed at 1900 h, one hour after lights went out. Control rats were fasted for 8 h, allowed to drink milk at 1800 h and sacrificed at 1900 h. Brains were fresh-frozen in dry ice, then cut into 6 micron sections for analysis by in situ hybridization. Single-stranded neuropeptide Y cDNA probes were labelled with tritium by asymetric PCR (using a plasmid generously supplied by S. Sabol). Sections were first exposed to film for 3 weeks, then dipped in emulsion and exposed for another 3 weeks. Quantification of both film and emulsion indicated that in 6-month-old rats NPY mRNA was significantly induced by fasting, but in 12- and 18-month-old rats the induction was not significant. These data suggest that in aging rats regulation of hypothalamic NPY mRNA is impaired. Supported by the American Diabetes Association and a Long Island Heart Foundation Equipment Grant.

ADVANCING AGE DOES NOT AFFECT α_2 ADRENERGIC RECEPTOR FUNCTION OR BINDING IN F-344 RATS. J. BUCHHOLZ* AND S.P. DUCKLES. Dept. Pharmacology, Coll. of Medicine, Univ. of California, Irvine CA. 92717.

Fractional norepinephrine (NE) release evoked by long stimulation trains significantly increases from 6 to 20 months of age in tail arteries of F-344 rats; however the maximal effect of idazoxan to increase NE release does not change with age. To examine further the effect of age on the overall function of prejunctional α_2-adrenergic receptors tail arteries from 6 and 20 month old rats were stimulated with short stimulation trains in the presence of 3 different concentrations of calcium for 4 sec at 8 Hz (60 V, 1 msec). Perfusate from 5 trains was pooled. Tail arteries were treated with 10^{-5} M deoxycorticosterone and cocaine and NE release measured by HPLC with electrochemical detection. The ability of idazoxan to increase NE release did not change with age regardless of calcium concentration, suggesting that the function of α_2 adrenoceptors in the tail artery remains unchanged with age. Binding studies in kidney and brain homogenates were performed with [^{3}H]-idazoxan. Idazoxan dissociation constant (Kd) and maximal binding (Bmax) did not change with age, suggesting that there are no age-related changes in the affinity or number of α_2-adrenoceptors in the kidney or brain. These data lend further support for the conclusion that advancing age does not result in an overall change in function of α_2-adrenergic receptors.

Increased Fractional Norepinephrine Release by 10^{-6} M Idazoxan pg/pg content/pulse x 10^{-6}

Age in Months	1 mM Calcium	1.6 mM Calcium	5 mM Calcium
6	19.1 ± 5.2	23.0 ± 4.7	18.2 ± 4.1
20	12.4 ± 2.2	21.4 ± 4.8	21.0 ± 6.0

624.14

EFFECT OF GOLD-THIO-GLUCOSE (GTG) ON HYPOTHALAMIC OXYTOCIN RECEPTORS AND NEUROPEPTIDE Y (NPY) mRNA. H. Bergen*, S.P. Kleopoulos, J. Pfaus, P.J. Brooks, and C.V. Mobbs. Rockefeller Univ., New York, NY 10021.

GTG administered systemically to mice causes specific hypothalamic lesions and increased eating. Since infusion of NPY into the periventricular nucleus (PVN) stimulates eating, and fasting increases NPY mRNA in neurons of the arcuate nucleus (AN) which project to the PVN, we hypothesized that the GTG-induced lesions in the ventromedial nucleus (VMN) might lead to increased NPY mRNA in the AN. Therefore oxytocin receptors (as a marker of VMN neurons) and NPY mRNA in the AN were assessed in male CBA mice given GTG (0.5 mg/ gm bw, i.p.) 6 weeks before sacrifice. Oxytocin receptors were assessed by I^{125}-ornithine vasotocin receptor autoradiography. NPY mRNA was assessed by in situ hybridization, entailing single-stranded NPY cDNA probes labelled with tritium by asymetric PCR (using a plasmid supplied by S. Sabol). Six weeks after the GTG injection, cresyl violet stain revealed a loss of cells in the VMN, and a glial bridge connected the VMN on each side of the brain. Oxytocin receptor binding was readily demonstrable in the VMN of control mice, and completely abolished by the GTG injection. NPY mRNA was demonstrable in the AN of GTG-lesioned mice, but not elevated compared with controls. Supported by the American Diabetes Association and the Long Island Heart Foundation.

624.15

REGULATION OF HYPOTHALAMIC OXYTOCIN RECEPTORS AND LORDOSIS REFLEX DURING REPRODUCTIVE SENESCENCE OF FEMALE FISHER RATS. S.P. Kleopoulos*, L. Krey and C.V. Mobbs. Rockefeller Univ., New York, NY 10021.

Reproductive senescence in female rodents is characterized by impairments in estrogen-regulated neuroendocrine functions. Some of these age-correlated impairments appear to be due to persistent deleterious effects of estrogen. We therefore examined if hypothalamic oxytocin receptors and lordosis behavior, both of which are induced by estrogen, exhibit persistent effects of estrogen during aging. 3- and 10-month-old cycling rats, and 15-month-old non-cycling rats were ovariectomized. Ten days after ovariectomy, rats were given silastic capsules containing 5% estradiol, or empty sham implants (n=6/group), and sacrificed four days later. Estradiol (E_2) significantly increased both oxytocin receptors (assessed by in vitro autoradiography using I^{125}-ornithine vasotocin) and lordosis reflex (assessed by daily manual stimulation) in all age groups; conversely, E_2 decreased plasma luteinizing hormone (LH) and follicle stimulating hormone (FSH). In the sham-implanted groups, 2 weeks after ovariectomy, oxytocin receptors and lordosis reflex increased with age, and LH and FSH decreased. These data suggest either that a non-ovarian source of E_2 increases with age, or that there is a persistent effect of E_2 on several neuroendocrine functions during aging. Supported by the American Federation for Aging Research.

FOOD RESTRICTION SUPPRESSES HYPOTHALAMIC PROOPIOMELANOCORTIN (POMC) MESSENGER RNA THROUGHOUT THE LIFESPAN OF THE MALE FISCHER 344 RAT. J.F. Nelson* and K. Karelus. Dept. of Physiology, University of Texas Health Science Center, San Antonio, TX 78284.

POMC is synthesized in the arcuate nucleus of the hypothalamus (HYPO) and is the precursor of several neuropeptides. HYPO POMC mRNA is suppressed by glucocorticoids. Because the diurnal rise of plasma free corticosterone is higher in food restricted than in ad libitum fed rats, it was of interest to determine if POMC mRNA is suppressed in food restricted rats. We also sought to determine if HYPO POMC mRNA declines with age in the Fischer 344 rat, as reported for other strains of rat and mouse. Rats were food restricted (FR) to 60% of ad libitum (AL) levels beginning at 6 weeks of age or fed AL and were killed between 0800 an 1200 h(lights on: 0400 h) at 6, 12, 18 and 24 months of age. HYPO were dissected, snap frozen in liquid N2 and RNA was extracted by the guanidinium cesium chloride method. POMC mRNA was measured by solution hybridization/RNase protection using a homologous 32P cRNA probe complementary to a portion of rat POMC mRNA. At all ages, POMC mRNA levels were 20-40% lower in FR than in AL rats ($p<0.05$). There was no age-related change in POMC mRNA in either group of rats, but this could be due to surprisingly low levels in the 6 mo AL group. Poly A RNA levels did not differ among treatment or age groups. These results are consistent with the hypothesis that the hyperadrenocorticism of the FR rat has physiological effects. They also indicate that the relatively high levels of POMC mRNA seen in AL rats are not essential for the extended lifespan of food restricted rats. (supported by a grant from the NIA).

5-HT FAILS TO ENHANCE NMDA DEPOLARIZATION OF CORTICAL NEURONS IN OLD RATS. R.S. Neuman*, S. Rahman, J. McLean and J. Reynolds. Fac. of Med., Memorial University, St. John's, Nfld. Canada, A1B 3V6.

A decrease in cortical 5-HT_2 receptors is found in both aged humans and rats, but little is known of the functional properties of these receptors. In immature rats, NMDA induced depolarization of cortical neurons is enhanced by co-activation of 5-HT_2 receptors (Rahman and Neuman, submitted). We now report this enhancement is dramatically reduced in 25 to 29 month old Fisher rats.

Wedges for "grease" gap recording were prepared from 500 μm thick slices of rat cortex (motor area). In young rats, amplitude of the NMDA (50 μM) depolarization was increased by co-administration of 5-HT (100 and 230% by 10 and 30 μM 5-HT respectively). In old rats 5-HT either had no effect (10 μM) or reduced the NMDA depolarization by 33% (30 μM). DOI (5 μM), a mixed 5-HT_{1C} and 5-HT_2 agonist, enhanced the NMDA response in young rats (175%) but not in old. Phenylephrine (10 μM) and carbachol (10 μM) enhanced the NMDA depolarization in both young (60 and 80% respectively) and old rats (82 and 162%). Functional 5-HT_2 receptors are present in the cortex of old rats since bath application of staurosporine (10nM; 40 min), a protein kinase C inhibitor, led to a 260% facilitation of the NMDA response by 30 μM 5-HT.

In conclusion, comparison of 5-HT_2 with α_1 and muscarinic effector systems demonstrates that the former is selectively reduced in old rats. We are currently using in situ hybridization to correlate 5-HT_2 receptor message with functional changes.

TRANSFORMING GROWTH FACTOR-β1 mRNA INCREASES IN RAT AND HUMAN BRAIN WITH AGING. N.R. Nichols*, S.A. Johnson and C.E. Finch. Andrus Gerontology Center and Dept. of Biological Sciences, Univ. of Southern California, Los Angeles CA 90089-0191.

Transforming growth factor-β1 (TGF-β1) is a cytokine with well-known roles in differentiation and tissue repair. Previously, we cloned TGF-β1 from hippocampus of 3 mo old rats (Mol. Cell. Neurosci. 2:221, 1991). In addition, TGF-β1 mRNA increased both at the cortical wound sites and in the deafferented hippocampus and striatum after lesioning (J. Neurosci. Res. 28:134, 1991). Both temporal and neuroanatomical expression suggested a role for TGF-β1 in synaptic plasticity and tissue repair in adult brain. Since infusion of TGF-β1 into the lateral ventricle resulted in an increase in GFAP mRNA and protein, we compared changes in hippocampal TGF-β1 mRNA during aging in F344 male rats with GFAP mRNA (positive control) by RNA blot hybridization analysis. In a single cohort of F344 male rats, TGF-β1 mRNA increased 50% in the hippocampus of 24 mo compared with 6 and 15 mo old rats. A similar increase at 24 mo was seen in both hippocampus and striatum of a second cohort of F344 male rats. Furthermore, hippocampal GFAP and TGF-β1 mRNA prevalence in individual rats are positively correlated when all age groups are considered together ($r^2 = 0.634$, $P < 0.0001$, $n = 22$). In human brain, GFAP and TGF-β1 mRNA prevalence also increase in total RNA samples from different cortical areas and hippocampus of old (73 ± 7 y) compared with young (41 ± 12 y) individuals. As in the rat, human GFAP and TGF-β1 mRNA prevalence are positively correlated ($r^2 = 0.395$, $P < 0.0001$, $n = 52$). Since an increase in TGF-β1 mRNA may result in a concomitant increase in bioactive peptide, these data suggest a role for this cytokine in gliosis and increased astrocytic reactivity contributing to age-related changes in synaptic plasticity. (Supported by NIH grant AG-07909)

625.2

ULTRASTRUCTURAL PLASTICITY CHANGES OF THE POSTERIOR PITUITARY (PP) DURING AGING. F. Marzban*, C.D. Tweedle, J.Y. Summy-Long,[a] Z. Wang,[b] S. Freeman,[b] M.L. Terrell[b] and M. Kadekaro[b]. Dept. of Anatomy and Neuroscience Program, MSU, E. Lansing, MI; [a]Dept. of Pharmacology, MS Hershey Medical Center, Hershey, PA; [b]Div. of Neurosurgery, UTMB, Galveston, TX.

The hypothalamo-neurohypophysial system (HNS) develops morphological and physiological changes during aging. Here we report the effects of aging and of dehydration on ultrastructural changes in the PP. Male Fischer 344xBrown Norwegian rats (3 and 30 mo. old) were given water or 2% NaCl to drink for 5 days. They were then decapitated and the PP processed for ultrastructural studies. Daily water and saline intake in young rats were higher than in old rats. The intake of saline, however, was higher than water in both age groups. Dehydration in young rats induced a significant increase in axo-capillary apposition and a decrease in the glia-capillary contact. Aging alone induced similar plasticity changes and the presence of large degenerating Herring bodies. Dehydration in aged rats did not induce further ultrastructural changes, probably because of the less intense osmotic stimulus in these animals. The ultrastructural changes in the PP of old rats are suggestive of higher functional activity of the HNS under basal conditions. Vasopressin and oxytocin concentrations in the plasma and glucose utilization in the HNS are being evaluated. Supported by NIH 2RO1NS-23055 (MK) and HD-25498 (J.Y.S.-L.).

625.3

DIMINISHED TRANSLATIONAL REGULATION OF SOMATOSTATIN mRNA CONTRIBUTES TO THE REDUCTION IN GROWTH HORMONE SECRETION WITH AGE W.E.Sonntag*, A. D'Costa, J.E.Lenham and R.L.Ingram. Department of Physiology and Pharmacology, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27157.

With advancing age, there is a decline in the capacity of tissues to synthesize protein. This decline in protein synthetic capacity appears to be closely related to a decline in insulin-like growth factor-1 and growth hormone since these hormones are potent anabolic agents, decrease with age and administration of these hormones increases protein synthetic capacity in tissues. Previous studies have indicated that part of the mechanism for the decline in the amplitude of growth hormone pulses is the result of an increase in somatostatin release from hypothalamic neurons. However, total somatostatin mRNA in the hypothalamus decreases substantially with age. In the present study, we compared polysomal bound and total somatostatin mRNA levels in Brown-Norway rats at 3 ages (6, 15 and 26 months) and in both *ad libitum* fed and dietary restricted animals. Total somatostatin mRNA decreased with age ($p<0.01$) and this decline was prevented by dietary restriction. Polysomal somatostatin mRNA increased approximately 46% with age ($p<0.05$). When data were expressed as polysomal bound somatostatin mRNA/total somatostatin mRNA a substantial increase was observed in *ad libitum* fed animals ($p<0.01$) which was not found in dietary restricted animals. These results indicate that with age there is increased recruitment of somatostatin mRNA onto polysomes suggesting a loss of translational control.

Supported by NIH grant AG07752.

625.4

DIFFERENT AGE-RELATED DECREASES OF ANKYRIN AND SPECTRIN OCCUR IN THE MOUSE TELENCEPHALON. N. Lam, B.A. Bahr, A.C. Godshall, R. Granger*, and G. Lynch. Center for the Neurobio. of Learning & Memory, Univ. of Calif., Irvine, CA 92717

Deteriorating neuropathologic processes are commonly associated with a decrease in neural activity and, eventually, brain function. It has been suggested that such neurodegenerative conditions are often, at least in part, a consequence of normal aging. The stable breakdown products of the membrane cytoskeletal protein spectrin, which act as biochemical markers correlating with the onset of many pathologic processes, have recently been shown to accumulate in the aged mouse telencephalon (Bahr *et al., Neurosci. Lett.* 131:237, 1991). In accord with this study, antibodies to cytoskeletal constituents were used to screen telencephalic immunoblot samples from three (n = 13) and twenty-five (n = 11-13) month old mice. The immunolabelling of neurofilament-200, talin, and Band 3, as measured by densitometric scanning, did not exhibit significant age-related changes, while actin decreased in the aged group as compared to the younger animals by a marginal 9.4 ± 4.5% (*mean* ± S.E.M., $p < 0.06$, two-tailed t-test). On the other hand, labelling of the α and β spectrin subunits decreased significantly with aging by 17 ± 3.5% ($p < 0.001$) and 18 ± 7.8% ($p < 0.05$), respectively. Labelling of the 220 kDa ankyrin had an age-related decrease of 37 ± 5.6% ($p < 0.001$) which is 2.1-fold greater than the decrease in α ($p < 0.01$) and β ($p = 0.05$) spectrins. In another group of mice, the difference in age effects on ankyrin and α spectrin was apparent between 3 (n = 4-5) and 10 (n = 4) months where the immunoreactivity levels decreased 26% and 3%, respectively ($p < 0.01$). Between 10 and 20 (n = 4) months of age, both antigens decreased 8% while between 20 and 25 (n = 4) months ankyrin and α spectrin diminished 1% and 14%, respectively ($p < 0.05$). In conclusion, aging processes appear to act differently on ankyrin and spectrin as far as rate and magnitude of decline (Supported by grant NIA AG00538).

625.5

EFFECT OF ACETYL-L-CARNITINE ON TRAUMA-INDUCED NEUROPATHIES IN THE YOUNG AND AGED RAT: MORPHOLOGICAL, MORPHOMETRIC, FUNCTIONAL EVALUATION. C. De Angelis, C. Scarfò, E. Perna, O. Ghirardi, M. Vertechy, E. Reda, M.T. Ramacci*, L. Angelucci[1]. Institute for Research on Senescence, Sigma Tau, Pomezia, Rome; [1]Institute of Pharmacology II, La Sapienza Univ. of Rome, Italy.

The favorable effect of acetyl-L-carnitine (ALCAR) on behavior and neuromorphological parameters of the CNS in aged rats prompted us to investigate its action on structure and function of intact and lesioned sciatic nerves in young and aged male Sprague Dawley rats. Sciatic nerve sections from animals sacrificed in anesthesia were stained with toluidine blue. In 24-month-old rats treated with ALCAR (150mg/kg/day in drinking water) for 6 months, sciatic nerves contained a lower number of altered myelinated fibers (-47%) and a higher number of normal fibers (+23%) than in age-matched controls. In rats aged 3 and 22 months, crush-induced injury caused 5 days later complete degeneration of the myelinated fibers. In both young and aged rats, treatment with ALCAR (15-60 days and 6-9 months, respectively) revealed an increased density of regenerating axons at 15 days (young) and 30 days (aged) after crush and an increased axonal size at 60 days. Also, the size of the entire myelinated fiber (sheath + axon) was larger in treated aged rats than in controls at 100 days after crush.

In agreement with the morphological features, the functional aspect (walking tracks) in ALCAR-treated rats showed a faster recovery of deambulation. Thus, the neurotrophic action of ALCAR in the CNS is also exerted in the PNS of both young and aged rats, even in the presence of other etiopathogenetic factors, e.g. trauma.

RATE OF CHANGE IN SIZE OF ABDOMINAL GANGLIA AS A FUNCTION OF WEIGHT IN *APLYSIA C.* J.M. Flinn*, C. Hong, M. Stanley, J. Estes, S. West, R. Holt. George Mason University, Fairfax, VA 22003.

The relationship between abdominal ganglia size and weight was examined for 194 *aplysia C.* whose weight ranged from .03 to 300 gms, by measuring the area of the abdominal ganglion. The area was determined using a compound microscope with calibrated objective. The best fit for the data required three different equations for the three weight ranges .03 - 2.5, 2.5$^+$ - 7.5, and 7.5$^+$ - 300 gms. The equations were:

$.03 < w \leq 2.5$ gms; $g_A = .308w + .08$; $r = .95$, $N = 140$, $p<.001$
$2.5 < w \leq 7.5$ gms; $g_A = .095w + .493$; $r = .85$, $N = 29$, $p<.001$
$7.5 < w \leq 300$ gms; $g_A = .016w + 1.01$; $r = .97$, $N = 23$, $p<.001$

Further analysis using dummy variables and curvilinear transforms will be performed. The transition points may be useful markers in development. dg_A/dw is greatest, .306 mm^2/gm, for the range .03 - 2.5 gms. 2.5 gm animals are approximately 2 - 3 cms, by Cash and Carew's criteria in late stage 12, at which time sensitization has developed. The second change in dg_A/dw at 7.5 gms marks the beginning of a much slower rate of ganglion growth. This is at the beginning of or earlier than other definitions (e.g., length > 10 cms) of early adulthood.

625.7

SYNAPTIC CONNECTIONS BETWEEN IDENTIFIED NEURONS DURING AGING OF A MOLLUSC, C. Janse, W. C. Wildering and M. van der Roest. (SPON: European Neuroscience Association). Department of Biology, Vrije Universiteit, De Boelelaan 1087, 1081 HV Amsterdam, The Netherlands.

Although many studies are known on age-related changes in the CNS, hardly any reports are available on the fate of synaptic connections between identified individual neurons during the animal's life span. The pond snail *Lymnaea* has a CNS with identifiable giant nerve cells permitting a life span approach to physiological studies of identified interneuronal synaptic contacts. This neurophysiological study reports on age-related changes in an electrical synaps between two giant peptidergic neurons (VD1 and RPD2) and in chemical synaptic contacts of an identified dopamine containing giant neuron (RPeD1). Experiments on VD1 and RPD2 showed that effectiveness of the electrical synaps between these neurons decreases with age. In addition pacemaker properties changed. The actions of the different changes together can explain the irregularities in the firing characteristics of the VD1/RPD2 system as found in old animals. In the study of properties of chemical synaptic connections attention was focussed on one particular group of follower neurons of RPeD1. These A-group neurons are situated in the right parietal ganglion. In young animals only a few A-neurons were found to receive synaptic input from RPeD1 whereas in animals of 6 - 10 months of age A-neurons receiving synaptic input were commonly found. In old animals (older than 12 months) the number of A-neurons with synaptic input from RPeD1 decreases again. These findings indicate that in *Lymnaea* electrical and chemical connectivity between neurons undergoe a continuous change with age. Future experiments will be directed to the the study of mechanisms governing these age-related changes.

THE EFFECT OF FIMBRIA-FORNIX LESIONS ON ASTROCYTE RNA EXPRESSION IN THE MOUSE BRAIN. J.R. Goss* & D.G. Morgan. Division of Neurogerontology & Dept. of Biol. Sci., Univ. of Southern California, Los Angeles, CA 90089-0191.

In previous studies we have examined age-related changes in astrocyte gene expression in the mouse brain and have reported a 40-80% increase in the message level for glial fibrillary acidic protein (GFAP) throughout the brain. To more fully understand the dynamics associated with this change, we employed a model of synaptic loss within the hippocampus by unilaterally transecting the afferent fimbria-fornix pathway in 7 month old C57Bl/6Nia mice. Success of the lesions was evidenced by loss of acetylcholinesterase staining in the hippocampus on the side of the lesion. *In situ* hybridization signals for GFAP RNA increased in both ipsilateral and contralateral hippocampi by 1 day post-lesion, peaked between 2 and 4 days post-lesion, was attenuated by 8 days post-lesion, and returned to non-lesioned control levels by 16 days post-lesion. Studies in progress are investigating this same lesion model in 3, 12, and 23 month old mice at 2, 5, and 10 days post-lesion. We will examine RNA for GFAP, glutamine synthetase, apolipoprotein E, sulfated glycoprotein 2, S-100, and amyloid precursor protein; all of which have been shown to have increased levels of RNA in astrocytes in various lesion models and/or neurodegenerative diseases. Supported by AG-07892, AG-00093, AHA-GIA 891079, and AHA-EIA 890173.

MICROGLIA OF THE AGED RAT BRAIN. M.N. Gordon*, M.A. Myers, L.S. Perlmutter and D.G. Morgan. Div. of Neurogerontology and Dept. of Neurology, Univ. of Southern Calif., Los Angeles, CA 90089-0191.

Increasing evidence suggests that microglia express immune-related antigens, function as antigen presenting cells and produce cytokines. Many aspects of peripheral immune function are reduced during aging, but little is known about microglia of the aged brain. Vibratome sections from F344/Brown-Norway F1 hybrid rats at 9, 18 or 24 mo of age were stained by lectin labeling with *Ricinus Communis* agglutinin I (RCA) or by immunocytochemistry using a monoclonal antibody against the rat MHC class II antigen (OX-6). The number of OX-6+ cellular profiles was counted and the percent area of tissue sections occupied by RCA reaction product was quantified using a video- and computer-based image analysis system.

The number of microglia expressing MHC class II antigen increased with aging in both grey and white matter. In neostriatum, OX-6+ cells increased from 14±3 cells/hemisphere/section (mean±SEM, n=4-5) at 9 mo to 43±4 at 18 mo and 96±25 at 24 mo. The number of microglia expressing OX-6 also increased 3-fold in the hippocampal hilar region (9 mo: 11±3; 18 mo: 28±4; 24 mo: 46±4 cells/0.5 mm^2), and 5-fold in the corpus callosum (9 mo: 24±5; 18 mo: 57±8; 24 mo: 152±16 cells/0.5 mm^2). OX-6+ cells also appeared larger in aged brain. RCA labeled a larger fraction of the microglial population than did OX-6. However, the percent area occupied by RCA reaction product was not increased as a function of age. These findings suggest some microglial markers remain stable during aging, but a larger fraction of microglia appear in an "activated" state, as more cells express MHC class II antigen. Supported by AG07892 & AHA-EIA 890173.

NEUROFILAMENT GENE EXPRESSION DECLINES IN THE DORSAL ROOT GANGLIA OF AGING RATS. I. M. Parhad*, J.N. Scott, C.A. Krekoski, A.W. Clark. Depts. of Pathology & Clinical Neuroscience, Univ. of Calgary, Calgary, Alberta, Canada.

Neurofilaments (NF)s are intrinsic determinants of axonal caliber. NF gene expression increases during maturation and is associated with an increase in Nf content and caliber of axons. In this study we asked whether a decline in Nf subunit gene expression occurs with aging, and whether this is correlated with axonal shrinkage. Fischer-344 rats were used at 4 ages (3, 5, 12, and 24 months; 3 rats / age group), L4-L6 dorsal root ganglia (DRG) were processed for quantitative Northern and *in situ* hybridization with NF-L (light subunit) cDNA. Morphometric evaluation was done of the L4 DRG and proximal dorsal root. Our results showed a 50% decrease in NF-L by Northern analysis at 24 months as compared to 3-12 months (Mann Whitney U, $p < 0.02$), and a similar decrease in NF-L mRNA grain density by *in situ* hybridization (n= 100 neurons / 1 rat / age group, $p < 0.001$, t test). No changes were seen in GAP-43 mRNA in these same samples with aging, by Northern or *in situ* hybridizations. Morphometric data showed a < 20% decrease in neuronal density in the DRG ($p < 0.05$), but no neuronal shrinkage (n = 100 neurons / age group, $p > 0.5$, F test). There was a 20% decrease in the diameter of large axons in the proximal dorsal roots at 24 months (n = 300 axons / age group; $p < 0.01$). These results indicate that NF-L mRNA declines with age and is associated with axonal shrinkage. Constitutive decline in Nf gene expression can result in axonal shrinkage and may be a substrate for age associated neural degeneration.

AGE-RELATED CHANGES IN MITOCHONDRIAL ENERGY METABOLISM IN THE SQUIRREL MONKEY. D.A. Di Monte*, M.S. Sandy, S.A. Jewell, I. Irwin, L.E. DeLanney and W.J. Langston. California Parkinson's Foundation, San Jose, CA 95128.

It has recently being suggested that impairment of energy metabolism plays a role in neurodegenerative disorders. In this study, we tested the possibility that age-related changes in mitochondrial activity may predispose to neurodegeneration. Squirrel monkeys were divided into three groups according to their age: young (n=4; age=3 year old), middle age (n=3; age=10 year old) and old (n=4; age= >16 year old). Animals were sacrificed, and brains were removed and dissected. Mitochondria were immediately prepared from the caudate, putamen and cerebellar cortex. Mitochondrial activity was measured as formation of ATP in the presence of different substrates, namely pyruvate and malate or succinate with rotenone. A significant decrease in the rate of ATP synthesis was measured between young and middle age monkeys in all areas of the brain when pyruvate and malate were used as metabolic substrates. In contrast, in the presence of succinate and rotenone, the decline in mitochondrial activity was only evident after middle age. The decreased rate of ATP synthesis could not be accounted for by a decrease in mitochondrial proteins in the tissues; indeed, the activity of other mitochondrial enzymes (*i.e.* citrate synthase and monoamine oxidase A) remained unchanged in all age groups. Thus, impairment of energy metabolism occurs with aging and may be involved in neurodegenerative disorders of the elderly. Our data also suggest that mitochondrial Complex I activity may decline at a relatively earlier age than the activities of other enzyme complexes of the respiratory chain.

625.12

CHARACTERIZATION OF AGE-ASSOCIATED INCLUSIONS IN BRAINS OF C57BL/6 MICE. M. Jucker*, L. C. Walker, L.J. Martin, D.L. Price, and D.K. Ingram. NIA Gerontol. Res. Ctr., NIH, Baltimore, MD 21224 and Neuropath. Lab., Johns Hopkins Sch. of Med., Baltimore, MD 21205.

In brains of C57BL/6 (B6) mice, age-associated inclusions were described (M Jucker *et al., Science,* 255:1443, 1992) that resemble lesions reported in transgenic mice produced with a construct of human amyloid precursor protein β-fragment (D Wirak *et al. Science*, 253: 323, 1991). Inclusions in B6 mice were first identified immunohistochemically with an antibody to a 110 kD laminin binding protein (LBP) and appeared as clusters (30-60 μm) of granules (1-3 μm) located predominantly in hippocampus but also seen in piriform cortex and cerebellum. Distinct inclusions first appeared about 6 mo of age and generally increased in incidence and size thereafter. The apparent immunoreactivity with several polyclonal antibodies, including β-amyloid, was not blocked by antigen preabsorption, indicating nonspecific immunoreactivity. Clusters were negative for hematoxylin and eosin, cresyl violet, thionin, Luxol fast blue, Bodian's Protargol, acetylcholinesterase, and glial fibrillary acidic protein (GFAP) stains. However, the presence of glycosaminoglycans was suggested by positive results using periodic-acid Schiff and Gomori's methenamine silver staining. Ultrastructural analysis revealed intracytoplasmic fibrillar material free of normal organelles; some inclusion materials were located within astrocytic somata. Association with astrocytes was also observed by using combined LBP and GFAP staining to identify inclusions in astrocytic processes and in proximity to capillaries. Etiology of the inclusions remains unidentified, but detection of faintly stained clusters in young mice (<6 mo) might provide clues to their development. Preliminary behavioral and morphological analysis has found little relationship between learning impairments and the density of hippocampal inclusions and glia cells in aged mice.

625.13

HIRANO BODY CONTAINS MOLECULES IMMUNOREACTIVE TO ANTI-HIPPOCAMPAL CHOLINERGIC NEUROSTIMULATING PEPTIDE (HCNP) ANTIBODY. S. Mitake*, K. Ojika*, K. Hayashi and O. Fujimori. 2nd Dept. of Int. Med., and 2nd Dpt. of Anat., Nagoya City Univ. Med. Sch., Nagoya 467, Japan.

A novel peptide (*HCNP: acetyl-Ala-Ala-Asp-ILe-Ser-Gln-Trp-Ala-Gly-Pro-Leu*) from rat hippocampus is involved in the development of specific cholinergic neuron in the *central nervous system in vitro* (*K. Ojika, et al; Brain* Res., 572:164-171, 1992). To investigate immuno-cytochemical distribution of the peptide in the central nervous system of old aged humans, anti-HCNP polyclonal antibody was raised in rabbits and affinity purified. The antibody specifically recognized HCNP and its 21KDa pro-protein. In histochemical studies, HCNP immunoreactivities in ABC method were exclusively associated with Hirano body in Sommer's sector of hippocampus, whereas no immuno-reactivity was observed in other bodies, such as Lewy's body, thalamic inclusion body or Pick's body. Immuno-histochemical mode of reaction of Hirano body were rod-like or granular in light microscope and antigens recognized by the antibody were closely associated with paracrystalline stracuture of the body in immunoelectron microscope.

The results strongly suggested that HCNP and its related molecules are involved in the formation of Hirano body.

625.14

S-ADENOSYLMETHIONINE DECARBOXYLASE IN HUMAN BRAIN. Lesley D. Morrison* and Stephen J. Kish. Clarke Institute of Psychiatry, Toronto, Canada, M5T 1R8.

S-adenosylmethionine decarboxylase (SAMDC) is a key regulatory enzyme in the biosynthesis of polyamines, substances which have been implicated as modulators of brain excitability. Little baseline information is available regarding SAMDC in human brain. We have measured in autopsied brain of neurologically normal subjects, basal SAMDC activity, sensitivity to substrate, activator and inhibitor; regional distribution and influence of aging. In a preliminary experimental animal study, brain enzyme activity declined by 47% after 24 hours postmortem. The specific enzyme activity in autopsied human brain was measured using a CO_2-trapping procedure with a specific inhibitor of SAMDC activity (MDL 73811; IC_{50}=31.5 nM) for blanks. The enzyme was characterised in parietal cortex with regard to substrate affinity (K_m=53 μM, V_{max}=74 pmol$^{14}CO_2$/h/mgP), and enzyme activity was markedly stimulated (+600%) by putrescine (K_a=16.7 μM).

The distribution of SAMDC activity in 12 human brain areas was measured (n=5 brains/area, except white matter n=3). The highest activity was observed in occipital, parietal, frontal and temporal cortices (58.3, 48.1, 44.7 and 36.1 pmol/h/mgP respectively); intermediate activity was observed in cerebellar and insular cortex, pulvinar, caudate and putamen (21.95, 19.46, 12.45, 26.9 and 17.37 pmol/h/mgP respectively) and lowest activity was observed in medial-dorsal thalamus, lateral globus pallidus and white matter (10.98, 6.44 and 2.86 pmol/h/mgP respectively).

The effect of aging on specific SAMDC activity was determined in occipital cortex (n=46, age range 1.3 weeks to 103 years). Enzyme activity increased from negligible levels at 1.3 weeks to ≈25% of adult values at age 2 years ($r=0.96$, $p<0.01$). Enzyme activity reached adult levels by age 14 and remained generally unchanged up to 103 years. (Supported by the Epilepsy Foundation of America).

Localization of Hemoglobin in Alzheimer's and Control Cerebellum. C.M. Hughes*, D.G. Flood, G.A. Campbell and J.R. Slemmon. Depts. Neurobio. and Anat., Neurol., Biochem., Univ. of Rochester, Rochester, NY 14642

Alzheimer's disease (AD) classically affects the hippocampus and association cortices. However, there has been some speculation that these areas are the first and, thus, most severely affected areas in a disease which proceeds progressively through the brain. Cerebellum, which is generally considered to be less affected in AD, may exhibit early changes if the disease is progressive. RP-HPLC analysis of cerebellum from AD and control cases (73-86 years old) demonstrates elevated levels of fragments of α and β hemoglobin in the AD cases with a percent change ranging from 592% to 164%. Immunocytochemical analysis of sections of cerebellum from most of the same cases shows human anti-hemoglobin immunoreactivity of granule cells and blood vessels. The granule cell staining appears to be membranous. The pattern of staining is similar in the AD and control cases although the staining is generally less intense in the control cases. One young control case (36 years old) shows blood vessel but no granule cell staining. This indicates that the localization of hemoglobin to the brain parenchyma may be an age-related phenomenon which is exaggerated in AD. The presence of hemoglobin in the brain parenchyma suggests the possibility of blood brain barrier malfunction in aging and AD cerebellum. Supported by-R35AG09016 (J.R.S.)

DISTRIBUTION OF PROTEIN SP40-40-LIKE IMMUNOREACTIVITY IN THE RAT BRAIN: A ROLE IN AGING? M.C. Senut, N.H. Choi (1), F. Jazat, and Y. Lamour*, INSERM U161, 75014 Paris, France; and (1) Showa University, Tokyo, Japan.

The protein SP40-40 is the human counterpart of the rat sulfated glycoprotein 2 (SGP2), whose mRNA has a widespread expression in the developing and the mature rat brain. In the present study, the distribution pattern and the cellular localization of the SP40-40 protein have been studied in various brain and spinal cord regions in young adult (3-4 months) Sprague-Dawley rats, using a well characterized polyclonal antibody. SP40-40-like immunoreactivity was mainly observed in the choroid plexuses and the ependymal cells; a consistent immunolabelling was also observed in the cingulate cortex (mainly layer VI), the retrosplenial cortex (layers II-VI) as well as in the hypothalamus. The SP40-40-like immunoreactivity was mainly observed within cell somata and their processes as a diffuse reaction product. Double-labelling experiments performed with antisera against GFAP demonstrated that SP40-40-like immunoreactivity was mainly localized within neurons. Although the function of protein SP40-40 in the central nervous system still remains to be elucidated, its involvement in neuronal death has been suggested. Therefore, we sought to determine the possible implication of SP40-40 in age-related cell death and atrophy. We performed a similar anatomical study in 12, 20-22 and 30-31 months old rats. With increasing age SP40-40-like immunoreactivity increased or appeared in specific brain areas (cingulate cortex, thalamus, hypothalamus, red nucleus, superior colliculus, olivary nuclei, cerebellum, cranial nerve nuclei). However, these changes did not seem to be associated with obvious signs of neuronal death or degeneration.

NEUROGLIA AND MYELIN V

$[Ca^{2+}]_i$ TRANSIENTS IN CULTURED SCHWANN CELLS EVOKED BY ACTIVATION OF NICOTINIC AChR's. E. Yoder*, V. Lev-Ram[1], and M. H. Ellisman. San Diego Microscopy and Imaging Resource, Departments of Neurosciences and [1]Pharmacology, University of California, San Diego, La Jolla, CA, 92093-0608.

$[Ca^{2+}]_i$ transients are known to mediate many cellular processes in developing and mature glia of the CNS. In the PNS, transient increases in $[Ca^{2+}]_i$ have been reported to occur in myelinating and terminal Schwann cells following axonal activation (Lev-Ram *et al.*, NS Abst. pg. 1519, 1991; Jahromi *et al.*, NS Abst. pg. 900, 1991); the physiological role of these transients is unknown. In order to gain insight into the nature of these signals, we have examined $[Ca^{2+}]_i$ transients in primary cultures of Schwann cells from neonatal rat sciatic nerves. Experiments were performed using cells loaded with the calcium indicator dye fluo-3 introduced via its AM ester. Carbachol, an AChR agonist, was found to induce a transient increase in $[Ca^{2+}]_i$ in many cells. Some exhibited an oscillation in $[Ca^{2+}]_i$ in response to carbachol. These effects were mimicked by nicotine and blocked by tubocurarine, but were not blocked by atropine. Thus, the observed action of ACh is via nicotinic (nAChR) rather than muscarinic ACh receptors. Nicotine induced $[Ca^{2+}]_i$ transients were observed in the absence of $[Ca^{2+}]_o$ plus EGTA indicating that the Ca^{2+} transient results from the release of Ca^{2+} from intracellular stores. The nature of this Ca^{2+} store was investigated by pharmacological manipulation. Thapsigargin stimulated an increase in $[Ca^{2+}]_i$ whereas caffeine did not. These results suggest that the release of Ca^{2+} from an intracellular store in cultured Schwann cells may be mediated by inositol trisphosphate receptors rather than ryanodine receptors. Mechanisms linking release of Ca^{2+} from intracellular stores in response to nAChR stimulation in Schwann cells, as well as the functional significance of such stimulation remain to be determined.

626.2

SUBPOPULATIONS OF SCHWANN CELLS RESPOND TO NEUROLIGANDS WITH INCREASES IN INTRACELLULAR CALCIUM. S.A.Lyons[1], P.Morell[1]*, and K.D.McCarthy[2]. [1]Dept. of Biophysics and Biochemistry and [2]Dept. of Pharmacology Univ. of North Carolina, Chapel Hill, NC 27599-7365.

Schwann cells interact with neurons during development to ensheathe or myelinate the axons shortly after birth. We hypothesize that one mechanism mediating neuronal/Schwann cell communication is signalling by neurotransmitters. We wish to determine if Schwann cells exhibit neuroligand receptors which are linked to calcium regulation and, if so, to examine the temporal relationship between the expression of receptors for various ligands on Schwann cell differentiation.

Schwann cell cultures were prepared from neonatal rat sciatic nerve and after 6 hours, 1d, 2d, 4d, 6d, and 14 days *in vitro* (DIV) were loaded with the calcium indicator dye, fura 2-AM. The influence of up to eight different neuroligands on Ca_i^{2+} levels was examined using a video-based imaging system. Neuroligands that elicited 2-4 fold increases in Ca_i^{2+} levels above vehicle responses in cultured Schwann cells were bradykinin (BK; 10μM) and adenosine triphosphate (ATP; 10μM). Both ATP and BK increased Schwann cell calcium levels within 15 seconds of drug addition, after which Ca_i^{2+} levels decreased toward baseline over 1-2 minutes. Calcium levels also increased in Schwann cells exposed to histamine (10μM) and glutamate (100μM). However, a smaller and more variable percentage of Schwann cells responded to these ligands. The results of these studies indicate that subpopulations of S100*B* immunopositive Schwann cells respond to one or more neuroligands with a rise in Ca_i^{2+} levels. Furthermore, it appears that developmental processes occurring *in vitro* influence the percentage of Schwann cells responding to different neuroligands with a rise in Ca_i^{2+}.

626.3

ASTROCYTES INHIBIT SCHWANN CELL PROLIFERATION AND MYELINATION OF DORSAL ROOT GANGLION NEURONS IN VITRO. V. Guenard*, P. Wood. The Miami Project to Cure Paralysis & Department of Neurosurgery, University of Miami School of Medicine, Miami, FL.

Schwann cells (SCs) aid central nervous system regeneration. However, little is known about the effect CNS glia may have on SC function. In the present study, the effect of astrocytes (AS) on SC proliferation and myelination was evaluated using pure neuronal cultures [prepared from dissociated embryonic rat dorsal root ganglia (DRG)] which were seeded with pure SC (50 x 10^3 cells/culture) isolated from neonatal rat sciatic nerve. SC function in these DRG-SC cocultures was compared to that in similar cultures to which were added either AS from neonatal rat cortices or fibroblasts (Fbs) from neonatal rat cranial periosteal membrane. To assess proliferation, AS or Fbs (0, 150 or 500 x 10^3 cells) were added to DRG-SC cultures; the cultures were maintained in medium containing 1% FBS. Two days later, the cultures were pulsed with ^{3}H-thymidine and after an additional 24 hours, immunostaining with 217c and GFAP antibodies and autoradiography were performed. AS inhibited SC proliferation in a dose-dependent manner whereas Fbs did not. SC proliferation was decreased by 25% in low astrocyte-density cultures and 82% in high astrocyte-density cultures relative to DRG-SC cultures. To evaluate myelination, DRG-SC cultures were maintained for 2 weeks and then AS or Fbs (0 or 100 x 10^3 cells) were added. For the next 2 weeks, cultures were maintained in medium containing 15% FBS and ascorbate, i.e. conditions which stimulate myelination in DRG-SC cocultures. Cultures were either immunostained (for O_4, GalC, O_1 and GFAP), stained for myelin (using Sudan black) or processed for electron microscopy. AS inhibited SC myelination by 90% relative to DRG-SC cultures. In the presence of AS, the expression of GalC was blocked, but that of O^4 was not. To determine if AS-SC contact played a role in the observed inhibition, AS were seeded on microporous membranes mounted in "tissue inserts" (Falcon) positioned above the DRG-SC cultures. Soluble factors released by AS induced a 27% decrease in SC proliferation and a 90% decrease in SC myelination relative to cultures with empty inserts. The present study demonstrates that AS can inhibit both SC proliferation and myelination in normal conditions in vitro. Our results suggest that AS mediate their effects through soluble factors.

IN VIVO IDENTIFICATION OF SCHWANN CELL NUCLEI IN MOUSE NEUROMUSCULAR JUNCTIONS. S. Nakashiro* and N. Robbins. Dept. of Neurosciences, Case Western Reserve Univ., Cleveland, OH 44118.

Little is known about the function of the terminal Schwann cell at the neuromuscular junction (NMJ). One strategy is to assess the function of this cell before and after deletion *in vivo*. For this reason, we have developed a technique to identify terminal Schwann cell nuclei in living mouse NMJ's. Superficial endplates in the mouse pectineus muscle were identified by staining the synaptic matrix with fluorescein-conjugated vivia vincia agglutin, and nuclei were stained with Hoechst 33342 in the living animal. By shape and location of the nuclei at the NMJ and the features of their nucleoli, the Schwann cell nuclei were then distinguishable from those of other cells such as muscle, fibroblasts, and capillary endothelium. This was confirmed through EM studies of serial sections of NMJ's. The Schwann cell nuclei, for example, have several small nucleoli which are also seen in Hoechst-stained nuclei above the nerve terminal, whereas muscle nuclei near NMJ's have only one or two prominent nucleoli. This identification was confirmed by S-100 immunostaining for Schwann cells in whole mounts. With this technique, we are now able to destroy the nucleus of the terminal Schwann cell *in vivo* using a focused laser beam. Deletion techniques such as these may make it possible to define the role of the terminal Schwann cell in the maintenance and plasticity of the neuromuscular junction. Supported by NIA grants AG08886 and AG06641.

UPTAKE OF AXONALLY TRANSPORTED LATEX NANOSPHERES BY PARANODAL AXON-SCHWANN CELL NETWORKS. K.P. Gatzinsky* and H. Persson. Dept. of Anatomy, Univ. of Göteborg, 413 90 Göteborg, Sweden.

The distribution of retrogradely transported red-fluorescent latex nanospheres (Molecular Probes) was studied by light and electron microscopy in lumbosacral ventral root axons of adult rats. The left sciatic nerve was crushed and immediately injected intraneurally with 50 µl of the tracer. After a 48-72 h postinjection survival period, the animals were perfusion-fixed by 4% paraformaldehyde. Vibratome-cut ventral root sections were examined with a Nikon FXA epifluorescence microscope. Spheroid granules exhibiting red fluorescence were distributed within many axons of the injected but not the control side. The granules were often concentrated at nodes of Ranvier, where they were situated in close association with the paranodal myelin sheath. For electron microscopical detection of elements showing this type of fluorescence, photoconversion was performed in epifluorescent light using a solution of 0.1% DAB in Tris buffer. With this procedure a black precipitate, which appeared electron dense at the ultrastructural level, was formed in association with membrane-delimited organelles of various sizes. In the internodal parts of the axons organelles of this appearance were situated in the axoplasm. By contrast, most organelles in association with the paranodal myelin sheath were situated within the so called axon-Schwann cell network, thereby being segregated from the main axoplasm.

Our results show that axonally transported non-neuronal materials can be removed from motor axons via a sequestration within paranodal axon-Schwann cell networks. Most likely, this process represents a local mechanism whereby motor neurons can eliminate retrogradely transported foreign substances before arriving to the neuronal perikaryon in the CNS.

ISOLATION OF HUMAN SCHWANN CELLS FROM PEDIATRIC DORSAL NERVE ROOTS FROM DORSAL RHIZOTOMY AND ADULT SCIATIC NERVE FROM AUTOPSY. P.J. Boyer*, L. Rutkowski, G. Tuite, R. Dauser, K. Muraszko, and G.I. Tennekoon. Department of Pathology and Divisions of Pediatric Neurology and Neurosurgery, University of Michigan, Ann Arbor, MI 48109

Human Schwann cells have been isolated, in limited numbers, from adult surgical (sural and sciatic nerves), transplant (phrenic nerve), and autopsy (trigeminal ganglion) specimens and from fetal tissues. We report methods for direct isolation of large numbers of human Schwann cells from two additional sources: (1) nerve roots obtained from pediatric patients undergoing dorsal rhizotomy for spastic diplegia (8 patients, age 4-12 yr, 5 preparations) and (2) sciatic nerves obtained from adults at autopsy (3 patients, age 52-66 yr, 5-12 hr postmortem). Major methodologic challenges included minimizing microbial contamination (for adult specimens) and optimizing enzymatic dissociation, Schwann cell population expansion, and fibroblast growth inhibition. Nerve fascicles were dissected out and cultured in the presence of cholera toxin for 1-2 wk prior to enzymatic dissociation. While less tissue was available from pediatric surgical specimens than from adult autopsy specimens (average 81 mg and 1525 mg of nerve fascicles, respectively), the total cell yield was nearly twice as high from pediatric specimens (average 5.1×10^4 and 2.6×10^4 cells/mg, respectively). Cell viability (over 80%), Schwann cell to fibroblast ratio (20:1), and Schwann cell antigen expression were similar in the two groups. Adult and pediatric Schwann cells responded similarly to mitogens but, while adult Schwann cell populations could be expanded with minimal fibroblast contamination, pediatric fibroblast proliferation was more vigorous and less inhibited by adenylate cyclase activators. In summary, pediatric surgical and adult autopsy peripheral nerve specimens provide additional sources of human Schwann cells. Funded by NIH NS 21700 and National Multiple Sclerosis Society RG 2395.

DETECTION AND REGULATION OF PMP-22 mRNA AND PROTEIN IN CULTURED SCHWANN CELLS. S. Pareek*, U. Suter#, G. J. Snipes#, A. A. Welcher#+, E. M. Shooter# and R. A. Murphy. Dept. of Anatomy and Cell Biology, Univ. of Alberta, Edmonton, Alberta, Canada T6G 2H7, # Dept. of Neurobiology, Stanford Univ. School of Medicine, Stanford, CA 94305-5401, USA.

Peripheral myelin protein-22kDa (PMP-22) is a novel myelin-membrane associated glycoprotein that has been localized within Schwann cells of sciatic nerve (Snipes et al., J. Cell Biol., 117, 225, 1992). The function of PMP-22 is unknown, however recent studies suggest that a point mutation in PMP-22 is a likely candidate for the mouse *trembler* phenotype (Suter et al., Nature, 356, 241, 1992). In this study, we have analyzed PMP-22 in cultured rat sciatic nerve Schwann cells to determine whether these cells express the protein in the absence of neurons and whether the controls that regulate its production are similar to those that regulate production of other myelin-associated proteins. Immunocytochemical studies using polyclonal antibodies raised against synthetic peptides of sequences within the protein show that PMP-22-like immunoreactivity is present within Schwann cells. Northern blot and RNase protection assays reveal that mRNA coding for PMP-22 is present in Schwann cells cultured in serum-containing medium supplemented with glial growth factor and forskolin. In the absence of forskolin, mRNA levels decline but are re-established within 36 hours after forskolin is added to the medium. Increases in PMP-22 protein levels also occurred following forskolin treatment as determined in studies in which Schwann cells were metabolically labelled with ^{35}S-methionine and cellular extracts were immunoprecipitated with anti-PMP-22 antibodies. Taken together, our results suggest that PMP-22 is present in axon-free Schwann cells and its expression is regulated in a manner similar to that of other myelin associated proteins such as MBP and P_0.

AXONS MODULATE THE EXPRESSION OF SCIP IN THE PNS. S.S. Scherer*, D.-y. Wang, L. Wrabetz, and J. Kamholz. Dept. Neurol., Univ. Penn. Sch. Med., Philadelphia, PA 19104.

SCIP (also known as tst-1 and Oct-6) is a POU transcription factor that is expressed by Schwann cells and appears to down-regulate the expression of myelin genes. We have analyzed the expression of SCIP mRNA in the peripheral nervous system of the rat. In developing nerves, the steady state level of SCIP mRNA was highest at the day of birth, and fell quickly to a low level that persisted into adulthood. We examined the steady state level of SCIP mRNA in adult sciatic nerves that were either permanently transected (to cause Wallerian degeneration but prevent axonal regeneration) or crushed (to cause Wallerian degeneration but allow axonal regeneration). After nerve-transection, SCIP mRNA increased slightly and transiently at 2 days post-transection, then returned to a low level for at least 58 days. After nerve-crush, SCIP mRNA increased substantially by 8 days post-crush, to much higher levels than in transected nerves, and this high level of expression was maintained for at least 58 days. Since Wallerian degeneration in crushed and transected nerves appears to be similar, the difference in SCIP expression appears to depend on regenerating axons. Thus, we believe that regenerating axons in crushed nerves interact with Schwann cells, leading to the up-regulation of SCIP mRNA.

THE EFFECTS OF ETHANOL ON TRANSFECTED SCHWANN CELLS. B.M. Labissiere, S. Moore, A. Springer, P.W. Archer, R.M. Knight. Dept. of Life Sciences Virginia State Univ., Petersburg, VA., 23806

Primary Schwann Cells transfected with the SV-40 T-antigen provides a model for obtaining cells that express properties associated with normal Schwann cells in culture. Ethanol has been shown to effect the nervous system, leading to alcohol-related peripheral neuropathy. The effects of various concentrations of ethanol on the morphology, proliferation and protein synthesis of the transfected Schwann cell were investigated. Increases in ethanol treatments (22, 43, 86, and 172 mM) caused a concentration dependent decrease in cell proliferation and protein synthesis. Light microscopic evaluation revealed cellular processes that thickened as the ethanol concentrations increased. These data indicate that transfected Schwann cells may provide an excellent model for studies of ethanol induced neuropathy in Schwann cells.

PHENOTYPIC FEATURES OF OLFACTORY ENSHEATHING CELLS: AN IMMUNOCYTOCHEMICAL EXAMINATION. R. Doucette* and R. Devon. Department of Anatomy, College of Medicine, and Department of Oral Biology, College of Dentistry, University of Saskatchewan, Saskatoon, Sask., Canada.

Olfactory ensheathing cells possess a mixture of Schwann cell and astrocytic phenotypic features and are the only glia that ensheath the 1^{0}olfactory axons. The objective of this study was to determine what additional phenotypic features ensheathing cells would express when grown under in vitro conditions known to be optimal for the growth-differentiation of Schwann cells or astrocytes. Ensheathing cells were obtained from the nerve fiber layer of the olfactory bulb of E18 rat embryos. For the first experiment, ensheathing cells were grown in either Bottenstein's G5 medium or in DMEM-F12/1%FBS/0.25 mM dBcAMP. Although dBcAMP did induce the appearance of weak GFAP-like immunoreactivity in these cells, they did not differentiate into typical astrocytes even when grown in either media for several weeks. The second experiment examined whether ensheathing cells would assume a myelinating phenotype (like Schwann cells) after being planted onto purified DRG neuronal cultures. By four weeks many of the S100-positive ensheathing cells were Gal-C+ and MBP+ and had begun to myelinate the larger axons, as visualized with the electron microscope. These myelinating glia were not residual Schwann cells that had survived the antimitotic treatment because control pure neuronal cultures contained no glial cells and no evidence of myelination. Thus, ensheathing cells can assume a myelinating phenotype in vitro. (This work was supported by a grant from the MRC of Canada).

GLIAL CELLS IN THE DEVELOPING OPTIC NERVE OF THE FROG *LITORIA (HYLA) MOOREI*. D.E. Playford* and S.A. Dunlop. Neurobiology Lab., Department of Psychology, University of Western Australia, Nedlands 6009.

We have recently shown that there is a biphasic sequence of myelination in the optic nerve of *Litoria moorei*. The first phase is initiated at the optic foramen in mid-tadpole life, spreads towards the eye and chiasm and is complete at metamorphic climax; the second phase is initiated at the chiasm, spreads towards the eye and results in approximately 2.5% of optic axons being myelinated in the fully mature adult. We have also reported that numbers of glial cells increase throughout life and that the proportion of oligodendrocytes mirrors the patterns of myelination (Playford & Dunlop, 1991, Neurosci. Abs. 17, 157.11). Here, we have examined glial cells ultrastructurally and show that although astrocytes and oligodendrocytes can be distinguished from mid-tadpole life, they continue to mature morphologically until the final adult stage. To determine when and where glial cell division is occurring, animals were injected with tritiated thymidine and killed 4-6 hours later. Dividing cells were seen at all levels in the nerve suggesting that differentiated astrocytes and oligodendrocytes undergo cell division. In addition to differentiated glial cells, there is a distinctive group of undifferentiated glial cells at the chiasmal end of the nerve. Serial reconstruction of wax sections shows that these undifferentiated cells emanate from the pre-optic recess, pass through the chiasm, enter the nerve as a dorsal cell mass and extend along the nerve for up to 50 microns. This cell mass diminishes after metamorphic climax. Dividing cells were also seen within the undifferentiated cell mass.

POTASSIUM CURRENTS FROM HEALTHY AND NEUROFIBROMA-DERIVED SCHWANN CELLS IN THE BICOLOR DAMSELFISH, A MODEL OF HUMAN NEUROFIBROMATOSIS. L.A. Fieber* and M.C. Schmale. Univ. of Miami Rosenstiel School of Marine and Atmospheric Science, NIEHS Marine and Freshwater Biomedical Sciences Center, Miami, FL 33149.

Schwann cells are the predominant cell type observed in neurofibromas in Type 1 neurofibromatosis (NF-1) in man. The development of this disease is marked by changes in morphology and growth patterns in Schwann cells which may have physiological correlates. Here we present electrophysiological results on cultured Schwann cells from the only naturally occurring model of NF-1, damselfish neurofibromatosis (DNF), from the bicolor damselfish (*Pomacentrus partitus*). Ionic currents were recorded using the whole cell patch clamp technique from cell bodies of healthy fish Schwann cells from peripheral nerve explant-derived cultures with or without axonal fragments present. These were compared to currents in cultured Schwann-like cells from neurofibromas. Each of these cell types expressed the glial specific antigen, S-100, but not fibronectin, an antigen found in both mammalian and damselfish perineurial cells. Multiple types of potassium currents were observed in both healthy and tumor derived cells, but with different currents predominating. All tumor derived cells had a transient current with a steep, sigmoid activation curve, which was partially blocked by external tetraethylammonium (TEA; 14 mM). This current is similar to A-type potassium current. Tumor derived cells often had only this current. All Schwann cells from healthy fish, regardless of the presence of an axonal fragment, had a delayed rectifier current, and often this current had little or no apparent inactivating component. This current was blocked by external TEA (14 mM).

CLONING, SEQUENCING, AND LOCALIZATION OF GLUTAMINE SYNTHETASE FROM THE NERVOUS SYSTEM OF THE SPINY LOBSTER. H.G. Trapido-Rosenthal*, R.A. Gleeson, W.E.S. Carr, R.M. Greenberg, E. Orona, L. Van Ekeris, W. Lesser, and P.J. Linser. Whitney Laboratory, University of Florida, St. Augustine, Florida 32086.

The olfactory organ of the spiny lobster, *Panulirus argus*, consists of a dense array of aesthetasc sensilla on the lateral filament of the antennule. Each sensillum contains the dendrites of several hundred chemosensory cells, and processes of a number of glia-like auxiliary cells. Electrophysiological studies have shown that sensilla include populations of receptor cells that respond to a variety of amino acid odorants, including glycine, glutamate, and alanine. Biochemical studies have shown that sensilla also contain amino acid uptake systems, as well as odorant-metabolizing enzymes. Messenger RNA isolated from the lobster's olfactory organ was used to construct a cDNA library in the vector λZAPII. The library was screened for olfactory enzymes by means of the polymerase chain reaction (PCR). Sequencing of two PCR products revealed an open reading frame of 1083 nucleotides, coding for 361 amino acids showing 63 % identity to the enzyme glutamine synthetase (GS) from *Drosophila melanogaster*. Immunohistochemical and *in situ* hybridization studies showed that, in the brain, GS is localized in glia, and in the olfactory organ, GS is localized in the auxiliary cells. Biochemical studies showed that the olfactory sensilla have 4-fold greater GS activity than does lobster brain. Olfactory GS may play a role in controlling the background levels of amino acids in the environment of olfactory receptors.

SUBCELLULAR ANALYSIS OF GLUT-1 IN DEVELOPING BRAIN. S. Hyman, E. M. Cornford*, and W. M. Pardridge. Depts. of Neurology & Medicine, UCLA, and West Los Angeles VA Medical Center, Los Angeles, CA 90073.

Glucose transporter density and localization was defined in the blood-brain barrier of newborn (NB), 14-day-old suckling, 28-day-old weanling and adult rabbits with immunogold electron microscopic methods (PNAS 88:5779, 1991). Newborn capillary profiles were grouped as prepatent, intermediate, or patent by ablumenal & lumenal membrane lengths, and lumenal & endothelial cytoplasmic areas. The number of gold particles/endothelium increased with age. Net cytoplasmic areas decreased, while mean lumenal & ablumenal lengths increased. Recruitment of cytpolasmic transporter to membranes in development is apparent from the reduced cytoplasmic GLUT-1 seen post-natally (Table). The increased (3.5X ablumenal-to-lumenal) transporter confirms previous adult rat studies.

Age	(n)	#Au	LUMEN %	ABLUMEN %	CELL %

QUANTIFICATION OF mRNA OF BRAIN GLUCOSE TRANSPORTER USING PCR AIDED TRANSCRIPT TITRATION ASSAY (PATTY) METHOD K. C. Wadhwani*, T. Giordano, K. Chandrasekaran, R. Fukuyama and Q. R. Smith. Laboratory of Neurosciences, NIA, Bethesda, MD 20892.

Changes in levels of mRNA of glucose transporters have been observed under various physiological and pathological conditions. In order to quantitate such changes in the glucose transporter, we tested whether the PATTY method (Nucl. Acid. Res., 17:9437, 1989) of quantification of mRNA could be used. A 405bp [^{3}H]-labelled riboprobe containing the coding and 3' noncoding sequences of the glucose transporter was prepared from rat-GLUT1 cDNA plasmid (prGT3). A known amount (400 pg) of this synthetic [^{3}H]-RNA was reverse transcribed using random primers. The cDNA was then amplified using 2 primers corresponding to the noncoding sequences of GLUT1. This resulted in the amplification of a 292 bp fragment specific to the rat GLUT1 gene (target DNA). An oligo nucleotide of 100 bp containing the same sequences as the first and last 50 bases of the 292 bp fragment was also prepared (competitive DNA). Identical amounts of 'target DNA' were then coamplified with different amounts of the 'competitive DNA' (ranging from 24 pg to 24 ng) using the same primers. The 5'- primer was end labelled with ^{32}P. The ratio of radioactivity between the 'target DNA (292 bp fragment)' and 'competitive DNA (100 bp fragment)' was determined quantitatively after separation by gel electrophoresis and radioactivity counting. The results showed that this method gave an accurate determination of the amount of synthetic [^{3}H]-RNA of the GLUT1 transporter and that a 2-fold change in the amounts of the synthetic RNA could be detected. This method is currently being employed to determine changes in the levels of mRNA of glucose transporter using *in vivo* and *in vitro* model systems.

UPREGULATION OF THE BLOOD-BRAIN BARRIER (BBB) GLUCOSE TRANSPORTER (GLUT1) mRNA BY GLUCOSE DEPRIVATION. L. Wang, R.J. Boado, W.H. Oldendorf*, and W.M. Pardridge. Departments of Medicine and Neurology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The absence of neuroglucopenia symptoms in chronic hypoglucemia may be due to an upregulation of the BBB-GLUT1 glucose transporter. Therefore, we investigated the effect of glucose deprivation on the abundance of the GLUT1 transcript in bovine brain capillary endothelial cells in culture (ECL). The GLUT1 gene is over-expressed in cell culture. Paradoxically, there is a marked downregulation of GLUT1 gene expression in brain ECL (Boado & Pardridge, Molec. Cellul. Neurosci. 1:224, 1990). Therefore, poly A+ mRNA from ECL was isolated by a single step procedure recently described (Boado & Pardridge, J. Neurochem., 57:2136, 1991). Northern blots preformed under high stringency conditions with 10 μg ECL poly A+ mRNA showed that glucose deprivation (5 mg % glucose) caused a 2.4 ± 0.2 (mean ± SE, n = 3) fold increase in the GLUT1/ actin mRNA ratio vs. control incubations (100 mg % glucose). This rise was time dependent and the maximum effect was observed at 20-24 hours after the hexose deprivation. Nuclear transcription run on assay showed no changes in neither the GLUT1 or actin gene transcription rate 24 hours after glucose deprivation.

Conclusion: i) glucose deprivation increases the abundance of GLUT1 mRNA in brain capillary endothelium, ii) this increase is probably due to enhanced stability of the GLUT1 mRNA without changes in the gene transcriptional rate, and iii) this may represent the initial step in the upregulation of the BBB-GLUT1 glucose transporter in chronic hypoglycemia.

627.4

ENDOTHELIN-1 (ET-1) RECEPTORS AT THE BLOOD-BRAIN BARRIER (BBB). P. Grammas*, T. Botchlet, B. Jacks. Univ. of Oklahoma Health Sciences Center, Okla. City, OK 73190.

ET-1, synthesized by endothelial cells (ECs), is well known role as a powerful constrictor of vascular smooth muscle cells although less is known about other possible ET-1 effects on other cell types. By analogy to another EC product, endothelial derived relaxing factor (NO), ET-1 could play a role as a neuromodulator in the nervous system. The objective of this study is to determine the possible role of ET-1 on the cerebral microcirculation characterizing ET-1 receptors on isolated microvessels (MVs). The results of the radioligand binding experiments show that in MVs from adult rats the binding capacity is 827 fmol/mg and the K_D is 1.31/nM In addition, ET-1 (10-1000 nM) significantly ($p<0.05$) stimulates Na^+- dependent neutral amino acid transport as measured by the uptake of methyl amino isobutyric acid. Furthermore, we have shown that in aged rats (>18 mths) the number of ET-1 receptors decreases approximately 50% with no change in K_D. Our results demonstrate that the cerebral microcirculation i.e.the BBB, possesses receptors for ET-1 and that in response to this peptide amino acid uptake can be modulated. In addition, in aged animals there is a decrease in the ET-1 receptor. These data suggest that BBB functions, such as amino acid transport, could be altered by ET-1 and that ET-1 responsiveness might be diminished in aging. (Supported by AHAF, OCAST and NIH NS 30457).

CHRONIC NICOTINE TREATMENT INCREASES BLOOD-BRAIN TRANSPORT AND CAPILLARY SEQUESTRATION OF VASOPRESSIN. M.N. Lipovac*, E. Barrón, L.S. Perlmutter, J.G. McComb, M.H. Weiss and B.V. Zlokovic. Depts. Neurol. Surg. and Neurol., and Divn. Neurosurg., CHLA USC Sch. Med., Los Angeles, CA 90033

Plasma vasopressin (AVP) may be responsible for reinforcing and withdrawal effects of nicotine (N) and tobacco smoking associated with cognitive functions. In this study, blood-brain barrier (BBB) transport and capillary sequestration of AVP were examined in N-treated guinea pigs. N tartarate was administered s.c. by osmotic mini-pumps (Alzet 2002; 4.5 mg/kg of N free base/day) for 14 days; 14-day plasma levels of N and cotinine (N metabolite) were 11.4 and 101.8 ng/ml, respectively. [^{3}H]-AVP (3 nM) and [^{14}C]-sucrose (vascular space marker) were simultaneously infused into brains of N-treated animals (for 10 min) by vascular perfusion technique [Biochim. Biophys. Acta (1990) 1025: 191-98]. Capillary depletion method [J.Neurochem. (1990) 54: 1882-88] was used to distinguish between AVP BBB transport vs. binding. The rate (K_{in}) of [^{3}H]-AVP entry into brains of N-treated animals was significantly increased in comparison to N-naive animals (control), i.e. by 117% as determined in capillary depleted brain tissue. A ten times greater rate of AVP capillary in situ sequestration was found as a result of N treatment. Compartmental brain uptake of sucrose was not significantly altered by N-treatment. [^{3}H]-AVP BBB transport and binding in N-treated animals were strongly inhibited (57% to 81%) by unlabeled AVP and the V_1-antagonist (TMeAVP) at 4.5 μM. It is concluded that N increases transport of AVP into the brain parenchyma and its sequestration at the BBB most likely by modifying a specific BBB AVP carrier and/or a V_1-like receptor at the luminal side of the BBB. (Supported by Tobacco Related Disease Research Program, grant 2RT0071).

627.6

MORPHOLOGIC ALTERATIONS IN NEUROHYPOPHYSEAL ENDOTHELIAL CELLS OF NICOTINE-TREATED GUINEA PIGS. E. Barrón[1], M.N. Lipovac[2], B.V. Zlokovic[2], L.V. Johnson[3]* and L.S. Perlmutter[1]. USC School Medicine; Neurol[1], Neurol Surg[2] and Anat[3], Los Angeles, CA 90033.

Chronic exposure to nicotine has been linked to morphologic changes in aortic and umbilical cord endothelial cells. To study its effects in brain, we treated guinea pigs with nicotine for 14 days (Alzet minipumps; final plasma level: nicotine = 11.4 ng/ml; cotinine (nicotine metabolite) = 101.8 ng/ml) and examined endothelial cells either within (cerebral cortex) or outside (neurohypophysis) the blood-brain barrier (BBB). Animals were perfused with aldehyde fixative and processed for electron microscopy. Qualitative comparisons of cortical endothelial cells from nicotine-treated (n=3) and control (n=3) animals revealed no obvious morphologic differences; capillaries from nicotine-treated neurohypophyses did, however, show a striking increase in microvillous-like projections into the capillary lumen. Quantitative ultrastructural morphometric analyses of neurohypophyseal capillaries determined luminal perimeter, endothelial cell area, endocytotic vesicle number and the density of microvillous-like luminal projections.
