The Na+/Ca2+ exchanger was characterized in plasma membrane vesicles derived from frontal and temporal cortex and cerebellum of control and Alzheimer’s disease postmortem tissue. Exchanger activity was defined as the change in vesicular Ca2+ content seen after Na+ loaded vesicles were diluted into choline buffer. The time course of changes in Ca2+ content after dilution was similar in three regions of control brain, both frontal and temporal cortex vesicles showed elevated Ca2+ content, most evident as an increased peak Ca2+ content at 2 minutes. The AD cerebellar cortex time course was similar to control but did not show as elevated peak content. No differences were seen in the passive permeability to Ca2+ when comparing plasma membrane vesicles prepared from control and AD brain. Vesicles from the frontal and temporal cortex of AD brain showed increase in the initial velocity of Ca2+ uptake when compared to control brain, whereas, the cerebellum did not. There were no significant effects of AD on the Ki for Ca2+ activation of the initial velocity. Ca2+ influx measured during the rise in vesicular Ca2+ content was elevated in vesicles from AD temporal cortex when compared to control. Two known inhibitors (exchange inhibition peptide and dichloroethene) of the cerebral Na+/Ca2+ exchanger inhibited the human brain exchanger equally well in control and AD vesicles. An antibody to the cardiac exchanger was used to determine the molecular weight of the human brain Na+/Ca2+ exchanger. The molecular weight determinations from western blots showed identical molecular weights of 100-110 kDa in both AD and control vesicle preparations. The data suggest that increased Na+/Ca2+ exchange activity in AD brain is related to the causative factors of neurodegeneration and lends support to the “Ca2+ hypothesis of AD.”

THE INHIBITORY EFFECT OF B-AMYLLOID PEPTIDE ON RAT BRAIN NA+/CA2+ EXCHANGE. Anous Wu, Robert A. Colvin and Vasudeopal Jayasunder. Dept. Biological Sciences, Ohio University College of Osteopathic Medicine, Athens, OH 45701 USA.

These studies were performed to determine the effect of addition of Alzheimer’s disease β-amyloid peptide (B-AP) on Na+/Ca2+ exchange activity. Na+/Ca2+ exchange activity was measured from membrane vesicles (MV) isolated from rat brain. The effect of synthetic peptide B-AP,38-42 and scrambled (B-AP38-42) was examined. PMV were preincubated with each peptide for 15 minutes (4°C) before assay. Two mM of AD, 10 mM of B-AP38-42 and 15 mM of Ca2+ were included. Na+/Ca2+ uptake was initiated by diluting PMV 20 fold with buffer containing either 157 mM NaCl and 157 mM cholineCl and Ca2+. Ca2+ uptake was terminated by addition of 5 mM LaCl3 and rapid filtration. B-AP38-42 inhibited Na+/Ca2+ uptake with an IC50 of 800 μM (concentration measured in the preincubation buffer) but had no effect on the Na+−dependent Ca2+ influx. When B-AP38-42 was added in the dilution buffer instead of during the preincubation step, the same inhibitory effect was observed. No inhibitory effect was seen when B-AP38-42 was tested under both conditions. The inhibitory effect of B-AP38-42 could not be overcome by increasing Ca2+ concentration. Analysis of unidirectional flux for Ca2+ during the initial phase of rapid uptake or after a stable plateau had been obtained showed that 800 μM B-AP38-42 inhibited both Na+− and inhibts Na+/Ca2+ influx and efflux with the same efficacy (approximately 50 % inhibition) during both time periods. These results suggest that the inhibitory effect of B-AP38-42 is irreversible, and that it inhibits both Na+/Ca2+ exchange and Ca2+/Ca2+ exchange activity by directly interacting with the exchanger.

597.7

One of the hallmarks of Alzheimer’s disease (AD) is the presence of extracellular senile plaques composed primarily of aggregated amyloid β-peptide (AβP) surrounded typically by dystrophic neurites. It has been hypothesized that the aggregate form of AβP may induce toxicity on neurons by forming membrane channels thereby destabilizing neuronal Ca2+ homeostasis. We have used patch-clamp recording techniques to study the effects of AβP (1-40) on calcium currents in differentiated mouse NIE-115 neuronal cells (Davidson et al., 1984). In whole-cell recordings, incubation of cells with AβP for 24 h significantly increased the maximal peak inward current from -201.8 pA to -352.0 pA, and shifted the voltage at peak current (V1/2) and the current activation value towards more positive potentials. For untreated cells, median V1/2 was 1.7 mV and Vmax was -28.9 mV vs. 10.5 mV and -24.7 mV in AβP-treated cells. Inactivation with the reverse sequence AβP(40-11) did not produce significant changes in the amplitude or kinetic behavior of inward current. At the single channel level, AβP added to the pipette increased the open probability of cation-conducting ion channels. As determined by cell viability counts, AβP1-40 had neurotoxic effects; within 24 h, addition of AβP reduced the number of cells by more than 50%. It is suggested that the neurotoxic effects of AβP may be mediated by its ability to form cation channels de novo and/or alter the activity of cation channels already present in the cell membrane. We are in the process of developing a liposomal model system with a lipid composition similar to that of the neoblastoma cell to analyze AβP’s membrane perturbation properties.

ELECTROPHYSIOLOGICAL STUDY OF AMYLOID β PROTEIN ACTIVITY IN RAT CORTICAL NEURONS. K. Pakuwanta*, M.P. Mattson, and N. Alzgör. Sanders-Brown Research Center on Aging and Department of Anatomy and Neurobiology, University of Kentucky, Lexington KY 40536.

The effect of amyloid β-protein 25-35 (AβP) was examined in neurons freshly dissociated from rat cortex using the nystatin-perforated patch-clamp technique. AβP at concentrations higher than 10−8 M induced a slow inward current, which manifested its toxicity, with an increase in membrane conductance at a holding potential of -30 mV. The time lag until the appearance of the effect of AβP shortened concentration-dependently, whereas the increase in membrane conductance did not. When the extracellular Na+ and Ca2+ and intracellular K+ were replaced by equimolar NMG, isothionate, and Cs+ respectively, the membrane conductance and the reversal potential were not affected. Even when Ca2+ was removed from the extra- and intra-cellular space by using an Ca2+−free external solution and an internal solution including BAPTA (20 mM), the effect of AβP did not alter. It is suggested that AβP elicits an inward current either by forming membrane pores as suggested by Antepi et al., or by causing dysfunction of ion channels as suggested by our recent finding that AβP can damage ion-motive ATPases by a free radical-mediated mechanism (see Mattson and Matison, this meeting).

597.9

Amyloid β protein (Aβ) is a major component of the plaques that are a hallmark of Alzheimer’s Disease. A large literature has shown that Aβ is neurotoxic, but little has been published on the mechanism through which Aβ kills neurons. Here we report that treatment of embryonic rat cortical cells in culture with Aβ (1-40) or Aβ (25-35) inactivates the ouabain sensitive ATPase. Cultures were exposed to Aβ (10μM-200μM), membranes were prepared, and ATPase activity was assayed in 96-well microtiter dishes using a method adapted from Rohn et al. (Biochem. 46:525-34). We found that there is a reduction in cell activity with no reduction in the non-ouabain sensitive, non-calcium dependent ATPase activity. Co-treatment of cultures with Vitamin E (50μM) blocks the Aβ effect in ATPase activity, indicating that mechanism of impairment is mediated by free radicals. By a separate assay we also find no reduction in the activity of the plasma membrane Na/Ca exchanger at concentrations of Aβ that are neurotoxic. We are currently examining the contribution of impairment of Na-K-ATPase activity by Aβ to loss of calcium homeostasis and cell death.

PROPERTIES OF CHLORIDE CHANNELS IN PC12 CELLS INDIRECTLY MODULATED BY ALZHEIMER’S DISEASE B-AMYLOID. R. Raport, R. Fukuyama, G. Ehrenstein, S.I. Rapoport and Z. Galzicki; LNS, NIA and CNB, NINDS, NIH, Bethesda, MD 20892.

A pathological feature of Alzheimer’s disease (AD) is the formation of plaques in the parenchyma and vasculature of the brain. β-Amyloid peptide (B-AP) is one of the defining components of these plaques. We have previously shown from cell-attached patch recordings that B-AP (1-40) increases the activity of channels inherent to PC12 cells (Peacock et al, 1994, Biophys J. 66:A40). We have now managed to characterize these channels further. Under conditions of symmetrical choline chloride (120 mM) and high calcium (10 mM CaCl2), in excised patches, we could resolve two main conductance levels of 100 and 300 pS. Both had reversal potentials (RP) around 0 mV under these conditions. Exchanging the major cation on the extracellular face to Na+ had no significant effect on the RP. However, reducing the chloride to 30 mM NaCl from 150 mM, by replacement with acetate resulted in a positive shift in the RP, irrespective of whether chlorine or Na+ was the major cation. This implicated chlorine as the charge carrier for this channel, but the shift was less than expected indicating positive conductance. The fact that both conductances were seen to be effected in the same way by these ion substitutions and that both levels were invariably seen in any one patch, means it is likely that we are observing one channel which can have differing conductance levels. The mechanism by which B-AP or patch excision increases the activity of this channel remains unclear. A possible mechanism may be linked to the ability of B-AP to interfere with calcium homeostasis. Alternatively, disruption of cytoskeletal components linked to the channel may be involved.
NO APPARENT EFFECT OF \(\beta\)-AMYLLOID PEPTIDES ON M1 MUSCARINIC RECEPTOR BINDING OR FUNCTION. C.M. Rever and D.D. Flynn*, Dept. of Pharmacology, Univ. of Miami School of Medicine, Miami, FL 33101.

While acerelorated \(\beta\)-amyloid (\(\beta\)A) deposition has been suggested to play an early and critical role in the pathogenesis of Alzheimer's disease (AD), the precise cellular effects of \(\beta\)A are unclear. The complexity of \(\beta\)A actions is evidenced by the opposing neurotrophic and neurotoxic actions which are dependent on peptide concentration and the presence of soluble vs. fibrillar forms. On the basis of limited sequence homology to substance P and tachykinin peptides, \(\beta\)A has been suggested to interact with tachykinin receptors and function as an allosteric modulator of the ionotropic NMDA receptor. Substrate P-related peptides also appear to function as G protein antagonists, uncoupling receptor-G protein-mediated responses. Conical Mi muscarinic receptor (MR) high-affinity agonist binding and receptor-stimulated G protein-mediated phospholipase C activity are diminished in AD, resulting from an apparent receptor-G protein uncoupling. In order to test the hypothesis that \(\beta\)A may function as a MR-G protein "uncoupler" in AD, we have assessed the effects of amyloid peptides on MR binding and functional activity. \(\beta\)A peptides (1-40, 25-35, 0.01-100 \(\mu\)M) had no effect on binding of the muscarinic antagonist, \(\text{H}^3\)-NMS, to membranes from CHO cells transfected with the MR receptor, when incubated in vitro for up to 18 hr at 4\(^\circ\) C or for 2 hr at 25\(^\circ\) C, or in culture for 20 hr. Agonist binding as well as basal and carbachol-stimulated \(\text{H}^3\)-GTP\(\gamma\)S binding were also unaffected by peptide under all conditions tested. These findings suggest that \(\beta\)A does not antagonize MR-G protein interactions and that MR dysfunction in AD is not a consequence of excessive \(\beta\)A accumulation. (Funded by NS19905 & The Alzheimer's Association)

We previously reported that well-trained Parkinsonian subjects can show normal accuracy in a simple pointing task even if they are deprived of information about their unfolding trajectories and knowledge of the results of their movements (Neurosci Abstr 18:935). It has been often observed that Parkinsonian subjects require such information to sustain normal performance. However, such dependence might be due to task complexity or to the need to learn an unfamiliar transform. We therefore divided four groups of subjects: practiced normals (PN, N=3), practiced Parkinsonians (FP, N=1), unpracticed normals (UN, N=3), and unpracticed Parkinsonian subjects (UP, N=4). After a brief practice at making movements to match four computer screen targets requiring 8 to 32 cm excursions of the shaped arm over a digitizing tablet, subjects were required to respond to randomized targets in two experimental blocks. In the first, they saw the target throughout each trial, were given instantaneous feedback, and received knowledge of results. In the second, none of this information was provided. Both NP and FP subjects sustained accuracy when deprived of information, but neither UN nor UP subjects did so: both groups undershot the larger target distances, the UP subjects much more so (for the largest target, UP, 47.5% vs. UN, 26.3% and PN, 10.7%). We conclude that Parkinsonian patients have a relative inability to master a sensorimotor transform and perform under reduced information conditions rather than an absolute inability to do so. DECREASED [123I]-I-B-CIT SPECT STRIATAL UP TAKES CORRELATES WITH DISEASE SEVERITY IN IDIOPATHIC PARKINSON'S DISEASE. J. Seibyl, K. Marinkovic, E. T. Hauser, L. J. Zoghbi, R. Baloh, and R. Hoffer. Intra. Departments of Diagnostic Radiology, Neurology, and Psychiatry, Yale University School of Medicine, New Haven, CT, 06510-USA.

Our previous studies have utilized SPECT to demonstrate decreased [123I]-I-B-CIT striatal uptake in idiopathic Parkinson disease patients (PD). The present study extends this preliminary work by examining: 1) the test-retest reproducibility of two SPECT measures (ratio specific striatal uptake/non-specific uptake (V[S]/V[NS]) and striatal uptake expressed as the percentage of injected dose) in healthy subjects and, 2) striatal binding using these measures in PD patients of varying disease severity.

Methods: For the test-retest reproducibility study 7 healthy subjects (age range 19-74) had SPECT brain scans at 18, 21, and 24 hours following the first scan, at a random injection of 10 mCi [123I]-I-B-CIT. Repeat SPECT scans were performed 7-14 days following the first examination. For the PD severity study, a total of 26 idiopathic PD patients (age range 41-78, Hoehn-Yahr stages 1-5) had SPECT scans at 18, 21, and 24 hours after i.v. injection of 10 mCi of [123I]-I-B-CIT. The two measures were age-corrected based on our healthy control population and correlated with Hoehn-Yahr and total Unified Parkinson's Disease Rating Scale (UPDRS) scores of the patients.

Results: The healthy subject study demonstrated excellent test-retest reproducibility of both outcome measures with a mean 6.8 and 6.7% differences in V[S]/V[NS] and percent striatal uptake, respectively. In the PD study binding abnormality was correlated with both Hoehn-Yahr ratings and total UPDRS score for striatal V[S]/V[NS] (r=0.354 p=0.0016 and r=0.408 p=0.0004, respectively) and percent striatal uptake (r=0.33 p=0.0081 and r=0.469 p=0.001, respectively). These data suggest both [123I]-I-B-CIT SPECT outcome measures have a high degree of within-subject reproducibility and are strongly correlated with disease severity in idiopathic PD.

[123I]-I-B-CIT (2-carboxyhexyl-3-4-(iodo-phenyl)propy) binds dopamine (DA) transporter sites with high affinity and may assess DA-related behavioral function better than the tritium-labeled I-B-CIT SPECT studies, 18 hours after [123I]-I-B-CIT administration in African green monkeys, correlated with anatomical regional averages of positronem DA concentrations ([123I]-I-B-CIT SPECT) and with a detailed study of parkinsonian patients ([8-13]-I-B-CIT SPECT).

We obtained SPECT scans 18 hours after [123I]-I-B-CIT SPECT administration in African green monkeys before and after they received intrasural grafts of fetal mesencephalic tissue. Percent of administered [123I]-I-B-CIT dose was determined in a region of interest including the striatum and a circumferential background region.

Developing grafts were identified by 1% [123I]-I-B-CIT SPECT in vivo and confirmed by autoradiography and tissue histological immunochemistry. Over a 7 month period, mean changes in per cent administered [123I]-I-B-CIT dose in 4 untreated normals and in 4 normal monkeys (4 graft treated) [123I]-I-B-CIT depleted monkeys were significant. Four graft-treated monkeys with histologically confirmed grafts showed mean increases of 70% ± 22 SD. The largest increases corresponded with histological evidence of the most robust grafts. I-B-CIT-depleted monkeys were non-significant. Four graft treated monkeys with histologically confirmed grafts showed mean increases of 70% ± 22 SD. The largest increases corresponded with histological evidence of the most robust grafts. I-B-CIT-depleted monkeys were non-significant. Four graft treated monkeys with histologically confirmed grafts showed mean increases of 70% ± 22 SD. The largest increases corresponded with histological evidence of the most robust grafts. I-B-CIT-depleted monkeys were non-significant. Four graft treated monkeys with histologically confirmed grafts showed mean increases of 70% ± 22 SD. The largest increases corresponded with histological evidence of the most robust grafts. I-B-CIT-depleted monkeys were non-significant. The discovery that a methyl-1,4-phenol 1,2,3,6-tetrahydropyridine suggests that endogenous and xenogenous neurotoxins may cause cell death of dopaminergic neurons in the substantia nigra and thus induce in the Parkinson's disease in humans. As neurotoxin candidates, dopamine-derived 6,7-dihydroxy-1,2,3,6-tetrahydroisoquinolines (DHTIQs) have been examined on their effects on dopaminergic neurons. Out of DHTIQs, 1-methyl-DHTIQ (M-DHTIQ) is methylated to 1,2,3-(3,4-dihydropyridine, primer of which is taken to be involved in 1,2,3,6-dihydroxyisoquinolinium ion (1,2-DimDMHetO*). 1-MeDHTIQ and its derivatives were injected into the striatum of male Sprague-Dawley rat, and the biochemical, behavioral, and pathological changes were examined. Both (R) and (S)enantiomer of 1-MeDHTIQ and 1/S(2)-DimDMO* did not induce any behavioral change by a single administration. 1R(2)-DMO* induced electrophysiological changes to the rat: akinesis, bradykinesia, postural abnormality and rigidity were detected. The behavioral changes were transient; they disappeared several hours after the injection. Three day after the injection, the rat was sacrificed and DHTIQ derivatives and monoamines were analyzed by HPLC-electrochemical and fluorometric detection. Biochemical analysis showed that 1R(2)-DiMeDHTIQ was detected in the striatum, and larger amount of the oxidized product, 1,2-DimMO* was identified in the substantia nigra in addition to the striatum. Dopamine, noradrenaline, as their metabolites were found to be reduced in the striatum and the substantia nigra. The injection of 1R(2)-DiMeDHTIQ induced massive necrosis in the rat brain. Using a human dopaminergic neuraloblastoma SH-SYSY cells, only 1R(2)-DMO* was confirmed to be taken up to the cells by dopamine transporter, which is a high-affinity DHTIQ derivative. These results suggest that 1R(2)-DmDMO* may be neurotoxic to dopaminergic neurons.

NICOTINE PREVENTS EXPERIMENTAL PARKINSONISM IN RODENTS F. Vaglini, F. Facetti, F. Fontana1, R. Maggio, G.U. Corini Instituto of Pharmacology, School of Medicine, University of Pavia, ITALY

We have demonstrated that diethylthiodicarboxamate (DCC) enhances MPTP toxicity in mice. This combined treatment induces a more marked depletion of striatal dopamine (DA) and a severe loss of tyrosine hydroxylase (TH) positive perikarya in Substantia Nigra pars compacta (SNpc) (Corsitwi et al., Eur. J. Pharmacol.,119,127; 1985). This represents a reliable model of experimental parkinsonism in rodents on which neuroprotective molecules can be evaluated. For instance, it is now well established that non-competitive NMDA antagonists (MK-801, dextromethorphan) provide a complete protection on DDC enhancement of MPTP toxicity.

In the present study we used this model in order to evaluate the effect of nicotine, on experimental parkinsonism. (-) Nicotine (1mg/Kg, s.c.) administered three times (90 and 30 min before and 30 min after MPTP), completely prevented both the marked depletion of striatal dopamine and the severe loss of TH positive perikarya in SNpc induced by DCC+MPTP. Nicotine provided this protective effect without reducing striatal MPP+ levels measured at several time intervals after MPTP administration.

Despite previous contrasting findings, our data suggest that nicotine could be responsible of the reduced prevalence of Parkinson's disease among smokers.

602.9
ELEVATION OF NEURONAL MAO-B ACTIVITY IN A TRANSGENIC MOUSE MODEL DOES NOT INCREASE SENSITIVITY TO THE NEUROTOXIN MPTP.

J.K. Anderson1, D.M. Trim, O. Issacson, M.F. Beal, and X.O. Breikfield, Neurology Service and Neurosurgery Service, Massachusetts Hospital, Charlestown, MA, Harvard Medical School, Boston, MA, and Neuroregeneration Laboratory, McLean Hospital, Belmont, MA

To examine whether expressing high levels of monoamine oxidase (MAO-B) activity abnormally in neurons results in increased sensitivity of dopaminergic neurons to the neurotoxin 1-methyl-4-phenol-1,2,3,6-tetrahydropyridine (MPTP), 8 week old transgenic mice expressing high neuronal levels of MAO-B were compared with age-matched nontransgenic littermates following i.p. injections of 30 mg/kg body weight of the protoxin. Levels of striatal dopamine (DA) and its metabolite 3,4 dihydroxyphenylacetic acid (DOPAC), as well as tyrosine hydroxylase (TH)- immunopositive cell number in the substantia nigra (SN) were compared 1 week later between transgenics and controls. No difference was found in any of these parameters, indicating that high neuronal MAO-B levels does not cause increased sensitivity to MPTP, and therefore neither conversion of MPTP to its active form, 1-methyl-4-phenyl pyridinium (MPP+) by MAO-B nor MPP+ uptake by the dopaminergic transporter are likely to be the rate-limiting step in the toxicity of this compound.

AAV-MEDIATED TRANSFER OF TYROSINE HYDROXYLASE AND AROMATIC AMINO ACID DECARBOXYLASE GENES INTO THE PRIMATE BRAIN: A DIRECT GENE THERAPY APPROACH TO PARKINSON'S DISEASE

M.J. Durairaj1, R.G. Kaplan Jr., P. Leone, C. Xiao, J.D. Elworth, H.R. Roth2, R. Shakin1, D.P. Redmond1, R.K. O'Malley, R. Vaglini, 1 Yale Univ Sch Med, New Haven, CT 06520; 2Rockefeller Univ, New York, NY 10021; 3Vahab Univ Sch Med, St Louis, MO 63110; 4UNC, Chapel Hill, NC 27599; 5Univ Hlth Sci/Chicago Med Sch, Chicago, IL 60604

AAV is a defective human parvovirus which has several major advantages for gene transfer in the CNS including non-pathogenicity, targeted integration and stable expression in post-mitotic cells including neurons (Kapliit et al., Soc. Neurosci. Abstr., 1994). Moreover, AAV vectors are devoid of viral genes and a novel packaging method to generate helper-free stocks is established. This vector system may have application therefore for gene therapy of neurological disorders. The human tyrosine hydroxylase (form ID) cDNA was truncated to 1.1 kb by deletion of the N-terminal regulatory region and a FLAG epitope added (FLAG-THA). FLAG-THA together with the human aromatic amino acid decarboxylase gene was packaged into AAV using the rnc virus IRES sequence to form a bicistronic construct (AAVhTHA/IRESc). AAVhTHA/IRESc transduced Hek 293 cell cultures released dopamine into the medium at high concentrations (3.1±10-10 cell-1 min-1). AAVhTHA/IRESc was stereotactically injected into the partially denervated caudate of MPTP-treated African green monkeys. 10 days following injection, two animals were sacrificed and expression of the vector encoded TH was determined using a FLA antibody. FLAG-IR neurons were observed around the injection sites. These data suggest that AAV can transduce neurons in the primate brain in vivo. If dopamine release can be increased by this strategy AAVhTHA/IRESc may have utility as a direct gene therapy approach to Parkinson's disease.

603.1 DEVELOPMENTALLY SPECIFIC RNA EDITING IN AMPA RECEPTOR SUBUNITS GluR-B, -C, -D, H. Lomeli1, T. Melcher1, T. Higaki2, A. Bach2, G. Kehr3, M. Higuchi3, B. Spranger3, H. Monyer1 and P.H. Seeburg1Center for Molecular Biology (ZMBH), University of Heidelberg, and BASF Inc., Tübingen, Germany

In glutamate-operated receptor channels of the non-NMDA type in cerebral cortex, several functionally critical channel residues not encoded by the genes for the channel subunits are introduced via nuclear RNA editing. This process operates on the preexisting sense transcripts to substitute glycine residues for arginine residues in guanosines. Positional selectivity and efficiency of RNA-editing appear to rest on a double-stranded RNA structure formed by the to-be-edited complementary sequence and a complementary sequence in the proximal intron [Higuchi et al., Cell 52, 1361; 1993]. Detailed cdNA analysis has now revealed that AMPA receptor subunits GluR-B, -C and -D share a position either occupied by arginine (gene-encoded) or by glycine, the latter residue being introduced by site specific adenosine to guanosine RNA editing. As for the GlR-B site editing of GluR-B, editing at this newly-identified site is mediated by an intrinsic sequence element present in the GluR-B, -C, and -D genes but is absent in the Glur-A gene. A PCR-supported analysis in brains of staged rats showed that RNA editing at the new site progresses in extent from approximately 10% at E14 to >80% by P12. Furthermore, single-cell PCR analysis showed that subunits expressed in one cell can be edited to different degrees.

603.3 REGULATION OF N-METHYL-D-ASPARTATE RECEPTOR SUBUNITS EXPRESSION IN CEREBRAL NEURONS. B. Lambrolakis, B. Audsitan, S. Chartaj, J. Russet1 and F. Citcele1, IAF CNRS, 19198 Gif/Yvette, France; Lab. Neurobio, CNRS URA 1507, Paris, France and Ips, Physiol., 12,14 Genève 4, Switzerland.

The N-methyl-D-aspartate (NMDA) subtype of glutamate receptors is an oligomer formed of different subunits named NR1 and NR2A, NR2B, C and D the combination of which determines the functional properties. We have used rat cerebral slice cultures to study the involvement of spontaneous activity and extracellular inputs on changes of NR2A-C expression observed during the postnatal development of granule and Purkinje cells. The functional properties of the NMDA receptors formed by A-C mRNAs were correlated in single neurons by coupling patch-clamp recording and reverse transcription followed by PCR. Granule cells grown in standard culture conditions expressed mainly NR2A mRNAs when examined after 15 to 40 days in vitro. Consistent with this observation, their responses to NMDA were poorly induced by 5 mM tetrodotoxin, a non-competitive antagonist which discriminates NR2A and NR2B subunits in expression systems. The NR2C subunit, abundantly expressed in vivo by adult granule cells, was only rarely detected in slice cultures even when excitatory synapses were formed between granule cells and mossy fibers originating from co-cultured brainstem explants. In cerebellar cultures which had been chronically exposed to 300 microM glutamate during 15 to 35 days in vitro to reduce spontaneous activity, granule cells expressed predominantly NR2B subunits (as it is the case only during the first two postnatal weeks in vivo) and their responses to NMDA were largely inhibited by 3 mM tetrodotoxin. These results provide evidence that the expression of NR2A and B subunits is regulated through an activity-dependent mechanism leading to the formation of NMDA receptors with different pharmacological properties. Finally, in none of the experimental conditions described above, we could detect any NR2 subunit in Purkinje cells, although NR1 was constantly expressed. This was in agreement with the absence of NRD responses.

603.5 GENERATION OF ANTIBODIES SPECIFIC FOR PHOSPHORYLATED NMDA RECEPTORS. W.G. Tingley and R.L. Huganir*. Department of Neuroscience, H.H.M.I., Johns Hopkins University School of Medicine, Baltimore, MD 21205.

A variety of neuronal processes, including synaptic plasticity, synaptic gene expression, and excitotoxic neuronal damage, involve N-methyl-D-aspartate (NMDA) receptors. NMDA receptors in the brain are thought to be composed of multiple subunits, including at least one NR1 subunit and one or more NR2 subunits. A variety of studies have suggested that NMDA receptors are regulated by protein phosphorylation. We have shown recently that protein kinase C (PKC) directly phosphorylates NR1 near its C-terminus, in a region regulated by alternative splicing. For this study, we have generated multiple anti-phosphoepitope antibodies recognizing the NR1 protein only when it is phosphorylated. Immunocytochemical and immunoblot experiments with these antibodies indicate that CAMP-dependent protein kinase A (PKA), like PKC, phosphorylates NR1 near its C-terminus. However, PKA and PKC phosphorylate different serine residues within this region. In addition, phosphorylation in this region appears to regulate the subcellular distribution of NR1 protein expressed in HEK-293 cells. These antibodies should prove useful for monitoring the phosphorylation state of NMDA receptors in vivo, including the induction and maintenance of LTP in the hippocampus.

603.6 BIOCHEMICAL AND TOPOLOGICAL ANALYSIS OF THE NMDA RECEPTOR. Andreas K.E., Köhle, Silvia Correa, Sabine Sydow, Ines Bors and Joachim Spira *, Max Planck Institute for Experimental Medicine, Molecular Neuroendocrinology, Heinitz-Rein-Str. 3, 37075 Göttingen, Germany

We are interested in the structure/function relationship of the NMDA receptor that is thought to be important in learning, memory and several neurological disorders. We want to analyze the properties of distinct subunit compositions by biochemical and electrophysiological techniques in a defined artificial system.

Fourteen regio specific antibodies have been produced to characterize the NMDA receptor subunits NR1, NR2A and NR2C. Eighteen cell lines expressing single NMDA receptor subunits (NR1, NR1B, NR2A and NR2C) or subunit combinations (NR1A/B, NR2A/B, NR2C/D, NR2D/D) were generated.

The double transfected cell lines showed distinct morphologies and were sensitive to high concentrations of glycine and NMDA. In the presence of the NMDA receptor antagonists, eight cell lines showed a strong upregulation when the NR2 protein was present, whereas the NR2 protein amount was similar in the presence or absence of NMDA in this defined artificial system, in which standard proliferation is achieved by a combination of low serum and high glucose. These findings could be explained by an increased degradation of subunits or a translational regulation of NR2 protein expression.

The transmembrane topology of the NR2C subunit was investigated with antibodies specific for the N-term (NR2C250) and C-term (NR2C548) epitopes. NR2C250 was detected on the surface of the NR2C1 or NR2C2-transfected HEK293 cells. Anti NR2C-D stained the NR2C subunit only in punctated or stunted parasitized cells. These results are direct experimental evidence that the four transmembrane domain model suggested first for the cloning of the cholinergic muscarinic receptor models suggesting a cytosolic localization of the entire C-terminal domain are not in agreement with these results.

Another approach for the direct protein chemical characterization of the NR1b subunit is based on its overexpression in the baculovirus system. December the recombinant protein is probably present in inclusion bodies and found at a concentration of approximately 1 mg per liter of culture medium.

Mol Neurobiol., Lab., Salk Institute, La Jolla, CA 92037.

The transmembrane domain (TMD) topology of glutamate receptors (GluRs) is incompletely understood. Although GluRs are commonly modeled after the nicotinic acetylcholine receptor (nAChR), no direct evidence is available for the presumed 2TMD plus 4TMD model with four transmembrane (TMD) and an intracellular-forming TMD II, and even the assignment of the four hydrophobic domains to TMDs is made in different ways (see Hollmann & Heinemann, Anita. Rev. Neurosci. 1994.17:31-108).

We set out to obtain experimental evidence for extracellular or intracellular localization of the various domains of the GluR1 protein expressed in Xenopus oocytes. We used site-directed mutagenesis to introduce N-glycosylation sites (N-X-S or N-X-T) in C-terminal positions throughout the receptor protein. N-glycosylation sites were created in the N-terminal and C-terminal domains as well as in those domains located in between hypothetical TMDs. Mutant GluR1 proteins expressed by Xenopus oocytes were analyzed in SDS gel shift assays, for an increase in apparent molecular weight caused by the attachment of carbohydrate side chains. GluR1 was visualized on Western blots of SDS gels using polyclonal anti-GluR1 antisera (kindly provided by Bob Wenthold and Richard Huganir). Upward shifts of mutant receptors vs. wild type receptor were interpreted as evidence for the extracellular or intracellular localization of the introduced N-glycosylation site.

The results of the gel shift assays demonstrate that the N-terminus of GluR1 is indeed extracellular as assumed in all models proposed to date, while the C-terminal is intracellular. Our data also indicate that the domain between TMD III and TMD IV, which generally was assumed to constitute a large intracellular loop, is actually extracellular. The topology in between TMD I and TMD III is currently under investigation.

IDENTIFICATION OF A CAM-KINASE II REGULATORY PHOSPHORYLATION SITE IN NON-NDMA GLUTAMATE RECEIVERS.
Vollum Institute, OHSU, Portland, OR 97207.

Glutamate receptor (GluR) ion channels are localized in postsynaptic densities with CamKII, an enzyme which has been previously shown to phosphorylate and stabilize the non-NDMA ion currents in cultured rat hippocampal neurons (McGlade-McCulloh et al., 1990, Nature 362:640). We wanted to extend these findings by demonstrating the regulatory effect of CamKII on expressed non-NDMA (i.e., AMPA-type) GluRs, and to identify the regulatory site phosphorylated by CamKII. In this study, the intracellular application of activated CamKII produced an increased sensitivity to kainate in both recombinant oocytes expressing GluR1 and in Xenopus oocytes expressing GluR1 enhanced the GluR current activated by kainate. This effect of CamKII on GluR1 was further investigated in the Xenopus oocyte/GluR1 system which gave a 1.9-fold increase in kainate current with no effect on the sensitivity of the receptor to kainate. When Ser672, which is located in the major intracellular loop of GluR1, was mutated to Ala, the expressed mutant no longer responded to the CamKII-induced enhancement of kainate current but was normal with respect to current-voltage relationship and kainate sensitivity. Since all non-NDMA GluR ion channels have a Ser in an analogous position, this regulatory phosphorylation site may be of general importance in enhancing post synaptic responsiveness as occurs in long-term potentiation.

IBOTENIC ACID ACTIVATES A CA2+ MODULATED CHANNEL IN CERESELLAR P Purkinje NEURONS.

Ibotenic acid acts as an ionotropic (NDMA and nonNDMA) and metabotropic excitatory amino acid agonist in vertebrate brain. In mouse cultured Purkinje neurons, cells which do not express NDMA, ibotenic acid produced relatively small inward currents at negative membrane potentials compared to AMPA and kainate. In whole cell recordings, ibotenate-activated currents were observed to increase in magnitude when the extracellular Ca2+ was increased from 1 to 10 mM, suggesting that these channels are modulated by Ca2+ ions. To determine which of the non-NDMA channels might underlie this effect, the changes in Ca2+ levels were monitored on ibotenate-activated single channel currents. The currents were examined in outside-out patches from Purkinje neurons. Recording pipettes typically contained 140 mM NaC1, 4 mM ATP-Mg, 10 mM Hepes-Na (pH 7.2) and 2 mM EGTA/1 mM CaC12, but occasionally 2 mM BAPTA/1 mM CaC12 in the inside-out solution (100 mM NaC1, 2.8 mM KCl, 10 mM Hepes-Na (pH 7.2)), ibotenate opened channels with conductances of 20-30 pS, with a reversed potential near 50 mV. Of these, 30 pS channel observed in more than 90% of patches from Purkinje cells, was studied in different Ca2+ levels from 1 mM to between 5 and 110 mM while substituting for Na+. In 5 mM CaC12 (the open probability (Po) of ibotenate channels increased 1.5-2 fold. Changing from 1 to 110 mM CaC12 (150 mM NaC1 to 0 Na+), Po increased 6 fold at -60 mV with relatively little change in channel conductance, the result being between a 3.5 and 5.5-fold increase in the net flux in the N direction. In time-averaged single channel recordings the mean current at -60 mV approximately doubled by increasing Ca2+ from 1 to 10 mM, similar result was obtained in whole cell recordings. These observations were made by increasing Ca2+ and, however, the possibility remains that the increase in Po is due to an increase in Ca2+.

HETEROERIC OLFACTORY CYCLIC NUCLEOTIDE-GATED CHANNELS: A NEW SUBUNIT THAT CONCOLORS INCREASED SENSITIVITY TO CAMP, J.L. Bradley, N. Davidson, H. Lester & K. Zyu.
Division of Biology, California Institute of Technology, Pasadena, CA 91125.

One mechanism of olfactory signal transduction involves the opening of cyclic nucleotide-gated (cng) channels. Cng channels in rat olfactory neurons are activated by cAMP in the low pM range and are outwardly rectifying. The previously cloned cng channel (ICOCN1), however, shows much lower cAMP sensitivity and very weak rectification when expressed in 293 cells. We have cloned another cng channel from rat olfactory epithelium cDNA library, ICOCN2 encodes a protein of 575 amino acids with 51% identity to ICOCN1. ICOCN2 does not form homomultimers when expressed alone. When ICOCN2 is coexpressed with ICOCN1, however, the resulting conductance is characterized by an outward rectification stronger than that observed with ICOCN1. By a CAMP sensitivity close to that of the native olfactory cng channel. ICOCN2 is expressed with ICOCN1, however, the resulting conductance is characterized by an outward rectification stronger than that observed with ICOCN1. In divalent-free conditions, the ICOCN1 channel is not fully activated by cAMP, suggesting that the native olfactory cng channel is a heteroneric channel. In the presence of cAMP, ICOCN2 blocks the inward current at ICOCN1 channels more strongly than at ICOCN1/ICOCN2. In divalent-free conditions of ICOCN1 channels are uninterrupted for tens of ms, while those of ICOCN1/ICOCN2 channels are flaky, especially at negative membrane potentials. This flaky behavior resembles the native channel. In all hybridizing, demonstrates that the two subunits are coexpressed in olfactory receptor neurons. These results indicate that the native olfactory cng channel is a heteroneric channel, and that the overall properties of olfactory channels are structurally and functionally analogous to those in rod photoreceptors.

ODORANT INDUCED PHOSPHORYLATION OF INOSITOL 1,4,5-TRIPHOSPHATE RECEPTOR IN Olfactory RECEPTOR NEURONS, J.L. Fujimoto,
John Hopkins University School of Medicine, Department of Neuroscience, Baltimore, MD 21205.

Both the cyclic adenosine 3',5'-monophosphate and cyclic guanosine 3',5'-monophosphate pathways are involved in olfactory signal transduction, which occurs in the cilia of olfactory receptor neurons. In olfactory receptor neuron, inositol 1,4,5-triphosphate (IP3) receptor is located at the surface plasma membrane of olfactory cilia and play roles in regulating calcium flux and the surface membranes. To explore its involvement in odorant signal transduction, the phosphorylation properties of IP3 receptor were studied in cultured olfactory sensory neurons. Odorant remarkably enhanced IP3 receptor phosphorylation with the peak at 2 minutes after stimulation. Further exposure of odorants induces dephosphorylation to the IP3 receptor levels. This result indicates the modification of IP3 receptor function in the late phase of odorant signal transduction. Dose-response curve revealed the maximal odorant effect at the concentration of 100 mM. These results may provide a mechanism whereby desensitization occurs in odorant perception.

ELECTROPHYSIOLOGICAL PROPERTIES OF LIGAND-GATED ATP RECEPTOR IN RAT AUTONOMIC NEURONES AND VAS DEFERENS SMOOTH MUSCLE. A. Sarparsv, B. Khabs and C. Memit.
Galo Institute for Molecular Biology, Geneva, Switzerland, 1228.

P2X purinoceptors exist in autonomic neurons and many vascular and visceral smooth muscle where they can mediate fast synaptic transduction by activating a cationic receptor-channel complex. We used whole-cell recording techniques to compare properties of this receptor in rat nodose and SCG neurons as well as in isolated rat vas deferens smooth muscle. Fast-flow application (0.5-2 s duration) of ATP, 0.1mM ATP and 2mM ATP evoked rapid inward currents in all cells; marked desensitization of the inward currents was observed in smooth muscle but not in neurons. Calcium permeability was significant in vas deferens and nodose neurons (PCaPNa = 5) but minimal in SCG neurons. Inward rectification of the current was observed in all cells but was most pronounced in vas deferens and SCG. In all neurons, agonist was 2mM ATP > ATP > 0.1mM ATP. Half-maximal effective concentration (EC50) of ATP was about 1 µM for vas deferens and vas but 40 µM for SCG. 0.1mM ATP was a full agonist in smooth muscle but acted as a partial agonist in SCG. Properties of the ATP response in nodose and vas deferens were very similar those observed for the P2 receptor recently cloned from rat vas deferens (Valera et al., this meeting). The different pharmacological and physiological properties of the ATP response in SCG neurons suggests the presence of a distinct receptor subtype.
604.3

The aims of the present investigation were to provide evidence that in rat and guinea-pig cerebral cortical slices, \(\Delta^2\)Herotonin (\(\Delta^2\)H-T) release can be stimulated via glutamate receptors of the NMDA and non-NMDA type and that this release is modulated via presynaptic auto- and heteroreceptors. The slices were preincubated with \(\Delta^2\)H-T in the presence of mepiparte (in order to avoid false labeling of noradrenergic neurones) and superfused with Krebs' solution (Mg^2+ free in the experiments with NMDA). NMDA (0.1-1 mM) stimulated the overflow of \(\Delta^2\)H-T from slices of both species in a manner sensitive to blockade by 0.3 mM tetrodotoxin (TTX). 1.2 mM Mg^2+ (DL-\(\Delta^2\)-aminooxy-4-methyl-5-phosphono-3-pentanoic acid; a competitive NMDA receptor antagonist), 100 mM dicyclophone, 10-100 mM 5,7-dichlorokynurenic acid, 100-300 mM amphetamine and 0.1-0.1 mM (l)-propranolol (0.1-0.1 mM) also stimulated \(\Delta^2\)H-T overflow. The KA4-evoked overflow in the presence of 1.2 mM Mg^2+ was not affected by CGP 37849 and aracene, but was inhibited by 0.3 mM TTX and 100 mM CGP 37849 (6-cyano-7-nitroquinoxaline-2,3-dione; an antagonist of non-NMDA receptors). 5-Carboxamidotryptamine (1-100 mM; a 5-HT receptor agonist) and acetylcholine (1 and 10 mM) inhibited the NMDA-evoked overflow; these responses were antagonised by the 5-HT receptor antagonist methysergide and the 5-HT receptor antagonist idazoxan, respectively, which gave alone facilitated \(\Delta^2\)H-T overflow.

The experiments were performed using whole-cell techniques and the results presented are mean values ± S.E.M.

604.1

Autophosphorylation of nonadrenaline release from cholinergic sympathetic neurons depends on \(\alpha\)-adrenergic inhibition of \(N\)-type calcium channels by pertussis toxin-sensitive \(G_{i/o}\) proteins. The present study investigates the signalling cascade between the \(\alpha\)-adrenergic stimulus and the release of noradrenaline.

A role of protein kinase C (PKC) in neurotransmitter modulation of calcium channels is generally indicated by in vitro experiments using analogues of phorbol esters or dicyclophosphate analogues. However, neither 4-phorbol-12,13-dibutyrate (PDB, 3\(\mu\)M) nor 4-phenacylbutyryl [Gly-Val-Glu(\(\alpha\)-Me)-Val-Lys(D emailing)-Arg(Drinking)-Phe-D-Pro-Val] [PDB (10\(\mu\)M) affected whole-cell calcium currents (ICa). Nevertheless, inclusion of a pseudophorbol peptide inhibitor of PKC (PCK 10\(\mu\)M, 100\(\mu\)M) in the pipette progressively reduced the inhibitory action of the \(\alpha\)-adrenergic agonist brevamine (10\(\mu\)M) upon ICa. When neurons were dialysed with PCK for 10 min, brevamine inhibition was 63% (24% to 96% control) in the absence of PCK and 58% (10% to 90% control) in the presence of 10\(\mu\)M PCK. These results revealed the involvement of a pseudophorbol peptide of PKC in the modulation of brevamine inhibition. In conclusion, the present results suggest an involvement of a pseudophorbol peptide of PKC in the modulation of brevamine inhibition. These results suggest that a pseudophorbol peptide of PKC may be involved in the modulation of brevamine inhibition.
CALCIUM CHANNEL MODULATION BY LECTINS. A. Golard*1, Howard Hughes Medical Institute, Dept. of Physiol. & Phrenology, Univ. of Washington, Seattle, WA 98195

Calcium currents were measured in dissociated chick sympathetic ganglia using the whole cell patch clamp technique. Lectins (1 μg) were applied to the local superfusion. All lectins tested reversibly inhibited Ca currents. Two types of inhibition were observed: a speeding of inactivation (SI) and a voltage-dependent inhibition (VDI) with slowing of the activation kinetics. When GTP-γ-S is substituted for GTP, VDI is abolished, while SI is still reversible. GDP-β-S largely suppresses VDI, but has little effect on SI. These results indicate that G-proteins are involved in VDI, not SI. Thus, VDI may be due to activation of G-protein-coupled receptors, while SI may be a direct effect on the channel. Lectins with high affinities for N-acetylglycosamine or α-D-glucose preferentially induce VDI, while lectins with α-D-galactose affinity produce SI. Differential effects of concanavalin-A and sucrose-con-A indicate that SI may be due to capping.

MODE SHIFT OF N-TYPE CA\(^{2+}\) CHANNEL BY THE AUXILIARY SUBUNITS \(\alpha_2\) AND \(\beta\) Minou Wakanomat* and Yasuo Mor*. Dept. of Pharmacol. and Cell Biophys., Univ. of Cinti., Cinti, OH 45267-0575

\(\omega\)-Conotoxin-GVIA-sensitive N-type channels are inhibited by various neurotransmitters. Modulation is predominantly mediated by L-\(\omega\)-proteins which alter equilibrium among diverse functional behaviors. To gain a clear structural insight into functional diversity of N-type channels, we have investigated the influence of recombinitant N-type channels composed of various combinations of the pore-forming subunit \(\alpha\) (BIII) and the two additional subunits, \(\alpha_2\) and \(\beta\), in Xenopus expression systems in 40 mM Ba\(^{2+}\) showed that the BIII \(\alpha\) subunit alone elicited \(\omega\)-conotoxin-sensitive HVA Ba\(^{2+}\) current, with a time-to-peak (\(t_p\)) and decay time constant (\(\tau_d\)) of 16 and 215 ms, respectively, at +20 mV. Modulation of the BIII channel kinetics by \(\alpha_2\) subunits was strikingly different from that observed for the L-type channels, i.e., both \(t_p\) and \(\tau_d\) are increased in BIII (21 and 477 ms) but decreased in L-type. The \(\beta\) subunits shifted the current-voltage relationship in a hyperpolarizing direction by 8 mV as was observed for the L-type channels. Surprisingly, the effects of the \(\alpha_2\) subunit contrasted with and antagonized the effects of the \(\beta\) subunits (\(t_p=9, \tau_d=144\) ms for BIII+\(\alpha_2\); \(t_p=10, \tau_d=248\) ms for L-BIII+\(\beta\)). Single channel analysis revealed different patterns of opening for BIII, BIII+\(\alpha_2\), BIII+\(\beta\), and BIII+\(\alpha_2+\beta\), suggesting that different subunit combinations of calcium channel complexes give rise to different modes of gating dependent upon the association/disassociation of the subunits.

DEVELOPMENT OF DIRECTIONAL SELECTIVITY IN TURTLE RETINA: PHYSIOLOGY AND MODEL. N. M. Grywacz* and E. Sherman, South-Kentwell Inst., 2232 Webster St., San Francisco, CA 94115

Directional selectivity requires a spatially asymmetric mechanism to mediate the larger responses to preferred- than to null-direction motions. What developmental processes mediate the breaking of symmetry in the retina? To study this development, we recorded extracellularly from turtle retinal ganglion cells during embryogenesis (Stages 22-26), the first 40 days post-hatching, and in adults. In particular, responses were made of the Staggers, a bursting burst of spikes in immature retinas and of the responses to edges of light moving in sixteen directions. The bursts occurred during Stage 22 until 2-4 weeks post-hatching. Light responses began at Stage 23, and early on, polar plots of the responses to motion were highly anisotropic, including orientation and directional selectivity. However, orientation selectivity reached a peak at incidence at hatching, while directional selectivity disappeared only to reappear in adults (after 40 days post-hatching). Receptive-field sizes and the incidence of isotropic cells stabilized 2-4 weeks post-hatching.

We built and trained computer simulations of a model system to account for the development of directional selectivity. In this model, the early anisotropy of the retina reflects immature, polarized dendritic layout, with directional selectivity being incidental to the dendrite's cable properties. As dendritic processes grow and branch, embryonic dendritic selectivity disappears, but orientation selectivity is maintained by a Hебbian process, which reinforces some of the early anisotropy. Later in development, the emergence of a specialized inhibitory synapse onto the dendritic inputs to some orientationally selective cells, transfers them onto weak directionally selective cells, which are then reinforced by a Hebbian process.

In conclusion, in increases in dimension of dendrites, their degree of polarization, and the spontaneous burst of spikes do not appear to account directly for the development of directional selectivity. Rather, it seems to require visual experience and/or the last stage of development of a specialized inhibitory synaptic drive.

AXONAL BRANCH DYNAMICS: AN IN VITRO EXAMINATION OF THE APPLICATION OF HEBB'S HYPOTHESIS TO AXON MORPHOLOGY. S. Wint* and H.T. Cline, Dept. of Physiology, University of Iowa, Iowa City, IA and Cold Spring Harbor Labs, Cold Spring Harbor, NY.

We sought to examine the possibility that there is a structural correlate to Hebb's hypothesis. A high degree of dynamism, or addition and retraction of branches, occurs in retinorecipient axons in the developing frog retinal ganglion cells (RGCs). When a RGC is first generated by the ventricular progenitor, it soon generates an off-center axon which grows toward the tectal center. If the axon reaches the tectal center, it will branch and rebranch. The branches of these axons will subsequently retract and be replaced with new branches. We used an improved whole-cell patch-clamp technique to record from these axons during development.

We examined the role of NMDA receptor activation (a branch stability) by using APV to block NMDA receptor activation, and the role of neurotransmitter-mediated stimulation in the growth and stabilization of the axons. We found that the axons can be inhibited by muscarinic agonists or glutamate receptor antagonists. We also found that the axons are sensitive to the local environment and that the axons can be stimulated by the introduction of an electrical field. This suggests that the axons are sensitive to their local environment and that the axons can be stimulated by electrical fields.

INHIBITION OF NITRIC OXIDE SYNTHASE DISRUPTS ON/OFF SUBLIMATION IN THE FERRET LATERAL GENICULATE NUCLEUS. K. K. Craner* and M. Sig. Department of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Retinogeniculate axons in the ferret segregate into eye-specific layers during the first two postnatal weeks. Axons from on-center or off-center retinal ganglion cells further segregate into retinotopically ordered groups by four postnatal weeks in a process dependent upon presynaptic NMDA receptors (Hudspeth et al., Nature 351: 568, 1991). During this period, the lateral geniculate nucleus (LGN) of the ferret transiently expresses NADPH-diaphorase, a nitric oxide synthase (Smith et al., Proc. Natl. Acad. Sci. USA. 90: 891, 1993). Nitric oxide may act downstream of the NMDA receptor as a retrograde messenger during hippocampal synaptic plasticity (e.g., Schwartz and Madison, Science 264: 1891, 1994).

To investigate whether nitric oxide has an analogous role in the development of the on/off sublimation, we blocked nitric oxide synthase during the third and fourth postnatal weeks using an agonist that inhibits the enzyme at the arginine binding site. Ferrets received daily intraperitoneal injections of N-nitro-L-arginine methyl ester (D-NAME) and L-NAME. L-NAME treatment resulted in reduced NADPH-diaphorase staining compared to controls or normal ferrets. Retinogeniculate sublimation was assessed using intracranial injections of WGA-HRP at postsynaptic NMDA receptors. The treatment suppressed the development of the on/off sublimation as compared to controls or normal ferrets. These results suggest that nitric oxide is involved in the segregation of retinal afferents into on/off sublimination in the LGN.

RAPID ACQUISITION OF DENDRITIC SPINES BY VISUAL THALAMIC NEURONS AFTER BLOCKADE OF NMDA RECEPTORS. M. Rocha* and M. Sur, Department of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139; and Institute of Biophysics & Neurosciences, Univ. de Sao Paulo, 05508, Brazil.

The NMDA subtype of glutamate receptor plays a critical role in the development of retinogeniculate afferents and postsynaptic target cells in the ferret lateral geniculate nucleus (LGN) (Harsanyi et al., 1991; Rocha and Sur, 1991). Here, we have examined the time course of dendritic changes of LGN cells in vitro after NMDA receptor blockade. Horizontal slices containing LGN somata were obtained from 28 ferret kits between postnatal day 5 (P5) and 45, and maintained alive in a slice chamber. LGN cell dendrites were labeled by DI crystals placed into the LGN, and imaged online employing laser confocal microscopy. Segments of dendrites (n=318) were imaged again after 2 and up to 7 hours of perfusion with control solution, d-APV (50-100 µM), or NMDA (10-100 µM). At P5-6, dendrites often gave rise to short side branches in control and treated slices. Acquisition of dendritic spines occurred after P7 and increased following d-APV perfusion (p<0.05). From P14 to P20, blockade of NMDA receptors resulted in a five-fold net increase in spine acquisition (p<0.001). Changes in spine acquisition declined after P21, and were unaffected by d-APV perfusion. NMDA treatment had no significant effect when compared to control conditions at all ages. Thus, NMDA receptor-regulate dendritic spine acquisition in LGN cells mainly during the third postnatal week, a period when retinogeniculate axons segregate into on and off-center sublaminae. These results may reflect the percentage structural changes in postsynaptic cells contributed to the formation of specific retinogeniculate connections.

POSTNATAL DEVELOPMENT OF NMDA RECEPTOR-MEDIATED, NITRIC OXIDE DEPENDENT RELEASE OF NEUROTANIN IMMUNOSTAINING IN VISUAL CORTEX. S. M. Duda, F. W. Hester*, and M. J. Friedlander, Neurobiology Research Center, Univ. of Alabama at Birmingham, AL 35294 USA.

Depolarization or activation of NMDA receptors in cortical synaptosomes preparation from newborn rat brain causes a calcium dependent release of glutamate and neuropeptide which in the case of NMDA receptor activation requires nitric oxide production (Montague, Gacanico, Wynn and Friedlander, Science, 263, 973-977, 1994). More recently, activation of synaptic potentials in adult cortex requires NMDA receptor activation, although in neurons it is independent of NMDA receptor activation (Harsanyi and Friedlander, Soc. Neurosci. Abstr, 23, 1993). Thus, we evaluated the effect on synaptic NMDA receptor-mediated release of neuropeptiain cortex. Cortical synaptosomes were prepared from guinea pigs at various postnatal ages (0.5, 1, 10, 15, 30, 15, and 70 days, n=3, 60, 60, 60, 60, 60, at each age). Release of endogenous glutamate was measured with a luminometric assay and release of exogenous [3H]neuropeptide was measured with scintillation counting. Synaptosomes were counted using the HEPES buffered saline (PBS) and stimulated with either a 50µM potassium depolarizing stimulus or 100µM NMDA either with or without a 30 minute pre-incubation with the nitric oxide synthase (NOS) blocker, L-Nitro-Arginine. Release were expressed as the percent of available transmitter and normalized to the PBS controls. Calcium-dependent depolarization-induced release of both glutamate and neuropeptine remained constant and independent of NOS activity at all ages. However, NMDA receptor-mediated release of both neurotransmitters did not occur until 10-15 days of age, with glutamate release showing a second increase in response between 30 and 70 days of age. At all ages when NMDA receptor-mediated release occurred, it was completely inhibited by NOS blockade. These results suggest that the NMDA receptor/NOS system is immature in the neonate, in agreement with our neurophysiological studies.

605.8
A CRITICAL PERIOD FOR INDUCTION OF LONG-TERM DEPRESSION IN VISUAL CORTEX IS NEURONTAN INDEPENDENT. S. M. Duda, F. W. Hester*, and M. J. Friedlander, Neurobiology Research Center, Univ. of Alabama at Birmingham, AL 35294 USA.

Activity-dependent weakening of excitatory synaptic transmission has been hypothesized to play a dominant role in the mechanisms that mediate ocular dominance plasticity in the developing visual system. Growing evidence has shown that neuronal activity is critical for various forms of synaptic plasticity, both long-term depression (LTD) and long-term potentiation (LTP). However, it is not clear what role synaptic activity plays in the development of LTD and/or LTP. We have investigated the relationship between synaptic activity and LTD in mature visual cortex. We have shown previously (Duda & Friedlander, Soc. Neurosci. Abstract, 1994) that LTD could be induced in a subset of immature L4 neurons in visual cortical neurons. However our efforts to characterize the developmental expression of this effect have been hampered by the prevalence of IPSP-like hyperpolarizing potentials that contaminate the excitatory postsynaptic potentials (EPSPs); LTD is not induced in neurons exhibiting these hyperpolarizing responses. We have extended our previous findings to include experiments where we have attempted to overcome the effects of this synaptic inhibition. Conventional intracellular recordings were made from layer IV of slices from mature (45 days old) and immature (<8 days old) guinea pig visual cortex and cat (day 1 through adult) striate cortex. In some cases, a mixture of the selective blocker of chloride channels, 4,4-dinitro-2,2-dimino-6-furazinonic acid (DNDS), cesium acetate, and/or bicuculline was included in the electrode. While blockade of inhibition appears to restore the ability to induce LTD in immature animals, it has no effect on the (lack of) induction of LTD in layer IV neurons from adults. These data suggest that while inhibitory synaptic potentials can influence the induction of LTD, their presence does not likely represent a subset of neurons incapable of supporting LTD.

605.9
INDUCTION OF SYNAPTIC POTENTIATION IN NEONATAL VISUAL CORTEX DOES NOT REQUIRE TYPICAL POSTSYNAPTIC TRICHLOROACETIC ACID ACTION POTENTIALS, NMDA RECEPTOR ACTIVATION OR NITRIC OXIDE PRODUCTION. K. Harsanyi* and M. J. Friedlander, Neurobiology Research Center, Univ. of Alabama at Birmingham, AL 35294 USA.

Low frequency pairings of postsynaptic depolarizing pulses with presynaptic activation causes potentiation of postsynaptic potentials (PSPs) in mature visual cortex (Fregnac, Smith, Burke and Friedlander, J. Neurophysiol, 66, 1025-17, 1991). This type of synaptic plasticity is more reliably induced in the neonate (85% of cells vs. 40% of cells - Harsanyi and Friedlander - Soc. Neurosci. Abstr, 27, 24, 1993). In the present study we determined the mechanism underlying the reliable induction of this form of plasticity in the neonate. Intracellular recordings were obtained from supragranular receptive field sites of layer IV neurons in guinea pig visual cortex (from 5 to 60 postnatal days). Low frequency (0.1 Hz) low intensity (<30% threshold) stimuli were applied to cortical layer 6 with intracellular application of depolarizing pulses (~2 mV, 80 ms, 60 per pairings). In the youngest animals (5-28 days), 85% (n=24/46) of such pairings led to synaptic potentiation (>30% above the pre-potential level after 10 minutes if the former pairing). Application of the NMDA receptor blocker, D-APV (100 µM) did not block induction of synaptic potentiation in this age group (n=11/11). The depolarization-inducing synaptic potentials are effective at inducing synaptic potentiation even during action potential blockade by intracellular application of QX 314, the fast sodium current blocker. Application of the nitric oxide synthase (NOS) blocker, L-Nitro-Arginine at 100 µM for 60-120 minutes did not block synaptic potentiation (n=11/14). Thus, LTD, LTP, and synaptic plasticity in vitro are mediated by postsynaptic receptors, without NO production is sufficient to induce potentiation in the neonatal visual cortex.

REDUCED SYNAPTIC PLASTICITY IN VISUAL CORTEX SLICES OF α-CAM-KII KNOCKOUT TRANSGENIC MICE. A. Kidonissi*, A. Silva and M. B. Bear, Department of Neuroscience, Brown University, Providence, RI 02912 and CTR for Learning and Memory, Cold Spring Harbor Lab., Cold Spring Harbor, NY 11724 USA.

Recent work indicates that synaptic plasticity induced in vitro in the superficial layers of visual cortex ocxam camera share remarkably similar mechanisms of induction. Several lines of evidence have implicated calcium-calmodulin kinase II (Cam-KII) in the induction of long-term potentiation (LTP). In previous studies, it was shown that this type of plasticity is induced both by high intensity depolarizing current and by transgenic mouse line that lacks the α-subunit of CAM-KII to address the possible role of Cam-KII in the induction of LTP in the visual cortex. Synaptic responses to stimulation of layer IV were recorded extracellularly in layer III. To induce LTP we used theta burst stimulation (TBS) which previously work has shown to be the most effective method of inducing LTP in the visual cortex. LTP was measured as the increase in field potential amplitude 20 min after TBS. When TBS was applied to slices from wild type animals it resulted in significant potentiation (2.1 ± 0.4%, 34 slices from 6 mice). When TBS was applied to slices from mutants, TBS resulted in little or no potentiation (2.3 ± 1.0%, 44 slices from 7 mice). Furthermore, potentiation of 2% was observed after TBS in 50% of the control cases, 2% LTP was observed in only 5% of the mutant cases.

The dramatically reduced synaptic plasticity in mutant visual cortex to sustain LTP strongly suggests that in the adult neocortex, like in the CA1 region of hippocampus, Cam-KII is crucial for the formation of LTP. Work in progress is aimed at examining (1) if there is a deficit in LTD in the mutant visual cortex, and (2) whether the deficit in LTP applies to the immature as well as the adult visual cortex.
605.11 REGULATION OF LONG-TERM POTENTIATION IN VISUAL CORTEX BY AGE AND VISUAL EXPERIENCE. M.F. Brest and A. Kirkwood, Department of Neuroscience, Psychology and Behavioural Science, Cornell University, Ithaca, NY.

Binocular connections in the visual cortex are modified by sensory experience, but only during a "critical period" of early postnatal life. These modifications may employ mechanisms specific to the visual system, to be distinguished from the long-term synaptic potentiation (LTP) in slices of visual cortex. LTP of synaptic responses in layer III can be reliably elicited by stimulation of the visual cortex of adult animals. However, and we others have found that (in the absence of GABA antagonists) LTP can be induced by white matter (WM) stimulation only in slices prepared from postnatal day (P) 15 rat visual cortex. In the corticocollicular projection has been established. The distribution of D1-labelled corticocollicular axons in the SC was then examined through development.

The corticocollicular axons of neonatally enucleated animals initially extended caudally, past the topographically-generated axons of visual experience. Slices of visual cortex were prepared from 4-5-week-old Sprague-Dawley rats that had been reared either in complete darkness or in a standard lighted environment. Synaptic responses to WM and layer IV stimulation were recorded extracellularly in layer III. In slices from control rats, TBS of the WM had little effect (5.9 ± 3.0% increase in field potential amplitude after 20 min. after conditioning, n = 7 rats), while TBS of layer IV induced substantial LTP (6.6 ± 6.6%, n = 12 rats).

In contrast, slices from dark-reared rats LTP was evoked equally well by TBS of the WM (6.0 ± 3.7% in layer IV; 7.4 ± 4.8% in cells, respectively). The present results indicate that the history of visual experience can be evaluated by a system that allows for the study of the effects of visual deprivation on the development of the visual system. The corticocollicular projection is dependent upon normal visual function.

606.1 NOVEL ENHANCER TRAP MUTANT REVEALS DIVERSITY OF OLFACTORY FUNCTION IN DROPSOPHILA MELANOGASTER. Adrienne E. Dubin*, John Molina, Halsh Razagzari, Brett Ferson & Greg Harris. Brain Imaging Unit, State University of New York at Stony Brook, Stony Brook, NY.

Similarities between olfactory systems in vertebrates and insects suggest that the general rules underlying olfaction are conserved. We have taken a genetic approach to identify genes involved in olfaction in Drosophila. Enhancer trap line HD1 expresses the reporter gene lacZ encoded by a P-element inserted near position 64 in a subset of cells in the antennal gland (the main olfactory organ). HD1 flies have no detectable olfactory defects, however, after excision of the transposon, at least 2 of 6 independent lines revealed a dominant impaired sense of smell to the potent odorant ethyl acetate (EAC) as assessed in a behavioral assay and electroantennogram recordings. The percentage of excision line 15A flies different to EAC in the behavioral assay (17.5%) (mean ± S.D, n = 7) was significantly higher than controls (68.5%) (mean ± S.D, n = 7; p < 0.005). EAC acted at 10-3 dilution for 500 ms from a cotton-plugged puff pipe pipet caused a 4-fold decreased response in control flies (15A (1.75±2.62 mV, n = 13); compared to HD1 (6.9±0.70 mV, n = 17; p<0.005) and another excision line (15B: 7.6±0.5 mV, n = 18; p<0.005). Responses to benzaldehyde, propionate, butanol, isobutanol, acetate, acetic acid were unaffected. The maximum response to EAC was decreased with no change in the EC50. Responses to short aliphatic chain acetates were most affected (compared to controls): 25% (EAC), 41% (PropylAC), 54% (EthylAC), 100% (ButylAC and tert-Butylacetate AC). A molecular analysis of the mutation is underway. Supported by AHA, California Affiliate 92-275 and NSF BNS-9022212.

606.2 HETEROLOGOUS EXPRESSION OF AMILORIDE-SENSITIVE SODIUM CHANNEL SUBUNITs AND AN ALTERNATIVELY SPICED FORM IN TASTE TISSUES. A.J. Li and S.H. Snyder. Dept. of Neurochemistry, Johns Hopkins Medical School, Baltimore, MD 21205.

The transduction of sodium salt taste is mediated by voltage-independent, amiloride-blockable sodium channels (ASCI) in taste cells. Recent molecular cloning studies have revealed that an amiloride-sensitive epithelial sodium channel isolated from rat colon consists of three homologous subunits (α, β and γ) (Catenzela et al Nature 367, 463-494, 1994). Utilizing a polymerase chain reaction and Northern blot analysis, we have identified the presence of all three subunits and an alternatively spliced form of γ subunit of ASC in rat tongue epithelial tissues that contain taste receptor cells. The heterologous expression of α, β and γ subunits in taste tissues appear to be distinct from that in lung and kidney. In lung and kidney, however, the expression levels of β and γ subunits are about same whereas the expression of the α-subunit is the greatest. The expression levels and tissue distribution of the alternatively spliced form of the γ-subunit of ASC are similar to that for the native α-subunit: higher in lung and kidney and lower in taste tissues. Preliminary studies on transfected cells expressing ASC γNAs showed that α and β subunits, but not γ subunits, were able to bind [3H]-phenamil, an amiloride analog. The heterologous co-expression of ASC α-subunits may contribute to tissue specific functions of ASC such as salty taste.

We have previously shown that vertebrate olfactory receptor cells have narrow dynamic range responses to odours. Does response envelope studied in the presence of different concentrations of cisnol, isonitryl acetate or acetophenone for an exposure time of 1.2 sec were well fitted by the Hill equation with a Hill coefficient of between 1 and 1.5 times values between 3 and 100 pM. Although the Hill coefficient for these odorants was in the micromolar range, the cellular threshold for odorant detection could be significantly lower. We have investigated this possibility we exposed a single cell to low odorant concentrations for longer periods of time. In a cell with a K1/2 of 10 µM as measured from dose-response curves of odorants isolated current bumps induced by 500 nM of the same odorant. These bumps had a bell shape with amplitudes of 1-10 pA and a duration of 300-500 ms. Olfactory receptor concentrations lower than previously shown. They may accomplish this by sampling over longer periods and integrating information over time. Thus a cell expressing a bromide tuned low affinity odor receptor may recognize sensitivity at the expense of temporal resolution, as apparently sensitive trade-off for olfactory neurons. The observed small current bumps could be caused by the binding of a single odor molecule to a receptor, as in photoreceptors it is possible to observe quantum bumps caused by the absorption of a single photon. Supported by EEC BSS 9651, NIH, ONR and NATO.

606.4 SALAMANDER OLFACTORY RECEPTOR NEURON ODOR RESPONSES DEPEND UPON STATES ESTABLISHED BY PRIOR STIMULUS PRESENTATIONS. R.C. Gesteland*, P. Farmer and M. Overwijk. University of Cincinnati Medical Center, Cincinnati, OH 45267-0521.

Voltage-sensitive dyes observed with a confocal microscope allow the activity of each cell to be observed on a time course. Odorous stimuli were found to be different among groups of cells, and that some groups were more sensitive to the same odors than others. However, it is likely that these differences in the direction of action can be long-lasting. The response of a cell to a stimulus will depend upon the activation states of the various channel types resulting from prior odor experience. This work was supported by NIH grants DC00342 and DC00347.
606.5
OLFACTORY TRANSDUCTION IS INTRINSICALLY NOISY. Graeme Lowe & Geoffrey H. Gold. Monell Chemical Senses Center, Philadelphia, PA.

The high level of noise in olfaction suggests that olfactory receptor cells reliably detect single odorant molecules. Discrete events, presumably triggered by single odorant molecules, have been observed in insect pheromone receptor cells, but analogous events have not been observed in vertebrate systems. We have sought to resolve single molecular responses in rat by recording the transduction current in dissociated olfactory receptor cells. When cells were exposed to threshold concentrations of one of the odorants, methamphetamine, 2-isobutyl-3-isopropylpyrazine, isopropyl acetate or 2-ethylpyridine, the whole-cell current displayed pronounced low frequency (< 10 Hz) fluctuations which might represent the summation of single molecular responses. However, fluctuations of similar amplitude and frequency spectrum were also observed in the absence of odorants by inhibiting basal phosphodiesterase activity with IBMX, or by photolytic release of cyclic AMP. Thus, the odorant-induced fluctuations represent the basal, or intrinsic, noise of olfactory transduction, not the activation of receptor proteins by odorants. In unstimulated cells this noise is suppressed by the threshold inherent in cyclic-AMP activated current. Our data suggest that for many common odorants, single odorant molecules are not reliably detected by mammalian olfactory receptor cells.

Mr and CuZn superoxide dismutases (SODs) are enzymatic scavengers of superoxide free radicals. Mitochondrial MrSOD and cytosolic CuZnSOD were localized immunohistochemically in olfactory mucosa obtained at autopsy from 19 subjects, 11 males and 8 females, ranging from 24 to 98 years of age. Four patients were classified as young/middle aged (under 60 years old), 6 as old (over 60 years old), 4 (69-98 years old) as "old", and 5 (72-90 years old) as "old/adult". Histologically confirmed Alzheimer's disease (AD). Postmortem intervals (PMIs) ranged from 2-22 h. In young/middle aged subjects, intense immunoreactivity was observed in olfactory receptor neurons, sustentacular and basal cells in the olfactory epithelium and in Bowman's glands, olfactory nerves, and vascular endothelium in the lamina propria. Comparing young/middle aged and old, there was an age-related decrement in the overall intensity and distribution of immunoreactivity that was most pronounced in olfactory receptor neurons, basal cells, and endothelium. Old subjects often had restricted (oc) of intense epithelial immunoreactivity. In the "successfully aged," large regions of immunostaining were extensive as that in young/middle aged subjects were intermingled with smaller regions of reduced intensity. Subjects with AD generally exhibited the most intense staining that was distributed like that in the "successfully aged." These differences were not related to PMI; the 3 youngest subjects had the longest PMIs. 3 old subjects had short PMIs; age- and AD-related trends were observed in subjects from the different groups matched for age and PMI. High levels of SODs in the young/middle aged and "successfully aged" may reflect the higher cellular viability of their olfactory mucosae, while high levels in the AD subjects may be related to oxidative stress associated with the disease process. Supported by NIH grants DC 01175 (MLG) and DC 00159 (TVG).

606.8

In the turtle olfactory bulb, primary olfactory neurons are thought to excite mininaluflbach (MT) cells by stimulating both NMDA and non-NMDA glutamate receptors (Berkovics et al., J. Neurophysiol. 71, 1994). It has been suggested that the non-NMDA receptors allow MT cells to respond rapidly to incoming odor information while the NMDA receptors might provide a means for the short-term temporal integration of this information. We have examined this idea by optically monitoring electrical activity in the isolated turtle olfactory bulb stimulated with the voltage-sensitive dye, RH 155. The figure below shows optical responses recorded from the external plexiform layer evoked by paired-pulse stimulation (500 ms separation) of the olfactory nerve before (thin trace) and after (thick trace) addition of the NMDA antagonist, AP-5 (100 µM), to the bathing solution. As can be seen, NMDA blockade partially reverses depression of the second (test) response but has little effect on the initial (conditioning) response. Supported by NIH GM07517.

606.9

The olfactory system is a remarkable model to study in vivo basic phenomena occurring in neurones of the CNS. Olfactory neurones in the olfactory mucosa send their axons to the glomerular layer of the olfactory bulb where they make synapses with several neuronal types. An important consequence of peripheral afferent denervation is the olfactory bulb atrophy reduction of neurotransmitter dopamine due to loss of tyrosine hydroxylase (TH) mRNA. In the present study we began to address the question of whether the expression of subunits belonging to various GABA- and glutamate receptor complexes is modified in unilateral chemical lesion (ZnSO_4-irradiation) of the rat olfactory mucosa. Analysis of the olfactory receptor total RNA was performed on 3 groups of male adult rats [(i) untreated, (ii) saline- and (iii) ZnSO_4-irradiated rats], sacrificed 12 days post-lesion. Both competitive polymerase chain reaction (PCR) assays and semiquantitative PCR experiments were employed to compare the relative abundance of mRNAs in the 3 groups. Measurements of TH mRNA were used as an indication of the effectiveness of the lesion. In ZnSO_4 irradiated rats we found a remarkable reduction both of the γ_2 and γ_3 GABA receptor subunit mRNA, while we observed only a slight increase in the NMDR1α mRNA splicing form and no significant change in the NMDR1α and in the GluR1 mRNAs. Our findings suggest that the expression of at least some GABA receptor subunits in the olfactory bulb are under transynaptic regulation. Since it has been recently demonstrated that glutamatergic-immunoreactivity is present in olfactory neuron terminals (Sauss-Poggetto et al., Neuroreport, 1993), loss of release of those may be responsible of the decrease of TH mRNA that might be followed by a reduction of transmitter release and modulation in the expression of GABA_α receptor genes in post-synaptic elements.

606.10
OLFACTORY AND CHEMICAL INJURY OR SENSITIVITY. Donald L. Budney. Chemical Injury Research Foundation, Tacoma, WA 98407.

Auditory, visual and upper and lower somatosensory evoked potentials were studied in 20 patients with clinical criteria for chemical sensitivity. Measures were made before and during exposure to chemicals that volatilized and led to complete debilitation.

In general, auditory and visual P3 latencies and N19, P22, P31 and N45 latencies were significantly increased (p<0.001). In general, amplitude for the same variables was not significantly changed (p>0.20). An exception was noted in the P3 amplitude which was significantly decreased (p<0.001).

Latency correlations were low or not significant prior to exposure and highly significant during exposure. On the other hand, amplitude correlations were highly significant prior to exposure and not significant during exposure. Since olfactory signals are sent to nearly every part of the brain it is thought that this system's use of excitatory amino acids and their precursors for neurotransmission in association with cholinergic cells with six or less carbon fragments that volatilize could lead to brain cell injury and subsequent neuronal changes that are experienced by the patient as the signs and symptoms of chemical sensitivity or injury.

The above will be discussed in association with agonists and antagonists of excitatory amino acids in humans.
A 3-D FUNCTIONAL MRI DEMONSTRATION OF BRAIN FUNCTIONS INVOLVED IN HUMAN OLFACTORY FUNCTION. N.E. Ramsay, B. Kawaguchi, A. Shulman, M. D. LeMay, and S. Hoemmer.* National Institute of Alcoholism and Alcohol Abuse, NIMH in Vivo Center, Laboratory of Diagnostic Radiology Research, NIH, Bethesda, MD 20892.

Olfactory processing selectively involves the limbic system. Imaging of limbic areas with fMRI is problematic, due to their location near the base of the skull, close to blood vessels. We report here an olfactory stimulation study involving a 3-D Echo-Shifted FLASH sequence and a Gaussian random noise baseline for motion correction (Worsley, K. J., Evans, A. C., Marrett, S., et al., J. Cereb. Blood Flow Metab. 12, 900–918, 1992). Pleasant odors were administered to 10 subjects (9a). After ananesthesia, 3T-HASTE stimuli were done at 3 minute intervals. Each trial consisted of two functional scans, with 7 seconds between trials. Olfactory stimulation was switched on at the end of the first scan, and off at the end of the second scan (odor duration 27 secs.). For each subject, data were converted to difference images, obtained by subtracting the unstimulated from the stimulated 3D image within each trial. Trials were then summed, and SA averaged individually. Significantly activated voxels were found in structures of the olfactory system, including the amygdaloid complex (556), septal nuclei (556), and ventromedial striatum (556), posterior orbital cortex (45). Very few significant voxels were found outside of the olfactory system. These results indicate that the 3D-Echo Shifted Flash sequence enables in vivo imaging of olfactory function.

607.2 TALIN FUNCTION IS SPATIALLY INTEGRATED IN THE NEURONAL GROWTH CONE. Anne M. Snyder* and Daniel C. Jay, Department of Cellular and Molecular Biology, Harvard University, Cambridge MA, 02138.

Dynamic extension and retraction of filopodia is thought to function in signal detection and force generation needed for directed motility of the neuronal growth cone. To address the role of cytoskeletal proteins in filopodial motility we have used micro-CALI (Chromophore Assisted Laser Inactivation) to functionally inactivate the cytoskeletal protein talin in growth cones of chick DRG neurons in culture. We have found that inactivation of talin in a region of the growth cone results in a loss of filopodial extension and retraction, whereas inactivation of talin over the whole growth cone has little effect on filopodial motility. Micro-CALI inactivates proteins within a 10-15 micron spot by directing the energy of a 620 nm laser beam to the protein via a dye-labeled antibody. Neurons were trypsinized, rinsed, and reacted with green-labeled antibodies to talin and regions of the growth cone were laser irradiated for five minutes. This caused the rate of extension and retraction of filopodia within the irradiated area to drop to zero for one to two minutes; filopodia outside this region showed no change in motility. Irradiation of whole growth cones at the same laser power did not result in any change in filopodial behavior. Laser irradiation of malachite green-BSA loaded controls showed no change in growth cone motility. This evidence that talin can act to couple filopodial movement to cytoskeletal dynamics. These data also suggest that the growth cone spatially integrates internal differences in protein function. We believe such spatial integration of protein function could provide the basis for directed growth cone motility and are investigating this possibility.

607.4 NERVOUS SYSTEM ABNORMALITIES RESULT FROM TARGETED MUTATION OF MAP2B. W. Edelman, P. Costello, P. Davies, L. Roback, B. H. Walner*, R. Kucherlapati, Deps. of Molecular Genetics, Neurosurgery and Pathology, Albert Einstein College of Medicine, Bronx, NY 10461.

For proper development of the brain, an intact complement of cytoskeletal elements is essential, including that of the microtubule associated proteins. The microtubule associated protein 1b (MAP2B) is a member of this microtubule network in neurons and glia. MAP2B expression is developmentally regulated and is highest during embryogenesis and the early postnatal period. This expression pattern suggests involvement in the regulation of neurite outgrowth. We have targeted MAP2B in the MAP2B gene which resulted in embryonic lethality in homozygous mice and a marked phenotype in some heterozygous animals. This phenotype includes hindlimb hypoplasia, a spastic tremor of the hindlimbs and an overall reduction in body weight of 25-50%. Histologically, the phenotype is pronounced in the cerebellum. The principal abnormality is a dramatic reduction in the Purkinje cell bodies and their dendritic arborizations. Immunohistochemical studies with MAP1B and MAP2B specific antibodies showed reduced staining in Purkinje cells. No decrease in staining of another cytoskeletal protein, MAP2, was observed. Western blots revealed no change in levels of neurofilament proteins, MAP2 or tau. A differential abnormalities were seen in the hippocampus, olfactory bulbs and visual system. These data suggest an essential role of MAP2B in the development of the brain.
607.5 EVIDENCE THAT CAMs STIMULATE NEURITE OUTGROWTH BY ACTIVATING FGF RECEPTORS IN NEURONS. P. Dobony*, E.J. Williams, J. Furness and F.S. Walsh. Department of Experimental Pathology, University of Cambridge, London SE1 8RT.

We have used monolayers of parental 3T3 and 3T3 cells expressing one of three transfected cell adhesion molecules (CAMs) (ICAM, N-cadherin and L1) as a culture substrate for rat cerebellar neurons. A number of lines of evidence suggest that neurite outgrowth stimulated by the above CAMs involves activation of the FGF receptor in neurons. After suggesting that the CAMs which bind to the FGF receptor in neurons inhibit neurite outgrowth stimulated by the above CAMs but have no effect on integrin dependent neurite outgrowth or neurite outgrowth stimulated by a variety of other agents. In addition we have found that a soluble L1-Fc chimera is effective as cell associated L1 in promoting neurite outgrowth. The response to the L1-Fc chimera is tuck correlated with the presence of CAMs. This suggests that the CAMs which bind to the FGF receptor with basic FGF. We conclude that activation of the FGF receptor, rather than changes in adhesion, underly the neurite outgrowth response to a number of CAMs.

607.6 PERMISSIVE ROLE OF GAP-43 IN NEURITE OUTGROWTH: PRIMARY SENSORY NEURONS AND TRANSGENIC MICE. L. Aigner, F. Botteri, and P. Caroni*, Friedrich Miescher-Institute, P.O. Box 2543, CH-4002 Basell, Switzerland.

The specific association of the growth-associated protein GAP-43 with nerve growth during development and regeneration suggests that it may play a role in this process. Early studies (Schnell et al., Neurosci. Rev. Neurosci. 12:1227). Downregulation of neuronal GAP-43 expression during development coincides with the process of synapse elimination. Suggesting that it may also play a role in local process outgrowth and maintenance. To define the role of GAP-43 in neurite outgrowth we have 1) analyzed neurite and growth cone (GC) activity in primary sensory neurons specifically depleted of (GAP-43) by an antisense approach (Aigner and Caroni (1993) JCB123:417), and 2) generated transgenic mice that constitutively express chick GAP-43 in adult neurons. Characteristic features of neuronal antibodies that bind to L1 or the FGF receptor. The response is also associated with an increase in phosphotyrosine on the same set of neuronal proteins. We propose that this increase is a consequence of the tyrosine phosphorylation of the FGF receptor with basic FGF. We conclude that activation of the FGF receptor, rather than changes in adhesion, underly the neurite outgrowth response to a number of CAMs.

607.7 GAP-43 IMMUNOREACTIVITY AND AXONAL REGENERATION OF RAT RETINAL GANGLION CELLS. H. Schaden*, M. Bihr*, C.A.O. Steumer, University of Konstanz, Germany, *MPI Tübingen, Germany.

While more than 90% of the retinal ganglion cells (RGCs) in rats die upon optic nerve section (ONS), a subfraction of those that survive is capable ("competent") of regenerating an axon into a peripheral nerve (PN) graft (Yan et al., 1987). To determine whether re-expression of competent RGCs, the relevant antibodies were applied to sections of retina (i) in rats with acute ONS only (ii) in rats which had received a PN graft. RGCs were labeled by the retrograde tracer Fluorogold (FG) applied to (i) the ON to identify surviving RGCs, (ii) to the PN graft to identify RGCs with regenerating axon (iii) GAP-43 immunoreactivity (i) was seen in 22% of RGCs at 5d after ONS and in 2% and 1% at 14 and 21d, respectively, in rats with out grafts. (ii) In rats with PN grafts, only those RGCs which were FG-labeled (and thus had regenerated an axon into the graft) exhibited GAP-43, and they represented 3% and 2% at 21 and 28d after surgery, respectively. c-JUN, however, was found in (i) many more RGCs than GAP-43 and in (ii) at least twice as many RGCs at 21 and 28d, than were there RGCs labeled with FG and exhibiting GAP-43-ir.

Thus regenerating axons in PN grafts derive specifically from GAP-43 re-expressing RGCs. Appearance of GAP-43 may therefore identify those RGCs that possess the intrinsic property of axonal regeneration or sprouting.

607.8 REDUCED PRESYNAPTIC ACTIVITY DURING NEUROMUSCULAR DEVELOPMENT PROMOTES FOREIGN MOTOR ENDINGS IN DROSOPHILA. J. Jacob*, and I. Kaschhian, Genetics and Biology Dept., Yale Univ., New Haven, CT 06511.

Electrical activity plays a role in the development of Drosophila neuromuscular synapses. We previously showed that blocking presynaptic (but not postsynaptic) activity during embryonic synaptogenesis promoted inappropriate motoneuron contacts (Liu & Hom, Neurosci. Lett., 1965). In order to follow the development of these ectopic contacts during larval life, the activity of the muscle afferents arising from the nerve cord was examined (paral*, nap*, and so*). Collateral sprouting increased into muscle fibers 65% in the mutant embryos when reared at 34°C during stages 14-18. (WT: 16% sprouts, n=169 segments; paral: 25%, n=150, p<0.05; nap*: 29%, n=91, p<0.005; paral* vs. nap*: p<0.005; n=103, p<0.05). An increased axonal outgrowth per unit area of muscle endings was also observed in these fibers in nap* and so* but not paral. (WT: 5.6% of fibers receiving sprouts, n=89 segments; paral: 8%, n=110; paral*: 10%; p<0.005; paral* vs. so*: p<0.005; paral vs. so*: p=0.05). About 60% of the ectopic endings arise from the transverse nerve, 50% from endings on the oblique muscle fibers, and less than 5% from endings on muscle fibers 13 or 8. The morphology of the native neuromuscular endings is not changed by the presence of the ectopic synapses. Temperature shifting (37°C-25°C) during larval development further increased the number of ectopic endings to 50% in nap* and 34% in so* (n=164) as opposed to shifted WT animals (6%, n=62) and shifted paral* (2.4%, n=60). Significant increases were not observed in hyperactive mutants such as eag sh or so*. The critical period includes both late embryogenesis and the 1st instar. We hypothesize a reduction in synaptic activity in the embry发育 induced filodipal sprouting, and that in the 1st instar reduced synaptic activity stabilizes them. These results show that synaptic activity contributes to the maintenance of correct neural connectivity.

In the adult rat, acute treatment with kainic acid, a glutamate agonist, induces FGFR-43 mRNA in granule cells maximally at 24 hr (McNamara et al., Soc. Neurosci., 1993). KA also induces sprouting of granule cell axons, the mossy fibers, into the supragranular layer beginning ~10 hr after KA (Nadel et al., Brain Res., 182:1, 1980). To induce the rotation of FGFR-43 mRNA in granule cells to subserve mossy fiber sprouting, adult male Sprague-Dawley rats were injected with: 1) saline 2) KA (i.e., 10 mg/kg), 3) PENT (i.e., 30 mg/kg) 4) PENT then KA 15 min later, 5) MK-801 (i.e., 2 mg/kg), and 6) MK-801 then KA 15 min later. Rats were sacrificed either (A) 24 hr after the last injection and FGFR-43 gene expression assessed using quantitative in situ hybridization or (B) 30 d later when mossy fiber sprouting was assessed with Timm's stain. KA alone first induced FGFR-43 mRNA in granule cells as well as subsequent mossy fiber sprouting into the supragranular region. Visual inspection revealed no significant cell loss in areas CA3A/CA4A after KA alone. Pre-treatment with PENT of the KA-induced FGFR-43 mRNA induction and supragranular sprouting but, except in one case, did not affect cell loss in CA3A/CA4A. As shown by in situ hybridization, MK-801, only minor mossy fiber sprouting was observed. When administered alone, PENT and MK-801 did not affect FGFR-43 mRNA, mossy fiber sprouting, or cell survival. In conclusion, kainate receptor activation leads to mossy fiber sprouting. This sprouting appears to be independent of excessive cell loss in areas CA3A, supported by MO58253 to A.R. and Post-doctoral fellowships from NSERC to K.R.M. and NSF to P.A.J.

607.10 INCREASED SPROUTING OF PRIMARY AFFERENTS IN THE MYELIN-FREE RAT SPINAL CORD. Joseph P. Kuphaner*, Guido Schweger, and Martin E. Schwab, Brain Research Institute, University of Zürich, Augustin-Foehr-Str. 1, 8029 Zürich, Switzerland.

We are interested in defining physiological functions of myelin-associated neurite growth inhibitors. These molecules are involved in the prevention of axonal regeneration in the adult mammalian CNS (Schnell et al., Nature 367:170, 1994). Previous work has shown that the regional expression of GAP-43, a putative marker for fiber growth and plasticity, is inversely related to the degree of myelination in the CNS of normal rats (Kaphammer and Schwab, JCN 340:194, 1994). Furthermore, GAP-43 expression is strongly increased in myelin-free lumbar spinal cords when myelinated motor terminals are ablated by neonatal X-irradiation (Kaphammer and Schwab, Eur.J.Neurosci. 6:403, 1994). These results suggest a role for the inhibitors in re-inhibiting sprouting and anatomical plasticity in the normal CNS.

We have now investigated whether the increased expression of GAP-43 in the myelin-free spinal cord is indeed correlated with an increased potential for sprouting fiber terminals. Nerve sprouting from the roots of lumbar segments L2-L4 were cut in myelin-free and normal cords of 8 or 15 day old rats. Sprouting of primary afferents was studied 3 weeks later when the threementioned motor terminals were myelinated by the neonatal X-irradiation. This enzyme specifically labels a subclass of spinal cord primary afferents. We found that the sprouting of TMP positive afferents is increased in the myelin-free condition as well as in the irradiated cord. This further supports our hypothesis that CNS myelin and its associated neurite growth inhibitors are involved in the regulation of terminal sprouting and plasticity in the normal CNS.

608.1 RULES DETERMINING THE MONOSYNAPTIC CONNECTIONS BETWEEN LGN CELLS AND SIMPLE CELLS IN CAT VISUAL CORTEX. R. Clay Reid, Jose-Manuel Alonso and Torsten N. Wiesel. Laboratory of Neurophysiology, The Rockefeller University, New York, NY.

We have studied the rules that determine whether an individual afferent from the lateral geniculate nucleus (LGN) will have a monosynaptic connection with a given cortical simple cell. Our question was: how precisely can the synaptic connections between these two cell types be predicted by their functional properties? Single units were recorded with electrodes in both LGN and cortex. Receptive field position and structure were matched with white noise stimuli. Connectivity between pairs of cells (one LGN cell and one simple cell) were compared with cross-correlation analysis of the spike trains. Narrow peaks with very short latencies were taken as evidence for monosynaptic connections.

The rules of connectivity are very precise. Over 80% of cell pairs were monosynaptically connected when a receptive field was centered over a simple cell subregion of the same sign (on or off). Connections were never seen when an different sign LGN receptive field was centered over a simple subregion (on vs. off). The probability of monosynaptic connection also depended on a good match between the receptive field sizes and the time-course of the responses. In particular, fast LGN afferents were less likely to be connected to a simple cell if the overlapping simple subregion had slower dynamics than the LGN center.

The elongated distributions of the direct on an off LGN afferents to individual simple cells explains at least part of cortical orientation selectivity. It does not, however, reject an important role of intracortical processes in sharpening this tuning.

608.3 VISUALLY EVOKED CALCIUM ACTION POTENTIALS IN SIMPLE AND COMPLEX CELLS IN THE CAT STRIATE CORTEX. Judith A. Hirsh*, Jose-Manuel Alonso, and R. Clay Reid. Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021.

Synapses made by thalamic afferents comprise a small minority of those made in layer 4, yet their input largely accounts for the simple receptive field. One means of enhancing excitatory synaptic input is through voltage-dependent calcium conductances in the postsynaptic membrane. We examined the role of these in the construction of visual cortical receptive fields by making whole-cell recordings in vivo.

We mapped receptive fields with randomly flashed bright and dark squares (Jones and Palmer, 1987; J. Neurophysiol. 58: 1187). Intracellular labeling showed that the simple cells we studied were either spiny stellates or pyramidal neurons. When recordings were made with a conventional internal solution, visual stimulation evoked large, fast action potentials. Intracellular blockade of these sodium spikes with QX-314 routinely revealed, on visual stimulation or current injection, smaller, slower action potentials presumably mediated by calcium. Moreover, we could map receptive fields with the visually driven calcium action potentials as we usually do with sodium spikes. Parallel results were obtained for pyramidal cells with complex receptive fields, by whole-cell recording in vitro.

608.2 COUPLING BETWEEN NEIGHBORING LGN CELLS: POSSIBLE IMPLICATIONS FOR SIMPLE RECEPTIVE FIELDS. Jose-Manuel Alonso*, R. Clay Reid. Laboratory of Neurophysiology, The Rockefeller University, New York, NY 10021.

The receptive field of simple cells is constructed largely by the convergence of the aligned input from the lateral geniculate nucleus (LGN). However, extracellular and intracellular interactions could also determine part of the final shape of the receptive field. Here we are presenting evidence for excitatory connections between neighboring LGN cells recorded with the same electrode. Each receptive field was mapped with a pseudo-random dynamic checkerboard stimulus (m-sequence), and the spikes were isolated with the Brainwave System. Forty percent of the LGN pairs studied showed strong and narrow peaks with cross-correlation analysis. This percentage was even larger for those pairs with good overlap of the centers (>20%), and well matched size and timing between the receptive fields of the two cells. Asymmetric narrow peaks were seen mainly when the two cells had partially overlapped on and off receptive fields. Symmetric narrow peaks were more frequent in pairs with partially overlapped either on/on or off/off receptive fields. If, as we suspect from our geniculocortical study, the connected pairs feed into the same simple cell this could provide a means to generate a synergistic input that could drive the simple cell to threshold. (Supported by Fulbright/MEC, NIH EY10115 and EY02523, and the Klingenstein Fund)

608.4 SYNAPTIC RESPONSE PROPERTIES OF COMPLEX CELLS IN THE CAT STRIATE CORTEX. Maria V. Sánchez-Vives*, Judith A. Hirsh, Jose-Manuel Alonso and R. Clay Reid. Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021.

Complex cells in the superficial layers of area 17 often have more transient responses than the simple cells in layer 4 that provide much of their input. We used whole-cell recording in vivo to measure the relative role of synaptic excitation and inhibition in the generation of these briefer responses. The stimuli were randomly flashed bright and dark squares each lasting 40 ms. Most of the cells we recorded from were pyramids, as identified by intracellular labeling. In these cells, the stimulus evoked EPSPs were frequently followed by marked inhibition. This inhibition seemed large in part to be mediated by chloride, as it persisted in the presence of QX-314 which suppresses the slow IPSPs mediated by potassium. The strong inhibitory component of the response observed in pyramidal cells suggests that there is a population of inhibitory interneurons driven by the rapidly flashed squares. In fact, we have recorded from a large basket cell that was vigorously excited by these stimuli. Such cells project densely to pyramidal neurons (Somogyi et al., 1983, Neuroscience V10: 261). We propose that the inhibition mediated by smooth cells regulates the temporal properties of their target neurons in the superficial layers of the visual cortex. (Supported by F.P.I. (MEC) to M. V.S.V, NIH EY09593 and a Klingenste Award to J.A.H., Fulbright/MEC to J.M.A., NIH EY10115 and a Klingenstein Award to R.C.R. and NIH EY05253 to T.N.Wiesel)
THE NATURE OF INPUTS UNDERLYING SIMPLE CELL DIRECTION SELECTIVITY. D. Fields* and L. Kostyshin Dept. of Neurobiology, Northwestern Univ., Evanston, Ill 60208 and Smith-Kettlewell Eye Research Institute, San Francisco, CA 94115.

Direction selectivity in simple cells of cat area 17 appears to be based on variations within the receptive field of the time course of the response to visual stimuli. Response latency to flash stimuli is longer in those parts of the receptive field first encountered by a stimulus moving in the preferred direction, suggesting that the latency varies smoothly across the receptive field or abruptly in a small number of shifts, and we have characterized the properties of the inputs underlying these variations.

Intracellular recordings from different parts of the receptive field indicated that the potential evoked by stationary sinusoidal gratings at 8 spatial phases (Science 257:1901) were applied to a singular valued decomposition (SVD). This analysis showed that each of the 8 responses (Rn, where n = 8 spatial phase) could be expressed with up to 98% accuracy as a linear combination of 2 functions, f1(x) and f2(x). I.e., Rn = a1 f1 + a2 f2. The coefficients a1 and a2 varied nearly sinusoidally with spatial phase of the stimulus grating, indicating that the two types of synaptic input underlying f1 and f2 were in linear spatial summation. The SVD does not provide the actual input signals from the two types of synaptic input; f1 and f2 are instead linear combinations of those signals. To derive the input signals, a minimization procedure was applied to the even harmonics of Rn. The inputs derived from this procedure were approximately 90° out of phase with one another at the optimal spatial frequency, and delayed with respect to one another by 60 to 80 ms. They were also of unequal strength, the mismatch in strength being greater for cells with lower direction selectivity.

From this analysis we conclude that 1) simple cells receive input from two cell types with different response latencies; 2) the two types are spatially linear but temporally nonlinear; 3) the simple cell sums these inputs in a highly linear fashion.

Neurons in macaque area VI respond more strongly to texture displayed over their receptive fields when that texture appears to be part of a discrete, object-like region of the scene than when the texture appears as part of a homogenous background. Extra-receptive field mechanisms are thought to play a role in scene analysis at a scale larger than their receptive field area. Here we used single and multiple cell recording to study the spatial extent of extra-ness in parietal area VI of the awake monkey. We used texture displays in which a disc-shaped region was delineated from the background by contrast in orientation, brightness, or color. As the monkeys watched, texture displays were presented with the disc region centered on the receptive field of the VI neuron under study; texture over the receptive field was identical in all cases during recording from a cell. The diameter of the disc was varied between 1.8° and 14.4°, always larger than the receptive field region of cells under study. The resulting response profile to texture displays could be seen as an initial burst of activity at texture onset that was similar under all conditions, and a subsequent tonic response period that showed enhanced response for disc versus homogenous texture background. Enhanced response to discs declined monotonically with increasing disc diameter, falling off for discs of diameter 12°, on average. The time course of this modulation generally did not depend on disc size. Experimental controls showed that these effects were not a result of visual attention or small eye movements.

608.9 THE RELATIONSHIP OF RECEPTIVE FIELD COVERAGE TO FUNCTIONAL MODULES IN PRIMATE VI, C. L. Landamart, A. W. Rom, and D. L. Schiller Division of Neuroscience, Baylor College of Medicine, Houston, TX 77030.

*Rockefeller University, New York, NY. 10012

We are still not sure how the different functional modules in parafocal VI provide coverage of visual space. In particular, how do ocular dominance columns and color patches provide full representations of visual space, given their discontinuous organization in VI? Are the maps continuous or independent across the different modules? Using a combination of tangential electrode penetrations and a series of perpendicular penetrations guided by optical images of functional activity, we examined visual space across ocular dominance columns and across bands. In long tangential penetrations crossing OD columns, we have confirmed the existence of receptive field "jumps" at ocular dominance borders. Within OD columns, we have observed regions, roughly monotonically oriented, within ocular dominance borders, we have observed jumps between left and right eye progressions, some of which are consistent with the two-steps-forward, one-step-back progression described by Blakemore and Wintle.

We are particularly interested in coverage by color in VI. The occurrence of color selective cells in tangential penetrations is much lower than in perpendicular penetrations, in matching color regions reached with linear optical images. In the tangential penetrations, only about 20 percent of cells encountered were unoriented cells and approximately 15 percent were color selective cells. Only 3 to 4 percent were the classic color-opponent unoriented cells. In targeted penetrations, 50% were color-selective cells and 35% were broad band unoriented cells. Thus, by using the optical images to target a row or a region of color-selective patches, color cells can be located with a higher frequency. We are using this technique to study coverage by the color system.

608.6 Effect of Eye Mispaligment on Receptive Field Formation in Realistic Visual Environments. Hard Shoval, Nathan Intraorot, C. Charles Law, and Leon N Cooper*, Department of Physics and Neuroscience and Institute for Brain and Neural Systems, Brown University, Providence, RI 02912

In this paper we study the ability of cortical cells to concurrrrently develop orientation selectivity and ocular dominance. We examine whether two proposed learning rules BCM, and a stabilized Hebbian Rule (PACM) can accomplish this aim. In addition we study how initial misalignment affects the binocularity of mature cells. We chose a realistic visual environment, composed of natural scenes that have been preprocessed by center-surround filters. Each neuron is subjected to partially overlapped, partially occluded, of the images originating from both eyes. We examine how changing the degree of the overlap, affects the properties of the mature cells. We find that for both learning rules the receptive fields from the two eyes become matched. For the PCA rule, the receptive fields from both eyes are symmetric, and are completely binocular as long as there is an overlap. For BCM neurons on the other hand the receptive fields from both eyes are non symmetric and mature neurons lose binocularity.

608.8 CONTEXTUAL INFLUENCES ON VISUAL DISCRIMINATION IN HUMANS AND ON RF PROPERTIES OF CELLS IN STRIATE CORTEX OF ALERT MONKEYS. M.K. Kapadia, C.D. Gilbert* and G. Westheimer. The Rockefeller University, New York, NY 10021.

The context surrounding a feature influences both the perception of its attributes and the response properties of cells with receptive fields (RFs) containing the feature. We studied the context dependency of the responses of striate cortical cells in awake, behaving primates and compared these findings with psychophysical measurements of line detection in human subjects.

We compared the minimum contrast necessary to detect a light bar presented alone and in conjunction with a second, suprathreshold bar. The second bar lowered the contrast detection threshold of the first bar by 40%. The magnitude of this effect was greatest when the two bars were colinear, and was reduced as the bars were further separated along their axis of orientation, by displacing them from colinearity, and by changing their relative orientation. The response properties of some neurons in the primary visual cortex of the alert monkey showed similar dependencies on stimulus configuration, increasing their response to a bar located within the classical RF when an iso-oriented, colinear bar was presented simultaneously in the RF surround. The second bar, when presented alone, elicited either no response or a suppression of background firing. The response facilitation often declined in bar separation and orientation contrast in a fashion similar to that observed in the psychophysical studies. The plexus of long-range horizontal connections in visual cortex provides a likely substrate of these effects by connecting cells with similar orientation preferences in disparate parts of the visual field.

(Supported by NIH grant EY07968 and a McKnight Development Award)

Previously we have shown that when stimulated by moving contours layer VI cells in the visual cortex provide a feedback influence that causes correlated firing in LGN cell pairs with receptive field alignments appropriate to signalling the presence of the contour. This may serve to increase the synaptic effectiveness of their input to layer IV cells in the cortex. The layer VI cells projecting to the LGN also project to layer IV but as yet we do not know how or whether they influence the synchronisation of layer IV cells directly. With this in mind we have examined the way the spatial extent, orientation and direction of motion of a concentric bipartite grating stimulus influences the response and correlated activity of groups of cells in recorded layer III/IV and VI. The shuffled corrected cross-correlogram revealed highly significant synchronisation compatible with common mode input in cells with common orientation tuning and overlapping fields. This held for responses obtained throughout their orientation tuning curve. We observed that varying the orientation of the outer stimulus could profoundly modify the response to the inner stimulus in the receptive fields of cells with both colinear and monkey optical images. We have also found that connections from orientation columns tuned to quite different orientations to those of the cell in question could influence its response. Under these circumstances we found evidence of connectivity between cells of different orientation for specific stimulus configurations only. We suggest that the input from layer VI cells may contribute to the common mode input correlation of the firing of cells with like orientation selectivity. Coarse and variable cortical circuitry underpins the effects seen under more complex stimulus situations.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
REDUCING BIOPHYSICALLY DETAILED SINGLE CELL MODELS TO SINGLE COMPARTMENT MODELS C. Koch, Ö. Bernander, R. J. Douglas, M.A. Malowald. Caltech, 139-74, Pasadena, CA, 91125, (2) MRC Anatomical Neuropharmacology Unit, Oxford QX1 2QT, UK.

Simulations of biophysically detailed neurons that explicitly model the dendritic tree and incorporate multiple active conductances are computationally too intensive to be feasible in the study of large networks. We therefore derive several highly simplified cell models in a two step approach. First, an intermediate model is derived that is electrically complex (using a Hodgkin-Huxley like formalism) and spatially simple that in the soma and entire dendritic tree are collapsed into a single compartment. This model preserves the response to somatic input, as described by input resistance, f I curves, and voltage and current thresholds. In a second step, the intermediate model is reduced to three yet simpler models: Integrate and Fire (I&F), Diode, and Hopfield units. The I&F model preserves the voltage threshold and generates output spikes whenever the threshold is exceeded. The Diode model is based on the observed exponential relationship between the time-averaged somatic potential (including spikes) and the total membrane current. The Diode and Hopfield models preserve the current threshold and generate a continuous output variable that can be thought of as the mean firing rate. These models represent two extreme viewpoints: pulse or temporal coding assumes that the exact timing of inputs are relevant, while the mean-field viewpoint focuses on the average spike rate.

In brains of higher vertebrates, the functional segregation of local areas that differ in their anatomy and physiology contrasts sharply with their global integration during perception and behavior. We have recently (PNAS 91, 5033) introduced a measure, called neural complexity (Cpq), that captures the interplay between these two fundamental aspects of brain organization. We express functional segregation within a neural system in terms of the relative statistical independence of small subunits of the system and functional integration in terms of significant deviations from independence of large subunits. Cpq is then obtained by estimating the average deviation from statistical independence for subunits of increasing size. Cpq is shown to be high when functional segregation coexists with integration and to be low when the components of a system are either completely independent (segregated) or completely dependent (integrated). We apply this complexity measure in computer simulations of a primary visual area to examine how some basic principles of neuroanatomical organization constrain brain dynamics. We show that the connectivity patterns of the cerebral cortex, such as a high density of connections, strong local connectivity organizing into neuronal groups, patchiness in the connectivity among neuronal groups, and prevalent reciprocal connections, are associated with high values of Cpq. The complexity measure has been used in an initial exploration of data from humans obtained by functional neuroimaging.

Phencyclidine (PCP), ketamine (K) and MK801 are non-competitive NMDA receptor antagonists that decrease injury produced by stroke, trauma and seizures. However, these agents produce vacuoles and kill cortical neurons. We have previously shown that the HSP70 heat shock gene is induced in the pyramidal neurons injured by PCP, K and MK801, that the HSP70 induction is age related, and that anti-psychoctics like haloperidol prevent the vacuoles and HSP70 induction in injured neurons (Sharpe, J. Neurosci Res, 33:605). The present study shows that ketamine also activates microglia around injured and possibly dying neurons in posterior cingulate of adult rats. This effect is dose related, the most microglia being induced at 80-100mg/Kg of ketamine. This effect was also age related, since ketamine did not induce HSP70 or activate microglia in 3, 10 and 20 day old rats, but did induce microglia in progressively older rats. Surprisingly, though haloperidol blocked hsp70 induction by ketamine, haloperidol did not block the activation of microglia in posterior cingulate produced by ketamine. The data is interpreted to mean that haloperidol blocks an injury pathway leading to induction of HSP70, but it does not block the injury pathway leading to microglial activation and possibly neuronal cell death produced by ketamine. The microglial activation and possibly cell death produced by ketamine, PCP and MK801 is not blocked by haloperidol alone, but may require multiple compounds.

A STATISTICAL MEASURE OF COOPERATIVE INTERACTIONS WITHIN CORTICAL NEURONAL GROUPS. J.D. Lamar, G. Tononi* and G.M. Edelman. The Neurosciences Institute, 3377 North Torrey Pines Court, La Jolla, CA 92037.

The neocortex of higher vertebrates is characterized by extensive functional and anatomical compartmentalization at different scales. It has been suggested that, at the scale of a few hundred neurons, the cortex is organized into dynamic and cooperative collections of strongly interconnected neurons, referred to as neuronal groups (G.M. Edelman, Neurosci. 10:115-125, 1993). Here, we investigate a dynamic criterion for the metatile partitioning of a cortical region into neuronal groups, which is based on a statistical measure of the degree of cooperative firing within a local population of neurons. This measure is the normalized third-order moment, or skewness, of the distribution of spike counts cumulated over a local set of simultaneously recorded neurons and a short time interval. The magnitude of positive skewness of the distribution is indicative of the degree of local cooperativity. We show that this skewness is sensitive to the level of coupling among the recorded neurons by means of detailed computer simulations of cortical regions. Such a measure also elucidates local cooperative interactions from firing biases due to shared inputs and, if applied repeatedly over neighboring spatial positions, it can detect statistical borders between neuronal groups. We shall also consider the relationship of a dynamic cortical partitioning of the kind discussed above to underlying factors, such as the activity-dependent changes in the distribution of synaptic strengths and the origin of the organization of axonal termines into segregated cortical patches.

Phencyclidine (PCP), ketamine (K) and MK801 are non-competitive NMDA receptor antagonists that decrease injury produced by stroke, trauma and seizures. However, these agents produce vacuoles and kill cortical neurons. We have previously shown that the HSP70 heat shock gene is induced in the pyramidal neurons injured by PCP, K and MK801, that the HSP70 induction is age related, and that anti-psychoctics like haloperidol prevent the vacuoles and HSP70 induction in injured neurons (Sharpe, J. Neurosci Res, 33:605). The present study shows that ketamine also activates microglia around injured and possibly dying neurons in posterior cingulate of adult rats. This effect is dose related, the most microglia being induced at 80-100mg/Kg of ketamine. This effect was also age related, since ketamine did not induce HSP70 or activate microglia in 3, 10 and 20 day old rats, but did induce microglia in progressively older rats. Surprisingly, though haloperidol blocked hsp70 induction by ketamine, haloperidol did not block the activation of microglia in posterior cingulate produced by ketamine. The data is interpreted to mean that haloperidol blocks an injury pathway leading to induction of HSP70, but it does not block the injury pathway leading to microglial activation and possibly neuronal cell death produced by ketamine. The microglial activation and possibly cell death produced by ketamine, PCP and MK801 is not blocked by haloperidol alone, but may require multiple compounds.

This study examined infiltration of hematogenous cells after occlusion of the middle cerebral artery in rats. Cryostat sections of the infarcts were stained immunocytochemically for CD4, a pan-T cell marker, lymphocyte subsets CD4 and CD8, and ED1, a marker for macrophages. Besides granulocytes, numerous CD5+ T cells were rare, while CD8+ cytotoxic/suppressor lymphocytes were abundant. Moreover, CD8+ lymphocytes greatly outnumbered CD5+ T cells indicating the presence of CD8+/CD5+ natural killer lymphocytes. ED1+ macrophages appeared on day 1 and were still present on day 30. As an early event ICAM-1 was upregulated on cerebral vessels. This study shows that ischemic lesions can lead to lymphocytic infiltration into the CNS. Blocking of lymphocyte-derived cytokines will help to elucidate the functional contribution of immune cells to stroke.
ISCHEMIA:

Xu, Supported FBP spectroscopy L.: H., University FRUCTOSE-1,6-BIPHOSPHATE brain, Nagafuji, 1.73 served middle levels studies). which decreased in vivo Chana, RAT and pre-treatment, there might the hypothesis that neuronal ischemic brain damage has been to be elucidated, our previous results conducted the conclusion that NO might mediate the ischemic cerebral damage. The present study aimed at not measuring neuronal expression in the ischemic brain, employing middle cerebral artery occlusion (MCAo) and reperfusion in rats. The newly developed microsensor was calibrated in NO containing solution, and the microsensor (pH) in oxygenometer (mmHg) and laser CBF flowmetry (ml/100g/min) were implanted in the L. MCA territory. A total of 20 animals were assigned into 4 hour MCAo (saline-N=5), LNA (l-Arg-tryptophan)-treated (N=3) or 2hour MCAo followed by 2hour recontruction (saline-N=5), LNA-treated (N=5). In this setting, the value obtained is not absolute NO concentration but relative to the baseline. The first peak (P1) of NO production, L73 ± 0.19μM, was found at the period of initial 20-30min MCAo. Three and a half hours later another peak was observed (P2, 553 ± 08μM). Also, P3 (0.93 ± 0.2μM) was induced by reperfusion. LNA inhibited or abolished P1-3. The present results support the hypothesis that overproduction of nitric oxide in the brain subjected to permanent and temporary ischemia might lead to the cytotoxic effects of nitric oxide in the ischemic brain.

FRUCTOSE-1,6-BIPHOSPHATE PROTECTS ATP LEVELS IN HYPOXIC NEONATAL RAT BRAIN SLICES. L. Lit*, M.T. Esparol, J. MacDonald, L. Chang, G.A. Gregory, P. R. Weinstein, T. James, and P-H. Chan.

University of California, San Francisco, California 94143

In vivo administration of fructose-1,6-biphosphatase (FBP) provides hemodynamic and metabolic protection during ischemia and hypoxia.2 However, mechanism of protection have not yet been elucidated, and, in turn, appear to not work in certain circumstances. We applied ex vivo NMR spectroscopy techniques, recently developed for studies of live rat brain tissue, to examine if there is direct metabolic protection by FBP in hypoxic (PO2<0 mm Hg) neonatal (7-14 days old Sprague Dawley) slices (350). Total acquisition time for interleaved 31P/H spectra was 5 minutes. With no pre-treatment, metabolic impairment was seen in 31P spectra obtained at 5 min of hypoxia, at which time the Lactate/NAA ratio was increased by a factor of 3. Pre-treatment with FBP decreased ATP loss and lactate production, and increased the rate of recovery during reoxygenation. Post-treatment with FBP did not protect the nearly full recovery found with pre-treatment. In this study protection comes primarily from intracellular effects in the tissue of interest, and systemic response such as calcium protection and increased blood flow. Mechanisms of FBP's protection are not understood and additional studies are needed. Hypotheses for FBP protection point to the involvement of calcium homeostasis, reduction of free-radical injury, and increased pentose phosphate pathway. INDUCTION OF PROTECTIVE MECHANISMS IN CEREBRAL ISCHEMIA 1 N. Kawahara, 2 C.A. Reutzel, 2 B.W. Wiegand, 2 S. Costioli and 1 L. Klatzow*. 1Stroke Branch, NINDS, NIH, Bethesda, MD 20892 and 2Regeneron Pharmaceuticals Inc., Tarrytown, NY 10591.

Our study is based on serendipitous finding indicating brain ischemia induced by injection of Sprague-Dawley rats, by local application of KCl. Assays on brain tissue after SD revealed that: 1. Increased c-Fos expression in the neurons of the cerebral cortex on the side of KCl application and bilaterally in the diencephal gyri; 2) No enhanced HSP-70 expression, 3) Conspicuous increase in protein synthesis measured by 3H-leucine incorporation associated with a pronounced reduction in deoxyglucose utilization, both demonstrable in ipsilateral hemisphere 3 days after SD and 4) Upregulation of mRNA for the brain-derived neurotrophic factor (BDNF), conspicuously noticeable at 4 h and 3 days after SD.

Our studies indicate that a subethal stress, such as SD, is capable of inducing a temporary state of resistance to cerebral ischemia, in which stimulation of protein synthesis and neurotrophic factors may play a significant role.

609.11
CHARACTERIZATION OF INDUCED ISCHEMIC TOLERANCE IN FOCAL CEREBRAL ISCHEMIA IN RATS. 1 R.P. Simon, 2 K. Chen, 2 R.A. Swanson* and 3 S.H. Graham. Neurology, University of California, San Francisco, CA 94143.

Background: Brief periods of non-lethal global ischemia have been reported to induce resistance against subsequent lethal ischemic injury in hippocampal neurons. We determined if a similar phenomenon occurs after focal ischemia.

Methods: Ninety-four adult Sprague-Dawley rats underwent either sham operation or brief intervals of focal ischemia by using the MCA/MCAo system. Twenty-four hours later the MCAa were isolated and the rats were subjected to 45 min ischemia. HSP70, HSP60 and HSP27 protein expression were assessed by immunoblotting. Results: Upon reperfusion the levels of these HSPs increased significantly compared to sham-operated rats.

Discussion: The induction of HSP expression during initial ischemia may play a role in protecting brain tissue during subsequent ischemic episodes.

609.12

We have demonstrated that chronic electrical stimulation of the FN of the adult rat increases cerebral blood flow (CBF) and reduces ischemic damage when cerebral blood flow is reduced by induced unilateral occlusion of the middle cerebral artery. This neuroprotection is not observed in young rats. In order to understand the nature of this protection, we have studied the effects of FN stimulation on the factors that are known to influence CBF.

The results of these studies suggest that the protection observed in the adult rat is due to an increase in the production of HSPs, which play a role in protecting brain tissue during ischemic episodes.

NEUROTROPIC FACTORS: EXPRESSION AND REGULATION VII

610.1
NGF-HIGH-EXPRESSING TRANSGENIC MICE CONTAIN INCREASED NUMBER OF PGP 9.5-IMMUNOREACTIVE FIBERS IN THE VOMERINOASAL ORGAN. 1 S. Takam*1, M.J. Getchell 2, 2 K. Albers* 2, M. Yamagishi* 2, T.Y. Getchell 2, 3, 4. Dept of Physiol., 2Sanders-Brown Ctr. on Aging, 3Div. of Otolaryngology, 4Dept of Pathology, University of Kentucky College of Medicine, Lexington, KY 40536.

The expression of protein gene product (PGP) 9.5 in extrinsic nerve fibers of the vomeronasal organ (VNO)-neighboring respiratory epithelium (RE), and the associated glands of the nasal cavity, is regulated by the expression of the NGF nerve growth factor (NGF)-high-expressing 6-week-old transgenic mice that contain the gene isolated from the 14-fold NGF-expressed rats. Increased density of extrinsic PGP 9.5-immunoreactive (IR) fibers was observed in the VNO-RE, and the glands of the transgenic mice. The soft palate, whiter pad tongue and nasal mucosa of the mice, which were used as positive controls, all demonstrated a marked increase in the density of extrinsic PGP 9.5-IR nerve fibers. The expression of transgenic PGP 9.5-IR nerve fibers were significantly greater in the VNO-RE (12.8 X control, P<0.01) and RE (3.5 X control, P<0.01) of the transgenic mice. Similar expression was observed in the VNO-RE and RE, these cells in the transgenic mice presumably contain the NGF transgene, resulting in continuous production and secretion of NGF, which induced significant hyperinnervation of the VNO-RE and RE. This hypothesis is supported by the fact that basal cells in the epithelia of positive tissue controls of transgenic mice express both K14 and NGF.

Supported by NIH grants DC-01595 (TVG) and DC-01715 (MLG).

610.2
MECHANICAL INJURY INCREASES bFGF AND CNF EXPRESSION IN THE RAT RETINA. 1 Rong Wen, 2 Ying Song, 3 Michael T. Mathes, 1 Douglas Yauamura, 2 George D. Yancopoulos, 4 Matthew L. LaVail, 5 and Ron J. Steinberg*. 1Dept. of Physiology, Ophthamology, and Anatomy, UCSF, San Francisco, CA 94143, and 2Regeneron Pharmaceuticals Inc., Tarrytown, NY 10591.

It has been shown that mechanical injury to the retina prevents photoreceptors from degenerating in the RCS rat with an inherited retinal degeneration, and in the light afferent field, which indicates that mechanical injury activates intrinsic retinal mechanisms that promote photoreceptor survival. To find out if factors that show neurotrophic activity are involved in injury-induced photoreceptor survival, we assessed the expression of bFGF, CNF, BDNF, and IGF-1 following mechanical injury. The retina was injured by making an incision through the choroidal blood vessel, that penetrated the subretinal space of each eye of an adult Sprague-Dawley rat. Control animals were without injury. Retinas were taken 0.5, 1, 2, 4, 7, or 10 days post-injury. Northern blot analysis showed marked increased mRNA of bFGF following injury. Compared to controls, expression of bFGF increased by more than 6-fold at 12 h post-injury; peaked at 2 days post-injury (more than 7-fold); and was still at a 5-fold level at 10 days post-injury. Expression of CNF increased more than 2-fold at 1 day post-injury; peaked at 4 days post-injury (about 5-fold); and was still at a 2-fold elevation 10 days post-injury. In situ hybridization showed that both bFGF and CNF were expressed in the inner nuclear layer and were more concentrated around the outer boundary. BDNF and IGF-1 did not show significant changes in expression levels of both bFGF and CNF up-regulate in the retina following mechanical injury, with the bFGF effect being earlier and greater than that of CNF. We conclude that these two factors are likely to be involved in injury-induced photoreceptor rescue.

610.3

CDF/LIF mRNA INCREASES FOLLOWING CORTICAL INJURY. N. N. Mouyei, L. R. Banner* and P. H. Patterson. Biology Division, California Institute of Technology, Pasadena, CA 91125.

The neurotrophic cytokine cholinergic differentiation factor/leukemia inhibitory factor (CDF/LIF), can act both as a trophic factor, enhancing neuronal survival, and as a differentiation factor to alter neuronal gene expression. CDF/LIF also plays a role in the response of adult neural tissue to injury. When peripheral nerves are transected, CDF/LIF mRNA is dramatically up-regulated near the site of injury (Banner & Patterson). Moreover, the neuronal response to nerve section is much reduced in LIF knockout mice (Rao et al., Neuron 11:1175, 93).

To test whether CDF/LIF expression is regulated in a similar manner after injury in the CNS, surgical lesions were made in adult rat cortex. Using a quantitative RNase protection assay, we find that CDF/LIF mRNA increases significantly relative to the contralateral cortex and to anesthesia-treated controls. The increase in CDF/LIF expression begins within 6 h after injury and reaches a peak at 24 h. CDF/LIF mRNA expression returns to baseline values by 7 days post-injury. Thus, this cytokine is likely to play a role in the response to adult brain injury as it dose in the periphery.

610.5

It has been shown before that several species that peripheral glial cells express receptors for nerve growth factor during development as well as following nerve injury. The functional significance of these glial receptors in the biology of NGF is not well understood. Since embryonic glial cells as well as glial cells in lesioned peripheral nerves also express NGF mRNA, we have explored whether NGF would affect NGF (neurotrophin) secretion by these cells.

Glial cells purified by a rapid procedure from chicken embryonic sensory ganglia were cultured in the presence of various concentrations of NGF. After two days conditioned media (CM) were harvested and assayed for the presence of neurotrophic activity in a single neuron bioassay. Anti-NGF antibodies were employed to probe for NGF in the CM.

Glial cells cultured without NGF were found to secrete neurite growth promoting activity which was not inhibited by antibodies against NGF. However, if the glial cultures were spinkled with very low concentrations of NGF (≤2pM), NGF-like activity in the medium rose dramatically (up to 50 fold). This was not observed, if NGF had been added to the glial cultures at 50 times higher concentrations.

It is concluded that the availability of neurotrophins during development may not only be regulated by the target of innervation but also by glial cells which appear to have the capacity to sense lines of NGF and respond in an autocrine fashion, finely tuned to the NGF concentrations present extracellularly. An autocrine function of glial NGF receptors can be expected to be of critical importance for morphogenetic effects of nerve development and in nerve regeneration. NERVE GROWTH FACTOR REGULATES THE EXPRESSION AND KINASE ACTIVITY OF p32cdc2 AND p34cdc2. K. J. Buchkovitch* and E. Ziff. New York University Medical Center and Howard Hughes Medical Institute, 550 First Avenue, New York, NY 10016.

Nerve growth factor (NGF) promotes the survival and differentiation of the pheochromocytoma cell line PC12. The function of NGF as both a survival and differentiation factor may be related to its ability to regulate PC12 cell cycle progression. NGF treatment of PC12 cells leads to a decrease in the percentage of cells in the DNA synthesis phase (S phase) of the cell cycle and an accompanying increase in G2 phase cells. We have investigated the mechanism by which NGF regulates PC12 cell cycling. Specifically, we have analyzed the regulation of two cyclin-dependent kinases, p33cdc2 and p34cdc2, which are required for progression through the G1/S and G2/M cell cycle transitions of the cell cycle. NGF treatment lead to a decrease in the steady state levels of p32cdc2 and p34cdc2, p32cdc2 and p34cdc2 form complexes with regulatory molecules known as cyclins. NGF treatments resulted in decreases in the kinase activity of several cyclins p32cdc2 and cyclin p34cdc2 complexes. The decreases in kinase activity could be attributed in part to the decreases in the steady state levels of p32cdc2 and p34cdc2. The timing of the down regulation of the kinases was dependent on the level of p140Raf NGF receptor in the cells. A clonal cell line that overexpressed p140Raf and differentiated with accelerated kinetics (BL Hempstead et al, 1992) also down-regulated the kinases with accelerated kinetics. This suggested that the rate of the decrease in p32cdc2 and p34cdc2 kinase activity was dependent on the level of p140Raf receptors and the strength of the NGF signal.

610.8

S-100 protein is a protein that is expressed in the neuron and glial cells of the nervous system. Previous studies have shown that it is synthesized in rat brain in response to NGF treatment, and that it is not synthesized in response to BDNF treatment. However, the current study shows that S-100 protein is synthesized in response to NGF treatment in human brain tissue. In fact, the current study shows that the levels of S-100 protein are increased in response to NGF treatment in human brain tissue. The current study also shows that the levels of S-100 protein are increased in response to NGF treatment in human brain tissue.

We report that both NGF-2 and IL-18 regulate the S-100 gene in astrocytes from the cerebral cortex, hippocampus, and hypothalamus. Total RNA was isolated from cultures, purified, and subjected to the solution hybridization assay using highly specific antagonists for rat S-100 and rat cyclinB, an internal standard which is not regulated by either NGF-2 or IL-18. We find that S-100 mRNA levels decrease 2- to 3-fold relative to controls in response to 24 or 48 hours of treatment with either 10 ng/ml NGF-2 or 10 U/ml IL-18 alone, and decrease 5- to 10-fold in response to combination treatment at the same doses over the longer term. Interestingly, in the presence of NGF-2, increases S-100 gene expression two-fold over control levels in cerebral cortical astrocytes. Furthermore, a similar time-course and at the same doses, we find that only NGF-2 suppressed S-100 mRNA levels in 24 and 48 h of treatment with NGF-2 has no effect on gene expression. These data demonstrate that both NGF-2 and IL-18 regulate astrocyte S-100 mRNA levels, which may be an important mechanism through which these factors modulate neuron-glia interactions.
61.0.9 CHARACTERIZATION OF NEUROTROPHIN-3 IMMUNEACTIVE SENSORY NEURONS IN RAT DORSAL ROOT GANGLIA

X.F. Zhou, C. Chen and R.A. Rush, Department of Human Physiology, University of Nebraska, Lincoln.

Neurotrophin-3 (NT-3) is a member of the NGF family known to support survival of sensory neurons in vitro but its physiological roles are not known. We recently reported, using a newly generated antibody, that a subpopulation of rat sensory neurons contained NT-3 like immunoreactivity (R. Zhou & Rush, 1993, Brain Res. 621, 189-199). In the present paper, we have identified NT-3-like immunoreactivity to be localized primarily in large sensory neurons. These NT-3-positive neurons were detected in cervical (56% of total) and lumbar (38%) but not in thoracic dorsal root ganglia (DRG; 18%).

61.0.10 REGULATION OF NEUROTROPHIN-3 BY BRAIN DERIVED NEUROTROPHIC FACTOR IN HYPOTHALAMIC MOTOR NEURONS.

R.A. Rush*, X.F. Zhou and D. Greenson, Department of Physiology, University of Arizona, Tucson, AZ 85724.

Identification of the cellular location of the neurotrophins has so far proved difficult, primarily due to the long half-lives and poor tissue specificity for techniques for neurotrophin immunohistochemistry. Recently we have generated antisera to peptide sequences of neurotrophin-3 (NT-3) which have proved useful for immunohistochemistry (Zhou and Rush, Brain Research, 621:188-199,1993). Purified antibodies from this serum show no cross-reactivity with nerve growth factor (NGF) or brain derived neurotrophic factor (BDNF). Within the brain the only fiber that is confined to motor neurons, consistent with in situ hybridization studies for mRNANT-3. We now show that unilateral lesion of the hypogasalus nerve leads to the loss of NT-3-immunoreactivity (IR) from the ipsilateral hypogasal nuclear mass. This is accomplished by a reduction of cholergic agent/transporter-IR (CHAT), but an up-regulation of both low affinity nerve growth factor receptor (LNGFR) and choline acetyltransferase activity. However, application of BDNF to the lesioned nerve leads to restoration of the NT-3-IR and Chat-IR, but does not reverse the up-regulated LNGFR or cholinergic activity. Our findings support the view that BDNF can regulate the synthesis of NT3 via a specific intracellular pathway, thereby providing a mechanism by which neuronal connectivity can be controlled.

61.1.1 HUMAN DELTA OPIOID RECEPTOR: CLONING, EXPRESSION AND PHARMACOLOGICAL CHARACTERIZATION.

University of Arizona Dep. of Pharmacology, Tucson, AZ 85724.

Antisense oligos selective for δ opioid receptor have fewer side effects than ligands selectively acting at μ or κ opioid receptors. Recently, we cloned a human δ opioid receptor for exclusive characterization in ligand requirements. The cloning was based on hybridization screening of several human cDNA libraries. The probe was obtained by FCR from the mouse δ opioid receptor cDNA and hybridized to a clone in a human stomach cDNA library that lacked the 5' end of the ORF. The probe obtained from this clone was used to identify the clone from human temporal cortex cDNA library that contained the missing upstream part of the ORF but ended before the termination codon. These two clones were ligated together using HindIII in E.coli present in the overlapping cDNA region. It is now shown that the ligated clones encode for the same receptor using southern blot analysis of human genomic DNA. Two probes, one present in δ opioid receptor cDNA clone and second obtained from 3' end of human striatum cDNA clone, gave a band of the same size (about 4.6 kb) while hybridizing to human genomic DNA digested with BamHI. The receptor is localized in the human temporal cortex and hippocampus. These observations indicate that the human δ opioid receptor is a homologous sequence.

61.1.2 6-OPIOD RECEPTOR IMMUNEACTIVITY: RELATIONSHIP TO BIOMIC ANENMMES AND ENKEPHALIN IN RAT SPINAL CORD AND BRAIN STEM.

Department of Anatomy and Neurobiology, University of Pennsylvania, Philadelphia, PA 19104.

During the development of neurotransmitter systems of the central nervous system, there is a close correlation between the localization of receptors, transporters and the synthesis of neurotransmitters. Utilizing an antisense oligo to synthesize a delta opioid receptor (OPRD), we have been able to generate antibodies specific to the receptor. In the present study, we have used OPRD antisense oligos to probe for the presence of OPRD mRNA in the rodent nervous system. The results of these studies, demonstrate a close correlation between the presence of OPRD mRNA and the presence of a specific opioid receptor. These results suggest that the delta opioid receptor is a potential target for the modulation of opioid receptor function in the nervous system.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
611.3 CELLULAR LOCALIZATION OF A \( \mu \) OPIOID RECEPTOR (MOR) IN RAT BRAIN AND SPINAL CORD. 1. A. Arvidson1*, M. Redl1, J. H. Lee1, A. Nakada2, D. J. Dove2, S. Chakrabarti2, H. Li1, B. P. Lass2, L. Y. Wu, M. W. Wessendorf1 and R. Eide1. 1Dept. Cell Biology and Neuroanatomy and 2Dept. Pharmacology, University of Minnesota, Minneapolis, MN 55455; 3Dept. Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN 46222.

The \( \mu \) opioid receptor (MOR) was localized by immunohistochemistry using antisera raised against a synthetic peptide corresponding to the C-terminal of the predicted amino acid sequence for the \( \mu \) opioid receptor. The MOR antisera immunoprecipitated I-125 \( \beta \)-endorphin cross-linked membrane proteins with mw's of 55-69 kDa that had been isolated from a cell line stably expressing \( \mu \) opioid receptor cDNA. Protein of similar mw were labeled by MOR antisera using Western blots. In addition, the MOR antisera stained cells transfected with native and epitope-tagged \( \mu \) opioid receptors. MOR-like immunoreactivity was frequently observed in neuronal membranes, both in the somatic and dendritic domains. However, in some areas such as in the dorsal horn, axon labeling could also be demonstrated. In the brain MOR-like immunoreactivity showed an excellent correlation with the distribution of mRNA encoding MOR, and also with earlier \( \mu \) opioid receptor binding studies. The distribution of enkephalin, the putative endogenous ligand for this receptor, showed a distribution complementary to that of MOR in many areas in the brain and spinal cord. However, double-labeling was not observed. These findings suggest that the CNS \( \mu \) MOR receptors are expressed in somatic and dendritic membranes, however, neurons also exist that transport MOR to the axon terminal. Supported by NIDA.

611.5 CELLULAR DISTRIBUTION OF \( \mu \), \( \delta \) AND \( \kappa \) OPIOID RECEPTOR mRNA'S IN HUMAN CNS. B. Anton1*, K. Mori1, M. Huh1, D. K. Kaufman1, E. Stickle2, T. Mauro1, T. Tran1, and C. J. Evans, Dept. of Pharmacology and the Neurology Branch of the National Institute of Neurological Disorders and Stroke, Los Angeles Ca 90024, and Dept. of Pathology, Veterans Administration Hospital, Little Rock, Arkansas.

The cloning and sequence analysis of cDNAs encoding \( \mu \), \( \delta \) and \( \kappa \) opioid receptor classes have allowed generation of specific nucleic acid probes to be used in experiments to correlate mRNA expression to the anatomical localization of cells expressing these opioid receptor classes in both mouse and rat brain. We have recently isolated genomic clones encoding the human \( \mu \), \( \delta \) and \( \kappa \) opioid receptors. Sequence information derived from these clones allowed us to generate specific cDNA probes to examine the expression patterns of these receptors within the human brain. We have also been able to detect the expression of \( \mu \), \( \delta \) and \( \kappa \) opioid receptor mRNAs in human tissue. Cerebrospinal fluid containing the three opioid receptor transcripts were found in the major human cerebral folia allowing distinct laminar and expression patterns within the 6 cortical layers. Cells containing the \( \mu \), \( \delta \) and \( \kappa \) mRNA sequence specific distribution were detected whereas cells containing \( \kappa \) mRNA seem to be localized predominantly in clusters, suggesting a possible patch-like distribution for this latter opioid receptor subtype in human caudate-putamen. Co-labeling experiments coupling opioid receptor in situ hybridization to choline acetyltransferase (ChAT) immunochemistry to explore preferential patch-matrix distribution of opioid receptors in human caudate-putamen are currently in progress as is the anatomical mapping of other human brain regions. Supported by a NIDA grant #DA05010 and the W.M. Keck Foundation.

611.6 KAPPA-OPIOID RECEPTOR AGONISTS SUPPRESS VOLTAGE-ACTIVATED POTASSIUM CURRENT IN CATHA CELLS. S.C. Baraban, E.W. Deitch, P.G. Gigante, and E. Friedman, Dept. of Pharmacology and Neurology, University of Virginia, Charlottesville, VA 22908.

The CATHa cell line is derived from tyrosine hydroxylase (TH)-positive tumors in transgenic mice. CATHa cells have a high density of \( \delta \) and \( \kappa \) opioid receptors (Suri et al, J. Neurosci. 13:1280, 1993). In this study we examined the opioid sensitivity of CATHa cells using whole-cell voltage-clamp techniques. Depolarizing commands to mid-membrane potential (holding potential +60 mV) produced sustained outward current (I_o). External tetraethylammonium (25 mM) reduced I_o by 40-60% (n=10). Depolarizing steps following a hyperpolarizing pre-pulse (-110 mV) elicited fast, transient outward current (I_t). I_t was selectively blocked by 3-aminopropionic acid (10 mM; n=5). Intracellular dialysis with TEA (25 mM) and CaCl_2 (150 mM) blocked voltage-activated potassium currents (n=5).

Phenyl (0.5-100 \( \mu \)M) reduced I_o, in a concentration dependent manner (EC_50 = 3.5 \( \mu \)M, max. inh. = 55%, n=30). Naloxone (10 \( \mu \)M) blocked the inhibitory effect of 10 \( \mu \)M morphine (n=8). The \( \mu \)-specific agonist DAGO (2.5 \( \mu \)M; n=6) and the \( \kappa \)-specific agonist DPDPE (2.5 \( \mu \)M; n=7) produced no effect. USO,488 (0.3-50 \( \mu \)M) and specific, reduced I_o in a concentration-dependent manner (EC_50 = 3.5 \( \mu \)M, max. inh. = 46%, n=8). The \( \kappa \)-specific agonist receptor antagonist RU-5,698 (10 \( \mu \)M) blocked the inhibitory effect of 10 \( \mu \)M morphine (n=5) or 10 \( \mu \)M USO,488 (n=7). Kappa-receptor mediated current reduction was prevented by intracellular dialysis with an inactive form of GDP (GDP-\( \beta \)-5 100-200 \( \mu \)M, 3.5-5 min, n=10). Incubation with perisotia tola (PTX; 500 ng/ml; 24 hr; n=10) did not couple kappa-opioid induced suppression of I_o. These results suggest that opioid suppression of I_o in CATHa cells is mediated by a kappa opioid receptor coupled to a PTX-insensitive G-protein.

Opiate Receptor Structure/Function Relationships and Molecular Modeling

Christopher K. Surratt*; Peter S. Johnson**; Akatsuki Morishita; Brian K. Sedlack; Carrie J. Blanchard; Jiu-Ben Wang; Luca C. Vahabzadeh and George R. Uhde*  

*Molecular Neurobiology Branch, Office of the Director, Intramural Research Program/NINDA, National Institutes of Health; **Scripps Research Institute, La Jolla, CA, USA

Opioid receptor cDNAs encode poorly conserved N- and C-terminal regions and conserved, charged transmembrane domain residues. Deletion of 64 N-terminal amino acids yields a receptor that binds DAMGO and reduces the affinity of DAMGO and other agonists. The complete receptor was expressed in Chinese hamster ovary cells and was purified by affinity chromatography. The purified receptor was tested in a radioligand binding assay and was shown to have high affinity for DAMGO and other opioids. The results suggest that the N- and C-terminal regions of the opioid receptor play a role in the binding of ligands and in the regulation of receptor activity.

CONSTRUCTION, EXPRESSION AND CHARACTERIZATION OF EPITOPE-TAGGED OPIOID RECEPTORS R.L. Zastawny Sr., S.R. George, R. Brown; Uribena; and B.F. O'Dowd  

Department of Pharmacology, University of Toronto, Toronto, Ontario, CANADA M5S 1A8

We have previously reported the cloning, pharmacological characterization and synthesis of a new opioid receptor antagonist, ET-743, which was found to be a potent and selective antagonist of the mu, kappa and delta opioid receptors. In the present study, we have used the cDNA expression system to express the ET-743 epitope-tagged receptor in COS-7 cells. The receptor was expressed and purified as a GST-fusion protein and was shown to have the same pharmacological properties as the wild-type receptor. The results provide a valuable tool for the study of opioid receptor function and the development of new therapeutic agents.

MORPHOLOGIC ALTERATIONS IN THE HYPOTHALAMUS OF RATS WITH OPIOID THERAPY FOR CHRONIC PAIN R. M. Rasmussen, H. Hjorth, L. B. Christiansen, and S. L. George  

Department of Pharmacology, University of Toronto, Toronto, ON, Canada

We have examined the effects of chronic opioid therapy on the morphology of the hypothalamus in rats. The results indicate that chronic opioid therapy leads to changes in the size and structure of the hypothalamic nuclei, as well as to alterations in the expression of neuropeptides and other markers of neuronal activity. These changes suggest that chronic opioid therapy may have long-term effects on the function of the hypothalamus and on the regulation of feeding and other homeostatic processes.

**611.12**

The Johns Hopkins Medical Institutions, Baltimore, MD

We have quantified the deactivation of the human brain in response to opioid administration using PET and [11C] METHYL NALTREXONE. Our results demonstrate that the deactivation of the primary motor cortex is greater in response to opioid administration than to placebo, suggesting a role for opioid receptors in the modulation of motor function.

COMPARISON OF A BRAIN PURIFIED METALLOPROTEASE WITH HUMAN CATHEPSINS G AND D: EVALUATION OF SEQUENCE SPECIFICITY USING PEPTIDE SUBSTRATES AND REGIONAL SELECTIVITY USING PURIFIED BRAIN APP I. S. Rosenberg-Reits*; A. S. Brown, D. M. Tumolo, M. A. Snyurt, and J. E. Jacobson  

Department of Central Nervous System Biological Research, Lederle Laboratories, Division of American Cyanamid, Pearl River, NY. 10965

A number of proteases have been proposed as candidates for the activity that cleaves at the amine-terminus of β-amyloid peptide (β-AP). No single protease has emerged as possessing all the required properties for β-secretase including sequence specificity, ability to cleave amyloid precursor protein (APP) appropriately, brain localization and correct sensitivity to sequence substitution. We have recently purified another candidate β-secretase, a 35-50 kDa metalloproteinase purified from monkey brain and found its activity using a synthetic peptide substrate (SEVMDKMDAEP) which flanks the N-terminal of βAP. The assay and amino acid analysis reveal that the major cleavage is between Lys and Arg. The enzyme is inhibited by EDTA, but not by EDTA. The pH optimum for this protease is 5.0-6.0, but activity is still retained at physiological pH.

We have compared three candidate proteases (catalyst D, cathepsin G, and the above metallopeptase) for their ability to cleave, in addition to SEVMDKMDAEP, a synthetic peptide substrate, dipalmitoylated Lys-Mp (1-Anilino-8-naphthalene) (Lys-Mp) which is a substrate for cathepsin G. The enzyme is inhibited by EDTA, but not by DTT or PMSF. The pH optimum for this protease is 5.0-6.0, but activity is still retained at physiological pH.

INCREASED NEUROPLASTIC CATHEPSIN D GENE EXPRESSION AND ACTIVE RELEASE OF COMPETENT PROTEASE IN ALZHEIMER DISEASE R.A. Nixon*, A. M. Casado, A. L. Scherzer, N. Kovass, L. A. Kasac-Sanderson, McLean Hospital, Harvard Medical School, Belmont, MA

We have found that activation of the tyrosinase system, evidenced by increased cathepsin gene expression and accumulation of secretory and tertiary lysosomes, is an early marker of synaptic dysfunction in Alzheimer disease (AD). We have demonstrated that cathepsin D, a 90-kDa form of the enzyme, accumulates in lysosomes of neurons in post-mortem AD brains. In addition, we have found that the expression of cathepsin D mRNA is increased in the hippocampus of AD brains compared to control brains. Our results suggest that the accumulation of cathepsin D in AD brains is mediated through a mechanism that involves the activation of the tyrosinase system.

INCREASED NEUROPLASTIC CATHEPSIN D GENE EXPRESSION AND ACTIVE RELEASE OF COMPETENT PROTEASE IN ALZHEIMER DISEASE R.A. Nixon*, A. M. Casado, A. L. Scherzer, N. Kovass, L. A. Kasac-Sanderson, McLean Hospital, Harvard Medical School, Belmont, MA

We have found that activation of the tyrosinase system, evidenced by increased cathepsin gene expression and accumulation of secretory and tertiary lysosomes, is an early marker of synaptic dysfunction in Alzheimer disease (AD). We have demonstrated that cathepsin D, a 90-kDa form of the enzyme, accumulates in lysosomes of neurons in post-mortem AD brains. In addition, we have found that the expression of cathepsin D mRNA is increased in the hippocampus of AD brains compared to control brains. Our results suggest that the accumulation of cathepsin D in AD brains is mediated through a mechanism that involves the activation of the tyrosinase system.

Alzheimer's disease (AD) is characterized by the deposition of β-amyloid protein (Aβ) in brain parenchyma and blood vessels. The formation of Aβ requires its proteolytic release from a larger molecule, the amyloid precursor protein (APP). Recently, we have purified and characterized a protease from human brain which is a candidate for an amyloidogenic APP processing enzyme. The enzyme is highly homologous to the rat metallo-
endopeptidase (MMP-9). It cleaves a carboxyl peptide ranking the N-terminus of Aβ at the Met-Asp bond and is capable of generating a 15 kDa amyloidogenic fragment from recombinant human APP in vivo.

To characterize the enzyme further, we developed monoclonal anti-
body against a 20 amino acid peptide derived from the sequence of the purified protease. These antibodies were used to characterize the tissue distribution and the cellular localization of the enzyme, using immuno-
histochemistry, immunoprecipitation and Western blots. The enzyme is present in all monkey tissues examined, with highest amounts being found in brain, testis and lung, as well as a variety of other tissues. In human brain, astrocytes were stained strongly. In human cultured cells, the metalloprotease was found in neuroblastoma and kidney cells but not in glioblastoma cells. Upon a rabbit retina/optic nerve system in vivo, we purified by equilib-
rium sucrose density gradient centrifugation three fractions containing transport vesicles. The optic nerves of APP and ApoE in the same vesicular compartments.

612.5 INTRACELLULAR AND EXTRACELLULAR ACCUMULATION OF AMYLOID Aβ PEPTIDE BY DIFFERENTIATED PC12 CELLS. Debra Burdick* and Charles G. Gilbe, Department of Molecular, Biol. and Biochem. Univ. of Calif., Irvine, CA 92717.
The mechanisms of amyloid accumulation in Alzheimer’s disease are largely unknown, but may be central to the etiology of the disease. Our previous results have demonstrated that Aβ1-42 accumulates in late endosomes, or secondary lysosomes of human fibroblasts and is resistant to degradation. We have extended these investigations to NFG-differentiated PC12 cells, and we find that while Aβ1-42 also accumulates in these cells, there are a number of differences from the results obtained with fibroblasts. Immunofluorescent confocal microscopy indicates a dual localization of the accumulated Aβ1-42, intracellular, punctate granules and aggregates of peptide at the cell surface. Unlike fibroblasts, the Aβ1-42 on the surface of PC12 cells is largely resistant to removal by trypsin. In contrast to fibroblasts, the shorter amyloidogenic peptides, Aβ1-26 and Aβ1-40, accumulate in PC12 cells but to a lesser degree than Aβ1-42. The accumulated Aβ1-42 is stable for at least 3 days while Aβ1-28 and Aβ1-40 are degraded within 90 min after exchanging the culture medium with fresh medium. The intracellular Aβ1-42 is located in a dense organelar compartment which overlaps the distribution of late endosomes and lysosomes and colocalizes with internalized horseradish peroxidase which has been targeted to lysosomes. The internalized Aβ1-42 is not sequenceable and highly aggregated, suggesting that it may be subject to modification by the cells. These results indicate the neuronal plasma membrane may sequester amyloid assembly or otherwise stabilize amyloid aggregates and suggests that a failure to degrade Aβ1-42 may be an important component of amyloid accumulation. Supported by NIH GM07311 and NS31290.

The levels of soluble Aβ amyloid peptide in biological fluids depends both on its rate of production and its rate of removal. Human neuroblastoma cells have been shown by several groups to secrete soluble Aβ. Here we show that human neuroblastoma cells also secrete a protease that degrades Aβ. Cells were metabolically labeled with [35S]Met and the labeled conditioned medium was separated from cells by filtration. The cell-free medium was then incubated on ice or at 37°C for 24 hours, and Aβ levels were measured by immunoprecipitation, electrophoresis, and phosphorimaging. Medium incubated at 37°C contained 60%-90% less Aβ than media incubated on ice. The metalloprotease inhibitors EDTA or α-phenanthroline prevented the degradation of the Aβ. Addition of EDTA or α-phenanthroline prevented the degradation of the Aβ. This proteolytic activity was a member of the metalloprotease class. Matrix metalloproteases are generally secreted as inactive zymogens that can be activated in vivo by the organonuclear compound p-aminosalicylic acid (APMA). APMA in addition prior to the incubation step resulted in a potentiation of Aβ degradation; however, degradation under these conditions was still inhibited by α-
phenanthroline and EDTA. Moreover, general inhibitors of the other major protease classes (1,4-dichloro-2-norbornanone for serine, E-64 for cysteine, and pepstatin A for aspartic) did not inhibit Aβ degradation. This pharmacology suggests that Aβ1-42 secretes a protease of the matrix metalloprotease family that degrades soluble Aβ. To the extent that cultured cells reflect processes in human brain tissue, we speculate that inefficient proteolytic removal of soluble Aβ from brain may contribute to the etiology of Alzheimer-type amyloid formation.

612.7 MOLECULAR CHARACTERIZATION OF THE APP/ALP SUPERFAMILY. W. Wasco*, D.M. Kovacs, A. Crowley, K.M. Felsenstein and R.E. Tanzi, Laboratory of Genetics and Aging, Massachusetts General Hospital, Harvard Medical School, Boston, MA and BioTrust Squibb, Wallingford, CT.

The Alzheimer-associated amyloid β-protein precursor (APP), which was first identified in 1987, is now known to be a member of an evolutionarily conserved gene family. We have identified and isolated cDNAs encoding two mammalian APP-like proteins (APL1 and APP2), and APP-like genes have also been identified in both Drosophila and C. elegans. All of these proteins show extensive amino acid and domain homologies, and like APP, the mammalian APLs have a number of alternatively transcribed forms. Interestingly, the direct comparisons of the amino acid sequence of the APP-like genes of APL1 have demonstrated that the amyloidogenic Aβ domain is not conserved in the family and is found exclusively in APP. For our current set of experiments we have established stably transfected human h4 neurogliaoma cell lines that overexpress APP, APLP1 and APLP2. These lines are being used to characterize the subcellular localization of the APL and to compare the effects that the overexpression of one member of the family may have on the expression and processing of the others. Reagents capable of indisputably distinguishing the members of the APP-like family by immunobiochemical and immunoblot analysis are currently being developed. In addition, we have compared the tissue distribution of alternatively transcribed forms of APP and the APLs. Finally, we have examined whether the APLP gene transcripts and the specific expression of APLP alternatively transcribed domains (such as the APLP2 KPI and 12 amino acid domains) are developmentally regulated.

612.8 TISSUE DISTRIBUTION, DEVELOPMENTAL EXPRESSION, AND PROCESSING OF ALP1 ISOFORMS IN MOUSE. G. Thinkanathan*, HS Slunt*, and BS Swaroop.1. Department of Pathology, Neurology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Amyloid precursor-like protein 2 (APLP2) is a member of a larger family of proteins that includes as amyloidogenic precursor protein and APP1. APLP2 pre-mRNA undergoes alternative splicing to generate mature isoforms that encode for at least four APLP2 isoforms. We have employed quantitative reverse-transcription polymerase chain reaction assays to analyze the expression of transcripts encoding various APLP2 isoforms in adult tissues and during mouse development. In parallel, the expression of specific APLP2 isoforms is being monitored with highly specific anti-APLP2 antibodies. We have also examined the metabolism of the APLP2-751 isoform in cultured mammalian cells. In transfected CHO, COS-7, and neuroblastoma N2A cells, APLP2 is modified by chondroitin sulfate (CS) glycosaminoglycans. Using site-directed mutagenesis strategies, we have identified the site for the modification of APLP2-751. We are presently characterizing the posttranslational processing of the other APLP2 isoforms.

This work was supported by grants from the U.S. Public Health Service as well as the Adler Foundation.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
612.10

Among the transmembrane glycoproteins constituting the family of APP-like proteins, APLP2 is the nearest relative of the Alzheimer B4-amyloid protein precursor (APP). We determined the complete cDNA and amino acid sequence of rat APLP2 comprising 765 residues, and compared its tissue-specific expression and alternative splicing to APP gene expression. In APP, there are three splicing events that alter the reading frame at which, as we have previously shown, the 1-APP mRNA isoforms lacking exon 15 are ubiquitously expressed in non-neuronal cells, but not in neurons (2). In APLP2, we were able to identify two alternatively spliced exons, of which the K-exon-enriched isoform is highly expressed in neurons and thus differs in its tissue-specific expression from the APP-exon encoding APP. While no equivalent to exon 8 of APP was detected in APLP2, there is another alternatively spliced exon with a highly similarly regulated expression, that is part of that APLP2 domain most divergent to APP, L-APLP2 mRNA isoforms lacking this exon represent the major part of APLP2 transcripts in non-neuronal tissues, but are only weakly expressed in neurons (3).

Because of the similar regulation of alternative splicing of exon 15 of APP and the described APLP2 insert, and because of structural similarities of the sequences and the predicted secondary structures, a functional relatedness of alternatively spliced isoforms of APP and APLP2 is suggested. Ubiquitous expression of high levels of L-APLP2 and L-APLP2 mRNA except for neurons indicates an important function in non-neuronal cells, and is remarkable since neurons are the primarily affected cells in Alzheimer’s disease.

613.1

Developmental events that shape the nervous system are often regulated by steroid hormones. During metamorphosis in the moth, Manduca sexta, when the larval nervous system is reshaped for adult function, the hormone 20-hydroxyecdysone (20-HE) controls diverse aspects of neuronal differentiation. Little is known, however, about hormonal effects on glial cells. In the antennal lobes of Manduca, glial cells are critically important because one type, the neuron-associated glial cells, forms boundaries for developing olfactory glomeruli as a result of proliferation and migration during metamorphosis. The temporal patterns of glial proliferation is similar to the pattern of changing hormone titers, suggesting a regulatory role for hormones. We have manipulated hormone titers in vivo by injecting 20-HE into the hemolymph during different stages of metamorphosis in normal animals, the glial cell number rapidly increasing. Later, after stage 6 (of 16 developmental stages), hormone treatment became less effective at enhancing proliferation; by stage 12, when 20-HE titers are near zero, there was no significant stimulation of proliferation. Thus, the ability of cells to respond to hormone is limited to the window of time when, normally, 20-HE circulates in the hemolymph. Two other glial classes, cell-body-associated glial cells and perineurial cells also proliferate in response to 20-HE. Our results indicate that glial proliferation in the brain, like neuronal survival and growth elsewhere in the nervous system, is under the control of steroid hormones during metamorphic development.

NEUROGENESIS AND SYNAPTogenesis OF THE DEVELOPING SEPTUM AND AMYGDALA IN THE BRAZILIAN OPOSSUM BRAIN. L.J. Sassevold, J. Hjalb, J. Kiiepin*, and C. D. Jacobson, Department of Veterinary Anatomy and Neurobiology, Iowa State University, Ames, IA 50011, *Department of Neurology, Harvard Medical School, Beth Israel Hospital, Boston, MA 02115.

The Brazilian opossum, Monodelphis domestica is a small marsupial whose young are born in an extremely immature state with a protracted postnatal period of neurogenesis. We have previously shown that neurogenesis in the hypothalamus continues postnatally. We have now studied postnatal development of the amygdaloid cortex, a region comprising the amygdala (Amyg), is a high proportion of labelled cells were found in the Amyg and Sp5 following postnatal injection of BrdU during the fetal period (PN) 7 or 8. The number of BrdU labelled cells decreased with increasing age of injection. No BrdU labelled cells were present in the Amyg and Sp5 following injections on PN 12 and 13 respectively. However, a few BrdU labelled cells were labelled in the lateral septum and amygdala following PN 13 injection. To correlate neurogenesis with synaptogenesis, immunohistochemical analysis of proteins associated with synaptic vesicles, synaptic membrane, and microtubule-associated proteins during development in the Sp5 and Amyg was conducted. From 1 through 9 PN the Sp5 and Amyg are lacking immunoreactivity for the synaptic vesicle-associated proteins (SVAPs) synaptophysin and synapsin I. After 10 PN, there is an increase in immunoreactivity for the SVAPs. Tau-1 (associated with axons) immunoreactivity follows a similar pattern of expression, whereas synaptopHesin-associated protein 25 immunoreactivity is not evident until after 11 PN. In contrast, immunoreactivity for map-2 (associated with dendrites) is present in the Sp5 and Amyg from 7 PN on. These results indicate that synaptogenesis begins as neurogenesis is completed in the Sp5 and Amyg of the opossum.

CELL SIZE REDUCTION DURING NORMAL SPINAL CORD DEVELOPMENT. A. Chen* and R.D. Heathcote, Department of Biological Sciences, University of Wisconsin, Box 413, Milwaukee, WI, 53201.

Regressive phenomena play as important role in the morphogenesis of the vertebrate nervous system. For example, cell death, pruning of neuronal arborizations and synapse elimination are frequently involved in the maturation of neuronal populations. During neural tube formation in the frog Xenopus laevis, average spinal cord cell body size underwent two phases of reduction. The initial phase was characterized by a corresponding increase in cell number. To determine if cell death in cell size was caused by cell division, animals were treated with a mixture of hydroxyurea and aphidicolin (HU) to block DNA synthesis and consequently cell division. The cells of spinal cords treated at the time of neural tube closure did not decrease in size. At the earliest stages treated, showing that the first phase of reduction in cell size was the result of cell division. Subsequently, a specific population of catecholaminergic spinal cord neurones underwent an additional phase of reduction. Since catecholaminergic neurones in the peripheral nervous system can divide, we tested the possibility that this second phase of reduction might also be due to cell division. Cell division was blocked by trexitin at this time, and neurones in this phase of catecholaminergic cell size continued to decrease in size, showing that the second phase of reduction in cell size was not the result of cell division. In this case cell size reduction could be caused by two phases of apoptosis of small axons and dendrites, elimination of cytoplasmic yolk droplets or cellular secretion.

Decreases in spinal cord cell size can be separated into two phases. During the first one to two postnatal weeks the decrease in cell size can be accounted for a marked decrease in the size of spinal cord cell bodies. During the subsequent one to two days, at least some differentiating cells undergo a greater than twofold decrease in size that is independent of cell division.

613.4

In adult lizard, CNS repair and regeneration processes are apparently carried out by cells originating from specific areas (i.e. sulci) of the ventricular wall. Little is known on these structures and on their embryogenesis in reptiles. We have thus begun a study on the development and differentiation of ependymal cells in Gallia galli, a lizard indigenous to the Caribbean Islands. By using EM and IHC studies we found that these cells are lined with an undifferentiated pseudostriatified columnar neuroepithelium where all cells are Vimentin positive. Between E33 and E37, Vimentin immunoreactivity decreases while GFAP appears in ependymal cells and vestiges of ependymal cells and microtubules become evident in the cytoplasm of ependymal cells. No apparent changes were observed in cell size or cell shape. We observed that glial cells begin to exhibit phenotypic differences. During this period three types of ependymal cells become distinguishable: columnar cells, subependymal cells and ependymal cells, which line the ependymal cell layer. These cells mature into radial glial cells (which in lizard is present also in adults), others into tanyctyes, like cell exhibiting microtubule rich processes. Possibly the processes of the first correspond to the GFAP rich processes while those of the latter correspond to the Glutamine synthetase rich processes. A comparison with rat ependymal development was also carried out.

Studies are now in progress aiming at identifying the factors that result in new cell multiply after CNS lesions in the adult lizard.

Although it has long been established that neocortical development occurs in a rostral to caudal direction, much less is known about the time course of events, which has not been elaborated in many species or regions of cortex. To this end we wished to establish when cells destined for specific layers of ferret somatosomatic cortex are generated. By means of the well-studied visual cortex and their association to intrinsic cortical connectivity. Timed-pregnant ferrets were injected IV with bromodeoxyuridine (BrdU) on embryonic days (E) from E22 to E38 and on postnatal days (PND) 1 and 4. Cortical tissue was collected from ferrets kits after various survival times, ranging from PND 1-60. As expected, a progressive sequence of inside-out maturation occurred in the genesis of cortical layers. Neurons labeled by BrdU migration into the ferret cortex and were found in the subplate up to PND 14. Injects of BrdU on E33-35 labeled neurons found in layer 4 in the mature cortex; and on E38 labeled neurons found in layer 2. Several features of the developing somatosomatic cortex differed from previous observations in the visual system. We observed a few neurons distinctly populating the cortex generated postnatally. Although occasional BrdU-positive cells were seen in the cortex after injections on PNDs 1 and 4, they were highly dispersed and not definitively localized in any particular layer. In addition, by PND 1, neurons residing in all cortical layers, including layer 2, were observed in the cortical plate. Therefore, experiments with fluorescent tracer reveal that many neurons are still migrating to the somatosomatic cortex during the first week after birth, elements of the laminar scaffolding are in place at PND 1. These findings confirm the notion of a rostral to caudal gradient of cell production and suggest that elements of ferret somatosomatic cortex development may occur up to a week prior to visual cortical development.

EFFECTS OF INTERLEUKINS ON NEURONAL AND OLIGODENDROGLIAL LINEAGES IN EGF-GENERATED CNS STEM CELL CULTURES: R.E. Gross*, M.F. Mehier, I. Santschi, and J.A. Kessler, Deps. of Neurology and Anatomy & Neurology, Albert Einstein College of Medicine, Bronx, NY 10461

Recent experiments have begun to demonstrate that various neurotrophic cytokines play an important role in the survival and maturation of neural stem and progenitor cells along the three neural lineages. We have previously reported that certain interleukins (IL) affect neuronal maturation of immortalized and primary neural cell lines, and in other studies, have identified cytokines for neurons in early development in vivo. Here we extend our studies of the role of ILs in neural development by investigating their effects on non-immortalized neural stem cell lines. EGF-dependent neural stem cells were generated from embryonic or adult rodent brains using a method developed by Reynolds & Weiss (1992). Neurons were dissociated, washed twice, and cultured on poly-ornithine coated coverslips in serum-free medium (SMF) with TGfβ in the presence of various ILs, followed by immunocytochemistry for markers of the three neural cell lineages. Control cultures contained a large number of map2-positive neurons and a relatively small number of myelin basic protein (MBP) - positive, highly active oligodendroglial progenitors (M2 and I1). IL-4, IL-2 and IL-12 and IFN-γ had a marked stimulatory effect on both the number and length of neuritic branches of a subset of map2-positive neurons without affecting the total number of neuron generated. Thus, certain neurotrophic cytokines may affect maturation of a set of neurons without influencing survival or proliferation. In contrast, cytokines present in the presence of cytokines contained four- to five-fold greater numbers of MBP-positive oligodendrocytes, suggesting a role for interleukins signaling through non-gp130 receptors in proliferation, survival or differentiation of cells of the oligodendroglial lineage.

613.8

Neurogenetic regulation has been extensively studied in insect brain development, including cerebellar granule and sympathetic neurons. In contrast, mechanisms governing the complex cerebral cortex in which multiple neuronal lineages, remain undefined. Do common signals regulate cortical precursors? Preliminary Adenylate Cyclase Activating Peptide (PACAP, bPP) action on other lineages, PACAP (109) inhibited cortical (bH)yamine incorporation 50%, reflecting a similar decrease in the percentage of neuroblasts entering the mitotic cycle. Inhibition was observed even in the presence of mitogenic stimulation elicited by serum, insulin, EGF and FGF. Other VIP family members, including PHI, secretin and VIP, were without effects at equimolar concentration, indicating that PACAP activity is highly specific. However, since VIP was inhibitory at higher doses (10), the peptide apparently acts via PACAP type I receptors. To begin defining mechanisms, we examined second messenger pathways: cAMP agonists, including forskolin, DI-AMP and IBMX, reproduced PACAP's effects. Further, the peptide elicited an 1.5-fold increase in cAMP.

In addition to inhibiting mitosis, the peptide increased trkB immunoreactivity by 30% and neurite outgrowth by 80%, suggesting that PACAP blockage of proliferation induced neuronal differentiation. In sum, while the PACAP ligand-receptor cAMP pathway regulates multiple precursors, effects are lineage-specific. Endogenous PACAP may play a critical role in regulating progress of cortical neuroblasts through the ontogenetic sequence.

LINEAGE OF SUBPLATE (SP) AND CORTICAL PLATE NEURONS IN FERRET STUDIED WITH AN ALKALINE PHOSPHATASE (AP) RETROVIRAL LIBRARY: C. Wahl*, I. Cepko*, C. Reid*, and L. Jiang. Neurobiology, Beth Israel Hospital, and Programs in Neuroscience and 2Biological and Biomedical Sciences, Harvard Medical School, Boston, MA 02115

Since the ferret allows analysis of early cortical development, we produced an amphotropic retroviral library that encodes AP and contains up to thousands of DNA tags for cell lineage analysis. Cortical cells were labeled by injections at E27- P0, and proceeded with immunocytochemistry and clonal analysis by polymerase chain reaction (PCR) (Wahl & Cepko, Science 255:432, 1992) at P17. As expected, early injections (E27 and E29) labeled deep layer cells, including subplate neurons, in addition to mitotic neurons (bromodeoxyuridine (bODU) and 5-bromo-2-deoxyuridine (BrDU) and IFN-γ had a marked stimulatory effect on both the number and length of neuritic branches of a subset of map2-positive neurons without affecting the total number of neuron generated. Thus, certain neurotrophic cytokines may affect maturation of a set of neurons without influencing survival or proliferation. In contrast, cytokines present in the presence of cytokines contained four- to five-fold greater numbers of MBP-positive oligodendrocytes, suggesting a role for interleukins signaling through non-gp130 receptors in proliferation, survival or differentiation of cells of the oligodendroglial lineage.

PROLIFIC EXPRESSION OF A TUMOR SUPPRESSOR GENE, APC IN GLIAL CELLS: Ratan V. Bhat*, Karen J. Act and Jay M. Baraban, Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205

Tumor suppressor genes act as brakes to control excessive cellular proliferation and therefore could play a key role during development. Adenomatous Polyposis Coli (APC) gene product. (APC) is a tumor suppressor gene that is mutated in a familial type of colon cancer. In previous studies, we found high levels of APC mRNA during ON development. Immunoblot of brain extracts confirmed the presence of APC protein (310 kD). To identify the cell types expressing APC protein during development, we performed immunohistochemical and biochemical studies on brain sections from E19-P30 rats. Prominent APC staining was present in olfactory and olfactory precursors as early as E19 in the brain of E19 rat. APC immuno-staining was observed in olfactory/oligodendrocytes of cerebellar white matter in immature mouse. In the cerebellum, APC staining was seen in the Bergmann astrocytes and ciliated satellite oligodendrocytes in the granule cell layer. The high levels of APC expression in astrocytes and oligodendrocytes indicates that this tumor suppressor gene may have a role in controlling glial proliferation.
613.11 A BRAIN-SPECIFIC ACTIVATOR FOR CYCLIN-DEPENDENT KINASE 5. L.-H. Tsai* and E. Harlow, Molecular Oncology, MGH Cancer Center, Charlestown, MA 02129.

Cyclin-dependent kinase 5 (cdk5) shares about 60% identity at the amino acid level with both cdc2 and cdk2, kinases that play key roles in cell cycle progression. Despite the fact that cdk5 is similar in structure to cdk2 and cdk2, it displays properties distinct from those kinases. First, cdk5 is expressed in a tissue-specific manner, being highest in adult nervous system and low or undetectable in embryos and adults. Second, we have detected kinase activity of cdk5 only in post-mitotic cells of neuronal origin in brain. Finally, cdk5 does not form an active kinase complex with the conventional cyclins. We observed a 35 kd protein that was associated with cdk5 from primary neuron cultures containing active cdk5 kinase activity. A CDNA for p35 has recently been cloned. Expression of p35 in human cultured cells line activated both the endogenously as well as exogenously overexpressed cdk5. Coexpression of p35 with a dominant negative version of cdk5 in these cells abolished the ability of p35 to activate cdk5. Cdk5 appears to be the only member of the cdk family proteins that is readily activated by p35. Therefore, p35 serves as a specific activator for cdk5. Surprisingly, p35 displays no sequence homology to any existing cyclin molecules. Northern analyses indicated that p35 is only expressed in brain. Among the central nervous system p35 is most highly expressed in the forebrain including cerebral cortex and thalamus, and it is not detectable in the hind brain or spinal cord.

613.12 CELLULAR DISTRIBUTION OF Dlx2 mRNA IN THE DEVELOPING BASAL GANGLIA. M. Ding, L. Robel, A. James, and P. M. Vaccarino*. Child Study Center, Yale University School of Medicine, PO Box 3333, New Haven, CT 06520.

The acquisition of a morphological and functional identity of different areas of the nervous system may be regulated by specific combinations of transcription factors. In the developing mammalian nervous system, expression of a given transcription factor is often associated with expression of other transcription factors whose expression is functionally relevant to the developing area. A recent study of the basal ganglia, a region of the brain that is responsible for the control of voluntary movement, revealed that the expression of homeobox genes of the Dlx family is restricted to the basal telencephalon, the anlage of the basal ganglia. However, the exact cellular location of these genes is presently not known. Cells obtained from the ventricular layer of the basal telencephalon at the embryonic day 13.5 and grown in primary culture express Dlx1, Dlx2, Dlx3 and Dlx6, as they do in vivo. In contrast, primary cultures of cells from the dorsal telencephalon do not express the Dlx genes. The time course of expression of Dlx2, Dlx3 and Dlx6 mRNAs peaks at 3-5 days in vitro and is protracted during the entire period of neuronal differentiation and maturation. Dlx2 mRNA, identified by in situ hybridization, is localized in young neurons, immunoreactive for the microtubule-associated protein MAP1B, and, to a lesser extent, in more mature neurons, which contain MAP2 immunostaining. Nestin-positive stem cells and GFAP-containing astrocytes never expressed Dlx2 mRNA. Blocking Dlx2 gene expression by means of antisense oligonucleotides resulted in lower numbers of MAP1B- and MAP2-immunoreactive cells and in a dramatic change in the morphological characteristics of the cultures. Nestin and GFAP immunoreactivity were unchanged by the antisense Dlx2 treatment. These data suggest that the expression of genes of the Dlx family may control important characteristics of the non neuronal phenotype in the developing basal ganglia.

613.13 TREATMENT WITH BFGF INCREASES THE EXPRESSION OF Otx2, Dlx2, and Dlx5 HOMEobox GENES IN PRIMARY CULTURES OF CELLS FROM EMBRYONIC DAY 13.5 RAT TELENCEPHALON. L. Robel, M. Ding, A. James, A. Simpence, J. Leckman*, and P. M. Vaccarino. Child Study Center, Yale University School of Medicine, New Haven, Connecticut 06520 USA.

The characterization of the domains of expression of homeobox genes specifically expressed in the mammalian forebrain (Dlx1, Dlx2, Dlx3, Dlx5, Emx1, Emx2, Otx1, Otx2) led to the hypothesis of its early regionalization. So far the role of these homeobox genes in cell specification has not been clearly demonstrated. To address this question, we studied the effect of basic fibroblast growth factor (BFGF) on the expression of these homeobox genes in cultures of cells obtained from embryonic day 13.5 rat telencephalon. In this in vitro preparation, stem cells multiply and then differentiate into aspartate-, glutamate- and GABA-containing neurons as well as in glial cells. We have previously shown that BFGF treatment leads to a 3-fold increase in the number of glutamate-containing neurons. Using an RNA probe protection assay we observed an increase in the expression of Otx2, Dlx2 and Dlx5 at 3 and 5 days in vitro, corresponding with active neuronal differentiation in the cultures. There was no such increase at day 12, after completion of the neurogenesis. Otx2 is expressed in the ventricular zone from E8.5, whereas the Dlx genes are expressed in the subventricular and mantle zones within neurons (Ding et al., Neurosci. Abstr. 1994). These results suggest that Otx2 genes mediate the effects of BFGF on neuronal differentiation through a concerted expression of downstream genes, including Dlx2 and Dlx5.

613.14 THE MOLECULAR GENETICS OF NEURONAL GROWTH CHARACTERIZATION OF THE Tau α-TUBULIN PROMOTER IN DEVELOPING TRANSGENIC MICE. A. Glover, A. Speedman, J. Toms, E. Chan, and F. D. Miller. Centre for Neuronal Survival, Montreal Neurological Institute, McGill University, Montreal, Canada.

The role of the α-tubulin gene is regulated as a function of neuronal growth in both developing and mature mammalian neurons. We have generated transgenic mice carrying 1,100 nucleotides of the upstream, putative Tau 1 promoter region linked to a nuclear [γ-galactosidase reporter gene. Developmentally, expression of the transgene appears early during embryogenesis and is coincident with neurogenesis. Expression of the transgene is limited to the transgenic nervous system, and is first seen in the spinal cord, brain, trigeminal ganglia, facio-acoustic ganglia, and in the heart at E9.5, and in the retina at E12.0. This expression remains high during neuronal maturation and is subsequently downregulated following neuronal maturation, as indicated both by X-gal staining and by Western blot analysis. However, in the adult the olfactory epithelium, a region of ongoing neurogenesis, expression remains elevated. Thus, sequences exist within this promoter region which are responsible for coupling gene expression to neurogenesis and neuronal growth exist during development. We now delineate regions within this 1.1 kb fragment of the α-tubulin promoter, to see which regions are responsible for conferring tissue and developmental specificity upon the expression of the transgene.

613.15 ANALYSIS OF CIS-ELEMENTS IN THE Tau α-TUBULIN PROMOTER. D. Rogers, N. Laferreri, A. Glover, D. Brown*, F. Miller. Centre For Neuronal Survival, Montreal Neurological Institute, McGill University, Montreal, Canada. # Dept. Biology, University of Ottawa, Ottawa, Canada.

The Tau α-tubulin gene is a neuronal specific isotype of α-tubulin which is expressed as a function of neuronal growth. We have previously utilized 1 kb of 5' upstream promoter region to drive the expression of the lacZ reporter gene in transgenic mice. The pattern of expression was found to mimic the spatiotemporal expression pattern of the endogenous gene. Furthermore, we have previously demonstrated that this promoter region is capable of driving lacZ expression in P19 embryonal carcinoma cells which are induced to adopt a neuronal fate using retinoic acid. To characterize the relevant cis elements, we have developed in the developing in the expression of Tau α-tubulin, deletion mutants of the Tau α-tubulin promoter were generated. Mutant promoters were assayed for their ability to drive lacZ expression in P19 embryonal carcinoma cells which can be induced to adopt a neuronal fate using retinoic acid. The effects of deletion of specific cis-elements on expression of the reporter gene in P19 cells was determined.

613.16 BIRTHDAYS AND SURVIVAL AFTER ABDOMINAL NEUROCHEMICALLY DEFINED SUBSETS OF TRIGEMINAL GANGLION CELLS. P. A. Whiteside, C. L. Macdonald, and F. R. Hoagland. Dept. of Anatomy, Medical College of OHIO, Toledo OH 43669.

Trigeminal (V) ganglion cells with different neurochemical phenotypes have different birthdates, which are affected differently by neonatal axonal transaction. This study attempted to determine whether trigeminal ganglion cell birthdate and neurochemical phenotype were correlated and if these variables could be used to respond to neonatal axonal transaction. Immunocytochemistry, previously used to determine the birthdates of V ganglion cells recognized by antibodies directed against the retinoic acid receptor (RANK), calcitonin gene-related peptide (CGRP), substance P (SP), and those that bound the lectin Bandeiraea simplicifolia (BS-1). The percentages (normalized to equal 100%) of NF-positive ganglion cells born on E-9.0, 10.5, 12.5, 13.5, and 14.5 were 0.9%, 27.3%, 30.3%, 37.0%, 4.2%, and 0.3%, respectively. The respective values for CGRP-positive ganglion cells born on E-9.0, 10.5, 12.5, 13.5, and 14.5 were 0.2%, 2.3%, 3.9%, 51.5%, and 42.1%, respectively. Those for SP-positive neurons were 0.4%, 0.2%, 16.0%, 65.0%, and 15.4%, and those for BS-1-positive ganglion cells born on E-9.0, 10.5, 12.5, 13.5, and 14.5 were 0.1%, 2.4%, 10.9%, 7.2%, 70.9%, and 8.6%, respectively. A significant correlation was found. The percentage of CGRP-positive ganglion cells born on E-9.0 was 2.3% in the axotomy group, which was significantly lower than the percentage of CGRP-positive ganglion cells born on E-9.0 in the control group, which is 27.3%. These findings do not indicate a strong relationship between cell birthdate, phenotype, and survival after neonatal axonal damage. Supported by NS 28848 and DE 07734.
613.17 ABLATION OF CEREBELLAR ASTROCYTES IN POSTNATAL TRANSGENIC MICE Catherine L. Delaney, Michael Bremer, and Albania Mussinat Neuroscience Training Program and Dept. of Pathobiological Sciences, Univ. of Wisconsin-Madison, Madison, Wisconsin 53706

Stroke Branch, NINDS, NIH, Bethesda, Maryland 20892

To study the role of astrocytes during CNS development, a transgene was designed with the ability to ablate astrocytes in a developable manner. The transgene consists of the coding region for the herpes simplex virus thymidine kinase (hsv-tk) under the control of the human glial fibrillary acidic protein gene promoter. The hsv-tk is innocuous, but converts the antiviral agent ganciclovir (ganc) with high potency into a toxic analog that interacts with replication in proliferating cells. Treatment of transgenic mice during the first postnatal week with ganciclovir, with evaluation at 19d postnatal, revealed markedly behavioral abnormalities and ataxia; clamped their feet when suspended, and had difficulty standing upright to obtain food. Histological examination revealed disrupted astrocyte development, particularly in the cerebellum, with marked secondary effects on other cell types. Cerebellar defects included an overall reduction in size and disruption of the normally well defined cellular layers. The radial glia were disordered, and there was an apparent defective myelination. The molecular and granule cell layers were greatly reduced in size. There was marked depletion of granule cells, and Purkinje cells were ectopically distributed in the molecular layer. These effects were more severe in animals treated 1d postnatal versus treatment at 5d. These results suggest a critical role for astrocytes in cerebellar development.

The mouse genetic mutation meander tail (gene symbol mea) results in the near total ablation of granule cells in the anterior lobe of the cerebellum. How the mea gene results in granule cell reduction remains unknown. Two approaches were used to determine whether the action of the mea gene is specific to anterior lobe granule cells. First, we find by estimating granule cell number in the anterior lobe, a significantly larger (nearly 90%) reduction in granule cell number was observed in the mea mea+/- genotype compared to the mea+/- and mea+/-+/- genotypes. Second, we studied intracellular calcium in two types of interspecies murine chimera (homozygous mea mea mice compared to heterozygous controls. EGF+bFGF treatment of mea+/- to mea+/-+/- cells from meander tail embryos labeled immaturecally at 19d postnatal with a streptavidin specific mouse neuronal antigen (Mullen and Chochick, 1989). We find that both cell types are labeled by this method but only the mea+/-+/- cells were labeled with the meander tail mutation. Thus the mea mea mea+/-+/- cells are found in both the anterior and posterior lobes. Additionally, the percentage of cells that are granule cells is reduced in the cerebellar granule cell layer in anterior and posterior lobes as well as in hippocampus, olfactory bulb granule cells, and in cerebellar molecular layer interneurons. Cerebellar granule cells that are genetically meander tail are found in both anterior and posterior lobes. However, the percentage of mea cerebellar granule cells is markedly less than the percentage of mea cells found in other neuronal populations including the cerebellar molecular layer interneurons. These results suggest that while the mea gene directly affects overall granule cell survival, there are extrinsic factors that promote the survival of mea+/- granule cells in the anterior lobe. Support: NS23475 to DG.

613.20 EPIDERMAL GROWTH FACTOR (EGF), TRANSFORMING GROWTH FACTOR-alpha (TGF-alpha) AND BASIC FIBROBLAST GROWTH FACTOR (FGF) DIFFERENTIALLY INFLUENCE NEURAL PRECURSOR CELLS OF THE MOUSE EMBRYONIC MENSECEPHALON. J. Santa-Ulalia and L. Gravellano. Departamento de Biologia Molecular, Instituto de Biotechnologia, UNAM, Apdo. Postal 510-3, Cuenavaca, Morelos 62271, Mexico.

The molecules generally known as growth factors are key elements in the process of neural cell differentiation. In this report, we examined the effects of classical mitogens on neural precursor cells, by culturing mouse cells of the embryonic (13.5 days post coitum) menencephalon and treating them with EGF, TGF-a, and FGF. Neuro Growth Factor (NGF) and Transforming Growth Factor (TGF-ß) were added in the initial cultures. The results showed that EGF, TGF-a or FGF but not NGF-ß induced general proliferation of the cultured cells, followed by the formation of colonies. Colonies maintained in the presence of EGF or TGF-a produced a neurophilic factor, while the population that was treated with FGF was not. The mea+/-+/-+/- cells are found in both the anterior and posterior lobes. The percentage of cells that are granule cells is reduced in the cerebellar granule cell layer in anterior and posterior lobes as well as in hippocampus, olfactory bulb granule cells, and in cerebellar molecular layer interneurons. Cerebellar granule cells that are genetically meander tail are found in both anterior and posterior lobes. Additionally, the percentage of cells that are granule cells is reduced in the cerebellar granule cell layer in anterior and posterior lobes.

614.2 MIGRATION OF LHRR NEURONS IN OLFATORY ENSLANTS: EFFECTS OF SERUM-FREE MEDIA, TETRODOTOXIN AND DEPOLARIZATION. S. M. Fuesko* and S. Wray Lab of Neurochemistry, NINDS, NIH, Bethesda, MD 20892.

We have previously shown that embryonic mouse olfactory explants maintain large numbers of LHRR neurons which emerge and migrate away from the olfactory pit in directional tracks along a sub-layer of peripherin positive fibers. To continue our study of the mechanisms guiding the neurophilic migration of LHRR neurons, we examined the migratory properties of LHRR neurons cultured in serum-free media (SFM). We also examined whether spontaneous electrical and synaptic activity and/or depolarization play a role in the movement of LHRR neurons. Olfactory explants from E11.5 mouse embryos were cultured in SFM for 1-7 days. Immunohistochemistry stained indicated that compared to explants grown in the presence of serum, SFM had no significant effect on LHRR cell numbers (25-50% of the total LHRR population was typically maintained) or on LHRR cell migration as determined by emergence, directionality and distance that cells migrated away from the olfactory pits. Inhibition of spontaneous electrical and synaptic activity by continuous incubation with tetrodotoxin (10-5M) from day 2-7 in culture had no significant effect on either LHRR cell number or the ability of cells to migrate. Similarly, depolarization by incubation with potassium (20 mM) had no significant effect on LHRR cell migration. Therefore, we propose that interactions at the cell surface which are independent of spontaneous electrical activity and/or depolarization influence secretion from embryonic LHRR cells.
614.3  GABA and NGF INDUCE CHEMOTAXIS IN CORTICAL NEUROBLASTS. T.N. Behar*, H.T. Tran, and J.L. Barker. Lab. of Neurophysiology, NINDS, NIH, Bethesda, MD. 20892

Chemotactic and chemokinetic migration of acutely dissociated embryonic cortical neurons in serum-free defined medium from 14 to 19 day-old rat embryos (E12-E15) was analyzed in vitro using a chemotaxis chamber.

Embryonic cells migrated toward γ-amino butyric acid (GABA) beginning at E15, indicating cells generated in the ventricular zone migrate towards GABA. In contrast, NGF-induced migration was not detected until E17, suggesting cells generated in the subventricular zone respond to NGF. A modified checker-board analysis revealed that micromolar GABA exerted a chemokinetic effect on cells (increased random motility), while PM NGF and low GABA concentrations (M) were predominantly chemotactic, inducing cells to migrate along a chemotactic gradient. Immunolabeling showed that the majority (>95%) of migrating cells expressed neurofilament protein (NF) and hence, were postmitotic neurons. The chemotactic effects of GABA were mimicked by diethylbarbituric acid (DEB) and GABA mediated motility via both GABA_A and GABA_B receptor proteins. These results demonstrate that both GABA and NGF are capable of directing the migration of newly generated neurons during early cortical development.

Following their birth in olfactory placode, genodatrophins releasing hormone (GnRH) containing neurons migrate across the developing cribiform plate and form a dispersed population in the mammalian basal forebrain. To study the migration of these neurons we are utilizing a paradigm to visualize cell migration in vitro, in tissue slices that maintain the structure and contact of the nasal cavity with the forebrain. On day 15 and 16 of gestation rat embryos were dissected, and the heads were embedded in agarose and cut by Vibratome into 300 micron slices. Individual cells were randomly labelled by briefly immersing the slices in the carbocyanine dye, Dil. Cells were selected for injection sites and rates of cell movements were analyzed throughout the rostral-caudal extent of the GnRH cell migration pathway. Characteristics of cell movements differed depending upon location along the pathway. Cell movements in the nasal cavity involved fewer turns than in the basal forebrain. These studies raise the possibility that there are constraints on the ability of cells to move in selective portions of the migration pathway from the nasal cavity to the basal hypothalami. Supported by PHS grants HD05515, MR Core Grant HD-04147, and the DMR-MA.

614.6  THE VENTRALLY GENERATED "U-SHAPED" GROUP OF CHOLINERGIC CELLS IN EMBRYONIC RAT SPINAL CORD EXPRESS NADPH-DIAPHORASE AND MIGRATE DORSALLY IN VIVO AND IN VITRO. P.E. Phelps*, R.P. Barber, R. Wett, and J.E. Vaughn. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

Most neuronal migration is thought to be directed radially from the ventricular zone (VZ), but members of the "U-shaped" group of cholinergic neurons, first detected around the ventral VZ, appear to move dorsally within the spinal cord between E15 and E18. Some of these cells translocate relatively long distances to the dorsal horn, and others, only short distances to surround the central canal. Both dorsal horn and central canal cluster ChAT-immunoreactive cells co-express NADPH-diaphorase, in contrast to the dorsal horn of the "V-shaped" group that are composed of only these immature neurons. As a first step in analyzing this dorsal migration experimentally, 300-400 μm slices of E16 cervical enlargement were cultured for periods encompassing in vivo migration times. Preliminary data suggested that diaphorase-labeled cells of the "U-shaped" group had moved dorsally in a relatively histotopic pattern before differentiating. Thus, these in vitro data provide additional information that the "U-shaped" group of cells have a unique migratory pattern from the ventral VZ into the dorsal horn. Supported by NIH grant NS 18858.

614.7  CALCIUM ION INFLUXES THROUGH THE PLASMA MEMBRANE TRIGGER SPONTANEOUS INTRACELLULAR CALCIUM OSCILLATION IN MIGRATING NEURONS. H. Komuro* and P. Rakic. Section of Neurobiology, Yale University School of Medicine, New Haven, CT 06510.

Recently, we found that Ca2+ influx, regulated by a combination of voltage- and ligand-gated channels, is essential for extension of the leading process and translocation of cell soma during neuronal cell migration (Komuro & Rakic: Science 257: 806, 1992; 268: 95, 1993). Furthermore, we reported that migrating neurons exhibit transient elevation of intracellular Ca2+ (Ca2+-influx) and basal oscillation of intracellular Ca2+ (Ca2+-oscillation) (Komuro & Rakic; Soc Neurosci Abstr 19: 34; 1993). Here, we study possible cellular mechanisms underlying spontaneous intracellular Ca2+ oscillation in migrating neurons. Rectangular pieces (100-200 μm) of cerebella from 3-7 day-old CD-1 mice were placed on poly-L-lysine- and laminin-coated Petri dishes containing 1 ml serum-supplemented culture medium. After 2-3 day incubation, cells were loaded in serum-free, defined medium with 1.3 mM Fluo-3/AM for 30-60 min at 36 °C. After rinsing and an additional 1-3 h postincubation in defined culture medium, granule cell migration from microexplants was examined using confocal laser microscopy. Changes in the rate of movement of the cells and the levels of intracellular Ca2+ were directly recorded in single optical sections collected at 1-60 sec intervals for up to 70 min. Migrating granule cells exhibited unidirectional movement, and spontaneous oscillations of intracellular Ca2+ levels at a frequency of 10-20 times per hour. The duration of each elevation lasted 1-2 min; the amplitude as indicated by Fluo-3 fluorescence ranged between 5-50% of resting levels. Reduction of extracellular Ca2+ concentrations eliminated the spontaneous Ca2+-oscillation and cessation of cell movement. Furthermore, the addition of antagonists to either N-type Ca2+ or L-type Ca2+ channels abolished the frequency and amplitude of Ca2+ oscillations and decreased the rate of cell migration. These results suggest that spontaneous oscillation of intracellular Ca2+ levels may be triggered by Ca2+ influx through a combination of N-type Ca2+ channels and NMDA receptors. Furthermore, the assembly and disassembly of neuronal cytoskeletal elements associated with migration may be controlled by the periodic increase and decrease in intracellular Ca2+ levels. (Supported by NS22807)

The avian forebrain is unique in its potential for extensive repair following brain injury, from ependymal/blood vessel zones (Tubingenz) cells crossing the ventral surface of the lateral ventricle. New neurons migrate from the SA along radial glial guides neurites and then migrate into the neostriatum via the longaxon fiber. The migration of these neurons varies with the extent of injury. In the cavitary sections of both adult finch and canary brain, NG-CAM/E9 was found throughout the ventricle and its adjacent territories, but very low (less than 1%) in the control brain. In contrast, the ependymoglia and ependymal/radial fibers upon which the neurons migrated were never found to express NG-CAM/E9, in vivo or in vitro. Addition of anti-NG2 Fab to these cultures yielded a dose-dependent inhibition of neuronal outrow from the parent explant. In addition, neurons exhibited the outgrowths at the time of antibody addition exhibited process retraction, cell rounding, and in some cases, late death. Migrating neurons responded to anti-NG2 with increased cell viability in cytocinotic cultures, as viewed by laser-activated confocal microscopy. Ependymoglia generated the antibody and the migration of new neurons from the adult avian brain were blocked by the expression of NG-CAM/E9, and their adhesion to a heterologous ependymal/radial cell receptor. Furthermore, the viability of new neurons may be regulated, directly or indirectly, by NG-CAM/E9 activation-dependent, calcium-mediated signaling processes. Supported by NINDS R29NS29813, NEI-05285, The Mathers Charitable and Lookout Foundations, The Hirsch Trust and American Paralytic Association.

Luteinizing hormone-releasing hormone (LHRR) neurones originate in the epithelium of the medial olfactory pit and migrate into the brain along a migration route formed by the vomeronasal and terminal nerves. This migration route, rich in neural cell adhesion molecule (NCAM), is formed before the LHRR neurones are first detected. In 26-31 day old embryos, NCAM-immunoreactive cells were seen in the epithelium of the medial olfactory pit and emerged to form a cellular aggregate below the rostral forebrain. Antibodies to a polyclonal form of NCAM (PSA-NCAM) showed an immunoreactive staining in the basal meninges at these ages. In 41-42 day old embryos LHRR-immunoreactivity was detected in some cells among the cords of NCAM cells in the nasal meninges, just outside of the epithelium of the olfactory pit. LHRR and NCAM were not co-localized. Many more LHRR cells were seen in the ganglion terminal of the terminal nerve and along the caudal margin of the cellular aggregate below the rostral forebrain and at the basal lamina of the medial forebrain, caudal to the developing olfactory bulb. A few LHRR cells were seen in the medial basal forebrain and NCAM was present in all parts of the migration route. The PSA-NCAM, in association with LHRR cells, was seen in fasiccies in the nasal meninges, in the ganglion terminal, along the medullar margin of the cellular aggregate but not in the cellular aggregate below the rostral forebrain.

Neuropileal cells continue to migrate from the spinal cord into the periphery after neural crest emigration is completed. Cells emigrating at st. 25 differentiate into dorsal root ganglion cells and melanocytes. Do spinal cells continue to migrate away from the cord at still later stages? If so, what is the developmental fate of these cells? Migration of neuropileal cells in the spinal cord was studied in st. 29-30 chicken embryos. Cells were labeled with Dil injected into the central canal of cultured spinal segments. Labelled cells left the spinal cord through the dorsal and ventral spinal boundary, adjacent to the roof plate and through the floor plate, and migrated into the meningeal anlage. To determine where in the spinal cord were migrating, we made small injections of fluorescent dextran into the floor plate of st 29 cultured spinal segments. After 12 hours, labeled cells had migrated into the meninges. Further evidence of the fate of these cells was obtained from chimeric embryos in which quail spinal cord was transplanted into chick hosts at stage 25-26. By st 31 to P3, quail cells were present in pia, arachnoid and dura. These cells were not seen in embryos in which neuroepithelium was labeled with Dil at stage 25-27 and embryos allowed to develop for only 24 hr, suggesting that emigration of meningeal cells occurs after st 27.

These results suggest that in avian embryos, spinal cord cells emigrate through the roof plate and the floor plate and contribute to the anlage of the developing pia, arachnoid and dura surrounding the spinal cord. Supported by the NIH.

The early expression of the cholinergic phenotype in sympathetic neurones appears to be species dependent. Moreover a dual phenotype status during the noradrenergic/cholinergic transition in rodent has been electrophysiologically and biochemically immunocitochemical evidence, indicating co-expression of tyrosine-hydroxylase and choline-acetyltransferase (CHAT) in avian sympathetic neurones. We investigated dissociated cells from the superior cervical sympathetic ganglia (SCG) of piglet days 10-13 from the presence of dopamine-β-hydroxylase (DβH) and CHAT using immunocytochemical methods, in control conditions, continuous stimulation with high K+ or in coculture with splenocytes. Four types of cells were distinguished: negative cells (non-neuronal cells), DβH+ or CHAT+ positive cells, double positive cells (DβH+ & CHAT+). After 2 days in culture the ratio of CHAT+ single positive cells was 0.15 ± 0.01, indicating the predominance of the adrenergic phenotype. After 8 days in control medium the ratio increased to 0.30 ± 0.02 indicating a shift to the cholinergic phenotype. After 8 days in high K+ medium, the ratio was 0.15 ± 0.03 while coculture of the neurones with splenocytes induced a shift in the ratio to 0.41 ± 0.03. For the double positive cells, after 8 days in culture, the percentage of the DβH+ & CHAT+ cells in total neuronal cells was 8.4%, 7.4% and 17.5% in control, high K+, and co-culture with splenocytes conditions respectively. We conclude that the fetal pig neurones are predominantly adrenergic and that during a certain culture period, catecholamines and acetylcholine biosynthesis enzymes are present in the same mammal sympathetic neurones.

Genetic deletion of NCAM-100 results in a smaller olfactory bulb (OB) and morphological alteration of the subependymal layer (SEL), the latter being the source and migration pathway for OB precursor cells. The mutant mice also showed a nearly complete loss of NCAM-associated polysialic acid (PSA) that is normally expressed in these cells. The present study was intended to determine the contribution of PSA to the phenotype of the SEL. Newborn mice received an intracranial injection of endonucleaseinase N (endo N), which completely and specifically degrades PSA, and the distribution of precursor cells was examined at P1 and P7. At P1, which is prior to the appearance of the mutant phenotype in the SEL, endo N injection did not produce any morphological alterations. That is, the precursor cells tended to be positioned in caudal SEL. At P7, however, the mutant and endo N-treated animals showed the same clear perturbation: the number of OB precursor cells remaining in the caudal part of the layer increased from less than 20% to over 50%, and there was a corresponding decrease in cells that have arrived at the OB. Pulse-labeling of the SEL cells at P1 revealed an arrest in migration of cells in the caudal SEL. By contrast, there were no detectable changes in cell proliferation or death. These results provide direct evidence that the NCAM-100 mutation causes a decrease in tangential cell migration in the SEL, and that this perturbation is due to the corresponding loss of PSA.

A subpopulation of neuropileal cells in the spinal cord migrate into the periphery after neural crest emigration is complete to develop as DRG cells and melanocytes, formerly thought to be late neural crest derivatives. Could these spinal cells develop other neural crest phenotypes if they encountered the environment that earlier crest cells find? This was tested by placing the neuropileal cells into crest migratory pathways at various developmental stages. Cells from dorsal or ventral halves of st 26 quail spinal cords were dissociated and placed into chicken hosts. Approximately 100 - 200 cells were injected under the skin at the dorsolateral margin of the neural tube in st 16-19 or st 22-24 embryos. Injected embryos were allowed to develop for 2 - 10 days and quail cells were identified using a quail-specific Mab. Cells isolated from ventral spinal cord failed to migrate from the site of injection whereas dorsal cord cells did migrate. This difference may result from the fact that more cells in the dorsal cord are undifferentiated and still dividing at st 26. The final location of the dorsal cells was dependent on the developmental stage of the host. When injected into st 16-19 hosts, dorsal spinal cells migrated into sympathetic ganglia and peripheral nerves, but in st 22-24 embryos these cells migrated to DRG, peripheral nerve and skin. The migration of spinal cells to different locations at different stages parallels the sequential developmental changes of crest phenotypes.

These results show that at least some undifferentiated neuroepithelial cells in the dorsal spinal cord retain the ability to develop a variety of neural crest-like phenotypes. Their differentiation as neural crest-like cells is dependent on the temporal environment they encounter during development. Supported by the NIH and the McKnight Foundation.

Previously, we have demonstrated that cardiac selective expression of NOF in a transgenic mouse produced sympathetic hyperinnervation and hypertrophy of an unknown cell population within the base of the heart (Hassahkani et al, Soc Neurosci Abst 18:1289, 1992). To further study this cell population, we have undertaken morphological, immunocytotoxic and physiological studies. Ectopic cells prepared from the base of hearts of 3-4 week old transgenic mice were dissociated and cultured in BIBS collagen, or 10% FCS. None of these cells showed spontaneous contractile activity and did not stain with an antibody against sarcomeric actin, ruling out myogenic phenotype. In primary culture, only 0.4-2% of the population was stained for GAP-43 and vimentin. Physiological studies revealed that they were not electrically excitable that they were poorly coupled. Unitary junctional conductance of these cells were 60 pS and junctional conductances were 0.4-2 nS. After 7 DIV, a second subpopulation of cells that adopt a fibro-like morphology were detected. These cells immunostained for glialFRA and peripherin. Overall, these results indicate that these ectopic cells are likely derived from neural crest. Experiments are being carried out to evaluate whether these cells arise by abnormal migration into the developing heart or abnormal mitogenic expansion of a normal cardiac neural crest-derived cell type.
614.15 TRANSIENTLY CATECHOLAMINERGIC CELLS IN THE BOWEL OF THE FETAL RAT EXPRESS mRNA FOR THE NMDAR1 RECEPTOR. M.S. Cumming*, G.A. Burns, C. Ullberns, and K.E. Stephenson, Department of VCAPP, Washington State University, Pullman, WA 99164.

Tyrosine hydroxylase-like immunoreactivity (TH-ll) has been shown to be a transient marker for precursors of enteric neurons (Baegte, Dev Biol 141:353 '90). In this study, we sought to ascertain whether neural crest cells, destined to innervate the fetal gut, express mRNA for the NMDAR1 subtype of the glutamate receptor. Serial sections of embryonic day 12 rat tissues were initially reacted with a polyclonal TH primary antisera (Peninsula Labs), using a standard avidin-biotin immunocytochemical protocol with DAB as the chromagen. The same sections were then hybridized with a 1.4 kb NMDAR1 riboprobe, which had been transcribed in the presence of 35S-UTP. The immuno-reacted/hybridized tissues were coated with radiosensitive emulsion and incubated for 5 weeks at -70'C. Clusters of silver grains were observed over cells exhibiting TH-ll in the primitive gut. The expression of NMDAR1 mRNA by TH-reactive cells suggests a possible developmental role for this receptor, such as neuronal migration.

The microphthalmia (mi) gene encodes a novel member of the developmentally important family of basic-helix-loop-helix-zipper transcription factors. Mice with mutations in this gene may be completely white, deaf and virtually blind. These abnormalities are due to deficiencies in neural crest-derived melanocytes that populate the skin and the stria vascularis of the ear, and deficiencies in the pigment epithelium (PE) of the retina that lead to microphthalmia.

To better define the pathogenetic mechanisms leading to these abnormalities, we now study the expression of this gene during development of normal and mi mutant embryos in situ hybridization. In wild type embryos, mi expression was first found at E8.5 in the PE and E11.5 in cells surrounding the otic vesicle (OV). TRP2, a marker for melanoblasts, was expressed almost as early as mi and apparently in the same cells. While mi expression started to decrease at E12.5 in the PE and E14.5 in the OV and was barely detectable at birth, TRP2 expression remained detectable even after birth both in the PE and in the stria vascularis. In embryos homozygous for a transgenic insertion at mi, expression of mi was weak in the PE and essentially non-detectable in the OV. TRP2, however, could be detected in the PE, but not in the OV, consistent with the observation that PE cells seem to remain intact, while neural crest-derived melanoblasts of the OV apparently do not. In embryos homozygous for a single cDNA deletion in mi that does not impair the gene's expression, both mi and TRP2 gave strong signals in the PE. However, in the OV, the expression of either gene remained low and became undetectable after E13.5, again suggesting absence of melanocytes. Thus, mi may play a role in melanoblast proliferation and differentiation but not the maintenance of the differentiated melanocyte phenotype.

615.1 DENDRITIC DIFFERENTIATION OF RETINAL GANGLION CELLS IN CHICK. R.L. Snow, D.J. Stelzner* and J.A. Robson, Dept. of Anatomy and Cell Biology, SUNY HSC, Syracuse, NY 13210.

Development of dendritic morphology of chick retinal ganglion cells was investigated using retrograde transport of Dil. Label was applied to the optic nerves of embryos fixed at E4 and E14. The embryos were stored in fixative for 6-8 weeks at 37°C. Retinal wholemounts were examined using epifluorescence and confocal microscopy. Selected retinas were photocovered and drawings of labeled cells were made using a computerized microscope.

At E6 many ganglion cells are still migrating. These cells are bipolar in shape and lack dendrites. They have axons in the optic nerve and trilling processes attached to the scleral margin. By E8 rapid dendritic growth is prevalent and trilling processes retrace. This early dendritic growth is characterized by the appearance of many short spiny projections from all sides of the soma. As the cells mature most of these spiny processes appear to retract. However, a few elongated and branchy processes giving the cells a mossy appearance. Later, many of these branches disappear. As dendrites continue to mature, distinct ganglion cell morphologies become evident. Gadolinium fields differentiate first, followed by several other distinct classes. [Supported by NIH grant EY03490]
615.3 NEUROBLAST MIGRATION IN THE DEVELOPING CHICK OPTIC TECTUM VIA PERIKARYAL TRANSLATION. J.A. Robson* and R.L. Snow, Dept. of Anatomy and Cell Biology, SUNY HSC, Syracuse, NY 13210.

Migration of neuroblasts in the optic tectum was studied using immunocytochemistry and retrograde transport of Dil. The results demonstrate that early neuroblasts do not migrate along radial glial processes. Instead, they retain connections with both the ventricular and pial surfaces while growing axons and translocating their nuclei. Immunocytochemical studies using an antibody specific for postmitotic neurons (TUJ1) reveal a cohort of bipolar cells spanning the neuroepithelium during the early period of cell migration (E4-E7). In older embryos, the immunocytochemical label is limited to postmitotic neurons with no tranning processes extending to the ventricular surface. Migrating neuroblasts were retrogradely labeled by applying Dil to the lateral margin of the tectum in embryos fixed between E4-E10. 6-8 weeks later the tissue was sectioned using a vibratome and examined using fluorescent and confocal microscopy. Many retrogradely labeled cells have a bipolar shape with leading and trailing processes contacting the pial and ventricular surfaces. Axons grow from the leading processes before somata reach their final locations and prior to retraction of trailing processes. Several sections were photocovered, mounted in Epon and serially sectioned at 2μm. Reconstructions of these cells show that labeling is not transcellular. These results support the hypothesis that many neuroblasts in thin tissues migrate by translocating their somata while retaining connections with the pial and/or ventricular surfaces.

During metamorphosis of the moth, the musculature of the abdomen is reorganized. While most of the larval muscles either die or are respecified during metamorphosis, several larval intersegmental muscles are maintained in a segment-specific manner; 0 in abdominal segments 1 and 2 (A1-A2) and A7-A8, in A3, and 5 in A4-A6. These muscles are used to carry out pupal-specific behaviors. In segments A4-A6, denervation triggers regeneration of two maintained muscles, the ventral internal medial muscle (VIM) and the ventral intercalated oblique muscle (VIO). Following denervation, both the VIO and the VIM were reduced to 33% of the normal size by the end of metamorphosis. Other maintained muscles are unaffected by denervation. We compared aspects of the induced degeneration in the denervated VIO with the normal degeneration in respecified muscles. Following denervation of the VIO, dying nuclei are observed between the second and the sixth day of pupal life (P2 through P4). In response present from P2 through P4. We used the thymidine analog 5-bromoodeoxyuridine (5-BrdU) to label nuclei undergoing DNA replication. No nuclei label in the innervated VIO, while some nuclei in the denervated VIO label beginning on P4. 5-BrdU labeling also begins on P4 in respecified muscles. The external fibers in the denervated VIO degenerate, while the internal fibers remain intact. It is the degeneration of the external fibers which leads to the reduced size of the denervated muscles. Unlike respecified muscles, no new adult fibers develop.

615.7 CHICK EMBRYO PURKINJE CELL DENDRITES ARE REDUCED IN SIZE FOLLOWING CHRONIC TREATMENT WITH A NMDA RECEPTOR ANTAGONIST, NPC 12626. B. White* and M.W. Vogel, MD Psych. Res. Center, UMBAR, Baltimore, MD 21228.

The development of Purkinje cell dendrites in the chick cerebellum interacts with afferents. The role of neuronal activity in this interaction is investigated by chronically treating chick embryos with a NMDA receptor antagonist. The NPC 12626 (Glytux Pharmaceuticals) was chosen as the target for pharmacological blockade because of its importance in synaptic stabilization, and because granule and Purkinje cells are more sensitive to NMDA early in development, suggesting that NMDA receptor activation is important for cerebellar development. Chick embryos were given daily injections from E14 to E17 of the competitive NMDA receptor antagonist, NPC 12626 (Glytux Pharmaceuticals). The dosage was increased daily, with a low dose group starting at 20 mg/kg (end 100 mg/kg) and a high dose group starting at 50 mg/kg (end 200 mg/kg). Drug-treated (n=52) and control (n=19) embryos were killed on E18 (HST 43 to 44) and their brains processed for Golgi-Cox staining. Purkinje cell dendritic arbors were measured using MacMeasur (S4 Purkinje cell/cerebellum).

The NPC 12626 treatment significantly reduced embryo motility after the first injections, but motility increased to control levels during the following days. The morphology of Purkinje cell dendrites in drug-treated embryos appeared to be within the range of normal variation. Morphometric analysis showed, however, that there was a 20% reduction in the average size of Purkinje cell dendritic arbors. The results suggest that NMDA receptor activation is involved in Purkinje cell dendritic growth. Research support provided by NIH grant NS29727.

During formation of the leech excretory system, the ecotodermal bladder contacts the mesodermal nephridia. Sensory and neurosecretory innervation of each excretory system occurs by a single 5-HT neuron (NNC). The NNCs contain, and presumably release, FMRFamide at (1) the urine-forming cells, (2) the ureteric sphincter muscles and (3) central neurons (Wenning et al., J Exp. Biol. 1982). Removal of the prospective bladder cells between embryonic days 8 and 10 (E8-10) causes the nephridium to degenerate. Until E16, however, its differentiation into two types of urine-forming cells is undisturbed, whether or not the NNC has been removed as well. As seen using immunofluorescence microscopy, the NNC contacts only differentiated parts of the excretory system (Wenning et al. Roux Arch Dev Biol 202, '83). At E16, normal nephridia contact their bladders and become functional, and the NNCs sprout extensively. The nephridia lacking bladders stop growing and degenerate. The NNC projections lose their immunoreactivity in the nephridium but not at the bladder. Degeneration of the nephridium is not due to a missing influence since the ecodermal urethra with its mesodermal musculature develop normally and persist. Thus, to form a functional excretory system, the nephridia must contact the bladder. Whether a special cell or subset of bladder cells (as described for Hebdobella in Mantlindale & Shanklin, Dev Biol 125, '88) is required is not yet known.

Supported by the Deutsche Forschungsgemeinschaft (WE745/4).

615.6 DIFFERENTIAL EFFECTS OF CORTICOSTEROIDS ON NEURONAL AND GLIAL CELLS IN THE DENTATE GYRUS OF ADULT RAT HIPPOCAMPUS. B. Liao* and E.C. Armenta, Dept. of Biology, New York U., Wash. Sq, NY, NY 10003.

Corticosteroids can enter the brain and regulate cell proliferation and differentiation. The hippocampus, as a central component in the limbic system, is a major target of corticosteroids. Long-term (2 mo) adrenalectomy (LT-ADX) induces a loss of Nissl staining and 5-HT+IR in the hippocampal dentate gyrus. Short-term desametamethone (ST-DX) treatment of the LT-42D rats for 24-72 hr produces a rapid recovery of 5-HT+IR, followed by a reappearance of Nissl staining. In the present study, we further explored the neuronal and glial response to the change of corticosteroid level. Female Sprague-Dawley rats weighing 150 g were adrenalectomized and given saline to drink. Sham operated rats were given water drink. After 2 months, some of the ADX rats were given DEX (10 μl) in saline drink for 72 hr. Bromo-deoxyuridine (BrdU) (50 mg/kg BW, i.p.) was injected into all three groups of rats at 24 and 48 hr later after the start of DEX to one group of ADX rats. LT-ADX produced a loss of cabaline immunoreactive (CAβ-IR) granule cells, which included a decrease in cell number, a swelling and pale-stained cytoplasm, a decrease in the density of dendrites, and a narrower dentate molecular layer. Double immunostaining for histone showed that small nuclei without cell body were sparsely distributed within the granule cell layer. ST-DX to LT-42D rats reversed partly all of above consequences. No massive neurogenesis after LT-42D or ST-DX were observed. After LT-42D, numerous BrdU-IR cells emerged in the dentate area, which corresponded to BrdU-IR area. ST-DX did not increase the BrdU-IR cell number, but promoted the elongation of the Vm-IR cell processes.

The evidence suggests a neuronal de differentiation and astroglial proliferation after the loss of corticosteroid support (Supported by NIA P01 AG10280 to ECA).

To study the expression of the Purkinje cell layer in the frog cerebellum during metamorphosis, tadpoles of Rana pipiens were immersed in a thyroxine solution (1 part per 100 million) to accelerate the metamorphic process, and batches of tadpoles along with control animals were anesthetized and killed at 2 day intervals up to 30 days of thyroxine exposure. The brains were fixed in Bouin's fluid for 3 hours, rinsed in buffer and embedded in paraffin. Immunocytochemistry was done on Bouin's fluid fixed, paraffin embedded sections using anti-calbindin D-28K, rabbit antisera (Swant, Switzerland), biotin conjugated secondary antibody, and visualized with a peroxidase chromogen.

Purkinje cells were immunoreactive at all stages of development, although the pattern of distribution was not uniform. We also noted a distinct gap in the Purkinje cell layer at a site where a cone of cells forms in the external granular layer (egl). Since the gap is present prior to the formation of the egl, the cone may not be responsible for forming the gap, rather, the cone may form at the site where a gap already exists. In addition to Purkinje cells, a population of small cells in the curricular lobes and the dorsal part of the corpus cerebelli were also immunoreactive. Because these small cells resemble the cells involved in postmetamorphic differentiation, our earlier contention that these may represent immature Purkinje cells may not be totally accurate. While some small cells which are immunoreactive during metamorphosis may be immature Purkinje cells, others appear to be cells of the extracerebellar granular band. Immunoreactive commissural fibers in the dorsal of the molecular layer of the cerebellum may be processes of these cells. Supported by NSAA Grant AA75377.
615.9 MORPHODIFFERENTIATION OF SUPRAEPENDYMAL CELLS: THEIR INTERACTIONS AND DEVELOPMENT OF THE SUBCOMMISSURAL ORGAN

I. Herrera-Vázquez*, G. Esponosa A. Zepeda. Dept. Anatomia, Facultad de Medicina UNAM.

The subcommissural organ (SCO) differentiates between days 10 and 16 gestational development in the rat, it is probable that supraependymal cells (SEC) participate in its differentiation. In this model the SCO’s susceptibility increases to diverse factors which could produce display and induced hydrocephalus. After learning, the SEC’s ontogeny with a scanning versus neocortical involvement in the neural type SEC (Kölliker I) and fagocytosis (Kölliker II) during their apposition in the ventricular lumen, migration: now we are observing their interactions and superficial changes (probably laminin, fibronectin and adhesion) using SEM. The fagocytic SEC appear with vesicles and filaments in the ventricular surface, in adjacent zones to the proliferative neuroependym (PNE), and in the infundibular region. In the dorsal ventricular zones there appears to be less vesiculation; part of their prolagnations in the (KL) seem to be flattened other cells present an irregular discoidal shape in ventricular surface. Fibriillary elements interconnect with the PNE near the blood vessels. Interpendymal cell unions with a central clila may be prominent or in a groove like form depending on the region analyzed. SEC and ependymocytes fuse together in some cases in others, the presence of pores suggest other types of SEC communication between intra and extraventricular spaces. We will continue with immunocytochemistry identifying this interaction. Acknowledgement for support of this work is provided by the V. DeP. Anatomia and Div. Investigacion y Posgrado Fac. de Medicina UNAM.

The subependymal layer (SL) is derived from the fetal subventricular zone and in the adult rat retains developmentally regulated adhesiveness as well as immature dividing cells. This study examined the hypothesis that mitosis, growth factors, cell phenotypes, and proliferation all contribute to the subependymal layer. In particular, the subependymal layer was analyzed after the removal of the SL, at the time of injury or reattachment at the adult rat. The number of Nissl-stained cells in the SL increased 2-fold after unilateral cortical lesions. However, the number of BrdU-labeled cells in the SL of the adult rat decreased and very few BrdU-labeled cells were observed outside of the SL suggesting that mitosis and migration remained constant after resection. Therefore the increased cell number in the SL may be due to decreases in the rate of cell death after cortical injury. The growth promoting factors fibroblast growth factor (bFGF) and epidermal growth factor (EGF) were also examined after resection. Whereas a robust decrease in the expression of bFGF was observed in the SL following cortical lesions, EGF was unaffected in the subependymal layer before and after resection. Cells isolated from adult subependymal layer can express neuronal or glial phenotypes in vitro. In vivo, however, cells in the subependymal layer did not express mature neuronal (synaptophysin, neuron-specific enolase, MAP-2) or astrocytic (GFAP) phenotypes before or after lesion. Vimentin—immature astrocyte protein—positive radial glia in the medial striatum also expressed GFAP after lesion. Immunoactivity to polysialylated neural cell adhesion molecule (PSA-NCAM) increased 3-fold in the SL and medial striatum after cortical lesion. In contrast, immunoactivity to tenascin decreased transiently in the SL and medial striatum after cortical lesions. This study demonstrates that in response to cortical lesion, the adult SL is a highly plastic area with regards to cell number and adhesion molecules. Supported by PH Grant NS29230.

The present study emphasize to characterize the morphological and neurological differentiation of mesencephalic dopaminergic neurons from human embryos, derived from elective first trimester gestations. Embryonic brain tissue was taken for analyses of tyrosine hydroxylase (TH) by immunohistochemistry and Western blot, and for analyses of endogenous dopamine (DA) content using HPLC-ECD. TH was first detected immunohistochemically at 4.5 weeks of gestational age. In parasagittal sections of embryonic brainstem at this developmental stage, a small, distinct population of rounded, densely packed, TH-immunoreactive perikaryon was seen in the mesencephalic tractus. These cells were located in the middle of the margin of the ventral base plate, parallel to the ventricular zone. During the sixth to tenth gestational week, the number of TH-positive cells increased exponentially as a function of the TH-immunoreactivity. TH-positive cells migrated ventrally and somewhat rostrally, away from the ventricular marginal layer. During this period, short primary processes developed into long axonal trajectories giving rise to the nearest neocortex marginalis and the periventricular zone. At the tenth gestational week, varicose fibers were detected in most areas of the striatal anlage. To confirm the identity of TH in the embryonic tissue, as recognized by the antisera used for immunohistochemistry (Pel-Freez, USA), mesencephalic tissue of 5-10 weeks of gestation was analyzed by Western blot technique. A single band with the molecular weight of 60 kDa was detected already at 5 weeks of age. The amount of TH protein increased approximately ten-fold during these developmental stages. Mesencephalic tissue and forebrain/basal ganglia ganglia was taken for analyses of dopamine (DA) content using HPLC-ECD. DA could be detected at 5.5 weeks of gestational age in both areas and was found to increase exponentially from 7.7-5 weeks of age to reach 4.5 - 0.55 mg DA/mesencephalon and 50-75 mg DA/caudate nucleus at the end of the first trimester.

We have identified two distinct chondroitin sulfate proteoglycan (CSPG) spots in chick brain which can be differentially controlled by their immunoreactivity with S103L mAb, which recognizes an epitope in the aggrecan core protein, and HNK-1 (Kruengr et al., 1997). The expression of this CSPG is regulated both temporally and spatially throughout neuronal ontogenesis at high levels and constitutively in neuronal cultures as compared to glial cultures. In addition, astrocytes produce an abundance of CSPG with a larger core protein (>500 kDa), probably related to versican. Our lab has recently identified a mutation in the aggrecan gene in the nanomelic chick. The mutation introduces a stop codon in the translated sequence, and as a consequence a truncated core protein is synthesized which is not glycosylated or secreted in chondrocytes (Li et al., 1993). No expression of the complete S103L CSPG was found in nanomelic brain but the expression of the other brain CSPGs was not affected. Synthesis and processing of the S103L CSPG core protein as well as the functional consequences were studied in nanomelic neuronal culture. The regular order of aggregates was dramatically interrupted, with neurons often traveling in parallel. These data further support our hypothesis that the S103L CSPG functions to halt neuronal migration and together with sequence data confirm that the S103L CSPG and the core protein are products of the same gene. (HD 09402)

615.13 CLINICAL CORRELATES OF UNRATIONAL COLUMNAR ORGANIZATION OF CORTICAL AREAS IN CHILDREN WITH CHOROID PECHE FISTULA. E. Kogut*, G. A. Barver, H. Deuchow, J. J. Hoppe, J. J. Hopper, J. T. Barrett, A. Al-Saif, J. Alvarez. Mina Children's Hospital, Department of Neurosurgery, Kula, FI 8355.

Developmental pathway is a well recognized cause of chronic epilepsy and mental retardation, yet there are few studies linking specific histopathologic abnormality with potential outcome. We report the clinical findings of 18 children (12 females, 6 males aged 3 months to 15 years (mean 7.1, SD 4.7) with abnormalities of cortical neurones, migration, and organization. All had undergone focal cortical resection (hemispherectomy or multilobar 9, frontal 5, temporal 4) for medically resistant partial seizures. Tissue analysis revealed lamellar pattern of cortical cytoarchitecture, lamellar arrangement of neuronal layers, and lamellar alignment of cerebral cortical organization than the usual horizontal lamination. Oligo-axonal white matter (W-M) while white matter gliosis (W-M), ischemicentially abnormal (I-M) were recognized occasionally blemished or multinucleated cells (M-M), and variable cortical width (W-M) were also identified. Mean age of seizure onset was 1.8 years (1 month to 7 years). Mean seizure duration (M-M) were 2 years (3 months to 13 years, SD 3.4). Fourteen children experienced daily secondary generalized motor convulsions. Eleven children were developmentally delayed and 5 functionally impaired. These findings indicate that abnormal columnar cortical organization occurs in association with other abnormalities of neurones, gliosis, and neuronal organization. This aneibe, cortical cytoarchitecture correlates with early onset epilepsy, widespread epileptomorphicity, and a high frequency of developmental delay.

615.14 DEVELOPMENT OF THE NEOCORTEX OF THE MOUSE USING BrdU IMMUNOCYTOCHEMISTRY. Dr. P. Humphreys, Dr. W. Hendelmann*, and L. Long. Dept. of Pediatrics (Neurology) and Anatomy & Neurobiology, University of Ottawa, Faculty of Medicine, Ottawa, ON, Canada, K1H 8M5.

Previous studies attempting to define the time of birth of neurons destined for layers II-VI of the mouse neocortex have given conflicting results, possibly due to differences in definition of embryonic day numbers, relatively long time periods (up to 12 hours) during which cells is permits to occur, and cell-strain variation. We have timed the generation of neocortical neurons in the Paris R-3 mouse. Animals were mated over periods varying from 1.5 to 5.5 hr (average 2.5 hrs); the day of conception was considered embryonic day 0.5. Pregnant mothers were given an intraperinatal injection of 5-bromo-deoxyuridine (BrdU, 100 mg/kg) at one of six precise times: E14.0, E14.5, E15.0, E15.5, E16.0, and E16.5. Ovulations were determined by visual inspection. Pregnant mothers were sacrificed on any of the following periods: 1 P1), P9 and P22. Brains were fixed in 10% ethanol, coronally sectioned at the anterior hippocampal level, and cut into 50-80 um sections. Brains were processed with the immunoperoxidase method (deFazio et al., 1987). BrdU-labeled nuclei in the dorsolateral cortical plate (P1) or neocortex (P9, P22) were counted using an image analyzer. Analysis of data produced two general findings that neurons born at 6 injection times were concentrated predominantly in specific layers as follows: E13.0-IV-VI; E14.5-IV-V; E15.0-III-V; E15.0-III-V; E15.0-II-I; E15.0-I-II; E15.0-III. MICRÓGLIAL REACTIVITY TO METHYL-D-ASPARTATE (NMDA) INDUCED EXCITOTOXITY IN THE EARLY POSTNATAL BRAIN. L. Azevin, B. Gonzalez, B. Caamaño and A. Cuesta. Dept. of Cell Biology, Neuroanatomy and Anatomy, University Chicago, Maywood, IL 60153; and Dept. of Cell Biology and Physiology, Autonomous University of Barcelona, Barcelona, Spain.

Injections of NMDA into the early postnatal brain causes severe and rapid neuroglial loss due to the excitotoxicity of the developing brain to this excitotoxicity. This excitotoxic process has been implicated in the neuronal damage occurring after hyperactive stimulus. In the present study the time course of microglial reaction was examined in cortical areas receiving NMDA injections as well as in cortical projection areas such as the parietal cortex. Under ether anesthesia, 6-day-old rats received an injection of 500 nmol NMDA (0.26 mg/ml) into the right sensorimotor cortex. At various times ranging from 10 hours to 2 days post lesion, microglial reactivity was studied using tissue immunohistochemistry.

Microglial reaction was seen as early as 10 hours after NMDA injections. Reactive cells in the neocortex, the hippocampus, and the rostral thalamus showed an asthmatic and pseudopod-like morphology. In the cortex, the microglia responded in association with autophagically degenerating cortical elements coursing through the pons. This reaction was already seen at 10 hours post injection, it peaked at day 1 and was nearly absent by day 7.

In summary, after NMDA injection in the early postnatal brain microglial reactivity was restricted to areas showing apparent neuronal or astrocyte degeneration. This reaction was characteristic of rapid onset of severe injury.

GLIAL ACTIVITY IN WILSON'S DISEASE. S.C. Page, A.N. Kaletha, A. Chlouptkova, G. Raychov and G.W. Kreutzberg. Max Planck Institute for Psychiatry, Am Klopferspitz 18a, 8133 Martinsried, Germany, and Institute of Psychiatry and Neurology, 19 Sobelka Str, 02-957 Warsaw, Poland.

Wilson's Disease (WD) is an autonomic neurodegenerative disorder characterised by the toxic accumulation of copper in a number of organs, particularly the liver and brain. The disease affects approximately 1 in 30,000 live births. Recently the gene for WD has been mapped to chromosome 13q14. It has been suggested that the gene product, the copper transporting lysosomal protein (COP) is expressed in the liver. However, little is currently known of the mechanisms by which neuronal damage occurs in the brain tissue, notably in the basal ganglia, although histological techniques have shown that reactive glia is a feature of the disease.

This study uses post-mortem tissue from 3 patients exhibiting neurophysiological symptoms and from 9 controls. Cryosectioning and immunocytochemical studies in WD brain tissue, screening with a variety of antibodies was performed. GFAP staining was carried out on both frozen and formalin-fixed free-floating sections as a marker for astrocytic activity. Microglial cells were visualised using either EMRIA or specific HLA-DR for frozen and fixed-free floating sections respectively. An antibody against the MHC-II (HLA-DR) antigen was also employed.

GFAP staining revealed a large number of reactive astrocytes in the basal ganglia tissue, notably the putamen, in addition to the thalamus and cortex. HLA-DR immunoactivity was localised to glial cells, shown to be GFAP-positive and therefore astrocytic, in double-labeling experiments utilizing DAB as the initial chromogen and HRP as the second. HLA-DR immunoreactivity was present with high incidence in many areas of the brain, including the basal ganglia, cortex, internal capsule, and the cortex. Within these tissues, HLA-DR immunoreactivity appears to be primarily, although not exclusively, located in the white matter.

To further characterise the role of reactive glial cells in neurodegeneration in WD, current studies are examining substances that may be secreted by such cells and which subsequently lead to tissue degeneration.

TOPICAL GLUCOCORTICOID MODULATES RESPONSE TO CEREBRAL CORTICAL STAB WOUNDS. M.S. Lu, S. David Centre for Research in Neuroscience, Montreal General Hospital Research Institute, Montreal, Quebec, H3G 1A4

Penetrating injury to the CNS results in the formation of an interface (glia limits and fibrous scar) across which axons fail to regenerate. Its maturation is associated with the deposition of a basal lamina. We have examined the effect of topical steroids on the formation of this interface. Stab wounds (2 mm long and 1.5 mm deep) were made in the parietal cortex of adult rats. Immediately after lesioning animals received either 1) a topical application of halocortisone 0.1% (intact), 2) placebo treatment or 3) no treatment. Animals were perfused 3 weeks later. Cryostat sections were labelled with anti-GFP and anti-laminin antibodies and visualised by immunofluorescence. The length of laminin immunoreactivity along the lesion interface, and the number of reactive astrocytes 300 μm lateral to the lesion were quantified. Laminin deposition at the interface was diminished in the treated animals by 24% compared to controls. The place treatment effect was negligible at 2% astrocyte reactivity was decreased in both the steroid and placebo groups by 36% and 26% respectively. This reduction in astrocyte reactivity may be part be from the barrier properties of the cisterns, preventing migration of foreign material into the lesion. These results suggest that steroids could alter the formation of the interface and may have implications for axon growth across CNS lesions.

GLIAL RESPONSE IN THE RAT SEPTAL COMPLEX FOLLOWING BILATERAL LIMBIC FIBRILLATION TRANSECTION. E. Heilbeck, M. Fronicher, and T. Naumann. Institute of Anatomy, University of Freiburg, P.O. Box 111, Germany.

Lesion of the limbic-fornix leads to degenerative changes in the septal complex as well as in the hippocampal formation. In particular, many parts of the neuronal circuit take place in the septal complex, whereas the hippocampus is in the septum or the hippocampal formation. Thus, the septal complex is a very important area for the understanding of the pathophysiology of psychiatric diseases. The main target of this study was to examine the cellular response to a lesion of the septal complex using immunohistochemistry.

GLial reaction was studied in adult Sprague-Dawley rats, r, 5 weeks and 6 months following bilateral limbic-fornix transection (BF). Immunohistochemistry was carried out on vibratome sections from perfusion-fixed brains. In some animals MS neurons were pretreated by intraperitoneal injections prior to axotomy in order to document both the fate of septohippocampal neurons and glial phagocytosis ultrastructurally.

At all postlesional stages only few microglial cells were detectable immunocytochemically by using a GF. Thus, there is only limited neuronal death and glial phagocytosis is mainly limited to the lesioned area (MS). In contrast, a strong increase in GFAP and GST-β-H2 staining in the LS and hippocampus was observed already 1 week post lesion. Moreover, increase in glial staining was not restricted to areas affected by BF. The intensity of all glial markers returned to that of controls at about 6 weeks post lesion. Thus, glial reaction after BF is a wavy curve, Naumann et al. (1992) J. Comp. Neurol. 325:219-242.

GLIA: IMMUNOREACTIVITY IN TRIGEMINAL GANGLION SATELLITE CELLS AFTER TOOTH INJURY IN RATS. J.L. Stephenson and M.R. Byers* Dept of Anesthesiology, University of Washington, Seattle, Washington, 98195 USA
An increase in glial fibrillary acidic protein (GFAP) immunoreactivity (IR) is often seen in astrocytes of the central nervous system in response to a wide variety of injuries. We have investigated injury induced GFAP-IR in ganglion satellite cells, in response to graded tooth injuries. We compared GFAP-IR of trigeminal ganglion (TG) after maximal mandibular molar injury at 1,3, and 7 days after the injury, and for different degrees of injury. Fixed ganglia (4% formaldehyde) were cut in the horizontal plane at 50 microns, and reacted with a 1:1 series of rabbit antigens encircled by reactive satellite cells. The number of neurons with satellite cell reaction in each experimental category was compared to the uninjured control TG, as well as to zones within each section that did not correspond to the site of injury. We found significant increases in the total number of GFAP-IR satellite cell profiles surrounding tooth related neuronal cell bodies in the 7 day group (p=0.016). The GFAP-IR at 3 days was dramatically increased, but with a larger variance in the total number of reactive cells than at seven days. The site of GFAP reaction in the TG, shifted depending on the injury site (max or mand). Satellite cell GFAP-IR corresponded to the zone labeled by retrograde labeling of neuronal cell bodies by Dil from the molars. EM confirmed the identity of the GFAP-IR cells to be satellite cells. We conclude that a GFAP-IR satellite cell reaction is induced in trigeminal ganglia by molar injury in a specific manner at 3-7 days. Supported by NIH DE05159.

616.8
FGF RECEPTOR EXPRESSION FOLLOWING TRAUMATIC BRAIN INJURY IN RATS. J. F. Reilly and V. K. Momoh* Department of Cell Biology & Human Anatomy, School of Medicine, University of California, Davis, CA 95616
Basic fibroblast growth factor (bFGF) is thought to play a role in astrogliosis following traumatic injury to the CNS. In the present study, trauma-induced changes in the spatial and temporal expression of FGF receptor 1 (FGFR-1, fgr) were examined. A stereotaxic lesion through the hippocampus was placed in adult, male Fisher 344 rats. After survival times ranging from 1 to 30 days, brains were removed and processed for immunohistochemistry using a monoclonal antibody to FGFR-1. Quantitative image analysis was carried out to evaluate the magnitude of the changes. Cortical expression of FGFR-1 was increased adjacent to the wound cavity by day 2 post-lesion. Levels peaked at day 4 and decreased to control levels by day 10, except for reactive astrocytes immediately adjacent to the wound cavity. In the hippocampus, FGFR-1 immunoreactivity was increased on day 4, peaked at day 7, and remained elevated beyond day 10. By day 30, staining had returned to control levels except for reactive astrocytes immediately adjacent to the wound cavity. Double immunohistochemistry for FGFR-1 and GFAP demonstrated that astrocytes are expressing FGFR-1. bFGF colocalized with FGFR-1, suggesting that FGFR-1-expressing astrocytes are also expressing bFGF. These data demonstrate a time course for astrocyte expression of FGFR-1 which precedes and parallels the established time course for astrocyte hypertrophy. This suggests that endogenous bFGF may act directly on astrocytes to induce astrogliosis.

616.9
TYROSINE PHOSPHORYLATION IN RAT SPINAL CORD AFTER SCATIC NERVE TRANSSECTION. W.A. Bickler1, J.O. Velatichoff,2 C.A. Ota2, A. Renton2 and R.J. Weintraub.3 Dept. of Physiology, and 2Cell Biology & Anatomy, UNC, Chapel Hill, NC 27599, and 3Dept. of Anatomy & Cell Biology, University of Virginia, Charlottesville, VA 22908
Nerve injury produces central changes reflecting both degeneration and regeneration of nerve fibers. Release of a growth factor, likely to act via receptor tyrosine kinases, may be an important signal associated with peripheral injury. Immunocytochemistry using antibodies for phosphotyrosine was employed to identify changes in tyrosine phosphorylation in the rat spinal cord consequent to sciatic nerve injury. Increased immunostaining in the spinal gray matter, dorsal columns and gracile nucleus on the side of the lesion became evident after three days and was more pronounced with longer survival times up to three weeks (the longest survival tested). This increase was most prominent in the fourth lumbar segment (the focus of termination of sciatic nerve afferents). Immunostaining was in astroglial cells and their processes in the dorsal horn; stained microglia was also seen. Immunopositivity also increased in glial cells surrounding motoneurons at the same levels. These results in combination with other work from our laboratory suggest that some factor released by primary afferent fibers over a sustained period results in sustained kinase activation, either directly or via a cascade involving sustained synthesis and release of other factors. This kinase activation is likely to play an important role in the full development of the glial response to nerve damage.

616.10
EXPRESSION OF A NOVEL NON-ANGIOTENSIN II [125I]CGP 42112 BINDING SITE IN HEALING WOUNDS OF THE RAT BRAIN. M. Viswanathan*, A.M. de Oliveira, F.M.A. Correa, and J.M. Savidra. Sec. on Pharmacology, LCS, Bldg. 10 Room 2D-45, National Institute of Mental Health, NIH, Bethesda, MD 20892
Angiotensin II (Ang II) receptor subtypes AT1 and AT2 seem to be involved in growth and repair processes during wound healing. Our studies using the AT1 ligand [125I]CGP 42112 unexpectedly revealed, in healing brain wounds of adult rats, a binding site that is recognized by CGP 42112 and not by angiotensin II. Using quantitative autoradiography, we localized and characterized this site. [125I]CGP 42112 binding was restricted to the wound edge and the immediate periphery. Immunocytochemical localization using ED-1 monoclonal antibody raised against rat macrophages showed good correlation between the distribution of ED-1+ cells and the binding which was saturable, reversible, and stable. Saturation studies and Scatchard analysis of the data revealed a single class of binding sites with a Kd 3.8X10^-1 M and binding capacity (Bmax) of 109 fmol/mg protein. The time course of injury-induced expression of the binding in the brain lesion revealed highest levels at 3 days after injury which became undetectable after 10 days. Our results suggest that activated microglia surrounding the penetrating wound express the novel binding site and that this site may have a role in mechanisms of tissue repair in the brain.

616.11
Brain injury results in activation of glial cells, including both astrocytes and microglia, and an increase in the expression of several endogenous pro-inflammatory cytokines such as IL-15 and TNF-α. Increased expression of these cytokines has also been observed in the brains of individuals with Alzheimer's and Parkinson's disease. Previous studies indicate that astrocytes make both prostaglandins (PG) and nitric oxide (NO) in response to IL-15. To determine whether cytokines influence the expression of genes responsible for the generation of PG and NO, we performed northern blot analyses of RNA from purified primary cultures of astrocytes and microglia which had been treated with various factors. Our results indicate that PGHS-2, but not PGHS-1, mRNA is strongly induced in astrocytes exposed to recombinant IL-15 in a dose-dependent fashion. Induction is highest at 2 h, and PGHS-2 mRNA levels return to control values by 24 h. Macrophages/inducible NOS mRNA levels are also increased in astrocytes treated with IL-15, and peak at a later time point (4 to 8 h of exposure). TNF-α, LPS, and basic FGF also induce PGHS-2 in astrocytes, whereas demethylxanezone pretreatment diminishes the level of PGHS-2 induced in response to IL-15. Interestingly, PGHS-2 mRNA was not detected in cultured microglia treated with IL-15 or GM-CSF; however, PGHS-1 mRNA was present in these cells under all conditions tested. In summary, our results indicate that brain glial cells transiently increase their expression of synthetic enzymes for PG and NO in response to cytokines and suggest the elaboration of a cascade of mediators for cytokine action in the brain. 616.12
EFFECTS OF PLATINUM-RELATED CHEMOTHERAPEUTIC AGENTS SUCH AS CIPLATIN AND CARBOPLATIN ON NEUROSCIENCE ACTIVITIES OF NIH MOUSE SCHWANN CELL LINE. Y. Chagou* and R.R. Kim. Div. of Neurology, Dept. of Medicine, Univ. of British Columbia, Vancouver, BC, Canada, V6T 2B5.
Specific toxic effects of platinum-related chemotherapeutic agents such as ciplatin and carboplatin on neurons or Schwann cells have not yet been thoroughly evaluated. The NIH mouse Schwann cell line (Watabe et al., J. Neurochem Exp Neurol, 49:455, 1989) was exposed to ciplatin and carboplatin, and the survival rates were measured by MT assay. Blocking effects of NFG, ACTH, and e-MSI against platinum toxicity were also examined. Ciplatin displayed a marked cytotoxicity at concentrations higher than 1 μg/ml and carboplatin at concentrations greater than 2 μg/ml. DGF protected cell death from cytotoxic effects of ciplatin and carboplatin at the concentration of 50 μg/ml. These results suggest that ciplatin and carboplatin can induce Schwann cell damage due to platinum-induced neurotoxicity and that ciplatin is far more toxic to Schwann cells than carboplatin.
GLIA: GLIAL RESPONSE TO INJURY, TOXINS, AND DISEASE

616.13

Treatment with the anti-tumor drug cisplatin (CPl) leads to sensory neuropathy in patients, indicating that CPl affects the dorsal root ganglia (DRGs). In vitro CPl inhibition neurite outgrowth from DRGs, (2) decrease neurite length of DRG cells, and (3) reduce cell survival and neurite outgrowth to Schwann cells. As glial cells seem to be very sensitive to CPl treatment, we studied the role of these cells in neuroprotection. These studies were extended to other cell lines obtained from E15 rat DRGs and Schwann cells from P4 rat sciatic nerves. The sensory neurons were treated with 1 μg/ml CPl, which reduced neurite outgrowth with 37% (measured with fluorescence studies). After treatment of 5 μg/ml CPl with conditioned medium from glial cells or medium containing 15 ng/ml BNGF, Schwann cell CM and BNGF diminished the toxic effect on outgrowth with 60%, but satellite cell CM was not effective. These results suggest that Schwann cells and not satellite cells produce a soluble factor that protects against CPl-induced neurotoxicity. BNGF also had a potent protective effect in the peripheral nerve system. As Schwann cells are known to produce NGF, the Schwann cell derived protective factor may be NGF.

LEAD INDUCED DEVELOPMENTAL ALTERATIONS IN GLIAL GENE EXPRESSION. N. Zawia* and E. J. Bailey. Environmental Immunology & Neurobiology, Laboratory of Biochemical Risk Assessment, N.I.H.S., P.O. Box 12323, KIP, NC 27709.

Lead is a neurotoxicant that is known to produce behavioral, biochemical and structural abnormalities in brain development. We have previously shown that lead treatment leads to decreased expression of glial cells in situ of glial gene expression. The goal of this study is to examine whether these alterations in gene expression are related to regional timetables of development. To accomplish this, two brain regions with distinct prenatal (brainstem) and postnatal (cerebellum) schedules of development were chosen. Long Evans hooded rats were lesioned at low levels of lead in utero and sacrificed in the drinking water of the dam before parturition. Tissue was then obtained from the brainstem and brainstem on postnatal days (PN): 3, 6, 9, 12, 15, 20, 25, 30, 40, and 50. No changes in either brain structure and weight or animal body weight were observed in the pups following such exposure to lead. Total RNA was isolated and probed for myelin basic protein (MBP), glial fibrillary acidic protein (GFAP) and actin gene expression by Northern analysis. In the cerebellum, lead produced long term elevations in both MBP and GFAP gene expression that began on PN17.20 and were maintained into adulthood, expression levels remaining unchanged. No such shifts in the expression of these genes were observed in the brainstem. These results suggest that glial gene expression is more susceptible to the effects of lead in actively developing regions and that the state of gene expression may be permanently altered by lead.

The development of neuroanatomical projections requires a complex series of spatial and temporally regulated cell interactions. The thalamocortical pathway is established proportionally, but grows most extensively in target cortical regions postnatally. This delay may be dependent upon target maturity, as well as neuronal cells. Exposure to methylaminooxethanol (MAA) (5) kills mitotically active cells and when administered late postnatally, appears to alter thalamocortical fiber organization. We investigated the effect of MAA treatment (of MRA) when administered on either embryonic day 19, 20 or 21. Analysis of single (intraventricular) and dual (intracerebral injection of MAA) and fiber connectivites (90 labeling of thalamus) was performed at birth, postnatal day (P) 5, and P10. GFAP staining was more pronounced in reactive astrocyte-like cells in allotopic white matter and intracerebral capitol at P10. Moreover, I-E1 stained macrophages accumulated in white matter at the earliest time point examined and were still evident even at P10, almost 2 weeks after the single injection of MAA. The degree of nonneuronal cell response appeared to correlate with the disruption of the Dil-labeled thalamocortical fibers. In some brains, disrupted projections, anamalous growth cone and fiber varicosities were seen at birth. The results suggest that the MAA treatment produced an abnormal gliotic and photogenic response in the fetal brain, one which can have longlasting effects on cellular organization and developing fiber projections. AXONAL DEGENERATION CAUSES A SLIGHT INCREASE IN ASTROCYTE PROLIFERATION IN IN VIVO. G. Gispen, G. Frisch, I.A. Greven, E. Urraca, and P.M. Weller. The Miami Project and Department of Neurological Surgery, University of Miami School of Medicine, Miami, FL.

Mechanisms inducing glia in the CNS after injury are not well understood. Astrocytes (AS) proliferate and gliosis have been implicated under similar insults 2. In this study, we analyzed axonal injury on astrocyte proliferation and evaluated at various times post-injury and related to axonal degeneration and regeneration. Since the transplantation of Schwann cells (SC) into gliotic areas of the injured CNS is of therapeutic interest, we also assessed whether factors released in injured N-A-S cultures affected SC proliferation on axons. Cultures of purified embryonic rat dorsal root ganglion neurons (N) were transplanted onto AS or SC monolayers. After the neurons extended axons on the AS or SC, a fast axon was cut 1.5 mm from the neuronal cell bodies. Non-injured cultures were used as controls. To assess proliferation, the cultures were exposed to H-thymidine, 1, 3 and 7 days post-injury (DPI) and processed for autoradiography. On 1 and 2 DPI, AS proliferation was slightly increased and SC proliferation was increased to approximately the same extent. Neurofilament staining distal to the lesion disappeared more rapidly in N-A-S than in SC cultures. Eight DPI, axonal regeneration was observed, but neither AS or SC proliferation changed. In two experiments conditioned media collected from injured and non-injured N-A-S cultures decreased neurite-induced SC proliferation when compared to uninjured N-S cultures, as assessed by autoradiography. However, no difference was observed between media obtained from injured and non-injured N-S cultures. Our data demonstrate that AS proliferation in gliosis may be caused partially by factors released after axonal injury. Supported by NIH grant ST82059, NMS grant 1R01 2210-2 and The Miami Project.

Glial cells in culture express several subtypes of functional adrenergic receptors. In order to determine which receptor types are expressed for glia in vivo we examined normal, crushed, and transected optic nerves of the rabbit and rat using quantitative adrenergic receptor autoradiography. We also obtained preliminary data regarding the expression of adrenergic receptors in normal and damaged human optic nerve. High levels of α1, α2, and β receptors were seen in all the adult species examined. The level of the 1 receptor in the rabbit and rat forebrain but only α1. α2 and β receptors were observed in the normal rat and rabbit optic nerve, and were seen in low to moderate densities. Normal, as well as damaged, human optic nerve also exhibited adrenergic receptor binding limited to the 1 and β species. After unilateral optic nerve crush or transection, only 1 adrenergic receptors were increased. This increase in 1 receptors was first significant at day 7 and 28 post-injury in the rabbit and rat optic nerve, respectively. The expression of 1 receptors in the transected optic nerve continued to increase with time so that by 90 days post-injury, the density of 1 receptors in both the rabbit and rat optic nerve was among the highest in any age of the forebrain. Taken together, these data suggest that in vivo, glia α2 adrenergic receptors may provide a therapeutic target for regulation of human astrocyte functions including astrocytosis, inflammation, and the hypertrophy and proliferation that occurs in response to neuronal injury. DENERATION-INDUCED CHANGES IN ASTROCYTIC GENE EXPRESSION ARE ALTERED IN AGING MICE. P.A. Timmerman. University of Virginia, Departments of Neurology and Neuroscience, Charlottesville, VA 22908.

This study is designed to evaluate if the time course of changes in astrocytic gene expression associated with Wallerian degeneration is altered by normal aging. Denervation was induced in the dentate gyrus of adult (60-65 days) and aging (1-2 years) C57BL6 mice by a unilateral lesion of the entorhinal cortex. In situ hybridization was carried out using a radiolabeled probe for glial fibrillary acidic protein (GFAP) was used to detect changes in levels of GFAP mRNA. In adult mice, there was a peak in GFAP mRNA levels at days 2 post-lesion (DPL). GFAP mRNA levels declined at 4 DPL but did not return to control levels until about 3 weeks post-injury. In adult mice, the peak in GFAP mRNA levels was reduced in size and was delayed until 4 DPL. GFAP mRNA levels returned to near control in lesioned aging mice by 8-10 DPL. These results indicate that up-regulation of gene expression in reactive astrocytes is compromised in the CNS of aged mice. Compromised astrocytic function as a consequence of normal aging could limit the ability of astrocytes to provide the metabolic and functional support neurons in the CNS need to cope with the degeneration that characterizes pathologic conditions such as Alzheimer’s disease. Supported by the Alzheimer’s and Related Diseases Research Award Fund.
16.1.7 CALCICTON GEN-RELATED PEPTIDE IMMUNOREACTIVITY IN YOUNG MUSCULOSERON AFTW NERVE INJURY. E. M. Blake and R. G. Berk. Dep. of Anatomy & Cell Biology, University of Maryland, Baltimore, MD 21201. Changes in calcium gene-related peptide immuno-reactivity (CGRP-IR) were examined in musculoserosa of young rats after nerve injury to determine whether during postnatal development, CGRP-IR typical of adult moto-neurons was elicited by axonal injury. Hypoglossal nerve crush or transaction was performed in rats at 10, 14 or 21 days postnatal (dpp). Rats were killed by aldehyde perfusion at 1, 3, 7, 14, 20 days postoperative (dpo). Results from the 21 dpo injury cases resembled those in the adult rat. Increased CGRP-IR continued after nerve crush until regeneration was complete. After transaction, a biphasic response of CGRP-IR consisted of an early increase (1-3 dpo), a decrease to basal levels (7 dpo) and a second elevation (14-20 dpo) that persisted until regeneration occurred. No consistent increase in CGRP-IR was seen after either injury at 10 dpo and regeneration was meager and nerve cell death was substantial. The same injuries in 14 dpo rats produced intermediate changes in CGRP-IR, regeneration and cell death compared to those obtained in the 10 and 21 dpo rats. The results strengthen the idea that persistent up-regulation or down-regulation of CGRP can be used to predict successful regeneration or apoptosis of injured motorneurons.

16.1.8 ANDROGEN RECEPTOR mRNA EXPRESSION IN ADULT HAMSTER FACIAL MOTOR NEURONS (HMFN). S.M. Dziegielewski*, R. J. Handa, K.J. Jones, Dept. of Cell Biology, Neurobiology, Anatomy, Loyola University of Chicago, Maywood, IL 60153. We have previously demonstrated that systemic administration of exogenous testosterone propionate (TP) to adult hamsters enhances the rate of facial nerve regeneration following injury in both genders, with the effects significantly greater in males as compared to females. Further studies also indicate that these effects of TP occur via a mechanism involving androgen receptors (AR), which are present in both male and female HMFN. In this study, we investigated the hypothesis that the differential effects of androgens on regeneration rate in male/female HMFN are related to gender specific differences in the levels and/or regulation of AR mRNA in these populations. Four groups of male hamsters were used: intact and gonadectomized males/females. In situ hybridization was performed using an 35S-labeled antisense AR cRNA probe encoding 350 NTs of the ligand binding region. Slides were processed for routine autoradiography and quantitative analysis was performed using a computerized image analysis system. Preliminary results indicate that AR mRNA levels are increased in male HMFN when compared to females. Gender specific regulation was also noted; gonadectomy decreases AR mRNA levels in males, but not in females. Studies in progress to evaluate the interactive effects of hormonal, injury states on AR mRNA expression in HMFN. Supported by NIH grant NS28238.

16.1.9 EXPRESSION OF MICROTUBULE-ASSOCIATED PROTEINS (MAPs) IN NORMAL AND REGROWING CAT TROCHELAR MOTONEURONS. A. A. Book*, I. Fischer, and E. H. Murphy. Department of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129. While previous studies have shown that the levels of actin, tubulin, and neurofilament proteins are altered in peripheral neurons following axotomy, much less is known about the role of MAPs in axonal regeneration. In this study, we examined the expression of a variety of MAPs, by immunocytochemical methods, in both normal and neurologically denervated trochlear motoneurons (TMNs) of the cat. The trochlear nerve of each animal (n = 4) was transected where it curved between the occipital bone and inferior confluence, and animals were allowed to survive 2 weeks. Three untreated cats served as controls. Brain sections were incubated with antibodies recognizing a high molecular weight form of tau, termed HMW tau, MAP-2, MAP-3, MAP-6, and a phosphoform of MAP-2 (pMAP-2). Terminals of pMAP-2, normal control TMNs, HMW tau and MAP-2 were observed in cell bodies and processes. In contrast, MAP-2 was present specifically in dendrites while pMAP-2 was found only in axons. Following nerve transaction, the levels of HMW tau appeared to decrease in axotomized TMNs, as compared to controls in the unaxotomized nucleus of origin or control animals. MAP-2 was increased in the axons of axotomized TMNs and was also observed in some cell bodies of axotomized TMNs. The levels of MAP-2 and MAP-6 in axotomized TMNs appeared similar to controls. These results suggest a potential role for MAPs in the regeneration of peripheral nerve since their expression was specifically regulated following axotomy. (Supported by NIH Grant NS 24707).
617.7 GALANIN EXPRESSION IN SYMPTOMATIC CANCER AFTER PARTIAL AXOTOMY. A. M. Shadack, D. K. McElroy, and R. E. Zigmond. Dept of Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

One of the ways neurons of the sympathetic nervous system display plasticity after axotomy is by alteration of expression of certain neuropeptides, such as vasoactive intestinal peptide (VIP), substance P (SP), and galanin (GAL). The increase in GAL-like immunoreactivity (IR) in the superior cervical ganglion (SCG) was significantly reduced, though remaining above control levels even at 14 days (Sun et al., 1993). In the middle and inferior cervical ganglia (MCGC), the increase in IR occurs by 2 days, plateaus through day 7, and then decreases further by 14 days. An increase returning to control levels by 60 days. The further increase in GAL-IR in the MCGC between days 7 and 14 may be related to the distance between the site of axonal transection and the ganglion.

With the use of a retrograde fluorescent marker, fast blue, we have shown that GAL-IR is mainly found in axotomized neurons of the MCGC. In order to determine whether changes in GAL mRNA are also related to axotomized neurons, we performed in situ hybridization for GAL. Using fast blue applied to the cut nerve trunk to identify axotomized neurons, we observed a high degree of coincidence between GAL mRNA- and fast blue-containing cells most of which appeared in the middle cervical ganglion region.

The functions of VIP, SP, and GAL after axotomy are yet unknown. Two possible sites of action for these peptides are within the ganglion and/or at the site of transection. We have found an increase in VIP and GAL, and perhaps a small increase in SP, in the proximal portion of the nerve trunk after transection and a further increase after ligation of that transected nerve. This suggests that VIP and GAL produced in the sympathetic neurons after axotomy are transported anterogradely within their axons.

617.9 THE CLONING AND CHARACTERIZATION OF A cDNA ASSOCIATED WITH NEURODEGENERATION AND SCAR TISSUE REGENERATION IN THE RAT. M. De Leenheer, R. L. Nahid, Y. Liu, A. A. Wielcher, E. M. Shooter. and M. A. Rudell. Dept. of Physiology and Pharmacology, Loma Linda University, CA; T. Dept. of Neurobiology, Stanford University, Stanford, CA; The Brandeis and Aesculapius Branch, NIDR, NIH, Bethesda, MD.

We report the cloning and characterization of DA11, a full length cDNA clone isolated from a transgenic rat dorsal root ganglion (DRG) cDNA library. The sciatic nerve of Sprague Dawley rats was crushed and allowed to regenerate. At three days after the crush the ipsilateral DRG were pooled together and the total RNA extracted. The RNA was purified through an oligo (dT) cellfree column, and 5g of RNA was used to construct a cDNA library (DA). The DA library was screened twice by differential hybridization (De Leenheer et al., J. Neurosci. Res. 29:437-448, 1991) and the cDNAs found to be elevated after sciatic nerve crush were analyzed. Prehybridization of the library library confirmed the isolation of a 0.6 kb DA11 cDNA clone whose expression was found to be induced after nerve crush. DNA sequencing and analysis of this clone revealed that the DA11 cDNA contained a single open reading frame that coded for a protein of a calculated molecular weight of about 15 kD. Northern blot analysis showed that the DA11 cDNA recognizes a single ~0.6 kb mRNA species that showed a three-fold induction in the DRG ipsilateral to the sciatic nerve crush, and increased to the contralateral DRG. The 0.6 kb DA11 mRNA was detected in total RNA extracted from the lung, heart, brain, sciatic nerve and spinal cord tissue, but the highest level was found in RNA extracted from rat DRG. The relative levels of DA11 mRNA did not change in the sciatic nerve during Wallerian degeneration. The DA11 mRNA was also higher in the cerebral cortex during the first two weeks after birth and it was significantly induced in P12 cell line cells after treatment with nerve growth factor. Our data support the hypothesis that the DA11 mRNA may play a role during sciatic nerve regeneration and cerebral cortex post-natal development.

The development of an animal model greatly affects outcome following CNS injury. For example, peripheral nerve transection in neonates elicits profound neurodegeneration in adult animals. We have previously reported that the expression of type I pro-collagen is significantly lower in adult animals, suggesting that these animals may have a mechanism for controlling the underlying molecular mechanisms governing recovery following peripheral nerve injury. The following study utilizes a transgenic approach to examine the effects of transcriptionally regulated, chemically altered, or deleted transgenes on the transcriptional cell lineages undergong degeneration, regeneration, plastic reorganization, and transient repair. This approach utilizes the c-fos-lacz or c-jun-lacz mouse lines, the left telibial and peroneal nerves were transected and a 2mm piece removed in either PO or adult subjects. Animals were allowed to recover for 2 hrs, 1, 2, 5, 14, or 28 days post-injury. Both fos and jun were transversely induced in spinal cord dorsal horn. In addition, fos and jun were upregulated in spinal cord dorsal horn. At 2 h post-injury, the gene expression of c-fos-lacz or c-jun-lacz in the spinal cord dorsal horn was significantly increased in both tissues. The level of c-fos-lacz or c-jun-lacz expression was significantly lower in adults than in neonates. These results suggest that jun is post-translationally regulated in adult and not in neonates. Luminogenic expression of the luciferase reporter was seen in the proximal stump of the injured nerve and was observed during transection into dorsal root fibers supplying the sensory neurons. These observations suggest that thymosin B10 plays an essential role in axonal growth during development, regeneration and in synaptogenesis.

617.12 INDUCTION OF THYMOSIN B10-LACZ TRANSGENE IN REGENERATING MOTOR NERVE AXONS IN THE PERIPHERAL NERVE INJURY. J. C. Chen, M. Butler, J. W. Worbarter* and J. L. Morgan. Roche Institute of Molecular Biology, Roche Research Center, Nutley, NJ.

In an attempt to identify molecular markers for regeneration, we found a progenitor cell marker used by thymosin B10-LacZ to reproducibly express in the developing and regenerating segmental nervous system. Its expression levels reach a maximum around the region of axonal outgrowth and decline sharply after birth. Biochemically, thymosin B10 has been shown to be a pro-thymosin protein. A previously developed model of thymosin B10 was cloned and used to generate transgenic mice that carry a thymosin B10-LacZ transgene. Th-LacZ is first detected atembryonic day 8.5 in the nervous system. During late neuroembryogenesis, its expression is widely distributed in the developing nervous system, including retina, cerebellum, and dorsal root ganglion neurones and ganglion. In the adult, high levels of thymosin B10-LacZ expression are restricted to neurones that have elevated synaptic remodeling. In addition to its synaptic expression in the neuronal cell body, thymosin B10-LacZ-fused protein is also detected in dendrites and axons.

The expression of thymosin B10-LacZ was monitored following peripheral nerve injury. Five days after facial nerve transection, an induction of thymosin B10-LacZ was observed in motor neurons in the ipsilateral facial nucleus. The expression remained elevated for several weeks during regeneration. Induction of thymosin B10-LacZ in the spinal motor neurons of L4 & 5 was also detected following sciatic nerve transection. Increased blue staining in axons in the proximal stump of the injured nerve was observed and extended into dorsal root fibers supplying the sensory neurons. These observations suggest that thymosin B10-LacZ plays an essential role in axonal growth during development, regeneration and in synaptic remodeling.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
617.13 DIFFERENTIAL DISPLAY PCR IDENTIFIES CHANGES IN GENE EXPRESSION FOLLOWING RAT FEMORAL NERVE LESION IN THE CORTICAL REGIONS OF THE MOLECRULAR BRAIN. J. A. Archibald, B. L. Robinson, and E. J. Madison. Depts. of 1.Med. and 2.Neurology, Duke University Medical Center, and Research Services, P.V. Hosp., Durham, NC and 3.Neurology, Duke University Medical Center (RDM). The femoral nerve divides into a terminal sensory branch (saphenous nerve) and a terminal motor branch to the quadriceps muscle. Motor axons preferentially regenerate into the terminal motor branch following nerve transection and repair proximal to the terminal bifurcation, even when the distal nerve branches are completely isolated from their end organs (Bhushan, J. Neurosci. 13 (5): 2752-2768 1993). To identify factors present in the denervated pathways which may underlie preferential motor reinnervation, we are starting to analyze lesion induced changes in mRNA expression using differential display PCR. (Liang and Pardee, Science, 227, 897-911, 1992). Total RNA was extracted from terminal motor and sensory branches from control nerves or nerves which had been transected and prevented from regenerating for two weeks. Subsets of the expressed mRNAs were reverse transcribed with an anchored dT3 primer, and amplified with PCR using end labeled random 10-mers. PCR products were separated by PAGE. Most labeled bands representing expressed mRNAs were similar between lesioned and control motor or sensory branches. Several bands were present only in lesioned motor or lesioned sensory branches, representing potential mRNAs which are expressed only under denervated conditions. Differentially expressed bands will be sequenced to determine the utility of this approach in identifying mRNAs that are up- or down-regulated following nerve transection. NS24040-09 (RDM) and VA Merit Review (RDM).

617.14 BDNF LEVELS INCREASE IN THE TERMINAL MOTOR BRANCH FOLLOWING LESIONS OF THE PARENT FEMORAL NERVE: A COMPARATIVE STUDY IN M. MURRABY, M. P. Raposa, J. A. Archibald, and E. J. Madison. Depts. of 1.Neurology (Neurosurgery), 2.Neurobiology, Duke University Medical Center, and Research Services, P.V. Hosp., Durham, NC and 3.Med. (RDM). A 273 bp fragment of mature BDNF (nt 2573-2846) was amplified from rat muscle RNA and cloned into the pGCRi vector (InVitrogen). An unrelated Hae III digested fragment of pGCRi (-100nts) was ligated into the Sal I site within the BDNF fragment (at position 2287) which was verified by DNA sequencing and used to make sense riboprobe. Increasing concentrations of riboprobe were then used to reprobe reverse transcriptase reactions of total RNA harvested from lesioned and non-lesioned terminal motor branch of the rat femoral nerve. The amount of radioactive label present in each band was determined by exposure of the gel to a Phosphorimager. Total counts were then used to construct a standard curve relating concentration of spiked cRNA to target RNA. In previous studies using ribonuclease protection assays Funakoshi et al. (Cell Biol. 1993: 123: 455-465) levels of BDNF were barely detectable in normal sciatic nerve. In our competitive PCR assays BDNF is easily detectable in normal sciatic nerve or normal motor nerve but is present at approximately 10-fold lower concentrations compared to muscle. The amount of BDNF in two week lesioned nerve increases 10-30 fold in the motor branch of the femoral nerve (terminal branch to the quadriceps muscle) as compared to unlesioned nerve. Experiments are currently underway to determine BDNF levels in the other terminal branch of the femoral nerve which is pure sensory. Supported by NS24040-09 (RDM) and VA Merit Review (RDM).

617.15 CONSTITUTIVE HEAT-SHOCK-70 mRNA IS INDUCED IN RESPONSE TO FACIAL NERVE AXOTOMY. M. M. Raposa, E. J. Madison, C.A. Head, and G.N. Kreutzberg. Dept. of Neurobiology, Max-Planck-Institut fuer Psychiatrie, Martinsried, and 1.Anatomical Inst. 1, University of Freiburg, Freiburg. We have shown previously that constitutive heat-shock-protein 70 (hsp70) is increased in the regenerating facial nucleus. In this study, we extended these findings and examined if hsp70 mRNA would be induced in the facial nucleus following peripheral nerve lesion. The transection was done in Wistar rats at the level of the stylo-mastoid foramen and animals were sacrificed 6h, 12h, 24h or 3d later. Facial nuclei from operated and sham operated rats were extracted and prepared for Northern blot analysis using a cDNA probe complimentary to constitutive hsp70 mRNA. Autoradiograms revealed a single band (ca. 2.5 Kbp) which appeared to be maximally induced in 24h following axotomy, as compared to controls. Preliminary results at 3 days post-lesion indicate that relative levels declined but remain elevated over time. The time course of hsp70 mRNA induction is consistent to that previously reported for constitutive hsp70 protein, where maximal protein levels were observed at 3 days post-axotomy and were maintained elevated thereafter. These results indicate that peripheral nerve lesion induces hsp70 mRNA. Further, these data suggest for a role of hsp70 in the early phase and long-term maintenance of the regeneration program of motorneurons.

617.16 EXPRESSION OF NITRIC OXIDE SYNTHETASE (NOS) IN MOTOR NEURONS AFTER AXOTOMY. A. G. L. Smith, R. S. Treadway, R. A. Neary, R. M. Zuniga, G. P. Rudge, and J. B. McQuarle. Inst. 1.Biol. & 2.Anat., City Univ. of New York Med. Sch., NY, NY 10031 and 3.Bio-Chem. Inst. of Hong Kong, Hong Kong. NOS, an enzyme for the synthesis of nitric oxide, becomes detectable in anterior horn cells following facial nerve lesion, and in motor neurons of cranial nerves after nerve avulsion. Since anterior horn cells died after axotomy, and inhibition of NOS reduced neuron death, it was postulated that NOS expression signals the impending death of injured cells. However, extensive studies have been made only when cranial nerves were cut at young age, and few cranial nerve axons have been expressed after Aplysia age when compared with axotomy at adults. We hypothesise that expression of NOS in anterior horn cells is involved in neuronal response to injury. In this study, we examined the time course of NOS expression in cranial nerve motor neurons. 2 weeks after axotomy, adult, female rats received either unilateral axotomy or transection of one of the cranial nerves. Animals were killed at 1 and 3 days, 1, 2, 3 and 6 wks post-operation (PO). Thirty-micron thick coronal sections cut through the brain stem were processed for RADPH-diaphorase reaction for NOS. Changes of RADPH diaphorase reaction were observed 3 days PO in the two motor nuclei ipsilateral to axotomy. In the vagus nucleus, increases in the number of NOS positive neurons and intensity of labelling persisted 6 wks PO. In the hypoglossal nucleus, the number of NOS neurons reached maximally 3 days and 2 wks, and declined 4 and 6 wks after crush and transection, respectively. These data suggest that NOS was expressed in cranial motor neurons in a time course which could be correlated with axon regeneration, consistent with the hypothesis that expression of NOS is involved in neuronal response to injury, possibly regulated by axon regeneration. 617.17 LONG-TERM CHANGES IN HEMEOPHIL AFTER PERIPHERAL NERVE INJURY. J. P. Swerts, N. Madure, L. Cambonie, M. J. Guignaud, J. Smith* and P. Courbard. Centre de Biologie du Developpement, U.M.R. 9925 C.N.R.S. Univ. P. Sabatier, Toulouse. France. Analysis of molecular environments that allow nerve repair has revealed the presence of hemeprotein in cut rat peripheral nerves and the dramatic increase in the level of this glycoprotein after nerve transection (Swerts et al., J. Biol. Chem., 267, 10596-10600). Although it is a soluble protein, hemeprotein is colocalized in the nerve with extracellular matrix proteins. Moreover, hemeprotein synthesis has been detected within the nerve itself; thus this plasma protein can no longer be considered as a liver-specific product. In the present study, we have documented long term changes in hemeprotein levels in permanently degenerated (transected) and regenerating (crushed) sciatic nerves, using western-blotting and immunohistochemical techniques. In both transected and crushed nerves, there was a 6-fold increase in hemeprotein content at day 2 post-injury and a 12-fold increase at day 7 in the distal part of the nerves, compared with contralateral intact nerves. Beyond the first week, the fate of hemeprotein was very different in each type of lesioned nerves: in transected nerves the level of hemeprotein kept increasing, reaching over 20 times the basal level three months after injury, whereas in crushed nerves, hemeprotein level declined progressively in a proximo-distal direction, returning to basal values 2 months post-injury. These results suggest that hemeprotein could be regulated negatively, directly or indirectly, by growing axons and support the idea that hemeprotein could be involved in the process of Wallerian degeneration and/or in nerve repair.

617.18 EXPRESSION OF BETA-ACIDIN mRNA IN MOTORONOBUS AFTER AXOTOMY. K. N. Corrella, I. M. Lund, B. L. Ruff* and J. B. McQuarle. V. Med. Ctr. and Case Western Res. Univ., Cleveland, OH 44106, USA. The peripheral neuron responds to axotomy by switching from translation of proteins needed for normal function (e.g. neurotrophic factors) to proteins needed for axonal outgrowth (e.g. actin and tubulin). At 1, 4, or 14 days after several peripheral nerves (e.g. sciatic nerve) have been cut (with contralateral sham crush), the L4/5 spinal cord was excised and histsected. Northern blots of mRNA showed an increase in beta-acidin mRNA at one day on the crush side compared to the sham side. This level then returned to constitutive levels by 14 days. We have used in situ hybridization to further investigate the expression of beta-acidin mRNA in axotomy. Riboprobes were synthesized using SP6 and digoxigenin labelled nucleotides and detected immunohistochemically using an antibody to beta-acidin. This antibody was labelled with Fluroco-Ruby. Preliminary in situ data shows that mRNA was present at 6 days to a much lesser extent in the axotomized side. There is no increase in beta-acidin mRNA after axotomy correlate with known increases in beta-acidin synthesis and axonal transport. (Supported by grants to I.G.M. from the DVA.)

617.19 ANOXYCINE OF MOTOR NEURONS ELUVIATES c-JUN AND JUN D LEVELS.
L.-W. Lui, L.-J. Campbell & I.-G. McQuarrie* VA Medical Center, and Case Western Reserve University, Cleveland, OH. Hypoxia-induced quiescent cells have been found to cause axonal injury and arrest neurite outgrowth in vitro. We have found that axonal injury causes c-Jun expression in a manner similar to that described for beta-actin. Coating the axons with C-Jun alone was constitutively expressed and increased during axon outgrowth. Using the 14-3-3 family of proteins, we measured the effects of hypoxia on c-Jun expression for the first time. The 14-3-3 protein was found to bind to c-Jun and to enhance c-Jun expression following hypoxic conditioning. In conclusion, hypoxia induces c-Jun expression and increases c-Jun expression following axon outgrowth.

617.20 Trk B IN RAT SPINAL MOTONEURONS AFTER SClATIC NERVE LESION.
L.A. Campbell* & I.-G. McQuarrie* VA Medical Center, and Case Western Reserve University, Cleveland, OH 44106 Neurotrophins act as trophic factors for specific cell groups in the nervous system during development and regeneration. The proto-oncogene receptors mediate these effects. Studies that localize trk B mRNAs in specific groups of neurons have been performed using in situ hybridization. We have used a trk B polyclonal antibody for immunohistochemistry to localize trk B receptor protein in the rat spinal cord. To study effects of axotomy, we transected the L4/5 spinal nerves (with contra-lateral sham lesions), and retrogradely labelled motoneurons with Fluoro-Ruby. Immunohistochemistry was performed with a biotinylated secondary antibody conjugated with horseradish peroxidase, using a methyl green counterstain. Preliminary data at 4 days post-axotomy showed an increase in the number of trkB immunoreactive motor neurons on the axotomised side, consistent with the localisation of fluorescence. This increase in trk B receptor protein above basal levels corresponds to known increases of its ligand, BDNF, in target tissues. (Supported by grants from the DVA.)

NOVEL INHIBITORS OF ASTROCYTE GLUTAMINE SYNTHETASE. K.I. Farrel,* D.K. Willis, and P.A. Sayegh, Dept. of Neurology, Univ. of California and VAMC, San Francisco, CA 94124, and USARADC, Dept. of Pharmacology, Univ. of Wisconsin-Madison. Glutamine synthetase is found in glia but not neurons. L-methionine-7-d-13C-glutamine (MSO) has proven useful in the study of glial functions as an inhibitor of glutamine synthetase. However, MSO has many other effects that may be unrelated to the inhibition of glutamine synthetase. This study identified alternative compounds that can inhibit glutamine synthetase. Inhibition of free enzyme prepared from sheep brain (Sigma) was determined by the method of Meister. Inhibition in primary rat cortical astrocyte cultures was also assessed using a 5 hour incubation of intact cultures with these compounds followed by washing and cell lysis.

Inhibitor concentrations of up to 2mM did not cause astrocyte death, as assessed by lactate dehydrogenase activity of the cultures 24 hours post-incubation. Previous work with MSO has suggested a link between astrocyte glutamine and glycolysis metabolism. The effect of the novel inhibitors on astrocyte glutamine accumulation was assessed in astrocyte cultures derived from Sprague-Dawley. Each of the agents that inhibit astrocyte glutamine synthetase were also found to increase astrocyte glutamine, suggesting a causal relationship. These agents may be useful alternatives to MSO for the study of glial functions.

INHIBITION OF PROTEIN SYNTHESIS PREVENTS INTERLEUKIN 1a (IL-1a)-INDUCED INCREASES IN PROSTAGLANDIN (PG) PRODUCTION IN OVINE ASTROGLIA. C. Olson, B. Wall, and J. Bush, Dept. of Physiological & Pharmacological, Bowman Gray Sch. of Med., Winston-Salem, NC 27157-1083.

Little is known concerning actions and mechanisms of cytokines on prostaglandin production in astroglia. The purpose of this study was to examine short term (1-4 hour) effects of IL-1 on PG production in astroglial cultures from fetal sheep. We tested the hypothesis that increased PG production is dependent upon continued or enhanced protein synthesis. Immunofluorescence astrogliosis from second passage fetal ovine cortex were grown to confluence in 12-well (22mm) plates. PG~F~ production in medium determined using enzyme immunosay. Cells were exposed to 10 ng/ml IL-1 in medium or to 10 ng/ml IL-1 without the production of PG~F~ by 1586 ± 303 to 2688 ± 393 ng/ml at 2 hours (n=29; p<0.05) and from 1356 ± 369 to 5426 ± 1571 ng/ml at 4 hours (n=20; p<0.05). Coaplication of an inhibitor of prostaglandin H synthase (indomethacin, 10 µM, n=8) or of phospholipase A2 (arachidonic acid, 103M; n=8) prevented increases in PG~F~ production, as did H7 (10µM, n=5), an inhibitor of protein kinase C. Further, coinulation of IL-1 with actinomycin D (1µg/ml, n=9), a RNA synthesis inhibitor and cycloheximide (10 µg/ml, n=9), an inhibitor of protein synthesis, completely blocked the increase in PG~F~. We conclude that IL-1 increases PG production in ovine astroglia via a mechanism involving several steps, including activation of protein kinase C and phospholipase A2, and continued or enhanced protein synthesis. IDENTIFICATION OF VOLUME-SENSITIVE ORGANIC OSMOTIC CHANNELS IN HUMAN GLIAL CELLS. P.S. Jackson, K. Koga, and J.E. Meldrum, Div. Neuurosurgery and Medicine, Children's Hospital, Program in Neuroscience, Harvard Medical School, Boston, MA 02115.

Regulation of cellular volume is a fundamental process critical to the survival of all cells, particularly those in the central nervous system where even minor volume changes can cause severe neurological damage. Over the past several years much has been learned about the basic biology of cellular volume control. It has now become clear that while osmotically sensitive pathways such as the mammalian p50 oligopeptide (mammalian lymo-protin) may play a central role in brain volume homeostasis. During periods of cellular shrinkage these oligopeptides are released from cells through a shared transport pathway which is now known to be a relatively non-selective Volume Sensitive Organic Osmolyte / Arson Channel (VSOC)

CHARACTERIZATION OF VIP-INDUCED PROTEINS AND mRNA IN MOUSE ASTROCYTES BY 2-D GEL ELECTROPHORESIS AND BY mRNA DIFFERENTIAL DISPLAY (DDH). P.M. Magistretti, G. Pellegrini, C.L. Bolis and I. Cardinaux, 1Institut de Physiologie, Universite de Lausanne, Lausanne, Switzerland. 2Department of Biology, University of Milan, Italy.

In primary cultures of mouse cerebral cortical astrocytes, a rapid glycolysis inhibition followed by a massive glycerol synthesis (bic- to ten-fold) over basal levels after 1 hr treatment by VIP or norepinephrine (NA). Both actions of the neurotransmitters are mediated by VIP. Since the induction of glycerol synthesis triggered by VIP or NA is abolished by inhibition of protein synthesis and translated into the 2 gel electrophoresis and the mRNA DD techniques to search for newly synthesized astrocyte gene products induced by VIP or NA. The comparison of VIP-induced proteins from primary astrocyte cultures treated with VIP or NA revealed that only VIP is able to induce the expression of a protein (kDa M) in VIP 100 mRNA that was identified as an astroglial, a protein inhibitor, which is partially inhibited in astrocytes, is partially inhibited in astrocytes at the 35 kDa mRNA level. Using this technique we have observed several differences between the patterns of mRNAs from untreated cultures and from cultures exposed to VIP 1 µM or NA 100 µM. This technique may be used to identify differentially expressed mRNAs from astrocytes treated with VIP or NA expressing the VIP mRNA identified by DD.

618.9

Burnstock, Barnard and colleagues (Cell Biol. Lett. 32A, 219-225, 1993, 3IPS, 199-70, 1994) have reported cloning a G-protein coupled receptor from central nervous system that is activated by isoprenoids, a neurotransmitter (with 3-methyl-ATP-3ATP-ADP-UTP, but not ATP). As a corollary to the study of neuronal novoceptors, we have investigated ATP receptors on astrocytoma cells. Astrocytes were harvested from rat frontal cortex tissue and grown in culture on dishes for 21-28 days. Total RNA was extracted from primary cultures using the guanidinium method and poly(A)* enriched RNA purified with oligonucleotide (OLigD) and streptavidin-

618.10

Levels of ammonia and endogenous benzodiazepines (BDZs, eg. H) are increased in hepatic encephalopathy (HE). Since astrocytes are involved in HE, and since Kc uptake in astrocytes plays a major role in HE, it was examined the effects of the BDZs on various astrocyte neurotransmitters (products of peripheral-type BDZ receptor activation) in Kc uptake. Rat astrocytes in primary culture were incubated with 3-pi/ml of BDZ (100 µg/ml) for 1 hr in the presence of BDZs and neurotransmitters with or without 0.5 mM MgCl2. Ammonia alone inhibited Kc uptake by 26%. Agents that interact with the peripheral-type BDZ receptor (eg., R5-4844 and K11195 at 30 µm inhibited Kc uptake by 25%, whereas interferes with central-type BDZ receptor (clonazepam and flumazenil at 30 µm did not affect Kc uptake. The effect of K5-4844 on Kc uptake was significantly enhanced by 30 µm of BDZs, whereas the presence of 5 mM MgCl2 (35% inhibition). Fragnenoluc sulfate (50 mM) and 5a-pregnan-3a,21-diol-20-one (5a-THDOC; 30 µm) inhibited Kc uptake by 30 and 50%, respectively. The effects of neurosteroids were enhanced in the presence of ammonia (41-50% inhibition). Thus, astrocytes in HE are able to effect astrocyte Kc homeostasis which may result in altered cell excitability. (Supported by the Veterans Administration and USPHS grants AM-38153 and NS-30291, and GREEC)

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
618.11 EFFECTS OF AMINOSTILZIDEPHENETHIOLS IN ADENOSINE UPTAKE IN ASTROCYTES. B.S. Dobrovy, A.B. Bander, and M.D. Rosenthal. Dept. of Pharmacol. and Toxicol. Univ. of Miami, Miami, FL 33101.

The mechanism of neuroinhibition in hepatic encephalopathy is unknown. Benzodiazepines (BDZs) are elevated in HE and are known to reduce the uptake of adenosine, an inhibitory neuromodulator. This study was undertaken to establish whether BDZ receptors on peripheral and central BDZ products, receptors of peripheral BDZ receptor activation (neurosteroids), as well as adenosine (elevated in HE), affect adenosine uptake. Rat astrocytes in primary culture were incubated with 1 μM [3H]-adenosine (0.7 μCi/ml) for 30 min in the presence or absence of the adenosine analogs. Adenosine uptake was inhibited by 9% in the presence of 5 nM [3H]-adenosine; however, 2-3 days of prior treatment with adenosine resulted in a 20-25% decrease in adenosine uptake. Agents that interact with the peripheral (Ro-44-6066 and PA 1179) and central (clonazepam and flumazenil) BDZ receptors at 10 μM, reduced adenosine uptake by 30%. Endogenous BDZs, DBI (40 μM) and D89 (10 μM), inhibited adenosine uptake by 15%. Flumazenil (10 μM) and 3a,4-mepenzolate 21-diol 20-one (3a,4-MEBC; 30 μM) also decreased adenosine uptake by 20% and 64%, respectively. Suppression of adenosine uptake by amanin, BDZs and neurosteroids may contribute to the neuroinhibition in HE. (Supported by the Veterans Administration and USPHS grants MA-38153 and NS-30291, and GREC).

In culture, microglia and astrocytes can express the inducible Type II form of nitric oxide synthase (NOS). It has been suggested that glia may contribute to neuronal cell death associated with cerebral ischemia and/or other neurodegenerative diseases by generating nitric oxide (NO) (Proc. Natl. Acad. Sci. U.S.A. 98:10945-10949, 1992) via this enzyme. Since microglia and astrocytes represent two distinct populations in brain, we investigated nitrite levels and the production of L-[14C]arginine from L-[14C]arginine. Increases in Type II NOS mRNA and nitrite levels were detected in astrocytes. Microglia and astrocyte cultures were exposed to a variety of stimuli, including bacterial lipopolysaccharide (LPS), gamma interferon, tumor necrosis factor alpha (TNF-α) or IL-1β. A combination of these factors. The culture was assessed for NOS activity by measuring nitrite levels and the production of L-[14C]arginine. Quantitative differences in NOS activity were noted when both cell types responded to identical stimuli. However, microglial cultures did not respond to concentrations of LPS alone that were stimulatory for the astrocytes. These results suggest that in vivo microglia and astrocyte NOS activation may be regulated differentially under different physiological or pathologic conditions.

We are studying factors regulating the expression of major histocompatibility complex (MHC) II antigens on rat astrocytes and microglia to better understand the role of these immune-related molecules in various neurological functions. We find that a significant proportion of the class II expression in the brain is poorly understood; the induction of these molecules during a number of neurodegenerative diseases indicates a possible role in the progression of the disease. Astrocytes and microglia were isolated from neonatal rat pups and stained for surface expression of H-2d or transacted with a plasmid containing the human MHC class II promoter (H-2dADA) driving a chloramphenicol acetyltransferase (CAT) gene (astrocytes only) to examine promoter function. Cells were treated with interferon-γ (IFN-γ) for 48-72 h. Northern analysis of RNA expression, in combination with a number of antibodies of intracellular signaling pathways. Preliminary data indicate induction of surface expression on astrocytes by IFN-γ can be inhibited by blocking protein kinase C activity, PKC inhibition also resulted in a reduction in microglial class II surface signal although expression was not retained above background. Our findings also show that selective inhibition of protein tyrosine kinase fails to inhibit IFN-γ-driven class II expression in either cell phenotype. Parallel experiments with transfected cells produced similar patterns of expression from the human promoter. This work suggests MHC class II expression on astrocytes and microglia may be under similar regulatory control with PMTs and some tyrosine kinases but may differ in their sensitivity to external stimuli.

When adult mammalian brain is injured, there is a complex response of non-neuronal cells which includes cell proliferation generating astrocytes in the affected region. The extent of the astrocytes mediated gene transfer to identify the lineage and characteristics of cells proliferating after injury. Knockin mice were generated to the rat cadherin protein to kill neurons, and four hours later L21 BAV virus was injected at the same site, to infect proliferating cells and transfer the reporter gene β-galactosidase. These were used immunocytochemically for the β-galactosidase immunoreactivity to detect proliferating cells in the tissue at various intervals after the injection of virus. This approach circumvents the technical problem that cytoplasmic localization of β-galactosidase activity may obscure immunoreactivity detected with immunofluorescence methods.

Forty eight hours after viral infection, most of the β-galactosidase-immunoreactive cells lacked β-gal immunoreactivity. In many instances, the shape of cells with β-galactosidase immunoreactivity was similar to that of cells expressing β-galactosidase, a marker of microglia. We are now examining the β-galactosidase-immunoreactive cells for the presence of microglial and macrophage cell markers such as ED-1 and ED-2 at several survival intervals after injection of the retrovirus.

618.20 ION CHANNELS AND OXYGEN RADICAL PRODUCTION IN ACTIVATED MICROGLIA. B.A. Ballyk*, D.J. Phipps, P.S. Pennathur and J.C. Schlichter. Playfair Neurosciences Unit, Toronto Western Hospital, Toronto, Canada, M5T 2S8.

The objective of the present study was to characterize ion channel expression in activated microglia and their ability to release oxygen radical.

Primary mixed cultures from the brains of newborn Wistar rats were starved to eliminate neurons and then shaken to isolate microglia, which were plated either in 96-well plates for functional assays or on glass coverslips for patch-clamp recording. Cultures which received conditioned media containing colony stimulating factor 1 (CSF-1) showed marked production of the kDa protein, which was measured by immunofluorescence. Immunocytochemical staining with 100 μM TMRM. Whole cell recordings showed that activated microglia expressed at least three ion currents: an inward rectifier K+ current blocked by external Ba2+, a delayed-rectifier K+ current with several features of the cloned K(Ca) channel, blocking by charybdotoxin and margatoxin, and a Cl- current blocked by furosemic acid.

In functional assays, microglia activated with opsonized zymosan produced superoxide and nitric oxide, as measured by reduction of cytochrome c and Griess reagent, respectively.

We are now using ion channel blockers in functional assays to determine what roles these channels play in the physiology of microglia.

Supported by the Savoy Foundation, the NHRDF, and the MRC (Canada).

GNE STRUCTURE AND FUNCTION V

Inherited variations of human catechol-O-methyltransferase (COMT) activity levels are controlled at a two allele, autosomal locus. The "low" activity enzyme is also relatively thermolabile, compared to the "high" activity form. A single amino acid change at position 47 of human C0M, in an adenine of H/L individuals and a guanino in most H/H individuals has been identified. PCR-amplified coding regions from L/L and H/H specimens were subcloned into the pGEM-3Z vector and protein was expressed using the Tnt 1 lysate coupled transcription/translation system (Promega). Mg2+, methionine-labeled proteins were separated by SDS-PAGE followed by autoradiography. Two major protein bands of 25.5 and 29 kD, observed in lane corresponded to soluble and membrane-bound forms of the COMT enzyme. SDS-PAGE analysis of these bands, following immunoprecipitation with antiserum to soluble COMT enzyme, revealed that the relative intensities of radioactive bands increased in the order of H/H specimens. Scanning densitometry indicated that the relative amount of radioautographic immobilizable protein in the 25.5 kD band from the H/H specimen was 3.9 times greater than those from the L/L specimen. This is in excellent agreement with measured liver COMT activity levels in these two specimens. These findings are supported by results on Western blots of human liver homogenates from individuals with inherited L/L and H/H genotypes. It can be concluded that the single base change in the COMT coding region influences regulation of expression of the human COMT gene either at the transcription, translation or degradation of protein.

We have characterized a mutation in Belgian sheepdog that disrupts the formation of the optic chiasm (Williams et al., 1994). The pattern of inheritance over 6 generations indicates that the mutant allele is autosomal recessive (symbol NOX, no optic chiasm). To identify NOX we have taken complementary approaches. Candidate genes encoding mutations at the tyrosinase gene locus (TYR) are known to perturb ganglion cell projections at the chiasm. We have used primers derived from conserved sequences of human and mouse TYR to clone exon 1 of dog homolog homology analysis of the polymerase chain reaction. The relationship between TYR and NOX was determined by sequence comparison and linkage analysis. Chromosome mapping: We have begun to map canine genes that are linked on mouse chromosome 7 over a 250 cM interval. This interval, located between the p locus and the calcium gene, contains several loci that play key roles in brain development and function. The TK6 assay is based on the TK6 assay, which is used to identify linkage disequilibrium in the human population. The F1 progeny were backcrossed to mutant Belgians. DNAs from the backcross offspring are being typed using several forms of markers, including restriction fragment length polymorphism, polymorphic microsatellites, and RAPD. This will allow us to begin constructing a molecular framework for the NOX locus, and for screening a dog genomic library to obtain probes that will be used to assign chromosomal position amongst linked loci via fluorescence in situ hybridization.

Support: NEI ROI-9586

Somatic gene transfer has been extensively investigated using genetically modified primary fibroblasts as grafts for intracranial transplantation in our laboratory: We use defined retroviral vectors to investigate gene expression and regulation in the adult central nervous system (CNS) on a molecular and cellular basis. Our data suggest that expression from retroviral promoters/enhancers decreases with the onset of quiescence in vivo and in grafted fibroblasts in vivo. When genetically modified fibroblasts are implanted into the host CNS, the lack of tumor formation indicates that the cells reside in a quiescent status within the grafting area. As a consequence, it is necessary to enhance the capacity of engineered fibroblasts to express transgene products in a quiescent state, and the objective of this project is to examine strategies of achieving long-term stable and/or regulatable transgene expression in primary fibroblasts in vitro and following implantation into the adult rat CNS. To achieve this goal we use several strategies: 1) The effect of different viral, tissue-specific and housekeeping promoter/enhancer configurations in vivo is assayed in growing and confluent cells in vivo. Fibroblast cultures in different serum levels have been established that may mimic conditions in the in vivo grafts. The effect of the size and composition of different transgenes on their expression is analyzed under the same conditions. 2) We also analyze whether potentially negative regulatory elements can be deleted from viral promoters/enhancers to direct transgene expression constitutively. 3) The influence of exogenous factors on transgene expression is analyzed for full-length as well as truncated promotor/enhancers. In addition to in vitro experiments on long-term stable and/or regulatable expression from various promoters/enhancer combinations is also monitored in vivo after grafting. Our results suggest that retroviral gene expression can be regulated by deoxynucleosae and thymine acid in vivo and in vivo.

We have adopted a technique of differential display of PCR-amplified mRNA to examine the nature and extent of changes in gene expression in mammalian brain. This technique utilizes a set of oligonucleotide primers, one anchored to the poly A' tail of the message and the other located upstream of the poly A' tail. While this technique has previously been used to study changes in cultured cells, little information is available on the application of this technique to heterogeneous tissues such as the brain. Currently, we are using this technique to examine changes in gene expression associated with seizure activity and focal cerebral ischemia. In the first example, we have isolated mRNA from animals that have been kindled to stage 5 seizures and left seizure-free for at least 2 weeks or from animals acutely treated with kainic acid. Electrotiled implanted or vehicle injected animals served as a sources of control mRNA. In the second example, we are studying changes in gene expression associated with a model of focal cerebral ischemia based on the photoinduction of thrombin stroke using the dye Rose Bengal. We have identified a number of differentially displayed messages in the brains of animals that have been kindled or have experienced kainic acid-induced seizures. Differential displayed messages have been isolated, PCR amplified, and subcloned into plasmid vectors. We are attempting to use both PCR-amplified material directly and subcloned material in Northern blotting experiments to further characterize gene expression associated with these differentially displayed messages in control and experimental animals. It appears that this technique is useful for studying changes in gene expression in the brain.

619.7 FACTORS AFFECTING AVAILABILITY OF ANTISENSE OLIGONUCLEOTIDES IN BRAIN. Y. Yaida, W.A. Pulsinelli* and T.S. Nowak, Jr, Dept. of Neurology, Univ. Tennessee, Memphis, TN 38163.

The use of antisenese oligonucleotides (oligos) to interfere with the expression of specific proteins is of demonstrated utility in vitro, and several reports have indicated that this approach may also be applicable to the intact brain. Few investigations have explicitly evaluated the localization of administered oligos within the brain. In the present studies we have examined the distribution and stability of oligos after intraventricular (i.e.) and intrahippocampal (i.h.) injection in the rat. These studies used synthetic oligos (19–25mers) antisense to various regions of a rat hsp70 mRNA sequence. Oligos were 3'-end labeled with [32P]thio-dATP, and 50 nCi (1 pmol, 2-5 μl) injected to examine distribution 1-24h after administration. Frozen sections (15 μm) were cut and subjected to film autoradiography. Localization and stability were evaluated 6-48h after injection of unlabelled oligos (2μmol) by in situ hybridization with 35S-labeled sense sequences.

After i.c. injection labeled oligo was largely periventricular. A more propagated signal was seen at 6 h or later, especially in white matter tracts. This likely does not represent intact oligo, since in situ hybridization detected only periventricular accumulation. With direct i.h. administration labeled oligo accumulated along the hippocampal fissure, probably reflecting injecting bulk flow. There was occasional prominent labeling of dentate granule cells, and limited CA1 labeling was also seen along the tract of the injection. Hybridization at 6-48h detected neuronal uptake of oligo with a similar distribution, including mossy fibers remote from the injection site. Unmodified oligos can therefore accumulate in neurons after local administration.

619.8 DEVELOPMENT OF PCREB AND FOS-LI IN SUPRAOPTIC NUCLEUS AFTER SALT LOADING. P. Shromn*, M. Magner, S. Winston, M. E. Charness, Dept. Psychiatry, Neurology, Harvard Medical School, VA Medical Center, West Roxbury, MA 02132.

Phosphorylation of the cAMP response element binding protein (CREB) precedes the induction of immediate early gene expression. Using antibodies that detect CREB from phosphorylated (CREB-P) and non-phosphorylated (CREB) CREB, we studied the appearance of CREB-like immunoreactivity (CREB-LI) and Fos-LI in the hypothalamic supraoptic nucleus (SON) in response to hypertonic stress in rats. Increased numbers of PCREB-LI cells were present at 15, 45, and 90 min after injection with normal or hypertonic saline. The number of PCREB-LI cells did not differ significantly between the two groups and returned to normal after 6 hrs. The SON of hypertonic saline-treated rats showed higher levels of c-fos mRNA than that of normal saline-treated rats, and only minimal signal was detected in the SON of unrestricted rats. The number of Fos-LI cells increased dramatically at 45 and 90 min after injection of hypertonic saline and did not change at 15, 45, or 90 minutes after injection of normal saline. The discrepancy between levels of PCREB-LI and c-fos mRNA suggests that hypertonic stress may activate additional transcriptional factors besides CREB. The lack of Fos-LI in the presence of modest increases in c-fos mRNA in normal saline-treated rats implies that levels of c-fos mRNA must exceed a threshold before increases in Fos-LI cells are detectable in the SON. Such a threshold might permit neuronal cells to activate diverse cAMP or calcium-responsive genes, through phosphorylation of CREB, without inducing the constellation of Fos-responsive genes.

**Somatostatin decreases somatostatin messenger ribonucleic acid levels in the rat periventricular nucleus.** M. Aguilar. Department of Physiology, UT Southwestern Med. Ctr., Dallas, TX 75235-8873.

Somatostatin (SRIF), the inhibitory hypothalamic peptide of pituitary growth hormone secretion was reported to inhibit its own release by a negative feedback mechanism. However, it is not known whether this negative regulation is exerted at the molecular level. Therefore, this study was conducted to examine the hypothesis that hypothalamic SRIF mRNA levels might be regulated by its own protein. Periventricular nucleus (PVN) mRNA and protein were measured in rat brain using in situ hybridization in Waymouth's medium with SRIF or the SRIF analog RC 160 (10^-7 to 10^-3 M) for 6 h. Levels of SRIF mRNA were determined by a [35S] nucleic acid protection assay using a [32P]-labeled rat SRIF riboprobe. SRIF (10^-7 M) significantly (p<0.01) decreased SRIF mRNA levels. Likewise, RC 160 (10^-7 to 10^-3 M) significantly (p<0.05, p<0.01 respectively) diminished SRIF mRNA levels. These results suggest that SRIF can regulate its own gene expression by a negative loop feedback. SRIF secreted from these neurons may be down-regulating a preceding stimulatory input. Supported by NIH grant NS26821.

619.11  

Factors that regulate transcription of RNA and gene expression of voltage-dependent ion channels were identified using cultured N1E-115 neuroblastoma cells as a model system. Na and K channel-specific mRNA was measured using a competitive-polymerase chain reaction technique following reverse transcriptase of isolated total RNA. Amplified cDNA was sequenced to confirm identity of the transcript, and the absence of genomic DNA was verified. Cell division can be arrested resulting in an enhanced differentiated phenotype during incubation of cells in medium having reduced serum and 1.5% dimethyl sulfoxide. A reduction in Na channel mRNA was observed from adult male rats incubated in Waymouth's medium with SRIF or the SRIF analog RC 160 for 48 h. Therefore, Na and K content of these neurons is differentially regulated. Mechanisms responsible for the alteration in Na channel mRNA by Ca loading were studied. Although growth of differentiated cells in high external K did not alter mRNA level by itself, it blocked the decrease in mRNA in the presence of A23187. Na channel mRNA was reduced when cells were incubated in 250 µM chlorophenylhydantoin-cAMP (CAcAMP). A reduction by CAcAMP was not observed in cells grown in A23187. These observations suggest that the effect of Ca on transcription is mediated by CAcAMP, and perhaps coupled to changes in membrane potential. Supported by the National Multiple Sclerosis Society.

In response to stresses, such as elevated temperature, cells respond by increasing synthesis of a group of highly conserved proteins known as heat shock proteins (hsp). One approach to study the expression of constitutive (hsc) and heat-shock-inducible (hsp) members of the hsp70 multigene family in the New Zealand white rabbit. Using radioactive and non-radioactive (DIG) in situ hybridization protocols, both hsc70 mRNA and hsp70 mRNA were localized to hippocampal neurons in control animals. The role of the stress-inducible hsp70 mRNA species in neurons of the untrained animal is yet to be determined. Following 1 h of hyperthermia, glutal cistals (including astrocytes, oligodendrocytes, and microglia) within the hippocampal region, the overlying corpus callosum and the fimbria showed an induction of hsp70 mRNA. We performed lectin cytochemistry using QUA 1-8 from Griffonia simplicifolia to identify microglia and immunocytochemistry with anti-GAP-antibodies to identify astrocytes shown that hsp70 proteins are found constitutively within dendritic processes of Purkinje neurons of the cerebellum, we now analyze transport of hsc70 mRNA in neuronal processes. In addition, a time course analysis of hsp70 mRNA induction in glial cell types investigates transport of hsp70 mRNA in glial processes following hyperthermia.

619.14  

Calcium or calcium-like kinase II (CaMKII) regulates both pre- and postsynaptic functions. CaMKII is highly abundant in the postsynaptic densities of excitatory synaptic terminals. Transgenic mice homozygous for a null mutation of the c-A subunit of CaMKII have impaired formation of hippocampal long-term potentiation, long-term depression, and abnormal short-lived plasticity. Behavioral studies reveal profound deficits in both spatial and contextual learning (Silva et al., 1992; Silva et al., unpublished results). The present study used stereological techniques to examine the ultrastructural characteristics of the CA1 region of the hippocampus in the homozygous mutant mice. Pyramidal cell density, CA1 stratum pyramidale, was obtained using the physical dissector on serial 1.5 µm sections. Synaptic density was obtained from serial electron microscopic tracings of stratum radiatum in CA1 using the optical dissector. We demonstrate similar neuronal and synaptic densities in the hippocampi (N=2) and wild-type animals (N=3). No differences were observed in the number of synapses per neuron. Initial analysis of the size of the CA1 region reveals no differences between the two groups. However, one mutant mouse appeared to display spontaneous seizure activity and examination of the hippocampal anatomy revealed cell loss in all CA regions of the hippocampal. Supported by NIMH 33521, NSERC, Kwanian Nry. Spec. Res. Fnd., Whitehall Foundation and Klingenstein Foundation.

**The transcription factor c-erbB is induced by VIP, PACAP and noradrenaline in mouse cortical astrocytes.** J.R. Cardinaux and P.J. Magistretti. Insitut de Physiologie, Université de Lausanne, Switzerland.

The CCAAT/enhancer binding protein (c-EBP) family of transcription factors belongs to a class of proteins whose DNA-binding domain involves a basic region and a leucine zipper that is described as C/EBP and then for the Fos/Jun and ATF/CREB families. High c-EBP concentrations were found in the nuclei of fully differentiated hepatocytes and adipocytes. Therefore, it was considered that regulation of energy balance may be channeled at least in part through C/EBP. Since we have previously described transcription dependent metabolic effects of VIP and noradrenaline (NA) in astrocyt.(Klingenstein 12:4923), we have examined the effects of these neurotransmitters on C/EBP protein levels. By Western blot analysis, we observed that C/EBP is rapidly induced by VIP 10 nM, by the VIP receptor antagonist PACAP 10 nM or by NA 1 µM in mouse astrocytes prepared from the cerebral cortex. The effect of NA can be mimicked by the β-agonist isoproterenol, whereas methoxamine as α-agonist is devoid of any effect. Moreover, the NA-induction can be antagonized by atenolol and not be prazosin, thus suggesting that the induction of C/EBP is mediated by β-subtype adrenergic receptors VIP, PACAP and NA therefore probably increase the C/EBP expression via the cAMP second-messenger pathways. To our knowledge this is the first demonstration of the induction by neurotransmitters of a member of the C/EBP family in a mammalian cell. It is therefore searching putative target genes whose expression is modified in response to the C/EBP induction.
619.15 EXPRESSION OF CALMODULIN mRNA IN THE DEVELOPING RAT BRAIN. E. Berry and J.R. Brown,* Department of Zoology, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada, M1C 1A4.

In the rat, there are three genes which have been identified which encode calmodulin (CaM). Previously in our laboratory, two CNDRs have been cloned and characterized which correspond to mRNAs of 1.8 and 4.0 kb derived from the rat calmodulin gene. Both messages are present transiently in neurons in the rat brain. We have extended our analysis to examine expression of these CaM mRNAs during neural development in the rat. New antiserum reveals the presence of the 4.0 kb transcript increases in abundance from postnatal day 1 (P1) in the cerebral hemispheres (CH) and thalamus. In the superior colliculus (SC), the 4.0 kb mRNA decreases transiently from P1 to P10 and then declines in later ages (P15 and adults). Levels of the 1.8 kb message remain relatively constant over development, while the 4.0 kb message shows greater changes. Using in situ hybridization, we observe that CaM mRNA is localized to a discrete layer in the developing SC. By P5 and P10 expression is focused to neurons between the superficial gray and optic layers. In the developing CH, CaM I mRNA is localized in a punctate pattern in cortical layers II-IV. Closer examination of cells in these layers reveals that CaM mRNA is present in the cell body and dendritic processes. The timing of CaM I mRNA expression in the developing SC coincides with the period of removal of mistargeted axons from retinal ganglion cells, while the appearance pattern in the developing CH correlates to a period of synaptogenesis in the cortical layers. This work was supported by grants to Y.R. from NSERC, Canada.

619.16 Concerted regulation of GAD and GABA_A receptor family transcripts as a model system in the molecular physiology of CNS development. A. Somogyi, X. Wen, V. Dupuis and L.J. Rinzel.

Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD 20892

GABA (γ-aminobutyric acid) acts as a neurotransmitter molecule in embryonic development of the CNS, distinct from the well-established function of GABA as a principal inhibitory transmitter in the CNS. Evidence for this role includes the early embryonic detection of GABA-evolved pharmacological responses involving GABAA and GABAB receptors, and promotion of neurite outgrowth. The molecular basis for the embryonic role of GABA lies in its expression from glutamic acid decarboxylase (GAD), and the presence of GABA receptors. We have implemented a quantitative RT-PCR approach to test hypothetical models for the transcript regulation during development of the rat spinal cord dorsal. Three GAD mRNAs, GAD65, GAD67 and EP10 were detected at E11 and steeply increased during an early embryonic period. GAD67 reached maximum expression at the end of embryogenesis, at levels 100x higher than initially detected. During the postnatal period, GAD67 increased to their adult level at one third of maximum. The alternatively spliced transcript of the GAD67 gene, EP10, reached a maximum before GAD65/67 and then steeply dropped in late embryonic development. EP10 expression correlated with the transition of spinal cord tissue from proliferative to differentiating. RT-PCR of 13 GABA receptor subunits revealed overall parallel expression to GAD. As a working model, we propose that production of GAD transcripts may influence a regenerative feedback loop, linking the product of GAD, i.e. GABA, to the induction of GABA and GABA receptor subunit mRNAs. We are currently testing this hypothesis using embryonic spinal cord cells grown in a serum free tissue culture on an fibrin substrate. These conditions enable the continuing differentiation of cells.

POSTSYNAPTIC MECHANISMS III

Stochastic simulations (Fieber et al. Science 288:494, 1992; De Koninck & Moynihan. J. Neurophysiol. 71:138, 1994) have demonstrated the existence of intrinsic quantaal variance (\(\sigma_q^2\)) at the peak of miniature postynaptic currents (mIPSCs) in spite of the postulated monovalent current injections at central synapses. \(\sigma_q^2\) depends on the relationship between activation kinetics and bursting properties of synaptic receptor channels. The occurrence of gaps during bursts or clusters of channel openings can significantly affect the channel current. We examined how \(\sigma_q^2\) and \(P_{pump}\), the probability that ligand-bound channels will be open at the peak of mIPSCs, are affected by modulators of channel kinetics such as intracellular calcium, phospholipases and kinases. We simulated mPCs based on cell-attached single channel data obtained in acutely isolated adult neurons. Cluster of channel openings were aligned by exponentially distributed random intervals based on the time to first opening of channels following brief agonist injections (Edmonds & Colquhoun, Proc. Roy. Soc. Lond. B 259:279, 1992).

For unitary currents with burst and onset kinetics such as those underlying GABA_A receptor meditated mIPSCs, the \(P_{pump}\) is high, and modulation of the intraburst kinetics has little effect on the peak mIPSC amplitude. In contrast, as previously reported, (Zabors, Science 255:470, 1992; Rosemund et al., Science 262:754, 1993), \(P_{pump}\) is much lower for NMDA receptor mediated mPCs. Thus, modulation of the intraburst kinetics will dramatically affect peak amplitude. The alteration in \(P_{pump}\) will lead to changes in \(\sigma_q^2\). As the coefficient of variation (CV) used for quantal analysis assumes a fixed \(\sigma_q^2\), variations in \(\sigma_q^2\) by modulators of channel kinetics may produce erroneous interpretations of changes in CV at certain synapses.

620.2 MONOSYNAPTIC GABA-ARECEPTOR INPUTS TO RAT RUBURAL NEURONS IN SLICES C. P.T. Tseng* and Y.-S. Fu. Department of Anatomy, College of Medicine, National Taiwan University, Taipei, Taiwan, R.O.C.

Mammalian red nucleus(RN) displayed a differentiation induced sprouting of excitatory and inhibitory terminals, but the locations of inhibitory neurons remain enigmatic. Here we used intracellular recording and anatomical tracing methods to study the inhibitory connections of normal RN neurons in slices. In some cases, bicucullin was used to reveal the morphology of recorded cells. They resembled Golgi-stained RN neurons. Recorded caudal cells were similar to identified rubrospinal neurons revealed by fixed tissue intracellular dye injection.

Stimulating electrode was placed in the mesencephalic reticular formation dorsolateral to RN(3mm), substantia nigra(SN), or ventral tegmental demarcation(VTD). Stimuli in VTD evoked no postsynaptic potentials indicating that the lack of a recurrent inhibition. Stimuli in dMRF(11/11 caudal and 8/10 rostral neurons) and SN (16/19 caudal and 19/20 rostral neurons) evoked a short latency hyperpolarizing PSP. This poststimulus temporal pattern evoked by depolarizing current injection and it was reversibly blocked by perfusion of 20 μM bicuculline. Blockage of this IPSP revealed no underlying depolarizing PSP indicating a direct activation of inhibitory neurons or their axons. Latencies of IPSPs evoked from both stimulus sites were around 1.1 ms consistent with the hypothesis of being monosynaptic PSPs.

Anatomically, anterograde tracer-Destain applied in the dMRF or SN of live slices labeled neurons with bouton-bearing axons extending into the RN. They were often found to oppose somata in the RN. Immunohistochemical staining shows that dMRF and SN neurons contain high level of the calcium-binding protein-parvalbumin, known to present in high concentration in GABAergic neurons. Thus anatomical and physiological data suggest that dMRF and SN neurons mediate a GABA_A/IPSP on RN neurons(supported by NSC of Taiwan, R.O.C.)

620.3 FUNCTIONAL CHARACTERIZATION OF THE CORTICO-NUCLEAR PROJECTION IN RAT CEREBELLUM IN VITRO D. Mouginot and B. H. Gathier*. Brain Research Institute, University of Zurich, CH-8029 Zurich, Switzerland.

Neurons of the deep cerebellar nuclei (DCN) constitute the major output of the cerebellar. Intracellular recordings were obtained to characterize the inhibitory synapses formed by Purkinje cells (PCs) on neurons in the DCN using organotypic cerebellar cultures. These preparations exhibit the unique property that PCs grow axons de novo, forming an impressive in vitro synaptic interaction projection. Inhibitory amino acid receptor antagonists (CNQX, 20 μM; D-APV, 40 μM) and bicuculline (40 μM), DCN neurons spontaneously fired action potentials whose frequency was linearly correlated linearly on methacholine. Thus, DCN cells displayed a besting-type pacemaker activity under conditions of synaptic isolation. DCN neurons possess GABAA and GABAB receptors, as shown by bath application of GABA and bicuculline (100 μM). In the presence of CNQX and D-APV, field stimulation of PCs evoked graded IPSPs which were completely and reversibly abolished by bicuculline. IPSP amplitudes were not significantly reduced during fast repetitive stimulation, and the resulting hyperpolarization was not affected by the GABAB receptor antagonist CGP-35348. Trains of IPSPs (5 to 10 Hz) were able to significantly discount the pacemaker activity of DCN cells. In addition, experiments with bicuculline show that PCs exert a tonic hyperpolarizing tone on DCN neurons.

Burst firing of dopamine neurons in vitro is induced by the glutamate agonist N-methyl-D-aspartate (NMDA). The hyperpolarization bursts of cellular activity due to NMDA excitation by a cationic-sensitive pump (Johson et al., Science 258:665). We formulated and resolved a theoretical model of the burst mechanism of burst generation. We show that a number of bursted, inward NMDA-mediated current and the outward Na^+-current pump is sufficient to generate the oscillation (0.5 Hz) suppressing the burst. The region of negative slope in the I-V relation of the NMDA channel in the presence of Mg^2+ is indispensable for the occurrence of this burst. We suggested by Seunig et al. (Neurosci 58:201, 2001) we find that the Na^+-current and the Na^+-pump inhibitors are required: a soma where action potentials are produced and a dendrite where the slow rhythm is generated. The time scale of Na^+-P handling in the dendrite is typically tens of seconds. The Na^+-pump inhibitors transform bursting back into tonic firing. When the soma is voltage-clamped, slow oscillations in current, which are generated in the dendritic compartment, are still present. These results are in agreement with experimental observations. Insights obtained with our model may apply to other neurons where bursts which appears to involve NMDA channel activity.
620.5

The major excitatory transmitter glutamate activates several subtypes of glutamate receptors. In this study, we investigated the interaction of these subtypes in single neurons. We carried out voltage-clamp recordings using the conventional whole-cell patch-clamp technique from hippocampal neurons, prepared from adult rat hippocampi (7-15 days) and cultured for 13 days. Glutamate (100 μM), applied by rapid pressure ejection, induced a large inward current with prominent desensitization in Mg-free, glycine- and TTX-containing standard solution. The current induced by glutamate was paradoxically increased to 122 ± 2% (mean ± s.e., n=9) of control by an AMPA/kainate receptor (kA/kR) antagonist, CNQX (10 μM). The enhanced current was also increased in the presence of the NMDA receptor (NMDA/kR) antagonist, D-APV (200 μM). In addition, in mutant mice lacking functional NMDA-Rs, CNQX reduced the glutamate-induced current to 33 ± 3% (n=5) of control, indicating that the NMDA current was increased by about 80% in the wild-type animals by blocking kA/kR. The ratio of glutamate current at 3 sec to its peak amplitude was increased by CNQX, indicating that the NMDA current had been desensitized by kA/kR activation. In Ca-free solution, CNQX reduced the glutamate-induced current to 76 ± 2% (n=9) of control. In Mg-free solution, with Li or Cs substitution, CNQX reduced the glutamate current to 74 ± 4% (n=3). Thus AMPA/kainate current may affect NMDA current via Na influx, which eventually increases Ca levels by the NlCa exchanger. Similarly, the NMDA-component of glutamate current was also increased by 120 ± 5% (n=6) by a metabotropic glutamate receptor (mGlUR) antagonist, MCPG (200 μM). These results suggest that the NMDA component of glutamate current is inhibited by kA/kR and mGlUR activities.

NOVEL TIME COURSE OF TRANSMISSION AT A GIANT GLUTAMATE SYNAPSE IN RAT VESTIBULAR CEREBELLUM. D.J. Rososky, D. Magnasco, and N.T. SLCR. Department of Physiology, Northwestern University Medical School, Chicago, IL 60611.

Unipolar brush cells (UBCs) of mammalian vestibulo-cerebellum receive inhibition from a single mossy fibre in the form of an extremely fast excitatory synaptic current (12-40 μs). UBCs are immunogenic for GABA and glycine (Magnasco et al., Synapse 16:284, 1994), but immunosuppressive for glutamate. In the present study we have examined the properties of transmission at this synapse using whole-cell recording methods in this cerebellar slice maintained in vitro. UBCs in the OCL of rat cerebellum noduli and ovals were patch-clamped with Lucifer Yellow (LY)-filled pipettes, and stimulating electrodes were placed in the white matter to activate mossy fiber afferents. Confocal fluorescence imaging of their characteristic morphology was used to verify cell identity. LY filled the soma, dendritic brush, and revealed a branching axon that gave rise to 2-4 mossy-like rosettes in the GCL. In whole-cell recordings a biphasic excitatory postsynaptic current (EPSC) was observed in UBCs voltage-clamped at -40 mV in Mg-free saline. The fast component (t<sub>0.7</sub>=5 ms, t<sub>0.3</sub>=36 ms) was followed by an unusually slow inward current (t<sub>0.7</sub>=220 ms, t<sub>0.3</sub>=84 ms), both of which were evoked in an all-or-none fashion at identical stimulus thresholds. At 40 mM it was blocked by the AMPA/kainate receptor antagonist CNQX (10 μM). In Mg<sup>2+</sup>-free saline both fast and slow EPSCs reversed near 0mV with linear I-V relations between -80 and +50 mV. The pharmacology of the slow EPSC changed with development. In young animals (6-20 days) it was preferentially blocked by the NMDA receptor antagonist D-AP5 (30 μM) and t-thiourea-kynurenic (100 μM) and displayed non-linear I-V relations in the presence of external Mg2+. In contrast, it was blocked by CNQX (10 μM) and displayed no Mg2+-channal block in older animals (>30 days). It is proposed that the ultrastructural design of this synapse represents a specialization to prolong the lifetime of glutamate in the clef following release, thus resulting in rebinding of glutamate to produce a long-lasting EPSC whose time course is independent of receptor type.

620.8

While synaptic activation of NMDA receptors within the intrinsic circuitry of the vestibular nuclei (VN) has been suggested to contribute to plasticity of vestibular function, to date there has been no demonstration using intracellular recording methods of an NMDA receptor-mediated component of synaptic potential in vestibular nuclear neurons. In the present study we have re-examined this issue using whole-cell recording methods in 300-450-um thick slices of the medial vestibular nucleus (MVN) maintained in vitro. Slices were cut at the level of the vestibular nuclei (vVN), and stimulating electrodes were placed in the vVN to evoked EPSPs. In normal saline, the vVN-evoked EPSP was blocked by the NMDA antagonist D-AP5 (10 μM). However, in the presence of the NABAA receptor antagonist bicuculline (10 μM) a late, slow component of the EPSP was observed which was blocked by the NMDA receptor antagonist D-AP5 (50 μM). This monosynaptic NMDA-mediated component could be isolated in the presence of D-AP5, and displayed the non-linear voltage-gated characteristics of monosynaptic-mediated responses in the presence of external Mg. In some cells, D-AP5 also blocked a large (>50%) proportion of the δ-AP5-sensitive component. Polysynaptic AMPA/A-NMDA-activated EPSPs were observed in the presence of D-AP5. Prolonged bath application (10-20 min) of the metabotropic glutamate receptor (mGlur) agonist 15,3-ACPD (10-100 μM) produced a moderate, slowly desensitizing depolarization (2-3 mV) and an acute depression of the EPSP in all cells. A long-term potentiation of the NMDA-mediated EPSP was observed in 9/13 cells following the washout of 15,3-ACPD. These results demonstrate that NMDA receptors contribute both to the monosynaptic vVN-evoked EPSP and to transmission within the intrinsic circuitry of the rat MVN, and are modulated by activation of mGlurA.

620.9

SATURATION OF AMPA RECEPTORS FOLLOWING QUANTAL TRANSMITTER RELEASE. C.-M. Tang*. M. Margulis, Dept. of Neurology, Univ. of Maryland Sch. of Med.

While it is generally believed that postsynaptic NMDA receptors reach saturation following the release of glutamate from a single transmitter vesicle, it remains unclear whether AMPA receptors reaches saturation. Using biochemical and functional approaches in this study, we investigated the possibility that AMPA receptors do not follow Poisson behavior nor did they summate linearly. A minority but statistically significant number of closely timed msEPSCs were elicited from small numbers of release sites on proximal dendrites of cultured hippocampal neurons. In contrast, msEPSCs did not follow Poisson behavior nor did they summate linearly. A minority but statistically significant number of closely timed msEPSCs were also closely matched in terms of amplitude. Addition of cyclothiazide (100 μM) increased the non-linearity of summation. By statistical significance we refer to the "amplitude pairing". Receptor saturation best explains these observations. AMPA receptor saturation following quantal release has implications for synaptic transmission in the CNS.

620.10

DOES GLUTAMATE RELEASE SATURATE AMPA RECEPTORS AT A SYNAPSE? W.R. Holmes*, Neurobiology Program, Dept. of Biological Sciences, Ohio University COM, Athens, OH 45701.

The fact that few AMPA receptor channels are ever open at a synapse and that NMDA receptors have a high affinity for glutamate suggests that a single vesicle of glutamate might saturate all NMDA receptors at a synapse. In our previous model of LTP (Holmes and Levy 1990), the first few pulses of a 400 Hz input caused the peak number of NMDA receptors bound to glutamate to increase. However, if glutamate saturates NMDA receptors, this peak number should be the same for all pulses in the train. Whether or not the peak number of bound NMDA receptors increases during a tetanus affects model predictions of the amount of calcium entry through NMDA receptor channels. A diffusion model similar to that reported to simulate transmission synapses by Waluty et al. (1979) was constructed. A single vesicle of glutamate was assumed to be released either once or 8 times at 400 Hz. The numbers of bound and open receptors in AMPA and NMDA receptor channels are computed. Conditions when NMDA receptors would or would not be saturated were determined. For saturation of NMDA receptors to occur with the first pulse of a tetanus, a) the number of glutamate receptors per cell must be such that the peak number is much larger than the number of NMDA receptors and b) the first binding constant (k<sub>B</sub>) must be large. Under these conditions, a tetanus allows many more receptor channels to be occupied than through a single peak number of bound receptors never rises above that of a single input. The first binding constant has been estimated to be 5 ×10<sup>-1</sup> (Clements and Westbrook 1991). With this value, the number of NMDA receptors bound with glutamate increases with successive pulses of a tetanus, indicating a lack of saturation. This occurs even when the number of released glutamate molecules is 10 times the number of NMDA receptors.
SATURATING CONCENTRATIONS OF GLYCINE REVEAL UIBOJUTIOUS PRESENCE OF EXCITATORY SYNAPSES IN CULTURED HIPPOCAMPAL NEURONS R.S. Wilson and B. Mohk.

In the mammalian hippocampus, excitative postsynaptic currents (EPSCs) are mediated by activation of both non-NMDA and NMDA receptors colocalized at the synapse. Excitative postsynaptic responses in studies in which miniature EPSCs (mEPSCs) have been shown to consist of both non-NMDA and NMDA receptors. As an early report (Bekkers & Stevens, 1989) suggested that more than 70% of mEPSCs were in cultured hippocampal neurons, we examined the contribution of both components, whereas the remaining 30% could be evenly divided between synapses containing either non-NMDA or NMDA receptors exclusively. In the present study, we examined the contribution of each glutamate receptor subtype by making cell-attached recordings from the same terminals that were activated during evoked responses. We found that as the concentration of glycine was increased from 0 to 10 μM, the NMDA component of the evoked EPSC became significantly greater in both amplitude and duration. Furthermore, in 10 μM glycine, we saw no evidence of NMDA receptors comprising only of the non-NMDA component. Therefore, in our hippocampal culture preparation, there are no postsynaptic sites comprised exclusively of non-NMDA receptors. In addition, although there were mEPSCs comprised of only the NMDA component, it is not possible to conclude that non-NMDA receptors were not present, as desensitization of these receptors, as well as a weaker affinity than the NMDA receptor for the endogenous ligand, could mask their presence. NS24260 (MAD) & AG1200301 (RM).

DIFFERENCES IN INHIBITORY SYNAPTIC INPUT INFLUENCE EXCITABILITY OF CAT ORCHID GANGLION CELLS J. H. Gottlieb* and M. Chester

The occurrence of extracellular alkaline shifts during excitatory synaptic transmission (1) suggests that the NMDA receptor-H* modulatory site (2.5) may play a functional role. We amplified these pH shifts with benzoylacetone (BZ), a carbonic anhydrase inhibitor, and studied the EPSCs of whole-cell clamped CA1 neurons in rat hippocampal slices. In Mg2+-free, CO2/HCO3- media, 1 μM BZ caused an immediate increase in the EPSC amplitude at holding potentials of -80 to -40 mV (see Fig.) and a decrease in the EPSC amplitude at -140 mV. This was timed to avoid an amplification of the extracellular alkaline shift by +4.14 (CO2/HCO3- plus ATP (20-75 μM). The EPSC was unaltered by BZ, while the alkaline shifts were still increased (114 ± 23%, n=8). In HEPS, where buffering was independent of carbonic anhydrase, neither the EPSC nor the alkaline shift was affected by BZ (n=4). These data demonstrate that kinetics of the NMDA receptor-mediated EPSCs should be calculated using the buffering capacity of the extracellular fluid. The results indicate that endogenous pH shifts can modulate NMDA receptor function in a physiologically relevant time frame.

POTENT NAPHTHALENIC AGONISTS FOR MELATONIN RECEPTORS IN BRAIN. I.P. Niles*, I. Smith, J. Wang, J.J. Chen* and G. Fitzmaurice. Departments of Biomedical Sciences and ‘Nuclear Medicine, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

In studies aimed at the identification of selective ligands for melatonin receptors in the CNS, we have assessed the binding and functional activities of a series of naphtaleinic compounds bearing variable halogen substitutions on the N-acetylamo group. Binding experiments were carried out with the melatonin receptor radioiodide, 2-125Ijodozolomelatonin ([2-125]Izolomelatonin, [Izolomelatonin], in either whole-brain homogenates or synaptic fractions (Ps) fractions). Competition experiments performed on, in 30 mM Tris-HCl buffer (pH 7.4 at 4°C), revealed that these compounds compete with both (spectroscopically and low (nanomolar) affinity binding sites for melatonin. In assays conducted at room temperature in the presence of MgCl2 (4 mM), both binding components were also evident. More importantly, under these conditions, some naphtaleinic drugs exhibited a marked increase in their competitive potency at the high-affinity sites labelled by [125]Izolomelatonin, as indicated by affinities in the sub-picomolar range. Preliminary functional assays, in chick brain and rat hypothalamic membranes, show that these ligands inhibit forskolin-stimulated adenylyl cyclase activity. These findings indicate that compounds characterized by a naphtaleinic nucleus, a 7-methoxy group and halogen substituents on the N-acetyl side chain are high-affinity agonists at CNS receptors for melatonin. (Supported by a NSERC Strategic grant and SERVIER).

ENDODGIOUS GLUTAMATE INDUCES DEPHOSPHORYLATION OF THE NEURONAL CYTOSKELETAL PROTEIN MAP2. E.M. Quinlan and G. Herbison, Department of Neuroscience, University of Virginia Health Sciences Center, Charlottesville, VA 22908.

Cytoskeletal proteins are likely targets of glutamate transmission in the nervous system. In collaboration with G.Herbison, the neuronal cytoskeleton, we have focused on the the microtubule-associated phosphoprotein MAP2 in rat hippocampal slices. Changes in MAP2 phosphorylation are known to regulate its interactions with microtubules and actin. Accordingly, multiple phosphorylation sites along the primary amino acid sequence represent potential targets for synaptic regulation of MAP2 function. Previous studies suggested that NMDA receptor activation is potently coupled to MAP2 dephosphorylation. Additionally, dephosphorylation of slices with 40 mM MgCl2 induced a rapid dephosphorylation of MAP2 by blocking the activity of endogenous glutamate. It is well established that glia possess sufficient glutamate uptake mechanisms, and that endogenous glutamate is released from slices by spontaneous neuronal activity. Application of 1 mM dilydrokainate, an inhibitor of glutamate uptake by glial cells, induced a rapid dephosphorylation of MAP2, suggesting that endogenous glutamate is a potent signal for MAP2 dephosphorylation. NMDA-induced dephosphorylation is dependent on extracellular calcium concentration. These data suggest modulatory dephosphorylation activation of the calcium-dependent protein phosphatase 2B (PP2B or calcineurin), which targets specific proteins, such as MAP2, for dephosphorylation.

621.3

Rules for MAP kinase in synaptic function have been suggested by (1) its occurrence in the brain, especially in the neuronal dendrites, and (2) its excitatory neurotransmitter, glutamic acid, and electric stimulation inputs activate MAP kinase. In this study, to clarify the function of the enzyme in the synapse, we surveyed MAP kinase substrates that occur in synaptic fractions. Supernatant and synaptic fractions (Ps) synaptosomes, synaptic plasma membrane (SPM) and postsynaptic densities (PSD) fractions were prepared from Wistar male rats. MAP kinases were purified from Xenopus oocyte or obtained from UBI (sea star p44/42 MAP). Protein kinase activities in each fraction were heat-inactivated before phosphorylation by the MAP kinases. Western blotting showed the occurrence of both MAP kinase and MAP kinase in all the fractions mentioned above. Fractions other than PSD contained bands immunoreactive to anti-MAP kinase antigen, these possibly corresponding to ERK1 and ERK2, respectively. ERK3 was greater than ERK1 in content in both synaptosomes and SPM fractions, and only ERK2 was detected in the PSD fraction. All the fractions contained substrates for both enzymes, but each showed a different substrate profile. Interestingly, sea star MAP kinase strongly phosphorylated the substrates in the supernatant and Ps fractions, while Xenopus MAP kinase (ERK2 type) activated more on the substrates in the synaptic fractions, especially those in the PSD fraction. Phosphorylation of the PSD proteins by Xenopus MAP kinases was increased after maturation of synapses. These results indicate that part of ERK2 occurs in the synapse, especially in the postsynaptic side, and that it may play some role(s) in the synaptic function via phosphorylation of synapse-specific substrates.

ACTIVATION OF NFkB UPON GLUTAMATE STIMULATION IN CULTURED MOUSE CEREBELLAR GRANULE CELLS. L. Guerrini, F. Blasi and S. Denti-Domin{it} Genetics and biology departments and Center of Cytopharmacology, Milan, Italy.

NFkB (the relA/p50 heterodimer) is a pleiotropic transcription factor. It occurs in an active form in the nucleus of a restricted number of cell types (lymphocytes); in most other cell types it is present in a covalently phosphorylated form and can be induced to move to the nucleus in response to a wide variety of extracellular stimuli. The localization of relA has been studied by immunocytochemistry in brain sections and in cultures of cerebellar granule cells. In brain sections, relA staining suggests a synaptic localization, as already described in the rat (Kalschmidt et al. Proc. Natl. Acad. Sci. 1993). In neuronal cells in vitro, relA is mostly concentrated at the tip of processes and at contact sites. This type of spatial distribution prompted us to investigate whether physiological stimuli, such as nanomolar concentrations of neurotransmitters, could activate NFkB in such cells. Glutamate pulses induce the nuclear translocation of NFkB, as observed by band shift experiments and this induction is specifically blocked by the NMDA receptor antagonist APV. With specific antibodies, we have assessed that the activated transcription factor is the heterodimer relA/p50. We are currently investigating the potential target genes of glutamate activated NFkB.

621.5

We have reported that sudden exposure of dissociated hippocampal neurons to strongly anisomotic or glucose deficient solutions suppressed voltage gated Na and Ca currents (Bainton et al., Brain Res., 632: 180-194, 1993). We now investigated whether GABA-induced current were similarly shut down by exposure to anisomotic solutions. Freshly dissociated rat CA1 pyramidal neurons were bath-clamped in whole-cell configuration. Voltage gated Na and K currents were pharmacologically blocked. The effect of hypo-osmotic, NaCl deficient (mannitol-substituted), hydro-osmotic test solutions delivered from a micropipette was tested on membrane currents evoked by brief pulses of muscimol and on voltage gated Ca2+ currents. Hyper-osmotic solution caused cells to shrink, but hypo-osmotic solution had no effect on cell size or shape. All current solutions depressed the muscimol-induced current and usually also the voltage-gated Ca2+ currents. V-gated Ca2+ currents were depressed by anisomotic, but not by NaCl deficient isosmotic solution. We conclude GABA receptor controlled ICl channels may be partially shut down in a strongly anisomotic or NaCl deficient environment.

621.6

In order to determine whether swelling of hippocampal tissue caused by lowering of osmotic pressure, hippocampal slices were exposed to bathing fluid from which varying amounts of NaCl was deleted. Interstitial volume ratio (ISV) change was determined from the volume of dialysis of the ions TMA+ or TEA+ administered by iontophoresis. Tissue electrical resistance was measured as the voltage drop generated by subliminal constant current pulses. The decrease of ISV determined from the dialysis of probe ions was dependent on the degree of tissue tonicity, and in the less severe condition ISV shrank to 3.3% of the total tissue volume. Prolonged hypertonic exposure revealed regulatory volume decrease (RVD). After restoring normal osmotic pressure, the tissue volume was increased in the volume of exchange of ions TMA+ or TEA+ administered by iontophoresis. All current solutions depressed the muscimol-induced current and usually also the voltage-gated Ca2+ currents. V-gated Ca2+ currents were depressed by anisomotic, but not by NaCl deficient isosmotic solution. We conclude that GABA receptor controlled ICl channels may be partially shut down in a strongly anisomotic or NaCl deficient environment. The Serotonergic Inhibitory Postsynaptic Potential in Peripotential Hypoglossal Motor Neuron: Is It Reversibly Patched?

Synaptic inhibition mediated by the activation of potassium channels has been reported from several types of neurons. In each case, the K⁺ conductance underlying the synaptic potential is activated by a G protein and inwardly rectifies. We report here a second K⁺ current that contributes to synaptic inhibition. Intracellular recordings were made from guinea pig nucleus prepositus hypoglossi in vitro, where we have described a 5-hydroxytryptamine (5-HT)–mediated synaptic postsynaptic potential (IPSP). Voltage-clamp analysis of the current induced by applied 5-HT revealed two separate conductances: an inwardly rectifying, rapidly-activating K⁺ current (Ig) and an outwardly rectifying, slowly-activating K⁺ current (Icq). Ig was blocked by extracellular Ba²⁺ (200 μM) and TEA⁺ (126 mM). Icq was blocked by Cd²⁺ and intracellular BAPTA, indicating Ca-dependence.

Single focal electrical stimuli evoked a 5-HT-mediated IPSP, or under voltage-clamp, an inhibitory postsynaptic current (IPSC). Ba²⁺ blocked only a component of this IPSC, which corresponded to the current caused by Ig. When multiple stimuli were applied (to prolong the release of transmitter), the time-dependent current Icq was more fully activated, resulting in an augmentation of the IPSC. We conclude that the IPSC is caused by both currents and that its amplitude is a degree to which Ig is activated. This represents a mechanism by which synaptic responses can be potentiated.

262.9

The role of metabotropic glutamate receptor (mGlur) in modulation of phrenic motoneuron excitability was studied in the in vitro neonatal rat brainstem/spinal cord preparation. Spontaneous PMN activity was recorded from cervical ventral root (C4) or by whole-cell patch-clamp techniques. In order to activate mGlur, trans-15(1R,2R)-2-amino-4-cyclothiazepane-1,3 dicarboxylic acid agonist (ACPD) was applied locally via pressure ejection over the ventral spinal cord surface at the level of the phrenic nucleus. To block mGlur, (R)-2-methyl-4-carboxyphenylglycine (MCPG) was added to the bathing solution. Local application of ACPD (0.2 - 0.7 μM) induced a spike of the inspiratory activity, in a dose-dependent manner. At higher concentrations (0.5, 0.7 mM), tonic activity was superimposed on the inspiratory activity. MCPG (0.1-1 mM) effects of ACPD. Local application of ACPD depolarized PMN resting membrane potential (10-15 mV) and produced a concurrent 9% decrease in the inspiratory drive potential. Current pulse injection under control conditions induced several spikes after ACPD application. Under voltage-clamp conditions, ACPD caused a tonic inward current (-150 pA) and a 32% drop in amplitude of the inspiratory synaptic current. The I-V curve exhibited a 10% increase of input membrane resistance. The ACPD-induced inward current remained after TTX was added to the bathing solution and was partially blocked by MCPG (0.4 mM).

These results show a postsynaptic action of ACPD and suggest that mGlur can modulate the excitability of PMNs. Supported by NIH Grant NS24742 and the Conseil Régional PACA.

LONG-TERM POTENTIATION: PHARMACOLOGY I

262.2

Electrophysiological studies of drug actions typically assess direct membrane effects on monosynaptic responses in order to characterize cellular mechanisms of action. However, the ultimate effects of drugs on behavior may depend on the compound's actions across serial cortical circuits. Drugs that modulate the function of AMPA-type glutamate receptors are of interest since AMPA receptors mediate responses at most excitatory synapses in the brain. The present study was undertaken to compare the effects of a novel AMPA receptor modulator, CX-516, on mono- and polysynaptic responses in hippocampus.

Hippocampal slices were prepared from adult male rats using conventional methods. Stimulation electrodes were positioned to activate a pyramidal tract (PP) fibers in the molecular layer of the dentate gyrus and Schaffer-commissural (SC) fibers in CA1. A recording electrode was placed in the CA1 apical dendritic field. PP stimulation evoked small (0.1-0.3 mV) negative field potentials in CA1 with latency and waveform characteristics consistent with them being mediated by the triphasic hippocampal circuitry. SC stimulation was set to elicit polysynaptic responses of the same amplitude as the triphasic response. CX-516 (25 μM, n = 6) reversibly increased the amplitude of the monosynaptic SC-evoked field EPSP by 52% (±18, S.D.) and that of the triphasic response by 188% (±56).

These results suggest that CX-516 is a new tool for studying the role of AMPA receptors in facilitating long-term potentiation in vivo. (Supported by AFSOR, ONR, NIH, and the Academy of Finland).

Previous work has shown that an experimental drug (BPD-1L3, benzodiazepine-5-y-carboxyloxypropionate) increases the amplitude and duration of EPSPs recorded in slices of hippocampus, while having little effect on the slope of responses. Studies with outside-out patches indicate that BDP modulates AMPA receptor gated currents. After intraperitoneal (i.p) injections and for 2 hours, BDP influences monosynaptic responses in the dentate gyrus and area CA1 in vivo in a similar manner to that observed in slices. Here we tested the effects of BDP on LTP in the CA1 of freely moving rats. LTP was induced using a minimal stimulation paradigm involving pairs of short high-frequency bursts (paired theta bursts) repeated 5 times at 30 seconds; this pattern produces a small and transient (24h) increase in the drug effect. Each of nine animals was tested both in absence and presence of the drug in a counterbalanced fashion. Injection of the drug prior to theta burst stimulation greatly facilitated the subsequent induction of LTP, i.e., the increase in slope and amplitude was larger in magnitude and more persistent (several days) following drug than vehicle injections. Biodistribution and pharmacokinetics were examined with positive emission tomography (PET) using BDP radiolabeled with carbon-11; the results confirmed that the drug rapidly migrates from the injection site and crosses the blood-brain barrier; time curve analysis for brain, heart and liver showed that the drug reaches a maximum in the brain in less than 4 minutes. The facilitatory effects on LTP induction in freely moving animals were replicated with an analogue of BDP (BPD-5), which was also found to improve retention in a radial maze and in an odor matching problem. These results define the first tool for enhancing LTP in vivo and confirm an important prediction from the hypothesis that LTP is a substrate of memory.

Recent studies have identified a novel class of drugs (Ampakines) that facilitates excitatory synaptic currents mediated by AMPA receptors. Since aging is accompanied by decreases in excitatory communication, it has been suggested that such drugs might offset certain types of age-related deficits. This idea rests on two unexamined assumptions about AMPA receptors in the aged brain i) that the binding site(s) for the drugs is unchanged from that found in young brains and ii) that the channel kinetic properties affected by the drugs are also comparable in young vs. aged brains. These assumptions were tested by comparing drug effects on synaptic responses in young (3-4 months) and aged (24-28 months) rats. Hippocampal slices were prepared using conventional methods and field EPSPs recorded in slices (CX-516 and CX-517) found to potent effect potentials in pilot studies were used. Both drugs produced qualitatively similar, dose-dependent, reversible enhancements of field EPSP amplitude and prolonged decay times in slices from young and aged rats. CX-516 had more potent effects on response amplitude whereas CX-517 was more potent in modulating the decay time. Quantitative comparisons involving several response parameters and patterns of synaptic activation will be described and shown to reinforce the conclusion that the drugs have essentially the same effects on synaptic responses in the young and aged hippocampus. Based on these findings, it appears that Ampakines may be used to test the hypothesis that facilitation of fast, excitatory transmission will have positive effects with regard to age-related changes in brain function. (Supported by APOSF, ONR, NIA, and NIH).

Quantitative in situ hybridization and reverse-transcriptase PCR were used to determine the relative levels of AMPA receptor subunit (GluR1-3) mRNAs in rat forebrain. In all regions sampled, Glur2 cRNA hybridization was dense, being greater than or equal to the other two subtypes. Levels of Glur1 and Glur3 mRNA, however, varied markedly between hippocampus, neocortex and piriform cortex. In hippocampal neuronal layers, Glur1 cRNA hybridization density was equal to Glur2 but was 3-4 fold higher than Glur3. In contrast, parietal cortex (layers II/III) had relatively low levels of Glur1 (40% of Glur2), but high levels of Glur3 (60% of GlrU2). In piriform cortex (layer II), Glur1 and Glur3 mRNA levels were both low (33% of Glur2). If relative levels of mRNA are predictive of relative levels of subunit protein, then it is likely that the stoichiometry of the AMPA receptor varies substantially between synaptic systems in cortical zones of the telencephalon. Attempts to test this using immunoprecipitation with antibodies directed at the subunits of the receptor are in progress. It will also be of interest to determine if the regional variations described here are associated with differences in plasticity of the LTP type which is reported to be dependent upon the AMPA receptor subunit composition as well as with the effects of recently developed drugs ("Ampakines") that facilitate AMPA receptor mediated responses in the hippocampus of behaving animals. Supported by AG00538.

62.7 TEA PRODUCES A PERSISTENT ENHANCEMENT OF SYNAPTIC TRANSMISSION IN RAT NEOCORTEX. Marc R. Pelletier* and John J. Habibitz. Neurobiology Research Center, University of Alabama at Birmingham, Birmingham, AL 35294.

We investigated the effects of teatetramyllanion (TEA) to induce long lasting changes in neocortical synaptic activity. Intracellular recordings were obtained from layer III/V pyramidial neurons in in vitro brain slices. Bath application of 25 mM TEA for 7 min produced transient effects on passive membrane properties and weak orthodromic input responses. However, input resistance was increased by 16 ± 4.2% of the duration action potentials, evoked by depolarizing current, was increased dramatically, an effect consistent with the blockade by TEA of K+ channels. Action potential duration was not different from control after 30-40 min of wash, TEA was then considered to have been washed out. TEA produced a persistent (45 min of wash) increase of 158% ± 7.6% in the amplitude of EPSPs evoked by weak orthodromic stimulation (layer IV/V, 0.05 Hz). The amplitude of EPSPs evoked by strong orthodromic stimulation was increased by 180 ± 10.0 %. These effects on synaptic transmission were APV (200M)-resistant (n=4). Orthodromic stimulation during TEA application was not required for enhancement (n=5). The enhancement of EPSPs, but not IPSPs, was blocked by recording with pipettes containing 200 mM BAPTA (n=4). TEA-induced enhancement of EPSPs in the neocortex is similar to that described in hippocampus. Additionally, we report an enhancement of IPSPs, which might be mediated presynaptically via an increase in GABA release.
622.9

In physiological conditions, the induction of LTP is mediated by NMDA receptors, whereas the expression is mediated primarily by AMPA receptors (AMPAR-LTP). To investigate the role of NMDA receptors in LTP, we have used the redox-sensitive probe 2,3-dinitrobenzenesulfenyl chloride (DTNB) to modulate the redox state of the NMDA receptor.

Our results show that the redox state of the NMDA receptor is crucial for the induction of LTP. In control slices, DTNB did not affect the expression of LTP. However, in slices treated with DTNB, the expression of LTP was completely abolished. This suggests that the redox state of the NMDA receptor is essential for the expression of LTP.

These findings have important implications for understanding the mechanisms underlying long-term potentiation (LTP) and may provide new targets for the development of anti-epileptic drugs.
622.15

PQQ is a putative essential nutrient shown in vitro to diminish NMDA ionic currents and neurotoxicity by direct oxidation of the NMDA receptor redox site (J. Neurosci. 1992;12). Administration of PQQ prior to hypoxia/ischememia induced rats. This effect was supported by a significant reduction in the slope of the EPSP (52.5 ± 8.5% (mean ± SE, n=12 slices, n=12 rats). DTT exposure (100µM for 30 min, followed by 30 min wash) did not affect the magnitude of LTP (88.9 ± 16.6% (n=8 slices, n=8 rats, p<0.04). In contrast, following exposure to DTT, PQQ (100µM) significantly reduced LTP (10.7 ± 4.7%, n=7 slices, p<0.005). These results are consistent with in vitro observations from cultured cortical neurons and demonstrate, in intact, that exposure to PQQ reverses the action of DTT on NMDA receptor mediated events (NS3718, EFA, AHA).

LONG-TERM POTENTIATION: PHARMACOLOGY I

623.1

THE INFLUENCE OF GABA, AND GABA-ANTAGONISTS ON THE MAINTENANCE OF HIPPOCAMPAL LONG-TERM POTENTIATION IN RATS. Klaus Schollmeier*, Franziska Krause & Uwe Frey, Inst. Neurolol., Neuroreg. & Plasticity, Bremencke- Str. 6, P.O. Box 1860, 38088 Mapleburg, Germany

Hippocampal long-term potentiation (LTP) is thought to serve as an elementary model for the investigation of processes underlying learning and memory formation. Since a possible involvement of GABAergic transmission on the prolonged maintenance of LTP (4 hours) has not yet been shown, we examined the influence of GABAergic antagonists on the maintenance of hippocampal LTP in the CA1 region in vitro. The method used has been described previously by Frey et al. (Brain Res.: 452, 57 - 65, 1988).

Here we present some evidence that bath application of the GABA, antagonist picrotoxin (10 µM) and of the GABA,A antagonist 5-aminovaleic acid (50 µM) did not block the induction and maintenance of LTP at least for 8 hours. Even the application of 50 µM picrotoxin and 50 µM 5-aminovaleic acid together had no influence on the induction or maintenance of LTP. Since application of 10 µM picrotoxin (as used in the first set of experiments) in combination with 50 µM 5-aminovaleic acid did not cause complete inhibition of the GABAergic transmission, 50 µM picrotoxin was used in experiments, where both substances were applied simultaneously.

Our results indicate, that the induction and prolonged maintenance of hippocampal CA1-LTP is independent of GABAergic transmission.

623.2

Inhibitory Synaptic Transmission Modulates the Induction of Long-Term Depression in CA1 Region of Hippocampus. P.M. Steele, M.D. Mauth*, Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School-Houston, TX 77225.

The goal of this study was to examine the role of GABAergic input in the induction of long-term depression (LTD) at the Schaffer collateral/commissural synapses in area CA1 of hippocampus slices. The induction of LTD in the hippocampus (Yang et al., Soc. Neurosci. Abstracts, #183, 1993) and possibly in the cerebellum (Elkot et al., Brain Research, 1985) is regulated by GABA. Therefore, we hypothesized that GABAergic input is required for LTD induction in the hippocampus. To test this hypothesis we attempted to induce LTD in the presence of 50 µM picrotoxin (GABA,A antagonist) and again in the same slice one hour after picrotoxin washout. We find that low frequency synaptic stimulation (600 pulses at 1 or 3 Hz) in the presence of picrotoxin produces only a transient decrease of EPSP slope. This decrease returned after 25 minutes to 98% ± 1 of baseline after 1 Hz stimulation and 95% ± 2 after 3 Hz stimulation. In the same slice LTD could be reliably induced after picrotoxin washout; EPSPs were reduced to 86% ± 2 and 80% ± 1 after 1 and 3 Hz stimulation respectively. These results suggest that GABAergic synaptic transmission can influence LTD induction.

623.3

GABAergic AND DEVELOPMENTAL MODULATION OF HOSONSYNAPTIC LTD AND DEPOTENTIATION IN THE HIPPOCAMPUS. J.J. Wagner* and B.E. Alger, Dept. of Physiology, School of Medicine, University of Maryland, Baltimore, MD 21201.

To test the hypothesis that GABA may regulate the induction of homosynaptic LTD and depotentiation (DPT), we compared the effects of GABA antagonists on hippocampal slices from young (16-22 days) and mature (5-10 weeks) rats. The slices of extracellular CA1 field EPSPs were used to monitor synaptic transmission and spines. Low-frequency stimulation (LFS, 1 Hz, 900 pulses) elicited LTD with respect to baseline synaptic transmission, or DPT from a potentiated level following LTP induction by HFS (100 Hz/1 sec) in young animals, LTD was inhibited by 1 nM CGP 35348 (a GABA,B antagonist), -1.2 ± 2%, n=10 vs a 27 ± 1%, n=9 decrease in EPSPs from control slices. In contrast, homosynaptic DPT was unaffected by CGP 35348. In mature animals, LFS did not induce significant LTD (4 ± 2%, n=38, from baseline), although significant DPT could be consistently elicited by an LFS given 30 minutes after LTD induction (24 ± 5%, of potentiation remaining, n=15). Bicuculline (10 µM, a GABA,B antagonist) had no significant effect on LTD magnitude in young animals, but significantly enhanced LTD expression in slices from mature animals. In addition, after HFS, LTD (relative to the initial baseline) was expressed in mature slices following 3-5 LFS episodes. Our results suggest that the influences of both age, and of prior synaptic activity (i.e. HFS) on LTD induction can be explained by changes in GABAergic systems in young vs mature, and naive vs tetanized slices.

623.4

NITRIC OXIDE REGULATES THE THRESHOLD OF FREQUENCY DEPENDENT PLASTICITY IN AREA CA1 OF RAT HIPPOCAMPUS. P.L. Malenzi* and P.F. Chapman, Graduate Program in Neuroscience and Department of Psychology, University of Minnesota, Minneapolis, MN 55455.

Inhibition of nitric oxide synthase (NOS) blocks the induction of certain forms of long-term potentiation (LTP) and disrupts the acquisition of several different forms of learning. We examined the effects of two nitric oxide (NO) donors and NOS inhibitors on plasticity in area CA1 of the rat hippocampus slice. Standard techniques were used for hippocampal slice preparation. Slices were obtained from Sprague-Dawley rats (14-35 day old) and experiments were performed in a continuous superfusion system. In the presence of an NO donor, stable LTP could be induced by a variety of tetanic stimuli that were normally below threshold for LTD induction. We were able to induce LTD at stimulus parameters as weak as 2 Hz pulses delivered at 10 Hz in the presence of the NOS donor hydroxylamine (200 µM) or 5-aminos- N-acetylpenicillamine (200 µM). In the presence of the NMDA receptor antagonist AP5, a subthreshold stimulus of 25 pulses delivered at 10 Hz in combination with hydroxylamine induced a slowly developing potentiation. The frequency of synaptic potentiation is a critical factor in determining the resulting plasticity. While holding the absolute number of stimulus constant (900), varying the frequency of stimulation from 1 Hz to 30 Hz will shift the resulting plasticity along a curve from depression to potentiation. The results suggest that nitric oxide alters the induction of long-term depression. Supported by a grant awarded to PFC from the Whitaker Foundation.
3.5 Long-term potentiation: Pharmacology II

3.6 Activation of adenosine A<sub>2</sub> receptors potentiates synaptic transmission in the hippocampus
D.J. Mogil*, L.S. Overstreet, K.M. Fleming, & B.L. Trommer
Dept. of Biomedical Eng., Neuroscience, Pediatrics, & Neurology;
Northwestern University and Evanston Hospital, Evanston, IL 60201
Adenosine is released as a retrograde messenger following theta frequency stimulation. Adenosine agonists have been shown to decrease synaptic transmission via activation of an A<sub>2</sub> receptor subtype. We have previously shown that non-A<sub>2</sub>-receptor activation significantly potentiates fast-type Ca current in layer II/III pyramidal neurons from the medial entorhinal cortex (Mogil et al., Neuron, 10: 1993). This effect appears to occur via activation of the A<sub>2</sub>-receptor since the effect is observed with the non-selective A<sub>2</sub>-agonist DMPA but is not observed with selective A<sub>2</sub>-agonists. We tested the effect of A<sub>2</sub>-agonists on synaptic transmission in young adult rat transcortical hippocampal slices. Stimulation was applied to Schaeffer pathway and extracellular potentials were recorded in stratum radiatum of CA1. The percentage potentiation was measured under brief stimulation (100 Hz, 1 sec) with a post-tetanic potentiation (PTP) that returned to baseline within 10 min. LTP induced by T<sub>2</sub> in control solution was not affected by subsequent DMPP exposure, however no additional LTP could be induced (although PTP was observed). These results suggest that A<sub>2</sub>-receptors may be involved in the induction of some component of LTP.

3.7 Developmental changes in cellular mechanisms of long-term potentiation: The role of NMDA receptors in the hippocampal maturation of the rat
The role of NMDA receptors in the hippocampal maturation of the rat was investigated. We report that in the immature rat, the NMDA receptor is essential for the generation of long-term potentiation (LTP). This was shown by the observation that in the immature rat, the NMDA receptor is essential for the generation of LTP. In the mature rat, the NMDA receptor is not essential for the generation of LTP.

3.8 Induction of LTP in a sympathetic ganglion needs activation of the 5-HT<sub>3</sub>-receptor
S. Attarzadeh Saboury, S. Appaageorgiou, S. B. Akakpo, & V. V. Hogan* Department of Biology, Texas Southern University* and Department of Pharmacological and Pharmaceutical Sciences, College of Pharmacy, University of Houston, Houston, TX 77004-2515
In the superior cervical ganglion (SCG) of rat, brief preganglionic supramaximal tetanic pulse induced LTP mediated enhancement of the compound action potential in the postganglionic pathway. LTP in the SCG is independent of activation of cholinergic or adrenergic receptors during tetanic stimulation. Serotonin has been reported to present in some of the ganglion interneurons; the small intensely fluorescent (SIF) cells. We examined the role of the serotonin 5-HT<sub>3</sub>-receptor subtype in LTP because it is widely distributed throughout the peripheral nervous system and exists at high density in peripheral neurones. Pretreatment of ganglia with the 5-HT<sub>3</sub>-receptor antagonist MDL22222 (0.5 μM) 1 hr before the high frequency stimulation prevented the expressed LTP. To confirm the role of endogenous serotonin in the generation of LTP, we used ganglia from rats treated with reserpine (3 mg/kg) 24 hrs prior to removal of ganglia. In contrast to ganglia from untreated rats, those from reserpine treated animals showed no compound action potential in the postganglionic pathway but prevented the expression of LTP.

3.9 Histamine and long-term potentiation
R.E. Brown, H.L. Haas, & K.G. Brayman
Long-term potentiation (LTP) of glutamatergic synaptic transmission in the hippocampus, a candidate mechanism for learning and memory formation, is mediated by a number of neurotransmitters. Since histamine can increase calcium influx through the N-methyl-D-aspartate (NMDA) subtype of glutamate receptors, we examined the role of histamine in the generation of LTP, we wanted to see if histamine could also mediate the induction of LTP.
We tested this possibility in the CA1 region of rat hippocampal slices, prepared according to standard protocols. Application of tetanus (10 26.5, 50 Hz) was delivered twice in the same slices with an interval of 140 min. In control experiments this tetanus led to a short-term potentiation (lasting less than one hour) of the field excitatory postsynaptic potentials on both occasions (n = 6, p > 0.05). However, when histamine (100 μM) was washed in 20 minutes prior to the second tetanus, a long-term potentiation was observed which was significant for up to 3 days following the tetanus (n = 8, p < 0.01). A higher concentration of histamine (10 μM) also gave significant potentiation at 60 min following the tetanus but by 90 min the potentiation was no longer significant (n = 7).
We tried to block this effect with the H<sub>1</sub> antagonist, mepramine (1 μM), and the H<sub>2</sub> antagonist, cimetidine (50 μM), applied together before the first tetanus but washout did not block the potentiation. This indicates that histamine did not affect the LTP produced by the combination of weak tetanus and histamine (100 μM) application. In additional experiments we confirmed that histamine could enhance NMDA receptors, we include in this experiment that histamine facilitated the induction of LTP by enhancing NMDA currents.

3.10 Propranolol suppresses LTP induction in both the lateral and medial perforant path inputs to the dentate gyrus.
J.M. Surveys & C.R. Bramham
Dept. of Pharm., Uniformed Services University, Bethesda, MD
Recent evidence suggests that the lateral (LTP) and medial (MPP) perforant path inputs to the dentate gyrus can exhibit different forms of long-lasting synaptic plasticity. Norepinephrine application induces a lasting potentiation of non-adrenergic and non-cholinergic depression of LTP responses, while LTP induction in the LPP, but not MPP, requires opioid receptor activation. β-Adrenergic receptor activation is also known to be important for LTP induction in the dentate gyrus. However, the role of β-receptors in LTP has not been assessed using selective stimulation of LTP and MPP fibers.
High-frequency stimulation (HFS; 100 Hz, 1 or 2 s) applied to the dentate outer or middle molecular layers of the rat hippocampal slices induced selective LTP of LPP or MPP responses, respectively, as assessed by field EPSP slope measurements obtained from the synaptic layers. The perfusate was continuously superfused with a physiological K<sub>P</sub> solution in the granule cell layer. In the MPP, the β-adrenergic receptor antagonist (-)-propranolol (1 μM) reduced in magnitude, but did not completely block, LTP of the field EPSP and population spike. In the LPP, LTP of the field EPSP appeared normal. These results suggest that β-adrenergic receptor activation is required for full LTP induction of both the lateral and medial perforant path inputs to the rat dentate gyrus. Supported by NIH NS23685.
623.11 DELTA AND MU OPIOID RECEPTOR ACTIVATION IS REQUIRED TO INDUCE LTP IN THE LATERAL PERFORANT PATH OF NORMAL, BUT NOT DISINHIBITED, HIPPOCAMPAL SLICES. C.R. Brambati and J.M. Survey. Dept. of Physiology, University of Pennsylvania, Bethesda, MD.

Opioid receptor-dependent LTP has been demonstrated in the lateral perforant path (LTP) input to the dentate gyrus, a system which is thought to use glutamate and opioid peptides as co-transmitters. However, both glutamate receptor pharmacology and the specific action of opioids have not been characterized. High-frequency stimulation (HFS; 100 Hz, 1 s) applied to the dentate outer molecular layer of rat hippocampal slices induces LTP of long-term potentiation (LTP) as assessed by EPSP slope measurements obtained 40 min post-HFS. In slices maintained in normal ACSF, LTP induction was blocked or significantly reduced in magnitude when HFS was applied in the presence of the general opioid receptor antagonist, naloxone (5 μM), the delta receptor antagonist, naltindoline (50 nM), the mu receptor antagonist, CTAP (100 nM), or the NMDA receptor antagonist, AP5 (20 μM), while the kappa-1 opioid receptor antagonist nor-BNI (60 nM) did not affect LTP.

Selective LTD of the LTP was also obtained in slices maintained in ACSF containing picrotoxin (50 μM) which attenuates GABA-A receptor mediated inhibition. However, in disinhibited slices, HFS applied in the presence of naloxone induced LTD equivalent to control values. The results suggest that delta and mu opioid receptors regulate LTP induction in the LPP by a mechanism which depends upon GABAergic inhibition. Supported by NIH NS23865

Physiological functions of the PCOM-derived peptide CLIP (ACTH 18-39) are scarcely documented. Recently, we have demonstrated that an intracerebroventricular administration of CLIP caused a marked enhancement of neuronal excitability in the hippocampal CA1 region as well as a selective increase of paradoxical sleep. The sleep studies led to suggest that the active sequence is located in the N-terminal part of CLIP.

The present study was conducted to test whether CLIP can modulate neuronal transmission in the dentate gyrus and if the N-terminal sequence of CLIP is responsible for these effects. Experiments were performed on freely moving male Wistar rats (8-9 weeks old), housed individually with food and water ad libitum. A monopolar recording and a bipolar stimulation electrode were implanted stereotactically in the granule cell layer of the dentate gyrus and in the perforant path, respectively. For recording of electrically evoked population spikes, an electrode was placed in the M2 region. The sequence was injected into the CA1 region (5 ng/μl, 0.5 μl) to test for its effects on LTP. The amplitude of LTP was found to be significantly enhanced after the injection of CLIP.

623.13 TEMPORAL DIFFERENCES IN THE PHOSPHORYLATION STATE OF PRE- AND POSTSYNAPTIC PKC SUBTYPES DURING LONG-TERM POTENTIATION IN HIPPOCAMPAL SLICES. Koji Fukanaga1, Dominique Muller2 and Eishichi Miyamoto1. 1Department of Pharmacology, Kumamoto University School of Medicine, Kumamoto 860, Japan and 2Center for Medical University, Universit‡it de Genf, Facult‡e de Medicine, CH 1211 Genf 4, Switzerland.

Among the molecular mechanisms that have been proposed to contribute to the induction of LTP in the hippocampus is the activation of Ca2+-calmodulin-dependent protein kinase II (CaMKII) following the stimulation of the NMDA receptor. Recently, we documented long-lasting increases in the Ca2+-independent and total activities of the enzyme as well as an increase in the ratio of Ca2+-independent to total activity following the induction of LTP (J. Biol. Chem. 268, 7853, 1993). It could suggest that autophosphorylation of the enzyme is responsible for the change in CaMKII activity. Here we demonstrate with [32P]-labeled hippocampal slices that high, but not low frequency stimulation applied to two groups of CA1 afferents resulted in increases in autophosphorylation of both α and β subunits of CaMKII I 1 hr after LTP induction. In addition, significant increases in phosphorylation of endogenous CaMKII II substrates, synapsin I and microtubule-associated protein 2 (MAP2), were observed in the same slices. The stimulations of phosphorylation of CaMKII II and its substrates could be blocked by preincubation of slices with an NMDA receptor antagonist, D-2-amino-5-phosphonopentanoate. These results suggest that LTP is associated with increases in phosphorylation of synapsin I and MAP2 during the activation of CaMKII II.

Aluminum (Al) intoxication is known to induce cognitive dysfunctions and multiple forms of neurodegeneration. The precise mechanism of Al toxicity is not clear. In order to investigate the action of Al on synaptic transmission and long-term potentiation (LTP) in area CA1 of hippocampal slices, field potentials were evoked by stimulation of Schaffer collaterals (0.2 Hz) and recorded in the stratum pyramidale of the CA1 region. After stable population spikes were recorded for 30 min in modified ringer solution, Al was applied for 30 min by bath perfusion. Low concentrations (0.68 μg/ml Al) increased the amplitude of the population spike slightly (121%) whereas 2.7 μg/ml (100 μM) decreased the amplitude (75%) and concentrations ≥ 4 μg/ml (150 μM) blocked the population spikes completely. The action on synaptic transmision was reversible. Induction of LTP by high-frequency stimulation in the presence of 0.68 μg/ml Al lead to a reduced level of potentiation compared to control experiments. In the presence of 2.7 μg/ml Al potentiation was further reduced and declined to baseline level within 60 min. Subsequent washout did not lead to any recovery of the signal. For low Al concentrations (0.68 μg/ml), a rebound of the effect was found in case of washout after potentiation. The blockade of the population spike increased to values above those in control experiments (> 250%).

Our data suggest multiple sites of actions of Al on synaptic transmission and LTP. Both stimulating and inhibitory effects were found as a concentration dependent manner. These interactions might contribute to the neurotoxic potency of Al.

623.15 ENDGENOUS SUBSTRATES FOR Ca2+-CALMODULIN-DEPENDENT PROTEIN KINASE II DURING THE INDUCTION OF LONG-TERM POTENTIATION IN THE HIPPOCAMPUS. Kohji Fukanaga1, Dominique Muller2 and Eishichi Miyamoto1. 1Department of Pharmacology, Kumamoto University School of Medicine, Kumamoto 860, Japan and 2Centre for Medical University, Université de Genf, Faculté de Medicine, CH 1211 Genf 4, Switzerland.

Recently, it has been demonstrated that the intracerebroventricular administration of CLIP caused a marked enhancement of neuronal excitability in the hippocampal CA1 region as well as a selective increase of paradoxical sleep. The sleep studies led to suggest that the active sequence was located in the N-terminal part of CLIP.

The present study was conducted to test whether CLIP can modulate neuronal transmission in the dentate gyrus and if the N-terminal sequence of CLIP is responsible for these effects. Experiments were performed on freely moving male Wistar rats (8-9 weeks old), housed individually with food and water ad libitum. A monopolar recording and a bipolar stimulation electrode were implanted stereotactically in the granule cell layer of the dentate gyrus and in the perforant path, respectively. For recording of electrically evoked population spikes, an electrode was placed in the M2 region. CLIP was injected into the CA1 region (5 ng/μl, 0.5 μl) to test for its effects on LTP. The amplitude of LTP was found to be significantly enhanced after the injection of CLIP.

Rb is the regulatory subunit of cyclic AMP-dependent protein kinase (PKA) that is expressed primarily in neurons and therefore might play a role in several types of synaptic plasticity. Mice carrying a null mutation in the gene encoding Rb were produced via homologous recombination in embryonic stem (ES) cells. These results established that a compensatory increase in Rb protein in various regions of the brain. The hippocampal slice was selected to employ specific mouse model. In the CA1 region, the mutants show normal field potentials in response to Schaffer collateral stimulation, normal paired-pulse facilitation, and normal long-term potentiation (LTP), even at three hours post-tetanus. In a protocol that reliably produced long-term depression (LTD), induced by 900 pulses @ 1 Hz in slices from control mice produced only a transient depression in mutant slices. Depression following LTD in the CA3 region was similar in both control and mutant mice. A protocol that normally produced NMDA receptor-dependent LTD of the field potential evoked by population spikes. Long-term potentiation (LTP) was induced by food stimuli (10 s) produced no LTD in mutant mice. Thus, the Rb isoform of PKA is necessary for at least two forms of hippocampal plasticity.
624.2

We have previously demonstrated that prolonged exposure of cultured cortical cells to amphetamine (AMP) increases [H]HT binding in a dose- and time-dependent manner. To examine whether there are similar effects of glucocorticoids on cortical cells, the cells were exposed to corticosterone (COR), dexamethasone (DEX) or dexamethasone (DECO) for 1 to 6 days. Glucocorticoids (COR, DEX) significantly induced increases in [H]HT/intact cell binding in a dose-dependent manner, but mineralocorticoid (DECO) did not. Scatchard analysis revealed that subchronic exposure of COR induced reduction of both Kd and Bmax values of [H]HT/intact cell binding as well as subchronic exposure of AMP.

In addition, AMP-induced increases in [H]HT/intact cell binding was enhanced by co-administration of COR. Considering the findings that cross-sensitization occurs between stimulants and a variety of stresses, it is of interest that glucocorticoid (one of the biological indicators for stresses) affects the [H]HT binding and suggested that NMDA receptor/ion channel complex is involved in the cross-sensitization.

624.4

Focal stimulation of fiber bundles from the hippocampus results in the appearance of an EPSP-IPSP-LHP sequence when recording from the DLSN slice preparation. GABA, acting at GABA_A and GABA_B receptors, mediates the inhibitory postsynaptic potential (IPSP) and the late hyperpolarizing potential (LHP), respectively. In addition to these inhibitory responses, excitatory postsynaptic potentials (EPSPs) mediated by excitatory amino acid receptor activation are also recorded from DLSN neurons. We now report that cocaine acts to inhibit synaptic transmission in the rat DLSN through pre- and post-synaptic mechanisms.

Standard intracellular current-clamp and voltage-clamp recordings were made from neurons in rat brain slices containing the DLSN. Orthodromically-induced synaptic responses were obtained before and during drug superfusion. Superfusion of cocaine (1 µM) produced a membrane hyperpolarization due to an outward current that gradually faded during continuous superfusion. The amplitude of the IPSP and LHP were reduced during the cocaine-induced hyperpolarization even after the membrane potential was returned to its pre-cocaine value. Following the hyperpolarization and during cocaine superfusion, the depression of the LHP and IPSP persisted. Voltage-clamp experiments revealed, moreover, that the amplitude of the late hyperpolarizing current (ILH) was decreased throughout cocaine superfusion. Cocaine did not reduce a hyperpolarization produced by bath application of baclofen. In addition, cocaine was able to reduce the EPSP and LHP without producing a membrane hyperpolarization. Our results suggest that cocaine suppresses synaptic responses in DLSN neurons, not only by changing the membrane potential, but also by producing a persistent increase in membrane conductance and by presynaptically affecting neurotransmission between the hippocampus and the DLSN. Supported by DA-07190.
624.5 PROPOFOL FACILITATES SUBSTANCE P-MEDIATED INHIBITION OF CALCIUM-ACTIVATED K-CONDUCTANCE IN A GUINEA-PIG HIPPPOCAMPUS. S. K. Nathanielsz, Dept. of Anesthesiology & CCM, Univ. of Pittsburgh, Pittsburgh, PA 15261, and VA Medical Center, Pittsburgh, PA 15240.

Free-running agent propofol (2,6-diisopropylphenol), DIPRIVAN® specifically augments substance P (SP)-but not VIP-mediated presynaptic responses of guinea-pig inferior mesenteric ganglion (IMG) neurons. Single-electrode current and voltage clamp studies on isolated perfused tissue demonstrated that perfusion of 100 µM SP had no effect on the resting membrane potential or input resistance of principal ganglion cells, but augmented in a dose-dependent fashion the amplitude and duration of membrane depolarization and inward current responses evoked by exogenous SP applied via pressure microinjection from nearby pipets (Picophoretzer). The increase in SP-evoked inward current responses resulted from propofol-induced inhibition of an outward current component which was also inhibited by 20 µM TEA, but not 1 mM TEA. SP-evoked inward current responses augmented by 20 mM TEA were not further altered by the additional administration of propofol. During the SP response in normal K+ solution, intermittent depolarizing voltage step (20 mV, 5 s) 0.05 Hz-evoked calcium-activated potassium (V_{Ca}K) tail currents were transiently reduced in amplitude. Propofol had no effect on V_{Ca}K tail currents in the absence of SP, but extended the time period during which V_{Ca}K tail currents were reduced following SP application for the duration of the prolonged SP-evoked inward current response. These findings suggest that the increase in SP-evoked inward current response by propofol is the result of an increase in SP-mediated inhibition of outward current, and membrane depolarization in response to SP. This action represents a novel mechanism of anesthetic action of propofol not attributable to the known facilitatory property of this compound on GABA-A receptor/channels complexes.

624.7 EFFECTS OF THIOPENTAL AND PHORBOL ON CAI FIELD POTENTIALS IN THE RAT HIPPOCAMPUS Y. C. Tsai, E. Narimatsu, T. Gerhold, S. Kamath and M. Sokolii, and E. Węgrzynowicz*. Dept of Anesthesiology, Univ of Iowa College of Medicine, Iowa City IA. 52242.

Thiopental (THIO) has been used primarily as an induction agent for the past 60 years. Because of its structural difference, it has been assumed that its site of action differs from that of the inhalational anesthetics in producing the anaesthetic state. We studied the effects of thiopental on the electrotonic potential of the CAI cell group of the rat hippocampal slice and its interaction with phorbol di-acetate (PDA). In previous studies we examined the interaction between halothane and PDA. Rats were anesthetized with ketamine, sodium pentobarbitone and 400µm thick slices of hippocampus prepared and mounted in a bath. The Schaffer pathway was stimulated using a platinum bipolar electrode and field potentials were recorded with glass microelectrodes (resistance 3-8 MΩ). The two negatively potentials N1 and N2 were analyzed for amplitude, and latency. N2 was also analyzed for slope of the onset of the potential. The potentials were recorded following which THIO (400 or 800 µM) was applied for 30 minutes. Recordings were again made and then PDA 0.25, 0.5 or 1.0 µM was applied sequentially and potentials again recorded. THIO application resulted in approximately a 50% decrease in the amplitude of N2. Application of PDA 1.0µM resulted in approximately a 20% recovery of the amplitude of N2. This reversal is less than that with halothane. These results support the concept that the inhalation and intravenous anesthetics, at least to some extent, act at different sites.

624.8 HALOTHANE AND PROPOFOL INCREASE THE COFACTOR SENSITIVITY OF PURIFIED BRAIN PROTEIN KINASE C. H. Hemming, J. A. Aller Adams, M. M. Hoffman, Departments of Anesthesiology and Pharmacology, Cornell University Medical College, NY, 10021.

Protein kinase C (PKC) has been implicated in a target for general anesthetics. The activation of purified brain PKC is stimulated by general anesthetics when assayed with a physiologically relevant lipid bilayer preparation in vitro. Here we report the further biochemical characterization of the stimulatory effects of halothane and propofol on PKC activation. PKC was purified to >98% homogeneity from bovine forebrain and assayed with 0.2 µg/ml histone H1, 2 µM 1-2,5-diacetylgluceraldehyde (DG)20 µM phosphatidylserine (PS)50 µM phosphatidylinositol lipid vesicles, 50 mM HEPES (pH 7.4), 1 mM EDTA, 5 mM CaCl2, 10 mM Mg-acetate, and 100 µM 1-2,5-ATP at 30°C for 30 min. The values are expressed as mean±SD. *p<0.05, **p<0.01 (paired t-test value without anesthesia).

Both halothane and propofol increased the sensitivity of PKC to activation by DG, PS, and Ca2+, without affecting its apparent affinity for the artificial substrate histone H1. These data suggest that general anesthetics may stimulate PKC activity not by mimicking one of its regulators, but by stabilizing its active conformation. Efforts are underway to extend these observations made with purified PKC in vitro to endogenous neuronal PKC and PKC substrates in order to further assess the role of PKC mediated protein phosphorylation in general anesthetic action.

Supported by a FAER/BAC Neuroscience Young Investigator Award and a Cornell Scholar Award in Biomedical Science.

624.4 INTERACTIONS OF APV, Picrotoxin and Phorbol Dl-acetate on Halothane Depressed CAI Potentials in the Hippocampus. E. Narimatsu, Y. C. Tsai, S. Kamath, and M. Sokolii*. Dept. of Anesthesiology, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

The effects of the inhalation anesthetic halothane and its interactions with phorbol di-acetate (PDA) and the NMDA antagonist d-2-amino-5-phosphonopentanoic acid (APV) were studied in CAI layer of hippocampal slices. Halothane was applied to CAI slices using 100 µM ketamine and 400 µm thick slices 400µm thick were cut and mounted in a bath. The Schaffer pathway was stimulated using a platinum bipolar electrode and recorded with glass microelectrodes (resistance 3-8 MΩ).

The two negatively potentials N1 and N2 were analyzed for amplitude, and latency. N2 was also analyzed for slope of the onset of the potential. The potentials were recorded following which THIO (400 or 800 µM) was applied for 30 minutes. Recordings were then made and then PDA 0.25, 0.5 or 1.0 µM was applied sequentially and potentials again recorded. THIO application resulted in approximately a 50% decrease in the amplitude of N2. Application of PDA 1.0µM resulted in approximately a 20% recovery of the amplitude of N2. This reversal is less than that with halothane. These results support the concept that the inhalation and intravenous anesthetics, at least to some extent, act at different sites.

These results show clearly that halothane affects neurotransmission in hippocampus, and indicate a possible mechanism for excitatory neurotransmitter systems. Supported by EFA fellowship(YS), by the VA research service and by research grant NS13815 from NINDS.

624.10 PHARMACOLOGY OF TRANSMITTER RELEASE IN THE DEVELOPING CHICK HEART. D. B. Gray* and C. E. Ellison, Department of Physiology and Neurobiology, Univ. of Connecticut, Storrs, CT 06269.

Potassium-evoked secretion of acetylcholine (ACh) and noradrenaline (NE) from cardiac parasympathetic nerve endings in cultured sympathetic cell somas respectively, is mediated by Ca influx. In this report we have examined the calcium pharmacology of ACh release from cholinergic terminals in medullated axons of embryonic stage 40 and hatching chick hearts. At embryonic day 14, evoked ACh release from cholinergic nerve terminals in area can be inhibited by over 80% with 10 µM nifedipine. This sensitivity to nifedipine is gradually reduced to less than 30% at hatching. The release remaining ACh release at hatching can be blocked by either picrotoxin suggesting a switchover from L type calcium channels to N type channels involved in exocytosis-secretion coupling. Cultures of SI 40 sympathetic ganglia release labeled NE during a high potassium challenge (56 mM), and this evoked release is not sensitive to nifedipine. However, sympathetic neurons with live heart cell cultures do show sensitivity to nifedipine (>80%) suggesting that exposure to target may induce coupling of L type channels to transmitter release at least transiently, in these neurons. The effects of muscle target and developmental age resemble those in other autonomic ganglia (Gray et al., Neuron 7:15, 1992).

Additionally, embryonic secretion of vertebrate autonomic ganglia to nifedipine may have implications for hypertensive pregnant women. Supported by a grant to B. Gray from the Catherine and Patric Weldon Donaghue Foundation for Medical Research.

RILUZOLE: FREQUENCY-DEPENDENT ACTIONS INHIBITION OF SODIUM CHANNELS AND INHIBITION OF SYNAPTIC TRANSMISSION.
R.A. Bertoluzza*, S.L. Gurney, Ph. Bouruet, and J.C.R. Randell, Phamacy.
Rhone-Poulenc Rorer S.A., Central Research, 94403 Visy-sur-Seine, France.
Riluzole (3-(5-fluoro-2-thienyl)-2-aminobenzoic acid) is an anti-convulsant and neuroprotective agent. Promising results Phase II study in
amyotrophic lateral sclerosis. In cultured cerebellar granule neurons and
NG108-15 hybrid cells, riluzole (0.3-30 μM) induced a 5-30 mV negative
shift of Na* current, but had little effect on Na* current activation. Riluzole slowed the recovery of Na* current from inactivation (h: control = 8-20 ms; r: 30-60 ms). Thus, inhibition of Na* currents was frequency-dependent only at high activation frequencies (≥ 20 Hz). Depolarizing current pulses evoked trains of action potentials at 20-
50 Hz that were slowed by 3 μM riluzole and reduced to a single spike
by 10 μM riluzole. Riluzole has previously been shown to inhibit the release of glutamate in vitro and in vivo. In hippocampal slices, riluzole (1-30 μM) increased the extracellular threshold of the Schaffer collateral→CA1 pathway evaluated as the appearance of an evoked pre-synaptic fiber volley and a post-synaptic glutamate-mediated field potential; and increased the latencies of these responses, but did not reduce the maximal response amplitudes evoked at high stimulus intensities. When trains of 10 stimuli were applied at 20-100 Hz, marked "use-dependence" of the inhibitory effects was observed that was not overcome at increased stimulus
intensities. We conclude that use-dependent Na* current inhibition
underlies riluzole's selective inhibition of high frequency electrical activity.
Reduced pre-synaptic excitability would contribute to the inhibition of
synaptic glutamate release and excitatory neurotransmission. This selective
action of riluzole may allow it to exert anticonvulsant and neuroprotective
actions while resisting lower frequency "normal" synaptic transmission.

625.1
INTRACELLULAR CI- DIMINISHES G-PROTEIN-ACTIVATED K+ CONDUCTANCES IN RAT HIPPOCAMPAL NEURONS. R.A. Lenter*,
We made whole-cell recordings from CA1 cells in rat hippocampal slices with various recording electrode solutions. We found that G-protein-
mediated K+-dependent responses are suppressed when 160 mM KCl is in the intracellular recording solution instead of KCl3SO4 or potassium gluconate (KGluc). When KCl3SO4 was used, outward currents of the GABA(A) agonist, baclofen, were reduced by 60% relative to responses in cells recorded with KCl3SO4 or KGluc electrodes. Additionally, nonselective KCl3SO4 responses in the presence of glutamate antagonists and 
NMDA, which were reliably obtained when using KCl3SO4 electrodes, were small or nonexistent in cells loaded with KCl.
Membrane potential and resting input resistance did not differ among
recorded with the different solutions. When the non-hydratable
GTP analog, GTPγS, was included in a KCl3SO4 electrode, cells were
usually hyperpolarized and input resistances were significantly reduced.
However, cells recorded with KCl electrodes containing GTPγS had
membrane potentials and input resistances that were not significantly
different from control. These data suggest that high [KCl], prevents activation of a K+ conductance by GTPγS.
We conclude that internal Cl- can interfere with the activation of G-
protein-activated K+ conductance. It will be important to determine if the
interference occurs at the channel, the G protein or at some other stop.

625.2
GDP IS REQUIRED FOR ACTIVATION OF A GLYBURIDE, ATP- AND CROMAKALIM-SENSITIVE OUTWARD CURRENT IN RAT HIPPOCAMPAL NEURONS. G. Dromerick* and K. Kreutzler, Anesthesiology Research Dept., McGill University, Montreal, Quebec, H3G 1Y6, Canada.
There is no agreement between different groups working on cromakalim (CROM) effects on hippocampal neurons. For example, according to Pelti and
sensitive K+ current in cultured neurons. However, we found that cromakalim decreases a voltage-dependent outward current - probably a delayed rectifier -
in CA1 neurons in slices (Yarowsky et al, Neuron, 1993,18:979). The present data were obtained with whole-cell recording from CA1 pyramidal neurons in slices. In blue cells, held at +54 ± 3 mV (where currents were not discerned) by brief depolarizing pulses: at +2 ± 30 mV, currents diminished by 30 ± 10 %.
When the standard internal solution contained also 1 mM GDP, there was a significant outward current at +64 mV, and CROM increased outward currents at +4.2 ± 0.9 mV by 99 ± 24 % (n=19). The enhanced outward currents were reduced by CROM washout (n=2 cells) and by 10 μM GLYB (in 4 cells). When six other cells were recorded with electrodes containing both CTP (5 μM) and
GDP (1 mM), there was no net outward current at +54 mV and CROM reduced outward currents (at +0 mV, by 38 ± 11%). We conclude that, like many muscle cells, CA1 neurons have outward current channels that are both ATP- and GLYB-sensitive, and are opened by CROM - and therefore resemble classical
KATP Channels - but can be activated only when cysolic GDP is present.

MUSCARINE-INDUCED INCREASE OF AN INWARD RECTIFIER K+ CURRENT IS MEDIATED BY GIZ IN ATT-20 CELLS. T. Kosaka, T. Ohtsuka, Y. Kario, S. Nakagawa* and T. Nakajima*, Dept. of Anat. and Cell 1.,... and Dept. of Pharmacol. Univ. of Illinois at Chicago, Chicago, IL 60612, and Institue of Med. Sci., Univ. of Tokyo, Tokyo 113.
Muscarine and somatostatin induce an inward rectifier K+ current in a pituitary tumor cell line (ATT-20), and these effects are mediated by a G protein, Gi or Go. To investigate which subtype(s) of Gi mediates these agonist effects, we constructed PTK-
sensitive mutants of a-subunit cDNAs of Gi1, Gi2, and Gi3, and transfected them stably into ATT-20 cells. PTX ADP-
ribosylates the cysteine residue at the 4th from the carboxyl terminal of Giα or Goα, and uncouples those subunits from receptors. We mutated this cysteine residue of Giα to serine. The function of the transfected Gi was examined after the endogenous Gi and Go of the transfected cells were inhibited by wild type Giα cDNAs (Giz, Giza, or Giza, PTX-sensitive) were transfected into ATT-20 cells. Muscarine (100nM) and somatostatin (500 nM) effects on cell lines were examined with the whole cell clamp. Only in the cell lines into which the mutated (PTX-
sensitive) Giza cDNA was transfected, did the muscarine response become PTX-sensitive, suggesting that GiZ couples to the muscarinic receptors and enhances the activity of the inward rectifier K+ channel. For the somatostatin response, transfaction of any of the mutated Giza cDNAs did not alter the PTX-sensitivity of the response. Supported by NSF grant IUB-9207855.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
625.5 COMPARISON OF THE INCREASE IN POTASSIUM CONDUCTANCE BY GALANIN AND OXY-M (OXOTREMORINE M) IN MUDPUPPY PARASOMATIC NEURONS. J.M. Malaglina2 and R.L. Petersen. Department of Anatomy and Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

Galaniand muscarinic agonists hyperpolarize muscimuloparasympathetic neurons by activating a similar inwardly rectifying potassium conductance (GK). The present experiments were done to quantify and compare the increase in GK produced by galanin and the muscarinic agonist Oxy-M. All experiments were done on isolated ganglia associated with the canal ganglia of the mudpuppy, Necturus maculosus. Recordings were made using the perfused patch mode of the whole cell voltage clamp technique on cells bathed in physiological solution containing as electrolyte cations 3 mM Ba2+ and 30 mM KCl, 75 mM KCl, 3.6 CaCl2, 10 Hepes. Both agonists produced a concentration-dependent increase in GK. At low concentrations (10 nM galanin and 10 nM Oxy-M) the increase in GK was additive. In contrast, at high concentrations of either agonist the response faded, the response to subsequent application of the other agonist. The time course of GK activation was very different. The increase in GK by Oxy-M occurred rapidly, relatively transiently constant in the presence of agonist, and reversed quickly following removal of the agonist. The galanin-induced GK developed slowly and then faded. The time course of the fade was consistent whether or not galanin was removed from the bath. Previous experiments demonstrated that aspartic acid (AA) activates an inwardly rectifying GK with a time course similar to the galanin-induced GK. At maximum concentrations of Oxy-M or galanin, the AA-induced GK was obscured. Our results indicate that galanin or Oxy-M activate the same inwardly rectifying GK but that the mechanism of activation may be different. We suggest that the galanin-induced increase in GK may be mediated through a second messenger, possibly AA.

625.7 INVESTIGATING THE SITE OF Zn2+ ACTION BY SINGLE AMINO ACID SUBSTITUTION IN A VOLTAGE-GATED K+ CHANNEL. S.J. Gibbons1, G. Talukder1, M.M. Tamkur2, H. Shear2 and N.J. Harrison1. 1Anes and Crit Care Pharm/Phys, U. of Chicago, Chicago, Illinois 60637, 2Mol. Phys. and Biophys., Vanderbilt U. Nashville TN.

Zn2+ modulates the gating of a human cloned voltage-dependent potassium channel (Kv1.3) by binding to a specific site on the extracellular surface of the protein (Harrison et al. 1993 Mol. Pharm., 42). We have employed the techniques of site-directed mutagenesis and transient expression of mutant channels in HEK-293 cells to establish the amino acids which are important for the integrity of the Zn2+ binding site. Single amino acids in the S5-S6 domain ("P region") were chosen for mutation by comparing the amino acid sequence of known Zn2+-sensitive (Kv1.4 and 1.5) and insensitive (Kv1.2 and 2.1) channels. Whole cell recordings were made at 25°C, using intracellular solutions based on K gluconate and continuous extracellular perfusion with HEPS-buffered saline containing 3 mM K+. hKvL.1 channels expressed in HEK 293 cells activated at a significantly more depolarized potential than the same channels expressed in mouse L cells. Modulation by Zn2+ was studied. Our initial approach has been to generate mutants of KvL.1 with similar amino acids in the P region to KvL.3, which is very weakly modulated by Zn2+. Activation gating of KvL.3 (AATSK) is shifted to the right (V3a=+25 mV) compared to the wild-type (V3a=+15 mV) whereas activation of KvL.1 (H465K) is not significantly changed (V3a=+15 mV, n=4). Robust modulation of gating by 200pM Zn2+ is still observed for both channels although the right shift (U) is slightly reduced (w.t.+25.3mV, A455K+20.2mV, H465K+17mV, n=3-9). We are presently examining the affinity of these channels for Zn2+.

625.9 AN ATP-SENSITIVE K+ CHANNEL IN ISOLATED RAT NECORTICAL NEURONS: ACTIVATION BY GANGLIOSIDES Z-TONG and X-D TANG Dept. of Physiol., First Military Medical Univ., Guangzhou 510515, P.R. China

Our previous studies have indicated that gangliosides (GM) protect cerebral ischaemia by measuring infra-red area, contents of free radical and ECG. The ionic mechanisms were further studied here with patch clamp technique. Single neurons were isolated from Sprague-Dawley rat neonates at 8~18°C. The pipette and bath were all filled with TTX (1µM) and CaCl2 (0.3 mM) contained but glucose-lacking solutions, with potassium concentrations of 5, 5.5, 6 or 7.5 mM. In 7 cell-attached patches, 2~10 µM of monosialo-ganglioside-GM1 (Sigma, approx. 95%) produced a class of single channel currents which durations of the burst openings showed concentration-dependence. The values of the burst times resulted from 2, 5, 10 µM GM1 were 6±2 s (n=3), 21.4±3 s (n=3) and 42 s (n=1), respectively. The long-time burst-like openings would disappear after washing GM1 out. After formation of inside-out recording from the same, cell-attached patch, the channel activities were depressed by either 2 mM of Na2-ATP (Sigma) or 1 µM of glibenclamide (Sigma). The reversal potential was ~ 0 mV (pipette plus 2 µM ATP-sensitive type). In 6 inside-out patches, after applications of 5~10 µM GM1, single channel recorded often became multicellular activities which then recovered to single channel openings. The GM-elicted currents were inhibited by applications of 4 mM ATP or 2 µM glibenclamide, with a reversal potential of ~ 0 mV and a channel conductance of ~ 50 pS.

The results demonstrate that, under the conditions of metabolism inhibition (both without glucose and ATP), GM can activate ATP-sensitive K+ channels in rat neocortex. The mechanism was suggested to involve protein kinase C.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

625.10 PROSTAGLANDIN E2 REGULATES VOLTAGE-GATED POTASSIUM CHANNELS IN NEUROHYPOPHYSEAL NERVE TERMINALS. Lei ZHANG, Edward KARPINSKI and Christina BENSON. Dept. of Physiology, Univ. of Alberta, Edmonton, AB Canada T6G 2H7.

A high concentration of prostaglandin E2 (PGE2) has been demonstrated in the neurohypophysis and may have an important role in hormone release from the posterior pituitary. In the present studies, the whole-cell version of the patch clamp technique was used to investigate the effect of PGE2, on potassium (K+) currents in nerve terminals of isolated nerve fibers permeated from the rat neurohypophysis. PGE2, initially increased the delayed rectifier K+ current (Iq).

The effect of PGE2, on Iq, was transient with a return to control levels after 15 to 20 min. Additionally, 15 to 20 min after PGE2, administration, the transient outward current (Iw) was increased. These effects were concentration dependent, within the concentration range of 50 to 500 µg PGE2. forskolin, 8-bromo cyclic-AMP and dibutyryl cyclic-AMP also significantly increased Iq and simultaneously decreased Iw. These results show that cyclic-AMP modulates K+ channels in nerve terminals, and may mediate some of the effects of PGE2 on K+ channels and, hence, hormone secretion from the neurohypophysis.
625.11
5-HYDROXYTRYPTAMINE MODULATION OF DELAYED-RECTIFIER-TYPE POTASSIUM CHANNELS IN ANTENNAL-LOBE NEURONS OF THE MOTH MANDECA SEKTA. F. Kleppenhorst2, A. R. More,1 and J. G. Hildebrand1. 1ARL Div. of Neurobiol., Univ. of Arizona, Tucson, AZ 85721; 2Dept. of Zool., Univ. of Otago, Dunedin, NZ.

A principal goal of our studies of the olfactory system of the sphinx moth Manduca sexta is to determine the role(s) played by 5-hydroxytryptamine (5HT or serotonin) in the antennal lobe (AL, the principal olfactory centers) of the brain. In Manduca, each of the two ALs is innervated by a single SHT-immunoreactive neuron (J. Neurobiol. 49:451-465, 1997). Synaptic contacts between AL interneurons and the SHT-containing cell occur within the glomerular neuropil of the AL. The majority of these contacts are output synapses from the SHT-containing cell (J. Comp. Neurol. 338:5-16, 1993). In the brain of the adult moth, exogenously applied SHT (100 µM) leads to blunting of neuronal excitability and decreases in SP in AL interneurons (J. Neurosci. Abstr. 18:303, 1992). These effects can be mimicked by application of SHT to AL neurons in primary-cell culture (J. Neurosci. Abstr. 19:126, 1993). Both in vivo and in vitro, treatment with SHT leads to an increase in cell input resistance. Here we report that SHT causes prolonged closure of delayed-rectifier-type K+ channels in these cells. Applied to AL neurons in vitro, in brain slices, or in semi-intact brain preparations, SHT (5-10 µM) decreases channel opening probability and causes reversible reduction of delayed-rectifier K+ current. Single-channel recordings in cell-attached mode suggest that the effects of SHT on K+ channels of these type are mediated via a diffusible second messenger, the identity of which has yet to be established. Closure of delayed-rectifier-type K+ channels could account for the increased duration of action potentials observed in many AL interneurons in response to SHT. [Supported by a grant to ARM from the USA/NSF Cooperative Science Program and by NIH grant AI-32525 to JVM.]

625.12

We studied large-conductance, Ca2+-activated K+ (BK) channels in smooth muscle cells from the basilar artery of the guinea pig using the patch-clamp technique. In inside-out patches, the single channel conductance was 260 pS and in outside-out patches, the apparent dissociation constant for block by tetraethylammonium (TEA) was 280 nM. Our principal goal was to assess the contribution of BK channels to conductance at negative potential in the resting membrane potential. We measured Np, (number of channels in the cell x open channel probability) at physiological potentials by recording single channel currents in a whole-cell configuration, a hybrid technique designated the "outside-out-whole-cell" configuration. With physiological solutions inside and outside, including 1 µM Ca2+ internally, values (mean ± S.D.) of Np were 0.17 ± 0.56 for -40 and -30 mV, respectively. Our results on the single channel properties of this current indicate that, under conditions that simulate in part those expected with active myogenic tone, including a membrane potential of -40 mV and [Ca2+]i=0.1 µM, BK channels could contribute on the order of 10-20 mV to the membrane conductance, a value that compared favorably with the amount of depolarization observed under current clamp following external application of 1 mM TEA.

TETRANYPE: EFFECTS ON BKCa CHANNELS. P. Winkl1, T. Glaser, and H. Sommermeyer. Institute for Neurobiology, Troponovens GmbH & Co. KG, Berliner Strasse 136, 50637 Cologne, FRG.

The aldilid tetranype (TET) is used in traditional medicine in China because of its analgesic, anti-inflammatory and for its vasodilatory and antipertussive properties. Recently, TET has been used for differentiation of certain subtypes of Ca2+-dependent unitary channels of high conductance (BKCa) in rat neurophysiological nerve terminals and par intercellular media (Wang and Lemos, 1992). In these systems, it has been shown to block only (charybdotoxin) CTX insensitive type II currents, whereas QA's sensitive type I currents remained unaffected. In the present study the effects of TET were characterized in detail in two different cell systems. In the rat glioma cell line C6-BU1, ionomycin stimulated rubidium (Rb+) efflux was found to be sensitive to (charybdotoxin, ibitoxin and tetraethylammonium (TEA), while apamin and 4-aminopyridine (4-AP) were ineffective. This pharmacological profile suggests the existence of BKCa currents in these cells. Since ionomycin stimulated Rb+ efflux was not influenced by TET, BKCa channels in C6-BU1 cells seem to belong to the class I BKCa channel subtype. In GH3 (rat anterior pituitary tumor) cells BKCa currents were characterized using the patch clamp technique. In particular, our results in the study above, external applied CTXs and TEA reversibly blocked single channel currents, whereas 4-AP had no effect. Surprisingly, also TET turned out to inhibit BKCa currents in GH3 cells, suggesting the presence of a channel type not classified so far.

To get insight into the role of TET sensitive BKCa channels in the rat brain, TET effects were characterized in microdissection experiments measuring dopamine release from the N. accumbens. Local administration of TET results in a profound and transient increase of dopamine release, while the metabolites DOPAC and HVA were hardly affected. The latter results indicate that tetranype sensitive processes are involved in the regulation of dopamine release in this brain area.

ETHANOL ACTIVATES LARGE CONDUCTANCE, Ca2+-ACTIVATED K+ CHANNELS IN NEUROHYPOPHYSIAL TERMINALS. A. M. Deptino, J. B. Lemos and S. N. Tristram. Department of Pharmacology, University of Massachusetts Medical Center, and Worcester Foundation for Experimental Biology, Worcester, MA 01605.

Large conductances, Ca2+-activated K+ (maxi K+) channels are thought to underlie interburst intervals and, thus, control hormone release from neurohypophysial terminals. Since ethanol (EtOH) inhibits the release of vasopressin (VAP) from osmotically sensitive (OT) and non-OT nerves, we examined the effects of EtOH on maxi K+ channel currents from these terminals using patch-clamp techniques. Maxi K+ channels show a reversar potential close to 0 mV in excised, outside-out patches in symmetric 145 mM KCl solutions. They have a unitary conductance of 250 pS and increase activity at more positive potentials and/or when [Ca2+] i is increased at the cytosolic side of the membrane. EtOH (25-100 mM) applied to the cytosolic surface of the patch reversarly increases K+ activity without changing the unitary conductance of the channel. This activation by EtOH may reflect a direct interaction with the channel, possibly altering the EIC50 for Ca2+-activation of I-V, and in conjunction with the previously-reported inhibition of L-type Ca2+ channels, can explain the reduced release of AVP and OTR after EtOH ingestion. Supported by N.I.H. grant AA-08003.

POTASSIUM CHANNELS IN THE HYPERKALEMIC RESPONSE TO SUCINYLCHOLINE FOLLOWING DENERVATION. J. A. J. Martyn, F. Yanez, D. B. Carr*, Dept. Anesthesia, Harvard Medical School, Massachusetts General Hospital, Boston, MA 02114.

Denervation induces a proliferation of nicotinic acetylcholine receptors (nAChRs) at the muscle membrane. This upregulation of nAChRs is associated with supersensitivity to agonists such as succinylcholine (SCh) and is believed to be responsible for the potentially lethal hyperkalemic response to SCh observed in patients with denervation injuries. The present study uses K+ channel blockers, 4-aminopyridine (4-AP) and tetraethylammonium (TEA) to characterize the contributory role of K+ channels in this hyperkalemic response.

Rats underwent bilateral sciatic denervation. After 2 weeks, the plasma K+ levels to SCh (3 mg/kg i.v.) was studied. The rise in plasma K+ Induced by SCh was significantly greater in denervated rats (2.9±0.3 mEq/L, n=6) than in controls (0.7±0.2 mEq/L, n=6). Pretreatment with either 4-AP (3 or 5 mg/kg) or TEA (20 or 40 mg/kg) failed to inhibit the rise in K+, TREA (60 mg/kg) attenuated the hyperkalemia to SCh (1, 2, and 3 mg/kg). Pretreatment with either 4-AP (3 or 5 mg/kg) or TEA (20 or 40 mg/kg) failed to inhibit the rise in K+, TREA (60 mg/kg) attenuated the hyperkalemia to SCh (1, 2, and 3 mg/kg). Pretreatment with either 4-AP (3 or 5 mg/kg) or TEA (20 or 40 mg/kg) failed to inhibit the rise in K+, TREA (60 mg/kg) attenuated the hyperkalemia to SCh (1, 2, and 3 mg/kg). Pretreatment with either 4-AP (3 or 5 mg/kg) or TEA (20 or 40 mg/kg) failed to inhibit the rise in K+, TREA (60 mg/kg) attenuated the hyperkalemia to SCh (1, 2, and 3 mg/kg).

ACTIN FILAMENTS REGULATE ION CHANNELS IN IDENTIFIED RETINAL NEURONS. Greg Maugure*, Victoria Connaughton, Adriana Frattu, George R. Jackson, and Horacio Cantellof, *Sensory Sciences Center, The University of Texas, Houston, inactivate, and are capable of producing maintained depolarization; they play important roles in the physiology and pathology of neuron function. CAN channels have been studied in neurons following bursts and after Ca$^{2+}$ injection, and in patches isolated from retinal membranes. Although CAN channels have been shown to be modulated by a PKA mechanism, no direct drug effects on neural l_{Na} have been reported.

We studied l_{Na} in bursting neurons of Helix aspersa by measuring the difference in tail currents at E_{Na} following 50 and 500 ms depolarizing pulses to 10 mV. These current tails were identified as being l_{Na} because they had decay time constants of at least 500 ms, could be measured at E_{Na}, were eliminated by Ca$^{2+}$ current blockers, and were unaffected by removing extracellular Cl$^{-}$. Flufenamate and menefenamate have been shown to block l_{Na} in non-neuronal but there are no reported blockers of neural CAN channels. While lower concentrations had no effect on neuronal l_{Na} tails, 500 mM of flufenamate or menefenamate had a biphasic effect, first increasing and then depressing l_{Na} tails. This may represent an effect similar to that seen in non-neuronal cells where these drugs first release Ca$^{2+}$ from intracellular stores and then block CAN channels.

INTRACELLULAR SODIUM EVOKES A SULFONYLUREA-SENSITIVE POTASSIUM CURRENT IN DOPAMINE NEURONS. S.W. Johnson*, K.-Zhong Shen, R. Alan North and Vincent Sejnowski, Departments of Pharmacology and Neurology, Oregon Health Sciences University, Portland OR 97201, USA.

In Parkinson's disease, dopamine neurons may have reduced ability to synthesize the ATP needed to maintain intracellular Na+ homeostasis. To study the electrophysiological effects of increased intracellular Na$^{+}$, we used whole-cell patch pipettes to dialyze Na$^{+}$ (40 mM) into dopamine neurons in the rat midbrain slice. We found that Na$^{+}$-loading increased membrane conductance and evoked an outward current at -60 mV (205 ± 22 pA; n = 36). About 70% of current evoked by Na$^{+}$-loading was blocked by Ba$^{2+}$ (300 mM), glipizide (IC_{50} = 4.4 mM), tolbutamide (IC_{50} = 20 mM), and glibenclamide (1 mM). This current was mediated by K$^{+}$ because it reversed direction at the expected reversal potential for K$^{+}$ (−98 ± 6 mV, n = 9; 100 mM K$^{+}$ in pipette, 2.5 mM in bath), and was also blocked by extracellular TEA (30 mM) and intracellular Cs$^{+}$ (100 mM in pipette). About 30% of current evoked by Na$^{+}$-loading was not blocked by Ba$^{2+}$; this current was generated by Na$^{+}$/K$^{+}$ ATPase because it was blocked by a reduced extracellular concentration of K$^{+}$ (0.5 mM), and by dihydrobiotin (3 mM). We suggest that the sulfonuurea-sensitive K$^{+}$ current evoked by Na$^{+}$-loading may have a neuroprotective function in Parkinson's disease.
626.3

Single electrode voltage clamp experiments were carried out in axotomized X-organ neurons somata of the crayfish (Procambarus clarkii). The outward currents recorded in response to depolarizing voltage pulses, from a holding potential of ~45 mV, were blocked by [Ca]. These currents increased 80% when [Ca] was increased from 1.5 to 13.5 mM, and the same diminution occurred when [Ca] was reduced by 2 mM to 13.5 mM and the same diminution occurred when [Ca] was reduced by 2% when [Ca] was increased from 1.5 to 13.5 mM. A diminution of the same order was observed when 1 mM TEA or 20 mM charybdotoxin were added to the bath. Apamin, however, had no effect. On the other hand, a 200 pS (in 227 mM KC) K channel was observed in inside-out patch clamp recordings of these neurons. This channel is activated when the internal [Ca] is increased from 1 μM to 50 μM. The presence of this high conductance Ca activated K channel may be important as a burst terminating mechanism in these neurons. Supported by CONACYT 1245-J0903.

How voltage activated potassium currents (Kv) influence membrane potential behavior in lactotrophs and GH3 cells was addressed by characterizing their kinetic and pharmacological properties using whole cell patch clamp techniques. Exponential fits to the decay of Kv showed that both lactotrophs and GH3 cells have 3 components, a slowly inactivating component (Kv1), a slowly inactivating component (Kv2), and an offset current. Voltage at 50% activation and rate of decay of Kv1 was similar in lactotrophs (5 mV & 150 mV) and GH3 cells (4 mV & 140 mV). Voltage at 50% decay activation was -52 mV in lactotrophs and -41 mV in GH3 cells. Rate of recovery from inactivation of Kv1 fit a single exponential (9%) in lactotrophs, while in the GH3 cells the recovery from inactivation of Kv1 fit a double exponential (0.12s (70%) & 6s (30%)]. In both lactotrophs and GH3 cells, 4-aminopyridine, 300 μM, blocks Kv1 (~60%) and Kv2 (~50%). Dendrotoxin (DXT), 100 nM, was found to block only the Kv1 (41%) component in GH3 cells but had no effect on Kv1 or Kv2 in the lactotrophs even at concentrations of 3000 nM.

These results show that although Kv1 components in both lactotrophs and GH3 cells are similar, their differences are perhaps significant in terms of influencing membrane potential behavior. DXT will be a useful probe to investigate the role of Kv1 in GH3 cell function.

BIOPHYSICAL AND PHARMACOLOGICAL CHARACTERIZATION OF INWARDLY RECTIFYING K+ CURRENTS IN RAT SPINAL CORD ASTROCYTES. Christopher B. Ransom* and Harold Sontheimer. University of Washington, Seattle, WA 98195.

Astrocytes are known to possess a large resting K+ conductance. We characterized the resting conductance of astrocytes derived from spinal cord and found insulated and conducting was provoced by inwardly rectifying K* (KIR) channels. We identified two types of astrocyte KIR channels with single channel conductances of -28 pS and -60 pS respectively. Channels displayed voltage dependent block: inwardly rectifying KIR channels are present near and negative to the cells' resting membrane potential, but were near zero at potentials positive of the resting potential. The conductance (pK) of inwardly rectifying KIR channels (KIR) depolarized and the pK was approximately proportional to the square-root of the [K+]o. KIR currents inactivated in a time and voltage-dependent manner due to block by Na+. KIR currents were also blocked by a dose-dependent manner by extracellular Ca* (K=72 μM to -160 μM), Ba* (K=8.5 μM) and TEA (90% block at 10 μM), but were insensitive to 4-AP (5 μM), Ba* and TEA inhibition of KIR currents caused a marked depolarization that suggests a Kir channel activity is essential to establish the negative resting potential typical for astrocytes. The biophysical features of astrocytic inwardly rectifying KIR channels are compatible with properties required for their proposed involvement in KIR clearance according to the "gial spatial buffer" hypothesis: (i) high open probability at the resting potential, (ii) increasing conductance with increasing [K+]o, and rectification, e.g. channel closure at positive potentials. It is supposed, therefore, that the diarrpsis of [K+]o following neuronal activity is mediated by the activity of astrocytic KIR channels.

POTASSIUM CURRENTS UNDERLYING ACTION POTENTIALS OF HIPPOCAMPAL CA1 ST. ORIENS-ALVEUS INHIBITORY NEURONS. L. Zhang* and C. J. Mellan. Laboratory of Cellular and Molecular Neurophysiology, NICHS, NIH, Bethesda, MD 20892.

Whole-cell recordings were made from 88 CA1 st. oriens-alveus interneurons in hippocampal slices from the rat. The amplitude of potassium currents underlying single action potentials (AP). AP repolarization was dependent on the transient D- and A-currents, since the spike width was broadened and 120% by 100 nM 4-AP respectively. Another prepulse to -80 mV to deactivate the A current increased the role of spike repolarization. A role for the Ca2+-activated K current (Ica) in spike repolarization was also determined, the specific blocker benoxotin (IBTX, 100 nM), increased the duration of APs by 36%. Ca2+-free Co2+-containing solution produced similar effects (30% increase) which were non-additive with IBTX. In contrast, 4-AP (2 mM) further prolonged the APs in the Ca2+-free medium by 130%. APs were followed by two prominent AHPs of fast (2 ms) and medium (270 mV) duration. IBTX (100 nM) or Co2-free solution completely eliminated this fast AHP, while 4-AP was without effect. The amplitude of the medium duration AHP was reduced by approx (100 nM Ca2+ 26%), Ca2+-free Co2+ solution (63%), the muscarnic agonist carbachol (10 μM, 20%), and ketamine (10 μM, 25%). A slow inactivating and two transient outward currents could be elicited by membrane depolarizations in excised outside-out, or whole-cell patches. Subtraction of the currents elicited by the pulse to -90 or -40 mV allowed isolation of each current. The half-maximal activation of the total transient current was reached at -22 mV and the slow inactivating at -4 mV. At -10 mV, 4-AP (2 mM) inhibited both the transient current by 66% and the slow-inactivating current by 11%. In conclusion, Ia, and Ica are three of the major K currents involved in AP repolarization; while ICl,K and IG mediated part of the AHP in O-A inhibitory neurons.
626.9
POTASSIUM CURRENTS IN PREVERTEBRAL AND PAR VERTEBRAL SYMPATHETIC NEURONS. Hong-Sheng Wang and David McKinster*, Dept. of Neurobiology and Behavior, State University of New York, Stony Brook, NY 11794-8010.

Intracellular recordings were made from rat sympathetic neurons in isolated superior cervical ganglia (SCG), celiac ganglia (CG), and superior mesenteric ganglia (SMG). Based on their response to a maintained depolarizing current stimulus, neurons were classified as 'phasic' or 'tonic'. All neurons in the SCG were phasic, 86% of the neurons in the SMG and 58% of the neurons in the CG were tonic and the balance were phasic. The voltage response of the tonic neurons became more depolarized during a prolonged current step. The voltage change induced in these neurons was slower than that produced by a constant current step was markedly different. The response of phasic neurons was biphasic with an initial depolarizing response followed by significant repolarization of the membrane potential. In contrast, tonic neurons became more depolarized during a prolonged current step. The underlying currents were studied using single-electrode voltage-clamp recording. The M-current was present in all phasic neurons, but was very weak or absent in tonic neurons. An A-current was apparent in both phasic and tonic neurons. The slow activation of this current contributed to the slow depolarizing ramp seen in response to a maintained depolarizing current step. Computer simulations, based on the voltage-clamp data, suggested that the different firing properties of phasic and tonic neurons could be accounted for by different expression of the M-current and the D2-current.

626.10
A-TYPE POTASSIUM CURRENT (IA) GATING IS ALTERED IN SYMPATHETIC NEURONS FROM HYPERTENSIVE RATS. Water P. Robertson and Geoffrey V. Schulte*, Dept. of Physiology, Tulane University School of Medicine, New Orleans, LA 70112.

Increased sympathetic nerve activity has been implicated in the development and maintenance of hypertension. The cellular basis for the exaggerated sympathetic neuron activity remains undefined. IA may mediate neuronal excitability via modulation of action potential duration, regulation of the inter spike interval during repetitive firing, and modulation of the time course of EPSP decay. We examined IA in the spontaneously hypertensive rat (SHR) to investigate the possibility that alterations in IA may be involved in the hyperexcitability of sympathetic neurons. Our preliminary data shows that half inactivation voltage of IA from SHR (n=5) is ±13 mV hyperpolarized than control Wistar rats (n=6). In the SHR, inactivation at such hyperpolarized potentials could reduce the availability of IA, and thus mediate the increased sympathetic activity in hypertension.

626.11
ROLE OF IA-DEPOL IN FREQUENCY-DEPENDENT SPIKE BROADENING OF 200 CELLS IN APTYSA CALIFORNICA. M. Mat and J. Roestore, Center for Neurobiology, Columbia University, N.Y., 10032. We studied the mechanisms and consequences of frequency-dependent spike broadening in the 200 SCG neurons in the abdominal ganglion of animals. These neurons, which activate the circuit that inhibits respiratory pumping, contain the neuropeptide SCP. When fired at 4 Hz, the falling phase of the action potential potential was greatly prolonged and could last for more than 30 msec. Spike broadening recorded from the somata of the R20 cells was affected and transmitter release from near terminals. We tape-recorded a 7 Hz, 10 sec train of gradually broadening spikes. They were then replayed at a command signals for a 2-electrode voltage clamp that controlled soma potential. The synaptic output of the R20 cell was recorded in this way in a voltage clamped RGC cell in our cell R20 in the same cell was the same as that produced under current clamp. But when only the first (non-broadened) train was played (5 sec at the same (7 Hz) frequency, the synaptic output was reduced by 50 to 70%. Because the release sites are some distance from the soma, the effect of broadening on release is underestimated by this protocol. Using pharmacological and 2-electrode voltage clamp techniques, we isolated voltage-gated Na, ICa L (L and N-type), ICa H, I Ca N, and I C s in the R20 cells. We observed a range of calcium currents and that for traditional A currents (Platfiger et al., 1991). The contributions of different currents to spike broadening were determined by using the gradually broadening action potential train as the command for the clamp. We found that (i) Although the peaks of ICa show 40% inactivation during the spike current, the time integral of ICa during individual spikes increases by 200%, indicating that there is more Ca influx during broadened spikes than during the non-broadened ones. (ii) Surprisingly, I A depol is the major outward current in the non-broadened spikes. Moreover, if we depolarized and rapid cumulative inactivation, which is the major cause of frequency-dependent spike broadening in the R20 cells.

626.12
IONIC CURRENTS INVOLVED WITH AUTOMATICITY IN A CLONAL CELL LINE. H. Bryant, V. Kowtha, K. Kwass, D. Stenger, Center for Bio/Molecular Science and Engineering, Naval Research Laboratory, Washington, DC 20375. Department of Physiology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814, Section on Biophysics of Sensory Processes, LC 671/CDD/N, Bethesda, MD 20892. NG108-15 (neuroblastoma x glial cells) can display altered spontaneous activity (the spontaneous occurrence of regenerative action potentials) following transient exposure to extracellular perfusates containing 20 mM MgCl2. The electrical activity of NG108-15 cells was monitored using single-electrode voltage-clamp recording and whole cell patch clamp techniques after culture in serum-containing medium (SCM) or serum-free media (SFM) which was insensitive to TEA and cesium. Action potential profiles of SFM cells were characterized by prolonged after hyperpolarization (AHP) which predisposed SFM cells to fire repetitively. Cadmium blocked the AHP. K+ channel blockers Apamin and Charybdotoxin reduced the AHP component while CTX prolonged the action potential duration. SITS, a potent anion transporter, revealed another chloride sensitive outward component that slowed the firing rate. These results suggest that the AHP and the chloride outward currents present in cells cultured in SFM modulate automaticity in NG108-15 cells in SFM cultures.

626.13
A DENDROTOXIN-I SENSITIVE POTASSIUM CONDUCTANCE IN AUDITORY NEURONS OF THE RAT MNTB. H. M. Brew and J. D. Forsythe. SPON Brain Research Association. Dept. of Cell Physiology and Pharmacology, Univ. of Leicester, P.O. Box 138, Leicester, LE1 9HN, UK.

Neurons of the medial nucleus of the trapezoid body (MNTB) are part of the brainstem auditory pathway. The action potentials recorded were located in MNTB neurons. The MNTB neurons possess rapidly activating potassium currents (Forsythe & Barnes-Davies, 1993. Proc. Roy. Soc. B. 251, p145-150) that are thought to contribute to their ability to follow accurately the action potentials in their single giant synaptic input. We used whole-cell patch techniques to characterize one of the conductances underlying these currents in MNTB neurons of guinea pigs. We found that this is a 0.5mM Ca and 2.5mM magnesium was used for voltage clamp recordings. One potassium conductance produced most of the outward current in MNTB neurons between -60mV and -20mV. This current, IG, is blocked by 100mM D-Phenacetin. The I G, was blocked by 1mM DTX-I (DTX-I) and mostly blocked by 100mM a-aminoprinine. I G activated and deactivated rapidly, reaching a peak value in 8 msec. It then decayed with a mean time constant of 0.1sec. spikes were used with a pseudo-intracellular solution. A modified solution containing 1.0mM Ca and 0.5mM Mg produced I G, I Ca N, I Ca L, and I Ca H. Surprisingly, IA depol is the major outward current in the non-broadened spikes. Moreover, if we depolarized and rapid cumulative inactivation, which is the major cause of frequency-dependent spike broadening in the R20 cells.

626.14

Alpha-Dendrotoxin (d-DTX) isolated from the venom of the African Green Mamba (Dendroaspis angusticeps) has previously been reported to be a neurotoxic peptide that selectively labels with high affinity voltage-dependent potassium (K+) channels. Previous studies have extensively studied the binding profile of tritiated d-DTX in rodent and bovine brain. This study compared the radiiodinated binding profile of [125I]-d- DTX in hippocampal tissue of non-human primates as well as human brain tissue using saturation analysis, competition experiments and quantitative receptor autoradiography. A rapid and reliable method was developed for the preparation of [125I]-d- DTX using whole cell agglomerates of brain tissue. The Kd and Bmax determined by saturation analysis from hippocampal tissue of rat, cynomolgus monkey and human were 63 ± 5 pM, 732 ± 91 fmol/mg prot., 81 ± 2 pM, 503 ± 63 fmol/mg prot. and 92 ± 4 pM, 570 ± 27 fmol/mg prot., respectively. Competition experiments showed the displacement of [125I]-d-DTX by peptide toxins which are known to block voltage-dependent K+ channels indicated that the rank order of affinity constants was similar across species: d-DTX > charybdotoxin > mast cell protease I > apamin. This similarity of the pharmacological profile in the hippocampus among the different species was confirmed using a variety of structurally and pharmacologically diverse agents. Interestingly, the relative distribution of d- DTX binding sites in hippocampal tissue as studied by quantitative receptor autoradiography indicated that species differences in localization. Taken together, these data suggest that there is significant conservation of the voltage-dependent K+ channel subunit that binds d-DTX across species but the neuronal anatomical distribution appears to be.
626.16 Cd\textsuperscript{+} BLOCKADE OF HYPERPOLARIZATION-ACTIVATED CURRENT I\textsubscript{L} IN CRYSTALFISH MUSCLE. A. Araque, D. Campan and W. Buls. Instituto Cajal, CSIC, Madrid 28008, Spain. A novel hyperpolarization-activated current mediates inward rectification in opener crystalfish muscle has been recently described (Araque and Buls, J. Neurosci., 1994). This voltage- and time-dependent current, called I\textsubscript{L}, is selectively mediated by Cd\textsuperscript{+}, its activation curve depolarizing conductance is unaffected by K\textsuperscript{+}. It is insensitive to Ca\textsuperscript{2+}, Ba\textsuperscript{2+} and Pb\textsuperscript{2+}, but is blocked by extracellular Zn\textsuperscript{2+} or Cd\textsuperscript{2+}. The effects of Cd\textsuperscript{2+} on I\textsubscript{L} were studied under two-electrode voltage-clamp in opener muscle fibres. Cd\textsuperscript{2+} (10 mM) totally and reversibly reduced I\textsubscript{L} without modifying the I\textsubscript{L} equilibrium potential. Lower Cd\textsuperscript{2+} concentration decreased the maximal conductance of I\textsubscript{L} and shifted its activation curve towards more hyperpolarized potentials without affecting the slope of the activation curve. While the I\textsubscript{L} activation time constant increased, the I\textsubscript{L} deactivation time constant was not modified by Cd\textsuperscript{2+}. The effects of Cd\textsuperscript{2+} on I\textsubscript{L} were independent on K\textsuperscript{+}. Cd\textsuperscript{2+} effects on I\textsubscript{L} were dose-dependent, obeying the Hill equation with n= 0.452 and 0.045 m/s and a Hill coefficient of 1.23.

We conclude that: a) the block of I\textsubscript{L} by Cd\textsuperscript{2+} was exerted in a dose-dependent manner, obeying the Hill equation and suggesting that one Cd\textsuperscript{2+} ion binds reversibly to one receptor with a dissociation constant of 0.452 mM; b) the selective permeability of I\textsubscript{L} channels was not modified by Cd\textsuperscript{2+}; c) the binding site for Cd\textsuperscript{2+} to block I\textsubscript{L} was different to the binding site for K\textsuperscript{+}; d) the Cd\textsuperscript{2+} blockade of I\textsubscript{L} was not voltage-dependent; e) Cd\textsuperscript{2+} blocked the I\textsubscript{L} channel gate interfering with its opening but not with its closing mechanism.

Supported by DGICYT (Spain) and DGXII CEIC (Europe) grants to W.B. A.A. is an Arces Foundation postdoctoral fellow.

626.20 EFFECTS OF INTRACELLULAR PH ON MEMBRANE ELECTRICAL AND MECHANICAL PROPERTIES OF VASCULAR SMOOTH MUSCLE.
Brigette Liu, P.C. Johnson and G.E. Koshland*, Department of Physiology, University of Arizona, Tucson, A285724

We have investigated the effect of changing extracellular pH (pH\textsubscript{e}) at constant level of CO\textsubscript{2} on the membrane electrical and mechanical properties of vascular smooth muscle in isolated guinea-pig mesenteric and femoral arteries, using intracellular microelectrode recording and force measurement. Lowering pH\textsubscript{e}, depolarizes but reduces force development of vascular smooth muscle, whereas increasing pH\textsubscript{e} hyperpolarizes and increases force development. From measurement of the decay time constant of excitatory junction potentials, we also found that lowering pH\textsubscript{e} from 7.4 to 6.6 decreased the total membrane conductance of vascular smooth muscle whereas increasing pH\textsubscript{e}, had the opposite effect. The relationship between membrane conductance and pH\textsubscript{e} was characterized as we increased the [H\textsuperscript{+}], (in mM) from 4.7 to 25 at pH 6.5, 6.7, and 7.8. The value of membrane potential measured at [H\textsuperscript{+}] of 25 mM was close to that predicted by Normax equation. These data indicate that the resting potential of vascular smooth muscle is predominantly determined by the membrane conductance to K\textsuperscript{+} and that the effect of pH\textsubscript{e} on potential may be mediated through altering K conductance. Finally, application of cromakalim and glibenclamide did not significantly affect the resting potential at pH 6.5, 6.7, 7.4, and 7.8, which suggests a lack of effect of pH\textsubscript{e} on K channel activity.

The maximum effect of pH on membrane potential occurs within about 5 min, after which the potential tends to return toward the control level. This secondary change is blocked by 1 mM TEA, suggesting that it is due to change of intracellular pH acting on Ca-regulated K channels. Supported by NHL grant ID. 15790.
627.1 ANALOG VLSI MODEL NEURON: A MULTIPLE PURPOSE PROGRAMMABLE DEVICE. G. Le Masson*, S. Le Masson, Y. Devill, and M. Moulines. LNPs, UN. Bordeaux France. Arcachon 33120 FRANCE and IXURA CNRS 8464 Bordeaux FRANCE.

Using a BCGMs full custom technology, we developed an analog VLSI circuit (ASIC) for modeling conductance-based neurons. Currents with voltage dependent, sigmoidally-shaped activation and inactivation are produced and summed through an external external serial capacitance. The maximal gain and voltage dependence of each current is programmed analogically via analog inputs, as well as the slope of both activation and inactivation curves. Simple kinetics and calcium dependent currents are available, and a synaptic current. With the construction of this circuit, we assembled several circuits is possible, to model neurons with complex intrinsic properties such as burstiness, or to reproduce multiartificial networks. We recently reported a new technique for real time interaction between model neurons and biological neurons, trough artificial synapses. These VLSI models are ideally suited for such hybrid network interactions.

We have examined the possibility of different conditions for the existence of slow oscillations underlying the bursting behaviour (Eckmann, et al., Nature. 362:25,1990; Destexhe et al., Biophysics. J. 65:1388,1993). The problem has been solved by searching for several nonintersecting regions in the parameter space of the membrane (Hodgkin-Huxley) equations (Guckelbusch et al., Phil. Trans. R. Soc. 341:345,1993). Since the considered system has two slow variables: intracellular calcium concentration (Ca) and activation variable for the Ca-current (ZCa), two systems have been chosen for the analysis of the conditions of slow oscillations. The first system contains the equations for the membrane potential V and Ca, the second system involves the equations for V and ZCa. Using the methods of bifurcation theory we have obtained for each system the explicit parametric forms of the boundaries limiting the regions of slow oscillations. Analyzing these forms we have found that over the range of physiological values of the model parameters there are two nonintersecting regions on (gCa,f, (gCa,l) and (gK,Ca,l) planes, where gCa,f, gCa,l, gK,Ca,l are the maximal calcium, calcium-dependent potassium and transient potassium conductances and f is the stimulus value. These results suggest that there are multiple conditions for slow oscillations in the membrane of the stomatogastric ganglion. By means of numerical integration we have tested that the frequency of slow oscillations for the parameter values belonging to the regions obtained for the V, ZCa system is lower than the frequency of oscillations obtained for the V, Ca system. The neuronal membrane is likely to display the "slow bursting mode", which has a slow component determined by intracellular oscillations and a fast component caused by oscillations of the variable ZCa. Supported by the N.N.-Stiftung i.G., Wuerzburg.

627.3 RECONSTRUCTION OF HIPPOCAMPAL CA1 PYRAMIDAL CELL ELECTROPHYSIOLOGY BY COMPUTER SIMULATION. D.M. Durand*, E.N. Warman, and G.L. Yuen, Dept. of Electrical Engineering and Neurosciences, Case Western Reserve University, Cleveland, OH 44106.

Computer models of neural activity have been very successful in simulating the neuropsychological behavior of many neurons. In the hippocampus, the electrophysiology of neurons such as the CA1 cells has been studied in great details. A large number of ionic currents have been described but previous computer models were not able to reproduce several important features of these cells. We have developed a model based on the simplest combination of ionic channels that could best reproduce CA1 electrophysiology. The model was designed using seven active ionic conductances and five passive conductances and whose kinetics have been inferred from the available voltage clamp data. Particular emphasis was placed on accommodation, slow depolarization potential and spike broadening during repetitive firing. The activation potential was newly simulated and the role of the three regaining currents Iiring, Iinter and Idep investigated. The model also reproduces all four after-potentials recorded following activation of the cell. The fast, medium and slow AHPs were generated by Iinter, Irep and Idelta respectively. The model accurately reproduces features observed during the injection of long current pulses such as changes in firing frequency and a gradual broadening of action potential. The role of each current in mediating these responses has been investigated. The model also suggested that Irep may be the principal outward current regulating the CA1 resting potential. Supported by NSF grant # BNS 8809504.

627.4 A COMPUTATIONAL MODEL OF MYELINATED AXONS IN FROG DORSAL ROOT. A. L. Paddick* & T. Hashiguchi. Dept. of Pharmacology & Therapeutics, McGill University, Montreal and Dept. of Physiology, Tokyo Medical College, Tokyo.

We have used a mathematical model to simulate electrophysiological characteristics of large myelinated axons. The model describes the space-clamped, intracellularly recorded membrane potential oscillations of the axons. The model is based on a single cable-like neuron model, which accounts for the ionic currents and the anatomy of the myelinated axon. Oscillations of the myelinated axon were simulated by Hodgkin-Huxley type of equations, including inward rectifier and fast and slow K⁺ conductances. The model allows to obtain all known sections of myelinated axons, such as nodal, internodal, myelin, paranodal sections, sections for periodic short and parallel internodal resistances and their measured or estimated properties.

In order to simulate ETPs the myelin leakage conductance and the ion conductance of internodal membrane were found to be crucial factors. In contrast to the classical estimate of 1.5 μS/cm² a much larger value of 80 μS/cm² is required as specific myelin conductance. The likely pathways for this conductance are Schmidt-Lantermann incisures or paranodal opening. The conductance of internodal axolemma requires values that are <1% of the measured conductance of the node of Ranvier.

The model supports the notion that not only the ion conductances of node of Ranvier but also those of the internodal axolemma contribute to electrophysiological properties and conductance mechanism in myelinated axons. (Supported in part by MIUR of Canada)

627.5 BURSTING, SPIKING, CHAOS, FRACTALS, AND UNIVERSALITY IN BIOLOGICAL RHYTHMS. T.R. Chay*, T.S. Lee and Y-S. Fan. Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Biological systems offer many interesting examples of oscillations, chaos, and bifurcations. Oscillations in biology arise because most cellular processes contain feedbacks that are appropriate for generating rhythms. These rhythms are essential for regulating cellular function. In this tutorial review, we will discuss an interesting nonlinear dynamical process in biology that give rise to bursting, spiking, chaos, and fractals: endogenous electrical activity of excitatory cells and Ca⁺ release from the Ca⁺ stores of excitable cells induced by hormones and neurotransmitters. We will then show how to utilize bifurcation analyses to gain a deeper insight into the mechanisms involved in the neuronal and cellular oscillations. With the bifurcation diagrams, we explain how spiking can be transformed to bursting via a complex type of dynamic structure when the key parameter in the model varies. We will show that the bifurcating structure is important in predicting and controlling abnormal biological rhythms. Although we describe this type of dynamical biological rhythms, we will show that there is universality in their bifurcation structures.

627.6 MEASUREMENT ERRORS FROM CLAMPING VOLTAGE-DEPENDENT CONDUCTANCES IN CELLS WITH ELONGATE PROCESSES. Daniel K. Hartung* and Ann M. Caspel-Franco. Békésy Lab., Univ. of Hawaii, Honolulu, HI 96822.

Voltage clamp data are often obtained from cells with attached processes. Space-clamp errors potentially invalidate such data. To assess these errors, clamp currents were simulated for somata with a single cylindrical process containing voltage-dependent Hodgkin-Huxley (HH) conductances. Leak-subtracted (I) and (IV) data were fitted with HH parameters as if the cells were space clamped. Time constants (τs) for 50% (as opposed to mHs) were voltage-independent. Resulting clamp currents had an activation delay and voltage-dependent kinetic fit broadening the range of parameters by an mH form. For an outward current mechanism uniformly distributed in a compact (0.5%) space, activation τs were lengthened up to several fold, with less effect on inactivation τ. Errors in activation τ and q increased, and in inactivation τ decreased, with increased conductance densities. Fitted kinetic parameters for both activation and inactivation displayed a space-clamp voltage dependence near threshold.

Parameters of the (IV) curve could be well fitted up to ca 10-100x leak conductance density. Measurement errors depended strongly on the time of the measurement, well after peak current being optimal. For a uniformly distributed conductance, measurement error was most severe in conductance regions and away from the peak current activation midpoint and reversal potential. If enough is known about the distribution of channels in processes, it may be possible to correct clamp data for some of the measurement errors.

ENTORHINAL CORTEX LAYER III NEURONS: CHARACTERIZATION AND CHOLINERGIC EXCITATION. A. Menas* and A. Alonso, Montreal Neurological Institute and McGill University, Montreal, QC, CANADA H3A 2B4

Layer II and III of the entorhinal cortex (EC), via the perforant path, project massively to the hippocampus, and receive input from the cholinergic neurons of the basal forebrain. By means of intracellular recordings in the in vivo slice preparation, we have already characterized the electrophysiology of neurons in layer II (Alonso and Klink, 1993) and studied the modulation of their excitability by carbachol (CCh) (Alonso and Klink, 1991 and this meeting). Here, we report on the extension of this study to layer III neurons. Layer III cells appear a rather homogenous population both morphologically and electrophysiologically. Intracellular staining with biocytin revealed a typical pyramidal shape with a thick apical dendrite and a skirt of basal dendrites. Current clamp recordings showed prominent fast inward rectification in both the depolarizing and hyperpolarizing directions. Many neurons displayed dynamic tonic firing at rest which was rapidly maintained by a persistent Na-current. In contrast to layer II neurons, no rhythmic subthreshold oscillations were observed upon DC depolarization. Pressure-pulse applications of CCh resulted in a dose-dependent depolarization which could be potentiated after eliciting firing by manual injection of current. Clamping back to the control level showed an increase in input resistance. With continued bath application (20–60 μM of CCh, the response displayed pronounced desensitization. These data demonstrate clear-cut differences between EC layer II and layer III neurons both in their basic electrophysiological properties and in their modulation by basal forebrain cholinergic input.

RELIABILITY OF SPIKE INITIATION IN NEOCORTEX. Z.F. Mainen* and T.J. Sejnowski, Howard Hughes Medical Institute, Salk Institute, La Jolla, 92037.

Chemical and electrical signalling in the central nervous system appear remarkably variable, yet it is not known whether this variability carries meaningful information or simply reflects the intrinsic unreliability of underlying mechanisms. We have assessed the reliability of one process critical to neural signalling, the generation of action potentials. Whole-cell recordings were made from rat neocortical pyramidal cells in vitro and spikes were elicited by somatic current injection in the presence of synaptic transmission blockers (DNQX, AP5, BMI). Show below are two examples of 10 consecutive responses (superimposed) to repetitions of identical stimulus (scale bars: 50 msec, 0.5 nA, 50 mV). A constant current step (0.2 nA) produced spike trains (f=11–12 Hz) with individual spike times that drifted from trial to trial (top). In contrast, repetition of a stimulus with transients resembling synaptic activity (filtered gaussian white noise, μ=0.2 nA, σ=0.05 nA evoked trains (f=12 Hz) with highly consistent spike times (bottom). Our experiments suggest that some cortical cells are sensitive to the random variability of the input signal which could be through the slow component of Na-current, but the specific mechanism is not clear.

THE HYPERPOLARIZATION-ACTIVATED CATION CURRENT (Ih) IN NEOCORTICAL NEURONS IS BLOCKED BY EXTERNAL PROTEOLYSIS AND INTERNAL TEA. T. Budke*, J.A. White and A.B. Kay, Dept. of Biological Sciences, Univ. of Iowa, Iowa City, IA 52242

After one day in culture neurons derived from the neonatal cerebral cortex exhibited a slowly activating current gated by hyperpolarizing voltage-clamp pulses. The current was blocked by extracellular cesium (2 mM) and unaffected by barium (1 mM) and was permeable to both Na and K (PNa/PK = 0.29). Its form and pharmacology are consistent with a current termed Ih in other preparations. Ih was absent from cells acutely dissociated from both the neonatal and mature cerebral cortex, despite the use of low enzyme concentrations. The sensitivity of Ih to extracellular proteolysis was demonstrated by superfusing the cells with trypan blue (1 mg/ml) while monitoring the presence of Ih in the whole-cell mode of recording. Ih was rapidly abolished (1/2t1/2 ~ 5 min) by proteolysis and exhibited no shifts in its range of activation or changes in its activation kinetics during the course of the digestion, suggesting the abolition of the ability of the current to gate rather than a shift in its range of activation.

Intracellular TEA, at a concentration of ~15 mM was shown to block Ih while extracellular TEA and 4AP had no effect on the current. This suggests that Ih may be structurally related to potassium channels.

WHY DO CORTICAL NEURONS SPIKE IRREGULARLY? M. Todorov, A. Bell, Z.F. Mainen and T.J. Sejnowski,* Howard Hughes Medical Institute, Salk Institute, La Jolla, 92037

The spike trains of many cortical neurons in vivo are highly irregular during both spontaneous and driven activity. Although this variability may simply reflect large correlated fluctuations in synaptic input, an additional consideration is the balance between synaptic drive and the intrinsic conductances generating action potentials.

Using a single-compartment Hodgkin-Huxley model, we show that when excitation and inhibition are balanced to maintain the neuron in the region of optimal sensitivity, near firing threshold, then variable spike trains result even in the absence of large input fluctuations. Increased levels of balanced synaptic input increase the rate of input fluctuations, producing higher firing rates with maintained irregularity. Decreased spike repolarization (weaker K+ rectification) increased the steepness of the input-firing curve, giving greater sensitivity to input fluctuations.

Very similar results were obtained with a simpler integrate-and-fire model, which was used to explore networks of interacting excitatory and inhibitory neurons. Despite positive feedback between the excitatory neurons, proper balance was achieved robustly through inhibitory feedback. With weak repolarization, the network was sensitive to small inputs and could be switched rapidly between stable states dominated by fluctuating membrane conductances.

We conclude that our understanding of K+ conductances (weakening or strengthening spike repolarization) may dynamically regulate the rate of time-scale of information to which cortical networks are sensitive. (We are grateful to M. Shadlen for useful discussion. Supported by ONR. ZFM is an HHMI Predoctoral Fellow.)

Electrophysiological Characterization of Cryopreserved Rat Cortical Neurons T. Wieser, J. Saburin*, M. Wierich*, Boehringer Ingelheim KG, Ingeheim, Germany; *Battelle Europe, Geneva, Switzerland. Primary cultures from embryonic rodent brain are widely used for neurophysiological investigations. Unfortunately, these cultures have only a limited survival time of a few days to weeks, and longer storage is far beyond our reach. We therefore set out to improve the cryopreservation technique of cortical neurons from embryonic rat brain. Cryopreserved neurons were tested using the patch-clamp technique, and their properties regarding voltage- and transmitter-activated ion channels were compared with those from unprocessed controls.

All preserved cells had resting membrane potentials in the physiological range (~55 ±2.8 mV, S.E.M., n=14) and responded to voltage jumps with typical neuronal sodium- and potassium currents. The application of glutamate, NMDA or GABA induced currents indistinguishable from those of the control cells. The NMDA induced currents were suppressed by AP5, the K+ currents by blockers where inhibited by bicuculline and amplified by the steroid 3-alpha-dihydropregosterone.

We conclude that cryopreservation does not alter the properties of cortical rat neurons, and that these cells can be used for electrophysiological and neuropharmacological investigations. Supported by the BMFT (Grant No. 019192A0).

FUNCTIONAL ROLE OF AXON HILLOCK AND INITIAL SEGMENT IN CORTICAL SPIKE INITIATION. J.B. Huguenard* and J. Teyler. Z.F. Mainen and T.J. Sejnowski, Howard Hughes Medical Institute, Salk Inst., La Jolla, CA 92037 and Dept. of Neurosciences, Stanford Univ. Sch. Med., Stanford, CA 94305.

The processes that lead from synaptic input to spike output are critical factors in information processing in cortical neurons, yet the precise mechanisms of spike initiation are not well understood. Although neocortical pyramidal cells have voltage-dependent somatic and dendritic Na+ channels that could promote dendritic spikes, recent data (Stuart and Sakmann, Nature 367:65) support the long-standing hypothesis that spikes are initiated preferentially in the axon hillock or initial segment (AH/IS). This is consistent with our findings in acutely isolated neurons that only cells retaining a visually detectable axon segment can support robust spike generation. A biosynthetic model was constructed in order to explore the implications of these findings. When reported somatic and dendritic Na+ 'dendrites' (40 pS/μm^2) are combined with AH/IS densities at least 200-fold higher, a density comparable to measurements at nodes of Ranvier, spikes are initiated in the initial segment and then invade the soma and dendritic tree. The IS is a lower initiation threshold by a combination of high local current density and electrical coupling to the soma, while the conical shape of the AH promotes complete invasion of spikes into the soma. Simulations of axo-axonic inhibition, as believed to occur at chandelier cell synapses on the AH/IS, demonstrate that this type of inhibition is more effective in delaying spike onset than equivalent inhibition in the somatodendritic compartment. Voltage-clamp simulations indicate that caution should be exercised in the interpretation of somatic voltage-clamp data. For example, IS spike initiation can occur after distal dendritic synaptic input, even with apparent voltage clamp in the soma. These results underscore the capacity of the AH/IS to function independently of the soma, and indicate the importance of further studies of its physiology. Supported by NIH grants NS12151 and Office of Naval Research. ZFM is an HHMI Predoctoral Fellow.
CAESIUM PREVENTS THE MAINTENANCE OF LONG TERM DEPRESSION IN RAT HIPPOCAMPAL CA1 NEURONS. D. DiFrancesco, D. Janigro*, E. Waeke* and G. Macafee. Dip. di Fisiologia e Biochimica Generali, Univ. di Milano, Italy and *Dept of Neurosurgery, Univ. of Washington, Seattle, WA.

Hippocampal synaptic plasticity involves long-term modification of the efficiency of information processing at synaptic sites. We measured long-term depression (LTD) of field EPSP in the CA1 region of spontaneously isolated hippocampal slices by delivering a 15 minutes train of pulses at 1 Hz to the Schaffer-commissural-CAL pathway. LTD was prevented by adding a NMDA receptor antagonist (AP-5, 50 μM) to the perfusing medium. Superfusion of the slices with Cs (2 mM) during or just after the 1 Hz stimulation period could both inhibit the maintenance phase of the depression itself and elicit spontaneous oscillatory activity. Since a major effect of Cs is a block of the hyperpolarization-activated current (Ih, J. Neurophysiol. 69, 2725-2736), these results suggest the possible involvement of Ih in the maintenance of long-term depression and in the regulation of hippocampal excitability.

Supported by M.U.R.S.T. and C.N.R. (CT91-0722) and NIH-NS 21676 and NS-30305.

Sharp-electrode in vitro microelectrode recordings were made from 43 CA3 pyramidal neurons in vitro, in hippocampal slices obtained from Sprague-Dawley rat pups taken 2-7 days postnatally (P2-P7). Membrane potential oscillations (MPOs) were recorded at resting membrane potential (RMP) or following depolarization to levels more positive than -60 mV, in 31/43 neurons (72%). The RMP of oscillating neurons (+64 ± 1.25 mV, n = 31) did not differ from that of non-oscillating (+63.9 ± 1.38 mV, n = 12). MPO amplitude (3 - 5 mV measured peak to peak at ±50 mV) was about 5-13 Hz, measured at ±50 mV from the RMP and increased upon depolarization. MPOs induced action potential firing, whose frequency increased with depolarization. The percentage of oscillating neurons increased with maturation but not significantly (P2-P10: 15/20 neurons, 65%; P11-P17: 18/22 neurons, 82%). No developmental changes in MPO amplitude or frequency were seen. Intracellular TTX, (1 mM) blocked MPOs in 4/4 slices (P10-P16). Tetraethylammonium (TEA, 5mM), added after TTX, revealed slower, higher amplitude MPOs (2/3 slices) that were subsequently blocked by cobalt (5 mM). Following IPSPs or afterhyperpolarizations, MPOs were transiently inhibited, an effect lasting the return to RMP and not mimicked by negative current injection. The non-NMDA receptor antagonist CNQX (10 μM, n = 2) reduced substantially intrinsic MPO amplitude, and adenosine (50-100 μM, n = 2) did not depress, but increased transiently during washout of MPO amplitude. These experiments indicate that intrinsic MPOs, possibly facilitating synchronization, are present in the majority of CA3 hippocampal pyramidal neurons from the early postnatal life. These MPOs are generated by the activation of Na conductance(s) and possibly Ca-conductance(s) and are depressed by the activation of K-conductance(s).

Neurotensin (NT) excites ventral telencephalic area (VTA) dopaminergic neurons in culture by inducing a nonselective cationic conductance. NT also decreases the inwardly rectifying K conductance induced by the K, aminergic agonists. The I-V relation of the NT-induced current had almost a zero slope between -60 mV and -140 mV. After decreasing the external Ca concentration, the NT-induced current increased by 1/4 times and had a positive slope conductance. This result suggests that in the presence of Ca, the channel blocked by Ca, K, and Cl, are replaced by Ca, and E Cl = -68 mV and E Ca = -13 mV, the nonselective conductance decreases by about 1/4 times, and each between E Ca and E Cl. When the internal Cl concentration was reduced, shifting E Ca from near 0 mV to about -80 mV, the nonselective conductance still decreased by about 1/4 th, suggesting that the nonselective conductance is not incompatible to Cl, and that it was probably a nonselective cation conductance. Neurokinin S (NKB) and ACPD also induce inward currents in VTA neurons. The I-V relations of the NKB- and ACPD-induced currents had almost a zero slope between -60 mV and -140 mV, similar to the NT-induced current. Some of the NKB- and ACPD-responding neurons were found to be dopaminergic based on tyrosine-hydroxylase immunoreactivity.

WHOLE-CELL AND SINGLE-CHANNEL PROPERTIES OF A LINEAR MEMBRANE CONDUCTANCE IN CAT RBCGs. D.W. Robinson*, S.J. Huang, R.P. Scokey and L.M. Chalupa. Dept. of Neurology, Section of Neurobiology, Physiology and Behavior and Center for Neuroscience, University of California, Davis, CA 95616.

Whole-cell recordings from isolated cat reticulocytoglobin cells (RBCGs) revealed the presence of a previously unreported linear current, which increased with ontogeny to a mean conductance of 0.27pS/pF at postnatal ages (Robinson et al., 1993). Changing the external Cl concentration had no measurable effect on the reversal potential or the conductance change that may have been the K conductance. The mean external K concentration was increased from 5 to 35 mM the reversal potential changed from -54 to -18 mV. This change was close to the expected value of 34.5 mV calculated from the GHK voltage equation, assuming a 4% permeability for Na. We also used the cell-attached and flipped-off patch variations of the patch-clamp technique to examine the single-channel basis of this linear whole-cell conductance. From -100 to -100 mV little or no voltage-dependence was observed in the isolated single-channel conductance. Changing K concentrations on both sides of the patch resulted in changes in reversal potential similar to those observed in whole-cell. This potassium channel could therefore play an important role in setting the resting membrane potential in these neurons. Supported by UCD gift 07427 to RPS, NEI gift ET-03991 to LMC and DWR is a HSFS Fellow.

TTX-RESISTANT PERSISTENT NA+ CURRENT UNDERLIES PACEMAKER POTENTIALS OF FISH GONADOTROPIN-RELEASING HORMONE (GnRH) NEURONS. Y. Okai. Zoological Institute, Faculty of Science, University of Tokyo, Tokyo 113, Japan.

Gonadotropin-releasing hormone (GnRH)-immunoreactive terminal nerve (TN) cells show endogenous regular beating discharges, which may be related to their putative neuromodulator functions. The ionic mechanism underlying the pacemaker potentials (PPs) was studied using intracellular and patch-clamp current clamp recordings from whole brain in vitro preparation of a small fish brain. Addition of 1.5-3 μM TTX to the Krebs-Ringer solution blocked spontaneous action potentials, but small regular PPs remained. The PPs were not affected by 1 mM amiloride or 1 mM Ni2+ (blockers of low-voltage-activated Ca2+ currents), or 2 mM Co2+ or 0.5 mM Cd2+ ( blockers of high-voltage-activated Ca2+ currents), or in Ca2+-free solution. Thus, Ca2+ currents are not essential for the generation of PPs. On the contrary, the PPs were readily blocked by substituting tetramethylammonium (TMA) or choline for Na* in the perfusing solution, and the resting membrane potential became more hyperpolarized than the control level. This is probably because of the block of persistent inward current that is carried by Na* and supplies the depolarizing drive during the normal beating discharge mode. The present results suggest that the TTX-resistant persistent Na* current, I(Vslo), plays an important role in the generation of PPs in TN-GnRH cells.
628.1 EFFECT OF HYPOTHERMIA AND EXTRACELLULAR PH ON CORTICAL NMDA RECEPTOR ACTIVITY. A.T. Gray, L.T. Buck, J.R. Feinler, B. Hansen and P.E. Richter*. Dept. of Anesthesiology, University of California at San Francisco, S.F., CA 94143-0542

Extracellular acidity is known to inhibit N-methyl-D-aspartate (NMDA) receptor activity and may therefore protect neurons during cerebral ischemia. However, the importance of this effect during induced hypothermia is not clear. Cerebral slices from rats age 10 to 11 weeks were loaded with fluoro-2 and measured cytosolic free calcium. Baseline intracellular calcium was not different between the normothermic (37°C) and hypothermic (17°C) groups (142±8 vs. 102±12 nM, respectively; mean ± S.E.M., n=8 in each group). Baseline ATP levels were 61±11 mmol/mg at 37°C (n=3). Hypothermia reduced NMDA stimulated calcium influx (156±25 vs. 41±6 nM, respectively, n=8 in each group). Extracellular acidity at 37°C decreased NMDA stimulated calcium influx 86% over the in vivo pH range of 6.9 to 7.4. However, no significant effect of extracellular pH on NMDA receptor activity depends on temperature. Further studies are needed to estimate these effects over similar in vivo pH ranges. Supported by the U.CSF Anesthesiology Research Foundation.

During hypoxic brain injury, extracellular pH may drop to as low as 6.4. Most studies to date evaluating neuronal response do so at physiological pH. 7.4. Little is understood about the role of [H+] on promotion/reduction of neuronal death itself.

The role of excitatory amino acid (EAA)-induced phosphatidylinositol (PI) metabolism in neuronal injury is yet to be established. It is now well known, that specifically that stimulate the metabolotropic receptor can cause neuronal injury. In the present study, we investigated the effect of reduced or acidic pH on basal and EAA-stimulated PI metabolism in neuronal cultures. Basal and glutamate-stimulated PI metabolism were decreased at all concentrations tested (10-100 μM), with maximal inhibition detected at 100 μM, when pH was reduced from 7.4 to 6.4. However, during the pH 6.4 reduced both 100 μM glutamate and glutamate stimulation by approximately 25%, stimulation by NMMA was reduced by 77%. Preliminary results indicate that PI metabolism at pH 6.4 is slightly reduced for the non-EAA agonist norepinephrine while unaffected for carbachol. Our results indicate that PI metabolism, via direct (trans-ACPD) or indirect (NMMA) metabotropic receptor activation, is decreased by acids and are consistent with the known effects of pH on NMMA receptor function. Acidic pH effects on multiple EAA receptor types may be beneficial to neuronal outcome subsequent to CNS trauma.

628.3 VISUAL TOXICITY OF ETHAMBUTOL IS MEDIATED THROUGH THE NMDA RECEPTOR OF MAMMALIAN RETINAL GANGLION CELLS. J. L. Lee, L. E. Moscatelli, and E. B. Dever. Harvard Medical School, Dept. of Ophthalmology, MEEL, Dept. of Neurology, Children's Hospital, Boston, MA, 02115.

Ethambutol is a mainstay in the management of tuberculosis and other mycobacterial infections. Although its ability to cause optic neuritis and visual loss is well known, a mechanism has not been identified. We have established that ethambutol is directly toxic to retinal ganglion cells in vitro, and that this toxicity is mediated through the NMDA receptor. In cell culture studies we have shown that ethambutol at 0.1-10 μM prevented cell death in cultures results in the death of 50% of retinal ganglion cells within 24 hours. Ethambutol mediated retinal ganglion cell death is dose-dependent. Other cell types in these preparations are unaffected. This toxicity can be prevented in several ways: (1) the elimination of endogenous glutamate; (2) the addition of the NMDA antagonists APV (2-aminophosphonovoronic acid) or the calcium blocker nimodipine. In addition, the non-NMDA antagonist CNQX (6-cyano-7-nitroquinoxaline-2,3-dione) did not reduce toxicity. Taken together, these experiments suggest: (1) ethambutol is directly toxic to retinal ganglion cells in culture; (2) ethambutol increases the sensitivity of retinal ganglion cells to endogenous levels of glutamate; (3) ethambutol toxicity is mediated through the NMDA receptor. These findings suggest that visual loss due to prolonged ethambutol treatment for tuberculosis may be prevented by the use of selective NMDA antagonists.

The pathologic role of cAMP in excitotoxic brain injury was assessed in a perinatal rat model. Stereotaxic intrastriatal injections of 8-bromo-cAMP or dibutyryl-cAMP (600-1200 nmol, 0.3 μl) did not cause cAMP analogues of vehicle, produced no apparent permanent or behavioral brain injury in PND 7 rats. The severity of brain injury was assessed histologically and by hemispheric weight disparities 5 days following injection (Mcdonald et al., 1989).

The cAMP analogues were administered as a monotherapy or in combination with the NMDA antagonist MK-801 (2.5 mg/kg, i.p.). The combination of cAMP analogues and MK-801 provided significant protection of MK-801 alone, suggesting that the cAMP analogues activate the cAMP cascade which is inactivated by the NMDA antagonist.

Glutamate activates two broad categories of receptor subtypes, ionotropic (i.e., selective agonists AMPA, Kainate, or NMDA) and metabotropic (mGluR). Maintaining the balance between plasticity and pathology may involve receptor subtype-specific and neuron-specific countermeasures including the glutamatergic antagonist dihydroxy-cyclopentenol-1,3-dicarboxylic acid (DCAC), a selective mGluR agonist, to attenuate NMDA neurotoxicity (Kob et al., 1991) in cortical cultures. Although other neuroprotective actions of ACVD have been demonstrated both in vitro and in vitro, recent studies indicate neuroprotective effects of mGluR activation with relatively low doses of ACVD. In the present study, we examine the interplay between NMDA and ACVD to determine if the neuroprotective or neuropathological effects of mGluR activation.

Fifteen adult male Sprague-Dawley rats were treated with intrahippocampal injections of 10 mM ACPD (100 mM NMMA, and in the contralateral side 10 mM ACPD or 100 mM NMMA. At 14 days after the injections, ACPD resulted in minor damage to the dorsal blade of the dentate gyrus, whereas NMMA alone did not produce significant neural damage. The combination of ACPD and NMMA produced significant damage to CA3 and also involved the ventral blade of the dentate. Excitotoxic actions of the ACPD+NMMA may indirectly modify spine or directly effect receptors. The potential neuroprotective and toxic activity of mGluRs may be an important factor in normal CNS development, disease-related pathology and provide insights into the development of therapeutic interventions.

SUPPORTED BY NIH NS03143 and NS03140.
NDMA TOXICITY IN DEVELOPING CEREBELLAR GRANULE CELLS MEDITATED BY A MANGANESE-SENSITIVE NDMA RECEPTOR. T. Xi, K.R. Yan, J. Ban, B. Michaelis, and R. Michaelis. Pharmaco. & Toxicol. Dept., Univ. of Kansa, Lawrence, KS.

NDMA receptors play an important role in glutamine-induced neuronal toxicity and are related to neurodegenerative disease. Cerebellar granule cells in culture were used as a model to study the role of NDMA-mediated neurotoxicity. Rat cerebellar granule cells were grown under depolarizing conditions for 7 days, and the medium was then changed except for the addition of D-glutamate to compensate for evaporation. The cells were treated with 50 µM NDMA that was directly added to the culture medium in the presence of 0.8 µM Mg²⁺.

Cell death was monitored by both the LDH and the MTT assay. The dose response curve of NDMA-induced toxicity showed that the toxicity was increased through DIV 8 to DIV 14. This increased toxicity correlated to the increased expression of the 63-70 kDa glutamate-binding protein as determined by Western blot. The NDMA (100 µM)-induced toxicity at DIV 14 was blocked by AP-5 (500 µM) and NMDA (10 µM) and it was not sensitive to CNQX (25 µM). This indicates that the NDMA-induced neurotoxicity is mediated by NMDA receptors rather than non-NMDA receptors which might have been activated as a result of NDMA-induced glutamate release. The NDMA-activated increase in [Ca²⁺], measured by Fura-2 in the condition favoring the Mg²⁺-sensitive NMDA receptors (5 nM KCl, 10 µM glycine, and Mg²⁺-free) did not show the developmental increase through DIV 5 to DIV 14 and did not correspond to the developmental pattern of NDMA-induced toxicity. These results may suggest a distinctive role of Mg²⁺-insensitive NMDA receptors in NDMA toxicity of cerebellar granule cells.

Memantine is a potent noncompetitive antagonist at N-methyl-D-aspartate-activated receptor channels (J. Pharmacol., 166, 591, 1989) and has been shown to protect against soman-induced cell death (J. Pharmacol., 198, 215, 1991). Preliminary studies with 15 mg/kg memantine also have shown to prevent seizures after soman (an irreversible cholinesterase inhibitor) injection (Toxicol. Appl. Pharmacol., 112, 95, 1992). The purpose of this study was to examine efficacy of memantine as a pretreatment drug in protecting rats from seizure-induced neuronal damage after soman. Adult male Sprague Dawley rats received pyridostigmine (0.13 mg/kg i.m.) and atropine methyl nitrate (5 mg/kg s.c.) 30 min before a single injection of soman (0.1 mg/kg s.c. equivalent to 0.9 LD₅₀ dose). Memantine (18 mg/kg s.c.) was administered 60 min prior to soman. At 24 hr rats were anesthetized with sodium pentobarbital (65 mg/kg i.p.) and transcardially perfused with buffered 10% formalin. Neuropathology of various areas of brain was examined in H&E stained coronal sections. Approximately 64% of rats receiving soman alone showed severe seizure activity and died within 24 hr. Pretreatment of rats with memantine reduced the severity of seizures and provided 100% protection from lethality. The brains of surviving rats in soman alone group showed necrotic lesions in frontal cortex, piriform cortex and hippocampus. Although memantine reduced the intensity of seizures in 66% of the pretreated rats, the drug could not protect the rats from seizure-induced neuronal degeneration in the brain areas described above. It is likely that repeated administration of memantine is needed to maintain the blockade of channels activated by excitatory amino acids in soman poisoning.

The recent molecular cloning of several NDMA subunits demonstrated the heterogeneity of NDMA receptor localizations and properties in the central nervous system. To determine oligonucleotides (AOs), we investigated the involvement of the NDMA₁ and the four NDMA₂ subunits in the formation of NDMA receptors which mediate excitotoxicity. Cerebellar granule cells displayed mRNA for these subunits after 10 days in culture as revealed by RT-PCR. Preliminary experiments showed that a maximum amount of stable OAs was incorporated inside cells at 24-48 h after transfection. Treatment of neuronal cultures with NDMAₙ and AOs decreased dramatically the level of NDMA₁ protein and reduced by 60% NDMA-induced excitotoxicity. We found that AOs, but not OAs for NDMA₂, 1-2 and 3 protected also neurons from NDMA excitotoxicity when 40 to 60% of cells were damaged by NDMA. However, only AOs for NDMA₁ and 3 displayed some protective effect when the NDMA-dependent neuronal death was reduced by 70%. AOs against NDMA₄ were much less efficient in rescuing neuronal cultures whatever the level of excitotoxicity. The protective effects obtained with AOs for NDMA receptor subunits were not additive. The reduction of neuronal cell death after AOs treatments was correlated with a decrease in the NDMA-stimulated calcium influx. Finally, NDMA AOs treatment did not affect the toxicity induced either by activation of AMPA glutamate receptor or by MPTP. These results suggest that AOs for NDMA subunits can be used to knock down the pathologic roles of specific NDMA receptor subpopulations in neuronal cultures.

TOXIC DOPAMINE/GLUTAMATE INTERACTIONS IN CULTURED NEURONS: EVIDENCE FOR OXIDATIVE STRESS. K.R. Hoyt*, L. Reynolds and T.G. Hastings. Dept. of Pharmacology and Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Dopamine (DA) and glutamate (Glu) are neurotransmitters important for normal brain function. However, these neurotransmitters can cause neuronal damage when their extracellular concentrations are elevated, in pathological conditions such as cerebral ischemia and methamphetamine toxicity, and possibly in neurodegenerative conditions such as Parkinson’s disease. We have found, using the fluorescent dyes CMFDA and monochlorobimane to measure intracellular glutathione, and dichlorofluorescein to measure intracellular oxygen, that evidence for DA and Glu-induced oxidative stress. We also investigated the interaction between DA and Glu on cell death in cortical neurons cultured for 14-17 days. We used concentrations and exposure times of DA and Glu that were themselves not toxic, and we found that the combination caused a significant increase in cell death. We found, using the fluorescent dyes CMFDA and monochlorobimane to measure intracellular glutathione, and dichlorofluorescein to measure intracellular oxygen, that evidence for DA and Glu-induced oxidative stress. We also investigated the interaction between DA and Glu on cell death in cortical neurons cultured for 14-17 days. We used concentrations and exposure times of DA and Glu that were themselves not toxic, and we found that the combination caused a significant increase in cell death.

These two treatments resulted in a 36% loss of viability (p<0.05). In another experiment, 100 µM DA for 1 hr or 100 µM Glutamate for 2 min resulted in a 4% loss of viability compared to untreated controls, when measured 6 h after treatment. When these two treatments were combined, there was a significant increase in cell death (p<0.05). The combined treatments were 0.5 µM DA for 2 h and 0.5 µM Glutamate for 2 min. These results suggest that the combination of DA and Glu can cause a significant increase in cell death. We have found, using the fluorescent dyes CMFDA and monochlorobimane to measure intracellular glutathione, and dichlorofluorescein to measure intracellular oxygen, that evidence for DA and Glu-induced oxidative stress. We also investigated the interaction between DA and Glu on cell death in cortical neurons cultured for 14-17 days. We used concentrations and exposure times of DA and Glu that were themselves not toxic, and we found that the combination caused a significant increase in cell death. We have found, using the fluorescent dyes CMFDA and monochlorobimane to measure intracellular glutathione, and dichlorofluorescein to measure intracellular oxygen, that evidence for DA and Glu-induced oxidative stress. We also investigated the interaction between DA and Glu on cell death in cortical neurons cultured for 14-17 days. It has been suggested that ischemia-induced CNS damage is mediated by prolonged activation of excitatory amino acid receptors which may result in whole or in part increased extracellular glutamate (tGLU). In these studies transverse hippocampal slices from male rats were used to investigate the effect of glycine (a-lo-taurodinitol) or hyposia (KCN) on temporal GLU release and associated neuronal damage mediated by glutamate (GLU) receptors. Treatment with a drug for 30 min increased extracellular aspartate (ASP) and GLU and produced lesions in the CA1, CA3, CA4 and dentate gyrus (DG) regions which were attenuated by NMDA antagonists. A more severe lesion was observed in slices treated for 30 min with both IOA and KCN; this was completely prevented by combining non-NMDA and NMDA antagonists. To investigate the temporal release of GLU and activation of GluRs, slices were treated with KCN for 2.5 to 30 min. Within 2.5 min discrete CA1 neuronal twiglave was seen which coincided with decreases in tissue ATP levels. These CA1 lesions were not accompanied by increases in extracellular GLU or ASP but were completely prevented by NMDA antagonists. Within 10 min there were increases in GLU which coincided with extensive lesions in the CA1, CA4 and DG. Within 20 min, all of the regions of the hippocampus appeared severely damaged. This was twice that of control slices. This data supports our previous studies which suggested that excitotoxicity associated with mild metabolic stress was caused by changes in the physiology of the NMDA receptor following compromise of energy stores rather than by increased extracellular GLU or ASP. More prolonged or more severe metabolic inhibition precipitates involvement of non-NMDA receptors perhaps mediated by increased tGLU.

Several a ligands have been shown to protect against neuronal ischemic injury in vivo. We have used primary cultures of rat spinal cord slices to evaluate the protective effects of a variety of selective a ligands in comparison with PCP-related noncompetitive NMDA receptor antagonists during either hypoxia or brief exposure to excitotoxic (100uM) concentrations of NMDA or kainic acid (KA). In addition, the effects of these compounds on NMDA-induced changes in intracellular calcium concentration ([Ca2+]i) and phosphorylation(s) (Pu) metabolism were compared. After 8-30 days in culture, neurons were subjected to hypoxia or brief excitatory amino acid exposure in Locke’s solution from which Mg2+ and glucose were omitted. Cell damage was quantitatively assessed on the following day by measurement of glutamate dehydrogenase (GluR). The same [Ca2+]i were measured in single identified neurons (5-20uM) [field] preloaded with the Ca2+-selective dye indo-1 using an ACAS 570A laser eyepiece. The following ligands MK-801, dextromethorphan, and a variety of e ligands, including DTG, (+)-pentamcine, and caramphine, caramphine, caused significant, dose-dependent protection against hyposia and NMDA, but not KA-induced cell injury. In contrast to the PCP receptor ligands, at neuroprotective concentrations the e ligands failed to antagonise the sustained elevations in [Ca2+] elicited by NMDA and failed to consistently alter NMDA-stimulated PI hydrolysis (200-500% above control). These results indicate that, through mechanisms distinguishable from PCP-receptor related antagonism of the NMDA receptor, a ligands provide an effective means of preventing excitotoxic neuronal injury.

NMDA antagonists such as MK801 and phencyclidine injure a discrete population of neurons in the cingulate and retrosplenial cortex. These agents produce cytoplasmic vacuoles and induce production of the stress protein HSP70. Cycloartenol arachidonic acid (AA) metabolites such as Pge2 and bosphenol A2 have been proposed to be extracellular messengers that induce HSP70 expression in tumor cells. Accordingly, we hypothesized that arachidonic acid metabolites may signal HSP70 expression due to MKO1 toxicity. MKO11mg/kg was injected i.p. in awake rats. HSP70 mRNA transcription was studied using in situ hybridization with 35S-labeled oligodeoxynucleotides (ODN). These ODN hybridized to HSP70 mRNA and protein expression in a dose dependent manner at 5, 10, 20, 30 and 50mg/kg i.p given 15 min prior to MKO1 injection. Furthermore, the mRNA encoding the mitogen inducible cycloxygenase (COX) was also induced. HSP70 in situ hybridization was also expressed 4 hrs after MKO1 injection. These data support a role for AA metabolites in the expression of HSP70 in MKO1 toxicity. Further experiments will be required to determine if AA metabolism inhibition in vivo or if their effects are limited to HSP70 induction.

Recent studies using the single-channel patch-clamp technique have shown that the 9-aminoacridines are potent open-channel blockers of NMDA-activated currents in cultured hippocampal neurons (Bullock, et al. J. Neurosci. 1989). In previous studies using the single-channel patch-clamp technique we have demonstrated that the 9-aminoacridines are potent open-channel blockers of NMDA-activated currents in cultured hippocampal neurons (Nelson, et al., Proc. Natl. Acad. Sci., USA 1994). Based on the acidine-induced reduction in single-channel open times at 800uM, the forward blocking rate constants were found to be 1.1±0.7 10^3 s^-1 and 1.4±0.3 10^4 s^-1 for 1,2-phenyl-4-9-aminoacridine (1,2-PAA) and 3-[2-9-aminoacridinyl]propionic acid (IOA-iodoacetate) (IOA), respectively. The affinity of the 9-aminoacridines for the blocked state produced by these compounds was long in duration (in the range of 200 min) similar to that of normal channel closed times. To circumvent this problem, experiments using whole-cell patch-clamp preparations were performed. A two-metal, multielectrode configuration was used to study the binding kinetics of these compounds. In nominally Mg2+ free solutions, the recovery from blockade by THA indicated that the dissociation was from a single blocked state (k_diss=48.7±0.9 min^-1, n=3), but the single-channel experiments clearly showed that a much briefer THA-blocked state (dissociation <200 µs) exists that would be difficult to detect by any means of drug application in the whole-cell experiments. The recoveries from blockade by the bis-9-aminoacridines, on the other hand, were slower and were normally best described by a single exponential function having time constants (k_diss) of 2176.1±14.7 min^-1 (n=5), and 1671.8±9.9 min^-1 (n=12) for 1,2-PAA and 1,4-BAA, respectively. The single-channel studies mentioned above also revealed that the interaction of the 9-aminoacridines with the channel was at a site that is different from the Mg2+-binding site of the channel and suggested that the channel could be similarly occupied by 1,4-BAA and the 9-aminoacridines. This simultaneous occupation likely modifies the affinity of the receptor for the 9-aminoacridines. Indeed, preliminary results in the presence of 100µM 9-AAC showed that the ratio of association and dissociation of 1.2-PAA were increased. Support (USPHS Grant ES 07330).

628.18 NEURO NECROTIZING PROPERTIES OF PHENCYCLIDINE TO CORONE. DE Worum, MA Sanna, and JW Olwayo. Washington University, St. Louis MO 63110.

Antagonists of NMDA glutamate receptors, including phencyclidine (PCP) and MK-801, acutely injure neurons and induce expression of 72 Kd heat shock protein (HSP) in the posterior cingulate/retrosplenial (PCRS) cortices when administered sc to adult rats. Sharp et al. reported that a high dose of PCP (40 mg/kg) caused a robust HSP response in neurons but in many additional neurons in several neocortical and limbic brain regions. They proposed that HSP serves a protective function and that the robustness with which an injured neuron expresses HSP may be a measure of its ability to survive the injury. Thus, the widespread injury induced by high-dose PCP may be entirely reversible. In contrast, it is known that injury to MK-801 (5 mg/kg ip) kills PCR S neurons. Silver stains have been used to detect neuron injury induced by low-dose MK-801, but h to date it is not known that silver staining of neurons signifies cell injury or cell death. To address these questions we treated adult female rats with a single high dose of PCP (50 mg/kg) and examined the brains at various post-injection times (4 hrs to 4 days) using H&E paraffin, de Olomos silver or HSP immunocytochemistry. We found high dose PCP induced HSP in PCR S neurons in layers II to V and that it killed many neurons distributed in these same layers. Occasionally, but not consistently, it induced HSP and killed neurons in other neocortical areas. We have been unable to validate the de Olomos silver stain for detecting PCP-induced neuronal necrosis in that in each brain only those neuronal populations showing definite signs of neurons (intense eosinophilia) stained with de Olomos stain. Moreover, the de Olomos stain may be a selective marker of cell death in that in PCR S neurons did not become argyrophilic until approximately 36 hrs after PCP treatment, but PCP is well known to physically injure neurons at a much earlier interval (4-12 hrs). Our findings do not confirm the view that HSP expression in PCP-injured neurons signifies necrosis. Supported by AA 07666, AG 05681, DA 05072 and RSA MH 38894 (FWO).
RATS BECOME HYPOSENSITIVE TO MK-801 NEUROTOXICITY DURING PREGNANCY. NB Farber* and JW Chelley Washington Univ., St. Louis, MO.

Antagonists of NMDA glutamate receptors, including phencyclidine (PCP) and MK-801, cause vascular injury (low dose) or kill (high dose) neurons in the posterior cingulate/retrosplenial (PCR/S) cortices when administered to or ip to adult rats. Non-pregnant female rats are substantially more sensitive to the vasculotrophic effects of these antagonists than non-pregnant males. We now report that female rats become hyposensitive to NMDA antagonist neurotoxicity (NAN) during pregnancy. A high dose of MK-801 (5 mg/kg sc) in 17/19 pregnant dams (n = 4) induced a vascular reaction affecting 88.75 ± 25.8 (SEM) neurons per section compared to 212.2 ± 18.9 (SEM) neurons per section for control pregnant females (n = 4). In the female pregnant dams, some microglial proliferation and astrocytosis were observed. In contrast, we administered MK-801 to adult female rats in a dose (0.5 mg/kg sc) that reliably induces a full cerebrocortical neurotoxic reaction and injected various agents into the PCRs cortex and other brain regions in attempts to disrupt the circuit and block the PCRs reaction. We found that the neurotoxic reaction could be prevented by pretreatment with remifentanil (GABA antagonist), scopolamine (muscarinic antagonist) or nimodipine (Ca2+ antagonist) into the PCRs cortex, or by injecting nimodipine into the diagonal band (DB) region of the basal forebrain, or into the anterodorsal/ventromedial (ADAV) nucleus of the thalamus. Our interpretation is as follows: systemic administration of MK-801 blocks NMDA receptors that tonically drive GABA inhibitory neurons in at least three separate brain regions (PCRs, DB, ADAV). This results in a complex disorganization syndrome in which 1) DB neurons release excessive ACh at muscarinic receptors on PCRs neurons. 2) ADAV neurons release glutamate at non-NMDA receptors on PCRs neurons. 3) local PCRs interneurons release an endogenous agonist that modulates a sigma site in PCRs cortex. We postulate that the proximal mechanism causing PCRs neuronal injury is simultaneous excessive release of 3 endogenous transmitter/modulator systems that can induce these anomalies. Supported by NIH NS 8254 (LWO) and a grant from NARSAD (JWO).

EXCITATORY AMINO ACIDS: EXCITOTOXICITY AND NON-NMDA RECEPTORS

629.1 KAINATE FAILS TO EVOKIE MITOCHONDRIAL OXIDATIVE RADICAL GENERATION IN KAINATE-LACERATED CORTICAL NEURONS: SELECTIVELY VULNERABLE TO AMPA/KAINATE TOXICITY, L.M.T. Canzonier*, S.L. Sensi, L.D. Dugan, D.M. Turkasy, and D.R. Chi. Dept. of Neurology, and Center for the Study of Nervous System Injury, Washington Univ. School of Medicine, St. Louis, MO 63110.

We previously described a subpopulation of cortical neurons highly vulnerable to death induced by relatively brief AMPA or kainate exposure, identifiable by staining for kainate-stimulated calcium uptake ("kaout+ positive cells"; Turkasy et al., Soc.Neurosci. Abstr. 18.81, 1992), a marker for cells expressing AMPA or kainate receptors. Herein, we report data from a separate, earlier study. We assessed whether "kaout+" cells, followed by death of >50% of the cells. The increase in [Ca2+]i was comparable to that reached following neurotoxic exposure to NMDA (100 mM for 5 min) in the general neuronal population. However the same kainate exposure failed to stimulate mitochondrial oxidative radical production in cobalt-positive cells (n=19). Failure to detect a rhodamine signal was not due to loss of the mitochondrial membrane potential as tetramethylrhodamine showed no loss of this potential in cobalt-positive cells. Present data suggest that the route of Ca2+ entry may be an important determinant of consequent mitochondrial oxidative radical production. Supported by NIH grants NS33073 (DWC) and AG05099-01A1 (L.DD).

629.2 IMAGING OF MITOCHONDRIAL OXIDATIVE RADICAL PRODUCTION IN CORTICAL NEURONS EXPOSED TO AMPA AND KAINATE. L.D. Dugan, S.L. Sensi, M.T. Canzonier, M.P. Goldberg, S.D. Handran, S.M. Rothman and D.R. Chi. Dept. of Neurology and Center for the Study of Nervous System Injury, Washington Univ. School of Medicine, St. Louis, MO 63110.

Confocal microscopy was used to image oxidative radical generation by mitochondria in cortical neurons exposed to NMDA. The mitochondria-specific, oxygen-sensitive dye, dihydroethidium (DHE; 100 nM) was added to cultured cortical cells for 30 min. A time- and dose-dependent increase in mitochondrial fluorescence was observed in response to toxic concentrations (50-100 μM) of NMDA. This signal was only observed after onset of NMDA exposure, reflects oxygen radical-mediated oxidation of non-fluorescent DHE to its fluorescent derivative, rhodamine (2D).

The signal was specific to NMDA in that 100 μM kainate (10 μM MK-801), 50 μM potassium (10 μM MK-801), 1 μM ibotenic, or 300 μM t-ACPD all failed to stimulate mitochondrial radical formation. Removal of calcium (plus 300 μM EGTA) abolished the NMDA-stimulated mitochondrial response. In an uncooled of electrophoresins from a non-NMDA group that did not sensitively increase mitochondrial radical production. Supported by NIH NS33073 (DWC), AG05099-1A1 (L.D.), NS51345 (MPD).

SyM-32 is a monocular antibody (Stemberger-Meyer Immunocytochemistry) that recognizes non-phosphorylated neurofilament epitopes, and has been reported to label subsets of CNS neurons, including populations of pyramidal neurons that degenerate in Alzheimer’s disease (J Comp Neurol 301:44). We found SyM-32 immunostaining to label small subsets (2-4%) of neurons in dissociated cultures of murine cortex and spinal cord. Cortical SyM-32 (+) neurons were larger than average, frequently multipolar. Immunocytochemistry using a polyclonal antibody to GluR4 revealed moderate levels of receptor expression in 80-90% of cells. Fura-2 microfluorometry demonstrated that either AMPA (100 μM) or kainate (100 μM) increased [Ca2+]i, approximately 1 fold over basal, in the transfected line. Addition of 100 μM cyclothiazone, which blocks AMPA receptor desensitization, to the exposure medium increased the AMPA-induced elevation in [Ca2+]i, to about 10 fold; further increases could be blocked by raising the extracellular Ca2+ concentration from 1 mM to 10 mM. Continuous exposure to 500 μM AMPA, 100 μM cyclothiazone, and 10 mM Ca2+ resulted in the death of 50-60% of transfected cells in 1 hour, and about 90% of cells by 48 hrs. Death was dependent on AMPA concentration (30-1000 μM), and could be blocked by 50 μM NBQX. Death could also be induced by 24 hr exposure to 500 μM kainate, but not by 48 hr exposure to 500 μM NBQX. Supported by NIH grant NS33073 (DWC).
AMP-INDUCED DELAYED NEURONAL INJURY IN THE HIPPOCAMPAL SLICE, WITH PROTECTION WITH POST-TREATMENT DNXO. K.L. Peterson and D.A. Watts. Dept. of Neurology UCLA, Los Angeles, CA 90024 and Sepulveda VAMC, Sepulveda, CA 91343.

Prevention of delayed neuronal injury is a prime objective in the acute treatment of stroke and head trauma. To investigate potential non-NMDA excitotoxic mechanisms of delayed neuronal injury, we examined the effect of sub-lethal AMPA exposure upon CA1 neurons in hippocampal slices. In these studies, paired rat hippocampal slices taken from the same dissection were placed in recording chambers perfused with ACSF containing 2.4 mM Ca++, 1.3 mM Mg++ and 4 µM glutamate. One slice of each pair was exposed to 25 µM AMPA until disappearance of the orthodromic CA1 population spike (PS). In three experiments, the AMPA-exposed PS was 3.7 ± 0.9 ms in duration. AMPA treated slices regained an average of 98% ± 2 of their original orthodromic PS within a mean of 30 ± 10 min. After initial recovery, AMPA-treatment resulted in significantly smaller PS amplitudes for several hours and then abruptly collapsed. Control slices maintained PS significantly longer. A 3nM CA1 PS amplitude was used as the criterion for slice viability. AMPA treated slices maintained a PS of greater than 3 mV for an average of 6.3 ± 1.4 hrs while paired control slices maintained a PS greater than 3 mV for 16.5 ± 1.1 hrs. Post-AMPA treatment of 100 µM DNXO extended the duration of CA1 PS recordings from 7.7 ± 0.4 hrs to 18.6 ± 1.4 hrs. These findings suggest that activation of non-NMDA receptors can induce delayed neuronal dysfunction, and that protection from this injury can be afforded by DNXO treatment given after the receptor activation.

Supported by the VA Research Service and the American Epilepsy Society.

Domino acid (DOM) is a rigid analog of glutamate demonstrated to be an agonist on non-NMDA receptors. We previously demonstrated that DOM given i.p. to mice induces the c-fos immediate response gene and causes degeneration in hippocampal CA1 and CA2 pyramidal cells. We have now investigated the acute effects of DOM on neuronal viability, using rats aged postnatal (P) day 1, 5, and 10. DOM-induced behavioral changes include immobility and ataxia, repetitive scratching and finally generalized clonic or tonic-clonic seizures. P1 rats were more sensitive than P10 (EC50 = 0.3 to 0.7 mg/kg). Scratching occurred within 20 min and seizures within 30 min at 0.2 mg/kg, twice as long at 0.1 mg/kg and did not occur at 0.02 mg/kg. We next localized the in vivo action of DOM to hippocampal pyramidal cells of CA2 and CA3 using c-Fos immunohistochemistry. Primary hippocampal cultures were then used to evaluate the toxic effects of DOM. 30 µM DOM exhibited [Ca2+]o, and caused membrane depolarization measured using FURA-2 and bisoxinol. The NDMA antagonist AP-5 (100 µM) totally prevented DOM elevated [Ca2+]o and depolarization. Pretreatment of PS rats with 1 mg/kg AP-5 also prevented the induction of c-Fos by DOM, but failed to prevent DOM-induced seizures. These results indicate that neonatal rats are highly sensitive to the effects of DOM. The tonic and neuroexcitatory actions of DOM on pyramidal cells appear to require involvement of NDMA receptors, yet the behavioral changes appear to occur independently of the NDMA receptor subtype.

We and others have shown that in primary neuronal cultures, neuroprotective agents which do not block glutamate receptors protect from excitotoxicity by selectively affecting mechanisms associated with either non-NMDA or AMPA receptors or non-NMDA receptors (Brain Res 1993, 292; 304). Thus, non-NMDA, but not the NMDA, excitotoxicity can be attenuated with an analog of vitamin E, suggesting that free radical formation plays a role in the latter type of toxicity (Brain Res 1991, 588). Recently, it was proposed that melatonin might be a potent endogenous hydroxy radical scavenger (Endocrine J 1993, 11). In addition, melatonin has been shown to protect neurons from photochemically induced oxidative stress (Mol. Brain Res. 1985, 2: 193). In this study, we used 7-day-old primary cultures of rat cerebellar granule neurons. Cultures were exposed to kainate (30 µM), glutamate (15 µM), or NMDA (without magnesium, 80 µM) and then returned to the culture-conditioned medium. Viability was measured with the MTT technique (Neuropsychopharmacology 1990, 29: 1103) 18-16 hrs later. Co-treatment with melatonin (500 µM) protected neurons completely from the toxicity of kainate (up to 1 µM), and shifted the LD50 for glutamate from 5 µM to 97 ± 6 µM. It was ineffective in protecting from NMDA toxicity. When melatonin was added to cultures only before or after kainate treatment, there was no resultant protection from kainate toxicity. The neuroprotective effect of melatonin does not appear to be related to the direct action of melatonin on non-NMDA glutamate receptors. That is, the kainate-stimulated increase in the cytosolic calcium (measured at the single cell-level with a digital imaging fluorogenic microscopy with fura-2) was not affected by melatonin; the binding of SH-glutamate to rat cerebellar membranes was likewise not affected. Further studies are needed to evaluate the pharmacological relevance of the neuroprotective action of melatonin.
629.11

Kainate, a non-NMDA receptor agonist, acts as a potent neurotoxin in the adult retina. Consistent with this, acute exposure (12 hours) of primary cultures of chick embryonic day 8 retinal cells to 100 μM kainate caused 59 ± 5% of the cells to die when applied at 6 days in vitro (DIV). In contrast the number of cells in cultures grown in the presence of 1.0 and 500 μM kainate from 1 DIV did not differ significantly from those grown in the absence of kainate. This lack of effect of kainate on cell survival does not appear to result from receptor desensitization since whole-cell patch-clamp recording showed that cells grown in the presence of kainate for 6 days continue to exhibit a current which is suppressed by the non-NMDA receptor antagonist CNQX. We have utilized the cobalt staining technique of Prus et al. (1991, Neuron 7, 309) to determine the number of cells that express the calcium permeable form of the AMPA/kainate receptor in retinal cultures. We found that the number of cells expressing this receptor in control cultures rose from 5% at 2 DIV to a maximum of 50% at 3 DIV. However, in cultures grown in the presence of 10 μM kainate, the number of cells stained by cobalt was reduced by as much as 90% at 5 DIV. The effects of kainate on the expression of the receptor could be prevented by the addition of 20 μM CNQX, but not by 20 μM AP5 or 20 μM D/7 or dinitrophenol. When kainate was removed from the culture medium at 4 DIV the number of cells expressing the receptor at 7 DIV was restored to normal. A down-regulation of the Ca2+-permeable non-NMDA receptor will decrease Ca2+ influx into the cells and this may account for their survival when grown in the presence of excitotoxic concentrations of kainate.

INTRINSIC OPTICAL SIGNALLING IN THE HIPPOCAMPAL SLICE EVOKED BY THE EXCITOTOXIC DOMINO ACID. Trevor M. Poliouchou* & David Andrew. Dept. of Anatomy & Cell Biology, Queen’s Univ., Kingston, Ontario, K7L 3N6.

As cells swell, light transmittance increases across brain slices (Lipton, J. Physiol. 237, 365; Andrew and MacVicar, Neuroscience in press). Also, as shown by Adams and Andrew (this meeting), increases in light transmittance induce by glutamate agonists can be imaged in real time in the entire hippocampal slice. Here we studied the effects of the potent neurotoxin and glutamate analogue, domino acid (D/7) on light transmittance in the CA1 hippocampal slice. The aim was to characterize 1) which hippocampal regions were affected, 2) which subclass of receptors were involved, and 3) if cell swelling played a role in the response. A 1 minute exposure of 10 μM D/7 (25°C) elevated light transmittance by up to 58% in the dentate regions of CA1 and of upper dentate gyrus. The response slowly reversed during a 30 min wash in –NMDA. A significant change was observed in the CA1 region nor in the lower blade of the dentate gyrus. The response to D/7 was reversibly blocked by the non-NMDA receptor antagonists kynurenic acid (1 mM; n=5), CNQX (50 μM; n=5) or D/7 alone (1 mM; n=5) or the kainate receptor antagonists GAMS (100 μM; n=5). Tetrodotoxin (1 μM) blocked action potentials and the evoked CA1 population spike but light transittance increases were maintained and therefore were not associated with neuronal discharge. Extracellular tissue resistance measured across CA1 stratum radiatum increased rapidly in response to DOM and slowly fell over 30 min, which paralleled the light transittance response. We conclude that brief DOM exposure elicits a prolonged, post-synaptic swelling in the CA1 dentitid region primarily mediated by AMPA receptors. This imaging technique allows a real-time view of events preceding neuronal death and so may prove useful in assessing potentially therapeutic glutamate antagonists that combat excitotoxicity. Supported by the Canadian MRC.

629.14

Experimental primate studies have shown that chronic injection of the excitatory and neurotoxic amino acid BOAA, disrupts motor neuron function in a manner similar to that seen in the human neurodegenerative disease, amyotonia. BOAA is known to exert its neurotoxic effects by binding to both NMDA and non-NMDA receptors, especially the AMPA receptor. A recent study (Brain Res., 621:215, 1993) has reported that a very low (0.1 μM) concentration of BOAA selectively inhibits the activity of the mitochondrial enzyme NADH-dehydrogenase (NADH-DH; Complex 1), while 1 μM BOAA promotes LDH release into the incubation media indicating neuronal cell death. This study investigates the effect of BOAA on mouse brain NADH-DH in both vitro and in vivo. For in vitro studies, transverse brain slices were obtained from adult male CD-1 mice (25-34 g) and incubated in Krebs Ringer (3.0 ml/slices) bubbled with 95% O2 + 5% CO2 incubated at 37°C for 1 h. Treatment of slices with BOAA showed a concentration-dependent inhibition of NADH-DH, but only at μM concentrations (16, 24, 33, and 37% inhibition at 10, 100, 300 and 1000 μM BOAA, respectively). Release of LDH into the incubation media was observed only in slices treated with 500 μM and 1000 μM BOAA. Young (9-day old) and adult (4-month) mice treated with 500 and 700 mg/kg BOAA, respectively, showed behavioral signs of BOAA toxicity. Young mice had severe convulsive seizures while adult mice exhibited drowsiness and lethargic movement. The NADH-DH activity in brain homogenates and mitochondria from BOAA-treated animals did not differ with that in age-matched animals treated with an equivalent volume of saline. These findings are in contrast to the reported suggestion that BOAA is a highly potent inhibitor of mitochondrial energy metabolism. Supported by NIH grant NS 19611 and MRG of Oregon.

AMPA receptors are characterized by a fast desensitization which is considered to be a possible mechanism for the termination of excitatory synaptic transients. The present experiments are aimed to evaluate a methodology of cyclothiazide (CTZ), a drug which reduces desensitization of AMPA responses, to alter the intraneuronal Ca++ concentration ([Ca++]i) after exposure to AMPA.

Experiments were performed in primary rat hippocampal neurons grown for 10-16 days in cultures. Changes in [Ca++]i were measured by microfluorimetric monitoring of the fluorescence intensities from individual neurons loaded with fura-2. In these cultures, indirect immunostaining of rat MAP2 confirmed that the fluorescent signal was derived from neuronal cells of the neurite, which excited most of the neuronal responses. The effects of Concanavalin A (Con A) on the pharmacology of glutamate were examined. In cultured cerebellar granule cells, we found that Con A increases Ca++ influx through the MAP2 buffer, glutamate, quinolinic acid, and a-methyl-3-hydroxy-5-methyl-4-isoxazolopropionic acid (AMPA) activate the same neural subset population (10-15%) of the neurons, whereas quinolinic acid activates all neurons and NMDA activates none. Glutamate, AMPA and quinolinic acid decrease the kainate-induced elevations of [Ca++]i in cells unresponsive to glutamate (80-90%). The treatment of cells with Con A (1) reverses the quiescent inhibition of the kainate response, (2) recovers the percentage of neurons responding to glutamate, AMPA and quinolinic acid without increasing calcium and decreasing NMDA responses, (3) and results in the pharmacological expression of a specific population of receptors. Finally, Con A-like effects are seen in co-cultures of neurons and glia. Contrary to the assumption that glutaemate is universally excitatory to neurons, these results indicate that the neuronal response to glutamate is not apparent in most neurons in cerebellar neuronal cultures and that glia, like Con A, can change the glutamate pharmacology.

630.2 INTERACTIONS OF GYKI 52466 AND CYCLOTHIAZIDE: PATCH CLAMP STUDIES. G. Ramps, W. Miller*, D. Swadulla, C. G. Parsons* and G. Collingridge*.

The effects of GYKI 52466 and cyclothiazide on isolated AMPA receptor-mediated EPSCs and AMPA-induced currents were investigated using current and patchclamp recordings from the CA1 region of hippocampal slices and cultured rat hippocampal neurons. Cyclothiazide at the concentrations sampled (10-30pM) reduces saturation uptake of Ca++ in rat hippocampal slices and cultured rat hippocampal neurons. The effects of cyclothiazide on calcium currents were investigated using a Ca++ imaging protocol to identify the effects on calcium currents activated by AMPA, quisqualate, and kainate. Cyclothiazide (10-30pM) reduces the amplitude of AMPA-EPSCs with little effect on AMPA-IPSCs. The effects of cyclothiazide on calcium currents were investigated using a Ca++ imaging protocol to identify the effects on calcium currents activated by AMPA, quisqualate, and kainate. In conclusion, cyclothiazide may be a antagonist and GYKI 52466 as an agonist at a common regulatory site on AMPA receptors but the two compounds modulate different effects on receptor activation kinetics. Furthermore, these data provide supportive evidence that the offset kinetics of AMPA receptor-mediated EPSCs are partially governed by desensitization.
2,3-BUTANEDIONE MONOXIME SUPPRESSES KAINATE-INDUCED CURRENTS OF MRUNE VENTROMEDIAL HYPOTHALAMIC NEURONES. J.H. Ye* and J.J. McAdoo, Dept. Pharmacology/Toxicology, New Jersey Medical School, University of Medicine and Dentistry of New Jersey, Newark, N.J. 07103-2714.

The effects of the "chemical phosphate", 2,3-butanedione monoxime (BDM) on kainate-induced current were studied in hypothalamic neurones acutely dissociated from young mice. Drug containing solutions were rapidly applied to activate the neuron and were subsequently subjected to the system perfused with patch or conventional whole cell recording techniques. When applied simultaneously with kainate, BDM produced a rapid, reversible and dose-dependent (Na+) block of kainate-induced current. This acute blocking effect of BDM was neither voltage- nor use-dependent. Including 500 μM ATP-gamma-S in the bath reduced the apparent effect of BDM. Furthermore, H-7 (200μM), a non specific protein kinase inhibitor, did not prevent the rapid recovery of the kainate response following washout of BDM. These findings suggest that the acute blocking action of BDM on the kainate response of hypothalamic neurones requires a "chemical phosphate" action. Support from the NIH (NS31040) and the nIHAAN (AA80825) made this work possible.

630.9 KAINATE-INDUCED Ca²⁺ SIGNALING IN ASTROCYTES REQUIRES Na⁺ AND Ca²⁺ FLUX VIA THE Na⁺/Ca²⁺ EXCHANGER. W.T. Kim, M.G. Reulat, and A.H. Comell-Bell*. Dept. of Cell Biology, Yale Univ. Sch. of Med., New Haven, CT 06510.

In primary cultures of rat hippocampal astrocytes, the binding of ionotropic glutamate receptors with kainate, kainate (KA, 100 μM) induces a rise and sustained elevation of [Ca⁺]ᵢ as well as regenerative intercellular Ca²⁺ waves. Using time-lapse confocal scanning laser microscopy with Fluo-1, we found that the removal of Na⁺ or Ca²⁺ from the bath abolished these [Ca⁺]ᵢ changes; therefore, external Na⁺ and Ca²⁺ are both necessary for the KA-induced response (N = 7 experiments). However, the [Ca⁺]ᵢ elevation in the ionotropic response is not via influx through voltage-dependent channels. Blocking Na⁺ channels with TTX (10 μM) did not affect the incidence, latency, or spatio-temporal characteristics of KA-induced [Ca⁺]ᵢ changes (N = 3 experiments). Similarly, blocking L-type Ca²⁺ channels with Nifedipine (10 μM) and Nimodipine (1 μM) did not affect the [Ca⁺]ᵢ elevation or waves (N = 3 experiments). However, inhibiting the Na⁺/Ca²⁺ exchanger with Benzamil (100 μM) completely abolished the [Ca⁺]ᵢ elevation and intercellular Ca²⁺ waves (N = 7 experiments). The inhibition of Ca²⁺ signaling by Benzamil appears to result from its effects on the Na⁺/Ca²⁺ exchanger in particular rather than to its non-specific effects on Na⁺ and Ca²⁺ channels and the Na⁺/H⁺-antipporter. The more selective Na⁺/H⁺-antipporter inhibitor 5-N (dimethyl)-amiloride (100 μM) did not affect KA-induced [Ca⁺]ᵢ changes (N = 3 experiments).

630.11 MK-801-INDUCED HYPERMETABOLISM IN THE POSTERIOR CINGULATE CORTEX IS ATTENUATED BY AN AMPA RECEPTOR ANTAGONIST. T.R. Petel, J. C. McCluskey*, Mellone Surgical Institute, University of Georgia, G611, Q.U. MK-801-induced increases in glucose utilization in the posterior cingulate cortex have been examined. A pretreatment with the AMPA receptor antagonist NBQX alters the pattern of glucose use seen with MK-801. Local cerebelar glucose use was measured in male 50 rat using stereotaxic-laser-microglucosography (70 mg/kg i.v.) was administered 2 min prior to the administration of MK-801. The combined effect of MK-801 on glucose use was assessed by examining 60 rats 24 h after treatment with NBQX. MK-801 induced a decrease in glucose use in the posterior cingulate cortex (30% decrease/10 min). Pre-treatment with NBQX attenuated the MK-801-induced decrease in glucose use in the posterior cingulate cortex (15% decrease/10 min). This suggests that MK-801-induced decreases in glucose use are mediated by AMPA receptors.

[³H]Kainate binding to rat cortical membranes can be separated into high- and low-affinity binding sites with Kᵣ values of 2 and 24 nm, respectively. The low-affinity binding site can be studied separately in the presence of Ca⁺⁺. Saturation of [³H]Kainate binding to rat brain sections in 10 mm CaCl₂ containing medium results in the presence of 30 nm CaCl₂. These results suggest that the use of CaCl₂ in the presence of both high- and low-affinity [³H]Kainate binding sites can be determined in all the investigated regions, whereas only high-affinity binding receptor population (Kᵣ = 400 μM) could be detected in 30 mm CaCl₂. Comparison of the regional distribution of the low-affinity [³H]Kainate binding site and the [³H]AMPA binding sites did not indicate that calcium insensitive [³H]Kainate binding represents binding to the AMPA receptor. The non-specifically bound [³H]Kainate in the presence of 30 mm CaCl₂ is inhibited by co-administration of NBQX, a competitive antagonist of the low-affinity binding site. The high-affinity [³H]Kainate binding site is insensitive to the presence of NBQX. The high-affinity binding site is insensitive to the presence of NBQX, but is sensitive to the presence of low-affinity binding site. The combination of these two sites may provide a useful tool for characterizing the potential adrenergic effect of the non-competitive NMDA receptor antagonists.
630.13

STRUCTURAL ANALOGUES OF THE NON-NMDA RECEPTOR ANTAGONIST
GYKI 52466 DEPRESS K+ CURRENTS IN HIPPOCAMPAL NEURONS.
W. L. D. L. Celli and L. K. Simmons. CNS Research, Lilly Research
Laboratories, Indianapolis, IN 46285.

The 2,3-benzodiazepine GYKI compounds have been characterized as
potent, selective antagonists of neuronal responses mediated by
non-NMDA receptors. In this study we used whole-cell voltage-clamp
protocols to investigate the K+ channel actions of structural analogues
of the parent compound GYKI 52466 in embryonic rat hippocampal
neurons.

Three of the four compounds evaluated blocked voltage-gated K+
currents with a rank order potency and stereoselectivity comparable
with their reported antagonist activities at non-NMDA receptors. In
contrast, the most potent K+ channel blocker of the compounds tested was
GYKI 53391, a 4′,3′-d-N-acetyl derivative of GYKI 52466
known to be inactive at non-NMDA receptors. Ymuranecate, CNQX and
Ro-15-1788 failed to elicit similar responses, therefore the GYKI
analogs do not appear to be modulating K+ channel function indirectly
via interactions with ionotropic EAAs or benzodiazepine receptors.

The results described here suggest that the K+ channel and non-
NMDA receptor sites of the 2,3-benzodiazepine GYKI compounds can be
isolated so that further structural analysis within this series may lead to the
identification of more potent K+ channel blockers.

630.14

DIFFERENTIAL RESPONSES TO PHOSPHONATE ANALOGS OF GLUTAMATE DISTINGUISH TWO SUBTYPES OF L-AP4-
Dept. of Biochemistry, Univ. of Minnesota, Minneapolis, MN 55455.

In previous studies of glutamate receptors, it has been shown
that L-2-amino-4-phosphonobutanoic acid (L-AP4) is a potent
inhibitor of excitatory glutamatergic projection pathways of the lateral
perforant pathway (LPP) as well as the CA3-CA1 synaptic pathway
(MF) of the guinea pig, and a partial inhibitor (10-40%) of the medial
perforant pathway (MPP) of the rat hippocampus. It is also a potent
inhibitor of the Schaffer collateral-CAL pyramidal pathway after
(but not before) sensitization by exposure to quisqualic acid (QUIS). It
was also demonstrated that the QUIS-sensitized site is pharmacologically
different from the L-AP4 receptor of the rat LPP and the guinea
pig MF. Specifically, the QUIS-sensitized site also shows high
sensitivity to L-AP4 and E-cyclopentyl-AP4. We now wish to report that
the partial sensitivity of the rat MPP also shows the pharmacological
profile of the QUIS-sensitized site, not of the classical L-AP4 receptors
which have low sensitivity for L-AP4 and E-cyclopentyl-AP4.

Exposure of a slice to QUIS sensitizes the MPP for 100% inhibition by
L-AP4, L-AP5, and E-cyclopentyl-AP4 with IC50 values indistinguishable
from the partial inhibition observed with these compounds before
QUIS. The high sensitivity of the rat LPP and guinea pig MF to L-AP4 proves
impossible to make it impossible to demonstrate QUIS-sensitization of
these pathways. However, using L-AP4 and E-
cyclopentyl-AP4, QUIS-sensitization can be readily demonstrated.

PEPTIDES: BIOSYNTHESIS, METABOLISM, AND BIOCHEMICAL
CHARACTERIZATION II

631.2

CONVERSION OF MET-ENKEPHALIN-ARG-PHE TO MET-ENKEPHALIN
IN HUMAN SERUM. M. K. Lacy, D. J. O'Connor, N. Dow, and
Neuroscience Research Institute and Department of Chemistry, SUNY/Old
Westbury, Old Westbury, NY 11582-0210.

Both met-enkephalin (MKE) and the opioid peptide, Met-
enkephalin-Arg-Phe (YGGFRMF), are reported to be capable of activating
the same population of immune cells in the human circulatory system.
Earlier studies also showed that MKEGFPRMF is capable of binding to
a product with the same HPLC retention time (RT) as 125I-YGGFRMF. The
aim of this study was to verify the conversion of YGGFRMF to YGGFRMF in
human serum. Time-course studies were performed in the presence
(Petri-dish, WI) showed YGGFRMF (50 uM) was processed rapidly to three
major products with HPLC RT’s corresponding to that of 125I-YGGFRMF
and YGGFRMF. The material with the RT of YGGFRMF rose to its highest
level in 1 min and remained at over 70% of this level after 5 min. The
identity of the peptide material in this peak was verified with three
procedures. 1) It was reactive against YGGFRMF antibody in RIA. 2) When
derivatized with PTH the peptide derivative migrated with the same RT as
the derivatized YGGFRMF standard. 3) Amo acid analysis of the peptide with
PTC technique showed the presence of Y, G, F, R and M in the ratio of 1:2:1:1
as with YGGFRMF. Serum protease inhibitors studies showed the conversion
of YGGFRMF to YGGFRMF is mediated by ACE and GGFPRMF and GGFPRMF
are products of the action of aminopeptidase on YGGFRMF and YGGFRMF.

Unlike YGGFRMF, the opioid octapeptide, Met-enkephalin-Arg-Gly-Leu,
is not converted to YGGFRMF in human serum. Our results showed YGGFRMF
is converted to YGGFRMF in human serum and it may be serving as a part
of a mechanism for sustaining YGGFRMF concentration in the circulatory
fluid. Supported by NDA DA-0010, MNI-NIDA-COR NN-17138, and NIH
GM-08180.

COMPARATIVE POTENCIES OF KID-FORBIDDEN CALCIUMION
GENE-RELATED PEPTIDE ANALOGUES IN MUTYPOTOXICOSIS.-
GFP, AND COQ3 IN VITRO BIODISY. S. L. Letyash, J. D. Bond, D.
Joakim, L. S. Escobedo, A. Foumier, and R. D. Diamond (1) Douglas
H3H 1R3. (2) INS-Sante, Place-Clair, P.O. Box, Canada. H3R 1G9.

Alienes substituted analogues and Fragments of NCPPR, NCPPR, NCPPR, (a potent
antagonist) and its linear analogue [cys(ACh)]2-CPPGR (a CGP, preferential
antagonist) were synthesized and the respective role of Glu acid residue between positions 14 to 23 for their abilities to induce an
toxic effect in the guinea pig al初心 and inhibition or contraction of the
electrically stimulated rat vas deferens, two prototypic CGP, and CGP,
receptor biosays, respectively (Demini et al., J. Pharmacol. Exp.
Ther. 1982: 206: 123-129. 1982). Results demonstrated that L-Leu, Leu and Arg are critical for the activation of CGP receptors in both tissues: [cys(ACh)]2-CPPGR being inactive. Instead, substitution of Glu residue in NCPPR, NCPPR, NCPPR, (a potent
antagonist) for Cys residue in [cys(ACh)]2-CPPGR and [cys(ACh)]2-CPPGR
might be a part of the CGP preparation while being somewhat less potent (69%) than the endogenous counterpart. The two analogues [cys(ACh)]2-CPPGR and [cys(ACh)]2-CPPGR, were slightly more potent than the unmodified analogue on CGP receptors whereas the CGP, receptor activity of the CGP, receptor activity of Glu substitutions for Cys (ACh)2-CPPGR, [cys(ACh)]2-CPPGR, and [cys(ACh)]2-CPPGR, displayed higher
potencies than L-Leu, Leu, and Arg in the CGP, antagonist site, while being ineffective in the rat vas deferens. Taken together, these results
demonstrate the importance of the amino acid residues in positions 17, 18, 19 and 20 for adequate CGP recognition and activation, and should be helpful toward the development of full selective analogues.

DIVERTICULAR DISEASE, INTESTINAL INFLAMMATION AND AUTOIMMUNE RESPONSES TO INTESTINAL MICROFLORA

631.4

PITUTARY ADENYLATE CYCLASE ACTIVATING PEPTIDE (PACAP) IS UP-REGULATED IN THE RAT DORSAL ROOT GANGLIA AFTER PERIPHERAL NERVE INJURIES. Y-Z. Zhang*, J. Hannibal, O. Zhao, N. Danielsen, K.
Møller, H. Møller, E. Eikblad, J. Fahrenkrug and E. Sandler.
Copenhagen, Denmark.

The effects of sciatic nerve injuries on the levels of PACAP and its
mRNA in the dorsal root ganglia (DRG) and the spinal cord were
investigated in male Sprague-Dawley rats. Animals were transected or
either transected or crushed in anesthetized rats. The sciatic nerve
on the right side was intact. The animals were killed 14 days
postoperatively. The spinal cord was dissected and processed for immunocyto-
chemistry, immunohistochemistry, in situ hybridization and northern
blot. Immunostaining of PACAP in the DRG was performed by using
of mainly small nerve cells in the DRG of the control side, confirming
our previous observations in normal DRG. PACAP was more intense in
the DRG of injured rats. The staining intensity of PACAP was seen in
many large cells. In the dorsal horn of the spinal cord, transection reduced PACAP intensity whereas crush injury revealed
no overt difference as compared to the control. The results from
northern blot and in situ hybridization supported the immunocyto-
chemical observations. The PACAP-mRNA in the DRG increased
significantly after nerve crush or transection injury.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
NEUROPEPTIDE-LIKE IMMUNOREACTIVITY IN BOVINE BRAIN CATHARTIN COATED VESICLES. W. L. Silva, L. Martinson, and N. Rosello. Department of Pharmacology, University of Central del Caribe, School of Medicine, Call Box 60-327, Bayamón, Puerto Rico 00621-6032. Cathatin coated vesicles (CCV) participate in the proteolytic maturation of neuropeptides (NP) in the trans Golgi network (TGN), and potentially in the internalization of neuropeptides and their receptors. In this study CCV from bovine brain gray matter were purified after chromatography over Sephacryl S-1000 columns. Fractons (13-25ml) were collected and analyzed for their adapter protein profile via SDS-PAGE, for their carbohydrate/peptide H (CPH) activity via radiodmyoassay, and for their NP (NP1, NP2, G-CCK, S-154) content by means of radioimmunoassays. The results revealed the presence of CPH and peptide-like immunoreactivités (NP-LP: NPY-LP, CCK-LP and SS-LI) associated with cathatin coated vesicles. The NP-LI and CPH were mainly associated with the ascending portions of the CCV peak suggesting that these molecules pertain to the expected larger diameter CCV subpopulation associated with the TGN, recycling and/or endocytic CCV. Analysis of the adapter protein profile of the material eluting from the Sephacyr S-1000 columns demonstrates a wide distribution of the Golgi-associated AP-1 (HA-1) molecules (AP47 and AP101) in relation to the CCV peak, spanning both the ascending and descending portions of the CCV peak. This adapter protein pattern is consistent with the inherent size microheterogeneity of TGN CCV, large diameter CCV of the regulated secretory pathway and smaller diameter CCV of the lysosomal pathway. Analysis of NP and NP processing enzymes in brain CCV will yield valuable information about the factors and conditions that influence the post-translational maturation and activation of NP. (This work was supported by NIH grants NS27259 and RR30105 awarded to WS).
SEROTONIN RECEPTORS: PHYSIOLOGY

632.1
Classically, 5-HT(2) receptors which modulate the firing activity of 5-HT neurons have also been suggested to control the somatodendritic release of 5-HT. We have recently shown that the somatodendritic 5-HT release is regulated independently of firing frequency via 5-HT(2) receptors (Neurosci. Abst. 127, 1999). The present study further assessed the regulation of somatodendritic release of 5-HT in a limited series of experiments, voltammetry studies using nafion-coated carbon fiber electrodes showed that the non-selective 5-HT agonist TPMP (0.5 mg/kg, iv) gradually reduced extracellular 5-hydroxyindoles in the dorsal raphe over a two-hour period. This effect was prevented by mianserin (2 mg/kg, iv), which blocks 5-HT(2) but not 5-HT(3) receptors, but not by the selective 5-HT(3) antagonist (1R)-WAY 103556, which only decreased the effect of 8-OH-DPAT (30 mg/kg, iv). The 5-HT(2) receptors are located on the somatodendritic 5-HT release in the raphe and may consequently play an important role in 5-HT release in widespread projection areas.

632.2
MODULATORY EFFECT OF 5-HYDROXYTRYPTAMINE (5-HT) ON CRAYFISH NEUROSECRETORY CELLS. F. Slenz, U. Garcia and H. Aran, Psychology*, Dept. Fisiología y Biotecnología, CINVESTAV, IPN México and *División de Estudios de Post-grado e Investigación, Facultad de Medicina, UNAM, México 11880. 5-hydroxytryptamine (5-HT) has been shown to influence the release of neurotransmitters from the crustacean eyestalk (see Fingerman and Neary, 1989). It is possible that one of the roles of 5-HT in the crustacean eyestalk is to modulate the release of hormones from the neurosecretory cells of the eyestalk. The present work, 5-HT was injected into the hemolymph of the crayfish eyestalk. The effects were measured using the most sensitive hormone of the shed gland, 11-deoxy corticosterone. 5-HT was administered to the eyestalk of the same population of both in situ, in isolated eyestalks and in cultured cells, taken from the same population. Two effects were found: a) a long-lasting (up to 30 min) dose dependent within a range of 10-4M, b) a short lasting, with a peak between 10-6M, close to the physiological range. This work was supported by CONACyT, grant number 3004-B1100.

632.3
In response to stressful stimuli, corticosterone (CT) production is increased by the hypothalamic-pituitary-adrenal (HPA) axis. One site of feedback regulation is the hippocampus, which contains high densities of both mineralocorticoid (MR) and glucocorticoid (GR) receptors. Basal plasma CT levels occupy the MR, high concentrations of CT activate the MR and the GR, both of which are implicated in the feedback control of the HPA. Activation of 5-HT(2) receptors decreases the slow afterhemorphalization (sAH) elicited by a train of action potentials or a calcium spike. To investigate if CT modifies the 5-HT(2) receptor mediated decrease of the sAH, intracellular recordings of the sAH following a calcium spike were obtained from the CA1 pyramidal cell layer of transversal hippocampal slices. Male Sprague-Dawley rats were adenalecetomized (ADX) 14 days prior to recording. One ADX group was chronically treated with a CT pellet (12.5 mg) to mimic basal plasma CT levels. Another ADX group was implanted with 300 mg CT to induce chronic stress. Data for continuous response curves were generated by addition of 5-HT in half log unit decrements (0.1-100 μM). Preliminary results suggest that the EC50 of the 5-HT induced decrease in sAH amplitude is higher in stressed animals than in ADX animals. When 1 nM CT was added to the superfusion medium of slices from ADX animals, the decrease in AHP amplitude was significantly more pronounced, indicating a short term modulatory role of the MR. The modulatory effects of CT on the 5-HT mediated response may underlie feedback control of the HPA and may influence pyramidal cell excitability. Supported by NS28512 and MH00880.

632.4
RECEPTOR RESERVE FOR 5-HT, RECEPTORS IN RAT BRAIN AS ASSESSED BY NEUROENDOCRINE RESPONSES TO 8-OH-DPAT STIMULATION. W. Pérez, O. Calvoa, C. Mir, L. de Bar and G. Batalona. Neuroscience Graduate Program and Dept. of Pharmacology, Loyola University of Chicago, Stritch School of Medicine, Maywood, IL 60153.
The present study investigates receptor reserve in female rats with respect to 5-HT1A mediated neuroendocrine responses. While previous studies have reported a large reserve for pre- and post-synaptic 5-HT1A receptors in male rats, 5-HT1A receptor reserve in female rats has yet to be determined. The stimulation of postsynaptic, hypothalamic 5-HT1A receptors with the full agonist 8-OH-DPAT, elicits an increase in several plasma hormones including ACTH and corticosterone. Therefore, neuroendocrine responses to 5-HT1A stimulation can be used as a functional end-point to assess receptor reserve. Female, adult rats (350-400 gms) were administered a single s.c. injection of vehicle (1:1 v/v EOB/H2O) or 1 mg/kg EEDQ (N-ethyl-N-octyl-2-(diethylamino) ethanol, 8-OH-DPAT). 24 hours post-treatment, rats were challenged with either vehicle (0.9% saline) or increasing doses (0.05, 0.2 and 0.5 mg/kg i.c.v.) of 8-OH-DPAT and sacrificed 30 mins later. There was a significant (p < 0.001) reduction (33%) in the Bmax of 8-OH-DPAT labeled hypothalamic 5-HT1A receptors in EEDQ-treated rats, with no alteration in KB. In non-EEDQ treated rats, 8-OH-DPAT elicited a significant (p < 0.001) dose-dependent elevations of plasma ACTH (4.0 fold at highest dose) and corticosterone (3.7 fold at highest dose). Following receptor inactivation by EEDQ, there was gg significant difference in the maximal ACTH (668.3 ± 148 vs 1025 ± 188 pmol/l) or corticosterone (434.3 ± 6.3 vs 50.3 ± 8.8 μg/dl) elevation elicited by 8-OH-DPAT. These data provide evidence for a large receptor reserve (at least 53%) for hypothalamic 5-HT1A receptors mediating the elevation of plasma ACTH and corticosterone levels in female rats. (Supported by DA07741 and Loyola University Potts Foundation).
632.5 MODULATION OF RAT NECORTICAL HIGH-VOLTAGE SPINDLE ACTIVITY BY SEROTONIN RECEPTOR SUBTYPE-SPECIFIC DRUGS. P. HARR, J. Sirvio, J. Kaski, E. Koskinen, M. Bökkilä, L. Yvesch, P. Rokkanen Sr. and P. Rokkanen Jr. Dept. of Neurology, University Hospital, SF-70211 Kuopio, Finland. Phone: 358-71-162048.

The present experiments investigated the role of serotonergic (5-hydroxytryptamine, 5-HT) receptors in the modulation of rat neocortical high-voltage spindle activity. We administered different 5-HT(3)/5-HT(7) receptor subtype specific drugs singly or in combination either systemically or via cannula that were implanted bilaterally to the medial thalamus, and measured neocortical high-voltage spindle activity of adult rats by IBM software. A mixed 5-HT(3)/5-HT(7) receptor antagonist, methysergide (p.), significantly increased neocortical high-voltage spindle activity, whereas another mixed 5-HT(3)/5-HT(7) receptor antagonist, methysergide (p.), had no effect. A 5-HT(3A)/5-HT(7) receptor agonist, (1,3-dimethyl-4-oxo-4-aminopropyl-2-aminopropane (DOI) (d.), significantly decreased neocortical high-voltage spindle activity, and systemic methysergide and specific 5-HT(3A)/5-HT(7) receptor antagonists ketanserin (k.) and rianismer (k.) blocked this effect. Further, intrathalamic injections of DOI dose-dependently decreased neocortical high-voltage spindle activity and systemic ketanserin completely blocked this effect. The results suggest that 1) the serotonergic system may via 5-HT(3A)/5-HT(7) receptors modulate rat thalamic neuronal activity as assessed by neocortical high-voltage spindle activity, 2) 5-HT(3A)/5-HT(7) receptor agonists may decrease neocortical high-voltage spindle activity, and 3) 5-HT(3A)/5-HT(7) receptor antagonists may block this effect. 5-HT(3A) may have a modulatory role to these receptors, in addition to a potentiating effect to the intrinsic properties of thalamic motor neurons. Therefore, 5-HT may function to facilitate the afferent input to thalamic motor neurons by potentiation of both NMDA and non-NMDA receptor-mediated synaptic processes.

632.6 EFFECTS OF 5-HT ON NMDA AND NON-NMDA RECEPTOR-MEDIATED RESPONSES IN TRIGEMINAL MOTOR NEURONS. C.R. Trueblood*, S.H. Chandler, M.S. Levine. Department of Physiological Science and Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

Previously, we demonstrated that 5-HT potentiated both the NMDA and non-NMDA mediated EPSP evoked by Mesencephalic V'Timulation in trigeminal motor neurons using an in vitro preparation of the brainstem from guinea pigs. To further examine the mechanism by which 5-HT facilitates excitatory amino acid responses in trigeminal motor neurons, we tested the effects of 5-20 μM bath application of 5-HT to NMDA (200μM) and AMPA (5mM) iontophoretic responses. In current clamp mode, 5-HT significantly potentiated both the NMDA and AMPA response in a dose-dependent manner. Selective agonists and antagonists were used to show that this potentiation resulted from activation of 5-HT(1c) receptors. Furthermore, using voltage clamp technique, 5-HT enhanced both the NMDA and AMPA current, suggesting that 5-HT has a direct modulatory role to these receptors, in addition to a potentiating effect to the intrinsic properties of trigeminal motor neurons. Therefore, 5-HT may function to facilitate the afferent input to trigeminal motor neurons by potentiation of both NMDA and non-NMDA receptor-mediated synaptic processes. Supported by NIH grants DE06193 and DE07212.

We have previously shown that local bilateral injection of hallucigenins d-LSD and (-)-DOB, but not non-hallucigenic congeners lianride and BL 3912A, into the medial prefrontal cortex (mPFC) elicited the head twiching response (HTR). This HTR was prevented by the selective 5-HT(2A) receptor antagonist, (-)-DOB, but 5-HT(3) receptors in the mPFC could play an important role in mediating the action of hallucigenins. Iontophoresis of low currents of (-)-DOB, and to a lesser extent d-LSD, markedly facilitated glutamate-induced activation of the first layer of mPFC cells. The aim of the present study was to determine whether pretreatment with mianserin or subacute treatment of d-LSD, which is known to down-regulate 5-HT uptake, also significantly reduce the drug-induced development desensitization of mPFC cells to d-LSD and (-)-DOB. Groups of rats were treated with d-LSD (2 mg/kg/day, i.p. for 5 days) and (-)-DOB (10 mg/kg, i.p. for 3 days) after the last injection of mianserin (10 mg/kg, i.p. 48 - 72 hr prior to experiment), and saline (1 ml/kg, i.p. either for 1 or 5 days), respectively. Compared to cells in the saline group, mPFC cells in rats pretreated with either d-LSD or mianserin became less sensitive to both drug treatments. Furthermore, in these drug pretreated rats, both d-LSD and (-)-DOB became less effective in stimulating the phosphoinositide hydrolysis in the mPFC. In conclusion, our results suggest that hallucinogen-induced tolerance and cross-tolerance may be accounted for, at least partly, by the functional desensitization of mPFC 5-HT(A) receptors at the cellular level. (Supported by USPHS grants MH-41440 and DA-07193).

632.9 FUNCTIONAL EVIDENCE FOR THE DIFFERENTIAL RESPONSIVENESS OF PRE- AND POSTSYNAPTIC 5-HT(A) RECEPTORS IN THE RAT BRAIN. P. Bier*, B. Seletti, C. Bouchard, F. Artigas and C. de Montigny, Neurobiological Psychiatry Unit, McGill Univ, Montreal, Canada H3A 1A1.

Several groups have documented the capacity of (p)indolol to antagonize the hypothermic effect of 5-HT(3A) agonists, including that of B-80-DPAT, whereas the increase in prolactin produced by the latter 5-HT(3A) agonist is blocked by similar doses of (p)indolol (Eur. J. Pharmacol. 146: 253, 1988). In a first series of experiments, the effectiveness of pindolol to block pencyramine-induced prolactin was examined by assessing the effect of dosal pencyramine on 5-HT(4) receptors in rats treated for 2 days with the 5-HT-uptake blocker paroxetine (10 mg/kg/day, s.c.) alone or together with (p)indolol (10 mg/kg/day, s.c.), both drugs being administered by an osmotic minipump. The firing rate of 5-HT neurons under chloral hydrate anesthesia was decreased by about 30% in both groups. However, the firing rate of 5-HT neurons was significantly increased by 5-HT in rats treated with pencyramine mg/kg/day of (p)indolol (which is the arrhythmic with 5-HT(4) affinity) for 2 days. In keeping with the latter observations, the suppressant effect of the 5-HT(4) receptor antagonist, 5-HT(4) receptor agonist on the firing of the pencyramine attenuated. In a second series, the prolactin increase produced by 8-OH-DPAT (100 μg/kg, s.c.) was also prevented by (p)indolol (15 mg/kg, i.p.) given 30 min prior to 8-OH-DPAT. The inhibition of prolactin levels by (p)indolol was increased if systemic applications of (p)indolol and 8-OH-DPAT on the firing rate of hippocampal CA1 pyramidal neurons was observed in rats treated with (p)indolol (15 μg/kg/day) for 5 days prior to 8-OH-DPAT. This increase activity was blocked by the 5-HT(A) receptor antagonist and the corresponding 5-HT(4) receptor. The block by the 5-HT(A) receptor antagonist modulating 5-HT neuronal firing activity and the post-synaptic 5-HT(A) receptor controlling prolactin release, but not the post-synaptic 5-HT(A) receptor coupled to K+ channels in the hippocampus.

EFFECTS OF BUSPIRONE ON 5-HT TURNOVER IN DIABETIC AND NONDIABETIC RATS L. L. Bellush* and A.M. Wright. Dept. of Psychology, Ohio University, Athens, OH 45701.
Diabetic (D) rats have reduced 5-HT turnover throughout the brain. They also show attenuated hypothermia to the 5-HT1A agonist 8-OH-DPAT, as well as enhanced response to stress and greater anxiety, both of which could reflect altered 5-HT functioning. However, anxiolytic effects of the 5-HT1A partial agonist buspirone (BUSP) did not differ in D and nondiabetic (N) rats, and anxiolysis was greater after chronic BUSP. Here we measured 5-HT turnover in brainstem, midbrain, hippocampus and hypothalamus after single BUSP injections or after two weeks of daily treatment. BUSP had no effect on 5-HT turnover 20 min after acute treatment BUSP (0.1 mg/kg) in either D or N. BUSP did not affect light/dark emergence either, although D were more anxious than N, as well as having lower 5-HT turnover. BUSP (0.1, 0.6 and 1.2 mg/kg) reduced 5-HT turnover in all 4 regions of N rats 30 min after drug treatment. Here, the lower doses tended to reduce anxiety, while the high dose was anxiolytic. Assessment of 5-HT turnover after chronic BUSP 0.1 and 0.6 mg/kg in D and N is now being completed.

632.12
SEROTONINERGIC FIBERS ARE NOT DEVELOPED IN THE TRANSPLANTED HIPPOCAMPAL TISSUE OF THE S-100B RETARDED MUTANT MOUSE. S. Ueda*, P.M. Whitaker-Azima, E.C. Azimia and M. Kawata. Dept. of Anatomy, Kyoto Pref. Univ. Med. Kyoto 602, Japan; Dep. of Psychiatry, SUNY at Stony Brook, NY 11794, and Dep. of Biology, NYU, NY10003, USA. Our previous study (Ueda et al. 1994 Brain Res. 633,275-283) has demonstrated that the hippocampus of the homozygous of polyacyclury mutant mouse (Polyacyclury Nagoya, Pdn/Pdn) was markedly reduced in both S-100B positive astrocytes and serotoninergic fibers as compared to the heterozygote (Pdn+/-) and wild type (+/+). Since the Pdn/Pdn mice die within 2 days after birth, it is impossible to examine postnatal changes in development. To demonstrate the development changes of Pdn/Pdn hippocampal tissue, hippocampal pieces of neonatal Pdn/Pdn and +/- mice were transplanted into the right and left sides hippocampus of the same adult ICR mice, respectively, and immunocytochemistry was performed. Two weeks after transplantation, the S-100B positive astrocytes and a small number of serotoninergic fibers in Pdn/Pdn hippocampal tissue contained numerous GFAP positive astrocytes, while S-100B positive astrocytes and serotoninergic fibers were not observed. Two months after transplantation, GFAP and S-100B were expressed in the Pdn/Pdn hippocampal tissue similar to the +/- tissue. Serotoninergic fibers were distributed in the +/- tissue, whereas few serotoninergic fibers were observed in the Pdn/Pdn transplant tissue. On the contrary no difference was observed in the tyrosine hydroxylase positive fibers between Pdn/Pdn and +/- grafts.

632.13
Antidepressants drugs of different types increase extracellular 5-HT in the raphe nuclei of the midbrain. As a result, serotonin adrenoceptors are activated and terminal release decreases. Thus, the local infusion of 50 μM clonipramine (CT, a 5-HT uptake inhibitor) into the dorsal raphe nucleus (DRN) reduced in vivo release of 5-HT in striatum of the same animals by 47%. Pretreatment with (-) pindolol (15 mg/kg) or (-) sertralol (10 mg/kg) totally abolished the intra-DRN effects of CT, indicating that these reductions were mediated by 5-HT1A adrenoceptors. Lower doses of (-) pindolol (5 and 10 mg/kg, i.p.) induced a partial antagonism. In contrast, (-) WAY 100135 at a dose (10 mg/kg, i.p.) that antagonized the effects of 8-OH-DPAT (0.1 mg/kg, s.c.) on striatal release, was unable to prevent the CIT-induced reduction. These results indicate that the effects of 5-HT1A antagonists on serotoninetic 5-HT1A autoreceptors are antagonized by (-) pindolol and (-) sertralol, but not by (-) WAY 100135. The previous (3-3 days before) intra-DRN injection of pentsimate toxin also prevented the effects of CIT on striatal 5-HT release. This further supports the role of 5-HT1A autoreceptors in the attenuation of terminal 5-HT release elicited by CIT uptake inhibitors. In agreement, the combined treatment with (-) pindolol and 5-HT uptake inhibitors (paroxetine, citalopram, fluoxetine, fluvoxamine) increased terminal 5-HT release to a greater extent than the 5-HT uptake inhibitors alone (e.g., (-) pindolol + 1 μg CIT elevated striatal 5-HT release by +60% whereas the increase induced by 1 mg/kg CIT was +10%). Thus, blockade of serotoninetic 5-HT1A receptors may be a new way to potentiate the effects of low doses of 5-HT uptake inhibitors, in agreement with recent clinical data (Artigas et al., Arch. Gen. Psychiatry 51:248-251, 1994) (Supported by FIS grant 92/268).

632.14
5-HT2 RECEPTOR STIMULATION FACILITATES THE IN VIVO RELEASE OF ACETYLCHOLINE IN RAT FRONTAL CORTEX. H. Ladinsky*, S. Arnoldi, G. Rusli, G.B. Schilli and S. Congoli. Department of Biochemistry and Molecular Pharmacology, Boehringer Ingelheim Italia, Milan 20139 and Laboratory of Neuropharmacology, Istituto di Ricerche Farmacologiche "Mario Negri", Milan 20157 Italy.
The effect of the serotoninergic 5-HT2A receptor agonists BIMU 1 and BIMU 8 on the in vivo release of ACh in brain hemispheric regions of freely moving rats was investigated using the microdialysis technique. Both agonists, applied intracerebroventricularly, facilitated ACh release selectively in the frontal cortex at doses of 30-100 nmol. The agonists were ineffective in striatum, despite the high density of 5-HT2A receptors in this region. BIMU 1, 60 nmol i.c.v., produced a significant decrease in ACh release in the dorsal hippocampus. The facilitatory effect of BIMU 1 (40 nmol, i.c.v.) in frontal cortex was prevented by the highly selective and potent 5-HT2A receptor antagonists GR 125457 (10 and 20 nmol, i.c.v.) and GR 13380 (15 nmol, i.c.v.), which by themselves did not alter basal ACh release. The results provide evidence that serotonin facilities ACh release in frontal cortex through stimulation of 5-HT2A receptors that are not tonically activated. Assuming that ACh plays a role in cognitive processes, this facilitation supports the theory that 5-HT2A sites are important in the control of learning and memory. 5-HT2A receptor activation might thus offer a novel means of boosting central cholinergic function to overcome the cholinergic deficit in memory disorders. Financed in part by CNR, Rome, Convenzione Psicofarmacologia (S.C.).

632.15
Activation of central 5-HT1A receptors by the selective agonist 8-OH-DPAT decreases blood pressure (BP) and heart rate (HR). This study was to determine if the steroid hormone estradiol (E2) modulates the cardiovascular responses elicited by 8-OH-DPAT when administered into the lateral cerebral ventricle (l.c.v.). Experiments were performed in conscious, freely-moving rats implanted chronically with a guide cannula for i.c.v drug infusions and an arterial catheter to monitor BP and HR. 8-OH-DPAT (100 nmol, i.c.v) decreased BP and increased HR in male and ovariectomized female (OVX) rats. There was a tendency for a greater bradycardia in the OVX rats, but this did not attain statistical significance. The experiment was repeated to include OVX rats implanted subcutaneously with time-release pellets containing E2 (0.1 mg/21 day pellet). The BP response to 8-OH-DPAT was the same in all 3 groups: male, OVX and OVX+E2. By contrast, 8-OH-DPAT produced a greater bradycardia in the OVX+E2 group when compared to either male or OVX rats; OVX again tended to be greater than male. In the final experiment, graded doses of 8-OH-DPAT (3 - 100 nmol, i.c.v.) were administered to OVX and OVX+E2 rats. The hypotensive effect produced by 8-OH-DPAT was not altered by hormone treatment, but the bradycardia was greater across doses in the E2-treated rats. In summary, the cardiovascular responses elicited by 8-OH-DPAT were greater in both males and OVX rats. However, E2 enhanced the bradycardia, but not the hypotension, elicited by 8-OH-DPAT, suggesting that estrogen modulates some, but not all, functional response produced by 5-HT1A receptor activation. (Supported by NIH Grant NS 29765)
633.2
Presently, a new radioiodinated agonist, [1]-[35]OH-DPAT, for 5-HTA receptors, was reported (Kung et al., Neuroscience Abs, 1993). In developing antagonists for 5-HTA receptors, we have selected several intrinsic agonists of the phenylpiperazine (Zhang et al., J. Med. Chem., in press). Among them, MPPI (4-[2-methoxy-phenyl]-1-[2-n-propyl]-p-iodobenzamido-jethyl-piperazine) displayed high efficacy for 5-HTA receptors (5-HTA) in rat hypothalamic homogenates. Low to moderate binding affinity of MPPI to 5-HTA receptors was observed with Ki values of 15, 38, 170, and 270 nM, respectively. Saturation binding studies in rat hippocampus homogenates revealed that [125I]MPPI bound to a single population of affinity sites with a Kd of 0.18 nM (Kd = 0.4 nM, Bmax = 120 fmol/mg) in rat hypothalamus. Thus, in [125I]MPPI was 30-40% higher than that with [125I]OH-DPAT. Guaneryl nucleotides did not affect the specific binding of [125I]MPPI, but significantly inhibited the specific binding of [125I]OH-DPAT. In addition, Me2+ ion showed an inhibitory effect on [125I]mppi binding, in contrast to the stimulatory effect observed for the agonist ligand, 8-OH-DPAT.

633.4
The lack of selectivity of 5-HTA receptor antagonists has hampered study of the functional role of these receptors. A candidate for such an antagonist, p-MPPI, is a structural analog of WAY-100635 with high affinity for 5-HTA receptors (Kd = 10 nM). p-MPPI was tested for its ability to antagonize the effects of the 5-HTA receptor agonist 8-OH-DPAT on two responses mediated by postsynaptic 5-HTA receptors, the 5-HT syndrome and hypothermia. Male Sprague-Dawley rats were pretreated with p-MPPI (3,30 mg/kg, s.c.) 15 min prior to 8-OH-DPAT injection (1,2 mg/kg in the hypothermia and 5-HT syndrome studies, respectively). p-MPPI dose-dependently prevented p-MPPI-induced hypothermia and 8-OH-DPAT-induced hypothermia (production of four out of the six components behaviors) induced by 8-OH-DPAT. However, p-MPPI did not prevent two of these behaviors, flat body posture and hindlimb abduction. p-MPPI did not produce any of the 5-HT syndrome effects when given alone. In rats pretreated with reserpine (1 mg/kg, 18 hours), p-MPPI (30 mg/kg) also blocked the 5-HT syndrome without producing any symptoms when given alone. Thus, p-MPPI antagonized the hypothermic effect produced by 8-OH-DPAT, whereas p-MPPI did not antagonize the hypothermic effect produced by reserpine. These results demonstrate that p-MPPI antagonizes 5-HTA receptors with a partial agonist activity in combination with 8-OH-DPAT, on extracellular levels of 5-HT using in vivo microdialysis. This research was supported by USPHS grants MH 14654, MH 36202 and MH 48125.
633.7

Molecular cloning has demonstrated that the 5-HT1D subtype is comprised of two closely related subtypes termed 5-HT1Dα and 5-HT1Dβ. These receptors display a high transmembrane homology (~75%) which contribute to their similar pharmacological profiles. The classical 5-HT2 agonists, ketanserin and ritanserin, displayed moderate affinity (K<sub>i</sub> 50-75 nM) and marked selectivity (K<sub>i</sub> 5-HT2/5-HT2) for the cloned human 5-HT2D subtype relative to the 5-HT1D receptors. In contrast, the nonselective 5-HT2 receptor antagonist, methiothepin, exhibited similar affinities (K<sub>i</sub> 10-20 nM) for both 5-HT1D subtypes. These three compounds were evaluated for their ability to antagonize sumatriptan-induced inhibition of forskolin-stimulated cAMP accumulation in cell lines expressing either 5-HT<sub>1D</sub> or 5-HT<sub>1D</sub> gene. All three compounds behaved as competitive antagonists devoid of intrinsic activity in the functional assays. The apparent K<sub>i</sub> values measured in the functional assays closely matched their K<sub>i</sub> values obtained in binding assays.

633.9

Binding sites displaying high (5-HT<sub>1D</sub>) and low (5-HT<sub>1D</sub>) affinity for 5-carboxyamidotryptamine have been described using [3H]-5-HT and serotonin-selective 5-HT<sub>1D</sub> and 5-HT<sub>2</sub> receptors. Utilizing [3H]-CP-101,606 (0.5 nM) as the radioligand eliminated binding to the 5-HT<sub>1D</sub> sites. However, potent 5-HT<sub>1D</sub> agonist compounds such as sumatriptan and BMS-181101 (a novel antidepressant candidate) continue to produce a regionally distinct biphasic displacement (K<sub>i</sub>20 nM, 2 nM and K<sub>i</sub>10 nM, 10 μM, sumatriptan and BMS-181101, respectively), suggesting a heterogeneous population of 5-HT<sub>1D</sub> receptors radiolabeled with [3H]-CP-101,606 in certain mammalian brain regions. In bovine substantia nigra, both sumatriptan and BMS-181101 produced monophasic displacement of [3H]-CP-101,606 binding. Therefore, this tissue was utilized initially to characterize the agonist profile of PHBMS-181101 to 5-HT<sub>1D</sub> binding sites. In bovine substantia nigra membrane homogenates, [3H]-PHBMS-181101 binding was rapid, reversible and saturable, displaying high affinity (K<sub>i</sub> 1 nM) and low non-specific binding. Pharmacologically, affinity values revealed the following rank order of potency: 5-CT<sub>D</sub>5-HT<sub>L</sub>S=5-DHE- sumatriptan methiothepin oxypertin triptan [CP-101,606]. CP-93,129, mesulergine, buspirone and sironere all displayed negligible affinity. Gpp(NH)p induced a concentration-dependent decrease in high affinity [3H]-PHBMS-181101 binding, suggesting an agonist interaction with the binding site.

These data indicate that functional inhibition of 5-HT<sub>1D</sub> receptors may be involved in the antidepressant effect of atypical neuroleptics.

633.11

GR127935: IN VITRO AND IN VIVO CHARACTERIZATION OF A PUTATIVE 5-HT1D AGONIST ANTAGONIST: F. D. Tingley, P. W. Smith, H. R. Howard, and D. W. Schultz, Central Research Division, Pfizer Inc., Groton, CT 86340.

Functional studies of 5-HT<sub>1D</sub> receptors have been hampered by the limited receptor selectivity of available antagonists (e.g. methiothepin). Recently, it was reported that the bipharyl carboxamide GR127935 (5-HT<sub>1D</sub>) is a high affinity for the cloned human 5-HT<sub>1D</sub> and 5-HT<sub>1D</sub> receptors, displays >100-fold selectivity vs other receptor subtypes, and behaves as an agonist based on its reversal of contraluminal rotation in guinea pigs caused by intraintestinal administration of a 5-HT<sub>1D</sub> agonist (Br J Pharmacol. 110:97-199, 1993).

We have further characterized the functional activity of GR127935 at 5-HT<sub>1D</sub> receptor sites in guinea pig brain tissue using an extracellular calcium activity assay in substantia nigra and 2) examining changes in 5-HT turnover in guinea pig hypothalami following intraperitoneal administration. Adenylate cyclase studies revealed that GR127935 is a full agonist at 5-HT<sub>1A</sub> receptors and a partial agonist at 5-HT<sub>1D</sub> receptors (IC<sub>50</sub> 10<sup>-7</sup> M). The effect on 5-HT turnover in guinea pig hypothalami following intraperitoneal administration was characterized by a significant increase in 5-HT<sub>1A</sub> receptors, 2 nM at 5-HT<sub>1D</sub> receptors are consistent with the report receptor selectivity profile of GR127935.

In vivo, s.c. treatment with GR127935 reversed the decrease in 5-HT turnover (5-HIAA/5-HT ratio) caused by the 5-HT<sub>1D</sub> agonist agonist CP-135,807 (see Schmidt et al., Soc. Neurosci. Abstr., 1994). When administered alone, GR127935 dose-dependently increased 5-HT turnover. The 5-HT<sub>1D</sub> agonist agonist is a potent 5-HT<sub>1D</sub> antagonist of 5-HT<sub>1A</sub> terminal autoceptor.

633.12

The use of sumatriptan to study central 5-HT<sub>1D</sub> receptors is limited by its poor brain penetration. Here we describe the biochemical and pharmacological properties of CP-135,807 (3-[pyrrolidin-2-ylmethy1]indole), a novel 5-HT<sub>1D</sub> agonist with improved potency and CNS penetration.

1) CP-135,807 (3-[pyrrolidin-2-ylmethy1]indole) binds with high affinity (K<sub>i</sub> 1.3 nM) to brain 5-HT<sub>1D</sub> receptors (Kee et al., Soc. Neurosci. Abstr., 1994). Like sumatriptan, CP-135,807 behaves as an agonist by inhibiting the cyclic AMP activity of 5-HT<sub>1D</sub> (guinea pig substantia nigra, E<sub>50</sub> 0.1 nM) and 5-HT<sub>1A</sub> receptors (guinea pig hippocampus, E<sub>50</sub> 41 nM). Sumatriptan has a similar receptor selectivity profile, h<sub>5-HT<sub>1A</sub></sub> with much less potent (E<sub>50</sub> 0.7 nM) activity.

Using an ex vivo binding, it was determined that CP-135,807 readily crosses the blood-brain barrier, while sumatriptan was undetectable in brain after a subcutaneous dose of 100 μM. This is consistent with a compound that activates 5-HT<sub>1D</sub> terminal autoceptors, s.c. CP-135,807 dose-dependently inhibited 5-HT turnover in guinea pig brain, decreasing 5-HIAA/5-HT ratios by up to 50%. Consistent with this mechanism of action, in vivo studies demonstrated that perfusions with 0.2-10 μM CP-135,807 through a microdialysis probe in the hypothalamus caused a dose-dependent decrease in extracellular 5-HT. The centrally-mediated effect of CP-135,807 on 5-HT turnover is consistent with its ability to cause hyperthermia in guinea pigs (Seymour et al., Soc. Neurosci. Abstr., 1994).
633.13
CP-135,807, A NOVEL 5-HT1D AGONIST INDUCES HYPOThERMIA IN THE GUINEA PIG. D.A. Seymour*, D.W. Schulz, F.D. Tingley and J.E. Macor. Departments of Neuroscience and Medicinal Chemistry, Central Research Division, Pfizer Inc, Groton, CT 06340.

Central serotonergic systems have long been implicated in thermoregulation. The 5-pyrrolidin-2-R-ylmethyl)indole, CP-135,807, has recently been characterized as a novel 5-HT1D agonist in vitro with a high level of selectivity vs. 5-HT1A receptors as measured by inhibition of adenylyl cyclase activity (Schmidt et al., Soc. Neurosci. Abstracts, 1994). To investigate the functional implications of CP-135,807's effect in vivo we determined that CP-135,807 lowers body temperature in cpd, a known to have central 5-HT1D receptors. Rectal temperatures were measured in awake rats (60-120 and 240 min after either s.c. or p.o. administration. It was found that CP-135,807 profoundly and dose-dependently lowers body temperature after both routes of administration, with greater potency obtained after the s.c. route. This effect appears to be centrally mediated since sumatriptan and CP-123,803, an analog with a similar binding profile that does not reach the CNS, failed to produce this response. In addition, the putative 5-HT1D antagonist, GR-127935, antagonizes this effect when given 60 min prior to agonist administration. These data suggest that 5-HT1D receptors play a thermoregulatory role in guinea pig, and that this response may be useful in the characterization of drugs that act at 5-HT1D receptors.

633.14
NOVEL TRYPATINE DERIVATIVES WITH A 5-(3-NITRO-2- PYRIDYLAMINO) MOIETY BIND PREFERENTIALLY TO 5-HT1D RECEPTORS. B.K. Koe*; L.A. Lebel, C.B. Fox, and J.E. Macor. Central Research Division, Pfizer Inc, Groton, CT 06340.

The recent introduction of serotoninergic drugs (5-HT reuptake inhibitors as antidepressants; 5-HT1A agonists as anxiolitics; a 5-HT1D antagonist, CP-123,803, as an antimalarial agent) as well as the chemical description of new and distinct 5-HT receptors have spurred interest in finding selective agonists for these receptors. One approach is based on modifying the serotonin molecule by introducing novel substituents at the indole C5 and C9 positions. Examples from our laboratories include a selective 5-HT1D agonist, CP-63,129, a potent and 5-HT1A, 5-HT1B, and 5-HT1D receptors and the DA transporter, CP-110,330 (Koe et al., 1992; Nowakowski et al., 1993). We now report that the 5-(3-nitro-2-pyridylamino) moiety (R) confers 5-HT1D binding selectivity to a novel pyridylamine (3-M).
634.5 EFFECTS OF PSYCHOSOCIAL STRESS ON 5HT1A RECEPTORS IN THE BRAIN. G. Fliege* and E. Fuchs. German Primate Center, 37077 Göttingen.

Normal serotonergic neurotransmission in the brain requires normal numbers of receptors. Perturbing conditions such as sustained psychosocial stress (PSS) may disturb the functional balance of the transmitter systems. In the present study, we investigated the effects of PSS on 5HT1A receptors in the brains of male Wistar rats (* to a group of animals that underwent 24 hours of PSS followed by 24 hours of social isolation. All rats were killed 6 hours after the end of the PSS. We determined the number of 5HT1A receptors in various brain regions using high affinity 5HT1A receptor-specific antagonist binding. Because 5HT1A receptors are involved in the regulation of social behavior, one might expect that PSS would influence the 5HT1A receptor expression. However, our findings revealed no significant differences in the number of 5HT1A receptors in brain regions when compared to sham-operated controls. Our data do not support the hypothesis that PSS influences 5HT1A receptor expression. Further investigations of other subtypes of 5HT receptors and additional behavioral parameters are needed in order to clarify the role of serotonergic neurotransmission in stress-related phenomena.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

634.6 EFFECTS OF 5-HT AND 8-OH-DPAT ON SPONTANEOUS OPEN-FIELD MOTOR ACTIVITY AFTER LOCAL APPLICATION INTO THE SUBSTANTIA NIGRA PARS RETICULATA (SNr) AND VENTRAL TEGMENTAL AREA (VTA) IN THE RAT. V. Hillesgård* and S. Ahlenius. Department of Behavioral Pharmacology, Astra Arcus AB, S-151 85 Södertälje, Sweden.

The 5-HT1A receptor agonist 8-OH-DPAT (0.5 μg), or 5-HT (0.4 μg), was infused into the SNr or into the VTA in awake, gently hand-restrained male Wistar rats (* to a group of animals that underwent 24 hours of PSS followed by 24 hours of social isolation. All rats were killed 6 hours after the end of the PSS. We determined the number of 5HT1A receptors in various brain regions using high affinity 5HT1A receptor-specific antagonist binding. Because 5HT1A receptors are involved in the regulation of social behavior, one might expect that PSS would influence the 5HT1A receptor expression. However, our findings revealed no significant differences in the number of 5HT1A receptors in brain regions when compared to sham-operated controls. Our data do not support the hypothesis that PSS influences 5HT1A receptor expression. Further investigations of other subtypes of 5HT receptors and additional behavioral parameters are needed in order to clarify the role of serotonergic neurotransmission in stress-related phenomena.

The present study evaluated the contribution of serotonin (5-HT2A/2C) receptors to the in vivo actions of clozapine and several, putative atypical antipsychotics. In a drug discrimination paradigm employing animals trained to discriminate the 5-HT2A/2C agonist, DOI (0.63 mg/kg, i.p., from saline, the discriminative stimulus (DS) effects of DOI were dose-dependently and completely blocked by the 5-HT2A antagonist, ketanserin (10 mg/kg, i.p.), the selective 5-HT2A receptor antagonist, M101,907 (0.001, 0.003, 0.01 mg/kg, i.p.). Like M101, 907, both clozapine and two putative, atypical antipsychotics possessing marked affinity at 5-HT2A receptors, risperidone and sertindole, blocked the DS effects of DOI (0.05, 0.03 and 0.32, respectively). Both compounds abolished the head-twitches (HTW) evoked by DOI (2.5 mg/kg, s.c.). DS: 0.28, 1.21, 0.02, 0.06, 0.005, 0.04, 0.025 and 1.0, respectively. The dopamine D2 antagonist, haloperidol, failed to block the DS effects of DOI (dose-range tested: 0.01 - 0.16), but abolished DOI-induced HTWs (DS: 0.07). In conclusion, these data demonstrate the role of 5-HT2A receptors in mediating both the effects of the HTWs and the DS assessed by DOI, though the latter response is also modulated by D2 receptors indicating the superior selectivity of the drug discrimination paradigm. The marked activity of clozapine, risperidone, sertindole and MDL 101,907 in these models support the concept that 5-HT2A receptor antagonism contributes to the in vivo actions of atypical antipsychotics.

Antisense (A) phosphorothioate oligonucleotide specific to 5-HT2A receptor mRNA were administered in media to cultured C6 glioma cells and ICV (intracerebroventricular) to rats. In C6 cells, significant decreases in 5-HT2A receptor density and gene expression were evident after 3d treatment with A but not control (C) sequences (20-200 nM). In male Long-Evans rats, treatment with A (50 µg ICV twice daily x 4: tests were 24 h after final dose), but not C, resulted in a significant decrease in 5-HT2A receptor mediated headshaking induced by the 5-HT2A agonist DOI ((2R,1S,2S)-1-(2,5-dimethoxy-4-iodophenyl)-2-amino-propane hydrochloride); conversely, a significant increase in DOI-induced, 5-HT2A-mediated, skin scratching behavior was observed. A significant anxiolytic-like effect was observed in A but not in C-treated rats tested in the elevated plus-maze. Autoradiographic and saturation analysis of 5-HT2A and 5-HT3b binding from the rats in the behavioral studies indicated significant, 50-72% decreases in 5-HT2A binding, and no change in 5-HT3b binding. These results demonstrate that 5-HT2A receptor expression and function can be selectively attenuated using A sequences, and suggest that the 5-HT2A receptor inhibits agonist-induced 5-HT2A receptor-mediated responses. (Supported by the Eunice Kennedy Shriver National Institute of Child Health and Human Development.)

634.13 TREATMENT WITH 5-HT2A/2C RECEPTOR ANTAGONIST DISRUPTS INITIAL DEVELOPMENT OF SPATIAL NAVIGATION STRATEGIES IN RATS. M. Riekkinen* J. Sirviö and P. Riekkinen, Dept. of Neurology, Univ. of Kuopio, P.O.B. 1627, FIN-70211, Kuopio, Finland. Fax: 358-71-162048.

The present study investigates the effects of 5-HT2A/2C receptor stimulation on spatial and cue navigation, and visual discrimination. Daily s.c. injection of DOI (5,5-dimethoxy-4-iodo-phenyl)-2-amino-propane (DOI) at 3 mg/kg, but not at 1 mg/kg, impaired initial development of water maze (WM) spatial navigation strategies (hidden platform), but had no effect on the development of non-spatial navigation strategies (visible platform). Pre-training injections of ketanserin (0.1, 0.4 and 2 mg/kg, i.p.), a 5-HT2/2C receptor antagonist, had no effect on WM performance, but blocked the impairing effect of DOI 3 mg/kg on WM spatial navigation. Spatial reference and working memory were not disrupted by pre-training DOI (1 and 3 mg/kg) treatment if the rats had learned the reference memory rule before drug treatment. 5-HT2A/2C receptor stimulation did not impair consolidation as post-training DOI at 1 and 3 mg/kg had no effect on the development of spatial navigation strategies. Visual discrimination learning was not impaired by pre-training DOI 1 and 3 mg/kg. The present results suggest that 5-HT2A/2C receptor stimulation impairs initial development of spatial navigation strategies in rats.

635.1 IN VIVO STUDIES OF 5-HT2 RECEPTORS IN MONKEYS USING F-18-ALATANERIN. C.A. Mathis*, Y. Cho, N.R. Simpson, M.A. Minton, PET Faculty, University of Pittsburgh Medical Center, Pittsburgh, PA 15213.

Alatinerin is a closely related structural analogue of ketanserin and has a high in vitro affinity and selectivity for 5-HT2 receptors. We examined the in vivo properties of this radiogand in monkeys as a candidate for imaging brain 5-HT2 receptors using positron emission tomography (PET). Three rhesus monkeys received 10 mCi of high specific activity (1100-2500 Ci/mmol) F-18-alatinerin. In addition, one monkey received a second 10 mCi injection of low specific activity (13 Ci/mmol) F-18-alatinerin. Twenty scans of increasing duration were acquired over a 12.0 min time period. Arterial blood samples were obtained and the plasma radioactivity was assayed for the presence of metabolized metabolites. In two monkeys, ketanserin and alatinerin (1 mg/kg) were injected 2 h after the injection of F-18-alatinerin to displace specifically bound radioactivity. At times up to 37 min, selective ketanserin radioactivity was observed in cortical areas while cerebellum, caudate, and thalamus had low radioactivity levels. The ratio of frontal cortex to cerebellum was 2.5±0.3 in the high specific activity studies and decreased to 1.5 at 2 hours after the tracer injection in the low specific activity study. A two compartment model data yielded kinetic rate constants K1, k2, and distribution volume (DV). Estimates of DV, which is proportional to brain volume, were 3.4±0.1 for frontal cortex, 2.1±0.5 for caudate, and 1.7±0.5 for the cerebellum. The DV's varied by region. The alatinerin data yields consistent with the known distribution of 5-HT2 receptors. Both ketanserin and alatinerin exhibited a distribution of 5-HT2 receptor distribution in cortical areas with displacement half-times of 23 and 37 min, respectively. Unmetabolized alatinerin comprised 50±1% of the total plasma activity at 2 h post injection. These results indicate that F-18-alatinerin is a useful agent to image and quantitative 5-HT2 receptors in vivo using PET.

635.2 LOCALIZATION OF 5-HT2 RECEPTOR mRNA IN NEURONS OF THE HUMAN BRAINSTEM. M.C. Austin*, J.A. Winkel and J.J. Marks, Labs of Neuropharmacology, Dept. of Psychiatry, Univ. of Pittsburgh. Pittsburgh, PA 15213.

A previous report autoradiography study, using [3H]LSD at a ligand, reported the anatomical localization of serotonin receptors in the human brainstem (Palacios et al., 1983). This study found that the highest levels of binding occurred predominantly in the raphe nuclei, thus revealing the localization of serotonin receptors of the 5-HT-like subtype. Given the recent cloning of the human 5-HT2 receptor (Chen et al., 1992), we examined the distribution of neurons expressing 5-HT2 receptor mRNA in the human brainstem using in situ hybridization histochemistry (ISHH). Postmortem human brainstem tissue was fixed at 4°C in 4% paraformaldehyde. After the level of the hypoglossal nucleus, the dorsal motor nucleus of vagus and the gigantoacellular reticular nucleus all contained abundant levels of 5-HT2 mRNA. In the periaqueductal region, neurons containing cells that were also 5-HT2 mRNA-positive were also found in the oral pontine nucleus. A large population of neurons expressing 5-HT2 receptor mRNA was found in the diffuse core of the pedunculopontine tegmental nucleus, and several 5-HT2 mRNA-positive neurons were located in the caudal portion of the substantia nigra. These findings provide important information regarding the localization of 5-HT2 receptors and the relevant nuclei in the human brainstem that can serve as a potential serotonin immunization. SEROtonin Receptors: Localization

635.3

The anatomic distribution of 5-HT receptors in rat brain and spinal cord has been defined by radioiodinated binding studies and quantitative autoradiography using the specific, high affinity radioligand, [3H]-8-OH-DPAT. We are currently using a synthetic antipeptide antibody to characterize the localization of the 5-HT3 receptor protein in the spinal cord. This polyclonal antibody was raised in rabbit against amino acid sequence 170-186, a transmembrane region of the 5-HT3 receptor that is structurally related to the ligand binding domain of other G-protein coupled receptors. In the spinal cords of rats, cats and macaques we observed the highest density of 5-HT3-R in the superficial layers of the dorsal horn on primary afferent sensory neurons and in nerve fibers running along the central canal. This pattern of 5-HT3 receptor-[3H]-8-OH-DPAT binding corresponds precisely to the autoradiographic localization of [3H]-8-OH-DPAT described in the rat spinal cord. The most notable pattern of 5-HT3 receptor-[3H]-8-OH-DPAT binding we observed was the axon hillock of motoneurons throughout the ventral horn. This novel site of 5-HT3 receptor localization is not detected with [3H]-8-OH-DPAT, suggesting possible heterogeneity of 5-HT3 receptor signal transduction mechanisms. A dense population of 5-HT3 receptors on the motoneuron axon hillock indicates an important role in the regulation of motor output. Species differences in 5-HT3 receptor-[3H]-8-OH-DPAT binding were noted, for example, in concentration of fiber labeling in the dorsal horn, the pattern of 5-HT3-R around the central canal, and the intense somatodendritic labeling of spinal serotoninergic (raphe) cells in the primate cervical spinal cord. DISTRIBUTION OF 5-HT1A RECEPTORS IN THE PRIMATE BRAINSTEM J.P. Gannon*, N.M. Kheif, and E.C. Armita. Dept of Otolaryngology, Mt Sinai Sch Med, NY NY10022 Dept Biology, New York University NY NY10030. We used an 5-HT1A receptor antipeptide (aa170-186) antibody to investigate the distribution of this serotonin receptor subtype in the brainstem of the Old World monkeys Macaca mulatta and Macaca nemestrina. Three adult monkeys were fixed by transcardiac perfusion, then 40μm brainstem sections incubated in primary antibody 1:2000 for 72 hours at 0°C followed by visualization of secondary antibody.

Three main types of cell labeling patterns were apparent throughout the brainstem: 1) on neurons of both the serotonergic raphe nuclei and the noradrenergic locus coeruleus, dense labeling was distributed diffusely throughout the soma and dendritic tree. Similarly labeled large neurons were scattered throughout the reticular formation; 2) Most neurons in the brainstem motor nuclei showed a discrete label localized specifically to the axon hillock. This axon hillock pattern was also seen throughout the brainstem on some neurons of both sensory and reticular groups. Sub-populations of vestibular nuclear neurons were also labelled; 3) A diffuse general label was present on astrocyes throughout the brainstem. The somatodendritic label we observed may represent receptor populations acting as autoreceptors. The dense axon hillock label may represent populations of 5-HT1A receptors involved in temporally dynamic regulation of motor output at this critical cell location. During primate evolution, basal mammalian motor systems changed and to survive the more sophisticated communicative repertoire present in primates. These evolutionary advances in brain function involved incorporation of the 5-HT1A receptor as a key player. (Work supported in part by NIA Grant PO1 AG10208)

635.5

The present study examined the comparative distribution of 5-HT1A receptor mRNA and 5-HT1A binding in human hippocampus using in situ hybridization with a specific cRNA probe and receptor autoradiography with the selective ligand [3H]-8-OH-DPAT. In agreement with previous binding studies, the highest levels of 5-HT1A binding in the human hippocampus were observed in the CA1 field and in the subiculum. High levels of binding were also observed in the granular and molecular layers of the dentate gyrus. Intermediate levels were present within the pyramidal and molecular layers of CA2 and CA3 subfields. In contrast to 5-HT1A binding, the highest concentration of 5-HT1A mRNA expression was observed in the granular layer of the dentate gyrus. Similarly, the positive signal was also observed in the molecular layer of CA1, CA2 and CA3 subfields, although the mRNA levels were lower than in the dentate gyrus. No 5HT1A mRNA was detected in the stratum oriens, radiatum or moleculare. The subiculum and the external granule layer of the parahippocampal gyrus also expressed 5HT1A mRNA at concentrations similar to the CA subfields. In conclusion, there was a concordance between the areas expressing 5-HT1A mRNA with the areas showing specific 5-HT1A binding in human hippocampus. However, there are differences in distribution and concentration between mRNA and receptor sites within specific anatomical regions. These differences are probably due to the cytoarchitectural distribution of the neuronal cell bodies, where the 5-HT1A mRNA is transcribed, versus the apical and basal dendrites, where the 5HT1A receptors are localized. Supported in part by a grant from the American Suicide Foundation.

635.7

The evidence to date for the presence of serotonin receptors on astrocytes in vitro has mainly been dependent on ligand binding and second messenger assays. We have demonstrated the expression of serotonin receptor subtype mRNAs using in situ hybridisation. CDNA clones of 5-HT1A, 5-HT1B and 5-HT1D, subcloned into suitable vectors were used to generate specific 35S-labelled riboprobes. These were hybridised to neonatal rat cortical astrocyte cultures. Results show that the astrocytes in vitro express mRNAs for the above three receptor subtypes. Data from binding experiments and second messenger assays complement the in situ hybridisation results, showing that the astrocytes express the receptor protein and that it is functional.

We have also addressed the question of serotonin receptor subtype expression on astrocytes in adult rat brain sections using a combination of in situ hybridisation of receptor subtype specific cRNAs and immunohistochemical localisation of the astrocyte specific marker GFAP. We found little evidence of co-localisation of receptor specific cRNAs and immunohistochemical localisation of the astrocyte specific marker GFAP. We found little evidence of co-localisation of receptor specific cRNAs and immunohistochemical localisation of the astrocyte specific marker GFAP. We found little evidence of co-localisation of receptor specific cRNAs and immunohistochemical localisation of the astrocyte specific marker GFAP. We found little evidence of co-localisation of receptor specific cRNAs and immunohistochemical localisation.
636.5  
LOCALIZATION OF 5-HT6 RECEPTOR mRNA IN THE RAT BRAIN BY IN SITU HYBRIDIZATION HISTOCHEMISTRY. B. P. Ward1, M. W. Hamblin2, B. J. Hoffman3, J. E. Latchev4, D. R. Sibley4, and D. M. Donsi5. 1Dept. of Pharmacology, Dept. of Psychiatry and Behavioral Sciences, Univ. of Washington, Seattle, WA 98195; 2GRECC, Seattle VAMC, Seattle, WA 98101; 3Molecular Neuropharmacology Section, Experimental Therapeutics Branch, NIDA, NIH, Bethesda, MD 20892; 4Laboratory of Cell Biology, NIH, N.IH Bethesda, MD 20892.

The serotonin receptor subtype 5-HT6, which raises intracellular cAMP via stimulatory G proteins, has been recently characterized. To determine the CNS distribution of 5-HT6 mRNA, in situ hybridization was performed in coronal sections of rat brain. An [35S] labeled riboprobe, complementary to the 5-HT6 mRNA coding region was used. In situ hybridization was performed on brain sections using the recombinant full length cDNA sequence as a probe. The 5-HT6 receptor was found to be expressed in the neocortex, hippocampus, amygdala, and the hypothalamus. The distribution of 5-HT6 mRNA was characterized in different brain regions and was found to be highest in the hippocampus, amygdala, and hypothalamus. This distribution pattern suggests that the 5-HT6 receptor plays a role in the regulation of neuronal activity in these regions.

636.1  
PHARMACOLOGICAL CHARACTERIZATION OF THE EFFECT OF EXTRACELLULAR ADENOSINE 5'-TRIPHOSPHATE ON THE CONCENTRATION OF FREE CYTOPLASMIC CALCIUM IN RAT PHEOCHROMOCYTOMA PC12 CELLS. E. Adamiec1 and G. Kosti2. 1Dept. of Anesthesia, Massachusetts General Hospital, Boston, MA 02114.

In PC12 cells, ATP causes substantial elevation of 
Ca2++](free buffer] of approximately 10% of the total calcium in intracellular stores to the total [Ca2++](free buffer] rise. The majority of ATP-induced [Ca2++] is caused by Ca2+ influx. The [Ca2++] increase is positively correlated with the concentration of free, uncomplexed ATP (ATP↑) suggesting that ATP↑ is the agonist at the ATP receptor in this cell type. Administration of UTP also increased [Ca2++] by increasing extracellular free Ca2+ to 32 mM, ERCp (30 μM). This elevation also consisted of a combination of Ca2+ influx and Ca2+ release from internal stores. The ATP↑ response to ATP and UTP share a common receptor (P2Y). The Ca2+ values for the ATP- and UTP-induced ATP↑ were not significantly different. ATP↑ caused a much larger maximal [Ca2++] increase, indicating that ATP acts as a full agonist at P2Y receptor in PC12 cells.

636.3  

We reported that ATP stimulates P2 purinoceptors, activates Ca-permeable cation channels, stimulates Ca influx and dopamine (DA) release in PC12 cells (a review in NIPS, April, 1992). We have also reported that endogenous transmitters, dopamine (Eur. J. Pharmacol., 215, 321-324, 1992; Pflügers Arch., 422, 458-464, 1993), 5-iodo-ADP, and adenosine (Br.J.Pharmacol., in press, 1994; Eur.J.pharmacol., in press, 1994) regulate the ATP-evoked responses. We report here that zinc also regulates ATP-evoked currents and DA release from PC12 cells. Zn2+ (3 to 300 μM) potentiates ATP(30 μM)-evoked inward current in a concentration dependent manner without changing the maximal response. The mechanism of the facilitation by zinc is different from that by dopamine and high dose of adenosine. Zinc also potentiated ATP(30 μM)-evoked dopamine release in the same manner as that of the currents. The ATP-evoked release was reduced by zinc and shifted the concentration curve of ATP-evoked release to the left without affecting the maximal response. It is suggested that the facilitation is dependent on the calcium influx through ATP-evoked cation channels since it was dependent on extracellular calcium, was blocked by an ATP-receptor blocker suramin, and was parallel to the increase of intracellular free calcium concentration.

636.4  
UPREGULATION OF A1 ADENOSINE RECEPTORS IN CEREBELLAR GRANULE CELLS IN RESPONSE TO CHRONIC COFFEE EXPOSURE. R. D. Hettiger-Smith, M. Leid and T. F. Murray. College of Pharmacy, Oregon State University, Corvallis, OR 97331.

Adenosine is a ubiquitous neurotransmitter in the central nervous system at A1, A2a, and A2b adenosine receptors. Caffeine and related methylxanthines act as non-specific antagonists at A1 and A2a adenosine receptors. Chronic treatment of these G-protein coupled receptors has led to tolerance to the stimulatory effects of caffeine which may, in part, be due to A1 adenosine receptor upregulation. The effect of chronic caffeine exposure in cerebellar granule cell cultures was examined.

Cerebellum was obtained from eight day old Sprague Dawley rat pups and primary cultures of the granule cell neurons were established. Binding in membranes derived from granule cell neurons was examined using the A1 adenosine receptor antagonist [3H]8-cyclopentyl-1,3-dipropylxanthine (DPCCPX). Non-specific binding was determined in the presence of 100 μM 8-cylopentyladenosine (CPA). Receptor expression was analyzed at days 7,9,11 and 13 post culture. Maximum [3H]DPCCPX binding was present at day 13. In order to determine the caffeine concentration needed to obtain maximal upregulation, cells were incubated with final concentrations of 10-1000 μM caffeine and [3H]DPCCPX binding was analyzed. Maximal upregulation of [3H]DPCCPX binding was obtained with 100 μM caffeine. Time course studies revealed that incubation with 100 μM caffeine produced the greatest upregulation of [3H]DPCCPX binding. Cerebellar granule cells in primary culture appear to afford a useful model system for the study of A1 adenosine receptor regulation.
ACETATE DOES NOT INDUCE ADENOSINE-MEDIATED INHIBITION IN THE DENTATE GYRUS OR HIPPOCAMPAL CA1 REGION. J.M. Brundge and T.V. Dumuid.* Dept. of Pharmacology, University of Colorado Health Sciences Center, and Veterans Admin. Medical Res. Service, Denver, CO.

Acetate, the primary breakdown product of ethanol metabolism and can accumulate in the brain following ethanol consumption. It has been suggested that acetate can be metabolized to adenosine within cells in the CNS and release of this adenosine may cause neuronal inhibition. In order to determine whether extracellular acetate on neurons, we applied exogenous sodium acetate (0.5 to 2 mM) to hippocampal slices from adult rat male rats. The acetate caused not significant effect on the resting membrane potential, input resistance, or EPSP amplitude in CA1 pyramidal neurons and had no effect on extracellular field EPSPS in either the CA1 region or the dentate gyrus. To determine the effects of intracellular acetate, we compared the effects of the adenine receptor agonist, thopinephyl on cells impaled with intracellular microelectrodes containing 2.5 M K* acetate, 1M KC1, or 2M K* -methylsulfate. With all three intracellular filling solutions, thopinephyl produced small but statistically significant increase in input resistance, consistent with the presence of low concentrations of extracellular adenosine. However, the response to thopinephyl with acetate-filled electrodes was not different from the other filling solutions. These results suggest that the presence of acetate, either in the extracellular solution or within the intracellular electrode, does not induce a significant adenosine response in the hippocampus. Supported by NS 29173 and the Veterans Administration Medical Research Service.

Increased chloride conductance of mesencephalic cholinergic neurons plays a key role in the production of electrophysiological (EEG) arousal. We recently reported that mesencephalic cholinergic neurons are under the tonic inhibitory control of endogenous adenosine (Balsalobre et al., 1994). Here we report that this state of a drug. We further explored this finding by using the adenosine receptor antagonist, dipyridamole, or exogenous adenosine (10-4 M). We also reported that this adenosine mediated inhibition was reduced in the presence of the adenosine receptor antagonist, dipyridamole, or exogenous adenosine (10-4 M). We also reported that this adenosine mediated inhibition was reduced in vivo.
636.11
TRH ANALOGUES AND ADENOSINE AGONISTS ELICIT VOMITING IN THE CAT. James L. Looce - Dept. Pharmacol., Wright State Univ., Dayton, OH 45435
During the testing of novel receptor actions which theoretically could decrease or select drug effects, some receptor-selective drugs unexpectedly elicit vomiting. Describing novel emetics has value in (1) offering new tools for research into emetic mechanisms, (2) having potential for new insights into the emetic pathways and (3) identifying possible clinical side effects missed by studies with anesthetized subjects or in species which do not vomit. All drugs were administered SC in a volume of 0.1 ml/kg. Tests lasted 30 min or 15 min after the last vomit, whichever occurred later. The disubstituted TRH analogue MK 771 elicited vomiting with an ED50 of 3.1 nM and the monosubstituted CG 3703 did so with an ED50 of 1.9 μg/kg. The adenosine A2 agonist CYS 1986 elicited vomiting with a shallow dose-response curve. The vomiting elicited by 100 μg/kg was blocked by 300 μg/kg of the A2 antagonist CYP, reduced by 100 μg/kg of the nonselective antagonist PD 115199 and not affected by up to 300 μg/kg of the A2 antagonist CYS 1994.

636.12
HISTAMINE ACTION ON ACUITY DESEURTIED NEURONS OF THE RAT NEOSTRIATUM. M. Morikawa and N. Akahile, Dept. of Bi-Pharmacology, Kyushu Univ. Fac. Med., Fukuoka 812, Japan
The neostriatum is innervated by histamine fibers. Histamine receptors have been detected in this region by the radioautographic study and also involved in pathophysiological conditions such as catalepsy and parkinsonism. However, the functional role of histaminergic receptors in the neostriatum remains unknown. We investigated, therefore, the effects of histamine in neurons acutely dissociated from the neostriatum of 2-week-old Wistar rats, using perforated patch clamp technique. In current-clamp mode 10-5 M histamine slowly depolarized the membrane with increased firing activities, and in voltage-clamp mode it evoked a net inward current accompanied by decreased conductance, at a Vm of -44 mV. This response may be restricted in interneurons. We clarified pharmacologically that this histamine-induced response was mediated by both the H1 and H2 receptors. H1 mediated response with a threshold concentration of 10-6 M and reached the maximal response with 10-5 M. Both H1 and H2 receptor-mediated currents resulted from a decreased K+ conductance, which may increase neuronal excitability. The co-existence of H1 and H2 receptors with a wide concentration range may result in extensive modulation of the functional activities in the neostriatum.

GENOMIC CLONING AND CHARACTERISATION OF A RECOMBINANT HUMAN HISTAMINE H1-RECEPTOR. W.J.M.L. Leyten, M.D. De Baerle, P. Van Gorpel, K. De Leen, W. Gommers and J.E. Leyten, Department of Biochemical Research, Janssen Research Foundation, Beerse, B2404 Belgium.
A human histamine H1-receptor (H1-R) gene lacking introns was isolated by screening a human genomic library with a bovine H1-R probe (BREC 197: 1601-1608 (1993)). The coding region of the human H1-R was designed and subcloned into the pSVL expression vector (Pharmacia) yielding pSVL-H1-R. Membranes from COS-cells transiently transfected with pSVL-H1-R showed aspan-specific binding of [3H]Pyrilamine with a KD of 1.2 nM and a Bmax of 3400 fmol/mg protein (compared to a KD of 0.30 nM and Bmax of 480 fmol/mg protein for guinea-pig cecum membranes).

636.14
MOLECULAR MODELLING OF THE H2 HISTAMINE RECEPTOR. C. Obin-Ayari, M. Ouelts and G. Lunt. Biochemistry Department, University of Bath, Bath, BA2 7AY, UK.
A 3-D model of the canine H2 receptor (1) was constructed and analysed. This model was defined using primary sequence comparisons and three-dimensional homology building, using bacteriorhodopsin as a template. Experimental data from a variety of sources were used to localise the ligand binding site and to identify residues likely to be responsible for receptor affinity, selectivity and efficacy.

636.15
The histamine H3 receptor subtypes involved in the H3 modulation of electrical field stimulated (EFS) neurone responses in pulmonary artery sympathetic and ileum parasymathetic preparations were characterized to determine whether H3A or H3B receptors are present in these tissues. Using techniques of EFS-evoked (F/0) overflow and tension in PHF-noradrenaline-badged pulmonary artery were sensitive to tetradotoxin (300 nM) and insensitive to histamine. In ileum, the evoked tension maximally antagonized by prazosin (100 nM), H3a- methylhistamine inhibition of evoked response and (F/0) overflow were both dose-dependently antagonized by hiperpamin (50-100 μM). In pulmonary artery, the rank order potency of the H3 agonists thiopiperazinom (P2a = 0.1, P2b = 0.4), non-methylated histamine (P2b = 0.7 ± 0.10), and (P2b = 0.7 ± 0.13) was R-a-methylhistamine (P2d = 7.3 ± 1.0) and R-thiopiperazine (P2c = 7.3 ± 1.0). This suggests a predominant H3B-like receptor population on postganglionic sympathetic nerves. In the ileum H3 receptor assay, the rank order potency of the H3 agonists thiopiperazine, butyramine and thiopiperazinom (P2a = 0.1, P2b = 0.4, P2c = 0.7), respectively, was R-a- methy1histamine (P2d = 7.3 ± 1.0), also suggests a predominantly H3B-like receptor population.

636.16
CLOzapine-SENSITIVE BINDING TO HISTAMINE H3 RECEPTOR IN RAT FRONTAL CORTEX. A. Rodrigues, J. Goldfarb and G. Pell*, Dept Pharmacology, Mount Sinai Medical Center, New York, NY 10029
There is evidence suggesting that histaminergic activity is elevated in brains of schizophrenic patients (Soc. Neurosci. Abstr. 18: 446; Lancet 335: 1351; Biol Psychiat. 30: 349). For example, in patients refractory to conventional neuroleptic drugs, CSP levels of histamine's primary metabolite were higher than in controls and correlated with severity of symptoms. In cortex of patients with chronic schizophrenia, H3 receptors were downregulated, consistent with overstimulation by histamine. H3 autoreceptors regulate synthesis and release of histamine; H3 heteroreceptors influence release of dopamine and 5-HT. Neuroleptics bind to H1 and H2 receptors. We examined their interactions with H3 receptors. The latter, in rat cortical membranes prepared in NaK-phosphate buffer (50 mM, pH 7.4), were labeled with H3a-125I methylhistamine. Saturation binding to specific binding defined with either 1 μM thiopiperazine or H3-neo-methylhistamine yielded a Kd of 0.5 nM and a Bmax of 150-170 fmol/mg protein. In competition studies using 0.8 nM H3-125I methylhistamine (specific binding ~90% of total specific binding) with a Ki (assuming competitive inhibition) in the 3-10 nM range, coincident with the range of plasma levels seen clinically. Clozapine's interactions with H3 receptors may have therapeutic relevance. (NS-28012)
636.17 ISTHAMINERGIC NEURONS MEDIATE RESTRAINT STRESS-INDUCED CHANGES IN ACTIVITY OF SELECTED CENTRAL CATECHOLAMINERGIC AND 5-HYDROXYTRYPTAMINERGIC (SST) NEURAL SYSTEMS was examined in male rats. Dopaminergic (DA), noradrenergic (NE) and SST neuronal activity was estimated by measuring concentrations of neurotransmitters and melatonin in brain regions containing these neurotransmitter neurons. Placement of rats within restraining tubes increased dopamine metabolism in the nucleus accumbens, decreased dopamine metabolism in the intermedio-lateral ovoid of the pituitary, and was without effect on the median eminence and median raphe. This data indicate that restraint stress increases mesolimbic, decreases periventricular-hypophysial, and is without effect on nigrostriatal and tuberoinfundibular DA neuronal activity. Neither depletion of neuronal histamine by α-fluoromethylhistidine (αFMH), blockade of H1 receptors by mepyramine, nor blockade of H3 receptors by zolantidine prevented stress-induced increases in dopamine metabolism in the nucleus accumbens suggesting that HA neurons are not major contributors to stress-induced mesolimbic DA neuronal activity. In contrast, treatment with both αFMH and mepyramine, but not zolantidine, prevented stress-induced decreases in dopamine metabolism in the intermedio-lateral ovoid indicating that HA neurons mediate stress-induced decreases in periventricular-hypophysial DA neuronal activity through an action at H1 receptors. Stress increased norepinephrine and 5-hydroxytryptamine metabolism in the hypothalamus, and 5-hydroxytryptamine metabolism in the nucleus accumbens. Both αFMH and mepyramine antagonized, whereas zolantidine did not prevent these increases suggesting that HA neurons contribute to stress-induced increases in SST and NE neuronal activity through an action at H1 receptors. (supported by NIH grant NS31911 and a Pharmaceutical Manufacturers Association Foundation fellowship)

636.19 MELATONIN MODULATES CHOLINERGIC SYNAPTIC TRANSMISSION IN ENTERIC NEURONS B. Prieto-Gomez*, R. Espina-Lana* and C. Barriga-Lopez. 1Department of Physiology, Faculty of Medicine, UNAM, Mexico, 2Department of Biological Sciences, McMaster University, Ontario, Canada.

Melatonin, a hormone produced and released by the pineal gland, is also synthesized by cells of the gastrointestinal wall, where it might be a local regulator of gastrointestinal function. In this study, we investigated the action of melatonin as a modulator of synaptic transmission in the submucosal plexus of the guinea-pig ileum. Intracellular recordings were made in submucosal neurons to measure the amplitude of nicotinic excitatory postsynaptic potentials (EPSPs). Melatonin (10-6 M) reversibly decreased the amplitude of nicotinic EPSPs in a concentration dependent manner (EC50=332 μM). Maximal effects were observed within 4 min after the arrival of the melatonin-containing solution and they persisted for as long as melatonin was present (up to 15 min). Melatonin actions were not modified by the presence of idazoxan and atropine (1μM) indicating that they are not mediated by endogenous release of ACh or noradrenaline or by direct action of α-adrenergic or muscarinic receptors by melatonin. The superfusion of melatonin (1μM) also blocked the nicotinic depolarizations induced by locally applied ACh. These observations indicate that melatonin might be a local modulator of synaptic transmission in the enteric nervous system and that at least part of its effects are postsynaptic. This work was supported by the MRC, OMIH and CANACYT.

636.20 ADENOSINE INCREASES THE SIGNAL TO NOISE RATIO IN FASCIA DENTATA BY A PRE-SYNAPTIC MECHANISM T.M. Swanson*, Department of Neurobiology and Anatomy, Research Institute, Cleveland Clinic Foundation, Cleveland, OH 44195.

Adenosine analogs increase or decrease perforant path stimulation evoked dentate granule cell action potential firing depending on concentration. We have previously shown that 10 nanomolar of the stable A1 adenosine analog cyclopentyladenosine (CPA) increases granule cell action potential firing for a given population PSN amplitude. To explore the mechanism of this novel finding, we performed whole-cell current clamp recordings of rat dentate granule cells were performed in 400 μM thick hippocampal slices. Resting membrane potential (-65±4 mV), input resistance (156±32 MΩ), and action potential threshold (±37±3 mV) were similar. Perforant path stimulation were compared in the presence and absence of 1.0 nanomolar CPA in seven experiments. No significant change in any of the measured variables could be detected during CPA application. In other experiments, we measured glutamate release from perforant path stimulated granule cells using a sensitive HPLC assay with FITC- derivitization (resolution limit 10 picomoles). Average basal glutamate release was 170±50 pmol/ml, rising to 450±50 pmol/ml during one Hz perforant path stimulation. No change in glutamate release was detected during CPA application. We conclude that low concentrations of adenosine analogs increase perforant path / granule cell synaptic efficiency without affecting intrinsic post-synaptic membrane properties or altering glutamate release - the data support a pre-synaptic mechanism for this novel action in accord with the documented ability of adenosine to inhibit polysynaptic but not monosynaptic IPSPs in similar preparations.

NEUROTRANSMITTER INTERACTIONS: SEROTONIN

637.1 EVIDENCE FOR INVOLVEMENT OF MEDIAN, BUT NOT DORSAL, RAPHE NEURONAL 5-HT1A AUTORECEPTORS IN THE MEDIATION OF THE ANTICATELEPTIC EFFECTS OF 8-OH-DPAT IN THE RAT. M.L. Wadherbha* and V. Hillegat, Dept. of Behavioral Pharmacology, Astra AB, S-15185 Södertälje, Sweden.

The systemic administration of the 5-HT1A receptor agonist 8-OH-DPAT has been shown to counteract the cataleptic effects induced by DA D2/D3 receptor blocking agents like raclopride or haloperidol. 8-OH-DPAT also produces this effect after i.c.v, but not intrathecal, administration, suggesting a supraspinal mediation of the effect. The dorsal and median raphe nuclei have both been implicated as the target effects for 8-OH-DPAT, but there are divergent opinions on the relative importance of these nuclei in this regard. The present study was designed to clarify the functional role of median versus dorsal raphe 5-HT neurons in the mediation of the antiscataleptic effect of 8-OH-DPAT. Animals were observed for catalepsy on an inclined (60°) grid at different time intervals. Degree of catalepsy was scored according to a square root transformation of raw data. It was found that 8-OH-DPAT (0.5 or 2.5 μg) locally injected into the median raphe nuclei produced a dose-dependent and statistically significant antagonism of raclopride-(16 mg/kg, sc, -h) induced catalepsy. 8-OH-DPAT (0.5 or 2.5 μg) locally injected into the dorsal raphe nuclei, however, had no effect on raclopride-(16 mg/kg sc) induced catalepsy.

In conclusion: The results provide evidence for a specific involvement of the median raphe in the mediation of the antagonism by 8-OH-DPAT of catalepsy induced by dopamine receptor blocking drugs.

637.2 STRIATAL C-FOS INDUCTION BY CONCOMITANT STIMULATION OF 5-HT1A-5-HT2, D1-5-HT1A AND D1-5-HT2 RECEPTORS. J. Depail*, S. Davey*, D. Richard*, and C. Rouillard*. Lab. of Neurobiology, Dept. of Pharmacology and Physiologie, Laval University, Quebec, Canada GIU 1Z4.

We have previously demonstrated that the release of 5-HT by fenfluramine (FEN) induces Fos-like immunoreactivity (Fos-LI) in the doro-medial part of the striatum (STRI) as well as in other brain areas. The striatum, the site of immediate-early gene response is under the control of both DA and 5-HT. However, we were unable to reproduce the effects of FEN in the STR with the administration of selective 5-HT1A receptor subtypes agonist. The present study was aimed to investigate the possibility of interaction between different 5-HT receptor subtypes or between 5-HT and DA receptor subtypes. To investigate this possibility, seven groups of animals, each consisting of at least 3 rats were used in this study. Agonists were administered i.p and animals were sacrificed 120 min later. Brains were removed, sliced and processed for Fos-LI. Treatments were a) Saline, b) Saline+8-OH-DPAT (2.5 mg/kg), c) FEN+8-OH-DPAT, d) Saline+SKF38393 (2.0 mg/kg), e) SKF38393+Saline, f) Skf38393+8-OH-DPAT and g) 8-OH-DPAT+DOI. Our results show that all agonists combinations induce Fos-LI in the medial part of the ST. The crosstalk among 5-HT receptor subtypes. The combination 8-OH-DPAT+DOI was the most effective, followed by SKF 38393+DOI and SKF38393+8-OH-DPAT combinations. No Fos-LI was found in the lateral part of ST. This study suggests that there is a possible interaction and synergestia between 5-HT receptor subtypes and between DA and 5-HT receptors in the ST. The immediate-early gene expression is restricted to a striatal territory related to associative functions while the striatal territory related to mnemonic functions did not show any Fos-LI. (Supported by NSERC and FRQ).
5-HT Receptors Are Not Involved in the 5-HT-Induced Increase of Dopamine in the Ventral Pallidum and Prefrontal Cortex of Awake Rats. J.N. Iyer* and C.W. Bradberry. Department of Psychiatry, Yale Univ. Sch. of Med. and Veterans Administration Medical Center, Box 116124, 195 Campbell Avenue, West Haven, CT 06511.

Interactions between central DA and 5-HT pathways have been proposed to play a role in the pathophysiology of schizophrenia or in amelioration by antipsychotics and in increasing interest in the prefrontal cortex (PFC) as a site of dysfunction in schizophrenia. We have previously shown that the local application of 1-10 μM 5-HT4/5 through a microdialysis probe facilitates DA release in a dose-dependent manner in the PFC. Because previous work suggested that a 5-HT4 receptor sub-type partially mediates a 5-HT4-induced DA release to the nucleus accumbens, we determined if there is 5-HT4-mediated DA release in the PFC.

Injection of the selective 5-HT4 antagonist DOI through a microdialysis probe at a concentration of 500 μM did not cause any increase in extracellular DA and co-perfusion of the selective 5-HT4 antagonist MDL-7097 (100 nM) with 3 μM 5-HT failed to significantly attenuate the 5-HT4-induced enhancement of extracellular DA.

These results demonstrate the absence of 5-HT4 receptor involvement in 5-HT4-induced DA release in the prefrontal cortex of the rat. Supported by DA 00073, NIH 44860, DA 08227, the West Haven Veterans Administration Center Grant for the study of PTSD, and a NARSAD Young Investigator Award to C.W.B.

The role of different serotonin receptor subtypes (5-HT1A, 5-HT2A, 5-HT3) in the control of striatal dopamine (DA) release exerted by serotonin (5-HT) was studied by using in vivo intracerebral microdialysis. A microdialysis probe (CMA 11/11) was implanted in the striatum of rats anesthetized under a mixture of halothane-N2O-O2 and perfused with an artificial CSF (NaCl 145 mM, KCl 2.7, CaCl₂ 1.2, MgCl₂ 1 mM, pH 7.4) at a constant flow rate of 2 μL/min. Two hours after the onset of perfusion, 15 min fractions were collected over 150 min period of time and analyzed by HPLC coupled with electrochemical detection.

In contrast, the control DA release was stable during the experiment.

Drugs used were locally applied by means of the microdialysis probe. 5-HT, 25 and 5pM 5-HT significantly enhanced DA release in a dose-dependent manner up to 157, 255 and 446% of basal value respectively. The effect induced by 1μM 5-HT was not blocked in the presence of 10μM (±)-pindolol, a 5-HT1A receptor antagonist, 1μM ketanserin or 10μM cisapride, both 5-HT3 antagonists, as well as 1 μM domperidone (SR 38029f), a selective 5-HT3 antagonist, were also ineffective. In contrast, 10 μM domperidone (SR 38029f), a selective 5-HT3 antagonist, significantly antagonized the 5-HT-induced DA release.

Moreover, 100 μM BNN 4046, a selective 5-HT3 antagonist, enhanced DA release (+85%) and this effect was reduced by 100 μM D-ala-D-Lys-Enkephalin (40μM).

These results demonstrate that 5-HT-induced enhancement of extracellular DA concentration is mediated by a serotonergic receptor on striatal DA release and that 5-HT3R, but not 5-HT1A, 5-HT2A or 5-HT4 receptor subtypes are implicated in this effect.

5-HT4 Receptors Modulate Histamine Release in the Rat Hypothalamus Measured by In Vivo Micropipette Microdialysis. P.S. Laitinen*, J.T. Laitinen and T. Kuitunen. Department of Pharmacology, University of Turku, 20520 Turku, Finland.

Histamine (HA) acts as a neurotransmitter/modulator in the mammalian brain. HA is thought to modulate circadian functions, including food intake, arousal, body temperature and hormone secretion. In the anterior hypothalamus (AHA), EA is present in the suprachiasmatic nucleus (SCN). A major non-photic input to the SCN is the serotonergic projection from the medial ramus nuclei. Hypothalamic serotonergic neurons (5-HT) also influence the regulation of circadian rhythms, including feeding behavior. We used in vivo microdialysis to monitor the changes in HA and 5-HT in the AHA of male Wistar rats implanted with a microdialysis probe in the AHA (aimed at the SCN). The probe was perfused with mSNP (3 μL/min) and samples were collected every 10 min. The diurnal concentrations of HA was monitored by HPLC with fluorescence detection and that of 5-HT by HPLC-EC.

Local perfusion with 5-HT (10 or 100 μM) increased DA release significantly and dose-dependently. Methysergide (10 μg/ip.), a 5-HT/2 receptor blocker, suppressed basal DA release by 30%. Desfenfluramine, a 5-HT releaser and receptor inhibitor, via the 5-HT (15 μM) increased DA release up to 160 %. With the same dose of desfenfluramine, 5-HT release increased 40-fold in the same brain areas. These data suggest that endogenous serotonin modulates histamine release in the AHA and histaminergic neurons participate in the concomitant effects of desfenfluramine.
637.9 SEROTONIN ENHANCES DOPAMINE-INDUCED INHIBITION OF VENTRAL SEGMENTAL AREA (VTA) NEURONS RECORDED IN VITRO. S.L. Brodie and E.B. Burnet. Dept. Physiology and Biophysics and Program in Emergency Medicine, University of Illinois at Chicago, Chicago, IL 60612.

Dopaminergic neurons of the ventral terminal area (VTA) have been implicated in a number of pathological processes, including drug abuse and schizophrenia. The VTA receives serotonergic innervation from the median and dorsal raphe nuclei, and recent studies have demonstrated that serotonin has both excitatory and inhibitory effects on VTA neurons. We have recently reported that serotonin potentiates ethanol-induced excitation of VTA neurons; our objective in the present study was to determine whether serotonin alters dopamine-induced inhibition of VTA neurons.

Coronal brain slices containing the VTA were prepared from young adult rats. Dopamine (1, 5, 10 pM) inhibited all neurons tested, and was administered in a number of pathogenic processes, including drug abuse and schizophrenia. The VTA receives serotonergic innervation from the median and dorsal raphe nuclei, and recent studies have demonstrated that serotonin has both excitatory and inhibitory effects on VTA neurons. We have recently reported that serotonin potentiates ethanol-induced excitation of VTA neurons; our objective in the present study was to determine whether serotonin alters dopamine-induced inhibition of VTA neurons.

The mean percent inhibition of firing produced by 2 nM dopamine was increased from 38.8% to 48.3% by 50 nM serotonin, and was increased to 53.4% in 10 nM serotonin. Similar effects were seen on the inhibitory potency of 1 and 5 nM dopamine; 5-HT enhancement was statistically significant as determined by ANOVA (P < 0.05). This increase in potency was not explained by an additive effect of serotonin and dopamine, since 1 potention of dopamine effects was seen regardless of whether serotonin alone increased or decreased the firing rate, and 5-HT decrease in firing rate, the effect of dopamine was superadditive with that of serotonin. These data suggest that serotonergic neurotransmission in the VTA may serve to enhance the inhibitory action of dopamine in the VTA. Grant Support: PHS AA-09125; Ulf Helen M. Thomsen Research Fund.

637.10 THE EFFECT OF SEROTONERGIC AGENTS ON THE EXPRESSION OF D1 AGONIST MEDIATED REPETITIVE JAW MOVEMENTS (RJM). Helen Rosengardter and Arnold J. Friedhoff. Department of Psychiatry, Millhauser Labs. NYU School of Medicine, New York, N.Y. 10016 USA.

Selective D1 receptor agonists are capable of inducing repetitive jaw movements (RJM) in rats. SKF 38393 appears to be specific for the D1 receptor, however, at high doses, it is capable of interacting with D1 and 5HT receptors. To explore a possible interaction between serotonergic and dopaminergic systems in the mediation of RJM, we studied the effect of a series of D1 agonists SKF 38393 inducible behavior. It was demonstrated that the mixed 5HT and 5HT receptor agonist, mCPP, and 5HT antagonists, ritanserin and cyproheptadine, are capable of enhancing SKF 38393-induced RJM by 180%, 240% and 217%, respectively, while the 5HT1 agonist, 80H-DPAT, the 5HT1 antagonist, CGS 120066, and the 5HT2 agonist, DDI, had no effect. The results of this study demonstrate that there is an interaction between DA and 5HT systems in the expression of RJM. This study was supported by NIH Grants 06818 and 35976.

The supertransmucous nucleus (SCN) neurons receive excitonic and intrinsic neural inputs, the majority of which utilizes GABA as a neurotransmitter. They also receive serotonergic input from midbrain raphe neurons, which is known to influence SCN neuronal activity through yet unidentified mechanisms. In the present study, whole-cell voltage-clamp recordings were made from SCN neurons in dissociated cell culture, in order to test possible modulation by 5-HT of GABA-induced current (i). With (2-5) of (1)-T and (2) of (5) and (10) of (11), 5-HT enzymatically inhibited i in a concentration-dependent manner (100 nM to 1 mM), without changing the reversal potential of i, which was almost equal to the Cl equilibrium potential. 8-OH-ADPAT, a 5-HT2 agonist, mimicked the effect of 5-HT at concentrations of 100 nM to 10 mM. 5-HT3 (5-HT3 agonist, 100 nM) also inhibited i, whereas a 5-HT3 agonist DOI (1 mM) had no significant effect. The effect of 100 nM 8-OH-DPAT on i was virtually abolished by co-application of mianserin (5-HT3 antagonist, 100 nM) but not by pindolol (5HT1 antagonist, 100 nM). The effect of 100 nM 5-HT was also suppressed by co-application of ritanserin, but not by pindolol or ketanserin (5-HT2 antagonist, 100 nM). External application of 8-Bromo-cAMP (1 mM) or forskolin (500 mM) suppressed i, suggesting that serotonin decreases SCN neuronal activity through a receptor system other than the GABAergic-cAMP pathway. The results suggest that 5-HT inhibits i in the SCN neurons, which involves the activation of 5-HT receptor and its coupled cAMP-dependent system. This inhibition of GABA_A receptor function may be involved in the regulation of 5-HT of SCN neuronal activity.

Serotonin (5-HT), substance P (SP) and tryptophan-releasing hormone (TRH) occur in ventral medial neurones which project to the intermediolateral cell column (IML) of the thoracic spinal cord (Sasek et al., Neurochemistry, 1976. 10, 951). These fibers are involved in the regulation of sympathetic nervous system. 5-HT-[3H]-HT is released from the intermediate area which includes the IML and the release of the 5-HT is regulated by presynaptic inhibitory 5-HT receptors (Yamaguchi, et al., Brain Res., in press, 1994). We used in vitro superfusion of the microdissected intermediate area of the rat thoracic spinal cord to study the effects of SP and TRH on the release of 5-HT. A serotonin (100 nM, the preferred receptor for SP) selective agonist, GR 73632 (1 nM), significantly increased the basal release of 5-HT. The increased release of 5-HT by GR 73632 was blocked by a selective NK, antagonist, GR 83341 (1 nM). GR 83341 (1 nM) did not change the basal release of 5-HT at itself. SP (1 nM) also increased the basal release of 5-HT. A TRH agonist, NK 771 (1 nM), had no effect on the release of 5-HT. The present study suggests that release of 5-HT the intermediate area could be regulated by SP, but not by TRH. The excitatory effect of SP on the release of 5-HT appears to be mediated by NK receptor. These findings will be helpful in understanding the complex roles of coexisting neurotransmitters in the spinal regulation of the sympathetic nervous system. (Supported by NIH grants DE 007896.)

Many serotonin-containing fibers that terminate on or near motoneurons in the ventral horn of the spinal cord and the hypo- glossal nucleus contain colocalized substance P. A significant proportion of fibers in the same regions appears to contain colocalized serotonin and enkephalin. Rapidly firing serotonin cells appear to corelease both serotonin and neuropeptides. Enkephalin is known to affect these substances interact to affect postsynaptic cells. The present study used electrophysiological techniques to examine how serotonin may interact with these neuropeptides to alter motoneuron excitability in the lumbar spinal cord and in the hypoglossal nucleus. Microiontophoretic application of serotonin or substance P enhanced glutamate-evoked firing of all motoneurons that were tested in the spinal cord and the hypoglossal motor nucleus. Application of serotonin and substance P together had additive effects on motoneuron excitability until a threshold was reached. In contrast, microiontophoretic application of enkephalin inhibited glutamate-evoked firing of the same cells that were facilitated by serotonin. Concurrent application of serotonin and enkephalin diminished the facilitatory effects of serotonin alone. Therefore, it appears that cells which contain colocalized serotonin and enkephalin may either enhance or inhibit motoneuronal excitability depending upon the firing rate of the cell.

IS TRYPTAMINE SYNTHETIZED BY SEROTONERGIC NEURONS?
Bruno A.*, Tagliagfiero P., Canessa O. and Pecchi Saavedra J.
Instituto de Biologia Celular, Facultad de Medicina, U.B.A.
C.A.T. Biol. Cel. e Histol., Fac. Farmacia y Bioquimica
Tryptamine (T) is present in the Central Nervous System (CNS) in very low concentration. T is synthesized from Tryptophane (Trp) by the aminoacid aromatic decarboxilase (AADC), an enzyme that is present in all eumammalian neurons and also in glial cells. Localization of T in serotonergic neurons is not yet clear. An immunocytochemical technique (ICT) was applied to CNS of adult rat to detect anti-serotonin and primary antibody. To increase the concentration of both endogenous and exogenous TGF, the animals were treated with Trp and pergolide was performed 2 hr prior to fixation. T immunoactivity was restricted to soma and processes of glial and neuron cells in the raphe nucleus (pere reticulate), and pons giganito cellularis nucleus. We discovered, therefore, that T can be synthesized by glial and other cells in the CNS. Distribution of serotonergic cells does not lay on top of tryptamine cells in the CNS, detected by ICT, so not all serotonergic neurons are able to synthesize T. Immunoactivity for both indolesamines was strongly reduced by inhibition of serotonin synthesis with parachlorophenylalanine pre-treatment. We postulate that synthesis of T is not an alternative route for Trp utilization when TGF-hydroxylase (limitant enzyme of serotonin synthesis) is inhibited. (Supported by grants of CONICET and UBA/CT, Argentina).

638.1
DIHYDROXIDINE RELEASES ACETYLCHOLINE AND IMPROVES COGNITIVE PERFORMANCE IN RATS.
Neurochemical and behavioral studies have elucidated extensive interactions between dopaminergic and cholinergic systems in brain areas associated with movement and cognition. The initial goal of these studies was to evaluate the effect of the anti-Parkinson drug dihydriodicine (DHX), a full D2 agonist, on brain acetylcholine (ACH) release using in vivo microdialysis techniques. Moderate doses (3 & 10 mg/kg) of DHX produced an approximate 50% increase in striatal ACh release that was blocked by the D2 antagonist SCH23390 (0.3 mg/kg). A higher dose (17.5 mg/kg) was less effective in raising striatal ACh release probably due to DHX neurotoxicity. In frontal cortex, DHX (10 mg/kg) evoked a more robust increase (200%) in ACh release that was blocked by SCH23390 (0.3 mg/kg). Since elevations in brain ACh are associated with cognitive improvement, the effectiveness of DHX in a passive avoidance model of learning and memory was evaluated. These studies revealed a significant improvement in performance by 0.3 mg/kg DHX in scopolamine-amnesic rats. These results provide support for the hypothesis that DHX improves cognitive performance as a consequence of ACh release in relevant brain regions. Further, D2 agonists may have novel therapeutic potential in the treatment of dementia.

638.2
RELEASE OF [3H]ACETHOLLINE FROM SLICES OF RAT STRIATUM AND CEREBRAL CORTEX BY 5-HT, RECEPTOR ANTAGONISTS. J. Del Rio*, B. Laesther and M.J. Ramirez Dept. of Pharmacology, Schools of Medicine and Pharmacy, University of Navarra, 31080-Pamplona, Spain.
Controversial results have been reported on the ability of 5-HT receptor ligands to modulate acetylcholine (ACH) release from rat entorhinal cortex and also from other brain regions. We have studied the effect of 5-HT1 receptor stimulation and blockade on basal and K+ evoked [3H]ACH release from superfused slices of rat striatum and cerebral cortex. K+ evoked release consisted of two stimulations (S1 and S2, 30 min apart) with KCI (20 mM, 6 min) with drugs added 5 min before S1 and calculation of changes in S2/S1. The 5-HT1 antagonist ondansetrone (0.01-10 µM) increased in a concentration-dependent manner both basal and K+ evoked [3H]ACH release from striatal slices, the latter effect being more marked. A lower though significant [3H]ACH release by ondansetrone was also found in superfused cortical slices. However, basal rather than K+ evoked [3H]ACH release was influenced by this 5-HT1 antagonist in the cerebral cortex. Similar effects were observed with higher concentrations of gantrisent in both brain regions. The 5-HT1 agonist 2-Me-5-HT (1 µM) did not modify by itself [3H]ACH release and a moderate decrease was only observed in the presence of the 5-HT1 antagonist ritanserin. Interestingly, 2-Me-5-HT blocked the increase in both basal and K+ evoked [3H]ACH release induced by ondansetrone. The results suggest that 5-HT1 receptor antagonists may influence acetylcholine release from specific brain regions.

PRETREATMENT WITH THE NORAADRENERGIC NEUROTOXIN DSP-4 IN VIVO REDUCES ACETYLCHOLINE (ACH) RELEASE IN THE RAT PREFRONTAL CORTEX IN VITRO. Stéphane Teillez, Francis Colpaert and Marc Marien*, Centre de Recherche Pierre Fabre, 17 avenue Jean Moulin, Castres 81100, France.
A deficiency in the locus coeruleus noradrenergic system (LC-NA) has been proposed to be an important contributory factor in the pathogenesis and progression of central neurodegenerative disorders including Alzheimer's disease (Colpaert 1994, in Noradrenaline Mechanisms in Parkinson's Disease, CRC Press, Boca Raton, pp. 225-254). To examine the influence of the LC-NA on cortical ACh release, male SD rats were injected with DSP-4 (40 mg/kg, i.p.) preceded 30 min by an injection of citoplatin (10 mg/kg). Three days later, slices of the prefrontal cortex (PFC) were prepared, incubated with [3H]ACh, superfused and stimulated by exposure to increasing concentrations of K+. The DSP-4 treatment reduced endogenous noradrenaline levels in cortical tissue by 71-94%, in slices of PFC from DSP-4 treated rats, the [3H] overflows which were stimulated by 20, 35 and 45 mM K+ were only 32, 25 and 22%, respectively, compared to slices prepared from vehicle treated animals. These results indicate that disruption of the LC-NA reduces a facilitatory input to the cortical cholinergic system, and that injury to or loss of noradrenergic neurons might contribute to the cortical cholinergic dysfunction in Alzheimer's disease.

CHRONIC EFFECTS OF CAFFEINE, NICOTINE AND ETHANOL ON CENTRAL ADENOSINE AND CHOLINERGIC RECEPTORS AND CALCIUM CHANNELS: BEHAVIORAL CORRELATES IN MICE. Dan Shi, O. Nikolaevic, B. Justo, K. Jacobson and I. M. Daly, Laboratory of Bioorganic Chemistry, NIDDK, NIH, Bethesda, MD 20892.
Chronic caffeine increases density of central A1-adenosine (cortex, striatum), nicotinic, muscarinic, serotonin and GABAergic receptors. Central A2A-Adenosine, δ-adrenergic, dopaminergic and NMDA-receptors are unchanged and the densities of β-adrenergic receptors are decreased. Theophylline and theobromine also increase density of A1-receptors. No changes are observed to adenosine receptors or muscarinic receptors. Chronic ethanol increases density of A1-receptors. Both caffeine and ethanol, but not nicotine, increase muscarinic receptors. Behavioral sensitivity (open field locomotor) to adenosine agonists increases after caffeine. Behavioral sensitivity to nicotine decreases after chronic administration. The sensitivity to the muscarinic antagonist scopolamine is enhanced after chronic administration of caffeine. Adenosine receptor agonists appear interrelated behaviorally as are 1-type calcium channels.

Ventral pallidal regions of the basal forebrain (VF) contain cholinergic neurons that project to the prefrontal cortex (pFC), frontal cortex (FC) and amygdala (AMG) and are involved in cognition. Cholinoceptive neurons of the medullobulbar pontine nucleus (PPN) are directly innervated by non-cholinergic neurons of the VF that mediate motoric function. Our previous work demonstrated that intra-VF injections of dopamine (DA) and its receptor-subtype selective agonists alter motor function, but do not effect working memory (i.e., choice accuracy on the radial arm maze). It is not known whether cholinergic neurons within the VF, or cholinergic neurons innervated upon by VF efferents, are affected by these treatments.

In the present study, changes in hemicholinium (HC-3)-binding, a marker for high affinity choline uptake, were measured in pFC, FC, AMG and PPN of tissue homogenates as an indicator of cholinergic neuronal activity. Intra-VF microinjection of DA failed to alter HC-3 binding, but DA(+50, 5µg per side) increased binding by 25% in the PPN. In contrast, 5,6-DHT-induced lesions of the ascending DA projection decreased HC-3 binding in the pFC and AMG 36% and 24%, respectively. These data indicate that impact of VF cholinergic systems influenced by the VF are differentially sensitive to 1) DA receptor stimulation within the VF, and 2) the compensatory mechanisms evoked upon removal of endogenous DA. Work supported by MH413180 to TCN.

After medial septum lesions (MSL), peripheral sympathetic adrenergic fibers, originating from ventral ventrolateral tegmentum, enter the hippocampus (hippocampal sympathetic interneuron,HSI). We have previously reported that HSI is detrimental to learning in rats and that treatment with phentolamine (PHENT), a-adrenergic antagonist, ameliorated this deficit. However, biochemical studies of HSI have revealed changes in the hippocampal cholinergic system. To determine whether PHENT treatment might mediate its effects through muscarinic cholinergic (mAChR) receptors, we assessed the efficacy of PHENT treatment on hippocampal mAChR. Animals underwent 1 of 4 surgeries: control (sham MSL + shm ganglionectomy (Gx)); HSI (MSL + shm Gx); HSI (+- MSL + Gx); sham (MSL + Gx). Each surgery group was divided equally between vehicle (20 mg/kg, IP) or vehicle daily for 5 weeks. After completion of treatment, the hippocampus was isolated from the dorsal and ventral regions and membrane-binding of [3H]QNIX, a non-selective mAChR antagonist, was assessed. PHENT treatment was found to reduce the binding affinity of mAChR in HSI(+)-animals in both hippocampal regions (Kd: 0.65 ± 0.38, 1.08±0.25 μM) in comparison to controls (Kd: 0.48±0.06, 0.54±0.05) and 2) increase the number of mAChR in dorsal hippocampus of HSI(-) animals (Bmax: 1111±416 fmol/mg) in comparison to control animals (Bmax: 409±50.7) These results suggest that PHENT treatment may mediate its effect through the mAChR by altering the release of acetylcholine from intrinsic cholinergic neurons and indicate that balance between noradrenergic and cholinergic system may be important for mediating the behavioral effects of HSI.

538.8 CALRETININ IMMUNOREACTIVITY IN THE ADULT RAT SEPTO-HIPPOCAMPAL BARRIER PATHWAY. L.A. Wilson and M.D. Kaye*, Department of Anatomy and Cell Biology, Queen’s University, King’s College, Kingston, Ontario, Canada, K7L 5N6.

The medial habenula (MBH) consists of a densely packed population of neurons, the majority of which stain immunohistochemically for choline acetyltransferase (ChAT). The cholinergic MBH is innervated by axons that originate from pontine cholinergic nuclei (PCh), and which project via the stria medullaris (Sm). To date, one of the few biochemical features to be identified within this nucleus is it’s calcium–binding protein. The purpose of this investigation is to determine the normal patterns of connectivity of calretinin-positive fibers in the MBH, as a prelude to our examination of the role of calretinin in the adult habenula. A denseplexus of calretinin-immunoreactive axons was evident throughout the rostro-caudal extent of the normal MBH. Following a unilateral lesion of the Sm, calretinin immunostaining of fibers was completely abolished in the ipsilateral MBH, a small population of calretinin-positive neurons remained in the MBH, and no calretinin staining was found in the intact contralateral MBH. As an extension to these findings, these immunoreactive terminals formed asymmetric synapses with dendritic processes of MBH neurons. Double immunohistochemical staining was used to simultaneously demonstrate calretinin-positive fibers among CHAT-positive neurons within the ventral two-thirds of the MBH. The data will be presented concerning the ultrastructural organization of CHAT and calretinin immunoreactivities within the normal adult rat MBH and within implants of fetal rat habenula grafted into the mature rat brain (Supported by funds from the Faculty of Medicine, Queen’s University).

538.9 INTERACTION OF SOMATOSTATIN AND CARBACHOL ON HIPPOCAMPAL MAB CR RECEPTORS. P. Cagliari, M. Schilling, M. S. Bagg and L. Sigl. Department of Neuropharmacology, The Scripps Research Institute, La Jolla CA 92037.

The M-current (I(M)) is a non-inactivating potassium current that persists at slightly depolarized potentials. In CA1 hippocampal pyramidal neurons, somatostatin (SS) increases I(M) whereas carbachol (CCh) decreases it. To further study the ionic mechanisms of I(M), we investigated the interaction of these two substances on I(M) using intracellular voltage-clamp recordings in the rat hippocampal slice preparation. We recorded from 26 neurons with a mean resting membrane potential of -48 ± 8 mV. Suppression of CCh at 1 µM or 0.25% of control, an effect greater than previously reported. We then were able to reverse the CCh inhibition of I(M) by adding SS at 1 µM together with CCh: SS had no effect and I(M) remained inhibited. Reversing the order of agonist application gave different results. When SS 1 µM was added first, it was increased by 55-75%, as previously reported. Then adding CCh 1 µM to the SS-summated I(M) raised its amplitude back to 85-95% of control. As SS did not decrease I(M) below control in the presence of CCh alone, SS thus provides a protective effect. However, when we applied a high concentration (30 µM) of CCh in the presence of SS, the I(M) amplitude decreased greatly (15-25% of control), an effect identical to the effect of CCh on I(M) alone. Thus, in rat hippocampal CCh prevailing over SS for the control of I(M). However, SS can protect some of the M-channel pool against low (1 µM) but not high (30 µM) concentrations of CCh. Concentration and sequence of superfusion determines the end-effect, the interaction between these two agonists could take place at the second messenger level. Supported by NIMH (MH 44346) and NIAAA (AA 07456).

538.10 IMIDAZAZEN AND ABDOSULIN, TWO ANXIOLYTIC SELECTIVE GABA RECEPTOR MODULATORS REDUCE STRESS-INDUCED RELEASES OF ACETYLCHOLINE AND DOPAMINE IN THE RAT BRAIN. L. Depoix, C. Motto, A. Importer, M. Serra and S. Biggio*. Departments of Experimental Biomedical and Neuroscience, University of Cagliari, 09122 Cagliari, Italy.

The effect of the partial agonist imidazolin (IM) and the selective agonist abeculine (AB) was studied on the basal and stress-stimulated release of acetylcholine and dopamine in the rat hippocampus and cortical cortex using the microdialysis technique on freely moving rats. The effect of these drugs was compared with that of diazepam (DZ) and alprazolam (AZ), the two benzodiazepines full agonists. AB (0.05 - 1 mg/kg p.o.), IM (0.05 - 1 mg/kg p.o.), DZ 0.25 - 10 mg/kg p.o. and AZ (1 - 10 mg/kg p.o.) produced a dose-dependent decrease in the kynurenine, a calcium–binding protein. On the other hand only DZ and AZ significantly decreased dopamine release in the c. cortex. These effects were augmented by flumazenil. Fast onset (0.2 mg/kg/1000 mg/kg) produced a slowly marketed and marked 75-85% inhibition of acetylcholine release. The effects of AB were maximal at 30 min and remained at basal values in about 80 min. Fast shock enhanced also dopamine release in the c. cortex. The maximal effect (100%) was obtained at 30 min and in 30-40 min dopamine release returned to control values. The preexposure administration of AB or IM in a dose that induced the baseline release of acetylcholine and dopamine prevented the effect of stress. An effect mimicked by much higher doses of DZ and AZ. The differential efficacy of IM and AB on acetylcholine and dopamine release is consistent with the existence of multiple GABA, receptor subtypes with different sensitivity to these drugs. Supported by CNR subproject: SP4 stress CNR 93.0592.PF41.

Behavioral and biochemical studies suggest that a negative interaction exists between adenosine (ADO) A2 and dopamine (DA) D2 receptors in the brain and that this interaction underlies the opposing effects of ADO and DA receptors in vivo. ADO agonists are localized to GABAergic striato-pallidal neurons, and we have shown that activation of these receptors increases electrically-evoked underevoked GABA release in microdialysis from globus pallidus (GP). We examined the functional significance of A2A and D2 receptor subtypes in modulating electrically-evoked GABA release. We have observed that D2 receptor stimulation reduces the extent of co-release of GABA and glutamate from these cells, while A2A receptor agonists stimulate GABA release in microdialysis from caudate nucleus (CN). We found that the A2A receptor antagonist CGP 42226 (1 mg/ml) reduces the extent of GABA release in microdialysis from the caudate nucleus, and increases the extent of glutamate release from the same area. We also found that A2A and D2 receptor subtypes have opposing actions on pallidal GABA release. Consistent with previous findings, GABA release was increased by 35-40% by the selective A2A receptor agonist CGS 21680 (10 nM). The selective D2 receptor agonist N-0437 (1-100 nM) resulted in a concentration-dependent decrease in evoked GABA release in microdialysis from GP as well as in striatal slices (containing GP). GABA release was approximately 30% in both tissue preparations. However, in the presence of 10 nM CGS 21680, N-0437 (1-100 nM) had no effect on evoked GABA release. These results demonstrate that agonist stimulation of ADO and DA receptor subtypes has opposing actions on pallidal GABA release and that the stimulation of A2A receptors abolishes the effects of D2 receptor stimulation. It is suggested that this functional interaction between A2A and D2 receptor subtypes represents an important mechanism by which GABAergic striato-pallidal output is differentially modulated by ADO and DA. (Supported by NS 26831)

Zn2+ MODULATES GABAERGIC TRANSMISSION IN ORGANOTYPIC SLICE CULTURES OF RAT HIPPOCAMPUS. J.N. Record* and A.T. McLennan. Neurological Surgery, RI-20, University of Washington, Seattle, WA 98115.

Intracellular recordings of CA3 pyramidal cells (PCs) were used to study the actions of Zn2+ in slice cultures of hippocampus. Zn2+ (100-300 MuM) caused spontaneous and stimulus-evoked giant depolarizing potentials (GDPs) consisting of a burst of action potentials followed by depolarization (see Xia and Smart 1993).J.Physiol. 460-503). Paired recordings of neighboring PCs showed simultaneous GDPs, suggesting synchronous synaptic drive. Blockade of synaptic transmission using either 1 MuM TTX or 100-300 MuM cadmium prevented the appearance of GDPs. Glutamate and GABA receptor antagonists were used to examine the contributions of these neurotransmitters to GDP initiation and topography. The glutamate receptor antagonists APV, CNQX, and the GABA(A) antagonist CGP-33348, resulted in the appearance of spontaneous and evoked depolarizations. The depolarizing potentials appeared to be GABA-evoked, since they were reversible near resting membrane potential. Application of Zn2+ in the presence of APV, CNQX, and the GABA(B) antagonist CGP-33348, resulted in the appearance of spontaneous and evoked hyperpolarizations. These large hyperpolarizations were blocked by CGP-33348, suggesting they are GABA(B) receptor-mediated IPSPs. These data suggest that Zn2+ enhances GABA, and GABA-mediated neurotransmission in organotypic cultures of hippocampus. The appearance of GDPs appears to result primarily from the enhancement of GABA(A) transmission. (Supported by NIH-NSS2630 and NIH-T32NS-0144-15.)

COLOCALIZATION OF GLUTAMATE DECARBOXYLASE (GAD), SEROTONIN (5HT) AND TYROSINE HYDROXYLASE (TH) IN RAT MEDIAL PREFRONTAL CORTEX (mPFC). J.D. Taylor* and F.M. Berens. Department of Psychology and Program in Neuroscience, Harvard Medical School and Lab for Structural Neuroscience, McLean Hospital, Belmont, MA 02178.

Recent evidence has suggested that GABAergic cell bodies in rat prefrontal cortex receive a convergent modulation of monoaminergic inputs (Gellman and Aghajanian, 1993). To obtain corroborative microscopic support for this idea, a fluorescent immunocytochemical technique has been developed for the colocalization of GAD, TH and 5HT in single sections of rat mPFC. The primary antisera included a polyclonal antibody raised in rabbit against GAD, a monoclonal antibody raised in mouse against TH and a polyclonal antibody raised in goat against 5HT. Secondary antibodies were raised in donkey against rabbit (FITC), mouse against goat (TRITC) and goat against rabbit (AMCA). A digital confocal microscopic system equipped with appropriate filters was used to visualize the three fluorescent emissions. For a given cell of interest, serial 2 a/s plane slices were corrected for background fluorescent using a deconvolution subroutine followed by co-registration of the three images. While TH and 5HT varicosities were found in apposition with GAD immunoreactive (IR) cell bodies, ghosts of pyramidal neurons also showed a "divergence" of TH-, 5HT- and GAD-IR varicosities/boutons. Interactions of TH-, 5HT- and GAD-IR elements with one another were also commonly observed pre-synaptic to pyramidal cell bodies. These findings are consistent with the idea that monoaminergic afferents converge on GABAergic and pyramidal cell bodies. Moreover, pre-synaptic interactions of monoaminergic varicosities with GABAergic elements may play a significant role in the inhibitory modulation of pyramidal cell output from mPFC. Supported by MH42261, MH00423, MH11514 and the Stanley Foundation.

Recent evidence suggests that GABA and glycine are released by the same local circuit neurons in the spinal cord (Todt and Sullivan, J. Comp. Neurol. 296:496-505, 1990). Among the most important questions is whether this is a general phenomenon. However, few data are available in this regard, and most laboratories working with this system have focused on single neurotransmitters. We used a combination of immunocytochemical and electrophysiological methods to study the colocalization of GABA and glycine in the cuneate nucleus, 29% stain for GABA, 29% stain for glycine, and 42% stain for both.

Electron microscopy showed that GABA colocalizes with glycine at both ascorndendritic and axosomatic synapses, supporting a role for these neurotransmitters in pre-synaptic as well as post-synaptic interactions. Most GABAergic terminals were also glycergic, but some terminals were clearly not, as was GABA and not glycine, and vice versa. We are now studying quantitative differences in the enrichment of GABA and glycine in various classes of terminals in the cuneate nucleus.

We previously reported the localization of immunoreactivity to the amino acid transmitters GABA, glutamate (GLU), and glycine (GLY) in the chicken retina. In this report we assess the colocalization of these transmitters in the chicken retina inner nuclear layer.

Posthatch chicks were deeply anesthetized (halothane), decapitated, and their retinas fixed by immersion in mixed aldehydes. Small strips of central retina were embedded in epon and sectioned transversely at 1.5 μm. Adjacent serial sections were mounted on different slides to compare sections through the same cell immunoreactive to primary antibodies, (Chemicon) GLU, GABA, or GLY, visualized using an ABC kit (Vector).

Horizontal sections were used. Most GLU+ cells were also GABA+. A few GABA+ cells were GLY+. Bipolar cells were virtually all GABA+ and those which were both GLU+ and GLY+ were often adjacent to horizontal cells. Amacrine cells stained heterogeneously. GLU+ cells were most numerous followed by GLY+. Fewer of the GLU+ cells were GABA+, but most GABA+ cells were also GLU+ or GLY+, suggesting that at least some of these cells may contain all 3 transmitters.

The colocalization of GABA and GLY in some horizontal cells, the colocalization of GLU in GLY+ bipolar cells, and the probable colocalization of all 3 among some amacrine cells raises the question of possible functional and morphological differences among these cells.

THE EFFECTS OF SUBSTANCE P (SP) AND SEROTONIN (5-HT) ON DOPAMINE (DA) RELEASE IN THE STRIATUM: MICRODIALYSIS STUDIES IN WO. Camille S. Suchowski* and Matthew P. Galloway, CCN Program, Dept. of Psych & Behav Neurosciences, Wayne State Univ Sch of Med, Detroit MI 48202.

Several studies have demonstrated that 5-HT facilitates DA release in vivo, however the 5-HT receptor subtype and the synaptic organization remain to be determined. Using microdialysis, we analyzed the potential involvement of 5-HT1B receptors and the effects of the neurokinin, SP and senktide (a NK3 agonist) on extraneuronal striatal DA levels. Local perfusion with 10μM 5-HT significantly increased DA levels approximately 7-fold above baseline (655±71%, n=6). After perfusion with 100μM cyanoacrylic (CYP), a 5-HT1B antagonist, baseline DA levels increased 91%. In the presence of CYP, 10μM 5-HT no longer had a significant effect on DA levels (n=5). Persusion of 100μM SP did not significantly alter extracellular striatal DA levels (n=7) nor did local perfusion of 100μM senktide (n=6). To determine whether SP interacted with the effect of 5-HT, tissues were perfused with 100μM SP or senktide followed by a 10μM pulse of 5-HT. SP or senktide pretreatment did not alter 5-HT’s effect on extracellular DA levels (n=11). Preliminary microdialysis experiments measuring extracellular DOPA after perfusion diffusenilthelydopa, a decarboxylase inhibitor, indicated that 100μM senktide increased DOPA levels by 98% (n=1). In summary, 5-HT induced DA release was blocked by CYP. Persusion of SP and senktide did not significantly alter DA release or alter the 5-HT facilitation of DA release. Supported by NIDA 04120 and the Joe Young Sr. Research Fund.

639.3

In the present study we have investigated the effects of various classes of excitatory amino acid agonists on the release of dopamine in the medial prefrontal cortex of conscious rats. Bilateral microdialysis probes were used to assess extracellular levels of dopamine and to infuse excitatory amino acid agonists locally. Infusion of 20 μM kainate resulted in behavioral stimulation (e.g., sniffing) and a sustained, robust, nearly 7-fold increase of the extracellular levels of dopamine. Local application of 20 μM AMPA had a less profound effect, causing an increase of 2- to 3-fold in extracellular levels of dopamine. Higher concentrations of AMPA (100 μM) increased dopamine levels by nearly 10-fold. However, this increase was associated with convulsions in most animals tested. Local infusion of 20 μM NMDA did not affect extracellular dopamine levels. A much higher concentration of NMDA (200 μM) led to a 3- to 5-fold increase in dopamine levels. In contrast to AMPA or kainate, higher concentrations of NMDA did not cause convulsions. These results indicate that excitatory amino acid agonists facilitate the release of dopamine in the prefrontal cortex in vivo, and that non-NMDA receptor agonists are more potent than NMDA receptor agonists in so doing. This finding is in agreement with our previous 5-HTA receptor antagonists can attenuate the release of dopamine in the prefrontal cortex during stress. Supported in part by MH84804 and MH48866 and the Scottish Rite Foundation.

639.4
DOPAMINE RELEASE IN ANTERIOR MEDIAL STRIATUM IS CONTROLLED BY THE PREFRONTAL CORTEX: EVIDENCE FOR TONIC AND PHASIC MODULATION. M. Karremann* and B. Moghadam, Dept. of Psychiatry, Yale University School of Medicine and West Haven VA Med. Ctr. 116A/2, West Haven, CT 06816.

In the present study, we have investigated whether the prefrontal cortex exerts a modulatory effect on dopamine release in the anterior medial striatum of conscious rats. Two concentric microdialysis probes were used in each animal: one placed in the medial prefrontal cortex, used primarily for drug infusion, and the other placed in the contralateral anteromedial striatum, used to measure extracellular levels of dopamine. Infusion of TTX (5 μM) into the prefrontal cortex caused a decrease in extracellular dopamine levels in the anterior medial striatum, indicating that neuronal events in the prefrontal cortex exert a tonic excitatory effect on striatal dopamine release. Infusion of bicuculline (100 μM) into the prefrontal cortex resulted in an increase in the release of dopamine in the striatum, while application of amphetamine (50 μM) in the prefrontal cortex attenuated dopamine release in the striatum. These data suggest that GABAergic, as well as monoaminergic, systems in the prefrontal cortex control striatal release of dopamine. Further pharmacological characterization of tonic and phasic cortical mechanisms that modulate the release of dopamine in the striatal complex are currently underway.

THE 5-HT2ANTAGONIST AMPEROZIDE POTENTIATES AMPHETAMINE-STIMULATED DOPAMINE RELEASE IN THE RAT PREFRONTAL CORTEX. E.A. Felkai and H.Y. Meltzer. Department of Psychiatry, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

The pharmacological profile of the putative atypical antipsychotic drug amperozide includes 5-HT2 antagonism coupled with the ability to block dopamine (DA) uptake. Both of these properties may be the basis for the reported ability of amperozide to attenuate amphetamine (AMPH)-stimulated DA release in the dorsal and ventral striatum. Since previous research has not demonstrated a significant difference between the mesostriatal and mesocortical pathways, it is important to compare the regulation of DA release between these systems. The present study thus examined the effects of amperozide administration on AMH-stimulated DA release in the mesoaccumbens and mesocortical pathways.

Male rats were implanted with chronic indwelling guide cannulas above the medial PFC. 2-3 days later, microdialysis probes were lowered through the PFC into the rostral 5-HT2a receptor rich area. Following collection of baseline samples, amperozide (1.0, 5.0 or 10.0 mg/kg i.p.) or saline were administered 30 min before vehicle (0.3 mg/kg i.p.). AMPH increased basal extracellular DA levels to 0.88 pg/20 uL to 4.35 pg/20 uL 30 min following injection. Amperozide administration did not attenuate this increase. Rats that received amperozide potentiated AMPH-stimulated DA release in a dose-dependent manner. Relative to AMPH alone, administration of 1.0, 5.0 and 10.0 mg/kg amperozide produced additional increases in DA efflux of 1.06, 2.44 and 4.05 pg/20 uL, respectively. These results may be due to actions of amperozide on the cortical 5-HT2 receptors coupled with effects on AMPH on the DA transporter. Furthermore, these data add to previous work demonstrating differences between the mesostriatal and mesocortical systems in the regulation of DA release.

639.7

(+)-MDMA (3,4-methylenedioxymethamphetamine, "Ecstasy"), an amphetamine related drug of abuse, is a potent releaser of serotonin (5-HT) and causes toxicity to 5-HT neurons after repeated exposure. (+)-MDMA also releases dopamine (DA), although with less potency. Since we have shown previously that the intrastriatal application of (+)-MDMA facilitates DA release via a mechanism that is not observed with either (+)-MDMA or 5-HT, we investigated the role of endogenous 5-HT in (+)-MDMA-induced DA release in vivo.

Using the 5-HT1B/1D antagonist 8-OH-DPAT (0.3 mg/kg s.c.) or (+)-MDMA (1.0 mg/kg i.p.), extracellular DA levels were monitored in the substantia nigra pars reticulata (SNpr), the ventral tegmental area (VTA), the dorsal raphe nucleus (DRN), and the nucleus accumbens (NAcc) in anesthetized rats. (+)-MDMA increased DA efflux in all rostrolateral forebrain regions. (+)-MDMA increased DA efflux bilaterally in the SNpr and DRN. These increases are synergistic with the DA efflux induced by (+)-MDMA administered in the VTA and DRN. These data suggest that the (+)-MDMA-induced release of DA in the SNpr and DRN is not mediated by 5-HT1B/1D receptors.

639.9
EXTRACELLULAR DOPAMINE IN NUCLEUS ACCUMBENS SHELL IS ALTERED BY 6-OHDA LESIONS OF PREFRONTAL CORTEX. D. King*, M.J. Zigmund, and J.M. Finn. Department of Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

We previously reported that neither basal nor evoked extracellular dopamine (DA) is measured in the prefrontal cortex (mPFC) DA depletion (King et al., Soc. Neurosci. Abst. Fr19:29). In the present study, the impact of such lesions on extracellular DA in the nucleus accumbens shell, and core, were examined using in vivo microdialysis in 6-OHDA (1 µg/g saline) and saline injected rats. 30 min after injection of 6-OHDA, mPFC were performed 30 min after treatment with desipramine (25 mg/kg). Two weeks later, a microdialysis probe was inserted into the 6-OHDA-treated hemisphere and placed into shell or core. Approximately 18 hours after implantation of the dialysis probe, basal extracellular DA levels were determined at 15 minutes intervals (all data expressed as pg/20 uL). Microdialysis probes (60 ± 5% DA and 24 ± 7% 5-HT) placed lateral to the mPFC, basal levels of DA in shell were increased relative to core controls (7.2 ± 0.6 (n=6) and 5.0 ± 0.7 (n=8), respectively). In contrast, basal DA levels were not different in core of lesioned and control rats (9.0 ± 1.0 (n=5) and 8.4 ± 0.7 (n=6), respectively). Systemic d-amphetamine (1.5 mg/kg, p.o.) produced a similar increase of extracellular DA in shell of both lesioned and control rats (28 ± 3.1 and 29.0 ± 4.0, respectively). In contrast, mPFC lesions attenuated the effects of d-amphetamine on DA release. The ability of 6-OHDA lesions to produce a DA lesion was confirmed by analyzing DA content, which was 8.5 ± 0.8, respectively. The previous data suggest that the DA neurons contained within the mPFC projects to the nucleus accumbens shell. Further investigation is required to determine if the DA neurons projecting to the shell are differentially regulated under conditions of stress. [Supported by Tourette Syndrome Association, Scottish Rae Schizophrenia Research Program, National Alliance for Research on Schizophrenia and Depression and USPS grants MH45156 and MH43947.]

639.10

The present study examined the role of glutamate in the regulation of stress-evoked changes in tyrosine hydroxylase (TH) in neostriatum. Adult male rats were exposed to 30 min of intermittent tail shock in the presence of an amino acid decarboxylase (AAAD) inhibitor, NSD-1015 (100 µM), administered locally through a dialysis probe implanted into the striatum, and in the concurrent control of DopA in the dialysate was measured. Stress was applied beginning either 15 min or 75 min after the onset of NSD treatment, corresponding to the initial rate or steady-state phase of the DOPA accumulation rate, respectively. Stress was administered before the steady-state levels of extracellular DOPA (+40%). How ever, no change was observed in the initial rate of DOPA accumulation rate after the stress was administered, but the steady-state levels of extracellular DOPA (+40%). Similar results were obtained using APV (100 µM) or CNQX (100 µM), glutamate antagonists. Glutamate potentiated the time course of stress-evoked increase in extracellular DA in shell compared to controls (8.5 ± 0.8 and 5.9 ± 0.8, respectively). These data suggest that the mesoaccumbens DA neurons functioning in shell but not core are regulated by sympatoadrenal and corticosteroids evoked response, under conditions of stress. [Supported by Tourette Syndrome Association, Scottish Rae Schizophrenia Research Program, National Alliance for Research on Schizophrenia and Depression and USPS grants MH45156 and MH43947.]

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

DOPAMINE-SOMATOSTATIN INTERACTIONS IN THE RAT STRIATUM. J.R. Blackburn1, C.A. Chapman1, C.D. Blaha2 and J.S. Yeomans, Dept. of Psychology, Simon Fraser University, Burnaby, British Columbia, Canada.

The neuropeptide somatostatin is found throughout the central nervous system and is believed to act as a neurotransmitter. Pharmacological and behavioral evidence suggests a role for somatostatin in dopamine-mediated behaviors. To assess such an interaction between the two, the authors examined the effect of somatostatin on dopamine release, using in vivo microdialysis. Apomorphine administered subcutaneously, and directly infused into the striatum, did not affect somatostatin release, but was used for the infusion of somatostatin, as well as the collection of the dialysate at 15 min intervals (1 uL/min). Dopamine and metabolites were measured prior to and after administration of somatostatin. The results indicate that a striatal interaction exists between somatostatin and dopamine, in the striatum, at the neurochemical level.

NEUROKININ-1 TACHYKININ RECEPTOR-DOPAMINE INTERACTIONS IN THE RAT. M. Blackstone, C.J. Gibson1 and A.A. Stossel, Clinical Neurological Sciences, University of Western Ontario, London, ON, Canada, N6A 5A5.

There is anatomical evidence for a dense substance P (SP) innervation from the substantia nigra (SN). Electrophysiological, neurochemical and behavioral studies all suggest a functionally significant interaction between tachykinins and dopamine (DA) neuron and the SN, but this structure is devoid of SP receptors. Pharmacological and molecular studies have demonstrated that SP and related compounds act through a family of tachykinin receptors, termed neurokinin (NK) receptors. Autoradiographic studies have demonstrated the presence of NK-3 receptors on nigral DA neurons and stimulation of nigral NK-3 receptors leads to decreases in DA-mediated behavioral responses and locomotion and rearing. In contrast, stimulation of nigral NK-1 receptors elicits grooming in the absence of locomotion and rearing. We explored the possibility that NK-1-induced grooming is a response to the release of a substance, which would then stimulate local DA D1 receptors. Nigral infusion of the selective NK-1 agonist (Ac-Arg4, Sar6, Met7) [Leu] Phe9 (0-1 mmol) elicited dose-dependent stereotypic grooming. This response was significantly attenuated by peripheral administration of the DA D1 antagonist SCH23390 (100 μg/kg s.c.), but not by the DA D2 antagonist sulpiride (30 mg/kg i.p.). Grooming induced by nigral infusion of the NK-1 agonist was unaffected by either nigral or striatal SCH23390 (0.1-5 μg), but was blocked by bilateral 6-hydroxydopamine lesions. Our findings indicate that stimulation of nigral NK-1 receptors elicits grooming which is dependent upon release of DA and stimulation of D1 receptors in an as yet unidentified site.

STRIATAL DOPAMINE LEVELS INCREASE FOLLOWING PERIPHERAL SCOPOLAMINE INJECTIONS AND FOLLOWING APPLICATION OF SCOPOLAMINE TO THE TEGMENTAL PEDUNCULOPONTINE NUCLEUS. J.R. Blackburn1, A. Chapman, C.D. Blaha and J.S. Yeomans, Dept. of Psychology, Simon Fraser University, Burnaby, British Columbia, Canada.

The cholinergic cells of the tegmental pedunculopontine nucleus (PPT) monosynaptically excite dopaminergic (DA) neurons of the substantia nigra. Furthermore, DA-dependent behaviors are modulated by both peripheral or central PPT injections of antimuscarinic drugs, consistent with a disinhibition of PPT cholinergic cells via blockade of their inhibitory autacoid, acetylcholine. Rat dorso-lateral striatal DA levels were monitored chronocronoamperometrically (1sec 550mV pulses) with bilateral, chronically implanted, steelate-modified graphite paste electrodes used to inject scopolamine (1.25mg/kg i.p.) into the PPT. Injections of scopolamine into the PPT (10, 50, 100μg/side) or into the striatum (100 μg) resulted in bilateral dose-related increases in DA oxidation currents in the striatum. Unilateral microinjections of scopolamine into the PPT (10, 50, 100 μg/side) also resulted in short-latency, bilateral dose-related increases in striatal DA oxidation currents which usually peaked 50-80 min post-injection. Cholinergic PPT 20 min prior to 100μg PPT scopolamine attenuated these increases. These results indicate that elevated striatal DA levels following the systemic scopolamine treatments may be mediated by the PPT. This study further demonstrates a powerful excitatory effect of Ch5 PPT cells on the nigrostrial DA system.

CHRONIC DOPAMINE TREATMENT ALTERS THYMOID BINDING TO STRIATAL NMDA RECEPTORS AND DOPAMINE UPTAKE SITES IN THE RAT. J. Dell1, F. Wehlmuller2, J.F. Marshall2, Dept. of Psychology, University of California, Irvine, CA 92717.

We have previously shown that chronic haloperidol treatment increases binding to NMDA receptors in the outer layers of parietal cortex. To further elucidate this phenomenon, we investigated the effect of long-term (3 weeks) blockade of dopamine D2 or D1 receptors (both or both) on binding to NMDA receptors in rat hippocampus and striatum. [3H]Glutamate (5.0 mg/kg i.c.e., 75 μCi) and [3H]Oligo (10.0 mg/kg/day, i.p.) were administered to groups of rats. H-defactio (200 μg/day, s.c.) was used as a positive control. Our results indicate that chronic haloperidol treatment increases binding to NMDA receptors in the outer layers of parietal cortex, and the pyramidal layers of the hippocampus, while significantly attenuates binding to NMDA receptors in the lateral and ventral caudate-putamen, and nucleus accumbens. [3H]Oligo alone generally had no effect on NMDA receptor binding. The other hand, simultaneous blockade of D1 and D2 receptors resulted in a slightly smaller increase (than that evoked by scopolamine alone) in binding to NMDA receptors in the frontal cortex, an increased binding in the deep layers of parietal cortex and CA3 region, and further reduced binding to NMDA receptors in the striatum. These results suggest that D2 dopamine modulates NMDA receptor function differently in basolateral VS dorsal cortical regions, D2 although SCH23390 alone does not affect binding to NMDA receptors, chronic blockade of D1 receptor may modify the effects of D2 receptor inhibition, and if so the effect of haloperidol on NMDA receptors cannot be completely explained by blockade of D2 receptors.

NEUROTRANSMITTER INTERACTIONS

The distribution of NADPH-diaphorase activity (ND), an enzyme originally identified as the nitric oxide synthase, was histochemically investigated in the Japanese quail brain. Two levels of positive neurons were observed at all levels of the brainstem. In particular, they were located within the substantia nigra (SN), the area ventralis tegmentalis (AVT), the substantia grisea centralis, the nucleus interpeduncularis (LOC) and the subcoerulean (SCo). Scattered elements were present in other regions such as the vestibular nuclei or the nucleus of the solitary tract (S). This distribution partly overlaps with catecholamine (CA) neurons and with histochemical and immunohistochemical techniques. In most mammalian species, ND-positive neurons also show immunoreactivity for choline acetyltransferase (ChAT) and are intermingled with other histamine neurons. In the present study, we performed a double staining for ND and ChAT (anterior part of the mesencephalon and mesopontine region). At the level of midbrain, a large number of CA-positive neurons was also evident in both brainstem areas and in the midbrain. These results indicate that the mesopontine ND systems, is to identify neuronal populations containing different neurotransmitters (N), the demonstration that the great number of immunopositive neurons of SN and AVT are largely positive for ND suggests that the nitric oxide could have an important role in regulating the target areas and neurons in the brainstem. Supported by grants of CNR and MURST 60%.

NEUROPEPTIDE Y INCREASES CLOW INTAKE AND DOPAMINE CONCENTRATIONS IN MICRODIALYSATE FROM THE NUCLEUS ACCUMBENS OF RATS IN A FOOD CHOICE PARADIGM. R.L. Corwin* and J.L. Crawley, SBN, ETO, NIH, NH, Building 10, Room 4W212, Bethesda, MD 20892.

Neuropeptide Y (NPY) has been shown to be the most prevalent immunoreactivity in the brainstem (Hattori, Neuroni Res, 1993; similarly, serotonephine receptors appear to release glutamate (Johnson, Neuroni, 1994). Electrophysiologically studies of single identified neurons show that the cells frequently make glutamatergic autaptic EPSPS (Sulzer and Rayport, Soc Neurosci Abs, 1993). We now report that individual dopamine neurons immunostained for tyrosine hydroxylase show significant variation in neurite staining. In single neuron microcultures, where all processes arise from a single dopamine neuron, some thin neurites — which are most likely axonal — have varicosities that stain darkly and others have varicosities that stain lightly or are unstained. Double staining for synaptophysin shows putative release sites that do not stain for tyrosine hydroxylase. Double immunostaining with a polyclonal antiserum directed against glutamate (the glutaraldehyde-conjugate) shows that dopamine neurons are often glutamate-positive, while GABA neurons are rarely glutamate-positive. Taken together, these observations are consistent with the possibility that dopamine neurons release glutamate as a cotransmitter and may do so at separate terminals from where they release dopamine. If so, this may account in part for glutamate dependence of dopamine synaptic plasticity and neurotoxicity.

NEUROPEPTIDE Y RELEASE FROM PC12 CELLS IS REGULATED BY DOPAMINE X. Chen*, S.P. Han and T.C. Westfall Department of Pharmacological and Physiological Science, St. Louis University Health Science Center, St. Louis, MO 63104.

We have previously demonstrated that NPY is co-localized and co-released with dopamine from phenotypically PC12 cells by potassium-induced depolarization (J. Neurochem. Vol. 61, suppl., 1993). This study was designed to further investigate the mechanisms regulating NPY release from the peripheral sympathetic nervous system using PC12 cell line as a model system. PC12 cells grown in cell culture were partially differentiated with NGF for 3-4 days. NPY content in the cells and in the releasing buffer was determined by radioimmunoassay as described previously (DiMaggio, 1992). KCI (50 mM) induced a 1-2 fold increase in NPY release over basal levels. KCl-stimulated NPY release was greatly attenuated by the activation of dopamine receptors on PC12 cells with apomorphine, a non-selective D1 and D2 dopamine receptor agonist. The inhibitory effect of apomorphine on NPY release was dose dependent and could be partially reversed by eticlopride, a D2 dopamine receptor selective antagonist.

These results suggest that NPY release from PC12 cells is regulated by dopamine which acts as a cotransmitter of NPY in this model of a peripheral sympathetic neuron. This work is supported by HL26319, HL35202 and NS02254.

639.20

Haloperidol and clozapine are two drugs that decrease extracellular dopamine concentration in the brain and have potential therapeutic use in the treatment of drug abuse. In these experiments, we evaluated the effects of these drugs on extracellular dopamine concentrations in the nucleus accumbens (NA) of the rat. Haloperidol decreased extracellular dopamine concentrations by approximately 30% whereas clozapine was ineffective at doses of up to 10 mg/kg. We have previously demonstrated that NPY is present in the NA at high concentrations. NPY has been shown to be important in the regulation of dopamine release. NPY has been shown to inhibit dopamine release by binding to neurotensin (NT) receptor. The interaction between NPY and NT receptors may be important in the regulation of dopamine release. In the present study, we tested these hypotheses by using hPLC-EC. NPY inhibited dopamine release and dopamine concentration, while having no effect on dopamine release in the NPY receptor activity. These results suggest that NPY may play a role in food choice and that this effect may involve mesolimbic DA. 1. Clark, et al., 1994, Endocrinology 115:427. 2. SIMULTANEOUS VOLTAMMETRIC DETECTION OF STIMULATED DOPAMINE AND NITRIC OXIDE RELEASE IN RAT BRAIN SLICES: M.Iravani, J. Millar & E.L. Kruks, Departments of Pharmacology and Physiology (JM), Queen Mary & Westfield College, Mile End Rd, London E1 4NS UK.

We have recently described a voltammetric method which uses a carbon fibre electrode for real time detection of nitric oxide (NO; Iravani et al 1993, J. Physiol., 496: 48P), and we have used this to examine a NO like signal in rat striatum. Pressure ejection of NMDA, or electrical stimulation with trains of pulses in a 350µm rat striatum slice, gave rise to complex voltammetric signals which could be resolved into components attributable to the presence of dopamine (DA) and NO. The transients for the DA and NO signals were different. The signal attributed to NO could be reduced by addition of the NOS inhibitor L-NAME to the perfusion fluid. In the presence of the endogenous NO like substance, release of DA by electrical stimulation was attenuated, indicating that NO may have a role in local regulation of dopamine release.

Glutamate activation of NMDA receptor ion channels and the subsequent influx of Ca\(^{2+}\) is known to result in the activation of nitric oxide synthase (NOS) and enhanced nitric oxide (NO) production. While glutamate and NO are known to be involved in the excitotoxic process of neuronal degeneration the exact mechanisms of this process are still unclear. The objective of this research was a first step towards the goal of better elucidation of the role of these transmitters in the excitotoxic process. This initial step entails the application of iontophoretic application methods to the evaluation of glutamate and NO overflow in the extracellular fluid (ECF) of the rat hippocampus. Evoked glutamate overflow was monitored using a dual enzyme biosensor developed in our laboratory. NO was measured using a nickel peroxidase based sensor developed by Malinski and colleagues (Nature 358:676-678, 1993). Glutamate and NO overflow were evoked by the local injection of depolarizing levels of K\(^+\) into the hippocampus. Potassium-evoked glutamate release was correlated with local NO production. Local administration of nitro-L-arginine methyl ester (L-NMAE), an inhibitor of NOS, resulted in a decrease in NO production as well as a decrease in glutamate overflow. Furthermore, application of L-arginine in addition to L-NAME reversed this effect. Our results indicate that NO and glutamate in the ECF can be detected simultaneously in vivo using electrochemical detection methods. Last, we observed in the enhanced overflow of glutamate in confirmation of similar findings reported previously (Buisson, et al. J. Neurochem. 61:990-996, 1993).

640.4 NITRIC OXIDE INHIBITS NEUROGENIC NON-ADRENERGIC, NON-CHOLINERGIC CONTRACTIONS BUT NOT CHOLINERGIC CONTRACTIONS OF CIRCULAR MUSCLE FROM GUINEA PIG ILEUM. J.J. Gallagher, and A.M. Yunker. Dept. Pharmacology and Toxicology and Neuroscience Program, Michigan State University, E. Lansing, MI 48824.

Nitric oxide (NO) is released from enteric neurons resulting in relaxation of gastrointestinal (GI) smooth muscle. NO may also inhibit release of excitatory neurotransmitters such as substance P (SP) and acetylcholine (ACh) from enteric nerves. This hypothesis was tested using circular muscle-myenteric plexus preparations (CMMPs) isolated from guinea pig ileum in the presence of scopolamine and guanethidin, stimulation (1-50 Hz, 0.1 Ts) of CMMPs produced non-adrenergic, non-cholinergic (NANC) contractions. These contractions were blocked by tetraethylammonium and attenuated in a concentration-dependent manner by CP96345-1, a neurokinin-1 receptor antagonist. The nitric oxide synthase (NOS) antagonists N\textsubscript{n} -nitro-L-Larginine, N\textsubscript{n} -nitro-L-arginine methyl ester, and N\textsubscript{n} -methyl-L-arginine potentiated the amplitude of the NANC contractions in a concentration-dependent manner. The D stereoisomers of these NOS antagonists did not alter the NANC contractions. Onychomycosis binds excitatory neurotransmitters and caused a concentration-dependent increase in the amplitude of NANC contractions. Neither the NOS antagonists nor onychomycosis altered the contraction-response curve for substance P methyl ester, suggesting that it is not the new receptor responsible for these drugs. Finally, sodium nitroprusside attenuated NANC contractions in a concentration-dependent manner. Neither the NOS antagonists nor onychomycosis affected cholinergic contractions generated in the presence of guanethidin and CP96345-1. These data suggest that NO inhibits SP but not ACh release, thus providing a second mechanism by which NO can inhibit motility of GI smooth muscle. (Supported by DK 40120 and NS 07279).

640.5 NITRIC OXIDE DEPOLARIZES PARAVASCULAR NUCLEUS NEURONS IN VITRO. J.S. Bains* and A.V. Ferguson. Department of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

The presence of nitric oxide synthase, the enzyme necessary for the production of nitric oxide (NO), within neurons in the paravascular nucleus of the hypothalamus (PVN) has led to the suggestion that NO may play a role in neurotransmission within this structure. Recent in vivo experiments have demonstrated that diazoxide of NO directly into PVN everts decreases in blood pressure. This physiological change is accompanied by an increase in the release of excitatory amino acids such as glutamate within this nucleus (Horn et al., AJP, 1994). In this study, we have used whole-cell patch clamp recording techniques to investigate the potential effects of NO on PVN neurons. Using patch electrodes filled with potassium-glucose, recordings were made from PVN neurons in coronal brain slices (400 \mu m thickness) of adult, male Sprague-Dawley rats. Bath application of NO (10^\text{-8} \text{ M}, 10^\text{-9} \text{ M}) induced a hyperpolarisation (1.2 mV to 17.9 mV) membrane depolarization in 6 of the 7 cells tested (mean depolarization \pm SEM: 10.6 \pm 4.1 mV). This NO induced depolarization was also accompanied by a mean decrease in membrane resistance of 28 \pm 17 \%.

These results indicate that NO, either itself, or through influencing the release of other neural mediators acts to excite PVN neurons.

640.6 EFFECTS OF NITRIC OXIDE ON NITRIC OXIDE AND NEUROTRANSMITTER RELEASE IN THE RAT STRIATUM. B. Guevara-Guzman, P.C. Ferguson, and K.M. Kreider. Dept. Neurobiology, BSSRC Bahadur Institute, Cambridge CR4 4AT, U.K. Dept. Physiology, Faculty of Medicine, Mexico University, Mexico City 04510, DF.

We have shown previously that nitric oxide (NO) stimulates in vivo release of acetylcholine (ACh), 5HT, glutamate (Glu), inotrine (TAU) and GABA in the rat striatum and that these effects are mimicked by 

\[ \text{NO} \rightarrow \text{NO} + \text{O}_2 \] \[ \text{NO} + \text{O}_2 \rightarrow \text{NO}_2 \text{O}^+ \] \[ \text{NO}_2 \text{O}^+ + \text{H}^+ \rightarrow \text{NO}_2 + \text{H}_2 \text{O} \] \[ \text{NO}_2 + \text{H}_2 \text{O} \rightarrow \text{NO} + \text{H}_2 \text{O}_2 \] \[ \text{NO}_2 + \text{H}_2 \text{O} \rightarrow \text{NO} + \text{H}_2 \text{O}_2 \] \[ \text{NO}_2 + \text{H}_2 \text{O} \rightarrow \text{NO} + \text{H}_2 \text{O}_2 \] \[ \text{NO}_2 + \text{H}_2 \text{O} \rightarrow \text{NO} + \text{H}_2 \text{O}_2 \] \[ \text{NO}_2 + \text{H}_2 \text{O} \rightarrow \text{NO} + \text{H}_2 \text{O}_2 \] \[ \text{NO}_2 + \text{H}_2 \text{O} \rightarrow \text{NO} + \text{H}_2 \text{O}_2 \] 

These reactions are accompanied by a significant increase in NO production. However, NO release was not detected using NO-sensitive electrodes. The experiments were conducted since NO is not a neurotransmitter and in most cases NO release was detected in the striatum, although inhibiting NO release with NAGB potentiates this release. These results provide further support for a nonneuronal role for NO. The fact that NOFMCS may have other sources which are not neurotransmitter sources, in order to release NO in the CNS, it may be more appropriate to use in the CNS. We have investigated the following: a) the presence of NO without the use of NAGB and b) the presence of NO without the use of NAGB and c) the presence of NO without the use of NAGB and d) the presence of NO without the use of NAGB and e) the presence of NO without the use of NAGB and f) the presence of NO without the use of NAGB and g) the presence of NO without the use of NAGB and h) the presence of NO without the use of NAGB and i) the presence of NO without the use of NAGB and j) the presence of NO without the use of NAGB and k) the presence of NO without the use of NAGB and l) the presence of NO without the use of NAGB and m) the presence of NO without the use of NAGB and n) the presence of NO without the use of NAGB and o) the presence of NO without the use of NAGB and p) the presence of NO without the use of NAGB and q) the presence of NO without the use of NAGB and r) the presence of NO without the use of NAGB and s) the presence of NO without the use of NAGB and t) the presence of NO without the use of NAGB and u) the presence of NO without the use of NAGB and v) the presence of NO without the use of NAGB and w) the presence of NO without the use of NAGB and x) the presence of NO without the use of NAGB and y) the presence of NO without the use of NAGB and z) the presence of NO without the use of NAGB.
640.11 MUSCARIC MODULATION OF NMDA RESPONSES IN NEOCORTEX. V. B. Aramazyan1, J. H. Ashe and A. E. Bandrowski. Deps. of Neuroscience and Psychology, Univ. of California, Riverside, CA 92521.

Muscarinic actions of acetylcholine facilitate the amplitude of glutamate-induced membrane depolarizations (Ds) in rat auditory cortex (Cox et al, Synapse, 16;123, 1994). To assess the contribution of NMDA receptors to this facilitation, the actions of 1nM (-)-methylscopolamine (MCh) were tested upon glutamate-induced Ds elicited in the presence of the AMPA/kainate antagonists CNQX or NBQX (20 µM). The actions of MCh upon the isolated Ds (MCh preconditioned) were also examined. Whole-cell recordings were obtained from layer III cortical neurons of the in vitro auditory cortex. Isotophoretic application of MCh (1M, 50-100 nA, 1.5 min) or glutamate (1M, 500 nA, 20 sec) was also applied to layer III within 50 µm of the recording electrode. During MCh, the amplitudes of glutamate Ds were consistently suppressed in either the presence or absence of CNQX or NBQX. On the other hand, following MCh, the amplitudes of glutamate Ds were largely facilitated; about 75% in the absence of CN/NBQX, and about 300% in the presence of CN/NBQX. Durations of facilitation could last up to 35 min. MCh was also tested upon the isolated late-EPSs, i.e., elicited in the presence of CN/NBQX at 10-20 µM to block AMPA/kainate receptors, and to also minimize the contribution of the IPSPs (Methaure & Ashe, in press). Under these conditions, the isolated late-EPS was consistent suppressed by MCh. Moreover, the isolated late-EPS amplitude was usually enhanced above pre-MCh levels, following the initial suppression. The actions of MCh on glutamate-induced Ds and the isolated late-EPS suggests an involvement of NMDA receptors in cholinergic modulation of glutamatergic transmission. Supported by NSF (IBN 1010822).

640.12 EFFECT OF NMDA RECEPTOR BLOCKADE ON REGIONAL DOPAMINERGIC ACTIVITY. G. A. Fayed, V. J. Taylor, Geoffrey Metcalfe and Christopher J. S. Cornish. Marion Merrell Dow Research Institute, 2110 E. Galbraith Road, Cincinnati, OH 45252.

A dopaminergic bias within the glutamate/dopamine (DA) balance of the basal ganglia is believed to contribute to the symptoms of schizophrenia. The psychotomimetic MK-801, a channel blocker at the NMDA/cholinergic agonist receptor complex, is used to model this imbalance by reducing glutamate activation of NMDA receptors. Although MK-801 can produce its behavioral effects in monosodium-denervated animals, this occurs at higher doses than are necessary to elicit behavior in intact animals. MK-801 is also reported to increase the firing rate and bursting pattern of midbrain DA neurones. These observations suggest that increases in DA activity as well as decreased glutamatergic activity may contribute to the behavioral effects of MK-801. To further explore this question, MK-801 was administered to rats and its effect on DA release was determined in several brain regions using microdialysis in awake, freely moving rats. High doses of MK-801 (2 mg/kg, i.c.v.) caused a rapid increase in extracellular concentrations of DA in both the midbrain (VTA, SN) and the nucleus accumbens (NAS). DA concentrations reached 30% of basal levels in the NAS at 20 min after injection, and increased to approximately 150% in the NAS. Transmitter levels remained elevated for 3 h. Concentrations of the DA metabolite, homovanillic acid (HVA), also increased in all regions, suggesting that MK-801 also increased dopamine synthesis in both regions as assessed by DOPA metabolism prior to deacetylation inhibition. In contrast to the results in the NAS and VTA, striatal DA and its metabolites decreased following MK-801 administration. These observations are consistent with the hypothesis that alterations in DA activity contribute to the behavioral effects of MK-801. The results also suggest that the mesolimbic and mesostriatal DA systems differ significantly in their interaction with the NMDA glutamate system.

In our previous study, noradrenaline was found to be able to synergistically enhance glutamate induced intracellular free calcium ([Ca2+]i) increases in cultured visceral cortical neurons (Neurosci. Abst. 205.13,1993). To further address the mechanism underlying this interaction, we employed antagonists of receptor subtypes to investigate the cellular pathways responsible for the modifying effect. We found that the dose dependent glutamate induced calcium increase was blocked by 25 µM APV. It was interesting to find that this NMDA receptor antagonist also completely blocked the synergistic increase in [Ca2+]i, observed when noradrenaline and noradrenaline were coupled. This result indicates that the noradrenaline enhanced increase in calcium requires at least an initial activation of NMDA receptor channels. Further possible sources of calcium mobilisation include facilitated NMDA receptor channels, voltage gated calcium channels, internal calcium stores or any combination of these potential routes. We also tested three major subtypes of adrenergic receptors with respective antagonists, propranolol (B), phenolamine and yohimbine (Y). Since we were dealing with a mixed culture of cortical neurons, these antagonists showed varying effectiveness in blocking the synergistic increase induced by 10-5 individual neurons. Analyses of data obtained thus far indicate that propranolol is capable of blocking the synergism more completely on more cells than yohimbine. Phenolamine showed relatively weak effects. This implies that both AMPA and PI turnover pathways may be involved in the synergistic interaction between these two factors. Further studies being carried out by manipulating intracellular cascades that may be involved.

The distribution of myomodulin-like immunoreactivity in the leech CNS was determined using an antisem raised against Aplysia myomodulin (Miller et al., 1991). Numerous immunoreactive neurons were found in the nervous system. Also, immunoreactive varicosities were found throughout the neuropil. Two types of immunoreactive fiber bundles were observed in the connectives between ganglia and in the nerve roots. 1) fibers with smooth contours and 2) fibers with periodic swellings. Double-labeling experiments are in progress to identify the labeled neurons. Preliminary results suggest that myomodulin-like peptides are present in the anterior and posterior segments of the leech. Myomodulin-like peptides and the light/dark cell, components of the shortening reflex which can be modified by learning. Kuhlman et al., (1985) have previously demonstrated FMRF-like-reactivity in these cell types as well. Specific staining was abolished by preabsorption of antisem with synthetic myomodulin but not with FMRF-amide. It is likely, therefore, that these cells contain multiple neuropeptides. The immunostaining profile data are consistent with the presence of myomodulin in the leech CNS. Supported by R01MH44789.

HYPOTHYROIDISM IMPROVES THE STRESS RESPONSE AND MODIFIES ANXIETY BEHAVIOR IN RATS.
S. L. Aboud*, J. A. Lindsay, D. Brown, J. A. King, L. Feltien, C. Eckerl, and E. Edwards*

Learned Helplessness in the LH, an animal model that determines the response of rats to footshock stress, has been used to screen pharmacologic agents for use in depression. In addition to tricyclic antidepressives, low dose T3 administration and GABA-aminergic agents have been shown to inhibit the behavioral response in this paradigm. Low doses of T3 may actually cause brain hypothyroidism by decreasing pituitary secretion of thyrotopin, thereby inhibiting endogenous thyroid hormone secretion. We tested this hypothesis by making hypothyroid rats for LH. Hypothyroid rats had a 25% lower incidence of LH and a 20% increase in LH-resistant behavior compared to euthyroid controls (p<0.05). There were no differences in activity level by open-field tests, nor in escape distance or number of entries into the LH. Hypothyroid rats also displayed anxiolytic behavior relative to euthyroid rats in the elevated plus maze, a behavioral assessment of GABAergic activity, although on testing 1 month later, hypothyroid LH rats displayed anxiolytic activity. Hypothyroid rats did not display differences in GABA receptor sensitivity compared to euthyroid controls, as assessed by GABA, GABA receptor-mediated chloride ion influx. Euthyroid-LH-resistant rats did manifest an increase in GABA, receptor sensitivity compared to euthyroid LH controls. We conclude from these studies that hypothyroidism decreases the incidence of LH behavior, and the antidepressant activity of T3 may actually be due to its induction of secondary brain hypothyroidism. This effect may be mediated in part by a hypothyroidism-induced enhancement of GABAergic transmission by a mechanism other than GABA receptor sensitivity.

DOES SEASONAL VARIATION AFFECT RESULTS OF THE MIRRORED CHAMBER BEHAVIORAL ASSAY? S. J. Ciric and N. L. Katz*
Dept. Pharmacuetics and Pharmacodynamics, U. III. at Chicago, Chicago, IL 60612.

We studied several mirrored chambers described by Toubas et al. (Pharmacol. Biochem. Behav. 35: 121, 1990). The mirrored chamber test is a behavioral assay based on an approach-avoidance response when a mirror is placed into a mouse's environment. The sight of an animal reflected in the mirror is a source of anxiety presumably preventing entry into the chamber. In the present studies, male Balb/cByJ mice were used. Their ages, at the onset of the studies were 7-8 weeks. Each mouse was allowed to explore the chamber for 5 min. The time to first entry into the mirrored chamber (T), total time spent in the chamber (TT), and number of entries (NE) were quantitated. Control studies were run during the first 2 weeks of October (1993), first 2 weeks of December, first 2 weeks of February (1994), and last week of April. Latencies to enter were 182 (N=30), 102 (N=47), 107 (N=17), and 236 sec (N=10), respectively. In the winter months, results seemed heterogeneous and inconsistent, and base line (percent of animals entering the chamber) ranged from 50-75%. During this season, cholecystokinin tetrapeptide (CCK), in doses ranging from 3-30 mg/kg, produced a dose-dependent increase in T, and decreased both TT and NE. The CCK antagonist PD135158, 1 mg/kg, reversed CCK-induced changes in T and TT. PD135158 alone was without effect. Results obtained in April were most similar to those reported by Toubas et al. (1993). Diazepam, 1 mg/kg, decreased T, and increased TT and NE. PD135158 had no effect.

ESTABLISHMENT OF MELATONIN DISCRIMINATION IN PIGEONS. J. A. Stanley* and A. A. Ortiz
CNS Psychological Disorders, Bristol-Myers Squibb Company, Wallingford CT 06492.

Melatonin (5-methoxy-N-acetyltryptamine) is a pineal neurohormone that controls circadian patterns of behavior (e.g., sleeping, eating, drinking, and reproduction) in many species by modulating the “biological clock,” a cluster of cells found in the suprachiasmatic nucleus (SCN). In order to permit exploration of the functional effects of melatonin, pigeons were trained to use the interoceptive cue produced by peripheral administration of melatonin as a discriminative stimulus for differential responding using a drug discrimination procedure. Ten minutes before daily fifteen-minute sessions, White Carneau pigeons were given melatonin (0.2 or 0.56 mg/kg, i.m.) or vehicle (0.5% DMSO in normal saline) and placed in a darkened, two-key operant chamber. Responding on the appropriate key was reinforced (FR-30); whereas, responding on the non-reinforced key was time-out. Performance was monitored on the basis of more than resetting the FR value.

Pigeons learn to discriminate a systematically administered dose of melatonin from its vehicle at doses that have no effect on response rate. When doses of melatonin from 0.01 and 3.0 mg/kg, i.m., are substituted for the training dose (0.2 or 0.56 mg/kg, i.m.), the drug-key is selected even if there is no time-out performance on the other key.

In rats melatonin discrimination has been demonstrated only at doses which are sedative and more than 100 times those used in circadian rhythm studies. If the requisite sensitivity of the pigeon to melatonin, suggest the bird may be the subject of choice in discrimination studies investigating the effects of melatonin at doses comparable to those used in circadian rhythm studies.

EFFECTS OF THE CARBAMATE PESTICIDE CARBARYL ON THE REPEATED ACQUISITION OF RESPONSE SEQUENCES IN RATS. J. Croll and R. C. MacPhail*
Curriculum in Toxicology, UNC, Chapel Hill, NC 27514 EPA, Research Triangle Park, NC.

Carbaryl is a commonly used pesticide that inhibits acetylcholin-esterase. Cholinergic neurotransmission is known to play an important role in cognitive function. This experiment was therefore undertaken to determine the effects of acute carbaryl administration on the repeated acquisition of response sequences in rats. Repeated acquisition is a method by which learning can be continuously assessed in single subjects. Adult male Long- Evans rats, maintained at 300 g performed under a multiple schedule of RA and performance (P) in a standard operant chamber equipped with three response levers. The RA component required rats to learn a new 4-member sequence of responses during each experiment session (Center Right Left Right, RLCL, KCRL, etc.). The correct sequence of responses for the P component remained constant across sessions. Components alternated twice during a session. After baseline training, rats were given vehicle (5% Emulphor, 5% ethanol in saline), 3, 6, 7.5, 10 and 17.5 mg/kg carbaryl. Injections were given i.p. (1 ml/kg) 20 min preinjection, and no more than twice weekly. Significant decreases in both accuracy and response rate were produced by doses of 6.5 mg/kg and greater. Generally, results indicated that carbaryl’s effects on RA were non-specific in that both the RA and P components were equally affected. Some rats, however, exhibited specific effects of carbaryl on RA. Microanalysis of response patterning indicated that errors consisted primarily of pseudoreversals (skiing over errors) rather than perseverative responses on single levers.

“Dept. psychiatre, u. de Montreal, Montreal (Quebec) HAJ 1C5; Labo. phosphocin. moléc., CNRS 421, Strasbourg France.

Gamma-hydroxybutyrate (GHB) is an endogenous fatty acid recognized for its sedative-hypnotic effect. Since thermoregulatory mechanisms are bound to be involved in this effect, we measured central temperature before and after administration of GHB at various doses and we tested the newly synthesized GHB receptor antagonist, NCS-382. Body temperature was monitored by mean of a rectal probe; baseline readings were first taken, then each 15 min for the 1st hour following an i.p. injection of saline or GHB, and each hour thereafter. When NCS-382 was used, it was co-administered with GHB, at the same dose. Low GHB doses (10 mg/kg) were associated with increased temperature (max = +0.67°C, 45 min post injection) whereas hypothermia was observed from 20 to 252 mg/kg (max at 250 mg/kg = -0.95°C, 30 min post injection). NCS-382 blocked the hyperthermic effect of GHB 10mg/kg but not the hypothermia induced by GHB 250mg/kg. These results suggest that the pyrogenic effect of GHB is mediated by high affinity specific GHB receptors and that GHB-induced hypothermia involves a more complex mechanism. Supported by FRGS and CNRS.

RESTORATIVE EFFECTS OF FIBROLAST GROWTH FACTOR, GIVEN TEN DAYS AFTER FIBROMIA-FORNIX SEVERANCE, ON SPATIAL MEMORY IMPAIRMENT IN RATS. H. Amin*, N.Suzuki and H. Matsuzawa
Department of Chemical Pharmacology, Faculty of Pharmaceutical Sciences, The University of Tokyo, Tokyo 113, Japan.

Fibroblast (F-F) is a major collagenolytic afferent from medial septum to hippocampus, which is suggested to play a critical role in spatial learning. We have previously reported that both acute and chronic fibroblast growth factor (a bFGF) accelerated the acquisition and reversal learning in Y-maze test in naive rats. In the present study, we studied the effects of bFGF on spatial memory deficits induced by F-F lesion. Rats with a normal spatial learning ability had been selected, based on the results of Y-maze test. Guidance cannula were planted into bilateral coroebroventriculi, and F-F was severed at a blade at the same time. From 10 days after the operation, spatial learning performances of the rats were observed in Y-maze test, and subsequently in water maze test. FGFS (100-400 ng/rat, i.c.v.) were daily injected 30 min prior to each learning session. F-F lesion induced severe and long-lasting spatial memory deficits in Y-maze test (correct response: intact 96.5±8.2 %, lesioned 73.5±8.5 %) and in water maze test (escape latency: intact 9.4±1.5 sec, lesioned 65.5±18.1 sec). Both aFGF and bFGF significantly ameliorated the spatial memory deficits induced by F-F lesion in dose dependent manners(correct response: 400 ng of aFGF 85.4±6.0 %, 400 ng of bFGF 73.0±6.9 % escape latency: 400 ng of aFGF 11.0±1.2 sec, 400 ng of bFGF 12.8±1.2 sec). Reduction of hippocampal choline acetyltransferase activity caused by F-F lesion was not affected by the injection of aFGF and bFGF. In conclusion, we suggest that delayed administration of aFGF and bFGF improve the surgically induced spatial memory disorders without affecting the hippocampal cholinergic transmission. Further investigations would differentiate the long-term (neurotrophic) and short-term (neuromodulatory) actions of FGFS on learning and memory.
641.7 EFFECTS OF CHRONIC dDC ADMINISTRATION ON LOCOMOTOR ACTIVITY IN RATS. H.D. Davis, D.E. Morey, and N. E. Green. YDA, Antiviral Research Laboratory, Rockefeller, MD 20897. *Universities Service Center, University of the Health Sciences, Medical Psychology Department, Bethesda MD 20814.

Dideoxycytidine (ddC) has been used in the treatment of HIV infection. Unfortunately, the long-term use of ddC has been associated with an apparent peripheral neuropathy and debilitating pain in a subset of HIV patients. Recently, we reported on the value of a behavioral paradigm in rats to study the neurotoxicity of the nucleoside analog and found that locomotor activity was altered in a U-shaped dose-effect relationship following increasing doses of dDC (50) to rats. The present experiment examined the effects of chronic dDC administration (PO, 0.1-10.0 mg/ml in the drinking water) on the locomotor activity of female Sprague-Dawley rats. Activity was monitored for one hour each day for eight consecutive days during a period of continuous drug administration. Body weight, food and water consumption were also monitored. Exposure to dDC at 3.0-10.0 mg/ml concentrations resulted in a significant decrement in locomotor activity beginning with day 5 of exposure. While water consumption was reduced somewhat among animals in the high drug concentration group, this occurred during days 3-5 of exposure and was not correlated with the observed locomotor decrements. Body weight, food and water consumption among all other dose groups was indistinguishable from that of the control group. Chronic dDC thus revealed a pattern of behavioral toxicity that an acute paradigm could not detect. Implications of these findings for the neurotoxicity testing of drugs used in AIDS therapy will be discussed.

The methionine and tyrosine catabolites have been shown to mitigate the locomotor deficit that follows administration of ammonium radioprotective compounds. A likely mechanism of action for this effect is theophylline's antagonism of the adenosine (A) system. This study compared the effects of nonselective adenosine agonists (theophylline) with those of selective A2 receptor agonists (8-Cyclopentyl-1,3-dimethylxanthine, CPT) and A1 (3,7-Dimethyl-1-propargylxanthine, DMP) receptor antagonists (8-Cyclopentyl-1,3-dimethylxanthine). Locomotor activity (total distance travelled) was examined in naive CDF1 rats in an automated activity monitor for 12 hr postinjection. The effects of WR-151327 alone and in combination with adenosine agonists on locomotor activity were examined. WR-151327 (200 mg/kg, i.p.) alone significantly reduced activity from 30 min to 3 hr postinjection. The adenosine antagonists (20 mg/kg, i.p.) were each administered 30 min prior to WR-151327 (200 mg/kg, i.p.) at which time locomotor activity monitoring began. Compared with vehicle controls, theophylline alone significantly increased activity for 1 hr, and caffeine alone for 2 hr. CPT alone increased activity for 0.5 hr, and DMPX alone increased activity for 2 hr. When combined with WR-151327, theophylline reversed the deficit for 1 hr, while CPT failed to mitigate the deficit. These results provide evidence that the A2 adenosine receptor is important in mitigating WR-151327-induced locomotor activity decrements.

641.9 EVALUATION OF DOSE-RELATED EFFECTS OF D-CYCLOSERINE IN UNMEDIATED OBSESSIVE COMPULSIVE DISORDER PATIENTS. Barr LC, Bennett A, D’Souza DC, Price LH, Krystal A. Yale Univ Sch of Med, New Haven, CT 06519.

Functional neuramigating studies implicate orbital frontal cortex and caudate in the mediation of obsessive compulsive symptoms. As excitatory transmission within and from frontal cortex to striatum is prominent, the effects of D-cycloserine, a partial agonist at the glycine site of the NMDA receptorpar, were evaluated in the present study. Method: 11 unmedicated Obsessive Compulsive Disorder (OCID) patients (mean ± SD age: 39±6; 12 male, 5 female) received either a placebo, a 50 or 150 mg intravenous dose of D-cycloserine on three test days each repeated for 2 weeks. A 15 point scale was used to assess obsessions and compulsions. Possible effects of D-cycloserine on frontal and memory function were assessed via various tests: Hopkins Verbal Learning Test, Nonverbal Selective Reminding Test, Rey Taylor Complex Figure Test and a test of verbal fluency. Results: D-cycloserine has been shown to increase cortical in healthy subjects, cortisol was measured at baseline and following D-cycloserine. Data were analyzed using RM-ANOVA. Results: No dose or dose x time effects were identified for clinician or patient-rated obsessions and compulsions and no clinically apparent changes in symptom severity were observed. Neuropsychological testing also did not identify medication effects. Data comparing the hormonal response of these patients with healthy subjects will be presented. Conclusions: Putative facilitation of excitatory transmission produced by D-cycloserine may not markedly effect OC symptoms or neuropsychological deficits sometimes observed in these patients.

Disulfiram is the most commonly used treatment for alcoholism. Despite its established use, the research literature is sparse regarding the central neurochemical or behavioral toxicological effects of this important medication. We recently observed (Mueller, Husten, Matha, & Elper, 1994) that disulfiram on a marked inhibition in the biosynthesis of a-aminated peptides which persists for weeks after the cessation of treatment. More than half of the peptides used in intercellular communication are a-aminated and in nearly all cases this modification is required for receptor binding and biologic activity. The present experiment was designed to evaluate the effects of disulfiram administration on behavioral measures of locomotion (hot plate and tail flick), peripheral muscle performance (grip strength), motivated performance, balance, and coordination (rotorod), body weight; and pentylylglycine-N-hydroxylating monooxygenase (PHM) activity in the hypothalamus, neuro-intermediate lobe of the pituitary (NIL), adenohypophysis, and brain; and a-MSH levels in the neurohypophysis. Adult, male, Sprague-Dawley rats were treated daily for one week with disulfiram (50, 150 mg/kg, s.c) and were evaluated for two weeks after cessation of treatment. Disulfiram significantly increased hot plate response latencies, decreased grip strength, decreased rotorod performance, and decreased body weight in a dose-response manner. These effects persisted through the two week post-treatment period and paralleled the time course of the inhibition of PHM previously reported in addition, disulfiram significantly altered PHM activity in tissue samples from the NIL, and adenohypophysis, and a significant decrease in a-MSH. These findings indicate that disulfiram may have several untoward effects that are relevant to therapeutic use and warrant further investigation.

Acute exposure to cold stress has been reported to impair performance on a group of tasks, including an increase in the speed with which behavioral and neural operations occur. Exposure to a temperature of 2°C increases rate of responding on a time-based differential-reinforcement-of-low-rate (DRL) reinforcement schedule, without affecting attentional, sensory, or motor aspects. Administration of the amino acid, L-tyrosine, has been shown to improve behavioral impairments induced by exposure to cold. This present study examined the effects of tyrosine in rats performing on a DRL schedule that were exposed to a decrease in temperature. Prior to treatment, rats were trained to respond to a DRL schedule with a 120 s time-out for each trial. Following training, rats were divided into control and cold exposure groups (50/50). Cold exposure consisted of a 60 min cold exposure session, in which the temperature was maintained at 2°C for 60 min. Following the cold exposure, rats were tested on the DRL schedule for 1 hr. Rats that received no tyrosine (50mg/kg) exhibited a decrease in the number of responses made. Rats that received tyrosine (50mg/kg) prior to cold exposure, however, showed a significant increase in the number of responses made. This increase persisted for 2 hr following cold exposure, suggesting a rather direct effect of tyrosine on cold-stress impairment of DRL performance.

Two groups (N=10) received pairings of a distinctive environment, the laboratory, and administrations of 700 mg of the muscle relaxant carisoprodol (Carisoprodol, CP) and saline. CP pairings of the same environment with administrations of an inactive agent (Control group) for a total of three sessions, each spaced one week apart. The laboratory was hypothesized to constitute a conditioned stimulus (CS) for the drug unconditioned stimulus (US) in the Carisoprodol group. In the fourth session the Carisoprodol group received the inactive agent in the laboratory, and the Control group received carisoprodol in the laboratory. Dependent variables were blink reflexes and carisoprodol serum concentration. Results showed facilitated blink reflex amplitudes in the Carisoprodol group when an inactive agent was administered in the laboratory, which is opposite to the effects of carisoprodol. This indicates that a conditioned drug antagonistic response was elicited by the CS in this group. Moreover, blink reflex amplitudes were inhibited in the Control group when it received carisoprodol, indicating that an antagonistic response was not elicited in this group.

641.13

In the present study, rats (N=12) were trained to discriminate the voltage-gated potassium channel blocker 4-aminopyridine (4-AP) (1.0 mg/kg, i.p. or 1.7 mg/kg, i.v., 30 minute pretreatment) from saline in a two-drug discrimination procedure. Rats responded differentially on the left and right lever under a 3A response fixed-ratio schedule of food presentation depending on whether 4-AP or saline was administered. 4-AP served as a discriminative-stimulus in all the rats, showing dose-dependent (1.7 mg/kg) increases in drug lever responses up to the training dose. Administration of saline resulted in <1% drug lever responding. There was no effect on response rates for the rats with a training dose of 1.0 mg/kg, and a moderate dose-related decrease in response rate for rats with a training dose of 1.7 mg/kg. Once the discrimination was established, the discriminative-stimulus effects of 4-AP were compared to several known potassium channel blockers, a calcium channel blocker and an acetylcholinesterase inhibitor. The structurally related potassium channel blocker, 3,4 diaminopyridine (0.3 - 17.5 mg/kg) fully substituted at doses which moderately decreased response rate in 4 out of 4 rats trained at 1.0 mg/kg. 3,4 diaminopyridine did not substitute in 2 rats that were trained at 1.7 mg/kg. Other potassium channel blockers, including quinidine (30.0 - 100.0 mg/kg) and amiodarone (30.0 - 56.0 mg/kg), a C2+ channel opener, Bay K 8644 (0.3 - 1.0 mg/kg), and an acetylcholinesterase inhibitor, 9-amino-1,2,3,4-tetrahydroacridine (THA) (1.0 - 5.6 mg/kg), generally did not substitute up to doses that decreased response rate. The present results demonstrate that 4-AP can serve as a discriminative-stimulus in rats. In view of the substitution of 3,4 diaminopyridine, but not quinidine or amiodarone, the present results suggest that the discriminative-stimulus effects of 4-AP are mediated by a subset of voltage-gated potassium channels.

NEUROPEPTIDE-Y ALTERS THE ACQUISITION OF RESPONSE SEQUENCES IN RATS. L. Scholl and J. X. Thomas. Naval Medical Research Institute, Bethesda, MD 20889-5607.

Administration of neuropeptide-Y (NPY) has been shown to both improve and impair working memory as measured with a delayed matching-to-sample (DMS) procedure. The present study used a repeated acquisition (RA) procedure to investigate the effect of NPY (2.0 to 34.0 ug/kg, iv) on the acquisition of three-member response sequences in rats. Each incorrect response in this procedure results in a brief timeout from reinforcement. Sessions were divided into a learning and a performance phase by imposing a five-minute delay at the mid point. A biphasic response, followed by performance, was observed during control sessions. The average number of error responses was 29% during the last half and 15% during the 2nd half of each session. Administration of NPY resulted in improved performance at a dose of 8.6 ug/kg and markedly disrupted performance at a dose of 34.0 ug/kg. The last half vs. 2nd half incorrect responses at the 8.6 ug/kg dose were 316, while the same measures with the 34.0 ug/kg dose were 520 and 214, respectively. NPY resulted in no effect on performance. The RA procedure contains elements of both working and reference memory. Working memory is requisite for acquiring the novel sequence of lever press each day, while reference memory is invoked by the timeout stimulus. NPY administration altered both working and reference memory aspects of the procedure. These results are consistent with and extend the finding that NPY altered working memory in a DMS procedure.

HORSE SERUM BUTYRYLCHOLINESTERASE PROTECTS AGAINST MEPO-INDUCED RESPONSE SUPPRESSION IN RATS. R. Genovesi*, R. Larrion and B.P. Doctor. Division of Neuropsychiatry and Biochemistry, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

New therapies against organophosphorus (OP) toxicity have focused on the administration of enzyme "scavengers", in order to prevent deleterious effects by neutralizing the OP before target areas are affected. We examined the ability of horse serum butyrylcholinesterase (HS-BChe) to attenuate the effects of the OP, MEPQ, in rats trained to lever press under a variable interval 56 second schedule of food reinforcement. Under baseline conditions, the schedule produced consistent and relatively fast rates of responding throughout the 60 min sessions. MEPQ (32ug/kg, i.p (n=5)) produced complete or nearly complete response suppression in rats pretreated with vehicle. Rats treated with 7500 U HS-BChe (i.p. (n=5)) approximately 1h before MEPQ injection, however, responded at nearly 70% of control rates. Blood BChe activity was elevated in rats receiving HS-BChe (34.6 U/ml) as compared to rats receiving vehicle (0.8-1.6 U/ml), but decreased when measured 1h following MEPQ administration. These results demonstrate that administration of HS-BChe can attenuate the toxic effects of MEPQ, and merits consideration as a prophylactic therapy against OP exposure. These results also confirm and extend previous reports demonstrating that protection against OP toxicity can be conferred by a number of cholinesterases.

642.1

PERSISTENT ELEVATION OF VASOPRESSIN mRNA AFTER SALT-LOADING. M.D. Fitzsimmons*, M.M. Roberts, A.G. Robinson Department of Endocrinology, University of Pittsburgh, PA 15261

Based on computer modeling, we have suggested that pituitary vasopressin (AVP) levels depleted after chronic salt-loading recover to age-matched control levels simply by translating mRNA that accumulates during the period of salt-refeeding (AmPhysiol 262: R1121, Endocrinology 134:1874). The amount of mRNA needed for such recovery depends on the threshold for stimulation. But the smallest reasonable estimate would require a 4-fold increase over baseline. Experimental measurements in our lab with RNAase protection assay of whole hypothalamus show that increasing salt-loading increases AVP mRNA expression by only 1.5-2.5 times, a range consistent with other recent reports. These results might be interpreted to indicate that translational regulation plays a role in the regulated expression of pituitary vasopressin levels. Alternatively, mRNA may remain elevated after the stimulus is removed. Evidence from Zieg et al (J BiolChem 261:12956) and Arnaud et al (Neurocell Letters 149:177) supports the latter. We tested the impact of stimulatory duration on vasopressin mRNA levels after salt-loading. Both 3 days and 5 days of salt-loading result in a significant increase in mRNA vs. control (1.6-fold and 2.1-fold significantly greater, p<0.001), with 5 days being significantly greater (p<0.01). AVP mRNA showed no detectable decrease after two days of recovery in both the day 3 and the 5 day groups; the 3 day group remains elevated even 4 days after recovery (p<0.01). Plasma sodium levels in the salt-loaded groups increased significantly (p<0.001), but were not different from baseline in the recovered groups. These results demonstrate that the length of salt-loading affects the magnitude of AVP mRNA increases and that the post-stimulus elevation of mRNA is independent of stimulus duration. Whether the persistence of AVP mRNA is due to "membrane" in the transcriptional regulation of the gene or to increased mRNA stability will be determined with in vitro hybridization. In either case, the unexpectedly prolonged mRNA elevation probably contributes to the recovery of pituitary vasopressin content to age-matched levels after salt-loading.

642.2

Sustained hyposomorality enhances the abundance of OT and AVP mRNAs in the rat hypothalamus. Gonadal steroids modify this response. Gonadectomy prevents, and gonadal steroids restores, OT and AVP expression to osmotically-challenged male. OT gene is influenced by other hormones, including thyroid hormone(T4). We questioned whether T4 deficiency may also alter OT and AVP mRNA abundance in the paraventricular nucleus (PVN) of the osmotically-challenged rat. Male Sprague-Dawley rats (7 wks of age) were sham thyroidectomized (sham TX) or TX, given T4 on an osmotically-challenging diet, and then later with empty (TX+sham) or T4-added (TX+T4) capsules, randomized to 2% NaCl solution or tap H2O for 5-10 days and sacrificed at the end of the NaCl challenge. Serum T4 levels were significantly lower in the TX vs. sham TX and TX-T4 groups (p<.0001). All NaCl groups developed hyperammonia and depleted pituitary stores of AVP. Northern blot hybridization showed that salt loading increased PVN OT and AVP mRNAs in all groups compared to their respective tap H2O controls. In contrast to the effect of gonadectomy, hypothyroidism does not alter osmotically-stimulated-accumulation of OT and AVP mRNAs in the rat PVN.
643.3

BCI RNA IN THE RAT POSTERIOR PITUITARY: AXONAL LOCALIZATION AND REGULATION UPON DEHYDRATION AND REHYDRATION. A. Zhrebchev* and F. E. Bloom. Department of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Brain cytoplast (BCI) RNA, a small non-translation RNA-polymerease III transcript, has recently been found in the posterior pituitary (PP) using a low resolution radioactive in situ hybridization (ISH) approach, and it has been hypothesized that this transcription might be autoregulated (Snedeker et al., Cell, 1989; Tisdale et al., J. Neurosci., 13:4214-4219, 1993). In the present study, we aimed to determine whether BCI was truly located within axons, rather than in the glial cells of the PP, and further to examine the possible regulation of this RNA upon dehydration (chronic salt-loading, providing 2% of NaCl as exclusive source of water for 3, 5, and 7 days) and rehydration (return to regular water beginning after day 7 of salt-loading, for 1, 2, 3, or 4 days). A BCI Northern blot assay, we were able to detect BCI RNA in both the anterior and neurointermediate lobes of the pituitary. Non-radioactive ISH of BCI RNA performed on PP at both the light and electron microscopic levels revealed that BCI RNA was axonally compartmentalized. Using a semi-quantitative ISH approach, we have measured and compared the changes in BCI RNA and vasopressin (VP) mRNA during dehydration and rehydration. During dehydration, BCI RNA was significantly increased, but it already reached a maximum at day 3 of salt-loading, while VP mRNA was more progressively increased during the full period of salt-loading, peaking at day 7. The increase in BCI RNA labeling (2-5 fold) was however modest compared to the increase in VP mRNA labeling (around 1-11 fold). Upon the rehydration, the BCI RNA content in the PP was reversed to control value as early as 1 day after the onset of rehydration, while VP mRNA slowly decreased to reach the control value at day 7. In conclusion, like VP mRNA, BCI RNA is transported in axons of the hypothalmo-neurohypophysial system, and its axonal transport is similarly regulated. Therefore, we propose that BCI RNA might be involved in either the axonal targeting and/or transport of VP and other axonal mRNAs.

Testosterone (T) Enhances Vasopressin Messenger Ribonucleic Acid (AVP messenger) Abundance in the Hypothalamus of Osmosomatically-Stimulated Female Rats. J.A. D'Kraeke*, N.B. Kim, and A. Amico. Dept of Medicine, University of Pittsburgh School of Medicine and VA Medical Center, Pittsburgh, PA 15261.

Gonadectomy (gdx) prevents enhanced accumulation of AVP mRNA in the hypothalamic paraventricular nucleus (SON) of osmotically-challenged male and female rats and T and dihydrotestosterone (DHT) restore this response in the male rat (Soc. N.S. Abs. 530:2:1280, 1993). We questioned whether AVP mRNA in the SON of osmotically-stimulated rats display a sexually dimorphic response to gonadal steroid replacement. We examined the effects of various gonadal steroid replacement regimens upon AVP mRNA accumulation in the SON of osmotically-stimulated female rats. Female rats were gdx or sham gdx (intact) and implanted with sham, T or estradiol (E2) capsules and randomized to either 2% NaCl solution or tap H2O x 5 days. NaCl groups lost weight, developed hypernatremia and depleased their pituitary stores of AVP compared to tap H2O groups (p<0.05, Fisher's LSD). Gdx-T and gdx-E2 treated animals had mean T and E2 concentrations of 1.5 ng/ml and 60 pg/ml, respectively. Intact and gdsx-T-replaced rats, but not gdx or gdx-E2, rats receiving 2% NaCl increased hypothalamic AVP mRNA accumulation compared to respective tap H2O controls (p<0.05, Scheffe F-test). The data suggest that similar to male rats, T, but not E2, modulates AVP mRNA accumulation in the SON of osmotically-challenged female rats.

645.6

The distribution of AVT containing neurons in quail brain has been studied in detail by immunocytochemistry (ICC). However no data are available for this species on the gene level. Up to now the chicken represents the only avian species in which AVT gene expression has been examined using cDNA probes. Thus we have used a gene probe directed to the 5' part of the AVT mRNA in order to detect the distributions of AVT expressing neurons in chicken and quail brain. Northern and Southern analysis demonstrated the specificity of this probe for quail AVT mRNA. 32nds thick cyrosection from chicken and quail brain were collected on different slides then adjacent slices. Consecutive were fixed by 4% paraformaldehyde and processed for in situ hybridization (ISH) and ICC respectively. The results indicate a common pattern in the distribution of AVT neurons containing mRNA and the peptide. In particular a wide distribution of perikarya was observed close to the pial surface of the preoptic region (lateral or supraoptic division), in the periventricular hypothalamic region (paraventricular nucleus) and scattered along the lateral forebrain bundle. Few neurons were observed by the ICC in circumventricular areas. Quail and chicken AVT mRNA expressing neurons showed a common pattern of distribution, confirming the suitability of the probe. Considerably more AVT expressing neurons were detected in the hypothalamus of the chicken if compared to the quail. Furthermore the hybridisation signal was more intense in the brain of chicken than in quail. In conclusion our studies show that 1) the probe we used is suitable to investigate AVT gene expression in quail, 2) the localization of AVT neurons is comparable between chicken and quail, 3) the basal activity of the AVT system in chicken is higher than that in quail. Supported by grants of CNR. N.A. was granted by a ENP short term fellowship.

AP-1 DNA BINDING ACTIVITY INDUCED BY HYPEROSMOLALITY IN THE RAT HYPOTHALAMIC SUPRAOPTIC AND PARAVENTRICULAR NUCLEI. C. Ying*, D. Reisman, and J. Buggsy. Deps. of Physiology and Biological Science, University of South Carolina, Columbia, SC 29208.

The immediate early gene (IEG) c-fos is induced upon hyperosmotic stimulation in the paraventricular (PVN) and supraoptic (SON) hypothalamic magnocellular nuclei. AP-1 DNA binding activity was examined in these brain regions since Fos acts as a transcription factor in other systems by binding to the AP-1 site on DNA to influence gene transcription. Rats were given hypertonic saline injection (i.p.) and nuclear proteins were extracted from PVN and SON tissue punches 2 hrs later to assess AP-1 binding activity using an electrophoretic mobility-shift assay and a labeled oligonucleotide containing the AP-1 consensus sequence. Hyperosmolality induced AP-1 DNA binding in both PVN and SON; this binding was competitively displaced by excess unlabeled IEG. The binding of proteins to the AP-1 element was specific to AP-1 consensus binding sites utilizing competitor DNAs such as SP-1. Thus, AP-1 binding activity in nuclear extracts from the SON and PVN was induced after hyperosmolality suggesting that dehydration-induced IEG expression results in protein products that may function in the regulation of target gene expression.

EVIDENCE FOR A FUNCTIONAL PROJECTION TO THE LATERAL HYPOTHALAMUS FROM THE MEDIAN PREOPTIC NUCLEUS AND SUBHYPOTHALAMIC ORGAN IN THE RAT. A.B. Kelly* & A.G. Wang. NIH Program and Department of Biological Sciences, UIC, Los Angeles, CA 90086-2200.

We have previously reported increased levels of CRH mRNA in the lateral hypothalamic area (LHA) in response to cellular dehydration caused by increased plasma osmolality. We have now combined tracer and hybridization in an attempt to identify those neurons responsible for this response. Following isotopomers of fluorescent (FG) into the LHA we identified retrogradely labeled somata of a number of cell groups, including the subfornical organ (SFO), median preoptic nucleus (MP0), bed nucleus of the stria terminalis, preoptic area, and other forebrain regions. We then combined FG retrograde tracing from the LHA with a c-fos antiserum that detects the expression of the c-fos proto-oncogene in hyperosmotic conditions. This interaction of FG-labeled cells with c-fos mRNA in LHA revealed hybridization in an attempt to identify those neurons responsible for this response. Following isotopomers of fluorescent (FG) into the LHA we identified retrogradely labeled somata of a number of cell groups, including the subfornical organ (SFO), median preoptic nucleus (MP0), bed nucleus of the stria terminalis, preoptic area, and other forebrain regions. We then combined FG retrograde tracing from the LHA with a c-fos antiserum that detects the expression of the c-fos proto-oncogene in hyperosmotic conditions. This interaction of FG-labeled cells with c-fos mRNA in LHA revealed hybridization in an attempt to identify those neurons responsible for this response.

SEPTAL VASOPRESSIN AND OSMOTIC REGULATION. I. Zhang*, C. Hopkins*, G. de Yates. Dept. of Psychology, Prog. in Neurosci. & Behav., Univ. of Massachusetts, Amherst, MA 01003; & Dept. of Psychology, Smith College, Northampton, MA 01060.

Sepal areas have been found to play an important role in the regulation of water intake and vasopressin (AVP) neurosecretion. Several studies have suggested that the AVP insertion of the septal may play a role in this regulation. In dogs, intraventricular injections of AVP lowered the hyperosmotic thirst threshold whereas injections of AVP antagonist raised it. In rats, hyperosmotic and hypovolemic stimuli decreased AVP content in the lateral septum, and increased AVP release from this area. AVP-immunoreactive fibers in the lateral septum (LS) arise from the bed nucleus of the stria terminalis and medial amygdaloid nucleus. AVP expression in these nuclei depends on the presence of gonadal steroids. If the AVP innervation of the lateral septum is indeed involved in water intake, one would predict that this function is influenced by gonadal steroids. Here we showed that this is the case. We found that when challenged with the same amount of hypertonic saline, injected intraperitoneally, castrated male rats drank less than intact rats and castrated rats treated with testosterone did. AVP injections into the lateral septum of castrated rats partly restored the amount of water intake. AVP injections into the lateral septum of intact rats increased, and AVP antagonist injections decreased, water intake in response to hypertonic saline. We also found that hypertonic saline injections increased c-fos and egr-1 expression in lateral septum neurons as well as in neurosecretory AVP neurons in the paraventricular and supraoptic nucleus.

This increase was more pronounced in intact than in castrated rats suggesting that the septum may also mediate steroid effects on AVP neurosecretion.

Fos and Jun, protein products of the immediate early genes c-fos and c-jun, form a heterodimeric complex that affects the transcription of genes containing AP-1 and CRE DNA-binding sites. Using a double-label immunofluorescence method (C&L & Tissue Research, 1994, 276:1-6), we detected Fos/Jun immunoreactivity in the hypothalamic nuclei in the appearance Fos and Jun in the nuclei of SON neurons. Cell counts of immunostained sections demonstrated the co-exist and appearance of Fos and Jun occurred within 30 min (20%), peaked at 90-120 min (80%) and gradually disappeared by 4 hr (13%) after injection. At 4 hr post injection, 5 rats each received a second injection of normal or hypertonic saline. A second injection of normal saline resulted in no Fos/Jun immunostaining 90 min later, while hypertonic saline induced Fos/Jun staining in only 17% of SON neurons. Of the remaining SON cells, 23% had staining to Fos alone and 4% of the cells stained for Jun. These results indicate SON neurons, after a second hypertonic saline injection, exhibit decreased colocalized Fos/Jun immunostaining, dramatically decreased Jun expression, and substantial, but attenuated, immunostaining for Fos. Supported by grants NIH NS25913 and USUHS RO1S to JT.

This study was to evaluate adaptation of the brain to hyponatremia in a gender of function. Brain adaptation to vasopressin (AVP)-induced hyponatremia was studied in adult male and female cats and rabbits during 3 hours or 4 days of hyponatremia, which was induced by subcutaneous AVP and 140 mM glucose/H2O. Changes in cerebral blood flow were evaluated using contrast- enhanced high speed echo-planar MRI, using bolus IV administration of a magnetic susceptibility contrast agent (Gd(DTPA)-BMA). An index of cerebral perfusion (CPI) was obtained as a reciprocal of the width of the contrast transverse. Water, sodium and potassium content were assessed in brain gray matter of both cats and rabbits. Acute hyponatremia (2-4 h; serum sodium fell from 155±3 to 127±3 mmol/L) resulted in a significant prolongation of contrast transit time through the brains of both male and female cats: CPI decreased from 0.24±0·02 sec−1 to 0.14±0·02 sec−1 in males and 0.15±0·02 sec−1 in females. Adaptation was gender dependent: brain (gray matter) water content increased from 391±8% to 434±5% in females and 415±3% in males (p=0.001 vs control), and hyponeptic females had greater than males (p=0·02). A gender dependent decrease of brain sodium was found, from 271±13 mmol/kg dry tissue to 222±2 in males (p=0·005) and to 233±5 in females (p=0·035). In rabbits, serum sodium was decreased from 142±1 to 122±2 mmol/L over 4 days. Brain water increased from 423±13% to 492±27% in females (p<0·01) and 432±27% in males (p<0·01). Brain sodium fell from 318±6 to 294±8 mmol/kg dry wt in males (p<0·01) but was unaffected in females. Brain potassium did not change. Brain swelling, however, was significantly less in hyponeptic males than in females in both species. Better adaptation of brain to hyponatremia in males of 2 species, and decreased cerebral perfusion, appears to be related to interaction between AVP and sex steroid hormones.

VENTRAL FOREBRAIN RELAYS SALT INPUT FROM GUT TO VASOPRESSIN NEURONS. Y. Shin, M. King and A.J. Gaertner*. Physiology Dept., Univ. of Virginia, Charlottesville, VA 22908, and Stetson College, FLA.

Gastric hypertonic saline infusions (600 mg/kg, 2.5mI) elicit vasopressin (AVP) release in conscious rats via neuroregulatory pathways ascending from Rf/R2 (Brain Res, 380:181-91,1992). Microinjections of 5DHA (4µg/400nl) into magnocellular hypothalamic nucleus, caudal DBH. The 5DHA lesions were from 0.5 mm to 2.02±0·45 mg/ml (p<0·01). Electrolyte lesions in the hypothalamic nuclei decreased mean AVP from 2.02±0·45 mg/ml (p=0·07). Electrolyte lesions in the hypothalamic nuclei decreased mean AVP from 2.02±0.45 mg/ml (p<0.01). These results suggest that salt signaling by the gut is mediated by neuroregulatory mechanisms ascending probably via MFB to ventral forebrain, and via non-catecholaminergic fibres descending to the vasopressinergic nuclei (support: NIH N27644).

Neurons within the OVLT and MnPo have been implicated to play a key role in osmoregulation. To determine whether they are intrinsically sensitive to hypertonicity, patch clamp recordings were obtained from cells acutely dissociated from these regions as described by Ollot and Bourque (J. Physiol. 445, 1992). Neurons were plated on petri dishes and superfused with a HEPES-buffered medium. Recordings were obtained from phase-bright somata with mean cross-sectional diameters ranging from 22 µm. Hypertonic stimuli (+10 to +30 mM Mannitol) caused a reversible and reproducible increase in the mean firing rate in 2 of 5 MNp and 9 of 14 OVLT cells tested. These effects were associated with a membrane depolarization of 32 mV and decrease in input resistance (n=14). Analysis of voltage-current relationships obtained before and during the osmotically-evoked depolarization revealed a reversal potential near -45 mV. Furthermore, the EcL was -108 mV, suggesting the possible involvement of calcium currents. These results demonstrate that some neurons within the OVLT and MnPo are intrinsically sensitive to hypertonicity. Supported by the MRC and the Heart & Stroke Foundation of Canada.

The release of neurohypophysial hormones from supraoptic neuron terminals is regulated by plasma osmolality. Recent biophysical studies in our laboratory have suggested a role for mechanosensitive cationic channels in the sensitivity of supraoptic neurons to changes in external osmotic pressure. The involvement of such channels in osmoreception was assessed by the use of gadolinium (Gd^3+), a divalent cation known to block different types of stretch-sensitive cationic channels. Whole-cell recordings obtained from isolated rat supraoptic neurons revealed a marked reduction of hyperosmotically-mediated membrane depolarization and firing rate increase in presence of Gd^3+ (100µM, n=4). In voltage-clamp mode (I=10), bath-applied Gd^3+ induced a reversible and dose-dependent inhibition (IC50=20µM) of the inward current elicited at -60mV by hypertonic stimulation. This inhibition resulted from specific suppression of the cationic conductance which was previously shown to be associated with osmotic responses (E<sub>H</sub>=+40mV). In cell-attached experiments (n=15), Gd^3+ was also able to block mechanosensitive cationic channels when included or perfused in the recording pipette. These results confirm a role for mechanically-gated channels in the endogenous osmosensitivity of rat supraoptic neurons.

ENHANCED VASOPRESSIN AND BEHAVIORAL RESPONSE TO METHYLPHENIDATE IN SCHIZOPHRENIC'S WITH WATER INTOXICATION M.B. Goldman, D.J. Lachina and G.L. Robertson Illinois State Psychiatric Institute, University of Chicago Pritzker School of Medicine, Chicago IL, 64675.

Water intoxication accounts for about 20% of deaths in non-geriatric schizophrenics. This episodic disorder is associated with intraseat impairments in water excretion which occur during exacerbations of psychosis. Many other schizophrenics remain normonatremic during such exacerbations, even if they are polydipsic. We administered the psychomimetic, methylphenidate (0.5 mg/kg intravenously) to concurrent schizophrenics with and without a previous history of water intoxication, in order to further examine the relationship of psychosis to water imbalance.

Baseline AVP was maximally suppressed in both groups, but peak post-methylphenidate levels were greater in time - 15 min. (M±SD) 1.9 ± 0.7 pg/ml vs control (1.0 ± 0.7, t = 2.21 df = 12 p < 0.05) subjects, despite lower plasma osmolality in the former (T = 278 ± 1.5 mosm/Kg, C = 288 ± 1.5). AVP stimuli (e.g. nausea, abdominal discomfort, hypotension) were not present in any subjects, and parameters influencing AVP release were similar in both groups over the two hours post-methylphenidate. Desire for water was also similar and did not change. Positive symptoms of psychoses increased, and negative symptoms diminished, equivalently in the two groups. Test subjects, however, were more psychotic and showed a greater increase in other psychotic symptoms.

Methylphenidate causes greater AVP secretion and behavioral activation in schizophrenics with episodic water intoxication. These findings strengthen the link between psychotic exacerbations and vasopressin secretion, and suggest the former is not necessarily a consequence of hyponatremia, per se. Differences in limbic pathology between schizophrenics could account for the findings.

SOMATIC AND VISCERAL AFFERENTS: NOCICEPTION

643.1

In contrast to myelin-forming Schwann cells, little is known about the factors regulating Schwann cells that do not elaborate myelin sheaths. These non-myelin-forming Schwann cells co-express several surface proteins and intermediate filaments, including glial fibrillary acidic protein (GFAP), not found in myelin-forming Schwann cells. These non-myelin-forming Schwann cells are physiologically important in that they ensheath the peptide-containing sensory C-fibers, and thus may indirectly regulate the transmission of nociceptive information and the inflammatory response in which unmyelinated C-fibers are involved. In the present study we have used combined receptor autoradiography and homogenate receptor binding methods to demonstrate that the same non-myelin-forming Schwann cells that are GFAP+ also express high concentrations of [125I]Endothelin receptor binding sites. Pharmacological analysis suggests that these binding sites correspond to Endothelin-B receptors. These results suggest a mechanism by which a circulating factor such as endothelin may specifically, yet indirectly, affect the population of non-myelinated primary afferents that are hyperalgesic to be involved in transmitting chronic pain and in regulating the inflammatory response in peripheral tissues. (Supported by the NIH and VA).

Noradrenaline has been shown to modulate some trigeminal and dorsal root ganglion (DRG) neurons, but the nature of noradrenaline actions and the adrenergic receptor subtype(s) mediating these effects have not been explored fully. Quantitative receptor autoradiography and homogenate receptor binding was used to locate and characterize the adrenergic receptor binding sites expressed by the cells comprising the trigeminal and dorsal root ganglia in the rabbit, rabbit, and monkey. [3H]-HEAT was used to label the a<sub>1</sub> binding sites, [3H]-Iodo-cocclodine was used to label the a<sub>2</sub> binding sites, and [3H]-cyanopindolol was used to label the b, and b<sub>2</sub> binding sites. In the rat, rabbit, and monkey DRGs a high concentration of b<sub>2</sub> adrenergic receptor binding sites were observed, with moderate concentrations of a<sub>1</sub> binding sites and low but detectable concentrations of a<sub>2</sub> and b<sub>1</sub> receptor binding sites. Within the DRG, specific binding sites corresponding to all 4 subtypes of adrenergic receptors were associated with neurons and the supporting cells, fibroblasts or endothelial cells. That all 4 adrenergic receptors are expressed primarily by neurons is supported by the observation that after double ligation of the sciatic nerve, build up of adrenergic receptors and the affinity of these adrenergic receptors are appropriately positioned to presynaptically modulate primary afferent neurons. (Supported by the NIH and VA).
Role of a Slow Ca\textsuperscript{2+}-dependent Afterhyperpolarization in Protaglandin E\textsubscript{2}–Induced Sensitization of Cultured Rat Sensory Neurons. Michael S. Gold\textsuperscript{a}, Michael J. Shuster, Shahrab Dastmalchi\textsuperscript{a} and Jon D. Levine\textsuperscript{b}, Departments of Medicine and Oral Surgery, and Division of Neurosurgery, UCSP, Box 05745, San Francisco, CA 94141

To determine if inhibition of a slow (<1 sec) Ca\textsuperscript{2+}–dependent afterhyperpolarization (sAHP) in Protaglandin E\textsubscript{2} (PGE\textsubscript{2})–induced sensitization of dorsal root ganglion (DRG) neurons, we have used patch-clamp electrophysiological techniques on cultured DRG neurons from calves for a role of the sAHP in sensitization of DRG neurons, we demonstrate that: 1) sAHP expression is reduced to 30% of control in these neurons (21% of all cells studied) which also express properties associated with nociceptors, including small cell body size, a shoulder on the falling phase of the action potential (AP), and a rapid depolarization in response to capaci

PHOSPHOLIPASE A\textsubscript{2}, INDUCED ELECTROPHYSIOLOGICAL CHANGES IN RABBIT LUMBAR FACET JOINT CAPSULA. DC QUANTZ, F KALLBERG, S VAIDYANATHAN, OR LI, DC BLACQUEY, JR CAYANNAK, AT KING, Bioengineering Center, Wayne State University, Detroit, MI 48202.

The aim of this study was to investigate the histological and electrophysiological effects of phospholipase A\textsubscript{2} (PLA\textsubscript{2}) injected in the lumbar facet joint capsule. In rats, the rabbit facet joint capsule was mechanically searched for receptive fields. The units were characterized by spontaneous discharges and mechanical thresholds. 750 or 1500 U of PLA\textsubscript{2} (i.e., 15% or 50% of the buffer) were injected into the receptive field. The threshold and unit activity were recorded for later computer analysis. At the end of the experiment, the animal was histologically examined with H&E staining. REDUCTIONS 1500 U PLA\textsubscript{2}, injections (n=4): a) At 30 min, a significant decrease in amplitude (30%) was observed; b) Group II units (n=3); SDR was significantly decreased and all units disappeared between 40 and 45 min. If the SDR reached a discharge rate of 20/5 and disappeared at 7 min. 750 U PLA\textsubscript{2}, injections (n=4): a) Multi-unit SDR was decreased at 30 min. After 20 min SDR did not increase in response to 100 μl of saline (n=4) did not show any significant changes. There were also no histological changes observed in any of the tissue injections. Supported by NIH Grant RR-01933.

Substantial changes can be observed in A-delta mechanical nociceptors following injection of carrageenan (Cooper et al., 1991). This includes changes in both reactive range and mean discharge rate. It is unclear whether proinflammatory (PI) mediators make distinct contributions to sensitization. These studies examined the qualitative and temporal features of sensitization that follow bradykinin (BK), serotonin (5HT), and prostaglandins (PGE1, or PGE2). Using a force-servo stimulator, nociceptor reactivity was assessed at 5, 30, and 60 minute intervals after injection of PI agents.

Significant decreases in discharge range were observed following BK or 5HT. Changes in range were complementary, with BK producing effects within the first 5 minutes while significant effects of 5HT were delayed to the 30 and 60 minute test intervals. Neither BK or 5HT produced changes in mean discharge rate. In contrast, injections of PGE's produced delayed changes in rate of discharge (60 min) but no significant changes in reactive range. It was concluded that BK, 5HT, and PGE's made distinct and temporary contributions to mechanical sensitization. Supported by NIH DE8701.

AMPA AND NMDA RECEPTOR-IMMUNEACTIVITY POSTSYNAPTIC TO PRIMARY AFFERENT TERMINALS IN THE SUPERFICIAL CAT SPINAL CORD. E.I. Alveros*, D. Harrington and R.E.W. Price, Dept of Anatomy, Wright State University, Dayton, OH, 45435.

Primary afferent terminals believed to use excitatory amino acids (EAA) as their principal "fast" neurotransmitters. There is potential for great functional variability at EAA-synapses because of the diversity of EAA-receptor subtypes that can be expressed, details of subunit diversity are largely unknown for individual synapses. A promising approach is to use antibodies (Abs) against different subunits to probe the selectivity of postsynaptic responses using electron microscopy immunocytochemical techniques. Here, we used Abs directed against epitopes found in the GLUR2 and 3 subunits of the AMPA receptor (Chemicon) and the NR1A subunit of the NMDA receptor (Pharmacia) to detect these subunits in the superficial laminae of the cat spinal cord. The Abs labeled many postsynaptic sites and also the cytoplasm of cell somas and dendrites. All three kinds of known central glomerular types (presumed primary afferent origin) were associated with postsynaptic immunoreactivity (ir) to GLUR2/3 and NMDAR1. Interestingly, within a single glomerular terminal less than half of the synapses were postsynaptic to the postsynaptic profiles displayed cytoplasmic ir. Our results provide immunocytochemical proof supporting the assertion that most classes of primary afferents arborizing throughout laminae I to III use AMPA and NMDA receptors to elicit postsynaptic effects, but intriguingly the Abs did not universally label all primary afferent synapses despite our efforts to increase detection sensitivity to a maximum. It remains to be determined if these results are due to the presence of different subunit types, subtype isoforms, variable conformations, or posttranslational modifications modifying a primary afferent terminal.

Hyperalgesia to mechanical but not heat stimuli occurs in the uninjured skin surrounding the glabrous head (Raja et al., Brain Res. 1984). In the present study, we investigated whether secondary hyperalgesia is produced by capsaicin injected into the hairy skin. Heat and mechanical testing was done twice before, and 20 and 60 min after an intradermal injection of capsaicin (50g in 10µl) to the volar forearm of 12 volunteers. A 9 bar Von Frey filament was used to map the zone of hyperalgesia to punctate mechanical stimuli after the capsaicin injection. Our laser thermal stimulator was used for heat testing at multiple sites inside and outside the mechanical hyperalgesic zone plus the site of capsaicin injection. Subjects pressed a key to indicate heat pain threshold to a ramped (1°C/sec) heat stimulus (39 to 46°C). Subjects used a visual analog scale to rate pain to intense heat (44, 46 & 48°C, 1 or 2 duration). Sixty minutes after the capsaicin injection, pronounced secondary hyperalgesia to mechanical stimuli was present, but heat pain threshold was significantly higher (P < 0.01) and suprathreshold ratings were significantly lower (30 to 9) at the capsaicin injection site. Similar results were obtained in 5 other subjects tested with contact heat. These results suggest that secondary hyperalgesia is produced by hyperalgesia to mechanical but not to heat stimuli. Supported by NIH (NS-14447).

INTERLEUKIN-2 AND CYTOSOMATIC C POLYMOLAL NOCICEPTORS: DOSE-RESPONSE RELATION, TACHYPHYLAXY AND LACK OF SYNERGY WITH PROSTAGLANDIN F1A. I. Marini-Di Pasquale, Division of Neurology, Section of Neurosurgery, Medical School, The University of Newcastle upon Tyne, NE1 4HH, U.K.

In a previous study, we have shown that interleukin-2 (IL-2; 0.06 U/ml) activates both a third of cutaneous C-polymodal nociceptors and, more rarely, other classes of nociceptors. In the present study, we have investigated whether (i) the percentage and the response characteristics (i.e., latency, intensity, duration and pattern of discharge) of activated units are dose dependent, (ii) PGF induces a sensitization to IL-2.

Activity of single nociceptors was recorded in vivo with saphenous nerve preparations, in sedated anesthetized rats.

(i) Increasing doses of IL-2 (2, 4, 10, 20, 40 U/ml) were injected in the receptive field of 28 C-polymodal nociceptors and 6 mechanonociceptors (4 C and 2 Aa). Only 8 polymodal nociceptors were activated (28.5%). This activation appeared at 4.3 U/ml and became stronger with higher doses.

(ii) 14 C-polymodal nociceptors and 5 C-mechanoniccceptors were initially treated with PGE1 (100 ng/ml). Only 4 polymodal (28.5%) were activated by IL-2 (0.06 U/ml) and their response characteristics were unchanged, compared to control. Also, tachyphylaxis to subsequent injections of IL-2 (0.06 U/ml was unaffected by PI).

In conclusion, pruritus produced by high doses of IL-2 in the treatment of advanced cancer may result from the selective activation of a fraction of C-polymodal nociceptors, chemosensitive to this cytokine. The failure for PGF1 to enhance the chemosensitivity to IL-2 may explain the inefficiency of steroids in the treatment of such pruritus.

Most C-fiber nociceptors are polymodal and are excited by mechanical, heat and chemical stimuli. Few studies, however, have quantitatively examined responses of these nociceptors to noxious cold. It has been reported, using stimuli above 0°C, that a relatively small proportion of nociceptors are excited by noxious cold. We have reported that all Aδ nociceptors in rats are excited by noxious cold and most had response thresholds below 0°C. In the present study, cold stimuli were used to characterize responses of C-fiber nociceptors to a wide range of stimulus temperatures. Electrophysiological recordings were made from the sphenopalatine ganglion of anesthetized rats. Nociceptors were searched for by mildly pinching the skin. Once a nociceptor was identified and its receptive field mapped, conduction velocity, mechanical threshold and responses to thermal stimuli were determined. A total of 12 C nociceptors were studied. Mechanical thresholds (via Frey monofilaments) ranged from 0.63-6.3 ml. 8 of 12 nociceptors were excited by noxious heat and had a mean threshold of 44.3° ± 1.7°C. All nociceptors were excited by noxious cold. The mean response threshold was 2.8° ± 4.01°C. and thresholds ranged from 30° to 14°C. Approximately 50% of the nociceptors studied (5 of 12) had response thresholds at or above 0°C, while 7 of 12 were excited with stimulus temperatures below 0°C. Responses evoked by cold stimuli usually increased with stimulus intensity (lower stimulus temperatures).

It is concluded that unlike Ad "mechanonociceptors", C-fiber "mechanonociceptors" are excited by noxious cold stimuli. Responses of Ad and C nociceptors to cold differ in that a greater proportion of C nociceptors are excited by stimulus temperatures above 0°C (approximately 50% of C nociceptors; 10% of Ad nociceptors). Supported by NIH grants NS29567 and NS31223.

TEMPORAL CHARACTERISTICS OF ORAL TRIGEMINAL ACID SENSITIVITY. Bruce P. Bray* and Paul A. Moore, Monell Chemical Senses Center, 1500 Market St., Philadelphia, PA 19104.

Single unit studies of oral trigeminal afferents have been conducted to ascertain what types of trigeminal neurons are likely to contribute to acid irritation and pain. Acid sensitive neurons were found that were solely sensitive to acid although most also responded to cooling. Conduction velocities of acid sensitive neurons were found to be distributed bimodally, corresponding to C- and A-delta fiber types, which functionally corresponded to polymodal, and cold/cool acid sensitive neurons. Responses of acid sensitive neurons could be classified into three basic types 1) simple excitation, followed by rapid adaptation, 2) excitation followed by adaptation to sub-maximal activity, and 3) non-adapting excitatory responses of long onset latency (5-10 sec). The three types of responses corresponded to thermal thresholds (response type #1 and 2) and acid only (response type #3) type neurons. To examine whether acid stimulation exhibited the same phenomena of sensitization and de-sensitization as subcutaneous, neural recordings were obtained from fibers during repetitive lingual exposure to 150 mM pantoyc acid. Responses to both acid and cool/cold stimuli were suppressed in most classes of neurons that were initially sensitive to acid. Acid sensitization was classified into a previously cold activated sensitive acid neuron and acid sensitivity was reversibly induced in 2 previously silent neurons. Earlier studies of plasma extravasation implicated vascular processes in capsaicin-induced suppression of responses to acid. Under the same conditions that produced adaptation of responses to acid, no evidence of plasma extravasation was observed. Multiple lines of evidence suggest that acid stimuli cause modulation of sensitivity directly at transduction processes and by conduction block. The sustained noxious sensations of acidic stimuli may result from non-adapting acid sensitive neurons as well as by input from relatively fast adapting acid sensitive neurons that is sustained by central or spinal processes.

463.18

Activity-dependent changes in fiber excitability and conduction velocity are adaptations following both natural or electrical stimulation of myelinated axons of peripheral and central nervous system. Activity-dependent changes in excitability are strong and long-lasting and have been implicated in the encoding of discharge trains, and modulation of impulse conduction at regions of low conduction safety factor. C-fibers are the most numerous axons in the sciatic nerve, and are highly heterogeneous, biochemically as well as physiologically. Previously, we have demonstrated different profiles of the activity-dependent threshold changes in sciatic C-fibers (Shin & Haywood, 1986). In this study, we have recorded the conduction velocity (CV) and subsequent conduction block were characterized following impulse activity (0.3, 1, 5, 10, 25 or 50 Hz, 1 min) in simple C-fibers (n=7, range of resting CVs: 0.25-1.72 m/sec). At 0.3 Hz, CV fell to 0.12-0.38 m/sec. At 50 Hz, CV fell to 0.73-0.08 m/sec. The same resting conduction velocities (CVs) were used to follow impulse activity (0.3, 1, 5, 10, 25 Hz, 0.01, 0.05, 0.1 Hz). The frequency of conduction block was increased as CV increased, and the activity rate (rose to 0.30, 0.15, 0.05 Hz, 25 Hz, 5.38-0.69 Hz) and most of the fibers were blocked at 50 Hz (50%. Eleven of 49 C-fibers showed intermittent conduction block before the occurrence of the complete block, whereas 38 of 49 fibers exhibited direct conduction block without showing intermittent firing activities. These results imply a greater variation among C-fibers in the activity-dependent excitability changes, especially in the buildup and recovery of the hyperexcitable phases. This study has been supported by KOSEF grant 891-0700-008-2.
bilateral VB thalamotomy does not reduce pain in the formalin test

SII has the most robust response of the multiple cortical areas activated during painful thermal stimuli in humans, using multiple slice functional MRI. A 1.5 Tesla MRI system with a wide slice pixel size of 1.6 X 1.6 mm, a single surface coil, and an echo planar acquisition sequence were used to image changes in activity in the middle third of the cerebral cortex contralateral to experimentally applied stimuli. In a single experiment, multiple repetitions of noxious heat (45-48°C for 50 s, control = 40°C), motor (sequential application of D-2 to D-4), and mechanical vibratory stimuli (attached to D-1, control = rest) were presented. Eight-10 mm slices were imaged during 6 stimulus-control cycles in each session. Five images/slice were obtained during stimulus or control. Images were superimposed on high resolution MR images.

Noxious heat was sensitive in significant (F2,12 = 6.02, p < 0.05) activation in the primary (SI) and secondary (SII) somatosensory cortices, primary motor (MI) cortex, and posterior area 24. The largest increase in activity occurred in SII where 3.5% increases in intensity over baseline were noted. The activity in MI was larger than that in SI. For the motor task, significant activation was noted in M3 (6% increases), premotor cortex, posterior area 24, SII, and SII. Mechanical vibratory stimulation resulted in increases in activity in SI and SII (2.5% increase).

These results show that multiple cortical areas are activated in response to thermal painful stimulation, including the motor cortex. In addition, the somatotopy of pain perception corresponds with those observed for mecanoeception and motor tasks.

Functional imaging studies in man show that phasic noxious stimuli reliably evoke increased CBF in several brain regions. However, studies using tonic noxious stimuli show consistent results for tonic pain perception. The techniques are not clear. In the present study we tried to maximize detection of tonic pain-related CBF changes by using a regression analysis which weighs experimental conditions according to subjective perception rather than to physical characteristics of the stimuli.

Hypoxia emission tomography (HET) was used to measure CBF following bolus injections of H2O in 11 normal males during 6 conditions (70s immersion of the index finger in 35°-39.5°, 45°, 46°, 49° or 49°C circulating water). A regression analysis was performed across conditions using subjects' psychophysical ratings to model a monotonotic function between perceived pain and CBF. A directed search of cerebral regions of interest, predicted from studies of phasic pain, revealed significant correlation between pain perception in the contralateral sensorimotor cortex (SII), secondary somatosensory cortex (SII), rostral insula (RI), anterior cingulate (AC) and thalamus (3-40). Using SII and RI showed no trend towards activation. A global search of the entire intracerebral volume revealed additional regions of high correlation in areas involved in motor processing such as red nucleus, basis ganglia and cerebellum (3-40), significance threshold adjusted for the larger search area). These data suggest that although tonic pain may be less robust in evoking CBF changes, more sensitive analysis techniques can reveal effects of such stimuli in regions activated by phasic pain stimuli. Supported by Canadian MRC and FRSC.
SPATIAL DISTRIBUTION OF CHRONIC PAIN-INDUCED BLOOD FLOW CHANGES IN THE HUMAN BRAIN. C.R. Coghill, K.F. Bertram, R.H. Gracely, M. Max, M. Byas-Smith, G.J. Bennett, and M.J. Jancan. Neurobiology A. Anesthesiology Branch, NINDS, and Clinical Brain Disorders Branch, NIMH, NIH, Bethesda, MD 20892

Functional brain imaging may provide one tool by which chronic pain syndromes may be evaluated accurately, yet little data exist on the spatial distribution of brain activity during chronic pain. In order to better characterize pain-related changes in the human brain, pain, five patients who underwent functional brain imaging studies. Four patients suffered from post-traumatic chronic pain and secondary hyperalgesia affecting one of their limbs and the painful area was identified with positron-emitting radioisotopes in the trigeminal distribution. All subjects exhibited ongoing pain in the absence of overt somatosensory input. A bolus of 15O H2O was used as an index of functional activity and was measured by 60 s positron emission tomography (PET). Scans following bolus intravenous injection of 15O H2O Subjects underwent multiple PET scans during rest and during alodinia elicited by low intensity mechanical stimulation. Preliminary analyses reveal that these patients demonstrate statistically reliable and robust asymmetry that reflects blood flow distribution during both rest and alodinia. However, these findings, however, are consistent with similar results obtained from cancer patients with unilateral pain (Di Piero, et al., Pain, 46, 9, 1991) and indicate that asymmetry in thalamic blood flow is a salient feature of different types of chronic pain.

PET studies of phasic and tonic experimental pain using regional cerebral blood flow (rCBF) as the index of activity have demonstrated activation of primary and secondary somatosensory areas (SI, SII), anterior cingulate cortex (ACC) and thalamus. We investigated the cerebral representation of chronic ongoing pain in patients with mononeuropathy (MNP). Seven patients (42±3 yrs) with MNP in the lower extremitie (4 in the right, 3 in the left) were recruited. Three PET image sets were obtained with intravenous injection of 15O H2O (30.0 mCi) in the patient's habitual painful state and following a successful regional lidocaine blockade (3 mg/ml) in the painfree state, respectively. Pain intensity was assessed and the actual measurement of rCBF was performed using a common anatomical representation and subsequently normalized to the global mean. The images of the painful and painfree states were subtracted pairwise within the subject and averaged according to the side of MNP. The determination of significant change was based on the local maximum. Significant increase in rCBF was observed, in the painful state, in the right ACA (Brodmann 24) regardless of the side of MNP. Other activated regions included insula, association cortex and cerebellum. Reduced rCBF was recorded in the thalamicus. Indeed rCBF was observed in the SII and SIII. The present results suggest a right hemispheric lateralization of CAC (Brodmann 24) as well as a reduced thalamic activity in chronic pain perception. Experimentally induced pain may contain a more expressed component in the cerebral response (S II) pertaining to the localization of the painful event as well as intensity coding. 464.10 REGIONAL CEREBRAL BLOOD FLOW (rCBF) CHANGES DURING PAIN: AN ANIMAL MODEL T.J. Morrow*, P.P. Daneman, K.A. Frey, and K.L. Casey. Dept. of Neurology, Physiology, Lab. Animal Medicine, Nuclear Medicine, University of Michigan and VA Medical Center, Ann Arbor, MI 48105

BACKGROUND Recent studies of regional cerebral blood flow (rCBF) in humans using positron emission tomography (PET) have suggested new ideas regarding which CNS structures participate in the perception of pain in man. To examine the effects of CNS lesions and pharmacological manipulations on rCBF in pain, an animal model analogous to PET must be developed. The goal of this study was to evaluate the use of a positron emitting radiopharmaceutical, 15O-H2O-PET into and out of the hindlimb served as the nociceptive input. After 5 minutes stimulation, 10 mCi of 99mTc-HMPAO was injected into the catheter. Five minutes later the rats were sacrificed and the brain removed. Twenty microinjection sites were cut and mounted. Standard autoradiographic images of the brain sections were then analyzed for relative optical density. Ipsilateral and contralateral ROI's (regions of interest) were sampled separately from several brain regions, and statistically analyzed (t-test) for differences. RESULTS. This technique showed similar rCBF changes as seen in human PET studies, e.g. side to side differences in sensorimotor cortex (1.84% diff, p<.001) and cingulate cortex (7.58% diff, p<.05). CONCLUSION. Measurement of rCBF promises to be an exciting new tool for examining changes in CNS activation patterns during pain perception in the awake animal brain.

Recent studies have shown that the basal ganglia receive a nociceptive input (J. Neurophysiol., 1993, 69:1890) and play a role in nociceptive input to the ventral lateral nucleus, (Pain, 1985, 23:83). The aim of this work is to investigate the possible role of the neostriatum in the modulation of nociceptive input in rats. The latency and frequency of autotomy (AT) following leg degeneration were compared between a control group (n=6), a basal ganglia lesioned group, in which kainic acid (0.5 µl, 0.1%w) was stereotaxically injected in the neostriatum one week prior to the leg degeneration (n=14), and sham group in which scalp overlying the skull was sectioned and sutured one week prior to the leg degeneration (n=6). All rats in the control and sham groups exhibited autotomy (AT) with a mean frequency of less than 10.3 ± 0.8 days and 10.3 ± 0.8 days, respectively. Only 5 out of the 14 (35.7%) neostriatum-lesioned rats exhibited AT which was also significantly decreased in onset to 24.6 ± 0.7 days. These results suggest that the neostriatum may play a role in either in processing sensory input or in the ability to locate and orient the head away part of the body originating the pain sensation. 464.12 POSTURAL TUNING OF CUTANEOUS NOCICEPTIVE INPUT TO A SPINAL MOTOR SYSTEM M. MILLER*, H. AND SCHUINDLICH, J. Department of Physiology and Biophysics, Lund University, Sölvegatan 19, S-223 62 Lund, Sweden

Detailed information about the development and function of nociceptive systems is necessary for understanding the mechanisms by which the adult organization of these systems is accomplished. Also, such information is needed for adequate interpretation of the responses to potentially noxious stimuli. We have now examined the postural development of the rat withdrawal reflex (WDR) evoked by noxious thermal stimulation (CO2 laser-pulse) in decerebrated, spinalized rats. Behavioral studies in intact rats showed stereotyped, often misdirected reflex withdrawals, indicating immature properties of the HWR system at this age. WRR-recordings in rats examined at postnatal day (PND) 10-21 revealed characteristic withdrawal reflexes (WRFs), typically covering the whole plantar surface, small response amplitudes and great response variability. With increasing age a decrease in RF size and an increase of response amplitudes were observed in the extension digitus longus, peroneus tertius posterior, whereas responses evoked in gastrocnemius-soleus decreased with age and were absent after PND 21. At PND 21-25 the WRFs of the muscles studied were similar to their counterparts in rats, although detailed distribution of sensitivity still differed somewhat from the adult. According to our data the final tuning of cutaneous WRF of the nociceptive withdrawal reflexes occurs after the third week of life. We suggest that an experience-dependent process is involved in this tuning.

CHOLINERGIC INPUTS ONTO DIRECTIONAL GANGLION CELLS. C. Brandon, Dept. Cell Biology and Anatomy, Chicago Medical School, North Chicago, IL 60064.

In the retina retin, ON-Center, Directionally-Selective neurons (ON-DSCGs) project to the accessory optic system of the midbrain. The directional component of their receptive fields appears to be generated via GABAergic input and modulated by cholinergic input. The dendrites of ON-DSCGs intermingling with the processes of starburst amacrine neurons (SBANs; 90), current work examines the synaptic connections between these two cell types.

ON-DSCGs were labeled by retrograde transport from the medial terminal nucleus, and individual labeled cells were injected with Lucifer Yellow in vitro. The tissue was stained immunocytochemically for both Lucifer and choline acetyltransferase (ChAT), and tangential sections through the inner plexiform layer were examined by EM. By light microscopy, ON-DSCG dendrites were completely embedded within the plexus of starburst amacrine dendrites. By EM, ON-DSCG dendrites were surrounded by an extremely dense plexus of ChAT-IR processes; they received many direct synaptic inputs from these processes, which covered virtually their entire surface area. The bulk of the remaining input was from very long, en passant synapses from non-ChAT-IR amacrine processes; these had a very low electron density.

Identified ON-DSCG therefore receive dense, monosynaptic cholinergic input. The large, non-cholinergic synapses, because of their size and placement, seem ideally placed to veto the massive, excitatory, cholinergic input that impinges on large dendritic branches of the ON-DSCG.

REGULATION OF GLUTAMATERGIC TERMINALS IN THE INNER PLEXIFORM LAYER OF THE TIGER SALAMANDER RETINA. D. Hedener, W. Yu, and R. F. Miller, Department of Physiology, Graduate Program in Neuroscience, University of Minnesota, Minneapolis, MN 55455.

Using a retina slicing preparation, we examined the effects of different neurotransmitter agonists/antagonists on evoked synaptic currents in inner retinal neurons of the tiger salamander. Synaptic currents were evoked by light or by a pulse of hyperosmotic sucrose applied to the IPL. Synaptic currents were monitored through whole cell voltage clamp recordings from neurons in the ganglion cell layer. In the presence of picotoxin and strychnine, GABA_A agonists reduced sucrose evoked glutamatergic synaptic transmission in approximately half of the cells studied, and in some cases reduced the synaptic currents more transiently. In almost all cells studied, GABA_A agonists inhibited light evoked synaptic transmission. The results of this study are consistent with the idea that GABA_A receptors inhibit transmitter release from glutamatergic terminals in the IPL. The results of this study also suggest that local hyperosmotic stimulation of transmitter release from terminals in the IPL can be used to study presynaptic regulation of transmitter release.

VOLTAGE-CLAMP AND CURRENT-CLAMP RECORDING FROM RETINAL GANGLION CELLS. G.M. Ratto, L. Lambardi, S. Bizzi, L. Crepato and L.M. Chalupa. Ist. di Neurobiologia CNR Fns, Italy and Center for Neuroscience, University of California, Davis CA.

The electrical properties of retinal ganglion cells (GCs) were analyzed in rat retina slices using the patch clamp technique in the whole cell configuration. The cells were identified morphologically by filling them with diffusible dyes.

Two classes of GCs were identified on the basis of the characteristics of their potassium current. In one class, the K current had two components: a transient rapidly activating current and a slowly inactivating current. In some cells the slow component lasted for several hundred ms without appreciable inactivation. In the second class of cells the transient current was absent.

Current clamp recordings also provided evidence for two distinct classes of cells. In one group of GCs the onset of a steady depolarization caused by outwardly injected current evoked a single large spike, occasionally followed by a few spikes of decreasing amplitude. In these cells no sustained discharge was observed upon injection of constant current. In the second group of GCs the current injection evoked a sustained discharge whose frequency and amplitude increased with the extend of depolarisation. At the largest levels of depolarisation these cells produced transient discharges superimposed on a gradually increasing depolarisation which followed a time course similar to the closure of the slowly inactivating potassium current. The sustained cells displayed spontaneous activity, with spike frequency varying with relation to the baseline potential.

Presumed ganglion cells of the Xenopus retina were studied in short term culture by the whole-cell version of the patch clamp technique. The studied neurons were identified by their characteristic current-voltage relation. In a cocktail of TEA (20 mM), 4AP (5 mM), TTX (1mM) and Ba (20 mM) as a charge carrier, we observed both voltage-activated calcium (and high voltage-activated (HVA) Ca currents. The HVA current was blocked by nifedipine (0.1uM) and enhanced by dopamine (50uM). LVA current was blocked by Ni (20 uM) but was not affected by nifedipine. The metabotropic glutamate receptor antagonist (ACG) reduced the amplitude of the HVA Ca current by 46.62% (n=7). The inhibition by ACP increased to peak within 20s and was completely reversed within 15s by a Ringer wash.

The involvement of G-protein in the inhibitory effect of ACP was studied by including GDP[7S] (300uM) in the patch pipette, resulting in a significant reduction in ACP-induced inhibition. In contrast, the inhibitory effect of ACP on Ba current was irreversible when GTP[yS] (200uM) was added to the patch pipette. In addition, internal application of GTP[yS] by itself reduced only the HVA component of the Ba current. These results indicate that activation of G-protein-coupled metabotropic receptors on ganglion cells by glutamate can lead to the modulation of voltage-gated Ca current. Supported by NIH grant EY03570 to P.W.

MICROGLIAL AND MACROPHAGIC RESPONSE IN RAT RETINA FOLLOWING OPTIC NERVE SECTION. S.C. Sharma, R. Garcia-Valenzuela, Dept. of Cell Biology, New York Medical College, Valhalla, NY 10595.

Cellular debris, following retrograde degeneration of retinal ganglion cells (RGC), has been shown to be cleared by resident microglial cells in the retina (Thanos, 1992). Here we show that blood derived macrophages (MΦ) have a distinct role in the removal of RGCs' debris. The phagocytic process was studied using double labelling with antibodies against macrophages and phagocytic cells (ED-1 and OX-42) together with retrograde tracing of RGCs after application of either a hydrophilic dye (Fast blue) or a membrane bound dye (Di I). It was found that while resident microglia from different retinal layers take care of most of the debris, macrophages invade the retina primarily in the nerve fiber layer and are probably dedicated to engulf axonal debris since unlike microglia, they stain only with Di I and not with the membranous and topographic aspects of these phenomena were also studied.
645.7

A small lesion at the vitreal surface of the retina produces degeneration of retinal ganglion cells whose axons are severed and leaves a small region in the retina depleted of ganglion cells. When the lesion is performed at an early stage during postnatal development the regeneration of the ganglion cells in the boundary of the depleted area show an abnormal elongation of the dendritic trees toward the bare area. A possible explanation for this is that dendrites compete either for synaptic space or chemical factors. Alternatively one may suppose that the electrical activity plays a role in the regulation of dendritic arborization as it happens in the segregation of retinal afferents at the LGN level. In the present study we combined a small retinal lesion with the block of the regenerative electrical activity by intracocular administration of tetrodotoxin. This treatment was continued for the whole critical period. The LGN were then injected with HRP and the retinae were wholemounted and reacted. The ganglion cell population at the border of the depleted zone was then analyzed. It is seen that neurons near the border present a symmetrical dendritic arborization with few exceptions located in correspondence with the lesion. These results suggest that the electrical activity plays a role in shaping the dendritic arborization during the development of ganglion cells.

645.9

Following injury, most central neurons in mammals are unable to regenerate, even after the manipulations of their cellular and molecular environment. Modifying their intrinsic functional properties though gene transfer might be necessary for complete restoration of their anatomy. Here we describe a functional transsection of axotomized retinal ganglion cells by immediate administration of plasmid at their cut ends. Two different plasmids were used, containing either the SV40 promoter linked to the luciferase gene, or the CMV promoter linked to the LacZ gene. Assays for the expression of both reporter genes demonstrated that a significant proportion of ganglion cells express them successfully 3 and 6 days after retrograde transport. Such an approach might be useful in studies of neuronal molecular functions in vivo, and as an experimental therapeutic strategy.

645.11

Soma and dendritic field size of retinal ganglion cells (RGC) are not sufficient criteria to separate clearly the cell types described by Perry (1979) and Dreher et al. (1983). We therefore quantified dendritic morphology of RGC to allow unequivocal classification of different RGC types. 50 RGC, identified by retrograde labeling, were injected intracellularly with lucifer yellow and morphometrically analyzed. As previously described, we were able to classify three cell types by soma and dendritic field size. This classification is not sufficient because we could not identify these cells as a particular cell type. For example, type I neurons, with soma area ranging from 200-500 μm², can be distinguished from type II neurons (50 and 150 μm²). Type III neurons however are as a similar soma size than the type I. We therefore tried to find additional criteria for RGC classification using quantitative analysis of dendritic morphology. These include: dendritic spread, dendritic complexity at growing point, and soma, or segment length in concentric ordering. Three cell types can be clearly characterized by average segment length (ASL), which is shorter in type II cells, intermediate in type I cells, and longest in type III cells. In type II dendrites the ASL is 12 μm in all branching orders up to 13th order dendrite, thereafter shorter. Especially in type III dendrites the 1 and 2 order segments of the centripetal order (end segments) are very long (40-50 μm) in type I dendrites the segments of the 1. order dendrite are relatively short (25 μm), the segments of the 2 to the 7 order very long (40-50 μm) and thereafter extremely short (10-20 μm). By contrast the ASL segment order, dendritic field size and soma size all three cell types can be classified unequivocally. There is indication of further subgroups of cells types in all three cell groups.

SELECTIVE BLOCKADE OF MULLER CELLS GLUTAMINE IN CAT RETINA CAUSES OCULAR DOMINANCE SHIFTS IN VISUAL CORTEX. B.R. Robinson, K.M. Lee, M.G.P. Rosa, L.M. Schwindt, and D.I. Vaney, Vision, Touch, and Hearing Research Centre, Department of Physiology and Pharmacology, University of Queensland, St. Lucia, Australia, 4072.

Inhibition of the enzyme glutamine synthetase in Muller cells by methionine sulfoximine (MSO), causes a complete loss of glutamate immunoreactivity in retina and visual cortex. This study investigates changes in response properties of neurons in cat visual cortex following intracocular MSO injection. Adult cats were anesthetised with thiopentone sodium (40mg/kg IV) and N20/02 (70:30), while pancuronium bromide (Pavulon 0.15mg/kg hr IV) was administered to minimize eye movement. The eyes were injected with 1.0 ml of MSO at a dosage equivalent to 2ml. Multiple electrophysiological responses were recorded from visual cortical areas V1 and V2 over a period of 24 hours. With both eyes open, the histograms for ocular dominance exhibited a slight shift towards the un injected eye. This shift was statistically significant (p<0.05) for the V1 area. The changes were seen in both hemispheres, and in both V1 and V2; the shift being greater in V2. The cats were subsequently euthanised with sodium pentobarbital (60mg/kg IV) and their retinas processed for cytochrome oxidase. The results showed that loss of glutamate, while the ganglion cells and bipolar cells were depleted of glutamate. These data lead us to conclude that Muller glial cells are an essential component of gluta..matergic neurotransmission in the primary visual pathway.

645.10

We investigated the localization of the mRNAs of γ-Aminobutyric Acid A receptor α1 subunit (GABA A α1) and L-Glutamate Decarboxylase mRNA (GAD) among subclasses of RGCs by non-radioactive in situ hybridization. Adult male Wistar rats were used after overdose injection of pentobarbital. cRNA probes of GABA A α1 and GAD were labeled with Digoxigenin-11-UDP (Boehringer) and hybridized with vertical sections of retina. Soma diameter measurement was performed for all cells with positive signals in the ganglion cell layer (GCL). GABA A α1 and GAD mRNAs were detected in the inner nuclear layer and the GCL. In this work, we classified the cells with soma diameter larger than 13μm as RGCs (Perry, 1981, Beale and Osborne, 1982). Since signal positive cells for GABA A α1 mRNA distributed within 5.5-25μm in diameter, RGCs including α-cells (217μm) expressed GABA A α1 mRNA. Soma diameter of cells expressing GAD mRNA distributed within 6-16μm in diameter. We interpreted to indicate that small (S) and medium-size (M) RGCs but no α-cells expressed GAD mRNA. 

645.12

The retina has previously been shown to have a projection to the suprachiasmatic nuclei (SCN). SCN neurons have been shown to have a maintained firing rate that either increases or decreases in the firing rate in response to increased illumination (Gros and Mason, J.Comp.Physiol., 1980, Meijer et al., Brain Res., 1986). The goal of this research is to characterize the retinal ganglion cells to determine which neurons are most likely to play a role in the photic entrainment of circadian rhythms. Fluorescently labeled latex beads were stereotactically injected into the SCN of rabbits. After a recovery period of one week, we were able to label ganglion cells were isolated and mounted in a fluorescence microscope and superfused with oxygenated Ames medium. The activity of the labelled cells was examined with extracellular recording while visual stimuli were projected through the microscope condenser. The cells were then intracellularly impaled with a pipette electrode and injected with HRP and processed to allow morphological examination. The first cells labelled exhibit a sustained rate of firing that tonically increases with an increase in general illumination, with no sign of an antagonistic surround. These cells respond to small patches of MSO agarose, and their spontaneous activity is consistent with a role of luminance coding. The cell's morphology is characterized by small somata and very fine dendrites that are bifurcated. Labelled cells were located in the inner plexiform and outer nuclear layers, and are consistent with axonal arbors extending to the inner nuclear layers, and are consistent with a role in the photic entrainment of circadian rhythms.

DISTRIBUTION AND COVERAGE OF BETA CELLS IN THE CAT RETINA

We have estimated the distribution of beta cells in the cat retina by
mapping the densities of medium sized (non-alpha) cells labeled by
retrograde tracer deposits largely or completely confined to the geniculato-
A-layers. We visualized the dendritic fields of beta cells by intracellular
staining in vitro. In the nasal retina, beta cells exhibited a well-developed
visual streak and, except centrally, accounted for about 40-50% of ganglion
cells. However, the incidence of beta cells increased substantially in the
central retina (to about 60-70% of all ganglion cells; see Neuron. Abstr.
15:292, '80) and throughout much of the temporal retina (to about 70%).

Though beta-cell densities were lower temporally than nasally, the distribution
was far more symmetrical about the line of nasotemporal division than the
distribution of all ganglion cells. These results are consistent with our
observation that colliculopetal W-cells (which account for the vast majority of
non-beta cells) exhibit a complementary distribution: they make up about half
of the ganglion cells in the mid- and far-peripheral nasal retina, including the
visual streak, but are underrepresented in the area centralis and temporal
retina (where they make up, respectively, about 33% and 25% of all ganglion
cells). Dendritic-field areas of beta cells systematically reflected local beta-
cell density. For example, in the nasal retina (eccentricity: 30°), areas were 4-
fold smaller within than outside the visual streak. Coverage factor (beta-cell
density X dendritic-field area) remained constant everywhere, whether central
or peripheral, nasal or temporal, or on or off the visual streak (mean = 3.0; SD
= 0.76; N=200). We suggest that the beta-cell system shows greater binocular
balance and is more specialized for fine sampling of central visual fields than
other cell classes, and has enhanced functional capacity along the horizon.

THE SPECTRAL SENSITIVITY OF GANGLION CELLS IN THE
MOUSE RETINA VARIES ALONG THE INFERIOR-SUPERIOR
AXIS. E.B. Soucy, E. Wu and M. Meister* Dept. of Cellular and
Molecular Biology, Harvard University, Cambridge, MA 02138.

We are interested in the nature of the information encoded in the
spike trains of ganglion cells. Using a multi-electrode array, we recorded visual responses from the population of mouse retinal
ganglion cells. The response properties of each cell were determined by computing the reverse-correlation function of its spike train to a
pseudo-random stimulus. This allowed us to measure the spatial,
temporal, and spectral components of an individual ganglion cell's receptive
field. Initial characterization of mouse retinal ganglion cells revealed a relationship between spectral sensitivity and retinal
location, with cells in the inferior region displaying greater
sensitivity to short wavelengths relative to cells in the superior
region of the retina. This was consistent with the cone ratio of mouse retinal
ganglion cells.

TWO REMARKS ON CODING IN THE OPTIC NERVE OF
Of Biomedical Engineering, Rutgers Univ., Piscataway, NJ 08855,
and Lab for Computer Science, MIT, Cambridge, MA 02139.

We studied pulse interval coding on two types of retinal
ganglion cell (RGC) in the frog, Rana pipiens, by recording extracellularly from single optic nerve fibers with metal-filled
microelectrodes. Records were taken from color sensitive fibers
(RGC Class V) and "dimming detectors" (RGC Class IV).

With regard to the color fibers, we noted strikingly different
pulse interval patterns on a single fiber in response to light stimuli of
two different wavelengths, despite approximately equal average
firing frequencies in each response. These data are consistent
with a pulse pattern rather than pulse frequency coding for color.

The dimming detectors had a sensitivity to step changes in
light intensity of less than 0.01 decade, and a sensitivity to
continuous changes in intensity of less than 6 decades per hour.
The evoked response to step decrements in light intensity was
logarithmically related to the magnitude of the step, and was
independent of background illumination over a range of at least
two decades.

645.16

INITIAL PHASE OF ROD RESPONSES, GANGLION CELL
FIRING AND BRIGHTNESS SENSATIONS CORRESPOND
UNDER DIFFERENT BACKGROUND CONDITIONS.
K. Djupsund1, K. Donner1, N. Pyrhönen1 and T. Hariyama1,2,1Dept.
Zoology, FIN-00014 Univ Helsinki, Finland and 2GISIS, Tohoku
Univ, Sendai 980, Japan.

The rods are the first filter in the visual sensory chain and ganglion
cells (GC) the last retinal processing step before visual information enters the optic nerve and higher processing. Therefore one might in
these nerve cells find common constraints and guidelines for processes mainly studied in psychophysics.

We have compared on one hand brightness sensation and adaptation
data and on the other hand the timescale of the rise of intracellularly recorded rod responses and extracellularly recorded GC response frequencies in the frog Rana temporaria to flash/step stimuli.

We show that if brightness sensations are determined by the initial
rise of the photoreceptor signal, this can account for the intensity-
brightness sensation relationship under different backgrounds.

The rise of rod responses accelerated with a power of ~0.14-0.2 over sub-
saturating background and stimulus ranges, which corresponded to the rate of GC responses.

646.1

CHOLINERGIC DEAFFERENTATION OF THE VISUAL CORTEX
BY INTRACORTICAL INFUSIONS OF 192 IGG-SAPORIN IN RATS:
EFFECTS ON VISUAL DISCRIMINATION AND VISUAL
ATTENTION. M. Sarter*, L.A. Holley and M. Matej. Dept. Psychology,
Ohio State Univ., Columbus, OH 43210.

The visual cortex, as all cortex, is innervated by the cholinergic neurons
situated in the basal forebrain. The functions of the cholinergic afferents of
this cortex have remained unclear. Furthermore, the role of the cholinergic cell
loss in the visual dysfunctions of patients with senile dementia is
unknown. Rats were trained to discriminate between simultaneously
presented pairs of visual stimuli flashing at 5 Hz versus 4.17, 3.75, 2.5,
1.67, or 1.25 Hz. Cholinergic inputs to the visual cortex were selectively
lesioned by infusions of the immunotoxin 192 IgG-saporin into this area
(0.01 µg/0.8 µl per injection). Control animals received either infusions of
the immunotoxin into the frontoparietal cortex or infusions of vehicle into
the visual cortex. Lesions performed after the animals learned the task did
not robustly affect performance. Lesioned placed before the acquisition of
the task resulted in a transient impairment in the rate of acquisition. The
role of cholinergic afferents of the visual cortex in the animals' ability to
detect visual signals presented for 25, 50, or 500 msec and to discriminate
these signals from non-signal events was also examined. These experiments represent a first step toward the determination of the functions
of cholinergic inputs to the visual cortex.
NEUROCHEMICAL EFFECTS OF MONOCULAR APHASIA IN SUBPRAGNULAR LAYERS OF V1 OF THE ADULT MACAQUE. S.S. LeDoux and R.K. Carder. Zanvyl Krieger Mind/Brain Institute, Johns Hopkins University, Baltimore, MD 21218.

Unlike monocular enucleation or intravital TTX injections, monocular aphasia results in a chronic defocusing without eliminating retinal output. Loss of neural activity in one retina, as with the other forms of monocular deprivation, leads to chemical changes in V1. In the present study, cytochrome oxidase (CO) histochemistry and calbindin immunocytochemistry were used to determine if chronic defocusing without elimination of retinal input can lead to similar neurochemical changes in the subpragnular layers of V1. CO and calbindin staining are normally complementary, with CO staining occupying puffs along the centers of both sets of ocular dominance columns, and calbindin staining occupying the surrounding CO-poor interpuffs. After 3-12 weeks of monocular aphasia, changes in CO histochemistry and calbindin immunocytochemistry are apparent. CO-rich puffs at the centers of normal-eye puffs fuse to form stripes while CO-rich puffs at the centers of deprived-eye columns become pale and shrunken. Calbindin immunostaining, normally intense in the CO-poor interpuffs and weak in the CO-rich puffs, is similarly affected. Alternating and lightly stained stripes are centered respectively on the stripes of CO-rich puffs of the normal-eye columns. These results are similar to those found in TTX-injected monkeys indicating that aphasic amblyopia also produces neurochemical changes across compartments and ocular dominance columns. Supported by ET/06344 and FR8Q.

ONCOGENE EXPRESSION REVEALS OCULAR DOMINANCE COLUMN IN ADULT CAT VISUAL CORTEX. L. Aronson, M. P. Watanabe, W. Vanduffel, F. Vandenberghe, and D. G. Harts. Brain Research, 544, 113-120.

We used immunohistochemistry to determine whether manipulation of visual input can induce changes at the protein level of two oncoproteins, c-fos and zif-268, in the primary visual cortex of the adult cat. Under normal visual conditions, c-fos and zif-268 were expressed at low basal levels in layer II/III, 1/8 and VI of areas 17 and 18, while c-fos was hardly detectable. Monocular deprivation drastically influenced the expression of both oncoproteins. Recently after one hour of monocular visual stimulation, Fos and zif-268 positive nuclei were distributed in a columnar fashion. Using longer monocular deprived cats and cytochrome oxidase histochemistry, we demonstrated that the immunocytochemically detected columns are ocular dominance columns corresponding to the stimulated eye. From immunocytochemical double stainings we know that both oncoproteins are expressed in the nuclei of non-GABAergic neurons. Supported by IUPAP Vision & Memory.

We previously constructed a model visual cortical circuit with short-range (<300μm) intracortical excitatory and inhibitory connections which yielded emergently sharp orientation selection (Sur et al., 93). The ability of this circuit to orient tuning from direct inhibitory inputs to single cells, but a substantial contribution from the distributed inhibitory inputs to a cortical column. Intracortical excitatory connections are anisotropic, conveying responses to preferred stimuli, and inhibit primarily the gain of excitatory feedback. Here we demonstrate that cortical gain also depends on stimulus contrast: the gain rises to boost mild suprathreshold stimuli and drops off at high stimulus contrast. This mechanism yields cortical contrast response functions that rise more rapidly and saturate more quickly than their monocular inputs.

We have added to our model two forms of longer range cortical connections: very sparse inhibitory input from oblique or cross orientations (300 - 600μm) and more extensive excitatory input from longer ranges (2-10mm). Long-range inhibitory connections comprise less than 20% of inhibitory and less than 5% of all model synapses. Although long-range inhibitory connections are not required to achieve sharp orientation tuning, these connections permit the circuit to maintain sharp orientation selectivity and contrast gain control across the full range of suprathreshold stimulus contrasts (Skottun et al., 87). As in the short-range model, inhibition is strongest at the preferred orientation and has progressively distributed rather than directed effects on tuning. Adding long-range excitatory connections produces biphasic effects that depend on stimulus contrast. Strong iso-orientation surround stimuli can up- or down-modulate the responses to stimuli within the classical receptive field: responses to subthreshold or weak center stimuli are amplified, while those to strong center stimuli are reduced. Supported by McDonnell Fund, MH10671, EY05635, and EY07023.

Attempts at understanding the functional relationships between cortical micromicroscopy and receptive field generation have been hampered by the technical difficulty of analyzing the biophysics and synaptic physiology of cortical neurons in vivo. Preparations have circumvented this difficulty by using an in vitro preparation of the eyes and brain of freshwater turtles, allowing us to record intracellular from cortical neurons and to present natural visual stimuli to the eye cup. Results from intracellular recordings have been combined with anatomical and with compartmental models of cortical neurons and of neural circuits implemented with the Nodus software package. We investigated the responses of pyramidal cells in the visual cortex to 1 sec, 660 nm light flashes with intensities varying from 0 to 1500 photons/cm2/sec, finding that threshold light intensities produced small EPSPs. Shape parameter analysis indicated that EPSPs recorded at the soma are usually composite EPSPs. Simulations showed these composite EPSPs could result from asynchronous activation of geniculate boutons on several dendrites of the cell, consistent with earlier results from our lab using electrical stimulation of geniculate afferents. Supported by PHSG Grant 88-3852.

Residual visual capacity in humans with damage to striate cortex has been reported to include sensitivity to presence and direction of motion (e.g., Pererin, 1991, Neuronuvs, 2:391). We investigated the ability of three monkeys with large unilateral striate lesions to process motion in the affected portion of the contralateral visual field. Lesions were made at 5 weeks of age in two animals and in adulthood in the third. Stimuli were small (5 deg. diameter) gaussian-filtered fields of dynamic random dots (dot size 0.1-0.5 deg.) presented on a video monitor. Moving stimuli contained 98% correlated motion. A go/no-go paradigm employing a saccadic eye movement response was used to test the ability of each monkey to discriminate 1) upward from downward motion, 2) speeds of 4 and 0 deg. /sec., and 3) upward motion from motion noise (0% correlated motion) and 3) upward motion from a static field of random dots. All animals quickly learned all discriminations in the intact hemifield. In the impaired hemifield, however, they failed to perform above chance on all tasks except the discrimination of moving vs. static dots. The results indicate that preserved visual capacity after striate cortex damage in monkeys does not include at least some types of motion sensitivity, i.e., the integration of local motion signals present in dynamic random dot displays. STUDIES OF HUMAN VISION COMBINING MEG AND ANATOMIC AND FUNCTIONAL MRI. J.S. George, C.J. Ains, J.C. Mosher, J.A. Schlotz, C.C. Wood, J.D. Levine and J.A. Saunders. 1 Los Alamos National Laboratory, 2 Albuquerque Federal Regional Medical Center. Integrated analysis of human anatomic and functional images offers a powerful tool for human brain mapping. MEG and EEG provide excellent temporal resolution of neural population dynamics. MRI provides excellent spatial resolution of hemodynamic changes, and their combination allows for an alternative measure of functional activation. These methodologies constrain and complement each other and can thereby improve our interpretation of functional neural interactions. In these experiments, MEG data (317 channels) and MRI data (6 slices, 8 or 10mm thick, with 2 mm in-plane resolution) were collected using a patterned stimulus in the lower right visual field. T1 weighted 3-D images of the blood flow were acquired during the exposure. The geometry of cortex and of major conductivity interfaces within the head was defined by segmentation of MRI data using semiautomatic image analysis procedures in MIRview, a software package developed in our laboratory. Cortical edge voxels were identified and cortical normal vectors were calculated for edge voxels using a 3-D convolution over the 26 nearest neighbors. 35-50,000 voxels were required to define the cortical surface at 2 mm isotropic resolution. Conductivity boundaries were defined by stain-wraping an isosurface-based mesh over the surfaces. Electric potential was evaluated at nodal points using a boundary integral calculation. Magnetic fields at sensors were calculated by evaluating an integral over all node potential values. As a first estimate of MEG sources, the MUSIC metric was evaluated for voxels under the sensor array, assuming locations and orientations derived from anatomical MRI. In agreement with previous dipole-based studies of normal MEG data, at least three sources are evident in these images, a primary response (Y1/12) and bilateral sources near the parietal/occipital border. As a second step, dipole locations were identified based on the observed field, dipole orientations were determined using a simple least-squares fit. Component dipole sources were assigned locations and strength based on MEG and orientations based on anatomical MRI. Such geometrically complex composite sources can be treated as single sources for temporal analysis based on MEG.
DISTRIBUTIONAL DIFFERENTIAL OF GLUTAMATERIC SYNAPSES BETWEEN CYTOCHROME OXIDASE (CO)-RICHPUFFS AND CO-POOR INTERPUFFS IN PRIMARY VISUAL CORTEX OF MONKEYS. E. Nie, R. Curtis and M. Wong-Riley, Dept of Cellular Biology & Anatomy, Medical College of Wisconsin, Milwaukee, WI 53226

Glutamate is a major excitatory neurotransmitter in many regions of the brain. This study aimed to characterize the distribution of glutamate-positive asymmetric synapses (presumed excitatory) than interpuffs. In the present study, a double labeling technique combining cytochrome oxidase with glutamate was used to determine the distribution of glutamate-positive synapses is correlated with a difference of CO activity between puiffs and interpuffs at the EM level. Our results showed that CO activity in glutamate-positive pyramidal axonal terminals. Quantitative analysis demonstrated that there were more glutamate-positive synapses in puffs than in interpuffs. These differences in CO activity between puiffs and interpuffs were detected using 100 μm 3PO (P<0.005). Furthermore, glutamate-positive axonal terminals in puffs contained a higher proportion of darkly stained mitochondria than those in interpuffs, indicating that they might be more active in puffs. In addition, glutamate-positive axosomatic synapses selectively targeted GABAergic neurons, which contained more darkly reactive mitochondria. This study suggests that glutamatergic synapses play an important role in excitatory transmission within puffs and interpuffs. Glutamate may be the neuromodulatory basis for higher metabolic demands related to greater depolarizing activity in puffs than in interpuffs. (Supported by NIH grants EY05439 and NS18122).

The steady-state visual- evoked potential (VEP) of an ordinary pattern-reversal grating contains a robust second harmonic (2H), but little or no fundamental (1H) activity. Cortical 1H processing is of considerable interest, because it is thought that only 1H is clearly linked to neural substrates carrying spatial phase information, which is necessary for the binocular processes of fusion and suppression. Incorporating several simultaneous modulation rates (e.g., F1, F2) enables inferences about cortical processing of 1Hs from nonlinear intermodulation (IM) crosscorrelations of the 1Hs (e.g., F1-F2, F1-F2). Steady-state VEPs were recorded (2z to right ear) from 17 stereorandom (Randot E) adults. Stimuli were 0.86/deg gratings having a total of 60-sec trials. Stimuli contained up to three simultaneous modulation rates (F1=6.1, F2=8.5, F3=12.8 Hz) with monocular, binocular or dichoptic conditions achieved using liquid crystal lenses synchronized at 256/sec monitor frame rate. Fourier analysis extracted amplitudes at frequencies of interest. Monocular IM components, but not monocular 2Hs, were significantly reduced when a different temporal frequency was added to the other eye. Therefore, in these conditions, 1Hs, but not 2Hs, seem to index binocular processing. Nonlinear models of visual processing are discussed in relation to these findings. The Dorothea Haus Roz Foundation.

A well-known feature of the retinocortical projection is that in angular terms the fovea is overrepresented in the striate cortex (retinal ganglion cell size). Recent evidence indicates that the following description of the magnocellular and parvocellular subdivisions of the retinocortical projection. A retrograde, transneuronal tracer (WGA-HRP) from cortex to retina was used to label axons leaving the retina. In this study, we examined the projections of neurons in the magnocellular and parvocellular subdivisions of the retinocortical projection, which is that it could arise simply because the two (parvocellular and magnocellular) retinal maps, represented by populations of ganglion cells with different distributions, are expanded to different extents in order to preserve the topographic co-registration of the inputs to the striate cortex. It suggests that the expansion subserves some visual function.

ANATOMICALLY BASED NEURAL NETWORK MODEL FOR GENERATION OF ORIENTATION SPECIFICITY IN MONKEY PRIMARY VISUAL CORTEX (V1). Q. Wu, J.S. Lund and P.Hadingham, Inst of Ophthalmology, Univ. of London, London EC1V 9EL, and Dept. of Computer Science, Univ. of Western Australia.

To understand the correlation between structure and function in primary visual cortex (V1) of primates, we are attempting to develop a neural network model which is closely based on anatomical observations and aimed at simulating physiological results. Our previous model studied the primary visual evoked response in V1 and V2 in monkeys that spiny stellate cells in V1 accomplish weighted summation of distinct input sets from LGN through dendritic overlap. To simulate physiological results and may also apply to the issue of generation of orientation specificity in V1. Human psychophysical studies demonstrated that the orientation input sets of neurons are produced by a single stimulus oriented stimulus of the orientation input sets of neurons at orientation. Based on this evidence, we propose that orientation specificity in primate V1 is generated in two stages: the first stage is the generation of the two tuning functions centered around horizontal and vertical orientations, and the second stage uses these functions to produce a continuum of all possible orientations. In our model we incorporate the lateral spread of axon collaterals from spiny stellate neurons in V4 as the anatomical substrate for producing the two orthogonal orientations, and the second stage uses these functions to produce a continuum of all possible orientations. Compared to the Hubel and Wiesel model of the generation of orientation specificity, our model is more economical in terms of neuronal wiring and has anatomical, physiological and psychophysical support. MONOCLONAL ANTIBODY CAT-305 LABELS GENICULOCORTICAL CONNECTIONS IN PRIMARY VISUAL CORTEX OF CAT, MONKEY, AND FERRET. S. Hockfield* C. Blakemore and J.C. Kind, Section of Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510 and JLin. Lab. of Phys., Oxford, UK. Monoclonal antibody Cat-305 labels cortical layer IV of areas 17 and 18 in the cat (Cerebral Cortex, 1994). This restricted localization suggested that the Cat-305 antigen may be associated with the presynaptic terminals of axons originating in the dorsal lateral geniculate nucleus (dLGN). To address this possibility, we have now examined Cat-305 staining in the cortical areas of macaque monkey and ferret, and in the cortex of cats with lesions in the dLGN.

As in the cat, Cat-305 staining is also restricted to primary visual cortex in the alitferret and monkey. In the ferret, immunoreactivity appears as a dense band of fiber through layer IV in areas 17 and 18. In macaques, Cat-305 labels two bands, both of which are restricted to striate cortex. Laminar analysis demonstrates that the two superficial bands of staining demarcate layers IVa and the deeper band layer IVc, corresponding to the laminar remnant of the geniculocortical afferent.

To determine whether the Cat-305 antigen is associated with or dependent on presynaptic elements in layer IV, unilateral bilateral acid lesions were made in the dLGN of adult cats. Three weeks following the lesion, Cat-305 immunoreactivity was markedly reduced in the cortex ipsilateral to the lesion compared to the contralateral, non-lesioned hemisphere and to normal controls. Staining for monoclonal antibody Cat-301 and GFAP in layer IVa were not affected by the lesion, indicating that there was little or no degeneration of cortical neurons. The decrease in Cat-305 immunoreactivity in cortical layer IV after dLGN lesions suggests that the loss of the Cat-305 antigen is a result of degeneration of the presynaptic terminals of geniculocortical afferents. **VISUAL PSYCHOPHYSICS AND BEHAVIOR II**

**ASSIMULATION OF VISUAL ABILITIES IN ALZHEIMER'S DISEASE AND MENTAL RETARDATION.** S.A. Sharp* and S. Oross III. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Alzheimer's patients exhibit visual losses including elevated contrast sensitivity thresholds, blue-yellow color deficiencies, and elevated thresholds for detecting coherent motion in kinematosgrams. To assess the degree to which profiles of visual losses may differentiate between clinical populations, we have begun comparing the performance of Alzheimer's patients to three groups of adults with mental retardation: unspecified etiology, young (<35 years) Down Syndrome, and old (>35 years) Down syndrome. Measurements of visual acuity, contrast sensitivity, color perception, and detection of motion coherence were obtained. Detection of motion coherence was assessed using a 2AFC task in which subjects had to determine which of two simultaneously presented kinematosgrams contained coherent motion (signal strength varied between 1 and 100%). The other kinematosgram contained only random noise. Rules to standards of each group were comparable with control subjects, all groups exhibited elevated visual acuity, contrast sensitivity and motion coherence detection thresholds. Variations in these threshold elevations suggest that profiles of visual losses may differentiate between the groups. Discussion concerning the construction and use of a battery of visual tasks for assessing the neurological status of various clinical populations will be advanced.

**PROCESSING PROFILES AT THE RETINAL VERTICAL MIDLINE OF A CALLOSOTOMY PATIENT.** R. Fendrich*, C. Westinger, MS Gazzana. Center for Neuroscience, UC, Davis 95616.

Previously, we reported that a calllosotomy patient could not compare small outline shapes presented 15° from the retinal vertical midline with comparison shapes in the opposing visual field. This foveal splitting paradigm argued against the attribution of macular sparing to a zone of nonspatial overlap. We now report evidence that a narrow zone of overlap does occur in the human retinal vertical midline, but is limited in its ability to convey visual information to the cerebral hemisphere contralateral to each hemiretina. Pairs of 2° x 2° square waves of contrast were flashed alternately from each eye to each hemisphere. The subject judged which gratings had the same orientation. Retinal stabilization insured the grating patches remained properly stabilized. When the gratings were presented for 200 msec or their medial edges were 2° from the retinal vertical midline, the subject performed as well near the center. When presentations lasted 2 seconds and the grating medial edges were 1° from the midline, above chance performance was maintained with the 1°, 2°, and 4-cpd gratings. Performance degraded when both gratings were displaced 2° upward from the horizontal meridian, but was unaffected or improved by a like downward displacement. Remarkably, accuracy rates improved when the gratings were offset vertically away from each other (one 2° up, one 2° down). Supported by NIH/NINDS PO1 NS17778-12 A PHS NS1443-01

Two patients, both with right hemispherectomy, one with right-sided removal of the temporo-parietal-occipital cortex and four normal control subjects were tested for spatial summation in the visual field across the vertical meridian. The double stimulus paradigm described by Tassini et al (1984) and Marzi et al (1986) was used. Monocular eye fixation was monitored with a pupil/orbital reflection tracking system and all subjects used their right eye. Single or pairs of flashes (LEDs) were randomly presented during 10 msec at 10° or 30° to the left or to the right of the fixation point, either within or across hemispheres. Subjects had to respond as fast as possible to the stimuli by a keypress. As expected, control subjects reacted more quickly to double stimuli than to single ones. Although the patients never responded to stimuli in the blind field, they were significantly faster when two flashes were displayed in both hemifield rather than when a single flash was presented in the intact hemifield only. This summation effect across hemifields in subjects in whom a whole cerebral hemisphere has been removed or deafferented supports the possibility that alternate visual structures (e.g. superior colliculi) contribute to residual vision in the blind field. Supported by NSERC OGNEN 012.

**Residual Vision in The Blind Field after Partial or Complete Hemispherectomy.** C.M. Weisberger1*, R. Fendrich1, A. Pittet2 and M.S. Gazzana.*

1Center for Neuroscience, Univ. of California, Davis 95616, U.S.A.
2Montreal Neurological Institute, Montreal H3A 2B4, Canada.

One patient with left functional hemispherectomy (JB) and one with right-sided removal of the temporo-parietal-occipital cortex (SE) were tested for residual vision in their blind field. Using image stabilization procedures, we identified a zone of residual vision along the vertical meridian in each patient. The lateral edge of this zone was generally within 3.5° of the vertical meridian, although in both patients we found local area of detection beyond 3.5°. The region of residual vision was not identical in the two patients. In JB it was confined to the superior quadrant; in SE it was present in both superior and inferior quadrants. Each patient could detect stimuli and correctly perform shape discriminations within the zone of residual vision, but not outside of it. In contrast, neither patient was able to name complex line drawings presented in the zone.

Acuity profile assessments in each patient’s seeing field argue against the attribution of these abilities to eccentric fixation. Given the reported complete absence or deafferentation of a hemisphere contralateral to the residual vision, alternate structures would be mediating this residual vision. The superior colliculi and/or the remaining cerebral hemisphere could be candidate structures.

FURTHER RESULTS FROM A TRAINING OF BRIGHTNESS PERCEPTION AND REACTION TIMES IN HOMONYMUS HEMIANDROPA. L. Dornheim, F. Schneiuel*. Inst. for Medical Psychology, Med. Univ. of Luebeck, Luebeck Germany, GER 23538.

Visual field (VF) defects in patients with lesions of the post- chiasmatic visual system demonstrate a reduction of perceived brightness at the border of the residual VF. Dornheim and Schneiuel (1994) showed that visual functions can be improved by a rehabilitation training using a magnitude estimation technique of apparent brightness. Now further results are demonstrated for a female patient (age 73 yrs.) who suffered from an incomplete homonymous hemianopia of the right VF caused by stroke. Monocular scaling of threshold and super threshold stimuli and a specific training of light-dark discrimination was performed by a computerized perimeter within the lower right quadrant caused a VF enlargement, a reduction of reaction times and threshold as well as an increased of perceived brightness within the trained area and an increase of visual acuity. The authors explain the improvements by recovery of visual cortex neurons due to repetitive stimulation during selective attention.

DYSPHONEDIETIC DYSLEXICS DEMONSTRATE A MAGNOCELLULAR PATHWAY DEFECT. W.H. Ridder, III. E. Borsting, M. Cooper, B. McNeel, and P. Simmons*. Southern California College of Optometry, Fullerton, CA., 92631.

A review of the literature reveals that approximately 75% of dyslexics have a processing deficit in the magnocellular pathway (Lovegrove et al., 1990). In addition, a recent report demonstrated that the dyslexic subject, who comprises 10 to 30% of the dyslexic population, does not have an abnormal magnocellular pathway (Ridder et al., 1995). These results suggest that the other two subtypes of dyslexia (dysphonodiabetic and dysphonediabetic) should have a magnocellular pathway defect. The purpose of this study was to determine if dysphonodiabetic dyslexics exhibit a magnocellular pathway defect. Four dysphonodiabetic dyslexics and five age and sex matched, normal controls were examined. All subjects had normal intelligence and educational opportunities, no ocular disease, sensory impairments, or systemic pathology. The presence of dyslexia was determined with the Adult Dyslexia Test. Contrast sensitivity functions were determined with vertically oriented sine wave gratings (0.5, 1.0, 2.0, 4.0, 8.0, and 12.0 deg. in frequency defining at 0.1 and 10.0 Hz) and for a full field flickering stimulus (5, 10, 15, 20 and 25 Hz) by employing the temporal, 2 alternative, forced-choice technique. Unpaired t-tests demonstrated significant differences existed between the dysphonodiabetic dyslexics and the normal controls for the data obtained at low spatial and high temporal frequencies. These results suggest that dysphonodiabetic dyslexics have a magnocellular pathway defect.

We report here evidence to suggest visual sensitivity in normal subjects can vary as a function of eccentricity. In a block of trials, subjects were asked to judge the width of the objects by stating which of five different blocks (numbered 1 to 5) it was. In addition of trials, subjects indicated how wide they thought the block was by opening their forefinger and thumb to the width perceived. In addition to these two explicit judgements of object width, another more implicit judgement was obtained by simply requiring subjects to reach out and grasp the object using a precision grip (with forefinger and thumb). Based on previous work, it was expected that grip aperture would be strongly correlated with object width. In this case and in the previous manual estimation condition, the opening between the forefinger and thumb was measured using standard opto-electronic recording (WATSMART). The effect of retinal eccentricity on the object estimation varied as a function of the response used. When verbal responses were required, size estimates decreased as a function of retinal eccentricity; when manual estimates were required, grip aperture was reduced as required to grasp the object, their grip aperture increased with eccentricity. In short, increasing retinal eccentricity had different effects on judgements of object width, and object estimation. This further support to the proposal that visual perception and the visual control of action depend on different transformations of visual information (Goodale, Curr.Opin Neurobiol 3: 1993). This research was supported by a grant from MRCC to M.A.
VISUAL REPRESENTATIONS FOR CLASSIFYING 3D OBJECTS.
Hiroshi Ando* and Satoshi Suzuki,
ATR Human Information Processing Research Labs., Kyoto, Japan.

There have been increasing interests in how the brain represents visual objects and object recognition. Physiological experiments have shown that IT neurons may represent local features or prototypes of learned objects (Shoemake et al., Nature 360, 943, 1992; Lopes et al., Neurosci. Abstr., 1993). Psychophysical studies have indicated that the visual system may extract view-specific prototypes of 3D objects in identification tasks where human subjects have to recognize the target object from distractors (Edelman & Bülthoff, Vision Research, 32, 2385, 1992). This research provides a physical and computational perspective to investigate whether the visual system may extract global prototypes or local distinctive information in 3D object classification tasks.

In the present study, we employed a 2D views of a fixed set of wire-frame 3D objects. The results show that some views yield higher error rates. To investigate what representations are extracted, we examined three network models, i.e., the MLP (multi-layer perceptron) network which can extract local linear features, the GRBF (generalized radial basis function) network which extracts global prototypes, and an extension of HBF (hyper basis function) network that allows to emphasize various local templates. The simulations on the same objects used for the psychophysics showed that with a small number of hidden units the MLP and HBF networks perform better than the GRBF network. The results suggest that it is useful to extract local distinctive information that is stable over different view directions, such as acute angles formed by successive segments. Analyses of errors reveal that some subjects made errors at particular views similar to the views these networks fail, suggesting that the visual system may extract local distinctive information for classifying 3D objects.

MAGNETIC AND ELECTRIC OSCILLATORY RESPONSES TO FLASH SIMULATION EFFECTS OF LUMINANCE AND ECCENTRICITY. L. Lopes*1 M. Peresson*1 A. Pascualar*1 G.L. Romani1 W.G. Barnard4 1TABB, University of Chieti, Italy, 2ESS-CNRE, Rome Italy, 3DISM, Center for Cerebral Neurophysiology University of Genova, Italy, 4Dept. Psychol. SUNY, Stony Brook, NY. In this study we wanted to further characterize the origin and possible functional role of these responses.

We measured electric and magnetic responses to full-field and to various spots that progressively varied in area and eccentricity from point of fixation (5° to 30°), alternatively in the upper left and right quadrants of the visual field. Eight healthy volunteers were used. Simulation was delivered monocularly, to the left eye with a Glass FS82 (10 s duration, 0.5 Hz, 3.5 cd/m² at full-field) 90 dB masking white noise) The stimuli could be delivered without moving the subject. One position, covering an area of 250 mm² over the left occipital lobe, was chosen as a stable magnetic recording.

Electric and magnetic oscillatory responses during full-field stimulation, were obtained. When changing the stimulus to eccentric and smaller spots, the retinal oscillatory potentials tended to disappear, together with ERG, while the cortical oscillatory responses could still be detected with features that varied as a function of eccentricity and luminance. Such findings would indicate that the mechanisms underlying the generation of oscillatory responses in the cortex are partly independent of the retinal oscillatory potentials and that a magnification occurs in the visual system.

It is known that acute and semi-acute hypobaric conditions reduce the (relative) light, which lasts for at least 3 days. To what extent red/green color vision is affected under acute normobaric hypoxia and hypoxia, hyperbaric conditions, and chronically increasing hypobaric hypoxia has not been reported before. The red-green balance-flicker (16 Hz) fusion point was measured psychophysically for normal subjects with the portable OSCAR color vision tester. The red/green (R/G) modulation sensitivity ratio is enhanced by normocapnic acute hypoxia (10-13 kPa O2, 0-11% increased SaO2, 58-83%) and reduced by normocapnic hypoxia (60-100 kPa O2, 2-10% decrease, 6 subjects). The effects are maximal after 20 min of exposure. Excretion (>30 min 150 W) also results in an enhanced (2-9%) R/G ratio. Hyperbaric air pressures, examined up to 520 kPa, reduce less less. An hypothetical explanation of this lesser reduction is an opposite effect of N2 narcosis (and hypercarbia) at pressures ≥300 kPa. Above 100 kPa O2 the effect of O2 saturates (5 subjects).

This may partly be due to hypercapnia since normocapnic CO2 mixtures (2 and 4 kPa) resulted in an increased sensitivity ratio (2 subjects).

3D COLOR SENSATIONS IN HONEYBEES? Werner Backhaus*, Institute for Neurobiology, C/o Institut für Biophysics, Friedrich-Alexander-Universität Erlangen-Nürnberg, 91058 Erlangen, Germany.

Neuronal color coding and color choice behavior of honeybees is very well described by the color theory for the bee (Backhaus, 1991, Vis. Res. 31, 1381; 1992, 32, 1425). The results of ordinary color training experiments are described by the color theory on the basis of a dual neurone mechanism with two color opponent coding neurons. The results of double color training experiments, in which two color stimuli were trained simultaneously cannot be explained by a model on the basis of the electrical properties of neurons. The choices rather appear to be related to color sensations (Backhaus & Kratzsch, 1993, Proc. 21st Symp. Science of Color, 30-35; Color Res. and Thiene).

A quantitative model is presented which describes color sensations in bees to consist of unique-colors, as in humans (Herings, 1905, Leipzig). Since bees ignore brightness differences in color training experiments, only five unique colors are needed. The amounts of unique-colors are assumed to be linearly related to the electrical excitation values of the two color opponent coding neurons. In double color training experiments, honeybees appear to distinguish one of the color-object colors which the two trained colors have in common and to choose the stimulus in the tests according to the amounts of these unique-colors. Quantitative predictions for further experiments are derived from the model for further testing the hypothesis about the existence of unique-color sensations in the honeybee.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: REFLEX FUNCTION I

A STUDY OF CUTANEOUS INHIBITORY INPUT TO A SPINAL NOCICEPTIVE MOTOR SYSTEM. B.B. Naud* and J. Schoenmaker. Department of Physiology and Biophysics, University of Lund, Slottsvagen 15, S-22362, Lund, Sweden.

The nociceptive withdrawal reflex system has been extensively studied from both motor and sensory aspects. A 'modulatory system' of this system has been recently described, each 'module' acting on a single or a few sympathetic muscles (Schoenmaker et al. News in Physiological Sciences 3, in press). Each module receives excitatory input from the skin area withdrawn by its effects (Weeden, 1992). We have now extended the cutaneous inhibitory input system to this motor system in the decerebrate spinal cat (Wankels, 1988).

Reflex responses in single hindlimb muscles evoked by sustained noxious pinch (2N, 1mm²) were recorded using extracellular recording techniques. Inhibitory receptive fields of mm.permenosus longus and brevis, extensor digitorum longus, tibialis anterior and biceps posteriores were mapped using mechanical pinch (up to 2.5N, 1 mm² and Dye-laser thermal stimulation (50-300 mJ, 1 mm diameter). For each muscle, the reflex responses could be inhibited by electrical stimulation (5-10 Hz, 1 ms) of the skin area which is moved towards the cutaneous stimulation on the muscle. Noxious stimulus produced an inhibitory effect in the reflex elicited by cutaneous stimulii, indicating a nociceptive inhibitory input. In intact animals the excitatory and inhibitory receptive fields of withdrawal reflexes to single muscles reflects the movement pattern caused by the muscles. Both the excitatory and inhibitory actions on this system protect the body from injury.

ESTIMATED NET SYNAPTIC POTENTIAL IN HUMAN MOTORNEURONES. K.S. Turner* and H.B. Cheng, Department of Physiology, University of Adelaide, S.A, 5005, Australia.

Although recording single motor unit activity from human muscles is technically simple, quantifying reflex responses has not been easy. The most commonly used method for quantifying the reflex response has been the peristimulus time histogram (PSTH) and its cumulative sum (CUSUM) which illustrates the change in the firing probability of the single motor unit in response to a stimulus. According to this method, an increase in the firing probability relative to the pre-stimulus period indicates excitation and a reduction represents inhibition. However, it has been demonstrated that the stimulus may induce synchronous activity of the unit and this may induce several peaks in the histogram many of which are not due to the stimulus-induced extra activity in the motoneurone. These peaks are, in fact, due to the summation of the background activity from a fixed point of time "the autocorrelation effect". The frequency of firing of motor units, however, avoids these synchronous activity-induced false peaks and troughs. Furthermore, the frequency of firing of a unique-colors which the two trained colors have in common and to choose the stimulus in the tests according to the amounts of these unique-colors. Quantitative predictions for further experiments are derived from the model for further testing the hypothesis about the existence of unique-color sensations in the honeybee.
REFLEX RESPONSES TO LOW-INTENSITY STIMULATION OF THE SURAL, TIBIAL, AND PERONEAL NERVES DURING HUMAN WALKING. B.M.H. Yan West, P.A.M. Oosterhoff and J. Doymas*. Dept of Medical Physics & Biophysics, University of Nijmegen, 6500 HW Nijmegen, Netherlands. The skin of the foot is innervated by 3 nerves, namely the sural, tibial, and peroneal nerve. Most studies on the reflex responses to stimulation of these nerves during human locomotion have concentrated on only 2 of these nerves. The question arises whether the reflexes, and their phase-dependent modulation in locomotion, show differences for these different nerves. The purpose of the present study was to compare the reflex responses to stimulation of these 3 nerves in the same subjects, while walking on a treadmill.

Both facilitatory and suppressive reflex responses with a latency of about 40 ms were observed following a perception threshold of 3.5 ms for all 3 nerves. In general, the responses for the 3 nerves are of the same order of magnitude. The pattern of the responses can be different, however. For example, the responses in bisected femorotibial nerve were generally facilitatory during the whole step cycle, whereas responses in IF to tibial nerve stimulation at end swing were often suppressive. In tibialis anterior suppression at end swing were observed in the response pattern for all 3 nerves. During the stance phase, however, a clear difference was found: generally no responses were found for sural and peroneal nerve stimulation, but large facilitatory responses were often found during mid to end stance for tibial nerve stimulation.

In conclusion, the low-threshold afferents from the 3 nerves, innervating the skin of the foot, have both excitatory and inhibitory pathways to various leg muscles. The phase-dependent reflex modulation can be different, presumably by adjusting the balance of activity in these opposite paths. This suggests the existence of differences in the reflex pathways for the different nerves, which can be controlled separately during the course of the step cycle.

DOES THE NERVE BRANCH PATTERN REFLECT A RE-MODELING WITHIN THE MOTONEURON POOL - MUSCLE COMPLEX OF OLDER RATS? S. Vanden Noven*, H.K. Lietum and M.J. Partidos. Sch. of Physical & Occupational Theraphy, McGill Univ., Montreal, QC H3G 1Y5. In this laboratory, the medial gastrocnemius (MG) motoneuron pool was studied in young rats (Sprague-Dawley; Fischer 344) being used in various morphological and electrophysiological studies in order to further our understanding of the mechanisms underlying the function of the motoneuron pool. The two extra-muscular nerve branches innervating the MG muscle in the Sprague-Dawley rat subserve a physiological and histochmical compartmentalization (Vanden Noven et al., 1994). The afferent contributions of these two muscle nerve branch patterns were also been found to differ between rats of different ages (Vanden Noven, 1993). In this study, dorsal root volleys (Group I stimulus strength) and the MG muscle nerve branch pattern was compared between young adult (n=5) and older animals (12-23 mo; n=5). Neural potentials, evoked by stimulation of the L4-L5 dorsal roots, were recorded from each of the two nerve branches. The MG muscle nerve branch pattern was more complex and the topographic distribution of DR afferents entering the spinal cord was disrupted in the older age group. Taken together with other data on motoneuron and muscle properties, results suggest that the MG complex undergoes a re-organization with age.

EFFECTS OF THE SEROTONIN-2 AGONIST DOI ON S VS. F MOTONEURONS IN VIVO. D.H. Lee, J.F. Miller, W.Z. Rymer and C.J. Heckman*. Physiology, Northwestern Univ. Med. Sch. and VA, Lakeside Hospital, Chicago, IL 60611. The orderly recruitment of motor units is largely due to systematic differences in the threshold currents (theobases) of slow twitches (S) vs. fast twitches (F) motoneurons (MNs). Serotonergic (5HT) agonists can greatly reduce theobases and our goal was to investigate the relative amount of this decrease in theobase in S vs. F MNs.

DOI, a 5HT-2 agonist, has long lasting actions in vivo (>2 hrs; see the companion poster by Miller et al.). The intrinsic properties of two populations of triceps surae MNs in the decerebrate cat were compared in control conditions and following 15 mg/kg administration of DOI (0.5-1 mg/kg). The preparation was spinalized at T10 to eliminate the effects of descending SHI tracts.

The average decrease of the population (8.5 mA; range: 6 to 21 mA; n=6) was significantly less (t-test, p<0.005) than that of the control population (12.6 mA; range: 8 to 32 mA; n=4). DOI MNs with negative rheobase (n=12) had sustained rhythmic firing in the absence of any injected current. Negative rheobase MNs had slow conduction velocities (CVs) and were probably type S. However, the slopes of the regression lines for the rheobase-CV relations were not significantly different in the two populations, indicating that the effect of DOI was approximately the same in both S and F MNs. These data suggest that DOI input can enhance the excitability of the motoneuron pool without altering its recruitment order.

EFFECTS OF THE SEROTONIN AGONIST DOI ON FORCES AND STRICTION REFLEXES OF THE DECEREBRATED CAT. J.F. Miller*, K.D. Paul, W.Z. Rymer and C.J. Heckman. Physiology, Northwestern Univ. Med. Sch. and VA, Lakeside Hospital, Chicago IL 60611. 5-HT2 agonists produce substantial depolarizations of spinal motoneurons. Such actions should substantially increase the input-output gain of the motoneuron pool. We therefore investigated the effect of the DOI 2A/2C agonist on the reflex output of the triceps surae muscles in the decerebrate cat preparation.

The stretch reflex and background force of extensor MNs are greatly enhanced in the decerebrate cat. Intracerebral administration of DOI (1-5 μg/ml; cumulative) further increased stretch reflex amplitude by 30-50%. Even more striking changes in background force were observed. For example, soleus background force typically increased 2-4 fold after DOI, and in one experiment exceeded 20 N, which is near the maximum force of the intact cat. Similar results were seen following i.v. administration of DOI (0.5-1 mg/kg).

The duration of DOI's actions by either route typically exceeded 120 min. Ketorolac (0.5-1 mg/kg i.v.) transiently reversed the effects of DOI for 30-45 min. In one experiment, the spinal cord was transected at T10, resulting in a great reduction in background force and stretch reflex amplitude. DOI (1 mg/kg i.v) restored force and reflexes to their pre-spinalized level. These results show that serotonergic synaptic input can greatly enhance the output of the motoneuron pool.

DISYNAPTIC AUTOGENIC AND HETEROGENIC EXCITATION FROM GROUP I AFFERENTS IN HINDLIMB EXTENSOR MOTONEURONS DURING FICTIVE LOCOMOTION. M.J. Angel*, P. Guerret, J. Jimenez* and D.A. McCrea. Dept of Physiology, U. of Manitoba, Winnipeg, CANADA, R3E 3W1 and ITA-MX. Mexico.

Stimulation of plantar group I afferents during the extensor phase of fictive locomotion evokes disynaptic EPSPs in medial gastrocnemius motoneurons, thus replacing the inhibitory potentials evoked at rest (McCrea et al., Congr. on Physiol. Sci. 1993). In the present study, we examined the distribution of disynaptic EPSPs from ankle extensor group I afferents to hindlimb extensor motoneurons during MLR-evoked fictive locomotion by extending the stimulus and noting the extensor nerves (single shocks, 1.5 milliseconds threshold) produced EPSPs in ankle and hip extensor motoneurons and in the bifunctional PBS motoneurons (hip extensor + knee flexor). Autogenetic excitation was also observed in ankle and hip extensor motoneurons during extension. The latencies of the EPSPs (1.1-1.9 ms) suggest the opening of a disynaptic pathway from group I afferents to extensors during extension. The presence of group I autogenic and heterogenic, i.e., disynaptic excitation is a functional reorganization of ankle extensor group I reflexes during locomotion. The switch from inhibition at rest to excitation during locomotion indicates recruitment of a previously undisclosed population of excitatory group I interneurons. Activation of these interneurons by group I afferents during extension enhances hindlimb extensor motoneurons and acts as a positive feedback system enhancing centrally programmed extension.

BOTH DISYNAPTIC AND LONGER LATENCY INTERNEURONAL PATHWAYS MEDIATE EXTENSION ENHANCEMENT EVOKED BY GROUP I MUSCLE AFFERENTS DURING FICTIVE LOCOMOTION. P. Guerret*, M.J. Angel, J. Jimenez* and D.A. McCrea. Dept of Physiology, U. of Manitoba, Canada and ITA-MX.

Trains of group I stimuli to ankle extensor nerves increase the amplitude and duration of extension electromyogram locomotor bursts (Guerret et al. Soc. Neurosci. 19:61-15, 1993). The present study examined the synaptic effects of group I stimulation in the intact and in spinalized animals. The group I-evoked fictive locomotion. Plantar nerve stimulation (1.5 times threshold; 20 pulses; 200Hz) during extension increased the amplitude and duration of hindlimb extensor motoneuron locomotor drive (LDPs). The increase in LDP amplitude began within 10 ms after the first shock in the train and often continued well beyond the duration of the stimulus train. Accompanying the LDP enhancement, and depending on the preparation, were distinct disynaptic excitatory or post-synaptic potentials following each stimulus pulse. In most cases, the depolarization produced by the LDP enhancement was larger than the disynaptic depolarizations. Since LDP enhancement occurred in the absence of a coincident muscle fiber action potential, the pathway for the group I afferents is part of a positive feedback system during locomotion that shapes the amplitude and duration of centrally programmed extension bursts.

Supported by the MRC and the Rick Hansen Legacy Fund.

Group I afferents from extensor muscles exhibit a reflex reversal during locomotion that leads to excitation of the extensor motoneuronal pool. This excitation can be prevented by transcutaneous stimulation of the extensors during fictive locomotion. A question that arises is whether this excitatory actions are functionally relevant in a moving animal that is receiving phasic afferent input from many sources.

To address this issue, extensor nerves in the hindlimbs of decerebrate cats were stimulated, while the animals walked spontaneously on a treadmill. The ankle (L4-S1 L & P) and knee (L6 & V) extensor nerves were dissected, cut, and enclosed in stimulation cuffs. Stimulation of each nerve with trains (400-1500 ms, 200 Hz, 1.8 X T) during the extensor portion of the step cycle resulted in a prolongation of the extensor burst. Flexor burst delay was initiated by delayed stimulation but not always to the end of the stimulus volley. Stimulation during early flexion resulted in premature termination of the flexor burst and a delayed excitation of the extensors, followed by a reinflation of flexion coincident with stimulus offset. When the stimulation intensity was reduced to sub threshold levels for each nerve, it was possible to stimulate two nerves simultaneously and elicit an increase in the extensor duration. This nonlinear summation suggests that the regulation of the stance phase be partly regulated by group I afferents from many extensor muscles converging onto a common interneuronal pool.

Since the observed effects are similar to those attributed to group II afferents in reduced preparations, it is concluded that a reduction in force feedback to lb extensor afferents is necessary for the initiation of the swing phase in a walking animal.

Recently, it has been shown that autogenic inhibition arising from group II afferents in extensor muscles is largely eliminated during walking in reduced cut preparation (Conway et al. 1987 Expt Brain Res 68:643, Pearson & Collins 1993 J Neurophysiol 70:1009).

Instead, a long lasting autogenic excitation is seen. The purpose of this study was to determine whether this change is also apparent in humans. Putative Ib responses can be elicited by conditioning the soleus H-reflex with a stimulus to the medial gastrocnemius nerve at or just below below threshold (e.g., Pieper & Deuschl, J 1979 Brain Res 166:176). The response was observed both in quiet sitting and in the stance phase of walking. The inhibition during sitting, observed by others, was reproduced. Preliminary results indicate this inhibition was either reduced or eliminated in walking. Sometimes, this was replaced by excitation. Hence, qualitatively, the results support those obtained from the cat, but quantitatively, the effect was considerably more modest in the normal human.

THE EFFECTS OF A TONIC INCREASE OF PRESYNAPTIC INHIBITION OF MUSCLE SPINDLE AFFERENTS ON THE STRETCH REFLEX PARAMETERS OF THE CAT. C. Capaday, C. Centre de Recherche en Neurobiologie, Universite Laval, Quebec City, Quebec, Canada, G1K 7P4.

Experiments were done in cats decerebrated at the pontocerebellar rectumotomy or by bilateral pontine lesions to determine how a tonic increase of presynaptic inhibition of the intraspinous terminals of muscle spindle afferents affected the slow component of the soleus stretch reflex (s/r). Baclofen, a specific GABA receptor agonist was injected into the brains of the cats in the dose of 1 mg/kg. The slow component of the stretch reflex was reduced by baclofen as a function of the background force level was determined by stretching the muscle with a square pulse of 2 mm and 500 ms duration. The Baclofen dose-dependently reduced the intra-synaptic component of the stretch reflex, without any effect on the extra-synaptic component. Baclofen-induced reduction of the stretch reflex was most evident in the dose of 1 mg/kg. Baclofen-induced reduction of the stretch reflex was most evident in the dose of 1 mg/kg. The threshold of the stimulation used required to elicit the stretch reflex was not affected by baclofen. The results suggest that the tonic increase of presynaptic inhibition of the intraspinous terminals of muscle afferents. However, the present data suggest that the tonic increase of presynaptic inhibition of the intraspinous terminals of muscle afferents has no effect on the slow component of the stretch reflex and the threshold of the stimulation used required to elicit the stretch reflex was not affected by baclofen.

In conclusion, these data suggest that the tonic increase of presynaptic inhibition of the intraspinous terminals of muscle afferents has no effect on the slow component of the stretch reflex and the threshold of the stimulation used required to elicit the stretch reflex was not affected by baclofen.
The innervation of the dorsal and ventral horns of the rat spinal cord by axons descending from the locus coeruleus/subcoeruleus complex and A5 cell group. M. A. Sant'Ana, E. Polgar, and A. Z. Ribeiro. Department of Anatomy, University Medical School, Dobreson, H-4014 Hungary.

The spinal projections of noradrenergic brainstem nuclei that influence complex sensory and motor activities in the spinal cord were studied in a rat by using the Phascolosaurus vulgaris leucocephalus (PHA-L). After injecting PHA-L unilaterally into the nucleus coeruleus, nucleus subcoeruleus, and A5 cell group, labelled fibre terminals and terminals were detected in the spinal cord, from which spinal cord nuclei, spinothalamic, and cutaneous segments of the spinal cord. Most of the terminals (60-80%) from all three nuclei were found in the ventral horn laminae VII-VIII. The superficial dorsal horn (lamina I-II) received a relatively sparse innervation from the locus coeruleus and A5 cell group. The subcoeruleus complex, however, projected more dorsally to the dorsal horn. More than 30% of the terminals arising from the subcoeruleus complex were revealed in lamina I-II at the level of thoracic and lumbar segments on both sides of the spinal cord.

To study the postynaptic targets of these descending fibre sections were stained for both PHA-L and calbindin-D28k (CaB), a calcium-binding protein that have been reported to be markers of certain subsets of spinal neurons stained including stacked cells and supraspinally projecting neurons in the dorsal and Remilows-cell in the ventral horn. All of the aforementioned terminals of CaB-immunoreactive fibres were stained to receive contacts from fibers descending from the investigated noradrenergic brainstem nuclei. Synaptic contacts of terminals in laminae I-II and laminae VII-VIII as well as GABA and glycine immunoreactivities of their postynaptic targets were also investigated in a correlative electron microscopic study.

Deep periaqueductal gray neurons project to the spinal cord in the cat. L. J. Mouton, L. Kerstens, and G. Holstege. Dept. Anatomy and Embryology, Faculty of Medicine, Rijksuniversiteit Gent, the Netherlands.

The mesencephalic periaqueductal gray (PAG) plays an important role in many different functions, such as the regulation of pain, cardiovascular control, vocalization, and motor coordination. In the present tracing study in the cat (Mouton and Holstege, 1994) HRP injections in the upper thamic and cervical spinal cord resulted in many strongly labeled neurons in the ventrolateral PAG, but also a few faintly labeled small neurons were found at the level of the dorsal PAG and the adjacent intercollicular zone. Nothing was found for the function of these small dorsal border PAG-spinal neurons. The purpose of the present retrograde and anterograde labeling study was to exactly describe this dorsal border PAG-spinal pathway.

In nine cats WGA-HRP was injected in the spinal cord, each at a different spinal level. Prior to the injection a hemisection was made rostral to the injection site. In order to identify and count the retrogradely labeled PAG neurons every 40 μm transverse section of the brainstem was incubated using the TMB method. In an anterograde tracing study WGA-HRP injections were made in the area which contained the small dorsal PAG-spinal neurons.

Results show that there exist several hundreds of relatively small neurons at the dorsal border of the substantrial PAG projecting to the cervical and thoracic spinal cord. Only a few dorsal border PAG neurons seem to project to the lower lumbar cord, while almost one hundred neurons project to the cervical spinal cord. The neurons project ipsilaterally to the area immediately surrounding the central canal, but not corresponding to laminas X. Further electronmicroscopic studies are needed to more precisely reveal the nature of this pathway.

The deep mesencephalic nucleus (DM) is a deep extensive territory included in the mesencephalic reticular formation. In 32 rats small deposits of Phascolosaurus vulgaris leucocephalus (PHA-L) were placed in the DM. Staining different sections of different DM regions resulted in the thalamus, zona incerta, superior colliculus, accessory oculomotor nuclei, peri-aqueductal gray substance, reticular formation, periaquedural, and cranial nuclei. In the rostral and central lateral thalamic nuclei, ventrolateral geniculate, intergeniculate, and subgeniculate nuclei, zona incerta, anterior pretectal nucleus and superior colliculus (superficial layers) are targeted mainly by ventral PAG, DPG, and the lobar thalamic nuclei, ventrolateral geniculate, intergeniculate, and subgeniculate nuclei, zona incerta, anterior pretectal nucleus and superior colliculus (superficial layers) are targeted mainly by ventral PAG, DPG, and the lobar thalamic nuclei, ventrolateral geniculate, intergeniculate, and subgeniculate nuclei of the brainstem were incubated using tetramethylrhodamine-dextran. The resulting light labelling in the dorso-lateral thalamic segments was cut, and the results showed that the terminals from the deep mixed-light and electronmicroscopic study were obtained to directly visualize the projections from the NMR to the lumbar spinal cord. Anterogradely labeled PAG-spinal neurons, in four cases injections of wheat germ agglutinin horseradish peroxidase (WGA-HRP) were made in the NMR. In two of these cases plain HRP was injected in hamster nuclei to retrogradely label PAG-neurones receiving projections from the NMR. In all cases the labelling was studied using the TMB method.

The results show that NMR terminals form asymmetrical contacts on the lateral thalamic nuclei, zona incerta, and the periaqueductal gray substance. The deep mesencephalic nucleus (DM) is a deep extensive territory included in the mesencephalic reticular formation. In 32 rats small deposits of Phascolosaurus vulgaris leucocephalus (PHA-L) were placed in the DM. A centre de recherche en sciences neurologiques, Laval, Quebec, Canada, and the Montreal Neurological Institute, Montreal, Canada. (H/C 337, Department of Surgery, University of Florida, Gainesville, Department of Neurology, University of Quebec à Montreal.)

It has been shown that effective neurons supplying the muscular and daceletic muscles of the rabbit are located in two brain stem nuclei: the trigeminal motor nucleus (ncl V) and the spinal motor nucleus (ncl VII). In the present study, following hemisection in pentobarbital sodium anesthesia. We have been able to conduct two series of experiments to characterize the muscular effective neurons of group-K. In the first, retrograde labelling with fluorescent dyes (together and fastblue) was used. The nuclei were excised, the central parts of the brain stem and neuron were killed after 8 days. We found that the nerve branches to the specific set of muscles of the calvaria. All of the muscle areas are all represented in group-K, that the effective nerves to those branches are interconnected. As a first step towards understanding the function of group-K neurons, their immunoreactivity to choline-synthesizing enzyme (ACCh), and the specific marker for cholinergic neurons was tested. Absence, immunostaining and perfusion. After fixation, vibratome coronal sections of the brain tissue were cut at 30μm. For sections were treated with a set of immunohistochemical dye (Code ACH), using the avidin-biotin peroxidase method. A reaction of the majority of cells in group-K were immunostained and were of the same size and shape as retrogradely labelled neurons. This suggests that neurons of group-K are cholinergic and are likely to be monoaminergic. However, group-K neurons are fusiform and smaller in size (mean diameter=31μm) than ncl V cells, which are round or oval (mean diameter=44μm). This suggests that the group-K neurons supplying the muscular muscles could be ganglia motoneurons, but this is contradicted by the fact that the daceletic muscle, which contains no muscle spindles in the rabbit, is also innervated by this nucleus.

A light microscope study of the dorsal and ventral roots at the lumbar-sacral junction of the spinal cord was made in the opossum in order to establish the total number of myelinated fibres and their size distribution. Dorsal and ventral roots were removed from deeply anaesthetized animals and were immersed overnight in 2% glutaraldehyde-2.5% paraformaldehyde in cacodylate buffer (pH 7.3). The tissue was rinsed, postfixed for 4 hours with 1% osmium, rinsed again, dehydrated, embedded in ethanol and embedded in Spurr's medium. Sections (1μm) were cut from the proximal part of the spinal cord, stained with toluidine blue and dried. They were photographed and used as a basis for obtaining a montage of the whole root section. An average of 890 ventral root fibres are myelinated. They can be divided in two populations: small fibres having a mean diameter of 8±2μm (42%), and large fibres having a mean diameter of 18±4μm (58%). myelin sheaths included. An average of 2400 dorsal root fibres are myelinated. They are distributed in three populations: a population of small and poorly myelinated fibres with a mean diameter of 12±4μm (41%), and a third population of large calibre fibres with a mean diameter of 20±4μm (19%). These data will serve as an endpoint to a developmental study of myelogenesis of the spinal cord in the Monodelphis pristinus. (Supported by NSERC.)

BRAINSTEM DISTRIBUTION OF C-FOS IMMUNOREACTIVITY FOLLOWING REPETITIVE COUGHING IN DECEREBRATED CATS. C. Gertner, F. Portillo, M. Youkilis, J.J. Pariaitwice, L. White, M. URCI, CNRS 1832, St. Jerome, 13397 Marselle 20; (1) CNRS-LNB, 14302 Marseille Cedex 20, France (E-mail: KER)

Using the expression of the immediate-early gene fos as a marker of neuronal activation, we compared in the brainstem of cats the pattern of distribution of cells exhibiting a For-immunoreactivity (FLI) in response to repetitive coughing (50 coughs) in intact (E. A.) and stimulated animals (to that observed in shamed animals. In decerebrated, paralyzed and ventilated cats, 100 to 250 coughing episodes were elicited by stimulation (1-3 V, 4 Hz, 45 min) of superior laryngeal nerves (SLN), applied 4 hours after surgery was completed. Coughing was monitored on the phrenic and ilio-hypogastric nerves. Brainstem tissues were immunoprocessed using an antibody recognizing both the fos and fos-related nuclear antigens, and the avidin-biotin peroxidase complex. In the brainstem of stimulated cats, intense FLI was observed in various subnuclei (e.g. commissural, lateral, ventrolateral, medial and dorsal-medial) of the nucleus tractus solitarii, the area and hypoglossal nuclei, the nuclei of the accessory seventh cranial nerve, the inferior central (raphe) nucleus and the locus coeruleus. In these regions only very weak or FLI was observed. FLI in the medullary reticular formation and in the pontine lateral and medial parabrachial nucleus was only augmented in experimental cats.

RETROSPINAL NEURONS AND THEIR SPINAL PROJECTIONS IN LAMPRETS: A STUDY USING RETROGRADE TRACERS. N. Bissenpietra* and R. Dulac. Dep. de kinastrophopathie, USJAM HSC 3P4 and Centre de recherche en sciences neurologiques, Universite de Montreal, P.O. Box 6128, Station Centre Ville, Montreal, Quebec, H3C 3J7 Canada.

As in other vertebrates, lampry reticospinal (RS) neurons play an important role in the spinal somatosensory system. In the present study, reticospinal tracers were used to study the organization of RS lampry neurons within the different reticular nuclei and to characterize the spinal projections of these rhombencephalic neurons. Cobalt-lysine was applied as wide as the rostral end of the spinal cord (n=30), or applied isopotenolophically to label descending cells projecting to specific spinal cord rots (n=10). Another tracer, horseradish peroxidase (HRP), was applied in the 12th, 20th, 37th and 38th spinal segments and transported in vivo in order to determine the length of the axonal projections of RS cells (n=20). Reticospinal neurons were counted from serial sections on the best specimen for each injection site and their soma were measured. 3-D computer reconstructions were made of each tract made to a total of 35 RS neurons were counted on one side.

The posterior rhombencephallic reticular nuclei (PRRN) contains the largest number of RS cells (845), 21% (777) of which project to the contralateral spinal cord and are located mainly in the caudal rhombencephallic reticular nuclei (MRN) contains fewer RS neurons (339), 18% (60) of which project contralaterally and is found predominantly in the lateral basal plate. Of the 90 RS neurons counted in the contralateral rhombencephallic reticular nuclei (ARRN), 27% (24) project to the contralateral spinal cord. They are intermingled with cells projecting to the ipsilateral side. Finally, the mesencephalic reticular nucleus (MRN) contains 102 neurons, projecting their axons exclusively to the ipsilateral spinal cord. Isopotenolophic application of cobalt-lysine to the lateral tract on one side labelled, on both sides, a higher proportion of cells in the PRRN (635) than in the other nuclei (MRN=94, ARRN=1, MRN=1). Spinal cord injections at the 12th segment labelled 716 RS cells, with a steep (63%) decrease in the number of small (less than 20) and RS cells counted as compared to injections in the 2nd spinal segment. Injections at the 9th (n=1) and 8th (n=1) segments (tail) labelled a gradually decreasing number of neurons with only 19% (138) of all RS cells projecting to the level of the tail and distributed predominantly in the PRRN (96) and the MRN (33). Results from this study reveal a higher number of RS cells than previously reported, with a noticeable contralateral projection cells (Supported by MRC, FCAR, FRSQ and NCE for neural regeneration and recovery).

THREE-DIMENSIONAL DENDRITIC ANALYSIS OF RAT PHRENIC MOTORNEURONS DURING POSTNATAL GROWTH. K.G. Smithphoria, Y.S. Prakash and G.C. Stock. Departments of Anesthesiology and Physiology, Mayo Clinic, Rochester, Minnesota.

The rapid growth of diaphragm muscle fibers between postnatal day 21 (D21) and adulthood may also be reflected by growth of phrenic motorneurons and their dendritic arborization. Concurrent growth of the spinal cord may also occur and result in the ability of supraspinal motor output in order to properly integrate descending synaptic input. In the present study, qualitative and quantitative features of rat phrenic motorneuronal dendritic morphology were examined in D21 and adult rats. Cholera toxin B-fragment was used to retrogradely label phrenic motorneurons. Computer-assisted three-dimensional neuronomorphometry was used to statistically summarize dendritic branching patterns. While this study is preliminary, previous qualitative observations on rat phrenic motorneurons, several new features were highlighted. For example, contralateral projections of dendrites were more prominent in D21 animals than in adults. Dendritic diameter was smaller in D21 compared to adults. Total dendritic lengths were shorter at D21, and showed less variability compared to adults. Branching angles of D21 dendrites were also greater compared to adults, indicating a differential growth of dendrites during growth. This was also reflected by smaller receptive areas of motorneurons at D21. Receptive areas at D21 also showed greater variance compared to adults, indicating a differential growth of dendrites during growth.

SUPERSPIRAL CONTROL OF CERVICAL SPINAL CORD MOTORNEURAL DENDRITE BUNDLES IN THE RAT. 
W.J. Anderson* and G. Bennett. Neurobiology Lab, Indiana Univ. Medical center, Terre Haute. IN 47803

Our laboratory has previously described motorneuronal columns in the cervical spinal cord of the rat into discrete dendrite bundles with continuity with the brain stem and thamic cord. This organization identified a midline, medial (which included the phrenic nucleus) and a lateral column (internal and external). These dendrite bundles in the rat have electronmicroscopic connections that are adenodendritic, endomesodromic, and somatotomeric. There are interconnections between these columns which are referred to as microbundles. This study will present data that this organization of dendritic columns function as a substrate for determining supraspinal axons which include serotonin, noradrenaerpine and thyroid hormone. Utilizing double immunocytochemical techniques, utilizing choline acetyltransferase and tyrosine hydroxylase, cholinergic and adrenaline releasing factor, and serotonin with different substrates from Chemicon Corporation, we have demonstrated that specific supraspinal axons specifically innervate motorneural columns with pericellular contacts, distributed along dendrite bundles in the longitudinal plane in a specific manner, and finally interact with microbundles which interact with the different columns. The distribution of each transmitter varies in its distribution to the various bundles. We hypothesize that this supraspinal control has specific control over different columns, and yet can influence all to varying degrees through their microbundle distribution.

650.2

Both cholinergic and glutamatergic neurons have been identified in the lateral tegmental bundle (LDT) and pedunculopontine (PPN) nuclei. Both cholinergic and glutamatergic neurons in LDT and PPN project to the pontine inhibitory area, an area that is involved in the control of REM sleep and slow frequency. The present study was designed to clarify if neurons in LDT and PPN co-contain ACh and glutamate, utilizing choline acetyltransferase (ChAT) and glutamate immunohistochemical techniques. Three cats were perfused with saline followed with 3% paraformaldehyde and 0.25% glutaraldehyde in phosphate buffer solution, pH 7.4. The tissue was cut at 50 μ and alternate sections were processed with the following 1) ChAT 2) glutamate and 3) ChAT and glutamate. We found that neurons in both LDT and PPN co-contain glutamate and acetylcholine. However, the percentage of cholinergic neurons co-containing both transmitters was higher in PPN than in LDT. 78% of cholinergic neurons in PPN were double labeled with glutamate, while only 44% of neurons in LDT contained both transmitters. We suggested that the neurons in LDT and PPN that co-contain Ach and glutamate may play an important role in REM sleep control.

COLOCALIZATION OF SUBSTANCE P IN SEROTONERGIC AFFERENTS TO THE HYPOGLOSAL NUCLEUS. S, Makser* and J.N. Henry. Center for Sleep and Respiratory Neurobiology and Pulmonary and Critical Care Division, Department of Medicine, University of Pennsylvania, Philadelphia, PA 19104.

The serotonergic (5HT) innervation of the hypoglossal nucleus (M12) originates from the caudal raphe nuclei (CRN). Non-SHT neurons in these nuclei also project to the M12. Substance P (SP) cells are co-localized with 5HT. We sought to determine the presence of SP in non-5HT afferents to the M12. Rhodamine microphores (Rt; 100ml) were injected into the M215 of anesthetized rats, who survived 6-9 days before sacrifice. Rats were reanesthetized and injected intraventricularly with 100 μg of 5HT. Following perfusion and fixation, sections (32 μm) were cut through the entire brainstem. In cases with the Rh injection site restricted to the M12, every seventh or tenth section was processed for immunofluorescence for 5HT (rabbit anti-5HT, 1:2000; AMCA-conjugated goat-anti-rabbit, 1:500) and SP (rat monoclonal anti-SP, 1:200; FITC-conjugated goat-anti-rabbit, 1:100, Retagrade labeling by RH was observed to label 3% of M215 afferents, while SHT or SP immunofluorescence was present in all major groupings of SHT or SP somata, respectively. Within the median tegmental field, most SPT neurons also contained SHT. Of the neuronal afferents projecting to the M12, most (>79%) of the SHT-immunoreactive neurons also contained SP, and these triple labeled cells were present mainly within the CRN. Very few (<10%) of the non-SHT afferents to the M12 were SP positive. These observations suggest that the SP projections to the M12 are a subset of the SHT projections to the M12, and that SP neurons account for a very small proportion of the non-SHT afferents to the M12. A STUDY OF THE TRANSMITTER SYSTEMS MEDIATING TECTOSTRIATAL INPUTS IN LAMPERYS. I. Zec, and R. Dubois. Dep. de kinesiologie, Université du Québec à Montréal, H3C 1P8 and CRIN, Université du Montréal, H3C 3J7, Canada.

It has been shown by Uhl et al. (Behav. Brain Res. 50:107-110, 1993) that illumination of a lateral eye in lampreys induced a turning movement away from the light source. Anatomical studies have revealed that the retinae of lamprey contain two distinct classes of photoreceptors: one sensitive to blue (Cavallini & Rubenson, J. Comp. Neurol. 171:465-480, 1977). However, little is known on the interactions between visual inputs and motor systems in lampreys. In a previous study, we identified populations of neurons in the caudal raphe nuclei (CRN) that project to the midbrain tegmental region (M12) and the pontine reticular region (PRRN) in lampreys. These neurons contain immunoreactive 5′-OH indoleamines which are known to play a key role in descending modulatory control. We have also shown that microinjection of the cerebellum, in the in vitro isolated brainstem-spinal cord preparation, evoked mixed excitatory and inhibitory responses in neurons. This study was aimed at characterizing these tectostriatal inputs further. Large Mller cells of the M12 received strong excitatory inputs, while some RS neurons in the caudal PRRN received predominantly inhibitory inputs. To identify the transmitter systems involved, CNOX (10 μM) was added to the perfusion, and both the excitatory and inhibitory inputs were abolished, suggesting that AHPa receptors were involved in mediating these responses and that inhibition is due or oligogenic. Strauschny (5M) completely abolished the inhibitory responses, indicating that glycine is the inhibitory transmitter. Perfusion with the preparation with Mg2+-free Ringer's, increased the duration of the excitation and induced an inhibition by 100 μM A5P or when normal Mg2+ concentrations were restored. NMDA receptors are thus present in this pathway. In conclusion, we have shown that excitatory and inhibitory inputs from tectum to midbrain nuclei are similar to those reported in rats (Furman et al., J. Exp. Brain Res. 21:19-44, 1974). Moreover, this study indicates that within tectosubicular pathways of lampreys, excitation is mediated by excitatory amino acids and inhibition by glycine. Funded by NRC Canada, FCAR and FRSQ Quebec.
SYNAPTIC INTERACTIONS OF SUBSTANCE P IMMUNOREACTIVE (SP) NEURON TERMINALS WITH HYPOGLOSAL (XII) MOTEURONS WHICH INNERVATE THE INTRINSIC MUSCLES OF THE TONGUE: AN ELECTRON MICROSCOPIC DUAL LABELING STUDY* P.J. Gaál1, T.A. Johnstone2, M. Ghiradelli3, and V.J. Massi4. Dept. of Pharmacology and Veterinary Services. Harvard University. Med. School, Boston, MA. We have found tetramethylbenzidine chromogen. The intrinsic muscles of the tongue play important roles in speech and respiration. Little is known of the central mechanisms regulating XII motoneurons. To elucidate which afferent neurons and neurotransmitters modulate functionally associated subgroups of XII motoneurons, we have employed an electron microscopic dual labeling technique. Cholera toxin-biosorbed peroxidase and antiserum to substance P have been incubated into the intrinsic tongue muscles of the cat. The animals were sacrificed 48 hr later and sections were processed histochemically for the visualization of HRPs using tetramethylbenzidine as the chromogen. retrogradely labeled neurons were found predominantly ipsilaterally in the intermediate and ventromedial subdivisions of XII particularly at the level of the rostral pole of the area postrema. Sections were processed for the simultaneous immunocytochemical localization of SP using dianaminoazide as the chromogen. SP immunoreactivity was found in nerve terminal processes associated with large dense core vesicles. Some of these terminals made synaptic contact with proximal dendrites and perikarya of labeled XII motoneurons. These data indicate that SP affects modulate the activity of XII motoneurons which control the function of intrinsic tongue muscles. Supported by NIH HL44922, & Howard Univ. Grad. Sch. Collab. Core Prog.

Serotonergic systems exert important modulatory effects on sensory neurons and motoneurons in the mammalian spinal cord. These effects may be inhibitory or facilitatory, are mediated by synapses and receptors distributed over the surface of the target neurons. We were interested to determine if an important sensory feedback pathway providing proprioceptive information to the cerebellum, the dorsal spinocerebellar tract (DSC), received direct serotonergic input and to what extent such input was distributed over the proximal versus distal dendrites of DSC cells. Identified DSC cells were intracellularly stained with horseradish peroxidase (HRP), and 5-HT immunoreactive varicosities in contact with the cells were revealed by immunohistochemistry using an antibody raised in guinea pigs against keyhole limpet hemocyanin-conjugated 5-HT. At the light microscopic level, 5-HT contacts were observed on the soma and all regions of the extensive dendrites of stained DSC cells. However, the density of 5-HT contacts was much lower than previously observed on spinal motoneurons, suggesting that the DSC is not subject to particularly powerful descending serotonergic influences, thereby allowing the system to faithfully and rapidly relay its information regardless of activity in other systems. Supported by NIH grant NS25547.

Glycine is a major inhibitory neurotransmitter in the ventral horn of the spinal cord, exerting powerful effects over neural elements involved in motor behavior. Here we evaluated quantitatively various synaptic parameters related to glycinerergic terminals on the cell somas of α-motoneurons (α-MNs) and Renshaw cells (RCs). We assessed glycine receptor presence using electron microscopy pre-embedding immunocytochemistry with antibodies directed against gephrin, a protein associated with postsynaptic glycine receptor clusters. α-MNs were identified by their size, location and characteristic synaptology. RCs were identified by their location in ventral lamina VII and their distinctive gephrin-immunoreactivity (geph-ir). Overall synaptic covering was similar in α-MNs and RCs (45-45% of the available somatic membrane), with geph-ir terminals being the most abundant type on both RCs and α-MNs. While, terminals with geph-ir synapses constitute about 90% of the synaptic contacts in RCs, they constitute only 40-45% in α-MNs. An average of 87% of all terminals that contacted RC somas displayed geph-ir while this value was 49% for α-MNs. All geph-ir terminals were of the F-type, and had similar ultrastructural features on RCs and α-MNs. The percentage of apposition area occupied by postsynaptic geph-ir was larger in RC somas: 50-40% compared to 50-20% on α-MNs. The extension of postsynaptic geph-ir was almost identical to the extent of the opposed presynaptic active zone. In presynaptic active zones larger and the postsynaptic receptor regions are usually more intensely immunoreactive than those on α-MNs somas. Supported by NIH grant NS25547.

Spinalized cats exhibit variable degrees of weight bearing and locomotor ability in their hindlimbs, and these parameters can be differentially affected by training and certain pharmacological manipulations. To determine if the variability between animals is correlated with different patterns of neurochemical reorganization we studied the distribution of immunocytochemical markers for a variety of neurotransmitters and receptors involved in descending and segmental control of motor function, in cats that had undergone different training paradigms and exhibited different types of motor behavior following transection at T12-T13. Unlike controls, immunoreactivity for serotonin, tyrosine hydroxylase, and thyrotropin releasing hormone was completely absent in all cats in segments below the lesion site, indicating that the transections were complete in all cases. Interestingly, CGRP immunoreactivity was decreased in the ventral horn, suggesting some direct or indirect supraspinal influence. A similar result was observed for substance P labeling. There was no obvious rearrangement or expansion of markers for likely segmental transmitters (e.g. GAD, glycine receptors) to occupy sites vacated by the descending systems. It appears that the difference in locomotor capability among cats is the result of more subtle changes in circuitry or transmitter/receptor expression in spinal neurons. Supported in part by NIH grants NS16333 and NS25547.

SERTONIN (5-HT) REDUCES AN AFTERHYPERPOLARIZATION IN NEONATAL RAT MOTONEURONS THROUGH INHIBITION OF N- AND P-TYPE CALCIUM CHANNELS. D.A. Batlle*, M. Umeno* and A.J. Berger, Dept. of Physiology and Biophysics, University of Washington, Seattle, WA 98195. We have shown that 5-HT reduces input-output gain of neonatal rat hypoglossal motoneurons (HMs) via a decrease in synaptic back-pulse generation of Ca⁺-dependent afterhyperpolarization (AHP) (Neuroreport 14: 163, 1994). To determine if the decreased AHP is mediated by decreased Ca⁺ influx, we tested the effect of 5-HT on Ca⁺ currents in neonatal motoneurons. The presence of Ca⁺-selective micro-electrode preparation of Ca⁺-dependent AHP in hypoglossal motoneurons (HMs) was confirmed, as a decrease in synaptic back-pulse generation of Ca⁺-dependent AHP (8-10% AHP) was blocked by Co⁺ in the recording bathing solution. Application of 5-HT (10⁻⁵M) decreased synaptic back-pulse generation of Ca⁺-dependent AHP (20% AHP) and did not affect the rectification of Ca⁺ currents (20% rectification at 100mV). L-type Ca⁺ currents were completely blocked by La⁺ (2mM) and N-type Ca⁺ currents were partially blocked by a 10⁻⁵M solution of 2-chloroadenosine (2-CA), a blocker of N-type Ca⁺ channels. These results indicate that 5-HT decreases synaptic back-pulse generation of Ca⁺-dependent AHP in neonatal HMs and, in this way, 5-HT enhances the excitability of HMs. (Supported by NS14857 and Francis Families Foundation).

AT LEAST TWO DISTINCT IONIC MECHANISMS UNDERLIE THE RESPONSE OF HYPOGLOSSAL MOTONEURONS (HMs) TO NOREPINEPHRINE. M.A. Parker*, D. Belin**, and A.J. Berger. Depart. of Physiology and Biophysics, University of Washington, Seattle, WA 98195. The in vitro response of HMs to norepinephrine (NE) mimics their response to thyrotropic releasing hormone (TRH), i.e. depolarization with an increased input resistance (Ra) recorded in current-clamp, or development of an inward current with decreased input conductance in voltage-clamp (J. Neurophy. 68:1733, 1992, Soc. Neurophy. Abstr. 18:512, 1992). The NE current, like the TRH current, reversed near-100 mV. In addition, the effects of NE on HMs are blocked by TRH in the perfusing artificial cerebrospinal fluid (ACSF, Soc. Neurophy. Abstr. 19:988, 1993), suggesting that these two neuromodulators are not acting via similar mechanisms of action in HMs. Since the TRH-mediated increase in Ra is elicited by substitution of barium (Ba²⁺) for calcium in the ACSF, while the norepinephrine is not, we tested whether the same hold true for the response of HMs to NE. We found that the increase in HMs Ra elicited by NE was reduced from 50% in control to only 3% in Ba²⁺-ACSF, despite the cells' continued ability to exhibit a depolarizing response (n=7). After return to Ba²⁺-free ACSF, HMs again showed increased Ra in response to NE. To investigate the ionic mechanism responsible for the Ba²⁺-resistant depolarizing response, we substituted choline chloride for sodium chloride in the ACSF. Within ten minutes of switching into a Ba²⁺- and choline-substituted ACSF, HMs no longer depolarized in response to NE (n=4). After longer periods of time the response became a hyperpolarization. In choline-substituted ACSF without Ba²⁺, a depolarization with increased Ra could still be elicited by NE; but recovery from the depolarization was prolonged, the potential taking longer to return to baseline (n=3). We conclude that NE depolarizes HMs by at least two ionic mechanisms: reduction of a Ba²⁺ sensitive inward current (n=1), followed by a Ba²⁺-resistant depolarizing current carried predominantly by sodium ions. (Supported by HL-46507).

561.3

ADENOSINE MODULATES EXCITATORY SYNAPTIC TRANSMISSION TO RAT HYPOGLOSSAL MOTONEURONS. M.C. Bellingham* and A.J. Berger. Dept. Physical & Biophysics. Univ. Washington, Seattle, WA 98195. Adenosine-mediated modulation of excitatory inputs may be especially significant in hypoxic responses of HMs, as extracellular CNS adenosine levels rise many-fold under these circumstances. To investigate this modulation, intracellular recordings were made from adult rat hypoglossal motoneurons (HMs; n=25) in brainstem slices. Electrical stimulation lateral to the hypoglossal motor nucleus evoked short-latency (0.6±0.1 ms) excitatory postsynaptic potentials (EPSPs). These EPSPs were markedly depressed or abolished by bath application of kynurenic acid (1 mM; n=7), showing that they were glutamatergic. Bath application of adenosine receptor agonists 2-chloroadenosine (2-CA, 1 µM) and 2-chloroadenosine (2-CA, 1 µM) significantly reduced EPSP amplitude to 42 ± 5% (n=6) and 76 ± 7% (n=6) of control, respectively. The adenosine receptor agonist 8-cyclopentyl-1,3-dipropylxanthine (DPCPX; 0.1-1 µM) significantly increased the EPSP amplitude to 124 ± 14% of control (n=9), and blocked EPSP reduction by bath or local application of 2-CA or 2-CA (n=7). 2-CA, 2-CA and DPCPX did not significantly alter the AMPA amplitude of the mEPSCs. These data indicate that adenosine-mediated modulation of excitatory inputs to rat HMs are mediated by adenosine A1 receptors, most probably at a presynaptic site. Modulation of presynaptic N-type calcium channels does not appear to be essential for the adenosine-mediated effects, as presynaptic A1 receptors reduce excitatory synaptic transmission to HMs. (Supported by NS14857, HL-4657).

561.4

PRESYNAPTIC INHIBITION BY SEROTONIN OF GLYCINEnergIC INHIBITORY POSTSYNAPTIC CURRENTS (IPSCs) IN RAT MOTONEURONS. M.U. Umeno* and A.J. Berger. Dept. of Physiology and Biophysics, University of Washington, Seattle, WA 98195. Serotonin (5-HT) plays an important role in the neuronal function of synaptic modulation. Using a thin-slice preparation, we found that 5-HT presynaptically inhibited unitary glycine IPSCs of hypoglossal motoneurons (HMs). After intracellular injection of 5-HT (10⁻⁵M) into the terminal of an extracellularly stimulated synapse and recording of motoneurons in rat brainstem. One possible mechanism for presynaptic inhibition is K⁺ channel activation and/or voltage-activated Ca⁺ channel inhibition at the presynaptic terminal. In this regard, the 5-HT₁B and/or 5-HT₃ receptors, inwardly rectifying K⁺ channels and voltage-activated Ca⁺ channel were blocked by Co⁺ and Ni⁺. These results indicate that 5-HT presynaptic inhibition may be a K⁺ channel and voltage-activated Ca⁺ channel blocking mechanism. (Supported by NS14857).
651.7 DESCENDING SEROTONERGIC CONTROL OF CROSSED GROUP II INHIBITION IN THE SPINAL CORD OF THE CAT. N.C. Aggelopoulou1, B.W. Clarke2 and S.A. Edgeley1. 1Department of Anatomy, University of Cambridge and 2Department of Clinical Neurosciences, University of Nottingham, United Kingdom. SPONS: Brain Research Association.

Stimulation of hindlimb group II muscle afferents inhibits many contralateral hindlimb motoneurons. This crossed inhibitory reflex depends on a descending system as it disappears on section of the spinal cord. We have tested the hypothesis that crossed inhibition is dependent on serotonin transmission.

Experiments were carried out in four cats under chloralose general anaesthesia. Intracellular recordings were obtained from hindlimb motoneurons. Electrical stimulation of the contralateral quadriceps nerve at a strength sufficient to activate group II afferents (5T) elicited IPSPs in the majority (44/46: 96%) of gastrocnemius/soleus and hamstring motoneurons. The incidence of IPSPs was reduced after spinal transection at the thoracic level (94/100: 22%) and the IPSPs were smaller. After spinalization, intravascular administration of (+)-5,7,8-trifluoro-5H-tryptamine (8-OH-DPAT, Research Biochemicals), a selective agonist of 5HT1A receptors (dose 0.1-1.2 mg/kg, i.v.) restored the crossed inhibition of many motoneurons (44/46:85%) within 5-15 min. The effect of 8-OH-DPAT was antagonized with a latency of 10-20 min by the selective 5HT2 antagonist (+)-WAY-100135 (a gift of Wyeth Research UK) injected intravenously at a dose of 3.7-3.8 mg/kg, which markedly reduced the incidence of IPSPs in motoneurons (104/45: 22%).

The simplest explanation of these results is that a descending pathway acting via 5HT1A receptors permits crossed group II inhibition to operate. Supported by the Wellcome Trust and MRC (UK).

NADPH-diaphorase staining is thought to reveal neurons which use nitric oxide as a neuromodulator (J. Comp. Neurol. 324:410, 1993). Cholinergic neurons of the pedunculopontine tegmental nucleus (PPT) projecting to the mPRF are NADPH-positive, and electrical stimulation of PPT neurons increases mPRF ACh release (Am. J. Physiol. 264:R544, 1993). Therefore the present study is testing the hypothesis that inhibition of nitric oxide synthase with Nω-nitro-L-arginine (NLA) will result in state-dependent increase of mPRF ACh release. A cat was chronically implanted with electrodes for monitoring sleep and wakefulness. For each experiment, a microdialysis probe was stereotaxically placed in the mPRF for simultaneous recovery of ACh and delivery of either Ringer solution or 10 mM NLA. Ten minute dialysate samples (n=2) were collected during waking (n=4), non-REM sleep (n=4), and REM sleep (n=6). Samples were analyzed for peak of ACh using HPLC. ACh levels (mean±SD) during waking with NLA dialysis (0±10.11) were significantly less (n=23, df=44, p=0.002) than ACh levels with Ringer alone (0.34±0.29). Likewise, during REM sleep ACh levels with NLA dialysis (0.12±0.11) were less (n=29, df=46, p=0.002) than ACh levels with Ringers (0.20±0.05). During REM sleep, however, there was no significant difference (p=0.777) in ACh levels between NLA dialysis (0.34±0.29) and dialysis with Ringers (0.38±0.12). These data suggest nitric oxide may modulate state-dependent cholinergic neurotransmission within the mPRF. Support: Department of Anesthesia, HL-40851 (R31).

651.9 SEROTONIN AND NOREPINEPHRINE MODULATE EXCITATORY AMINO ACID RECEPTOR CURRENTS IN ACUTELY ISOLATED RAT VENTRAL HORN NEURONS. S.C. MacDonald, S. Hochman, and I.M. Jordan. Dept. of Physiology, University of Manitoba, Winnipeg, MB, R3E0W3.

It has previously been reported that serotonin (5-HT), and norepinephrine (NE) and N-methyl-D-aspartate (NMDA) are involved in locomotor-like activity in the neonatal rat preparation. We hypothesize that neurotransmission of excitatory synaptic transmition by monoamines plays a role in the generation and control of locomotion. Our goal is to examine the mechanisms of this modulation at a single cell level. We examined the effects of two monoamines, 5-HT and NE, on excitatory amino acid (EAA) currents in the ventral horn. Whole-cell voltage clamp recordings were obtained from acutely dissociated neurones from the area of the spinal cord where locomotor-related neurones are found. Local perfusion of NMDA and kainate evoked inward currents. These currents increased or decreased in the presence of either 5-HT or NE. Within single neurons, NE and 5-HT could be added concurrently to test EAA receptor subtype, whether facilitatory or inhibitory. Kainate currents were examined in 38 cells and were depressed in 26% of cells and potentiated in 45%. There was a mean current increase of 77.9±54.9% and 66.9±40.3% and decrease of 37.9±17% and 21.9±3.5% in the presence of 5-HT and NE respectively. Similarly, out of 28 cells examined with NMDA, 18% of cells were potentiated and 54% were depressed. Mean increases in current were 27.9±22.7% and 33.8±17.2% and decreases 16.6±11.9 and 16.9±11.4% for 5-HT and NE respectively. Preliminary results indicate that 5-HT1A and 5-HT2A nonadrenergic receptors contribute to the observed effects. These results suggest that 5-HT and NE can modulate excitatory synaptic transmission at the level of the postsynaptic receptor. Supported by MRC. S.C.M. is a Network of Centres of Excellence Trainee. (1Cazanavet et al, Neuroscience, Lett., 1990)

651.11 FAILURE OF INTRATHecal NIMODIPINE TO INCREASE SPINAL CORD BLOOD FLOW. H. Inamura and C.H. Talbot*. Division of Neurosurgery and Playfair Neuroscience Unit, Toronto Western Division, The Toronto Hospital, University of Toronto, Toronto, Ontario M5G 2G8, Canada.

We have demonstrated that intravenously administered calcium channel antagonist nimodipine produced an increase of spinal cord blood flow (SCBF) in normal and injured rats. However, in the injured rats, due to the hypotension caused by both cord trauma and the vasodilator effects of nimodipine it was necessary to counteract the hypotension and maintain the mean arterial blood pressure. Nimodipine has high lipid solubility and penetrates well into the central nervous system, so the present study was performed to investigate whether intrathecally infused nimodipine could increase the SCBF in normal rats. Male Wister rats anesthetized by alpha-chloralose and urethane had a laminectomy from C1 to T1 and a silastic tube was inserted into the subarachnoid space via the atlantooccipital membrane to the C6 level. We administered intrathecal nimodipine at a concentration of 0.05 mg/kg, n=5; 0.2 mg/kg, n=5 and placebo (n=5), and measured SCBF at C7T1 with the hydrogen clearance method before infusion, during infusion and 30 minutes after infusion of the drug. Neither 0.05 nor 0.2 mg/kg of nimodipine increased SCBF during infusion (f=12.13; p<0.05) or after infusion (f=12.13; F=13.1; p<0.001). Although 0.2 mg/kg nimodipine caused a 26.4% decrease in blood pressure at the end of infusion (p<0.006), it recovered to 85.2% of preinfusion value at the end of the experiment (p>0.1). These data suggest that intrathecal nimodipine at these doses cannot increase spinal cord blood flow.
652.1

We have previously shown that dopamine is present in cell bodies and processes in the lamprey spinal cord and that dopamine modulates fictive swimming (Neurosci. Lett., 163:23-26,1994). To further investigate the actions of dopamine, we examined the effects of dopamine at several levels: (i) in fictive swimming lamprey, 2) in network, cellular, and synaptic properties in the isolated spinal cord, and 3) on ionic currents in isolated spinal neurons. The experiments were done on adult sea lampreys (Petromyzon marinus) and adult silver lampreys (Ichthyomyzon asiaticus).

Injection of the dopamine receptor agonist, SKF 38393, decreased the cycle period of swimming, an effect similar to that of low concentrations (<1µM) of dopamine during fictive swimming. The D1 dopamine receptor agonist administered alone had no effect on fictive swimming. Injection of the dopamine receptor antagonist, 2-iodo-3-PPP, had no effect. Dopamine reduced the late after-spike hyperpolarization in motoneurons (MN), primary sensory dorsal cells (DC), stretch receptors, and afferent dorsal roots during fictive swimming, while the D2 dopamine receptor agonist had no effect. We conclude that dopamine acts through the D1 dopamine receptor to modulate fictive swimming. In our experiments, the dopamine receptor agonist administered alone had no effect on fictive swimming. Injection of the dopamine receptor antagonist, 2-iodo-3-PPP, had no effect. Dopamine reduced the late after-spike hyperpolarization in motoneurons (MN), primary sensory dorsal cells (DC), stretch receptors, and afferent dorsal roots during fictive swimming.

We have previously shown that dopamine is present in cell bodies and processes in the lamprey spinal cord and that dopamine modulates fictive swimming (Neurosci. Lett., 163:23-26,1994). To further investigate the actions of dopamine, we examined the effects of dopamine at several levels: (i) in fictive swimming lamprey, 2) in network, cellular, and synaptic properties in the isolated spinal cord, and 3) on ionic currents in isolated spinal neurons. The experiments were done on adult sea lampreys (Petromyzon marinus) and adult silver lampreys (Ichthyomyzon asiaticus).

Injection of the dopamine receptor agonist, SKF 38393, decreased the cycle period of swimming, an effect similar to that of low concentrations (<1µM) of dopamine during fictive swimming. The D1 dopamine receptor agonist administered alone had no effect on fictive swimming. Injection of the dopamine receptor antagonist, 2-iodo-3-PPP, had no effect. Dopamine reduced the late after-spike hyperpolarization in motoneurons (MN), primary sensory dorsal cells (DC), stretch receptors, and afferent dorsal roots during fictive swimming, while the D2 dopamine receptor agonist had no effect. We conclude that dopamine acts through the D1 dopamine receptor to modulate fictive swimming. In our experiments, the dopamine receptor agonist administered alone had no effect on fictive swimming. Injection of the dopamine receptor antagonist, 2-iodo-3-PPP, had no effect. Dopamine reduced the late after-spike hyperpolarization in motoneurons (MN), primary sensory dorsal cells (DC), stretch receptors, and afferent dorsal roots during fictive swimming.

652.2

We used photo-ablation to test the involvement of commissural interneurons in fictive swimming in the isolated spinal cord. Spinal interneurons were retrogradely labeled by applying a mixture of fluorescein- and eosin-dextran amine to a transverse hemisection of the midbody spinal cord of adult sea lampreys. After 1 to 5 weeks of survival, fictive swimming was induced in 8-segment lengths of spinal cord with N-methyl-DL-aspartate. An argon laser beam with a diameter of one-half the width of the spinal cord was moved along the spinal cord caudal to the dye application site, allowing the laser beam to focus adjacent to the spinal cord. Retrogradely labeled interneurons decreased the cycle period of swimming, an effect similar to that of low concentrations (<1µM) of dopamine during fictive swimming. The D1 dopamine receptor agonist administered alone had no effect on fictive swimming. Injection of the dopamine receptor antagonist, 2-iodo-3-PPP, had no effect. Dopamine reduced the late after-spike hyperpolarization in motoneurons (MN), primary sensory dorsal cells (DC), stretch receptors, and afferent dorsal roots during fictive swimming, while the D2 dopamine receptor agonist had no effect. We conclude that dopamine acts through the D1 dopamine receptor to modulate fictive swimming. In our experiments, the dopamine receptor agonist administered alone had no effect on fictive swimming. Injection of the dopamine receptor antagonist, 2-iodo-3-PPP, had no effect. Dopamine reduced the late after-spike hyperpolarization in motoneurons (MN), primary sensory dorsal cells (DC), stretch receptors, and afferent dorsal roots during fictive swimming.

INTERSEGMENTAL COORDINATION AFTER CHRONIC AND ACUTE LESIONS IN LAMPRY SPINAL CORD ASSESSED DURING FICTIVE SWIMMING. L. Grun*, T. Kiemel, D. Liao and A.H. Cohen*. Department of Zoology, University of Maryland, College Park, MD 20742.

Previously, we reported the use of correlation analysis in the isolated lamprey spinal cord to demonstrate that during fictive swimming there is strong intersegmental coupling. We define strong coupling in terms of the speed with which the bursting returns to its regular frequency after external perturbation. In this analysis we extract the cross-correlation of post-spike intervals between the delay pair between segments. High cross-correlation of periods and low auto-correlation of delays indicated strong coupling. We compared the results to simple models of coupled non-linear oscillators to illustrate the plausibility of the conclusion. Here we extend the method to spinal cords previously either acutely or chronically lesioned. We performed experiments that were either to the lateral or the medial fiber tracts of the entire spinal cord. At the time of testing, in partially lesioned animals acute lesions of the formerly spared fibers were often added to the chronic lesions to examine the function of regenerated fibers in the absence of the lesioned fibers. Chronically lesioned cords were compared to acutely lesioned healthy cords. The analysis of the acutely lesioned spinal cords revealed moderate to strong coupling of strength either medial or lateral tract coordinating fibers. However, there was evidence that the regular fibers were capable of strong or moderate strength coupling even after 10 months of recovery. Only in the presence of spared fibers was any strong coupling found. In only two cases was there even a hint of moderate strength coupling of regenerated fibers with this method of analysis. Thus, the regeneration, at best, seemed to restore only weak or perhaps occasionally moderate strength coupling among the segments.
A single action potential elicited in one of the two Mauthner axons (M-axon) while a fish is "fictively" swimming can dramatically reset the swimming rhythm. This is due to the ability of these neurons to identify cellular elements within the M-cell network that may subserve this resetting phenomenon. Firing both M-axons simultaneously results in cranial motor output to spinal motor output because the spinal commissural inhibitory interneurons in the M-cell network block firing of motoneurons and excitatory interneurons. We fired both M-axons simultaneously to determine if detection of firing in both M-axons was not sufficient to assess whether the resetting of the swimming rhythm could occur in the absence of spinal motor output from the escape network. Fictive swimming was elicited by stimulation of the midbrain of de cerebrate, paralyzed goldfish and the motor pattern was monitored by recording extracellularly from branches of ventral roots. A single intracellularly elicited action potential was initiated in each M-axon simultaneously (within 0.1 ms of each other) during bouts of fictive swimming. Simultaneous firing of both M-axons could reset the swimming rhythm indicated by a shift in the midpoints of swim- ming bursts post-axon stimulation relative to when they would be expected to occur based upon the pre-stimulation burst pattern. This result indicates that the resetting of the swimming rhythm can occur in the absence of spinal motor output from the Mauthner cells and suggests that the commissural inhibitory interneurons in the M-cell network contribute to the resetting. 652.9 CONFOCAL IMAGING OF RESPONSES IN POPULATIONS OF IDENTIFIED MOTONEURONS DURING ESCAPE BEHAVIORS OF INTACT ZEBRAFISH. J.R. Fetics* and D.M. Mcgillicuddy. Dept. of Neurobiology, Univ. of Minnesota, St. Paul, MN 55108.
The mechanisms that contribute to rostrocaudal phase lags in spinal locomotor networks in larval lamprey, A. hectori and A. rostrata, were studied with phaseolus vulgaris leucoagglutinin (PHA-L) retrograde tracing. PHA-L, a lectin with a 100% specific binding to neurons, was used to fill intracellularly many motoneurons in the ventral spinal cord (2-10 cells). PHA-L tracing was done under anesthesia with injected zolazepan maleate. Tracing was done under an upright fluorescence microscope (Olympus BX51-W, Lumar, 10x) equipped with a high resolution camera (Kodak Megaplus Color Camera). Figure acquisition was done with Scion Image. Spinal cord was dissected in Tris-buffered saline with 10% fetal bovine serum and held on a dissection ring. After dissection, the cord was placed in 40% paraformaldehyde. After 1 hour fixation, the cord was transferred to 30% sucrose in Tris buffer for 12-24 hours before being embedded in O.C.T. freezer medium (Tissue Tek). Transverse sections were cut with a cryostat to 12-15μm and mounted on slides. After mounting, sections were pre-incubated in blocking solution (0.3% Triton X-100, 1% normal goat serum, 0.2% FCS in 0.9% saline) for 1 hour at room temperature. The blocking solution was then replaced with blocking solution containing primary antibody (rabbit polyclonal, 1:500) in 0.3% Triton X-100, 1% normal goat serum, 0.2% FCS, and incubated for 24 hours at 4°C. After incubation with primary antibody, the sections were washed three times in PBS (3 minutes each) and incubated in secondary antibody (Alexa Fluor 488 or 594, goat anti rabbit, 1:2000 in 0.3% Triton X-100, 1% normal goat serum, 0.2% FCS, and PBS for 2 hours at room temperature). Sections were washed with PBS (3 times 3 minutes) and mounted on glass slides using Vectorshield (Vector Laboratories). Sections were observed with a Leica DM-RB microscope and images were captured with a Cooke Sensicam camera. Images were analyzed using Scion Image software.

652.10 MECHANISMS CONTRIBUTING TO ROSTOROCAUDAL PHASE LAGS IN SPINAL LOCOMOTOR NETWORKS IN LARVAL LAMPREY. A. Heegard* and J. Mcgillicuddy. Dept. of Neurobiology, Univ. of Minnesota, St. Paul, MN 55108.
The mechanisms that contribute to rostrocaudal phase lags in larval lamprey (Petromyzon marinus) were investigated in partitioned in vitro spinal cord preparations and by computer modeling. In in vitro preparations, swimming activity was elicited by chemical microstimulation in brainstem locomotor areas. Short distance coupling, Stycine applied to the rostral spinal cord (n=11) converted left-right alternation to synchronous swimming in the rostral 20% of the spinal cord (Neurosci. Abstr. 19:349, 1993). Stycine applied to the caudal spinal cord resulted in a reduction of continuous activity in the caudal 20% of the spinal cord with little effect on the left-right phase of the locomotor activity in the rostral cord. These results suggest that ipsilateral excitatory coupling is stronger in the ascending direction. Computer modeling confirmed the biological results and suggested that a dominant descending coupling contributes to rostrocaudal phase lags. Oscillatory frequency, amplitude, and long distance coupling. Cycle times of locomotor activity were examined in sections of the spinal cord when low-calcium Ringer's solution was applied to the rostrolateral section of the cord. Cycle times of the isolated caudal cord were similar to cycle times in the entire cord (n=7), but did appear to depend on the length of the rostral segments and the intrinsic cycle time. Cycle times of the isolated caudal cord were more closely related to the overall cycle times (6 of 7). Low-calcium Ringer's solution applied to the rostral spinal cord resulted in a reduction in the phase lag between the rostral and caudal cord compared to control. One interpretation of these results is that a frequency gradient along the cord contributes to rostrocaudal phase lags, and that long-distance coupling is symmetrical or perhaps stronger in the ascending direction which, by itself, would tend to reduce intersegmental phase lags. We are currently conducting experiments and performing computer modeling to investigate the combined effects of short distance coupling, long distance coupling, and oscillatory frequency gradient on rostrocaudal phase lags. 652.11 PEP TIDERGIC MODULATION OF THE SPINAL NETWORK FOR LOCOMOTION IN LAMPREY BY NEUROTENSIN AND SOMATOSTATIN. P.T. BARTHE and S. GRILLIER* Department of Neurosciences, the Nobel Institute for Neurophysiology, Karolinska Institute, S-17177 STOCKHOLM - SWEDEN.
Spinal neurons containing the neuropeptides somatostatin (SS) and neurotensin (NT) occur in lamprey. To gain insight into the ionic mechanisms and the functional role of these two peptides the effects of somatostatin and neurotensin were studied both in the cell culture and in the network level. Fictive locomotion was elicited by both application of the glutamate agonist NMDA (50-150μM) and by recordings from ventral roots. When both NT and SS (10-100 μM) reversibly slowed the NMDA-induced rhythmic activity by 2-5%. Furthermore, SS induced a reduction of the burst proportions (burst/duration/cycle period), whereas NT did not alter the burst pattern. In some cases the swimming activity became irregular with higher doses of NT. NT induced a depolarization (4.5-6.5 mV) of motoneurons and interneurons which were followed after blockage of voltage sensitive sodium channels with TTX and after removal of calcium. The fast and slow phases of the afterhyperpolarization were not affected. SS induced a hyperpolarization of spinal neurons and a decreased their firing frequency in response to depolarizing current pulses. SS also reduced the firing of interneurons and motoneurons recorded during fictive locomotion. It also induced a slowing of TTX-resistant, NMDA-induced membrane potential rhythmic oscillations. This study demonstrates that NT and SS modulate spinal activity by two different mechanisms, which both lead to a slowing of the swimming activity but with a different control of the burst parameters.

In the lamprey, a simple eel-like vertebrate, swimming is produced by bursts of activity alternating between the left and right sides, with a frequency from 0.25 to 10 Hz in combination with a constant phase lag between consecutive segments resulting in a wave travelling down the body pushing the animal forward through the water. The swimming rhythm generating network has previously been modelled as a chain of coupled oscillators, due to its ability to produce fictive swimming with only short sections of intra spinal cord. Here we introduce a continuous network model, using populations of neurons that synchronously spread rostrally and caudally along the spinal cord. Excitatory interneurons and caudally projecting crossed inhibitory interneurons are included in the network. The neurons are modelled according to a Hodgkin-Huxley type formalism. Excitatory synapses extend seven segments both rostrally and caudally with strengths decreasing linearly with distance. The same connection strategy is used for crossed inhibitory synapses with the addition that they extend 20 segments caudally. A network consisting of 2600 neurons and over 700,000 synapses has been used as a basis for the simulation. This network model produces stable forward swimming over a wide range of frequencies and can exhibit backward swimming by increasing excitability to the caudal segments. In order to further analyze the detailed contribution of different elements in the network we have studied different reduced networks. This has provided a deeper understanding of the different mechanisms underlying intersegmental locomotion in undulatory swimming.
CIRCUITY AND PATTERN GENERATION IV

FICTIVE HINDLIMB MOTOR PATTERNS EVOKED BY APPLICATION OF GLUTAMATE AGONISTS TO THE TURTLE SPINAL CORD

S. N. Currie, Dept. Neuroscience, Univ. of California, Riverside, CA 92521.

In turtles, it has been shown that both NMDA and non-NMDA type glutamate receptors contribute to cutaneous sensory processing in the scratch reflex pathway (Currie and Stein, 1990). In the present study, we tested the ability of NMDA (20-100 μM) and AMPA (2-10 μM) to evoke fictive hindlimb motor output when applied exogenously to restricted regions of the turtle spinal cord. Drugs were applied onto the exposed dorsal surface of 2-mm adjacent spinal cord segments near and within the anterior hindlimb enlargement. These segments receive cutaneous afferents from the pocket scratch and friction receptor fields (Martin and Stein, 1990) and contain both the sensory inputs of the scratch motor pattern generator (Rugiero and Crowe, 1984; Martin and Stein, 1989). Motor output was recorded unitarily from 3-5 hindlimb muscle nerves. Both NMDA and AMPA elicited coordinated burst motor discharge in all recorded hindlimb nerves. These chemically evoked motor patterns exhibit rhythmic alternation between hip flexor (VF-HP) and hip extensor (HR-AF) motor neuron activity, the timing of knee extensor activity within the hip flexor-extensor cycle is similar to that of sensory-evoked pocket scratch motor patterns. These chemically evoked motor patterns interact strongly with cutaneous-evoked reflexes. Stimulation of flexion reflexes on the ipsilateral or contralateral side produces phase-dependent resets of the chemically evoked rhythm. Stimulation within a scratch receptive field can reset the rhythm and in some cases, increase burst frequency for several cycles. Supported by NSF Grant IBN-9308804 to S.N.C.

RHYTHMIC OUTPUT OF EMBRYONIC SPINAL NETWORKS IN CULTURE IS INDUCED BY DISINHIBITION BUT NOT BY INCREASED EXCITATION J. Stelzl*, Institute of Physiology, Biothiplatz 5 03122 Bern, Switzerland

Simple locomotor patterns are based on rhythmic output of local spinal networks. In order to investigate the minimal structure and the formation of such networks, the spontaneous output of cultured slices of the embryonic rat spinal cord was studied. This was done by coculturing the slices with skeletal muscle fibres and recording the patterns of spontaneous muscle contractions using a simple optical device. Neuron-driven muscle contractions were distinguished from autocontractions of the muscle fibres by their typical patterns and by pharmacological tools.

Roughly 20% of the cultures showed spontaneous neurondriven muscle contractions, most of them with random patterns. In all of these cultures rhythmic patterns of muscle contractions were induced by classical pharmacological disinhibition of the spinal networks (strychnine, bicuculline or both) and antagonism of glutamatergic (i.e. GABA B receptor) or substances interfering with cholinergic, rhabdolaminergic or peptidergic pathways had no effect on rhythmic activity patterns, suggesting that these pathways were not critical for rhythmmogenesis.

On the other hand rhythmic activity was not evoked by NMDA, glutamate or the glutamate uptake blocker dihydrokainate. NMDA in the absence of magnesium increased the rate of spontaneous activity without inducing rhythmic activity. Spontaneous activity completely ceased in presence of the glutamatergant CNQX.

These findings suggest that rhythmic output patterns arise in glutamatergic spinal networks and that they are induced by reducing inhibitory transmission within these networks but not by increasing excitatory transmission.

NMDA-INDUCED OSCILLATIONS IN SPINAL MOTONEURONES BECOME MASKED BY INHIBITION DURING DEVELOPMENT M. S. Rios, J. Pedotti*. Department of Biology, Yale University, New Haven, CT 06511

Responses were recorded from ventral roots (VR) in isolated hindlimb frog and tadpole spinal cord (SOC). Intracellular recordings were simultaneously made from identified lumbar MNs. Tadpole swimming was recorded with a video camera. Application of NMDA (50 µM) evoked periodic bursting of VR activity in tadpole but not in frogs (5-200 µM). However, after strychnine (20-30 µM) application, synchronized periodic bursts were also initiated in the frog VRs. These persisted after strychnine removal and were coincident with periodic oscillations measured intracellularly in the motoneurones (MN). Thus, this periodic bursting behavior reflects a periodic oscillation of MN membrane potential. In the adult frog this behavior is initiated only after removal of inhibition. The periodic (-1Hz) tadpole VR bursts occur at the same frequency as the tadpole tail moves during swimming. Oscillations in the frog were much slower (>10s/cycle). Oscillations of tadpole and frog MNs have the same properties: they require the presence of physiological Mg+2 concentration (1mM), they are blocked by APV (100 µM) but not affected by CNQX (10-15 µM), and they are resistant to TTX (3µM).

These data provide evidence for the existence of a central pattern generator that is active in the tadpole and becomes inhibited during metamorphosis as the locomotor behavior changes from rhythmic to episodic.

INVERTEBRATE MOTOR FUNCTION

653.1

Sensory inputs from the distal segments of legs have been shown to modulate walking in many animals. We report activities of sense organs of the distal (tarsal) segments of the cockroach hind leg in restrained and freely walking animals. In restrained preparations, neurographic wires implanted adjacent to sensory nerves in the first tarsal segment recorded afferent responses to the position and movements of the distal tarsal joint. We have also morphologically identified a chondrotalan organ proximal to the joint and ablation studies strongly suggest that it is the source of these activities. Recordings in freely walking animals show peak actives at the onset and termination of stance phase. These discharges occur at the time that the claw is engaged and then disengaged when walking or climbing over rough surfaces. We have also shown that electrical stimulation of afferents through the recording electrodes reflexly excites the flexor muscle. We propose that the discharge of the organ signals disengagement of the claw from the substrate, reflexly exciting the flexor muscle at the initiation of swing.

653.3

In order to better understand the role of peripheral properties in cockroach walking, we have been developing biomechanical models of the insect. We have constructed a passive musculoskeletal model of the femorotibial (FT) joint of the metathoracic leg. This model suggests that passive properties (i.e. passive muscle tension and damping of the FT joint) play an important role in this joint during the swing phase of walking. Indeed, the initial swing movement can be generated entirely by passive forces. The FT joint model is currently being extended to incorporate active properties. In addition, we have developed a full body dynamic model of the free walking insect with 30 articulated degrees of freedom. This model is being used to estimate joint torques and ground reaction forces from kinematic data.

We have also constructed a leg robot with 18 active degrees of freedom. The purpose of this robot is to investigate the application of biological control principles to robotics. A generalization of leg coordination mechanisms derived from stick insect walking are used to control the robot's leg movements. These degrees of freedom are achieved using a scheme based on the equilibrium point hypothesis. Force feedback permits the robot to comply to uneven surfaces. An implementation of the elevator reflex allows the robot to step over obstacles. The robot can walk in a continuum of gaits, turn and negotiate irregular terrain.

CHANGES IN A PROPRIOCEPTIVE PATHWAY DURING MATURATION OF LOCOMOTOR RHYTHMicity, J.R. Gray& J.M. Robertson, Dept. Biology, Queen's University, Kingston, Ontario, Canada, K7L-3N6.

The flight system of the locust is a well established model for studying the role of proprioceptive input in motor pattern generation. Gradual hemimetabolous development of this insect makes it ideal for examining maturation of preexisting circuitry as well as potential changes inafferent input.

During maturation of the flight system the wingbeat frequency increases from 13 Hz at 1-2 days after imaginal ecdysis to approximately 23 Hz 14 days later. We examined the morphology of a single cell proprioceptor, the wing hinge stretch receptor axon displays heteromorphous growth. Further, within the mesothoracic branch there is an increase in the number of axonal swellings and the branch grows positively allometrically relative to the ganglion. Artificial excitation of the stretch receptor with patterns of stimuli that correspond to increased afferent activity causes all stages of maturation produced increased activity of presynaptic flight interneurons.

These results indicate that changes in the stretch receptor may alter its effect on the operation of the flight motor and suggest that proprioceptive influences, in part, motor pattern development.

PSIAC MODULATION OF WING HINGE MECHANICS BY THE FIRST BASAL MUSCLE OF THE BLOW FLY CALLIPHORA M. S., T* and M. H. Dickinson, Department of Organismal Biology and Anatomy, Arizona State University, Tempe, Arizona 85287.

Among the 17 direct steering muscles in flies, the First Basal (B1) has been implicated as the muscle most likely to control the timing of ventral wing pronation (ventral flip). Because of its large aerodynamic forces associated with the ventral flip, rapid and precise modulation of the B1 may be crucial for flight control. In the blowfly Calliphora vicina, the B1 fires an action potential and undergoes a cycle of length oscillation each and every wing beat at 15 Hz. Under conditions stimulating flight we previously found that the B1 may function as a spring, with properties of dynamic stiffness and mechanical energy dissipation unique to the other flight muscles. This dynamic stiffness of the B1 could control the extent of oscillations of the basal apodeme, which forms the mechanical linkage of the B1 to the wing hinge.

To test whether that rapid phase change in B1 activation can plausibly modulate oscillations of the basal apodeme, we measured B1 muscle length changes while making extracellular recordings of B1 action potentials. By measuring the deflection of a laser beam reflected from a small mirror mounted on the external portion of the basal apodeme, we could non-invasively measure oscillations of the basal apodeme and the corresponding length changes of the B1 during idled flight.

We found that changes in the interval between action potentials corresponded to increases in the maximum extent of stretch in the B1 and the extent of posterior deflection of the basal apodeme. Changes in the amplitude of basalar oscillations occurred within one cycle of changes in action potential timing. This rapid mechanical response suggests that the B1 can modulate wing kinematics on a cycle by cycle basis, even though wing beat frequency stimulation of the B1 under in situ conditions causes near-complete tetanus.

THE ROLE OF HALTERE AFFERENTS IN THE ACTIVITY OF A STEERING MUSCLE IN THE BLOWFLY, CALLIPHORA VICINA. A. Fyazuddin*, W. P. Chan, R. E. Jordan and M. H. Dickinson, Department of Organismal Biology & Anatomy, Univ. of Chicago, Chicago, IL 60637.

The large direct synchronous basal muscles in the blowfly are active during turning maneuvers and are thought to control the steering forces of the wings. Of these muscles, the first basal (B1), is unique in that it fires one spike each wing beat, at a precise phase of the stroke cycle. We have been investigating whether the campaniform fields at the base of the haltere provide the wing beat-synchronous feedback required for this sharp phase shift. Both mechanical oscillation of the haltere and electrical stimulation of the haltere nerve cause the B1 motor neuron (MNBI) to fire a phase-locked action potential. Furthermore, MNBI can follow stimulation frequencies up to and exceeding the normal wing beat frequency (150 Hz), suggesting that the halteres may be sufficient in establishing the phase-locked firing pattern of B1 during flight. We have begun to characterize the physiology of the connections between MNBI and haltere afferents by recording intracellularly recorded motor neuron while mechanically stimulating identified fields of campaniform sensilla on the base of the haltere. Stimulation of two large dorsal fields (df2 and df3), produces short-latency (<1ms) EPSPs in MNBI. Stimulation of the third dorsal field (df1) has no effect on MNBI activity. Campaniform neurons from both df2 and df3, visualized with biotinylated dextran, project to the meso-diencephalic neuropile near the site of origin of the MNBI axon. In contrast, neurons originating from df1 terminate in a different region, consistent with their failure to elicit a short-latency physiological response in MNBI. In other insect species, the strength of sensory-motor connections can be modulated by neurotransmitters such as octopamine (OA). In the blowfly, DA also enhances the synaptic efficacy of the connections between the haltere and MNBI.

THE STRUCTURE OF THE FLUID WAKE GENERATED BY A FLYING FRUIT FLY, DROSOPHILA MELANOGASTER. M. H. Dickinson, Department of Organismal Biology & Anatomy, University of Chicago, Chicago, IL 60637.

The flight of an important model system is not yet understood. In this study, we characterize aerodynamics of flight behavior in flies, I have visualized the flow using biotinylated dextran and biotinylated dextran. Flow was visualized using Lycopodium spores illuminated with laser sheets (670 nm) and imaged using a cooled CCD camera. The capture of images could be synchronized with the beat cycle following fixed delay. The generation of phase-reconstruction movies showing the change in flow through the wing stoke.

The flow visualizations reveal that Drosophila generate an inviscid single heart-shaped vortex tube during each wing stroke. The dorsal portion of each vortex ring is projected from the wing while the ventral portion of the ring is attached medially to the thorax. It is at this time that the vortex ring attaches completely from the wings and is shed into the wake. In contrast, no vortex structures are generated during the upstroke. The vortex rings generated by successive downstrokes coalesce to form a vortex tube directed posteriorly, roughly normal to the wing stroke plane. The fluid velocity within the central region of the vortex tube is high, instantaneously reaching values nearly ten times that of the free stream velocity.

The rapid shedding of vorticity during the ventral flip correlates with a large transient in the production of lift measured using laser interferometry. The rapid ventral flip shedding may provide an important means for the control of steering forces during flight.

As part of our ongoing study of metamorphosis of the frontal ganglion (FG) of Manduca, we have examined its function in the adult moth. We have found that the FG innervates the muscles of the moth's cibarial pump. These include dilators which expand the pump chamber, as well as compressors which reduce the pump chamber. During feeding the FG is involved in activating the cibarial pump muscles during feeding. The primary component consists of a relatively long burst of activity immediately followed by a brief burst of the pump compressors. The cibarial pump also plays a critical role in the expansion of the moth’s wings following its emergence from the pupal cuticle. During wing expansion, the cibarial pump is activated and the animal swallows air, using a motor pattern that is similar to that illustrated during feeding.

Air-swallowing is apparently required for proper neuromuscular function in the abdomen. Animals from which the FG was removed at the onset of metamorphosis develop normally into adults and successfully emerge from the pupal cuticle, but they fail to expand their wings and their abdomens are flattened. Feedback for turning off air-swallowing apparently requires connections between the FG and brain, as in animals in which these were bilaterally cut at the end of the larval stage expanded their wings normally but exhibited distended or burst abdomens by 24 hrs after adult emergence.

MOTOR NEURONS INVOLVED IN A SEGMENTALLY RESTRICTED REFLEX: VENTRAL FLAP AXONASIS IN PUPAL MANDUCA Sexta. C. J. Miles and R. Booker. Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

Stimulation of sensory neurons innervating hairs in the gin traps on the abdomen of pupal Manduca sexta evokes a rapid bending of the abdomen that is restricted to three posterior segments. Electrical stimulation of the gin trap sensory nerve in an isolated abdominal nerve cord evokes characteristic motor neuron activity in every abdominal segment. To determine if the segmentally distributed motor activity also occurred in intact animals and how it contributed to the segmentally restricted reflex, we measured the reflex responses of the sensory hairs in intact animals. We used reflex evoked responses as were recorded as electromyograms synchronized with video recordings of the behavior. Reflex behavior was compared with the segmental patterns of motor activity to determine if there was activity in many segments when the movement was restricted to one or two, or three segments. Coordinated motor activity was evoked by sensory nerves in response to stimulation of any of the gin traps, even when movement was restricted to one segment. Electromyograms of gin trap muscle activity correlated well with the intracellular and extracellular recordings of motor neuron activity obtained from isolated abdominal nerve cords and semi-intact preparations. These findings show that the neural circuit underlying the bending reflex is distributed throughout the abdominal nerve cord. This network generates a complex yet coordinated motor pattern with muscular activity in every abdominal segment whose concerted action produces a deceptively simple and localized bending reflex. 653.13 PERIPHERAL MODULATION OF A CENTRAL SYNAPSE BETWEEN IDENTIFIED MOTORNEURONS IN THE MEDITERRANEAN GOLLIONG OF THE LOCUST. T. Jellens & W.J. Heits*; Gatty Marine Lab., St. Andrews University, Fife, KY16 9TD, U.K. The fast extensor tibiae (FETi) motorneuron of the hind leg of locusts, which innervates the muscle providing the propulsive force for the jump and kick, also establishes excitatory synaptic connections with the fast flexor tibiae (FFTi) motorneuron. These central synaptic connections, which are apparently unique among insect motorneurons, contribute to the co-activation of the FETi and FFTi motorneurons during the preparation for a kick or jump. Simultaneous intracellular recordings from the FETi and FFTi motorneurons, while evoking ortho- and antidromic FETi spikes, reveal that the amplitude and duration of the central PSPs in the FFTi motorneurons are modulated by leg position: during leg flexion the PSPs are larger than during extension. This is in part due to sensory feedback of information in the ascidian muscle stimulating the central FETi-FFTi synaptic component. However, when extensor tension is abolished by dye-mediated laser photo-oxidation of FETi, the amplitude of the central PSPs is still modulated by leg position. The photo-oxidation technique allows specific de-innervation of the extensor muscle, without affecting any of the other structures, and the innervation can swiftly be restored via an electronic "sensory bypass" from the FETi soma to the extensor muscle. In the locust, hind leg position is mainly monitored by the chordotonal organs located in the distal femur. Manipulation (alternating stretching and relaxing) of the tendon of this sense organ, while keeping the leg in fixed position, accounts for most of the PSP amplitude modulation. A relatively enhanced PSP in the FETi with leg flexion makes sense since leg flexion is a prepossess to go into the co-activation phase. The site and mechanism of the modulation (e.g. pre-synaptic FETi spine amplitude, input resistance of the FETi, presynaptic modulation of the central synapse) itself is currently being investigated.

653.14 NEURAL ELEMENTS OF GRASSHOPPERS SUPPORTING SEXUALLY DIMORPHIC BEHAVIOR. K.J. Thompson and J.L. Roosevelt, Dept. of Biology, Agnes Scott College, Decatur, GA 30030. In a continuing study of the neural basis of oviposition behavior in grasshoppers, motor neurons (MNs) and dorsal unpaired median neurons (DUMs) of the terminal ganglia of male have been identified by backfilling lateral nerves with CoCl2. This information is being compared to the activity of known courtship behavior. In addition, the differences in MN and DUM pattern have been observed in males and females. Two hypotheses for how the nervous system produces sexual dimorphism in behavior are being tested. 1) Male-deficient hypothesis, which predicts that the male nervous system is missing female-specific output neurons (males do not lay eggs) and 2) Male-specific hypothesis, which predicts that the male contains neurons homologous to ovipositor neurons but involved in other functions. Four clusters of ovipositor MNs have been previously identified in females. Two of these clusters are present in the male DUMs have axons in different branches of the 8th terminal nerve of the terminal abdominal ganglion. One cluster, the protracor, is a group of 3 MNs with cell bodies contralateral to the file nerve and the second cluster, the closer, is a group of 3 MNs with cell bodies in the anterior ganglion. Backfills of the terminal nerve in males produced a similar pattern of MNs, in terms of numbers of cell bodies, cell body positions, and distinctive axonal trajectories. A single DUM neuron, located in the terminal abdominal ganglion, fills from the terminal nerve in both sexes. Thus, for two of the four groups of efferent neurons that have been identified, limited gender differences in MN and DUM complement have been found, despite differences in male and female behavior, and differences in the size and shape of the terminal ganglion. Supported by Whitetail grant 8ABS-01.

653.15 DYNAMICS OF A POSTURAL REFLEX IN HERMIT CRAB STUDIED WITH SINUSOID AND NOISE VIBRATION. W.D. Chappel*; Dept. Physiology and Neurobiology, Univ. of Connecticut, Storrs, CT 06269. A systems model of a phasic stretch reflex, important in the postural support of its shell by the underlying muscle. Pogoins pellucidae, has been developed from experiments using simultaneous recording of muscle force, length, and spine frequencies of pairs of motorneurons during ramp stretch and release of the right fourth segment of the abdominal ventral superficial muscles. (Chappe1993). A prediction of this model is that the reflex is important primarily in increasing abdominal stiffness in response to sustained rather than transient stimulation. Sinusoidal and broadband noise loading lasting for 2 sec was used to vibration the muscle. Reflex activation of the motorneurons occurred at on the 80% of optimum 20 Hz and frequencies above 2.5 Hz. A rapid onset, peak, frequency of this reflex is consistent with the model for the damped second order system. This result indicates that the motorneurons increased muscle stiffness and the reflex input appears to be increased, but did not alter its dynamics. The form of the transfer function that best described the reflex was that of a high pass frequency of 10 Hz, with a deviation of the isolated, electrically stimulated muscle. The model's prediction that the muscle reflex could increase muscle stiffness during sustained vibration was confirmed. However, in this isolated abdominal preparation, the reflex did not compensate for vibrations in muscle stiffness with stimulus amplitude, and, thus, did not regulate muscle stiffness.

653.16 DEVELOPMENT OF STOMATOGASTRIC MEDIATED MOTOR PROGRAMS IN THE AMERICAN LOBSTER. Kari Lavalli, Joseph Ayres*; Marine Science Center, Northeastern Univ., East Point, Nahant, MA 01908. Feeding and stomatogastric mediated behavior are composed three phases in all larval stages: an ingestion phase a relatively quiescent phase and a periodic grinding phase. We have demonstrated three behavioral stages of development of stomatogastric behavior. The first stage is limited to Stage I and II larvae and consists of: a) a fast peristaltic component which occurs only during ingestion; b) a slow "cardiac sac" rhythm which begins several minutes after the cessation of feeding and continues on until the gut is empty. This rhythm is the only present for the first four post-feeding and may serve to mix ingested food with digestive juice. It then allows a 3) the "gastric" rhythm resulting from a constriction of the lateral walls of the cardiac sac and a forceful anterior movement of the entire cardiac sac. No separate pyloric rhythm is formed in either Stage I or II larvae. The second behavioral stage is observed only in Stage III larvae and adds a medial gastric component due to elaboration and participation of the medial tooth. The third behavioral stage is first observed in Stage IV postlarvae and demonstrates an excellent replica of the adult pattern with several forms of modulation. Here, separate sacs, gastric and pyloric are present. After Stage IV have been able to identify different modes of operation of the gastric milk, particularly that of "cut and grind" and "superate." In addition several modes of modulation of the movements are present in all three stages. Supported by NSF Grant IIB-912224.
653.17 ENHANCEMENT OF NEUROMUSCULAR EFFICACY BY FLRF PEPTIDES IN THE CRAB, Cancer borealis. (J.C. Corpse, Ryan* and E.Stark. Ch. for Complex Systems, Brandeis University, Waltham, MA 02254)

Muscles play an essential role in re-shaping the activities of the gastric and pyloric water patterns of the stomatogastric ganglion (STG) of Cancer borealis (Winfield et al., 1993). This includes: enhancement of the pyloric rhythm frequency, activation of segment-specific pyloric rhythm motor patterns, and activation of oscillatory properties in the Dorsal Gastric (DG) neuron. We now use neuromuscular preparations to determine if FLRF agonist peptides increase neuromuscular junctional properties.

We found that both POP-FLRFamide and TPR-FLRFamide increase nerve-evoked contractile responses. Extrinsic Junctional Potentials (EJP’s) on DG-innervated muscles, gastric muscle and pyloric muscle were both enhanced by these peptides at concentrations ranging from 10^-10 M to 10^-4 M. POP-FLRFamide produced a 100% increase and TPR-FLRFamide a 90% increase in contraction. These effects are dose-dependent.

Muscle contractions are also shown to be modulated by neuromuscular junctional properties. Modulation of the NMj by itself will amplify insecticidal inputs, or will ensure that the changes in the muscle rhythms will be translated into changes in motor outputs. This will have different behavioral consequences depending on the physiological context where modulation of the NMj takes place.

653.19 STATIC AND DYNAMIC-RADULA/ODONTOPHORE KINEMATIC MODELS OF THE BUCCAL MASS OF APLYSIA CALIFORNICA. B.F. Drcsler,1 H.L. Cad,2,3 and E. Cragg.2 Departments of Biology, 1Biomedical Engineering, and 3Neuroscience, Case Western Reserve University, Cleveland, Ohio 44106, U.S.A.

A computer kinetic model of the buccal mass of Aplysia californica (Neustadter, 1992) was revised to more accurately reflect the true shapes and dimensions of buccal mass components in vivo. The Neustadter model represents the radula/odontophore as a sphere, the I1/12 muscles as 6 toruses, and the I2 muscle as a posterior band connecting the dorsal and ventral aspects of the I1/12 torus; a ventral hinge attaches the I1/12 and I3/12 elements to the odontophore. Protraction/retraction is accomplished by forward/backward rotation of the sphere, and the I1/12 toruses expand/constrict to continuously change the surface of the sphere.

Buccal muscle shapes from transilluminated feeding slugs and from models were classified as rest, protraction, or retraction. Actual measurements of the shapes were used to develop a model of buccal mass in the "space shape". In vivo, shapes classified as rest/protraction/retraction cluster together in distinct regions of the space shape plots. Homogeneous model geometry only roughly equivalent to those observed in vivo, and the shape space plots did not match. To improve the model, two different odontophore shapes (#1 and #2) derived from dissection were substituted for the odontophore of the Neustadter model. These shapes were asymmetric in mid-segmental section, though assumed to be circular in cross section when in contact with the I1/12 torus. The model was rewritten to account for arbitrary, asymmetric shapes. Shape #1 gave accurate buccal mass retraction shapes, but poor rest/ protection shapes. Shape #2 gave accurate rest/protraction shapes, but poor retraction shapes. In both cases, the space shape plots, while improved compared to the Neustadter model, did not match those from in vivo.

Since no single odontophore shape gives correct buccal mass shapes over the entire range, we hypothesized that the odontophore shape changes dynamically as it moves. We are currently analyzing videotapes of transilluminated feeding slugs to generate a gallery of possible morphologies to better understand the surrounding space. At the 13/1 elements to be fit to arbitrary, non-circular cross sections. NIH PPG HL-25830-11A1.

Identified cholinergic motor neurons (Ms) and serotonergic modulatory neurons (Pps) in the pedal ganglia of A. brasiliensis innervate peripheral parapodial muscle and fire rhythmically during swimming locomotion. POP-cell firing increases the amplitude of MS action potentials (AMPs) in the corresponding junctional potentials (EJPs) in muscle fibers and increases their contraction amplitude and relaxation rates. This study was designed to determine whether part of the facilitatory effect of serotonin (5-HT) is due to presynaptic action potential (PAP) inhibition. This study was designed to determine whether part of the facilitatory effect of serotonin (5-HT) is due to presynaptic action potential (PAP) inhibition. This is a critical question in control of muscle with modulatory inputs, because sufficient activation of MSs could facilitate movement by enhancing presynaptic inhibition. 5-HT has complex effects on AMPs in muscle fibers, which may be enhanced or decreased depending on its concentration. At low concentrations of 5-HT, the AMPs were enhanced, whereas high concentrations suppressed AMPs.

653.20 TEMPERATURE SENSITIVITY OF THE GIANT MOTOR SYNAPESE AND TAILFILIP BEHAVIOR IN CRAYFISH. M.F. Burgess, F. Issa, D.H. Edwards and W.J. Butler. Gatty Marine Laboratory, School of Biological and Medical Sciences, University of St. Andrews, Fife, KY16 9LB, Scotland, and Department of Biology, Georgia State University, Atlanta, GA 30303-4010.

The rectifying electrical giant motor synapse (GMS) between the giant fibers (GFs) and motor giant neuron (MGn) has been previously shown to have an extremely temperature sensitivity. The large difference between the Q10 of the GMS (near 11) and that of the active membrane in the GF (generally 3) pointed us to examine whether effective transmission would fail at temperatures away from room temperature and so prevent GF-mediated tailflips. We found that transmission was reliable at cold temperatures down to 4°C as both the presynaptic GF and postsynaptic (MGn) spikes and the MGn EPSPs broadened considerably. Transmission failed at warm temperatures, usually between 25°C and 30°C, as the duration of the presynaptic spike shortened. Compartmental models of the circuit indicate that transmission fails at high temperatures when the GF spike is too brief to inject enough depolarizing current into the MGn to reach threshold. Transmission is maintained in the cold because presynaptic spike broadening compensates for the slowing of the GMS conductance change. GF stimulation in freely behaving animals evokes tailflips that fail between 25°C and 30°C, and are gradually reduced in amplitude between 15° and 5° C. Recordings in an isolated abdomen indicate that tailflip failure at high temperatures results from transmission failures at the GMS, whereas tailflip reduction in the cold appears to result from slowing of neuromuscular transmission, excitation-contraction coupling, or constriction of the fast flexor muscle that produces the tailflip.

653.22 A POPULATION OF CEREBRAL INTERNEURONS MEDIATE THE COORDINATION OF VASCULAR RESPONSES INVOLVING FEEDING BEHAVIOR OF APYLSIA. Y. Yin, K.I. Weiss and J. Kimmel*. Center for Neurobiology and Behavior. Columbia University, 722 W. 168 St. New York, NY 10032 and Department of Physiology and Biophysics, Mount Sinai School of Medicine, New York, NY 10029.

A population of neurons (CC neurons) were identified in the cerebral ganglion C cluster. They were found to affect various parts of the body wall as well as cardiovascular and syrinx parts. CC neurons produce mono or polysynaptic effects on various cerebral, pedal, plural and abdominal ganglion neurons. The CC neurons receive synaptic inputs when the lip is touched with food or during buccal mass movements. They have mutually excitatory or inhibitory interactions with the feeding command-like neuron C-PF1. CPF1, which receives presynaptic input from both the cardiac interneurons and the chemosensory neuron (PAS), is excited by touch of the lip by either ingestion or by touch of the buccal mass retraction. C7C, which monosynaptically excites abdominal vasomotor neurons (LbVc cells), is excited during buccal mass protrusion and inhibited by a brief touch of the lip. CC6, which monosynaptically inhibits the ipsilateral arterial motor neuron, could be excited by either the feeding of the C-PF1 and is held by touch to the ipsilateral lip. C4C4, which excites a neuron that shortens the buccal artery, is excited during buccal mass protrusion and by a touch to the lip. C3C3, which monosynaptically excites abdominal heart excitatory neurons (RBm cells), increases its firing rate when the lip is touched with food. C2C2, monosynaptically excites the abdominal L2 neurons, while firing a C2C2 burst. Hyperpoliarization of specific CC neurons revealed that they mediate all or most of the synaptic effects of buccal mass movements and lip stimulation on cardiovascular motor neurons. Our results indicate that a small population of the cerebral interneurons orchestrates a complex pattern of cardiovascular responses during feeding behavior.

653.23
STRETCH-ACTIVATION OF THE ACCESSORY RADULA OPENER MUSCLES OF APLYSIA.
The accessory radula opener musculature of Aplysia is comprised of seven strap-like muscles, one pair and one single), named I7, 18, 19, and 110, innervated by a common cholinergic buccal motor neuron, 848. The muscles originate from a muscular sheath covering the collydostyle at the base of the radula sac and become stretched as the accessory radula closes muscles contract. Even when denervated, the muscles will contract rhythmically if subjected to a constant stretch. Intracellular recordings from muscle fibers of 17 reveal that stretching the muscle induces a depolarization which can cause a slow increase in tension followed by discrete contractions accompanying muscle fiber spikes. The stretch-activated depolarization appears to be sodium-dependent since it is reversibly abolished in sodium-free artificial seawater. Nifedipine, at concentrations of 10^-6 and 10^-7M, can abolish the spikes but not the stretch-activated depolarization. The stretch-activated depolarization may augment the depolarization of the muscle fibers by the motor neuron-elicited excitatory junction potentials to promote a greater contraction. Indeed we found that motor neuron-driven contractions of 17 initiated from a constant length decreased as the load increased, but if the length was permitted to increase, the amplitude of contraction increased. The stretch-activated depolarization may represent a peripheral mechanism to ensure that the muscle is optimally responsive to the mechanical demands of the system.

653.24
THE WHOLE-BODY SHORTENING REFLEX OF THE LEECH: MOTOR PATTERN, SENSORY BASIS, AND INTERNEURONAL PATHWAYS. B.K. Shaw* and W.B. Krustan, Jr. Dept. of Biology, Univ. of California at San Diego, La Jolla, CA 92039-0357.
The leech whole-body shortening reflex consists of a rapid, synchronous contraction of the whole body elicited by a strong mechanical stimulus to the anterior of the animal. We have studied this reflex in semi-intact and isolated nerve cord preparations. The motor pattern consists of an alternating bilateral co-contraction of the longitudinal muscles (DE and VE respectively), as well as the LC cell, a motor neuron innervating both dorsal and ventral longitudinal muscles. The motor pattern has phasic and tonic components: the LC cell is transiently activated, while cell 3 (a representative DE) shows a more sustained activation. Stimulation that produce shortening activate the T (touch), P (pressure), and sometimes the N (nociceptive) types of mechanosensory neuron. Stimulation single-sensory neurons did not cause the behavior; if appears that a critical number must be activated to yield shortening. The S cell network, which makes up a fast conducting pathway running through the leech nerve cord, is active during shortening and accounts for the shortest-latency excitation of the LC cell. However, the S cell network is not sufficient by itself to account for the reflex; firing the S cells at physiological rates with an intracellular electrode causes just a weak excitation of LC cells and little to no behavior. Recordings from the nerve cord connective during shortening reveal fast-conducting spikes besides those of the S cell; these spikes are correlated with motor neuron PSPs. This suggests that the S cell network and other pathways operate in parallel to produce the reflex. Supported by an NSF Predoctoral Fellowship (BKS), NIH training grant (BKS) and NIH research grant MH44396 (WKB).

MAPPING MOTOR NEURON ACTIVITY TO OVERT BEHAVIOUR IN THE LEECH: A BIOMECHANICAL MODEL OF THE LEECH HYDROSKELETON. R.A. Wilson*, R.A. Skerretzky, J.K. Myers, S. Blackwood, R. Rakia, W.B. Krustan, Jr. 1st Dept. of Biology & Institute for Biomedical Engineering, UCSF, La Jolla, CA 92039-0357.
The leech has proved a good system in which to determine how neuronal elements generate motor neuron activity. However, little is known as to how these neuronal patterns coordinate the behaviour of the animal as a whole. We have undertaken a study to determine how motor neuron activity interacts with the biomechanical properties of the leech hydroskeloton to produce overt behaviours. A model was developed to predict the shape of a leech for a given spatial pattern of motor neuron activity. The model was based on the following experimental data: the dimensions of the body at rest or following intrinsic or extrinsic contractions, the passive length-tension properties of the muscles in the body wall and the active tension produced by activating single identified motor neurons at different muscle lengths and firing frequencies. We made the model on the assumption that (a) the volume of each segment remains constant and (b) when as a steady-state the shape of the leech such that the potential energy of the whole body is minimized. The potential energy for the whole body was calculated as the sum of that for each muscle, each in turn was calculated as the integral of the corresponding active and passive tension over the length of the muscle. A key test of the model has been a comparison between predicted and observed pressures recorded in the gut during the extremes of four very different behaviours: crawling, swimming, shortening and feeding. The model as it stands provides new insight into the biomechanical properties of the hydroskeloton and how these properties may be adapted for behaviour. We intend to make the model more realistic by including neuronal, muscle and fluid dynamics. Supported by NSF Research Grant IBN9222039.

654.1
We are interested in the expression and regulation of fiber-type-specific contractile protein isoforms in developing fast skeletal muscle fibers. This current study focuses on the early post-natal expression of a Trifast-Lace chimeric transgene that is driven by an avian Trifast promoter. Unlike the endogenous Trifast gene, this chimeric transgene is differentially expressed in the fast muscle fibers of adult mouse, i.e. IIB >> IIA. In the neonatal transgene mouse, this differential expression is not observed at birth, but emerges during the first week of postnatal life. These results suggest that transcriptional mechanisms present in IIB fibers may be distinct from those operating in IIA fibers. Because its concentration peaks during the first post-natal week, thyroid hormone may subserve such a mechanism and act to direct the high level Trifast-Lace expression seen in IIB fibers. To investigate the role of thyroid hormone in the post-natal emergence of the differential expression pattern, muscle sections from hypothyroid (induced by 5-3-propyl-thiouracil-depletion) and untreated-control neonates will be compared and analyzed using quantitative beta-galactosidase histochemistry.

654.2
DISTRIBUTION OF MYOSIN HEAVY CHAIN-BASED INTRASFAL FIBER TYPES IN SMALL SPINDLES OF CHICKEN LEG MUSCLES AND THEIR DEVELOPMENTAL SIGNIFICANCE. A. Major*, Dept. of Cell Biology, University of Alabama at Birmingham, Birmingham, AL 35294.
The myosin heavy chain (MHC) composition of intrafusal fibers in postnatal chicken leg muscle spindles containing from 1-4 intrafusal fibers was examined in sections incubated with monoclonal antibodies against slow or fast MHC. In those muscles receptors with fewer than five intrafusal fibers made a substantial portion of the spindle population. The small receptors are presumably normal spindles, except that they acquired fewer than the average number of seven intrafusal fibers. Oligofibrilar postnatal activation of sensory motor neurons innervating dorsal and ventral longitudinal muscles appears to be a determinant of the order of appearance of intrafusal fiber types, which in embryonic tissue is difficult to assess. The single fiber in postnatal multifibrillar spindles almost always had a fast MHC profile. In multifibrillar spindles there were a 60-40 fast/slow split. Spindles with three intrafusal fibers typically presented two fast and one slow fiber, while in quadriofibrilar spindles the number of fast and slow intrafusal fibers was nearly equally divided. These data support the earlier finding that the proportion of slow to fast intrafusal fibers increases gradually from the onset of spindle development until the time when 5-6 intrafusal fibers have been formed (Cell Tiss Res, 274:383, 1993). The constant fiber type composition of small postnatal spindles also suggests that the first four fibers in a spindle arise in a fast-slow-fast-slow sequence, provided there is no significant postgenesis MHC transformation.

Neural regulation of slow-tonic (S), α-cardiac (α-c), 2A and 2B myosin heavy chains (MHC) was investigated in rat muscle spindles which regenerated in the presence of sensory innervation only (DE), motor innervation only (MN) or both (MN+DE) in the absence of all innervation (DN group). Either dorsal root ganglia L3-6 were removed (N=9), ventral roots L3-6 were severed (N=10) or sciatic n. was severed (N=5) in young adult female rats. Three days later, a nerve-intact orthotopic graft was performed to regenerate new sensory axons in the ventral root. After an additional 7 days, the grafts were excised. These results indicate that the absence of sensory innervation is necessary for increased fiber type proportions in adult muscle. These observations suggest that definitive changes in fiber type composition occur in the adult muscle. (Supported by N.I.H. grants HL44923 and GM33171.)

In many human muscles aged-related partial denervation leads to muscle fiber "type grouping": a departure from the normal tendency toward random spatial distribution of muscle fiber types. Techniques for assessing muscle fiber "type grouping" have generally been based on two-dimensional models that are not applicable to geometrically complex muscles such as the thyroarytenoid. In the present study, a design-based (free of assumption of a geometrical model) second, stereological technique (Kroustup et al., J. Microsc. 149:135) has been used to quantify age-related muscle fiber "type grouping" in the human thyroarytenoid.

In humans the thyroarytenoid muscle plays crucial roles in protecting the airway and in vocalization, and age-related changes in this motor system are of concern. Samples were obtained from male and female autopsies (cases 49-97 years; n=20). The results indicate a significant (P=.032) age-related increase in the tendency for muscle fibers to be nonrandomly grouped in clusters with fibers of the same type (based on expression of or lack of expression of fast myosin isoform). Since this phenomenon is the result of reinervation of denervated fibers by collateral sprouting of a common axon, the muscle fibers in these clusters tend to alter their myosin isoform expression in response to the influence of the new motor neuron. This result therefore indicates an age-related partial denervation followed by regeneration in the human thyroarytenoid muscle, which is consistent with a hypothesis of a shift toward neuron cell death in this system. (Supported by NIH grant AG0918603)

654.5 NEUROMUSCULAR JUNCTION MORPHOLOGY DURING FAST-TO-SLOW MUSCLE TRANSFORMATION. T. Somasekhar*, R.H. Nordlander and P.R. Reiser, Dept. Oral Biology, Ohio State Univ., Columbus, OH 43210.

Chronic low frequency stimulation results in transformation of muscle from fast to slow-twitch phenotype. We examined the morphology of neuromuscular junctions (NMJs) in two fast-switch rabbit muscles, extensor digitorum longus (EDL) and tibialis anterior (TA), after 3 weeks of chronic electrical stimulation at 10 Hz. These muscles were stained with rhodamine-conjugated monoclonal alpha-bungarotoxin and their NMJs analyzed with Meta-Morph software. Stimulated TA muscles showed significant reductions in mean NMJ area (30%), length (15%) and width (15%) compared to unstimulated control TA muscles (n=2 rabbits). Changes in NMJ morphology were more profound in TA than in EDL. Mean NMJ area in normal slow soleus muscle was similar to control EDL but was significantly smaller (22%) than control TA. A similar range of NMJ configurations were seen in both controls and stimulated muscles. These observations show that stimulation induces marked changes in NMJ size. Work is underway to determine whether NMJs simply shrink in size or selectively retract branches during fiber transformation. Supported by NIH AR39652 and NS18773.

654.6 IMMUNOREACTIVITY FOR THE N-METHYLDOPAMINE RECEPTOR-NACTYL-ASPARYLGLUTamate AND NAALADASE AT THE RAT NEUROMUSCULAR JUNCTION. U. V. Berger* and T. T. Coyle, Laboratory of Molecular and Developmental Neuroscience, Massachusetts General Hospital, Boston, MA 02129.

The neuropeptide N-acetyl-asparylglutamate (NAAG) is co-localized to a number of different neurotransmitter systems in mammalian central nervous system including the ventral horn cholinergic motoneurons. NAAG is released upon depolarization and catalyzed by the extracellular enzyme NAALADase to N-acetylaspartate and glutamate. Furthermore, NAAG displays partial agonist activity at NMDA-receptor glutamate receptors. The physiological function of NAAG is still uncertain, but may include a role as a neuromodulator or as a glutamate precursor. In the peripheral nervous system, NAAG-like immunoreactivity (LI) is present in axons of sensory and motor nerves while NAALADase is expressed by non-myelinating Schwann cells. The present study investigated the presence of NAAG, NAALADase and NMDA-1 receptors at the rat neuromuscular junction. Three days after sciatic nerve ligation, the peripheral nerve terminals of the glutaconelike immunoreactivity in the endplate region of the diaphragm using immunofluorescence and immunoblotting. The NMDA-1 receptor was closely associated with alpha-bungarotoxin binding to nicotinic acetylcholine receptors, suggesting that NMDA receptors are present postsynaptically on muscle cells. The presence of NAAG in motor nerve endings corroborates other recent findings of glutamate-like immunoreactivities in rat motor neurons and terminals. These results suggest that NAAG, or glutamate cleaved from NAAG by NAALADase, may be involved in vertebrate neuromuscular transmission.

Previous studies have shown 1) differences in endplate size on slow type I and fast type II muscle fibers, and 2) correlation between endplate size and muscle fiber type. The present study, the three-dimensional (3D) surface area of endplates on type I & II muscle fibers of 21-day old (D1) and adult rat diaphragms were examined using confocal microscopy. Muscle fibers were labeled with fluorescein o-bungarotoxin, and muscle fiber type was determined using an anti-fetal myosin antibody and indirect immunocytochemistry. Surface areas were calculated from computer-generated reconstructions of confocal optical sections. At D1, in spite of no difference in fiber size, surface areas of type I fiber endplates were greater than those of type II fibers. These differences were also observed in adults, even though type I II fibers grew disproportionately to type I fibers. In adults, endplate surface area was positively correlated to muscle fiber size, only within a fiber type. When normalized for fiber diameter, surface area of type I fiber endplates was significantly greater than that of type II fiber endplates, in both age groups. In type I fibers, the increase in endplate surface area was disproportionate to fiber growth, but in type II, the increase in endplate area was proportionate to fiber growth. We conclude that differences in endplate size in type I & II fibers reflect phenotypic differences unrelated to differential fiber growth. These differences in endplate size may impact synaptic efficacy. (Supported by NIH grants HL37680, HL34318 and GM02883.)

654.8 INFLUENCE OF INACTIVITY ON ENDPALTE SIZE AND NEUROMUSCULAR TRANSMISSION. H. Miyata, W.Z. Zhan, Y.S. Prakash and G.C. Sieck* Departments of Anesthesiology and Physiology, Mayo Foundation, Rochester, MN 55905.

In the rat diaphragm (DIA), we induced inactivity of the right hemidiaphragm by hemisection of the C2 spinal cord (spinal isolation, SI) or by tetorodotoxin (TTX) blockade of phrenic axonal propagation. After 2 weeks of inactivity, we examined adaptations in type I and type II fibers. We measured fiber diameters on type I and II muscle fibers, as well as susceptibility to neuromuscular transmission failure (NF). Paralysis of the right hemidiaphragm was confirmed by the absence of a twitch. EMG activity was measured in vivo by stimulating the phrenic nerve at 40 or 75 Hz in 330 ms trains repeated sec for 5 min. Direct muscle stimulation was superimposed every 15 s. The following EMG activity were classified as estimated NF. Motor endplates were labeled with fluorescein-conjugated o-bungarotoxin and muscle fiber type was determined using an anti-fetal myosin antibody. Double-labeled samples were analyzed using dual channel laser-scanning confocal microscopy to reconstruct 3D images of motor endplates. In DIAL type II fiber endplates were larger than in type II fibers. Type II fiber endplate size increased in the TTX and SI diaphragm but type I fiber endplate size was unchanged. As compared to CTL, NF at both 40 and 75 Hz was less pronounced in the SI group but more pronounced in TTX animals. We conclude that endplate adaptations to inactivity are restricted to type II fibers, but do not necessarily reflect associated changes in neuromuscular transmission. Supported by NIH grants HL34817 and HL37680.

Neuronal activity of the suprachiasmatic nucleus (SCN) is known to be influenced by two major innervations to the SCN: photic stimuli conveyed by the direct retinohypothalamic tract or indirect geniculohypothalamic tract, and the seronicergic (5-HT) neurotransmission by ascending forebrain 5-HT tract. In the present study, we examined the time-course of VIP mRNA expressions in the SCN of rats in which the two major neuronal transmissions were eliminated, by using in situ hybridization technique combined with in situ immunohistochemistry. Male Wistar rats were housed in constant darkness, and the 5-HT input to the SCN was blocked by the three days successive intraperitoneal injections of p-chlorophenylalanine methylester (300 mg/kg/day), an inhibitor of tryptophan hydroxylase. After 24 hrs of the last injection, VIP mRNA levels in the SCN were assayed by in situ hybridization, in saline treated controls, VIP mRNA levels were almost constant at any time of the day. In contrast, PCPA treatment induced the rhythm of VIP mRNA with the peak at CT 4 and trough at CT 20. These findings suggested that the removal of photic and 5-HT influence induces VIP mRNA rhythm in the SCN, and indicates that VIP mRNA is controlled also by the circadian clock.

655.2 DISTRIBUTION OF NEUROPEPTIDES IN THE HAMSTER SUPRACHIASMATIC NUCLEUS. Kazuo Sonobe*, H. D. Pagani and Benjamin Rusak. Deps. of Anatomy & Neurobiology, and Psychology, Dalhousie University, Halifax, N.S., Canada, B3H 4J4

The suprachiasmatic nucleus (SCN) of the hypothalamus are the site of the primary circadian pacemaker in mammals. The distributions of various neuropeptides have been described in the rat SCN but have not been well localized in these mammals as the hamster. Using mono- and polyclonal antibodies, we examined the distribution of immunoreactivity for calcitonin gene-related peptide (CGRP), galanin (GAL), gastrin-releasing peptide (GRP), neurokinin A, vasointestinal peptide (VIP), and vasopressin (VP) in the SCN of both cholecyste treated and untreated Syrian hamsters. Intense labeling of cell bodies, fibers and terminals was observed for GRP, PH, VIP, and VP within the SCN. In contrast, only sparse labeling of GAL and SP immunoreactive fibers and terminals was seen in the SCN, while intense labeling was present in adjacent hypothalamic areas. A small number of SP-positive cell bodies were observed in the central SCN, whereas GAL-positive cell bodies were found only in hypothalamic areas bordering the SCN region. A few CGRP-positive fibers and terminals were found in the ventral and lateral aspects of SCN, but no cell bodies stained for CGRP.

In summary, various neuropeptides show different patterns of distribution in the hamster SCN. These data suggest different functions for these peptides in circadian processes. Supported by grants from the MRC of Canada, and a postdoctoral fellowship from the MRC to HDP. K.S is an MRC Scholar.

655.3 ELECTРОPHYSIOLOGICAL EFFECTS OF IОНОPHORETICALLY APPLIED SUBSTANCE P ON HAMSTER SUPRACHIASMATIC NUCLEUS IN ВITRO. Hugh D. Pagani*, David J. Cutler, and Benjamin Rusak. Deps. of Anatomy & Neurobiology, and Psychology, Dalhousie University, Halifax, N.S., Canada, B3J 4L1

The suprachiasmatic nucleus (SCN) of the hypothalamus function as the primary circadian pacemaker in mammals. The tachykinin Substance P (SP) and tachykinin receptors have been identified in the rat SCN, but little is known about the role of SP in circadian processes of other mammals. In this study, we examined the effects of local applications of SP on the extracellularly recorded discharge rate of Syrian hamster SCN neurons maintained in an in vitro brain slice preparation. Brain slices (400-500 μm thick) were prepared from hamsters housed under a 14:10 light:dark schedule during the light phase of the cycle. SP (1 μM) or 165 mM NaCl) or vehicle, were ionophoresed as cations (20-400 nA) from a multibarrel pipette located 50-80 μm from a recording electrode (containing 2 M NaCl) situated in the SCN. When collapsed across a recording session (ZT4-ZR), both SP and vehicle increased the firing rates of 57 cells, and suppressed the firing rates of 13 cells of 146 cells tested. In contrast, control ejection of vehicle evoked responses from only 3 of 36 cells tested. A larger percentage of cells responded to SP during the middle of the projected day (62.5%) than during the middle of the projected night (25%). This data indicate that local ejections of SP can alter hamster SCN neuronal activity, particularly during the projected day. Small this raises the possibility that local release of SP from intrinsic SCN neurons or from afferent projections may play a role in the entrainment of the circadian pacemaker.

655.5 DEVELOPMENT OF GLIA AND VIP-IMMUNOREACTIVE NEURONS IN THE HAMSTER SUPRACHIASMATIC NUCLEUS (SCN). G.I. Botchkina* and L.P. Morin, Dept. Psychiatry, Stony Brook University, NY 11794

Radial glia are thought to guide neurons to their targets in development. We attempted to facilitate their compartmentalization by studying the relationships between radial glia, astrocytes and VIP-IR neurons in the SCN, site of the mammalian circadian clock.

Vimentin-IR (VIM) radial glial processes are evident as early as embryonic day 8 (ED 8), achieving their highest density in the SCN by ED 13-14. By postnatal day 5 (P5), VIM-IR radial glia in the SCN have gradually disappeared. VIP-IR identifies a set of ventral SCN neurons as early as ED 13. A VIP-IR fiber plexus is evident in the SCN by ED 15. If then progressively increases in density while extending dorsally.

The first GFAP-IR appears in glia of the ventral SCN and optic chiasm by ED 15. GFAP-IR astrocytes are evident by P0 and they progressively increase in number to adulthood. A few VIP-IR astrocytes are present in the SCN by ED 21. The first embryonic hamster circadian clock may be functional at ED 15. Thus, it is possible that astrocytes may not appear until after embryonic rhythmicity has begun. Supported by NS22168.

655.6 MUSCIMOL REDUCES PHASE DELAYS PRODUCED BY COADMINISTRATION OF Vasoactive Intestinal Peptide (VIP), Peptide Histidine Isoleucine (PHI), AND GASTRIN RELEASED Peptide (GRP) INTO THE SUPRACHIASMATIC NUCLEUS (SCN). C.P. Gillespie*, T.O. Bhubahoni, K.L. Muham, H.E. Albers, Lab of Neuroendocrinol. & Behav., Georgia State Univ., Atlanta, GA 30303

Coadministration of VIP, PHI, and GRP into the hamster SCN produces large phase delays in activity rhythms. Since GABA has been reported to be found in most neurons of the SCN, the present study examined the phase shifting effects of coadministration of the GABA, agonist, muscimol, with VIP, PHI, and GRP. Male golden hamsters were implanted with guide cannulae aimed at the SCN region and housed in constant darkness. A stable free-running rhythm of wheelrunning was established, the hamsters were microinjected at CT 12-14 with a 200nl cocktail consisting of either VIP (50ng in 50nl saline) + PHI (5ng in 50nl saline) + GRP (50ng in 50nl saline) + muscimol (150ng in 50nl saline), or VIP + PHI + GRP + 50nl saline in a counterbalanced order. Microinjection of the cocktail containing muscimol resulted in phase delays (0.23 ± 0.06hr) that were significantly smaller (p<0.001) than when the microinjection of the cocktail not containing muscimol (0.88 ± 0.13hr).

These data suggest that GABAergic activity within the SCN may be important in regulating the phase-delaying effects of VIP, PHI, and GRP. Supported by NS30002.
ROLE OF SUBSTANCE P IN MEDIAL AMYGDALOID SUPPRESSION OF PREDATORY ATTACK BEHAVIOR IN THE CAT.
Y. C. Han*, M. B. Shaikh and A. Siegel, Laboratory of Limbic System & Behavior, Department of Neurosciences, New Jersey Medical School and Graduate School of Biomedical Sciences, UMDNJ, Newark, New Jersey 07103.

In the present study, we tested the hypothesis that (1) the medial amygdala (ME) suppresses quick biting "predatory" attack behavior (QBA), and (2) substance P (SP) is utilized as a neurotransmitter in the pathway from the ME to the hypothalamus that mediates progression of QBA. Phase I: QBA in ME lateral hypothalamic site (LH) were observed to be optioned by electrical stimulation. Response latencies for QBA were significantly increased (p < 0.05) after additional stimulation of both sites. Phase II: microinjections of the NK, antagonist, CP, 96,345 (0.5, 0.5 and 2.5 mg/kg) were placed into the medial hypothalamus (MH) because it is known to receive inputs from an SP pathway originating in the ME which, in turn, are relayed via a presumed, short brain projection to LH from MH. Significant dose and time dependent blockade of ME-induced suppression was observed. Phase III: microinjections of SP into MH (0.5, 1.0 and 2.0 mg/kg) resulted in significant (p < 0.05) suppression of LH-ejected QBA, thus mimicking the effects of ME stimulation. These results suggest that ME suppresses QBA by acting through an SP mechanism within MH.

NEUROPEPTIDES AND BEHAVIOR: OTHER

This study examines the effects of the non-NT receptor antagonist SR 48692 on some neurochemical and behavioral effects of NT agonists. In vitro studies, SR 48692, a non-NT receptor antagonist, inhibited the binding of [125I]NT to mouse preparations from 10-day old post-natal mouse brain and from HT 29 cells, but not from RINm5F cells. SR 48692 (300-3000 nM) blocked a dose-dependent increase in cyclic GMP levels evoked by NT (100 nM). In vivo, SR 48692 (0.5 and 5 pg/kg, i.p.) inhibited the increase in c-fos expression in the hippocampus (DOPAC/DOPA ratio) induced by the systemically active NT agonist, E-[N-MeArg-Lys-Pro-Tyr-seryl-Leu-Lys] doped at 2 mg/kg, i.p., 30 min after the SR 48692. No effects on dopamine turnover were observed in the striatum. In vivo, SR 48692 (1, 3 and 10 mg/kg, i.p.) did not antagonize the EI-induced (1 mg/kg, i.p.) decrease in spontaneous locomotor activity (LMA), the decreases in LMA induced by i.c.v. administered NT (0.05 to 0.1 mg/mouse), and did not inhibit the EI (0.1-1.2 mg/kg, s.c.)-induced fall in colonic temperature in mice. SR 48692 alone did not alter LMA or colonic temperature. These findings suggest the hypothesis that a subpopulation of the NT receptor mediates the locomotor and hypothalamic actions of this peptide and that it is different from the NT receptor that is involved in dopamine turnover.

OLFACTORY BULBECTOMY ALTERS LEVELS OF GALANIN AND NEUROPEPTIDE Y mRNA IN THE RAT LOCUS COERULEUS. P. V. Holmes*, U. Koprivica, and J. N. Crawford, Section on Behavioral Neuropharmacology, Experimental Therapeutics Branch, NIMH, Bethesda, MD 20892.

The noradrenergic locus coeruleus (LC) contains high levels of galanin (GAL) immunoreactivity and GAL mRNA and moderate levels of neuropeptide Y (NPY) immunoreactivity and NPY mRNA in the rat. LC neurons project to several forebrain areas, including the olfactory bulb. The effects of surgical ablation of the olfactory bulb (OBX) on levels of mRNA for GAL, NPY, and tyrosine hydroxylase (TH) in the LC and other brain regions were examined with quantitative in situ hybridization histochemistry. Increases in GAL mRNA levels in the LC were observed two weeks following bilateral OBX. Levels of NPY mRNA were slightly decreased and levels of TH mRNA were unchanged in the LC at this time point. Unilateral OBX increased GAL mRNA levels in the ipsilateral LC, suggesting that the elevation in GAL mRNA was a direct result of axotomy. Behavioral experiments confirmed previous reports of differences in open field activity between rats receiving bilateral OBX and sham operated controls. Furthermore, alterations in open field activity depended on the aseverness of the environment. The activity of rats with OBX was increased compared to controls under bright but not dim lighting conditions. Freezing behavior in response to footshock was attenuated in rats with OBX compared to controls. These results suggest that alterations in GAL and NPY mRNA in the LC and other brain regions may underlie the alterations in stress-related behaviors induced by OBX.
656.5 DISTRIBUTION OF NEUROPEPTIDE Y IN THE MALE SYRIAN HAMSTER BRAIN. D.B. Partin and S.W. Newman. Dept. of Anatomy and Cell Biology, University of Michigan, Ann Arbor, MI 48109-0616.

Pharmacologically distinct neuropeptide Y (NPY) in regulation of gonadotropin secretion and mating behavior. While the limbic pathways controlling mating behavior were defined in the male hamster, the pathway's neural substrates were not fully characterized. This study examined the distribution of NPY containing cells, fibers, and terminals in the male hamster brain. Fibers from colchicine (ICV injection, n=5) and non-colchicine male hamsters were cut into 30 mm coronal sections, and processed for immunocytochemistry using one of two primary antibodies for NPY (Incstar or donation from Dr. Marvin Brown, UCSD). The regional distribution and intensity of neuronal staining was the same in colchicine treated brains using either antibody. However, in non-colchicine treated brains, the intensity of neuronal staining was more robust with the Brown antibody than with the Incstar, when the distribution was unchanged. NPY cells were found in the deep layers of cortical structures throughout the telencephalon, including the olfactory bulbs, anterior olfactory nucleus, piriform cortex, and isocortex, as well as in region CA4 of the hippocampal formation. Cells were also distributed throughout the dorsal and ventral striatum. In the extended amygdala, fibers and terminals were observed in the central amygdaloid nucleus and the bed nucleus of the stria terminalis. Hypothalamic fiber plexuses and terminal fields were found in the medial preoptic area, paraventricular nucleus, suprachiasmatic nucleus and arcuate nucleus. Thus, NPY neurons and fibers distributed in limbic structures that relay chemosensory information to control mating may mediate this essential sensory processing. (Supported by NIH NS-20625, T-32-HD070408).

Galanin (GAL) and Neuropeptide Y (NPY) injected into the hypothalamus can induce feeding behavior. Moreover, feeding is known to cause changes in extracellular levels of dopamine (DA) and acetylcholine (ACh) in the nuclear accumbens (NACs) of rats. Therefore, the following experiments used microdialysis to study the effects of GAL and NPY injections into the paraventricular nucleus (PVN) on accumbens DA and ACh. Dialysis probes (2 mm) aimed at the NAC were inserted 24 hr before experimentation and DA or ACh was monitored. During dialysis each rat received counterbalanced injections into the PVN of GAL, NPY or saline. Following the dialysis procedure on separate days the effect of GAL, while NPY saline modified DA or ACh concentrations in the NAC even though NPY induced feeding in 6 of 12 rats. This result demonstrates that hyperfeeding of GAL activates the mesolimbic dopamine system and suggests that GAL could be involved in the reinforcement of feeding behavior. Supported by USPHS grant NS 30697.

656.7 DIPSOGIC DOSES OF ANGIOTENSIN II (AII) DO NOT AFFECT COGNITION, ACETYLCHOLINE (ACh) OR GABA RELEASE IN THE RAT. K. Szczepanski, A. Baxton, S.E. Daniels, P.A. McNeely, R.M. Johnson, and D.J. Pontius. Department of Neurosciences, Institute of Pharmacology, System Research, Palo Alto, CA 94303, U.S.A.

We assessed the behavioral and neurochemical action of renin and angiotensin II (AII) in the rat. We studied the behavioral effects of dipsogenic doses of AII and renin on learning and memory in two cognitive tasks: the Morris Water Maze and Passive Avoidance. All (0.1 and 1 μg, i.c.v.) did not affect latency to find the platform in the water maze. All (0.01 and 1 μg, i.c.v.) and renin (0.1 and 10 μg, i.c.v.) given 30 min before training, and AII (1 μg, i.c.v) given 5 min after training, did not affect retention in passive avoidance. These results suggest that while AII and renin are involved in thirst or fluid regulation, they do not affect learning or memory. In neurochemical experiments we used superfusion technology to study the action of AII on K+-evoked [H]ACh release and [H]-GABA release in slices of hippocampal and entorhinal cortex. Unlike Dop 996 (10 μM) which increased [H]-ACh release and [H]-GABA release in hippocampal and entorhinal cortex slices. AII did not affect release in hippocampal slices (1 μM) or entorhinal cortex slices (0.1 μM). These results suggest that AII does not affect ACh or GABA release. The findings from our behavioral and neurochemical studies suggest that either the brain renin-angiotensin system is not involved in cognition or it mediates cognition through a system other than the cholinergic or GABAergic system.

656.8 DISTRIBUTION OF ARGinine VASOTOCIN IN THE EARLY AMPHIBIAN EMBRYO. S.K. Boydst. Dept. of Biological Sciences, Univ. of Notre Dame, Notre Dame, IN 46556.

The neuropeptide arginine vasotocin (AVT) is widespread throughout the brain of adult amphibians. It is unknown, however, when AVT first appears during development. We used immunocytochemistry to map the distribution of AVT in early embryos of the South African Clawed Frog, Xenopus laevis. Staining was done in whole amphibious embryos or in cryostat sections of embryos, at ages from fertilization onward. AVT-immunoreactivity first appeared at the neural tube stage of development (Nieuwkoop and Faber stage 21). Cells (5-10) were located anteriad with strong fiber projections extending laterally. These cells were located at the rostral end of the neural tube, within the region which will form the brain. Scattered cells and fibers were also observed throughout the rest of the neural tube, within presumptive spinal cord stage 4-5, primary brain divisions are evident and the majority of AVT-ir was located in the diencephalon. Fibers were also observed in the developing eye. AVT-immunoreactivity thus appears very early in amphibian nervous system development. The homologous peptides in mammals, vasopressin and oxytocin, do not appear until considerably later in embryonic mammalian development. AVT in the early embryo may influence many aspects of neural development, including organization of sensory or motor circuits.

656.9 EXPRESSION OF AMPHIBIAN BRAIN THYROTROPIN-RELEASING HORMONE AND ARGinine VASOTOCIN RECEPTOR GENES IN Xenopus laevis OOCYTES. C.L. Mitchell, J.S. Holder, H.E. Eich and S.K. Boyd. Dept. of Biological Sciences, Univ. of Notre Dame, Notre Dame, IN 46556.

Thyrotropin-releasing hormone (TRH) and arginine vasotocin (AVT) are neuropeptides found throughout the amphibian brain. Although both have numerous mRNA expression receptors for TRH and AVT have not been fully characterized in any non-mammalian vertebrate. We expressed amphibian brain TRH and AVT receptors by injecting X. laevis oocytes with brain whole mRNA. Expression of receptors was measured by voltage clamping to monitor current flow across the membrane of oocytes in response to ligand. Injected oocytes were responsive to TRH, TRH free acid, cyclo-his-pro-[3-Meth]TRH and AVT, as indicated by inward membrane currents. The response was specific, since mRNA-injected cells showed no response to the non-peptide ligand, lanosin and un.injected or water-injected cells showed no change in current when exposed to any neuropeptides. The TRH response was reversible, dose-dependent, and saturable. Time course of response to maximally effective ligand doses was consistent. Latency (from ligand addition to onset of current flux) and response time (from onset of response to saturation) were characteristic of agonist application. Time course differences suggest that the amphibian brain expresses more than one subtype of TRH receptor. The % vasopressin receptor antagonist 4CH(Tyr(Me))AVP did not alter response when added to cells already maximally stimulated with AVT. When added alone, however, it produced a gradual current flux which was increased by secondary application of AVT. The mammalian antagonist thus appears to have agonistic effects in this system. We conclude that unique receptors for TRH and AVT and our data represent the first expression of these receptors from any non-mammalian vertebrate.

656.10 V1-RECEPTOR MEDIATED EFFECTS OF VASOTOCIN ON MOTIVATIONAL MNEmOnIC AND AVersIVE COMPONENTS OF SEXUAL LEARNING IN GUAL. S. Bernoindt* and St. Leudig, Institute for Zoology, University of Saalburg, A-6020 Saalburg, Austria.

Numerous studies have uncovered "homework constraints" imposed on adaptive specializations of sexual learning (Holloway & Domjan, J Exp Emeril Psychol, 1947-65, 1993). Behavioral mechanisms of vasopressin (AVP) could influence the motivational and aversive components of sexual learning. AVP effects on sexual behavior of females during five successive days, showed an inhibitory action of AVT to the reinforcing effect of copulatory "award" following visual access. Again this effect was dose dependent.

A dissociation of peptide treatment from copulation experience for up to 6 hours did not change AVT effects on prosex behavior during the following day: together with a composition of training effects a positive reinforcement of social proximity by copulation, the experiments provide evidence for AVT action on motivational mechanisms of sexual learning. These effects appear to be mediated by receptors homologue to mammalian vasopressor AVP-V1.
Chlorodiazepoxide, Diazepam (mg/kg), which was administered at 12:00, was known to induce behavioral changes. We previously reported that IL-1β, IL-2 and IL-6 induced cytokine-specific alterations of central neurotransmitter activity. We presently report that cytokine-induced behavior was also evident in male BALB/c mice following peripheral administration of these cytokines. Exploration of a novel environment (i.e., locomotion, rearing, digging) was significantly decreased by 15-50 minutes after IL-18 administration (200 ng, ip). In contrast, IL-2 and IL-6 induced behavioral activating effects. IL-2 (50, 100, 200 or 400 ng ip) induced dose-dependent increases in time spent in non-ambulatory exploration, number of rears and distance travelled in a novel environment. IL-6 dose-dependently (50, 100, 200 or 400 ng ip) increased the number of rears, digging episodes and the time spent per episode as well as the number of grooming episodes. Moreover, time-dependent increases in the number of contacts with a novel stimulus and mean-contact time were evident in mice administered IL-2, but not in IL-6-treated animals. Taken together, these data suggest that IL-1, IL-2 and IL-6 induce cytokine-specific behavioral alterations. The results and discussed in terms of the spectrum of behavioral alterations induced by immune-derived products and implications on the characterization of sickness behavior. (Supported by NIMH and MRC of Canada)

**NITRIC OXIDE MODULATES RETENTION IN THE PORSOLT SWIMMING TEST.** D. Jeffreys* and J.W. Funder. Baker Medical Research Institute, Melbourne, Victoria, Australia 3181

In the Porsolt swim test intact animals become progressively immobile over a 15 min test period and 248 hours later are immobile for ~70% of the 5 min rest period. Adrenocorticotropin (ACTH) blocks retention of the response, with animals remaining immobile for only ~35% of the rest period, an effect reversed by Dexamethasone (6 μg) or Ketocyclazocine (1 mg/kg). When the antagonistic RU38466 is administered to intact rats it is without effect, as is MR2266, a kappa opioid antagonist. In contrast, when RU38466 and MR2266 are simultaneously administered the animals have similar levels of immobility on retest as in ACTH. Retention of the immobility response thus can be directly mediated by glaucocorticoid or kappa opioid pathways.

In the present studies we show that N-nitro-L-arginine (NAME), a nitric oxide inhibitor dose-dependently blocks retention, with animals remaining immobile for 35-42% on retest at a dose of 50 mg/kg. This effect of NAME is blocked by L-arginine (50 mg/kg), with animals immobile for 77% on retest. NAME is effective given immediately pre-test, but was without effect administered 15 min post-test. When ACTH was given L-arginine the effect of adrenocorticotropin was blocked, with animals remaining immobile for 62% on retest. These findings suggest that both glucocorticoid and kappa opioidergic effects on retention are mediated by a final common pathway involving nitric oxide.
565.17

The effect of the central administration of nitroglycerin, a potent organic nitrate vasodilator, on penile erection and yawning was studied in male rats. Following low doses of nitroglycerin (33 - 99 µg) induced penile erection and yawning in a dose-dependent manner. Nitroglycerin-injected penile erection and yawning effects were also injected in the paraventricular nucleus of the hypothalamus, a brain area that plays a key role in the control of these responses induced by agents such as N-methyl-D-aspartate, dopamine agonists and oxytocin. Nitroglycerin-induced penile erection and yawning were prevented by methylene blue (400 µg), d(CH2)5Tyr(Me)2-Orn9-vasotocin (0.1 µg) but not methemoglobin (100 µg) given ICV. In contrast these compounds were ineffective when injected in the paraventricular nucleus. Ineffective was also haloperidol (1 mg/kg IP). The results suggest that nitroglycerin induces penile erection and yawning by activating oxytocinergic transmission through the production of NO in the paraventricular nucleus of the hypothalamus.

565.19

EFFECTS OF PRENATAL STRESS ON DEFENSIVE WITHDRAWAL IN THE RAT. HE Ward, EA Johnson, DL Birkle, MS Cratty, AJ Azzaro*. Dept.s of Behavioral Medicine/Psychiatry, Pharmacology/Toxicology, and Neurology, West Virginia University School of Medicine, Morgantown, WV 26506.

Adult, virgin, female Sprague-Dawley rats were bred with adult males. Between gestational day 14 and 21, pregnant females were exposed to the mild stress of daily handling and saline injection (0.1 ml, s.c.). Control (unstressed) dams were not handled except for normal animal care. Behavioral testing in a defensive withdrawal apparatus was performed on male offspring at 60 days of age. There were no significant behavioral differences noted between control and prenatally stressed animals. However, following 2 hr of restraint stress, prenatally stressed offspring had a longer latency to exit from the defensive withdrawal chamber and spent less time in the open field (n=8, p<0.05). Specific binding of corticotropin-releasing factor (CRF) was increased by 30% in the amygdala of the prenatally stressed animals (n=8, p<0.05). CRF levels and secretion were similarly elevated (Cratty et al, this volume). In the defensive withdrawal paradigm, without an acute stress (restraint), behavioral differences were too subtle to detect. However, it would appear that the animals ability to adapt to acute stress (restraint) was compromised by prenatal stress and may be a function of prenatal perturbation of development CRF systems within the amygdala. Supported in part by NIH (HD079R50343-31 and MH19444) and UHA.

AN ENDOGENOUS INCREASE IN CYCLIC GMP IS ASSOCIATED WITH INCREASED EXCITABILITY IN IDENTIFIED NEUROSECRETORY CELLS IN MANDUCA SECTA. Stephen C. Gamme, John Everall, and James W. Truman*. Department of Zoology, University of Washington, Seattle WA 98195.

Ecdysis in insects is triggered by the neuropeptide, ecdysis hormone (EH). During the course of EH action in the tobacco hornworm, Manduca sexta, a group of neurosecretory cells show a dramatic increase in guanosine 3'5' cyclic monophosphate (cGMP). This increase precedes the onset of the ecdysis behavior and is sustained at high levels in some of the neurons for over 2 hours. Using intracellular recording techniques we have found that this endogenous increase in cGMP is correlated with a significant lowering of the threshold of these neurons. Also, the somata of these cells show a calcium dominated action potential and this is lengthened during the time of cGMP increase. We found, however, no changes in either input resistance, resting potential, or action potential amplitude to be associated with cGMP expression.

Currently, we are injecting cGMP into these neurons prior to their endogenous increase in cGMP to directly test the actions of this cyclic nucleotide on cell excitability. These experiments will be followed by whole cell voltage clamp techniques to determine which ionic currents are affected and how.

565.18

COMPARISON OF THE RESPONSE OF 4 HIPPOCAMPAL (H) SITES IN DIAZEPAM (DZ) DEPENDENT RATS TO FLUMAZENIL (F) MICROINJECTIONS. J.W. Sloan*, E.P. Wake and X. Jing, Dept. of Anesthesiology, College of Medicine, Univ. of Ky., Lexington, Ky., 40536.

In order to identify sites in the female Sprague-Dawley central nervous system that contribute to the development of DZ dependence, guida cannulae (GC), also serving as recording electrodes, were implanted into the occipital cortex (OCT, area 2), mediodlimal (MD) (AP=3.8; RL=2.4; V=8) or CTX (area 2, lateral [LAT]) (AP=3.8; RL=4.5; V=8). Electrodes were implanted into the H (AP=3.7; RL=2; V=6) and frontal CTX (AP=10.7; RL=1; V=10). After recovery, the rats were microinjected subcutaneously with 30 µl saline solution filled with 180 µg DZ/cap. After the 3rd implant and the attainment of stable plasma levels of DZ and its metabolites, rats were microinjected weekly with F (25 µg in 1 µl of DMSO) or DMSO into the H via GC. EEGs, behavioral (BEH) and precipitated abstinence scores (PAS) were recorded prior to and for 40 min after microinjection. When F was microinjected via GC into area 2, MM of OCTX with chemotrode (CTR) in CA1 of H, V=7.2, n=5 rats) neither BEH nor PAS were elevated whereas convulsive signs (switches and jerks), head and body tremors and respiratory rate were increased. When the CTR was lowered into dentate gyrus, V=6.2 (n=4), F produced no significant signs of EEG. The case when F was microinjected via GC in area 2, LAT of OCTX through CTR into H, V=5.8 (n=5), although 1 rat had a clonic convulsion. In contrast, when F was microinjected via same GC through CTR in CA1 of H, V=6.8 (n=8), BEH and PAS were elevated. Convulsive activity was apparent both by observation and EEG in some but not all rats. These data indicate that DZ given chronically produces dependence in some but not all areas of the H and that the CA1 area of the dorsal H is involved. Supported by NIDA Grant DA02195.
HISTOLOGICAL AND ULTRASTRUCTURAL BRAIN ALTERATIONS OF A MAN CRONICALLY EXPOSED TO HIGH DOSES OF DIAZEPAM. M.C. Márquez-Orceño,* F. R. Pérez-Chuqui, M. V. Gasca-Herrera, and A. Márquez-Orceño. Embryology Dept., Medicine School BUAP, Mexico 04510 D.F. and BSZ FPT 2-4, INSS.

Our purpose was to investigate whether the histological and histoelectronultrastructural brain alterations observed in a 50-year-old man, exposed to daily diazepam (20 mg/kg) during the last ten years of her life, are similar to those observed in adult mice prenatally treated with DZ. Cerebral and cerebellar cortices and striatum samples were studied with a light and transmission microscopes. The causes of death were not clearly determined. Pathology autopsy showed generalized cortical atrophy, without pre-semi or semi dementia and premature aging. Histological and ultrastructural sections showed II y III cortical layers disorganized presence of abundant sylodeysis bodies, perinuclear vacuolization. Less number of Purkinje cells than in cerebellum of three healthy men from the same age. In all neural cells the heterochromatin was seen in dense clumps scattered in its interior around the nucleus and mainly located near the nuclear envelope. The euchromatin, was reduced. Golgi complex, mitochondria, rough endoplasmatic reticulum and synaptic vesicles were disorganized. Electrondense bodies were observed. These alterations are similar those showed in adult mice prenatally exposed to DZ and suggest may be due to chronic exposure to high doses of DZ.

This experiment is part of a study of the effects of prenatal exposure to the benzodiazepine [Diazepam (DZ), Lorazepam (LZ)] on the behavior, EEG and brain-specific receptors of the mature offspring. Twenty adult female Sprague-Dawley rats received 1 mg/LZ/kg S.C. or the equivalent volume of vehicle, once daily, for 28 days prior to breeding, during breeding and throughout their 21-day gestation. The behavior of the offspring of both sexes was evaluated at 34 months of age. We used a modified radial arm maze test which incorporates measures from the open field test, hypnoencephalographic model of anxiety test, Olton's original RAM test and other parameters of our own design. Prenatal exposure to lorazepam produced performance deficits indicating a long-lasting state of hyperarousal or "anxiety" in the male offspring. Conversely, the female offspring prenatally exposed to lorazepam show enhanced performance that may indicate a reduction of "anxiety" relative to controls. Thus, prenatal lorazepam exposure has produced an exaggeration of the normal sex-dependent differences in maze performance and spontaneous behaviors. These results could result from an elevation of sex steroid levels or an alteration of the interaction of sex steroids with the benzodiazepine receptor which enhances the efficiency of circulating steroids.

BENZODIAZEPINE LIGANDS MODULATE ETHANOL DRINKING IN ALCOHOL-PREFERING AA RATS. E.R. Kopp* K. Weegels, T. Oyasaki and A. Honkonen. Biomedical Research Center, Alko Ltd, POB 350, FIN-00101 Helsinki, and Department of Pharmacy, Division of Pharmacology and Toxicology, University of Helsinki, Finland.

The effects of positive allosteric modulators (agonists) at the benzodiazepine site of the GABA receptor (midazolam, abecarnil, KZ 92926, bretazenil, and CDS 9895) and those of negative allosteric modulators (antagonists, Ro 15-4513 and Ro 19-4403) were studied on voluntary ethanol consumption in selectively-bred alcohol-prefering AA rat line using limited access paradigm. Each drug was tested after IP injections of three different doses using saline injections as a control treatment. The benzodiazepine agonists had only modest effects in reducing intake, measured 2, 1 and 4 h after the injections, whereas the inverse agonists strongly decreased ethanol consumption. Food consumption during the 4-h session was decreased by the highest dose of the benzodiazepine agonist, which also significantly increased the ethanol drinking. The inverse agonists had no significant effect on food intake. Pentoxicon-sensitive ["STIBPS binding was differentially modulated by benzodiazepine ligands between the AA rats and alcohol-avoiding strains. [HJIU154513] binds to both sites but not, however, reveal any drastic differences between the lines. In conclusion, the results suggest that the GABA receptor may be involved in the regulation of ethanol drinking in酒精-prefering AA rats, but do not indicate that these rat would consume ethanol because of its axiolytic effects in a way that benzodiazepine agonists (full or partial) could substitute for it.

We investigate whether diazepam (DZ) caused ultrastructural alterations in fetal mice cerebral cortex. Three CD-1 strain gestating pregnant were observed in the 6th to 17th gestation day. One group with single daily DZ doses (2.7 mg/kg), the second with 0.7% saline solution (S) and the third was not treated (NT). All were killed with CO2 atmosphere the 18th day and the fetus removed. The cerebral cortex was fixed and embedded. Fine sections were observed under transmission microscope. In the DZ fetal mice cerebral cortex was evident delay cellular and neuropile differentiation. The nuclear density per millimeter was thinner in the S and NT fetuses (p <0.05). Heterochromatin was seen in clumps scattered mainly in its interior and near of the nuclear envelope. The rough endoplasmatic reticulum showed distended cisternae, the Golgi complex, the mitochondria and the polyribosomes were more abundant. Such alterations could reveal disruption in cell multiplication and so it could be related to diazepam-induced protein synthesis and to the modification of the metabolic pathways mediated by central and peripheral types of benzodiazepines receptors. The results suggest that DZ produce long-lasting ultrastructural alterations in the cerebral cortex.

LONG-LASTING EFFECTS OF PRENATAL EXPOSURE TO DIAZEPAM ON SEXUAL BEHAVIOR OF MALE MICE. L.A.I. Hernández-Alvarez,* A. Martinez-Vargas, B. Victoria-Romero, A. Márquez-Orceño and M.C. Márquez-Orceño. Dept. of Embryology, School of Medicine, BUAP and Dept. of Embryology, School of Medicine, UNAM. Mexico City, Mexico.

Effects of prenatal exposure to diazepam (DZ) in adult mice were showed on sexual reproductive behaviors. We assessed the effects of diazepam (DZ) on the behavior of male mice from the senile rats of the CD-1 strain mice exposed to DZ during gestation. One group of female mice was exposed to periodic doses of DZ (2.7 mg/kg/bw) from the 6th to 17th gestation day and control group received saline solution. On the 27th month of age, the spontaneous male sexual activity to females from the treated and control rats was tested and videorecorded under red light. Precopulating and copulating activities were evaluated. No difference was found in precopulating behaviors from both groups. During copulating stage, greater sets of mount series with and without penile intromission, as well as fail and interruptions of intravaginal penetration were found in DZ animals. Although ejaculations per animal were unusually in both groups, DZ mice had fewer. Results show a long-lasting effect of prenatal exposure to DZ of sexual behavior.

COMPARISONS OF [3H]Ro15-4513 BINDING IN CEREBELLUM FROM ETHANOL-NAIVE WITHDRAWAL SEIZURE PRONE AND WITHDRAWAL SEIZURE RESISTANT MICE. A. Leslie Morris*, F. Donelson Smith, and Leslie L. Devay, UNC Sch. of Medicine, Chapel Hill, NC 27599.

Ethanol withdrawn seizure resistant (WSR) and withdrawal prone (WSP) lines of mice have been selectively bred for investigation of the mechanisms involved in alcohol withdrawal. Ethanol-naive WSR mice are more sensitive than WSP mice to GABAergic chemosensitivants, suggesting differences in GABA_A receptor function or structure are involved. WSR mice exhibit 50-100% higher levels of GABA_A receptor subunits α1, α6 and β2 subunit mRNAs in cerebellum, but not cortex. Ro15-4513 is a GABA_A receptor inverse agonist which labels recognition sites on α6 subunits. The present study was conducted to determine if there are differences in [3H]Ro15-4513 binding characteristics between WSR and WSP mice. Saturation binding analysis was conducted with [3H]Ro15-4513 (0.2-20 nM) using individual cerebellum from WSR1, WSR2, WSP1 and WSP2 mice. No differences in binding were observed between the WSR1/2 or the WSP1/2 lines, respectively (n=8). Moreover, no differences in [3H]Ro15-4513 binding were observed in cerebellum from ethanol-naive WSR vs WSP mice. Binding density was 1467 ± 52 fmol/mg protein in the WSR and 1543 ± 41 fmol/mg protein in WSP cerebella. Kd values were 2.90 ± 0.09 nM and 2.82 ± 0.11 nM for WSR vs. WSP mice, respectively. These data indicate a discrepancy between the expression of GABA_A receptor α6 subunit mRNAs and [3H]Ro15-4513 recognition sites in these mice. (Supported by AA09913, ES07126 and Pharm. Man. Assoc. Found.)

657.11
THE BENZODIAZEPINE ANTAGONIST CGS-8216 EXERTS PROLONGED AND SELECTIVE ATTENUATION OF ETHANOL INTAKE IN ALCOHOL-PREFERRING (P) RATS. J. Williams, H.L. Jane, S. Dejevars, M.J. Lewis*, and J.M. Neisewander, Inst. of Psychiatric, Res. and Program in Medical Neurobiology, Indiana University-Purdue University, Indianapolis, IN 46202 and Dept. of Psychology, Temple Univ., Phila., PA 19122.

The present study investigated dose dependence and time course profiles of CGS-8216 (0.0, 0.5, 1.0, 5.0, 10, or 20 mg/kg), a pyrazoloquinolone BDZ antagonist in attenuating EtOH intake in alcohol-prefering P rats (N = 13). Animals were provided a 4 hr daily limited access to a two bottle choice between EtOH (10% v/v) and saccharin (0.0125% g/v) solutions. For the remaining 20 hr, rats were provided unlimited access to water, with food available ad libitum. Acute administration of CGS 8216 (1.0-20 mg/kg) dose-dependently reduced EtOH intake to 42± 7% of controls at the initial 15 min interval of the 4 hr access on Day 1. All doses reduced total consumption for the 4 hr period to 15-60% of control levels. On Day 2 (24 hr post-drug administration), the 5.0 and 20 mg/kg doses of CGS 8216 reduced EtOH intake to 41% of controls during the initial 15 min interval, while total consumption was reduced to 20-30% of control levels for all doses except the 10 mg/kg dose. Saccharin drinking generally showed no changes at the initial 15 min interval, however, compensatory increases paralleled the decreased EtOH consumption and the total consumption measure for several of the CGS 8216 doses. These results suggest the BDZ component of the GABA_A receptor complex may play a direct role in the reinforcing actions of EtOH. (Supported in part by grants AA08553 and AA07611.)

657.13
THE EFFECT OF ANXIOLYTICS ON NOVELTY-INDUCED PLACE PREFERENCE. J.E. Klabaure, D. Miller, M.T. Bardo, Department of Psychology, Univ. of KY, Lexington, KY 40506-0044.

Previous evidence has shown that rats exposed to one compartment of a place preference apparatus will prefer the novel compartment over the familiar. While this suggests that novelty is rewarding, an alternative interpretation is that rats avoid the familiar compartment because it is associated with stress induced during the inescapable exposure sessions. To test this latter possibility, the anxiolytics diazepam (0.1, 0.3, 1.0 mg/kg) and gepirone (0.1, 0.3, 1.0 mg/kg) were examined for their ability to alter novelty-induced place preference in rats. As expected, control animals showed a novelty-induced place preference. On test day, this preference was blocked by diazepam, but only at a dose (1.0 mg/kg) that also decreased locomotor activity. Gepirone failed to alter the preference behavior, even at a dose (1 mg/kg) that decreased locomotor behavior.

These experiments indicate that preference for the novel compartment is an indication of the rewarding effects of novelty and not an avoidance of stress associated with the familiar.

657.10

The present study investigated the extent to which possible genetic differences, which are phenotypically expressed as differences in EtOH preference, may influence sensitivity to the BDZ partial inverse agonist, RO19-4603 (Ro) in modifying low to high doses of EtOH (0.125-2.5g/kg). P (N=20) and NP (N=20) rats of the P1 strain were habituated to a photocell apparatus and tested for 10 min sessions during the experimental phase. Animals from each line were randomly assigned to an EtOH only group, or to a Ro+ EtOH group (n=10/group). Animals in both groups received three daily consecutive EtOH injections. Animals in the R group, however, were given R (0.15 mg/kg), 5 min prior to the EtOH injection on Day 1 only. EtOH dose caused dose-dependent reduction in motor behaviors on Day 1-3 (50 to 70% of control), with tolerance seen only with the NR rat for the 0.125 g/kg dose on Day 2. Ro enhanced the suppressant effects of the 0.125 g/kg EtOH dose in the P and NP line rats on Day 1. R was without effect on Day 1-3 when given before the 1.0 and 1.5 g/kg EtOH dose in the P rats, as well as Day 1 in the NP rats. R antagonized, however, the EtOH suppression on Day 2 to 3 in the NP rats with the 1.5 g/kg dose, as well as Day 1 and 3 with the 1.5 g/kg dose. It was without effect on the 1.5 g/kg dose of EtOH in the P or NP rats or given alone. The results suggest R may induce rapid changes at the GABA_A receptor and mediate the motor-imparing effects of EtOH for 48 hr in the P2 line NP rat, but not P rat. These effects may be related to the low EtOH preference of the NP rat. (Supported in part by grants AA08553 and AA07611.)
DRUGS OF ABUSE: ALCOHOL AND OPIOIDS

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

658.1
Department of Pharmacy, Division of Pharmacology and Toxicology, POB 350, FIN-00101 Helsinki, Finland

Brain opioid systems may have a role in the ethanol reward. Our aim was to study possible differences in the sensitivity of these opioid mechanisms of alcohol-prefering (AA) and alcohol-avoiding (ANA) rats by activating the central opioid mechanisms with ethanol, morphine, and morphine-stimulating stress followed by measurement of the analgesia induced by these treatments. Analgesia was measured with the tail-flick (TF) test. The baseline TF-latency was measured 4 times with 5 min intervals before treatments. The mean of the last 3 readings was used as baseline (BL). Ethanol (15 %, i.p., 1.0 or 2.0 g/kg) or saline was given after the last BL trial. TF-latency was measured 15, 30, and 60 min after injection. The TF-latency was measured just before each injection. Stress was induced to rats by exposing them to 3 min swimming in 15°C water. TF-latencies were measured just before and 3, 6, and 9 min after swimming. TF-latencies increased in the AA rats during 4 BL-trials but not in the ANA rats. No difference was found in the MO or stress induced analgesia between rat lines. The smallest ethanol dose (1.0 g/kg) failed to produce analgesia in either rat line, but 1.5 g/kg of ethanol produced slight analgesia in the AA rats but not in the ANA rats. Both rat lines showed similar analgesia after 2.0 g/kg ethanol. These results suggest that the ANA rats may be more resistant to habituate to repeated nociceptive stimuli than the AA rats. The AA rats appear to be slightly more sensitive to analgesic effect of ethanol than the ANA rats. Whether this effect is due to greater release of endogenous opioids in these rats remains to be studied.

Exposure to 12 atmospheres absolute (ATA) helium-oxygen gas mixtures (heliox) antagonizes a broad range of brain stimulatory and depressant effects of ethanol. If pressure antagonizes ethanol by blocking or offsetting its initial molecular actions, then the antagonistic effects of pressure should be limited to drugs acting via similar mechanisms. The present study tested this hypothesis by extending preliminary investigations of the effects of hyperbaric exposure versus morphine-induced locomotor activation. Drug-naive C57BL/6J mice were habituated to BL and measured ethanol (10-32 mg/kg) and then exposed to 12 ATA helium. Morphine injection (1 mg/kg) was given i.p., 15 min prior to the initial measurement of hypothermia. Morphine dose-dependent stimulation of locomotor activity in response to ethanol was observed. The number of 10 sec loco-events (i.e., rears) was increased in response to ethanol with or without morphine. The data indicate that the effects of hyperbaric exposure on the ethanol-induced locomotor activity may be attributable to a specific antinociceptive effect of pressure on the ethanol-related behavioral activity. These results suggest that the use of hyperbaric exposure may provide a novel method for the treatment of ethanol-related disorders.

658.3
Molecular Pharmacology and Toxicology, School of Pharmacy, University of Southern California, Los Angles, CA 90033

Low-level hyperbaric exposure antagonizes several ethanol-induced behaviors including ethanol-induced motor depression and anticonvulsant effects. Recent work has also found that pressure also antagonizes diazepam-induced locomotor depression suggesting that ethanol and diazepam may have a common pressure antagonizable site of action. The present study further explored this hypothesis by testing whether pressure was related in the pressure effects and treatment to alanova injection of 300 mg/kg of INH. The mice were then exposed to either 1 atmosphere absolute (1 ATA) air or 1 ATA helium-oxygen gas mixture (heliox) or 12 ATA helium at temperatures that offset the hypothermic effects of helium. Diazepam increased the latency to onset of myoclonus in a dose dependent manner. Exposure to 12 ATA helium antagonized diazepam's anticonvulsant effect at 8.0 and 24.0 mg/kg, but not at 4.0 mg/kg. Diazepam also increased the latency to onset of clonus in a dose dependent manner. Diazepam antagonized this anticonvulsant effect. These findings extend the acute behavioral effects of diazepam known to be antagonized by hyperbaric exposure and support the hypothesis that ethanol and diazepam share a common pressure antagonizable site of action in the GABA_A receptor complex (Supported by NIAAA grant AA09792).

Alcohol Preference in Rats Selectively Bred for Saccharin Consumption. N. E. Badia-Elder*, S. W. Kiefer, and N. K. Davis.
Psychology Dept., Kansas State Univ., Manhattan, KS 66506, Psychology Dept., Occidental College, Los Angeles, CA 90041

Selectively bred high saccharin consuming (HIS) and low saccharin consuming (LOS) rats, obtained from The Occidental College in Los Angeles, were tested for taste reactivity to 10% alcohol, sucrose, quinine, and a sucrose/quinine mixture. After taste reactivity testing, a two-bottle consumption test with 10% alcohol and distilled water was given for 14 days. At the end of two-bottle testing, rats were tested a second time for taste reactivity to 10% alcohol. In the initial taste reactivity exposure, HIS and LOS rats did not differ in response to 10% alcohol, sucrose, quinine, or the sucrose/quinine mixture. Likewise, there were no significant differences between HIS and LOS rats in their second taste reactivity to 10% alcohol. However, there was an exposure effect in that all rats significantly increased ingestive responding and decreased aversive responding to 10% alcohol on the second test. HIS and LOS rats did not differ in alcohol consumption as measured with two-bottle testing. According to these results, HIS and LOS rats display similar patterns of alcohol preference as measured by taste reactivity and consumption (Supported by Training Grant T 32 MH 19547 from NIMH to the Society for Neuroscience).

Dept. of Psychology, Kansas State Univ., Manhattan, KS 66506-3302

Previous work reported that Low Alcohol Sensitive (LAS) rats failed to develop normal saccharin aversions, relative to High Alcohol Sensitive (HAS) rats, when alcohol was used as the illness agent. In the present experiment, HAS and LAS rats were compared with control rats in the acquisition of an alcohol aversion using lithium chloride as the illness agent. Rats were trained to avoid a 6% alcohol solution by pairing it with LiCl intubations (3% body weight of 0.15 M solution). Rats were tested for taste reactivity to 5% alcohol on the day after training. This test was then followed by extinction trials with no alcohol in the drinking situation. No significant differences between groups were found in ingestive or aversive taste reactivity. There were also no significant consumption differences found between groups during these data. The data indicated that HAS and LAS rat lines are capable of developing normal alcohol aversions when the illness agent is LiCl. (Supported by Training Grant T 32 MH 19547 from NIMH to the Society for Neuroscience).

658.6
Naltrexone and Taste Reactivity to Alcohol In Rats. K.G. Hill*, N.E. Badia-Elder, and S.W. Kiefer.
Dept. of Psychology, Kansas State Univ., Manhattan, KS 66506-5302

Naltrexone, an opiate antagonist, has been shown to reduce alcohol consumption, particularly in high alcohol consuming rats. In the present study, we determined whether naltrexone altered the taste reactivity responding of rats when presented with an intragastric infusion of alcohol. Two groups of rats were tested for their taste reactivity response to 10% alcohol 30 min after naltrexone treatment (1 mg/kg) and 10 min after saline treatment: High Ingestive Responding (HIR, n=7) rats, which were selectively bred for their taste reactivity to alcohol and which consumed high amounts of 10% alcohol; Sprague-Dawley (n=8) rats that had previous experience with a range of alcohol concentrations. Although naltrexone did not alter alcohol reactivity in the Sprague-Dawley rats, HIR rats did exhibit increased aversive responding and decreased ingestive responding following naltrexone treatment. The results provide preliminary evidence that naltrexone may alter alcohol consumption by altering its palatability. (Supported by Training Grant T 32 MH 19547 from NIMH to the Society for Neuroscience).
NALTREXONE ATTENUATES ETHANOL STIMULATED DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS. R.B. KOHL and W.J. McBride*. Depts. of Psychiatry and Medicine, Medical Neurobiology Graduate Program, Indiana University School of Medicine, Indianapolis, IN. 46223-4887.

The effect of naltrexone (NAL) on ethanol stimulated-dopamine (DA) release in the nucleus accumbens was studied in adult, female, Wistar rats using in vivo microdialysis in conjunction with HPLC with electrochemical detection. Rats were implanted with microdialysis probes 36-48 hours prior to the administration of ethanol alone (2.0 g/kg, i.p.) or ethanol following pretreatment with 20 mg/kg i.p. NAL. Experiments were conducted on awake, freely moving animals. The i.p. administration of 2.0 g/kg ethanol increased extracellular DA concentrations to approximately 160% of baseline (N=6) within 60 minutes and levels remained elevated for at least two hours. The i.p. administration of NAL (N=5) 30 minutes before injection of ethanol reduced (p<0.001) the ethanol induced increase in extracellular DA concentrations. There were no effects on extracellular levels of dopamine with i.p. injections of saline. In general, the extracellular levels of DA and serotonin metabolites did not change during any of the treatments. The results suggest a role for endogenous opioids in mediating the actions of alcohol on the mesolimbic DA system. (AA 00900, AA 08533)

NALOXONE FAILS TO BLOCK INHIBITORY EFFECTS OF ETHANOL ON SPONTANEOUS AND AMYGDALA-INDUCED SINGLE UNIT ACTIVITY OF NUCLEUS ACCUMBENS NEURONS. R.S. Lee, J.S. Criado, C.I. Berg, and S.L. Merchenthaler, Alcohol Research Center, Dept. of Neuropharmacology, Scripps Research Institute, La Jolla, CA 92037.

Previous studies from our group have shown diverse effects of ethanol on nucleus accumbens (NAcc) physiology. For example, systemic administration of ethanol reduces the firing rate of spontaneous and glutamate-activated NAcc neurons in both acute anesthetized and unrestrained rats. It has not been determined whether the effect of alcohol on the firing rate of these NAcc neurons is mediated by the reinforcing properties of ethanol. In the current study we examined the inhibitory effects of alcohol on ethanol-dependent injection of glutamate-activated NAcc neurons. In our experiments the firing rate of NAcc neurons was significantly reduced by ethanol (1.2-1.4 g/kg, i.p.) and has been significantly reduced by ethanol (1.2-1.4 g/kg, i.p.) and has been significantly reduced by ethanol (1.2-1.4 g/kg, i.p.) significantly reduced the firing rate of spontaneous and glutamate-activated NAcc neurons in both electrophysiological preparations. Similarly, ethanol inhibited the occurrence of amygdala-activated single unit in NAcc neurons. Naloxone did not reverse these inhibitory effects. These data indicate that the inhibitory effects of ethanol on NAcc physiology are independent of opioid mechanisms (supported by ARC AA06420 to SJH).

THE EFFECT OF NALTIRINDOLE ON EXPRESSION OF ETHANOL-INDUCED CONDITIONED PLACE PREFERENCE. S.D. Dickinson and C.L. Cunningham*. Dept. of Medical Psychology, Oregon Health Sciences Univ., Portland, OR 97201.

Recent research has suggested a role of the endogenous opioid system in the reinforcing properties of ethanol. Research in our laboratory has shown that the expression of ethanol-induced conditioned place preference in mice can be attenuated by naltirindole (1.5 - 10 mg/kg). However, at these doses, naloxone may act as a nonspecific antagonist, occupying both mu and delta opioid receptors. The current study was designed to determine whether naloxone's actions were delta-receptor mediated. Three groups of male DBA/2J mice underwent a Pavlovian conditioning procedure that paired injection of ethanol (2 g/kg, IP) with a distinctive tactile stimulus and injection of saline with a different stimulus. After four pairings of each type, a preference test was conducted in which mice were exposed to both tactile stimuli. Prior to the preference test, mice were injected with either 0, 3, or 10 mg/kg of naltirindole (NTI), a selective delta opioid receptor antagonist. All groups demonstrated a conditioned preference for the tactile stimulus that had been paired with ethanol. Unlike naloxone, NTI had no effect on the expression of the conditioned preference. This indicates that naloxone's ability to interfere with expression of ethanol place preference is not mediated via delta opioid receptors. Supported by an N. L. Tartar Fellowship.

IBOGAINE ATTENUATES ALCOHOL INTAKE IN ALCOHOL DRINKING RATS. Y.W. Lee, Amir H. Rezaei* and D.H. Overtstreet. Skinner Bowles Center for Alcohol Studies, University of North Carolina School of Medicine, Chapel Hill, NC 27599-7175.

Bogaine, the principal alkaloid of the root bark of Tabo subermuthi grown in West Central Africa, has been claimed to possess anti-addictive properties for cocaine and morphine. This study was designed to determine the effect of Ibogaine on alcohol intake in two strains of alcohol drinking rats. Alcohol preferring (P) and Fawn Hooded (FH) rats were injected IP with either vehicle or one of the doses (10, 30 and 60 mg/kg) of Bogaine and their alcohol intake was measured 24 hr later. In the experiments the effects of acute and subchronic intragastric as well as acute subchronic administrations of Bogaine in FH rats were determined. Intraperitoneal injections of Ibogaine significantly and dose-dependently attenuated alcohol intake in both strains. However, FH rats were less affected by the drug. Subchronic administration of the drug did not exert any effect. Both acute and subchronic intragastric administration of 60 mg/kg Bogaine significantly reduced alcohol intake without development of tolerance. The fact that Bogaine reduced alcohol intake when injected intraperitoneally and intragastrically, but not subchronically, suggests the involvement of its metabolite(s) in reducing alcohol intake. Although the true mechanism(s) of action of Bogaine in reducing voluntarily alcohol intake is not yet clear, the fact that FH rats with genetic serotonin dysfunction were less affected by this drug suggests that, in addition to other neurotransmitters, Bogaine may interact with serotonergic systems in the brain to reduce alcohol intake.

EFFECT OF CHRONIC ALCOHOL ADMINISTRATION ON DIURNAL ACTH AND CORTICOSTERONE SECRETION IN INTACT AND ADRENALECTOMIZED RATS WITH CORTICOSTERONE REPLACEMENT. T. Chevret, T. Torres, R. Deval, J.G. Ordone*, and R. Estany, NIAAA, NIH, Bethesda, MD 20892.

The hypotalamo-pituitary-adrenal (HPA) axis is characterized by a circadian variation of corticosterone (CS) and ACTH levels near lights on and highest hormone levels near lights off. Intact or adrenalectomized (ADX) male rats Implanted with CS pellets (plasma CS levels of 3 to 6 µg/dl) were fed every four hours for up to 10 days via an intragastric cannula with the Leiber-DeCarli liquid food diet (LCD) or ethanol diet (LED). Blood samples were taken via a carotid catheter at the trough of the circadian rhythm. In intact alcohol-treated rats, daily plasma CS levels were 2 to 10 fold higher at the nadir, when compared to control rats, whereas daily plasma ACTH levels at the nadir were elevated less than 50% of the time. In ADX rats with CS replacement, plasma ACTH levels were significantly higher only during the trough in LED-treated rats compared with LCD-treated rats. Furthermore, chronic alcohol treatment decreased thymus and spleen weight in both intact and ADX rats with CS replacement. These results indicate that continuous alcohol exposure (150-300 mg/dl) leads to a persistent activation of the HPA axis, particularly during the nadir of the diurnal rhythm.

Recent studies from our laboratory have demonstrated that chronic alcohol exposure (OT) pathways in the inhibitory control of solute ingestion, whether the solute is taken as food or as a concentrated NaCl solution. These data led us to investigate whether central OT may be similarly involved in the control of (ethanol) ingestion, since OT also affects ethanol intake. In the current study, male rats were pretreated with central injections of ricin A toxin conjugated to OT (AOT, 5 µg; i.c.v.) or the non-OT peptide, α-thrombin (2 µg; i.c.v.) 46 hours before the injections. Central injections of OT at either 1 µg (a specific receptor agonist) or 25 µg (a non-specific receptor agonist) resulted in significantly increased daily ethanol intakes compared to the controls at all ethanol concentrations tested (p<0.01). This marked ethanol preference in the AOT-pretreated rats produced significantly greater degrees of tolerance, as measured by lack of responsiveness to ethanol (EtOH) following 5, 10 and 15 sec i.c.v. (p<0.01). In addition, studies using potentiated OT injection in rats with pretreatment with central injections of AOT significantly increased daily ethanol intakes compared to the controls at all ethanol concentrations tested (p<0.01). These data indicate that central OT pathways are involved in the inhibition of ethanol intake. Our data suggest that ethanol is a potential therapeutic tool for the treatment of alcohol dependence.

**DISCRIMINATIVE AND AFFECTIVE STIMULUS PROPERTIES OF THE CALCIUM CHANNEL BLOCKER NIMODIPINE IN RATS.**

J. De Vis, M. de Jong* and R. de Bruijn. Institute for Neurobiology, Tropenwolke GmbH & Co. KG, Brain Research Ass. 156, 5163 College, FRG

The L-type calcium channel blocker nimodipine, a 1,4-dihydropyridine (DHP) derivative, is effective in reducing alcohol intake and preference in animal models of alcoholism. In order to gain more insight into possible mechanisms underlying the alcohol intake-suppressing effects of this drug, the discriminative and affective (rewarding/aversive) stimulus properties of nimodipine were evaluated in Wistar rats. It was found that the drug was equally effective in a standard all-delivered, lever-pressed reinforced discrimination (DD) procedure and, in subsequent generalization tests, inverted U-shaped dose-response curves were obtained with nimodipine with an effectiveness value of 9.0% (S.E.M. = 0.011). This response was generalized completely to (+)-nimodipine (again, an inverted U-shaped curve was obtained), but only partially to (-)-nimodipine. Although effective as a discriminative stimulus, the quality of this stimulus appears to be dissimilar to that of ethanol as it was found that rats trained to discriminate ethanol from saline in a similar procedure did not generalize to nimodipine. The latter finding was confirmed in a cross-familiarization conditioned taste aversion (CTA) procedure, an alternative method to reveal stimulus similarities between drugs. In addition to discriminative stimulus effects, nimodipine has also affective stimulus properties, as the compound was found to induce conditioned taste aversion (CTA), as well as, conditioned place preference (CPP). Racemic (+)-nimodipine were active in CTA and CPP, whereas (+)-nimodipine failed to produce either CTA or CPP; suggesting that, in contrast to the DD effects, the affective stimulus effects are mainly mediated by the activity of (+)-nimodipine. Because the alcohol intake- and preference-reducing effects of nimodipine reside mainly in the (+)-enantiomer, the mechanism involved in these effects may be related to the affective stimulus properties of nimodipine.

659.2

**THE USE OF A SUCCROSE-SUBSTITUTION PROCEDURE TO ESTABLISH ETHANOL AS A POSITIVE REINFORCER IN AN OPERANT RUNWAY.** C.I. Czechowski* and A. Ittenberg. Behavioral Pharmacology Lab., Dept. of Psychology, Univ. of California, Santa Barbara, CA 93106.

The reinforcing properties of self-administered ethanol were examined in nondeprived rats trained to traverse a straight-arm runway for the opportunity to drink an ethanol solution. Animals were tested once each day in the runway where each trial culminated in 6 min of access to a drinking bottle containing 5-10% ethanol. In order to ensure reliable and significant levels of ethanol consumption, we employed a modified version of a sucrose-substitution procedure originally described by Samson (1986) in an operant lever-pressing paradigm. In the present study, subjects initially ran the alley for access to high concentrations of sucrose (20% w/v) without ethanol. Over the course of days/trials the concentration of sucrose was gradually reduced while the concentration of ethanol was increased from 0 to 10%. This procedure successfully resulted in a mean ethanol intake of 6.65 g/kg (S.E.M. = 0.14) - a dose that rendered several animals ataxic and had clear behavioral/intoxication effects. These data suggest that the runway/sucrose-substitution procedure may provide a unique model for investigating the reinforcing properties of high doses of ethanol in nondeprived animals.

659.3

The objective of this study was to determine the effects of taste aversion training during adolescence on subsequent alcohol intake of the selectively bred alcohol-preferring P and high-alcohol drinking HAD lines of rats. Beginning at 30 days of age, male and female rat pups were fluid deprived 24 hrs before a 30 min access to a 10% (v/v) ethanol solution. Following ethanol exposure, the animals were given an i.p. injection of either saline or 0.15 M LiCl (10 ml/kg). A total of five training sessions were administered every other day with ad lib access to water on intervening training days. Twenty-four hrs after the last training trial, rats were given continuous free-choice between water and 10% ethanol for four weeks with food available ad lib. There were no obvious gender differences or line differences to the effects of taste aversion training. All LiCl-treated subjects avoided the usually preferred ethanol-habituated rats. For the entire four week test period (intake in week 4 was 0.6±0.1 g/kg/day; N=8), while saline-treated rats steadily increased their alcohol intake from 8±0.7 g/kg/day during week 4 (p<0.01 vs LiCl treated). Total volume of fluid intake did not differ between groups (39±4 ml/day for saline-treated and 39±5 ml/day for LiCl-treated group). Approximately 60% of the total fluid intake was ethanol for the saline-treated group, while the LiCl-treated rats this value was less than 3%. Rats in the saline and LiCl-treated groups gained weight at equivalent rates. These data suggest that early environmental intervention can prevent the onset of alcohol drinking in the selectively bred alcohol-preferring P and high-alcohol-drinking HAD lines of rats. **CO-MORBID DEPRESSION, DRUG DEPENDENCE, AND ALCOHOLISM.**

Norman S. Miller, M.D.(1), Norman G. Hoffmann, Ph.D.(2), Mark S. Gold, M.D.(3) University of Illinois at Chicago(1), The University of Minnesota(2) and The University of Florida Brain Institute (3).

We examined the relationship between a lifetime diagnosis of major depression in 6535 patients with drug dependence and/or alcoholism. Evaluations were performed in a personal interview on admission (383 questions) and follow-up data was gathered by a structured telephone interview (110 questions) at 6 and 12 months. The most common diagnosis of a substance use disorder was alcohol (31.3%), followed by cannabis (19.7%) and then marijuana (12.3%). The rate of lifetime diagnosis of major depression was 43.7% and subclinical depression was 9.6%. Over half of the patients had two or more symptoms of depression and more than 35% described more symptoms. The rates of depression were significantly greater for females than males, for alcoholism than other drug dependencies. A lifetime diagnosis of major depression was significantly associated with poly-drug dependence.

**NEURAL EXPRESSION OF C-FOS PROTEIN FOLLOWING AGGRESSIVE BEHAVIOR OR ETHANOL ADMINISTRATION IN MICE.** K. Bechter, G. Gunn, J. Murankaj, and F. von Saar* Division of Biological Sciences, University of Missouri-Columbia, Columbia, MO 65211.

We employed immunocytochemistry to detect the presence of c-fos protein in the brains of male wild mice one hour following i.p. treatment (20mg/kg) with 1.03 g/kg ethanol (EtOH) 21.67 g/kg EtOH 3.9% saline or 4.9% saline and an agnostic encounter with an unfamiliar conspecific male in a neutral arena 10 min. following injection. Mice subjected to an aggressive interaction or treated with 1.67 g/kg EtOH exhibited elevated c-fos expression in the anterior and olfactory cortices of the amygdala, medial preoptic area and entorhinal cortex relative to mice treated with 0.33 g/kg EtOH or saline. C-fos was also expressed in the piriform cortex of mice that fought and in the hippocampus of mice given the higher dose of EtOH. These results demonstrate c-fos activation in olfactory and limbic structures that have been implicated in the mediation of aggressive and sexual behaviors in other mammals. They also suggest that EtOH may affect mouse expression of c-fos gene expression in the olfactory-limbic pathway.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
The importance of temporal factors in the establishment and maintenance of ethanol withdrawal signs in the rat was questioned by a user who puts a tremor to his/her natural scale, and acoustic startle test. Ethanol dependence was invoked in naive male Wistar rats either by ethanol liquid diet administration for four exposures (n=16) for 14-17 days prior to withdrawal in both cases. The rats maintained in the ethanol vapor chambers were divided into 3 groups with target BALS of 120-140, 170-190, and 220-240mg/dL to determine the effects of BAL concentration on withdrawal measures. Both test groups had appropriate controls (n=8). Repeated measures ANOVA was performed on the data. Disturbance of the floor produced a piezoelastic response which was amplified, filtered, and stored in an IBM computer. Following each tremor trial, subjects were rated for withdrawal signs: verticromelic distal flexion reflex, irritability, tail stiffness, and abnormal body posture/ splayed gait. For acoustic startle, movements were detected by a piezoelectric accelerometer beneath the Plexiglas chamber, digitized and recorded on an IBM computer. Mixed trials with sound pulses of 105 and 120dB were included in each test session. Data analysis revealed that most withdrawal signs reached peak intensities between 8 and 12hr postwithdrawal. Most quantified signs of withdrawal were greater in the vapor chamber subjects than in the liquid diet subjects, probably reflecting higher chronic BA's in the former case. Results suggest that both liquid diet administration and chamber exposure produce quantifiable, time-dependent measures of ethanol withdrawal.

EXTRACELLULAR CONCENTRATIONS OF ETHANOL IN THE BRAIN FOLLOWING IP, IG OR CONSUMED ETHANOL IN RATS. K. Kilian, M. Nurm, and J.D. Sinclair, Biomedical Research Center, Alko Ltd., and Department of Zoology, University of Helsinki, Helsinki, Finland.

The distribution was examined by studying the extracellular levels of ethanol in the nucleus accumbens of the alcohol preferring AA (Alko Alcohol) and alcohol avoiding ANA (Alko Nonalcohol) rats with in vivo microdialysis. Samples for the assay of ethanol with head-space GC were collected from freely moving animals at 1 min intervals after administration of ethanol (1 g/kg) IP or IG, as well as during voluntary drinking of 10% (v/v) ethanol solution provided by the access to ethanol solution IP 30 min before daily. Tail blood was drawn every 5 min. The results show that there is a steep rise in brain ethanol concentration within minutes after IP injection, but there is no obvious difference between the two rat lines in the distribution of ethanol into the brain. The slopes revealed curvses from the same animals peaked much later. With IP administration, however, the time courses were similar for brain and tail-bloood ethanol. In the drinking study ethanol was found in the brain only a few minutes after the rats started to consume ethanol. The results and so far give no indication that the differential ethanol consumption by AA and ANA rats could be explained in terms of differences in the distribution of ethanol to the nucleus accumbens. Nevertheless, the observed level of brain ethanol after voluntary drinking is sufficiently large and rises quickly enough to provide positive reinforcement. Furthermore, the study shows that microdialysis coupled with head space GC gives detailed information of the brain ethanol curve in individual, freely moving animals after relatively small doses of ethanol.

LATENCY OF CONDITIONING TRIAL AND EXTENT OF CHRONIC CONDITIONING EFFECT EKMO-INDUCED CONDITIONED PLACE PREFERENCE AND AVERSION. G. G. Blassley, M. J. Lewis. Neurobehavioral Laboratory, Dept. of Psych., Temple U., Phila. PA 19122

The present study was designed to examine the effect of latency of conditioning trials and the extent of chronic conditioning upon a EKMO-induced place preference and aversion. Preliminary preference studies suggest that ethanol may gain its reinforcing effect only after a latency of one hour prior to exposure to the drug. Moreover, research from our lab has suggested that the latency of the conditioning trial to the time of administration is an important factor in EKMO's rewarding properties. Male albino rats were subjected to a paradigm of 1 hr stimulus (CS) and ip injections of varying doses of ethanol (0.25g/kg to 4g/kg). Subjects received one trial per day for four consecutive days and were given a free choice test on the fifth day. Each subject received three consecutive occurrences of this schedule. Conditioning sessions lasted 15 minutes and began at latencies ranging 15 or 30 minutes post-injection. Significant interactions between dose, extent of conditioning, and latency with preference and aversion were observed. It was suggested that EKMO has a synergy in rewarding and aversive properties depending upon these experimental variables.

We have continued our studies of the relationship between regional cerebral metabolism of glucose (CMRglc) and subjective responses to drugs of abuse. In order to focus on individual differences in behavioral effects, we have applied PET and parametric comparison procedures which enable us to character cerebral metabolic responses in two groups of 12 subjects each. Our previous PET and 1H MRS studies have demonstrated significant differences in regional metabolism between groups preferring and not preferring ethanol (E) placebo, and those preferring and not preferring the placebo, subjects were categorized into two equal groups: high liking (HL, mean difference of liking for ethanol compared to placebo +4.49, SD = 1.48) and low liking (LL, mean difference of liking for ethanol compared to placebo +4.53, SD = 1.29). PET data on CO2 uptake were correlated with anatomical MRIs, transformed to standard volumes based on the Talairach atlas, interpolated, and averaged across subjects for HL and LL. For each group the ethanol condition and placebo were compared using paired t-tests. No significant differences were observed.

CHRONIC INTRACEREBROVENTRICULAR ETHANOL ADMINISTRATION IMPAIRS NONSPATIAL MEMORY IN RATS. C.L. Weaver, L.M. Copley, R.S. Cottulett, and G.L. Dubner, Dept. of Psych., University of Michigan, Ann Arbor, Michigan, 48109.

Chronic IP injections of ethanol (ETOH) reduces behavioral flexibility by spatial learning tasks (Davenport et al., Behav. Neurosci., 103:1259-1266). We tested the effects of chronic ICV ETOH administration on spatial and nonspatial, working and reference memories on an eight-arm radial water maze (Hamm) task. Male rats were given sham (n=8) or chronic (21 days) ICV ETOH (20% in saline) or saline via mini-osmotic pumps. Both ETOH- or saline-treated rats could solve the spatial task at unoperated control levels. Rats receiving the ETOH made significantly more reference memory errors into channels that never had escape platforms) and working memory 'incorrect'(re-entries into channels previously visited within a trial that never had escape platforms) errors than both saline and unoperated controls during nonspatial testing. Our results indicate that chronic ICV ETOH can disrupt some aspects of both reference and working nonspatial memory. Supported by NSF Grant DUE 9352395 and Research Excellence Fund.

INTERACTIONS OF ETHANOL WITH NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS EXPRESSED IN XENOPUS OOCYTES. C.M. de Faria* and E.M. Mayer, Dept. of Pharmacology & Therapeutics, Univ. of Florida Col. of Med., Gainesville, FL 32610-0267.

While the correlation between smoking and drinking is very large, little is known about the biological factors which regulate the co-use of nicotine (Nic) and ethanol (EtOH). Previous evidence has suggested that sensitivity to these agents is genetically correlated because EtOH may modulate nicotinic acetylcholine receptor (nAChR) function by stabilizing nAChRs in the nonfunctional, desensitized form. Here we report that ethanol affects neuronal nAChRs in a subtype-selective fashion. Neuronal nAChRs subtypes (α3β2, α2β2 and α3β3) were expressed in Xenopus oocytes from cRNA and studied under two-electrode voltage clamp for responsiveness to bath-applied, Nic and EtOH. While EtOH displayed no direct agonist effects, it modulated the function of each of these receptor subtypes. At all receptor subtypes, there was a trend for cooperation of EtOH to enhance responses to Nic. In oocytes expressing α3β2 and α2β2 receptors, application of Nic 2.5 min after the start of a 5 min application of EtOH attenuated responses to AC applied 5 min following Nic (2.5 min after the end of the EtOH application). This effect was not seen at α3β3 receptors. Dose-response and time-course analyses are currently being conducted at these as well as at other nAChR subtypes. These results suggest that EtOH may display complex pharmacological properties at specific neuronal nAChR subtypes. Supported in part by training grant AA-07861. The cDNA clones were kindly provided by Dr. Jim Boulter of the Salk Institute.

ETHANOL MODULATION OF RECOMBINANT ACETYLCOLINE RECEPTOR CHANNELS EXPRESSED IN HEK-293 CELLS. A. Ravindran*, K. Masood and F. F. Weight, Laboratory of Molecular & Cellular Neurobiology, NIAAA, NIH, Bethesda, MD 20892.

The nicotinic acetylcholine receptor (AChR) is a ligand-gated ion channel located in the postsynaptic membranes of nerve, muscle and electric organ. The AChR from electric organ and muscle consist of four distinct subunits assembled into a α2β2γ (or αβγ) pentamer. The modulation of acetylcholine (ACh) induced current by ethanol was studied in HEK-293 cells transfected with mouse αβδ AChR subunit cDNAs. 40-48 hr after transfection whole-cell and out-side out patch clamp techniques were used to record ACh induced inward current from cells expressing AChR. ACh alone and in combination with ethanol (EtOH) were applied to the recorded cell and out-side out patch by a theta-tube rapid perfusion system that enabled complete exchange of solutions in 1-5 ms. ACh activated rapidly desensitizing inward currents with an EC50 of 20 μM. Co-application of EtOH (10-150 mM) potentiated, in a concentration-dependent manner, currents activated by 5 and 10 μM ACh. The potentiation was between 20-50% of the control response. With higher concentrations of ACh > 25 μM, EtOH seem to induce significant reduction in peak current amplitude. Further studies are being undertaken to elucidate the mechanism of ethanol modulation of AChR channels.

660.3

Ethanol (EtOH) has an extremely complex profile of actions on the CNS, and attention has increasingly focused on factors that create selective vulnerability of specific cell types. The hypothesis tested here was that EtOH effects in the somatosensory cortex may be related to specific neural attributes of membrane function, including electrical or biological signaling and morphological intracellular recording techniques combined with dye injections were used in vitro to investigate the actions of EtOH on synaptic transmission within layer V of the somatosensory cortex. Bath application of EtOH (1-100mM) revealed a large spectrum of effects on membrane parameters and postsynaptic potentials of cortical neurons. In some regular spiking neurons with a "bursting" type characteristics, EtOH (10mM) did not change input resistance and thebase but produced a blockade of accommodation. In this cell type, excitation postsynaptic potentials (EPSPs) evoked by electrical stimulation of white matter or adjacent layers were monophasic and very sensitive to the depressant action of EtOH. On the other hand, in a population of "bouffet" cells, the membrane and input resistance were altered by EtOH (10mM) in response to stimulation of the white matter, these neurons displayed a characteristic high-frequency response with early and late components. The late component was more strongly affected by EtOH. Neurons of the "intrinsinc bursting" type also had biphasic EPSPs whose late components were preferentially depressed by EtOH. Finally, in neurons with a regular spiking" neuronal circuitry, EtOH altered input resistance, blocked accommodation, decreased duration and amplitude of the slow afterhyperpolarization and reduced excitability effects in the late EPSP of the burst component. These results confirm that EtOH can exert variable effects on different neural elements of layer V neocortical circuits. The influence of EtOH on specific intracellular signaling pathways may underlie its effect on specific tasks. (Supported by NIDA DA 08405 to FMS and DA 08349 to AED).

EFFECTS OF CHRONIC ETHANOL EXPOSURE ON GABA$_A$ RECEPTOR $\beta_2$ and $\gamma_2$ SUBUNIT mRNA LEVELS IN RAT BRAIN. L. D. Dravet$^1$, D. R. Graven$^1$, and A. L. Morrow$^1$.

The expressions of mRNA encoding different subunits of the GABA$_A$ receptor were studied using RT-PCR method. In the brain of ethanol-exposed rats, the expressions of $\beta_2$ and $\gamma_2$ subunit mRNAs were affected, with a significant decrease in the $\beta_2$ subunit mRNA level and an increase in the $\gamma_2$ subunit mRNA level. These changes may contribute to the development of ethanol dependence.

660.6

AN IN SITU HYBRIDIZATION STUDY ON $\nu$-SUBUNIT mRNA OF GABA$_A$ RECEPTORS OF PENTOBARBITAL (PB) TOLERANT / DEPENDENT RAT BRAINS. T. Ito, T. Suzuki, D.K. Lim and X. H. Ho.*

The mRNA expression levels of the $\nu$-subunit of the GABA$_A$ receptor were studied in the brains of rats tolerant and dependent on pentobarbital. The results showed a significant increase in the mRNA levels in tolerant and dependent rats compared to the control group, indicating a possible role of the $\nu$-subunit in the development of tolerance and dependence.

660.7

GABAERGIC NEURONS IN THE EXTENDED AMYGDALA MODULATE ALCOHOL REINFORCEMENT. F. Hyvälä$^1$ and G. F. Koob$^1$.

The role of GABAergic neurons in the extended amygdala in the modulation of alcohol reinforcement was studied. The results showed that the activity of GABAergic neurons in the extended amygdala was increased in rats with a history of alcohol exposure, suggesting a potential role in the development of alcohol dependence.

660.8

CHANGES IN GABAERGIC SYNAPSES OF DENTATE GRANULE CELLS DURING CHRONIC ETHANOL TREATMENT. E. Filley$^1$, H. Eason$^1$, K. Buntzem$^1$, P. Schuck$^1$.

The synaptic changes in the dentate granule cells of rats exposed to chronic ethanol were studied using immunohistochemistry. The results showed a decrease in the number of GABAergic synapses, suggesting a potential role of synaptic changes in the development of ethanol dependence.

660.9

INTRA-STRATUM ADMINISTRATION OF FLUMAZENIL (FL) TO DIZEPAM (DZ) DEPENDENT RATS. E. P. Winter$^1$, J. A. Sloman$^1$, J. Ying$^1$.

The effects of intra-stratum administration of flumazenil on the behavior of dizepam-dependent rats were studied. The results showed a decrease in the sedative and hypothermic effects of dizepam, suggesting a potential role of flumazenil in the modulation of dizepam-induced effects.

660.10

ETHANOL INCREASES TAURINE BUT NOT GLUTAMATE NOR GABA IN THE NUCLEUS ACCUMBENS USING MICRODIALYSIS. A. Dachhour$^1$, K. Quertermont$^1$, Ph. Durbin$^2$ and Ph. De Witte$^2$.

The changes in the levels of taurine, glutamate, and GABA in the nucleus accumbens of rats treated with chronic ethanol were studied using microdialysis. The results showed an increase in the levels of taurine and a decrease in the levels of glutamate and GABA, suggesting a potential role of taurine in the modulation of ethanol-induced changes.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
DECREASE OF PAIRED-PULSE INHIBITION IN CA1 AREA OF HIPPOCAMPAL SLICES OF CHRONIC INTERMITTENT ETHANOL TREATED RATS: M.E. Kandy, L. Spiegelman, D.M. Rapp, and R.W. Olsen. Dept. of Pharmacology, UCLA School of Medicine, School of Dentistry, Los Angeles.

Chronic intermittent ethanol (CIE)-treated rats showed severe withdrawal signs including a persistent kindling-like decrease in the pentetrazol (PTE) seizure threshold (Kokka et al., Alcohol Clin. Exp. Res., 525-531, 1993). To understand the cellular mechanism underlying this plasticity, the involvement of GABA receptors, the target of ethanol and PTE pharmacological effects, was studied utilizing biochemical and electrophysiological functional assays. We observed a significant decrease in muscimol (100 μM)-induced GABA efflux in hippocampal slices from CIE rats. Paired-pulse inhibition, which is considered to be predominantly due to GABA-mediated recurrent inhibition, was significantly (p<0.005) decreased in the CA1 area of hippocampal slices from CIE rats measured 2 days post-ethanol. This study suggests that a hypofunction of GABA receptors in the hippocampus may play a key role in kindling-like decrease in the seizure threshold in the CIE rat model of alcohol dependence. Supported by AA07640.

This study was designed to determine the effects of alcohol upon: (1) defensive rage behavior (DB) elicited from the medullary hypothalamus (MH), and (2) MH facilitation of DR elicited from the doral midbrain periaqueductal gray (PAG). Experiment I: peripheral administration of alcohol (0.02, 0.5 and 1.0 g/kg, i.p.) reduced latency responses in a dose and time dependent manner, the maximal effect occurring at 60 min, postinjection, at the highest dose level. Experiment II: peripheral administration of alcohol at the same dose levels markedly enhanced MH facilitation of DR elicited from the PAG in a dose and time dependent manner. Experiment III: microinjections of the NMDA receptor antagonist, AP-7, into PAG-DR sites blocked MH facilitation of DR elicited from the PAG. These results indicate that: (1) alcohol administration facilitates the occurrence of DR; and (2) the excitatory effects of alcohol upon rage may be manifest through the MH-PAG pathway which involves NMDA receptors. [Supported by NIH Grant NS 07941-24]
ROLE OF PROTEIN KINASE C IN ETHANOL INDUCED INHIBITION OF METABOTROPIC GLUTAMATE RECEPTOR FUNCTION IN PRIMARY CULTURES OF ASTROCYTES. T.L. Smith* and M.S. Birrick. Research Service (151), Dept. of Veterans Affairs Med. Ctr., Tucson, AZ 85723

Chronic ethanol (E) exposure selectively inhibits metabotropic-glutamate receptor (mGluR) activation in astrocytes (Smith, Alcohol, in press 1994). Because this receptor system is highly sensitive to modulation by protein kinase C (PKC), the aim of the present study was to determine whether the inhibiting effect of E could be reversed in the presence of staurosporine, a PKC antagonist. Astrocytes were cultured in DMEM with 5% FCS in 35 mm dishes in the absence of 100 mM Fe for 4 days. In some studies, control and E treated cells were co-incubated with 10 mM staurosporine for 3 days or with 2 μM calphostin C 10 mins prior to addition of agonists. After a 24 hr. preincubation with [3H]inositol (1μCi/mL), astrocytes were stimulated with 1S, 1R -ACPD and subsequent [3H]InsP3 determined. Chronic E significantly inhibited the InsP3 response to 1S, 3R -ACPD. Moreover, exposure for 10 min to 10μM phorbol ester (PMA) further inhibited the response in E treated cells, indicating that the effects of E and PKC activation were additive. The results suggest that the inhibitory effect of chronic E is not mediated primarily by PKC. (Supported by a research grant from the Dept. of Veterans Affairs, Washington, DC).

MODULATORY EFFECTS OF ACUTE ETHANOL ON METABOTROPIC GLUTAMATE RESPONSES IN CULTURED PURKINJE NEURONS. J.G. Netzeband* and D. L. Grudel. Dept. Neuropharmacology and the Alcohol Research Center, The Scripps Research Institute, La Jolla, CA 92037.

Of the many actions contributed to ethanol in the brain, little attention has been given to possible interactions with metabotropic glutamate receptors that may be involved in synaptic transmission and plasticity. To this end, we modified organotypic cultures were prepared from embryonic day 20 rat cerebella and extracellular recordings were made from Purkinje neurons at 21-37 days in culture (37 °C). Metabotropic glutamate responses were induced by pressure ejection of (a) 300 μM (1S,3R)-1-aminocyclopentane-1,3-di-carboxylic acid ([1S,3R]-ACPD) or (b) 5 μM quisqualate (50 μM DNGQ was used to block the ionotropic component of quisqualate-evoked responses). Both (1S,3R)-ACPD and quisqualate produced biphasic responses consisting of an initial brief excitatory phase (5-20 s) followed by a prolonged inhibitory phase (10 s ≥ 2.5 min). These agents also induced increases in the appearance of burst-like activity. In the presence of 66 mM ethanol, (1S,3R)-ACPD-mediated responses exhibited a decrease in the magnitude of the excitatory phase and an increase of the total response duration, with no change in the induction of burst activity compared to controls. In contrast, 66 mM ethanol had much different effects on quisqualate-mediated responses. For quisqualate, ethanol decreased the total response duration and the induction of burst activity, but had no effect on the magnitude of excitation. These studies suggest a complex interaction between the effects of ethanol and metabotropic glutamate receptors in cultured Purkinje neurons. Supported by ARC 8420 and AA 0765.

Embryonic exposure to ethanol (ETHO) often produces motor dysfunction consisting of poor balance, altered gait and decreased tendril (stretch) reflexes. To determine if alterations in the development of serotonergic somata and fibers in the spinal cord contribute to these symptoms, chick embryos were exposed to ETHO. Surprisingly, the development of serotonergic neurons and fibers was studied with immunohistochimical techniques using a polyclonal antisera to serotonin (5HT). Groups of chick embryos were treated with 10% ETHO in sterile Tyrode's w/v as compared to control embryos. Immunolabelings of either 0.1 μM or 0.2 μM w/v (medium dose) or 0.275-0.352 μM w/v (high dose). Control embryos were treated with equivalent volumes of sterile Tyrode's. The ETHO was administered as a single beginning day 1 (E1) and continued until the animals were sacrificed. Serotonin immunoreactivity [5HT-IR] was examined in the first 3 lumbosacral spinal cord segments in animals sacrificed on E10, E12 and E14. At all stages examined, the density of 5HT-IR fibers was less in both ETHO-treated groups than in control groups. Camera lucida drawings of 5HT-IR neurones were utilized for number of primary dendrites (those originating directly from the soma) and secondary dendrites (any dendrite originating from a dendrite). At all stages examined, the number of secondary dendrites was significantly less in both ETHO-treated groups as compared to controls. There were significantly fewer primary dendrites in both ETHO-treated groups at E12 and E14 and in the embryos treated with the high ETHO-dose at E10. These ETHO-induced alterations in the serotonergic system may be involved in the motor dysfunction observed after embryonic ETHO exposure. (Supported by AA02055).

IMPACT OF ETHANOL ON DEVELOPMENT OF ORGANOYTIC CULTURES FROM NEOCORTEX AND SPINAL CORD. D.L. Davies* and B. Mendelson. Dept. of Anatomy, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72205.

Development of the CNS is adversely influenced by exposure to ethanol. As part of an endeavor to assess the effects of ethanol on neural development in the absence of confounding systemic variables, organotypic cultures were stereotopically evaluated following ethanol exposure. Organotypic cultures were prepared from the neocortex of 4-day-old postnatal rats and the spinal cords of embryonic day 10 chicks. Groups of cultures from both sources were incubated in medium containing 0%, 0.25%, 0.5% or 1% (v/v) ethanol; cultures were harvested for evaluation after 1, 3, 6 and 9 days of in vitro ethanol exposure. At these timepoints, both control and ethanol exposed cultures from neocortex and spinal cord retained features of the fetal structures. In these cultures, a detailed set of astrocytes identified by immunolocalization of glial fibrillary acidic protein. Throughout the culture interval, serotonergic neurons in the spinal cord were immunocytochemically labeled. The exposure of embryonic cultures to ethanol exposed cultures. The somatic and dendritic arbors of motoneurons and particular classes of interneurons were labeled by placement of small crystals of DiI at specific locations on the fixed spinal cord. In the neocortex, ethanol exposed has exhibited cultures exhibited smaller dimensions than control cultures; this was more evident at the high (0.5%) ethanol concentration and may reflect lower cell viability. These studies suggest the utility of organotypic cultures as alternative models for delineation of the direct effects of ethanol on development and cellular interactions in the CNS. Supported by NIH grants AA07145 (DL) and AA09205 (BM).
NO REDUCTION OF SPONTANEOUSLY ACTIVE MESOLIMBIC DOPAMINERGIC NEURONS IN ETHANOL-WITHDRAWN RATS. [661.5] (D.C. Mab, J. Stuel, M. Basile*, E. M. Dole, J. Wagger, F. E. Livin, and R. P. Palmier, Dept. of Neurology, Pharmacology & Pathology, Univ. of Miami School of Medicine, Miami, FL, 33101 and Dept. Psychiatry and Centre for Human Genetics, McGill University, Montreal, Canada) The binding characteristics of dopamine synaptic markers were studied in four different test systems: alcohol withdrawal, pre-drinking, alcohol-pretreatment, and short-term alcohol abstinence. We have used radioligand binding and autoradiography to quantify and map the status of D1 dopamine receptors in ethanol-consumption and alcohol-preferred monkeys. Our analysis demonstrates that the number of D1 receptors labeled with [HHSCH 23900 is elevated over limbic structures of the basal forebrain and striatum. Saturation binding analysis demonstrates a high density of D1 receptors in the nucleus accumbens, but not in the prefrontal cortex. This finding suggests that ethanol withdrawal could lead to increased D1 receptor expression, which could potentially contribute to the increased alcohol consumption observed in ethanol-withdrawn animals. The implications of these findings for understanding the mechanisms underlying alcohol withdrawal and relapse are discussed.

DEFICIENCIES IN DOPAMINE AND SEROTONIN CNS SYSTEMS ASSOCIATED WITH HIGH ALCOHOL PREFERENCES. [661.6] (L.M. McDermott, E. Hamlet, J. Sokoloff, and T. L. G. Dept. of Psychiatry, Univ. of Miami, Med. & Med., Univ. Indiana Sch. Med. and VA Med. Ctr., Indianapolis, IN 46202-4860). The hypothesis that high alcohol preference is associated with abnormalities in certain dopamine (DA) and serotonin (5-HT) CNS systems was investigated. In one study, the contents of DA and 5-HT were determined in 4 CNS regions of adult male rats in the F2 generation selectively bred alcohol-prefering P and alcohol non-prefering NP lines. Rats with the highest (N) and lowest (N) alcohol intakes (6.3±0.3 g 0.24±0.2 g/day, p=0.001) were compared. The results show that there is a reduction in the number of spontaneously active dopamine neurons from ethanol-withdrawal in a D2-neuroesterase rat. Since there is a possibility that the use of anesthetics could be a confounding factor in the number of spontaneously active dopamine neurons as evidenced by a calculated index unchanged between ethanol-withdrawal and saline-treated control rats, in chronic alcohol-treated rats, we repeated the experiments in anesthetized and chloral hydrate anesthetized rats. In conclusion, the results suggest that there is indeed a reduction in the number of spontaneously active mesolimbic DA neurons recorded from chloral hydrate anesthetized rats but this is confirmed to the anesthetized rats (D2). This finding does not provide evidence for the idea of impaired dopamine function in ethanol-withdrawn rats.

INVOLVEMENT OF THE DOPAMINE AXIS IN A VERTET MONKEY MODEL OF ALCOHOL ABUSE. [661.7] (R.M. Palermo, D. Miles, F. E. Livin, and S. N. Young*, Dept. of Psychiatry, McGill Univ. Sch. Med., Montreal, Que, Canada, H3A 1A1 & Dept Neurology, U Miami Sch. Med, Miami, FL) Approximately 15% of vertet monkeys voluntarily consume large quantities (≥ 5 g/kg/day) of unrestrained ethanol (Enlin et al., 1990). Several convergent lines of evidence suggest that dopaminergic neuronal transporters may differ between Alc:preferring (AA07462) and Alc:avoiding (AA09562) animals. As noted previously (Marchant et al., 1993), the density of DA transporters is high in abstinent Alc:monkeys and reduced in Alc:apomorphine-treated animals. In this study, we measured the effect of ethanol withdrawal on the expression of DRD1, DRD2, DRD3, and DRD4 mRNA levels in the mesolimbic dopaminergic system of naive and ethanol-withdrawn rats. The results show that ethanol withdrawal leads to a significant reduction in the expression of DRD1, DRD2, DRD3, and DRD4 mRNA levels in the mesolimbic dopaminergic system, suggesting that ethanol withdrawal leads to a significant reduction in the number of spontaneously active mesolimbic DA neurons as evidenced by a calculated index unchanged between ethanol-withdrawal and saline-treated control rats, in chronic alcohol-treated rats, we repeated the experiments in anesthetized and chloral hydrate anesthetized rats. In conclusion, the results suggest that there is indeed a reduction in the number of spontaneously active mesolimbic DA neurons recorded from chloral hydrate anesthetized rats but this is confirmed to the anesthetized rats (D2). This finding does not provide evidence for the idea of impaired dopamine function in ethanol-withdrawn rats.

CLOMIPRAMINE ALTERS THE RESPONSE OF VENTRAL TEGMENTAL AREA (VTA) NEURONES TO ETHER-INJECTED EXCITATION. R.D. Trinjooyil and M.S. Rodehe. Dept. Physiology and Biophysics, University of Illinois at Chicago, Chicago 60612.

Exitation of dopamine neurones of the ventral tegmental area (VTA) may be a critical factor for the rewarding effect of ethanol (EtOH). EtOH increases the firing rate of VTA neurones in vivo and in vitro and the potency of EtOH to excite VTA neurones is increased by serotonin (5-HT). Drugs which block the reuptake of 5-HT, like zimelidine and clomipramine (CLOM), have been used clinically to decrease the firing rate of VTA neurones. Our objective was to test whether clomipramine, at concentrations which block 5-HT reuptake, alters the response of VTA neurones to EtOH, as we have shown for 5-HT.

Coronal brain slices from the VTA were prepared from young adult F344 rats. Concentrations of EtOH (40 - 120 mM) were tested in the absence and presence of CLOM (125 mM to 2 mM). All neurones (n = 21) studied had electrophysiological characteristics typical of dopaminergic neurones and were excited by EtOH in a concentration-dependent manner. Clomipramine itself had little or no effect on the firing rate of VTA neurones. In the presence of 500 mM CLOM, EtOH-induced excitations were approximately doubled; with CLOM, the mean excitatory effect of EtOH increased from 10% to 20% for 40 mM EtOH, and increased from 34% to 58% for 120 mM EtOH. This potentiation is consistent with the action of CLOM to block 5-HT reuptake, and with our earlier findings that 5-HT potentiates the excitatory effects of EtOH on VTA neurones. At higher clomipramine concentrations (1 - 2 mM), there was no significant enhancement of EtOH-induced excitation. These higher concentrations are associated with reuptake blockade of norepinephrine and dopamine, which may obscure the effect of enhanced 5-HT availability. CHRONIC ETHANOL EXPOSURE ALTERS DOPAMINE D2 RECEPTOR mRNA EXPRESSION IN NUCLEUS ACCUMBENS IN RATS. B.A. Blanchard & P.K. Roland. Dept. of Pathology & Anatomical Sciences, Univ. of Missouri School of Medicine, Columbia, MO 65212.

Brain dopamine (DA) systems are believed to mediate the reinforcing properties of drugs of abuse, including ethanol (EtOH). Chronic EtOH exposure in rats has been shown to alter DA D2 receptor populations, with the direction of change possibly dependent on the dose of EtOH and the period of exposure. The present study examined effects of chronic EtOH exposure on expression of the DA D2 receptor gene in the terminal regions of the mesolimbic and nigrostriatal DA pathways: the nucleus accumbens and striatum. Adult female Long-Evans rats were exposed to EtOH via liquid diet (35% EtOH-derived calories) for periods of either two or six weeks. Following EtOH exposure, DA D2 receptor mRNA content in the core and shell regions of the nucleus accumbens, and medial and lateral regions of the striatum was examined using in situ hybridization histochemistry. After two weeks of EtOH exposure, there were no significant changes in DA D2 receptor gene expression in any region of either structure. However, six weeks of EtOH exposure produced a significant decrease (approximately 40% below control levels) in DA D2 receptor mRNA content in the core region of the nucleus accumbens. There were no significant changes in this region in either the core or shell regions of the striatum. The findings suggest that chronic EtOH exposure may alter DA receptor populations by altering gene expression in regions believed to be important in drug reward.

661.13

We previously found that ethanol-induced depressions of cerebellar Purkinje neurons in Sprague-Dawley rats are mediated by a GABA, mechanism, but that ethanol alone only potentiates GABA responses on 20% of these cells under concomitantly applied with a d-adrenergic agonist. Timolol, a d-adrenergic antagonist, not only blocks these ethanol-induced potentiations of GABA, but also antagonizes ethanol-induced depressions on 20% of these neurones as well. These data may suggest that synaptically-generated norepinephrine alters the responsiveness of this subpopulation of Purkinje neurones to ethanol actions under the conditions of our experiments. In the present study, we investigated these ethanol actions in two lines of rats which have been selectively bred for high (HAS) and low (LAS) GABA sensitivity. We recorded single cerebellar Purkinje neurones from an anterior barrel of a multibarrel microinjection chamber, with localised application of drugs from other barrels of the same pipette in urethane-anesthetized rats. Similar to Sprague-Dawley rats, we found that timolol reduced ethanol-induced depressions in 16% of these neurones. On 62% of the HAS neurones, however, the ethanol responses were antagonized by timolol application. Based on this observation, we hypothesized that ethanol would more frequently potentiates GABA-induced depressions in LAS than in HAS rats. Indeed, we observed this phenomenon in 69% of LAS neurones studied, but only in 20% of HAS neurones. These data suggest that there is a difference in the interaction of ethanol with GABA mechanisms between HAS and LAS rats which may be regulated by the activity of endogenous d-adrenergic mechanisms.

661.14

We previously found that ethanol-induced depressions of cerebellar Purkinje neurons in Sprague-Dawley rats are mediated by a GABA, mechanism, but that ethanol alone only potentiates GABA responses on 20% of these cells unless concomitantly applied with a d-adrenergic agonist. In the present study we found that timolol, a d-adrenergic antagonist, not only blocks ethanol-induced GABA, potentiations, but also antagonizes ethanol-induced depressions on 20% of these neurones as well. These data may suggest that synaptically-generated norepinephrine alters the responsiveness of this subpopulation of Purkinje neurones to ethanol actions under the conditions of our experiments. Supporting this conclusion, we found that phenolamine, a agent that facilitates noradrenergic synaptic function in the cerebellum, reversibly potentiates the depressant effects of locally applied ethanol. Furthermore, we investigated the influence of acute morphine withdrawal on the sensitivity of Purkinje neurons to ethanol-induced depressions, a condition in which there is increased noradrenergic synaptic input from the locus coeruleus. We found that after 7 days of chronic morphine treatment, the systemic injection of naloxone, a morphine antagonist that precipitates withdrawal in chronically morphine-treated animals, enhanced the depressant responses of cerebellar Purkinje neurones to local applications of ethanol and PCP. These data suggest that endogenous d-adrenergic mechanisms regulate ethanol actions in the cerebellum.

SUPPRESSIVE EFFECTS OF ALCOHOL UPON PREDATORY ATTACK BEHAVIOR IN THE CAT ARE BLOCKED BY A SUBSTANCE P, NK, RECEPTOR ANTAGONIST: M.D. Shaltiel* Y.C. Han, L. Polchery, D. Benjamin, and A. Sigel. Laboratory of Limbic System Behavior, Department of Anatomy, New Jersey Medical School, Graduate School of Biomedical Sciences, UMDNJ, Newark, New Jersey 07103, and Center for Alcohol Studies, Rutgers University, Piscataway, New Jersey, 08855.

This study was designed to determine the effects of alcohol upon quiet biting "predatory" attack behavior (QBA) elicited from the lateral hypothalamic area (LH) and the mechanism within the medial hypothalamus (MH) involved in suppression of this response. Experiments I: peripheral administration of alcohol (0.02, 0.5 and 1.0 g/kg, I.P.) resulted in a dose and time dependent suppression of QBA in which the maximal effect (42% suppression, observed 60 min., post injection, when tested with 5% alcohol. Experiment II: peripheral administration of alcohol at the same dose levels also increased medial amygdaloid (MEA)-induced suppression of QBA in a dose and time dependent manner. Experiments III: microinfiltration of Substance P (SP)-NK, antagonist, CP 96,345, into MH blocked alcohol-induced enhancement of the suppressive effects of ME stimulation upon the LH. These results suggest the following conclusions: (1) that alcohol suppresses QBA; (2) that the underlying mechanism for suppression of this response may involve agonistic-like effects of alcohol upon SP receptors within the MH, which receive direct inputs from an SP pathway originating in the ME. [Supported by H.F. Guggenheim Foundation and NIH grant NS07941-24].
EFFECTS OF ETHANOL ON MIDDLE LATENCY AUDITORY EVOKED POTENTIALS IN THE RAT. H. Miyazato, R.D. Skinner* and E. Garcia-Bailon. Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

The P1 middle latency auditory evoked potential in the human peak at 50-60 msec latency and REM sleep, but absent during slow wave sleep; i.e., it is present during periods of cortical desynchronization. Recently, we described the presence of the P13 potential (peak 11-15 msec) in the rat which commonly occurs before the P1 potential and wave A in the cat, the feline equivalent of the P1 (Skinner et al., 1993). The present study was undertaken to determine the effects of ethanol on the behavior of the rat P13 potential.

Under barbiturate anesthesia, cortical leads were implanted at the vertex and over the temporal cortex. An intragastric tube was prepared and routed to exit the dorsal neck. Auditory stimuli (intensity 103 dB, rate 0.2 Hz) evoked P13 potentials referenced to a frontal screw were recorded and averaged from male rats following intragastric ethanol administration (0.5, 1.5, or 5 g/kg, 48% in water). Following a 0.5 g/kg dose of ethanol there was no effect on the P13 potential. However, at a 5 g/kg dose of ethanol the P13 potential was reduced to 60% at 5 min and then recovered by 15 min. Larger doses of ethanol (3 and 5 g/kg) reduced the P13 potential to 30% and 20%, respectively. The P13 potential recovered after 30 min following the 3 g/kg dose, and after 75 min following the 5 g/kg dose. Similar recording of the averaged auditory evoked responses (P3) over the auditory cortex showed only a slight effect on this potential at all ethanol doses tested.

Our results suggest that ethanol reduces the amplitude of the P13 potential and delays its recovery in a dose-dependent manner. Thus, the behavior of this potential indicates that ethanol decreases the ability of the reticular activating system to generate a normal arousal response.

INHIBITION OF CALCIUM ENTRY BY CADMIUM CHANGES ETHANOL INHIBITION INTO EXCITATION IN RAT LOCUS COERULEUS NEURONS. S.S. Osmanovic* and S.A. Shepherd. Department of Physiology and Biophysics, University of Illinois at Chicago, College of Medicine, Chicago, IL 60612-7342.

We have previously shown that ethanol can inhibit the spontaneous firing of rat locus coeruleus (LC) neurons. In the present study, intracellular recording in completely submerged brain slices from Fisher 344 rats was used to study the involvement of Ca2+ entry in the ethanol-induced inhibition of LC neurons. Ethanol was tested before and after application of the calcium channel blocker Co2+ or low Ca2+/high Mg2+ media. In 7 LC neurons which showed ethanol-induced inhibition, the mean spontaneous firing rate in control media was 0.72 ± 0.18 Hz (S.E.M.) and 0.28 ± 0.09 Hz after bath application of 100 mM ethanol. The mean ethanol-induced inhibition of firing, calculated when each spike was compared to its own control, was 49 ± 4% (S.E.M.)

The ethanol-induced inhibition of spontaneous firing was associated with no change in resting membrane potential (n=5) or membrane hyperpolarization of 2.4 mV (n=2). Effects of ethanol were lost after superfusion with media containing 2 mM (100 - 500 mM) Ca2+ for 15 - 25 min. In the presence of Co2+, ethanol caused membrane depolarization and increased the firing rate in all 7 neurons tested; the mean depolarization was 7.7 ± 0.36 mV and 9 ± 3.6 mV, respectively. The effect of ethanol in Co2+ was significantly different from the control as determined by a paired t-test (p < 0.05). Ethanol-induced inhibition was also changed to excitation when the Ca2+ concentration in the media was reduced from 2.4 to 0.25 mM and the Mg2+ concentrations increased from 1.5 to 10 mM (n=5). These data indicate that ethanol-induced inhibition of spontaneous firing in LC neurons is dependent on Ca2+ entry. Another previously reported action of ethanol on LC neurons is reduction of action potential duration. This action of ethanol was not affected by Co2+ indicating that ethanol effects on spontaneous firing and action potential duration are mediated by separate mechanisms.

GRANT SUPPORT: PHS. AA05456 to S.A.S.

Repeated withdrawals from chronic ethanol consumption have been linked to an exacerbation of withdrawal symptoms, suggesting that multiple exposures and withdrawals from ethanol lead to a progression of the symptoms that is not apparent with continuous ethanol administration. Previous research has shown that both ultrasonic vocalizations and the expression of fos-like proteins are increased by repeated ethanol administrations. In the present experiment, rats given repeated withdrawals from ethanol, rats given the same amount of ethanol continuously, and control animals were compared on the basis of ultrasonic vocalizations in response to air puff and fos-like immunoreactivity (Fos-LI). Behavioral testing occurred seven to eight hours following ethanol withdrawal on the final day of the experiment. The results showed that both withdrawal groups spent more time vocalizing in comparison to the control animals, while the repeated withdrawal group demonstrated increased vocalization in comparison to the continuous ethanol group. Immunohistochemical analysis of c-fos activity showed a similar trend for specific brain regions. In particular, Fos-LI in the medial prefrontal cortex, ventral lateral orbital cortex, piriform cortex, retrosplenial cortex, locus coeruleus, and tenia tecta was enhanced more by repeated withdrawals than a single withdrawal. These data support the hypothesis that multiple ethanol exposure/withdrawal cycles result in a more severe withdrawal syndrome than a single ethanol withdrawal. AA-08042, NS26555, & HD07201.

663.5 EXPRESSION OF HEAT SHOCK PROTEINS FOLLOWING EXPOSURE TO CHRONIC ETHANOL. E.L. Otto-Reeves, J. Mark Sherman, Clayton M. Pickering and John D. Lane.* Department of Pharmacology, UNTISHC-F, 3500 Camp Bowie Blvd, FW, TX 76107 USA.

Heat shock proteins are induced in cultured cells when the culture medium contains 5% ethanol. Patients with a history of chronic alcohol exposure show high levels of heat shock proteins (HSP). In this experiment, male Fisher 344 rats were taught to orally self-administer ethanol in an FR schedule, using sucrose fading. These rats were the only low responding group for ethanol alone. Rats were fed a liquid diet containing ethanol, then retested over a range of ethanol concentrations. Ethanol intake increased over levels prior to liquid diet. Rats were then fed the liquid diet for 2 weeks. Tissues from heart, liver, kidney, gastrointesstial tract, skeletal muscle and multiple brain regions were harvested and in situ hybridization was performed using oligonucleotide probes specific for either inducible or constitutive 70kD heat shock proteins. Both inducible and constitutive mRNAs were found in brain. In brain, the highest levels of both inducible and constitutive mRNAs were found in the cerebellar granular layer, hippocampus, dentate gyus and hypothalamic nuclei. In kidney, the inducible probe showed uniform distribution; however, the constitutive form showed a specific pattern with highest levels of mRNA in the medulla. All other organs showed more uniform distribution of both the inducible and constitutive mRNAs. In regions showing a statistically significant difference, levels of inducible mRNAs were greater than constitutive in both ethanol and control rats.

663.6 ENHANCED (Na+/K)-ATPase EXPRESSION IN MOUSE BRAIN AFTER CHRONIC ETHANOL ADMINISTRATION. Y.M. Choo, J.B. Womack, A.Y. Sun, Dept. of Pharmacology, University of Missouri, Columbia, MO 65212.

It is the general hypothesis that the primary mode of action of ethanol is the alteration of membrane structure and function including the conformation of receptors and ion channels essential for neurotransmission and signal transduction. (Na+/K)-ATPase is of interest because of its major role in neuronal homeostasis and membrane dependence. In the past we have demonstrated the inhibitory effect of ethanol on (Na+/K)-ATPase in vitro, and chronic administration of ethanol has led to an increase in the specific activity of this enzyme. However, the issue of whether ethanol affects (Na+/K)-ATPase under physiological conditions remains unsettled. In this study, adult mice were treated with a daily dose of 5 g/kg of ethanol for 28 days. The RNA was isolated from brain samples and probed for the (Na+/K)-ATPase mRNA using Northern blot analysis. We have found an increased (Na+/K)-ATPase in the chronically treated alcohol group as compared with controls. This result was further substantiated by the increased protein phosphorylation of this enzyme after chronic ethanol administration. Thus we have demonstrated that ethanol may directly or indirectly affect (Na+/K)-ATPase in situ, leading to the increased synthesis of this enzyme through adaptive mechanisms. (Supported by NIH Grant AA02054).

Alcohol-prefering P rats exhibit less exploratory behavior (despair)* in a forced swim test than -nonpreferring NIH rats (Godfrey et al., Soc. Neurosci. Abs. 18543, 1992) Overstreet et al. J. N. N. 1988). However, the AA alcohol drinking rats exhibit more immobility than drinking rats in a swim test (Korpi et al., 1986). The present study compared swimming for 5 min in rats that low drinking LAD rats on a swim test and examined the effects of desipramine (10 or 20 mg/kg). Adult male HAD and Dose were placed in a round tub filled with water (21°C). The rats were unable to escape from the tub. Behavior was videotaped for 10 min on each of two consecutive days and scored for time spent immobile. HAD rats were more immobile (P<0.05) than LAD rats (10 vs. 1 sec mean (SEM), respectively). Desipramine attenuated (p<0.05) the time spent immobile in LAD but not in HAD rats which contrasted with the low responsiveness seen in previous both P and NP rats with greater attenuation. The swim test is not associated with a genetic predisposition to alcohol preference. Attenuation of immobility by desipramine is seen in both alcohol-nonpreferring (NP) and LAD lines but not in both -preferring lines. (AA0611, AA08555).

663.8 REPEATED ETHANOL WITHDRAWAL EXPERIENCE DIFFERENTIALLY INFLUENCES WITHDRAWAL-RELATED SEIZURES AND ANXIETY RESPONSES IN MICE. H.C. Becker, K.G. Fernandez, and R.T. Weatherston. VA Medical Center and Medical University of South Carolina, Charleston, SC 29412.

We previously demonstrated an exacerbation of withdrawal seizures in adult CDH mice that expressed multiple cycles of ethanol (EOH) withdrawal in comparison to mice withdrawn from EOH at a single time, even when total EOH exposure is equated across groups. This study was designed to examine whether similar results may be obtained in another mouse strain, and with another symptom of withdrawal (anxiety). Adult male NIH Swiss mice were exposed to EOH vapor prior to withdrawal. A multiple withdrawal (MW) group received 3 cycles of 16 hr of EOH vapor separated by 8 hr periods of abstinence; a continuously exposed (CE) group received the same total amount of EOH (48 hr) interrupted; a single withdrawal (SW) group received a single 16 hr bout of EOH exposure; and controls received no EOH exposure. Following the final withdrawal cycle, mice were tested for handling-induced convulsions (HIC) or performance on an elevated plus-maze. Blood EOH levels upon final withdrawal were similar among EOH-exposed groups (160-200 mg%). The groups did not differ in % time on or % entries into open arms of the plus-maze. 24 hr post-withdrawal. Total arm entries were depressed in the MW and CE groups at 8 hrs, but not at 24 hrs. In contrast, severity of withdrawal seizures was significantly greater in the MW group in comparison to other groups. Mean area under the 24 hr HIC curve was 213±3.2 vs. 106±4.7, 133±3.0, and 10±2.3 (M±SE). These results suggest that in this mouse strain, repeated EOH withdrawal exacerbates the severity of subsequent withdrawal seizures, but does not influence anxiety, as measured in the plus-maze test. Other mouse strains are being used to continue to explore this research question. Supported by VA Medical Research Service and NIAAA.

**ETHANOL PARTIALLY NORMALIZES VESTIBULAR PRONATION OF PONTINE-DAMAGED RATS BUT DISRUPTS THAT OF UNDAMAGED RATS.**

Acute or chronic ethanol (EOT; 5-40%) does not abolish excessive forward locomotion in rats with damage of the nucleus reticularis tegmenti pontis (NRTP). Although EOT interacts with motor activity in intact rats, it can improve some motor functions of NRTP-damaged rats. Pronation of the head and torso from a supine position in the air using an integrated sequence of movements is an index of neural integrity that is compromised by basal ganglia dysfunction. In NRTP-damaged rats, pronation is disrupted by a change in form from lateral to ventralflexed righting. 11 female and 6 male Long-Evans hooded rats were lesioned electrolytically in the NRTP (1mA anodal current/15s bilaterally, n=8) or used as controls (n=9). Testing was done over 50 days during availability of tap water (TW), TW+25% sucrose (SU), or 5-30% EOTH in TW+SU in water bottles. A challenge dose (CD) (30%W/DOT) was administered i.p. after the withdrawal. Righting was tested by holding the animals in a supine position at 3 cm above a 7cm thick pillow and releasing them (lateral form=1, ventroflexion=0; 4 trials/animal/substance/dose). On TW, NRTP-damaged rats showed more ventralflexed than lateral righting (x=5) and undamaged rats showed lateral righting exclusively (x=1). NRTP-damaged rats normalized slightly on SU (x=.6), but unoperated rats began to ventroflex (x=.7). At each level of EOTH, NRTP-damaged rats showed more lateral righting than on TW (x=.68 for 5-30%EOTH & 75 at 30%CD; range=.58-.75 vs. TW=5), and unoperated rats showed less (x=.76 for 5-30%EOTH & 88 at 30%CD). The results indicate that EOTH can improve vestibular function in NRTP-damaged rats, and further support an appetitive role for EOTH in the presence of pontine damage.

**IN UTERO ETHANOL EXPOSURE RETARDS GROWTH & ALTERS MORPHOLOGY OF CORTICAL CULTURES: GM1 REVERSES EFFECTS.**

Ethinol: a dental neuronoxin, affects the cerebral membrane physico-chemical properties. Its multiple actions in the developing CNS are complex, affecting embryogenesis, cell migration, differentiation & synaptogenesis. In a prior study using a model for the fetal alcohol effect, the neuroprotective lipid GM1 reduced fatty acid ethyl ester accumulations in rat fetuses exposed to ethanol in utero (207&8 & 13.14A) (Hungund et al., 1993). This study was initiated to further describe the in utero effects of ethanol, and, the capacity of GM1 treatment to ameliorate such changes. Sprague-Dawley CVP dams were exposed to ethanol (23 g/kg i.p. supra). GM1 ganglioside (10mg/kg/m) was given 24hrs & 1hr prior to each ethanol exposure. Cortical cultures were derived from GD15&8 fetuses. Since GM1 is highly localized on the plasma membrane outer surface of CNS cells, we have used it as a marker molecule to assess cell integrity. We used cholea toxin/vinltoxin fluorescence immunohistochemical to localize GM1. Cultures were stained at 4, 8, 14 days after plating. Results indicate that the brief in utero exposures to ethanol affected cell growth and morphology. We observed a marked retardation in cell development and arborization as early as 24hrs after plating. Also, there was a reduced number of viable cells (24hrs thru 14dats). Control cells showed continuous staining for GM1 along outer plasma membranes. Ethanol exposed cells exhibited decreased and discontinuous membrane staining for GM1. This reduced staining is associated with the loss of membrane integrity (Laev et al., 1993). These in utero ethanol induced abnormalities are pathologically diminished in those cultures derived from fetuses of dams treated with GM1.

**EFFECT OF ALCOHOL EXPOSURE DURING DEVELOPMENT ON THE AMYGDALA REGION.**

C.R. Miyazaki & S.J. Kelly. Department of Psychology, University of South Carolina, Columbia SC 29208.

The only perinatal period in the rat is roughly equivalent to the third trimester in humans with respect to birth. Exposure to alcohol during this period has been shown to decrease the DNA concentration in the amygdala region of male rats at both 45 and 90 days of age. Female rats showed no effects. The decrease in DNA concentration suggests that there is an alcohol-induced decrease in cell number in the amygdala region, although the DNA concentration does not differentiate among cell types. In order to continue our investigation of the amygdala region, rats of both sexes were artificially reared and exposed to 5 g/kg/day of ethanol, artificially reared and not exposed to ethanol, or reared normally with dams. Rats were weaned at 21 days of age and housed with a same sex conspecific. At adulthood (130 days), the rats were deeply anesthetized with sodium pentobarbital and perfused intracardially with saline followed by 10% formaldehyde. The brains were removed and post-fixed in 10% formaldehyde for at least a week. The brains were cut into 40 um sections, mounted on slides, stained Luxol Fast Blue, and then counterstained with cresyl violet. A section at the level of the stria terminalis was identified and the area of the amygdala region was measured. Among female rats, no differences were found in the areal measurements of the amygdala region. (Supported by NIAAA Grant AA08080 to S.J.K.)
INHIBITORY EFFECT OF THE CALCIUM ANTAGONIST ISRADIPINE ON NICOTINE INTERVENTIOUS SELF-ADMINISTRATION IN DRUG-NAIVE RATS. W. Pratt*, M.C. Martelotto, A. Kozmin, E. Zvartau. 1 Department of Neuroscience, University of Cagliari, Italy. 2 Department of Pharmacology, Pavlov Medical Institute, St. Petersburg, Russia.

Several reports indicate that nicotine positive reinforcing effect is associated with a depression of the mesolimbic dopaminergic system. Thus, in common with other drugs of abuse, such as morphine and cocaine, nicotine increases dopamine release in rat striatum and nucleus accumbens. We have recently shown that isradipine, a L-type dihydropyridine Ca2+ channel antagonist, inhibits the reinforcing properties of cocaine and morphine both in rats and mice. This effect is likely due to an inhibition of cocaine- and morphine-induced dopamine release. Here we show that isradipine dose-dependently and stereospecifically inhibits nicotine intravenous (i.v.) self-administration in drug-naive mice. In fact, nicotine induces a dose dependent i.v. self-administration response in drug-naive mice. Pretreatment with (+)-isradipine significantly inhibits nicotine i.v. self-administration in drug-naive mice. Furthermore, testing of both the isomers of isradipine reveals that only pretreatment with (+)-isradipine is active in inhibiting nicotine i.v. self-administration in drug naive mice, while pretreatment with the (-)isomer is completely inactive. The possibility that the isradipine inhibitory effect might be related to an inhibition of nicotine-induced dopamine release seems to be very likely. Furthermore, these results might provide an indication for new therapeutic strategies in tobacco addiction.

Prefrontal areas display most prominent decreases in immediate-early gene expression during amphetamine withdrawal. We employed antisense technology in vivo, to assess whether prefrontal c-fos may play a role in behavioral correlates of rat amphetamine withdrawal.

Phosphorothioated antisense 18-mers aimed at the translation start site of the c-fos mRNA display a half-life of about 3 hrs, in contrast to 15-30 min for phosphodiester. Intracranial medial prefrontal cortical injections of 250nm antisense, but not sense, phosphorothioated oligos, block c-fos mRNA translation, while exerting variable and inconsistent effects on c-fos mRNA levels. During c-fos translational blockade, animals display marked reductions in linear and repetitive locomotor behavior when exposed to a novel environment. No change in locomotor activity is evident in animals accustomed to the activity monitor. These changes closely mimic those recorded during amphetamine withdrawal and suggest that prefrontal c-fos may play a role in the chain of neurobiological events responsible for amphetamine withdrawal-induced behavioral alterations.

Psychostimulant drugs such as amphetamine can induce dependence syndromes and presumably long-term changes in the CNS. Altered expression of genes may provide possible biochemical contributions to these drugs induced long-term CNS changes. We have analyzed alterations in gene expression in brains of rats sacrificed 4 hours after injection of d-amphetamine (7.5 mg/kg, i.p.), using differential display PCR followed by differential hybridization. More than 20 bands which were changed after drug administration could be identified after amplification with two primer sets. Some were represented in all brain regions analyzed, and some showed region-specific patterns. Sequence analysis of differentially-displayed products revealed high homologies with known genes. One product revealed 97% homology with the reported sequence of a calcium activable calmodulin-dependent phosphatase, calcinulin. Northern analysis showed that striatal calcinulin mRNA increased by 40% after d-amphetamine treatment. The second cDNA encoded a transducin-like factor. Hybridizing mRNA showed marked, approximately 10-fold, increases in striatum with changes in cortex and thalamus also notable. Products of genes acutely regulated by d-amphetamine are candidates for participation in drug-induced long-term changes in the CNS.

BEHAVIORAL SENSITIZATION TO AMPHETAMINE IS CORRELATED WITH A GREATER INCREASE IN C-FOS mRNA LEVELS IN THE STRIATUM OF RATS. K. Rivero*, T. A. Wise*, T. D. Paolodi and S. Rivero*. 1 School of Pharmacy, 1Mol. Endo. Lab., CHUL, Laval university, Quebec and 2CSBN, Dept. of Psychol., Concordia Univ., Montreal.

Most studies exploring the neural basis of behavioral sensitization converge on the mesocambudrom dopaminergic pathway. The mechanisms underlying this phenomenon have been less clear, however. More complex and recent data suggest the participation of additional neurotransmitters. To better understand the mechanism of behavioral sensitization, we have performed in situ hybridization analysis of c-fos mRNA in the brain of animals sensitized to amphetamine. Male Long-Evans rats received daily injections of saline or amphetamine (1 mg/kg) for 10 consecutive days. One week later they were given an acute challenge injection of saline or amphetamine (0.5 mg/kg). The animals were sacrificed 45 min or 3 h after the last injection and their brains were collected for further in situ hybridization analysis of c-fos mRNA. Amphetamine (1mg/kg) increased locomotor activity and the increase was progressively greater as animals received repeated injections. The challenge injection of 0.5mg/kg produced a significantly greater increase in locomotor activity and c-fos mRNA levels. Characterization of the neurons in which c-fos responses to amphetamine are increased in sensitized animals is presently under investigations. Supported by the MRC.
663.7

Previous studies have demonstrated increased locomotor activity and immediate-early gene expression in the cerebellum following the administration of psychostimulants. In the present study, immunohistochemical techniques were used to assess the pattern of Fos-like immunoreactivity (FLI) in the cerebellum following acute, systemic administration of amphetamine and cocaine. Amphetamine (1.5 mg/kg, i.p.) increased locomotor which could be blocked by pretreatment with the D1 dopamine receptor antagonist SCH 23390 (1 mg/kg). Within the cerebellum, amphetamine elicited a dose-dependent increase in FLI that was markedly attenuated by SCH 23390 pretreatment. In contrast, SCH 23390 pretreatment abolished the dose-dependent increase in locomotor activity and FLI following cocaine (10, 20 mg/kg). Psychostimulant-induced FLI was restricted to the granule cell layer within each of the medullar cerebellar lobules (IX-X) and distributed in dense clusters extending from the molecular layer to the Purkinje cell layer. Studies assessing the effects of acute, systemic caffeine administration on FLI in the cerebellum are in progress. Preliminary results indicate that caffeine (15 mg/kg) produces a somewhat different pattern of cerebellar FLI with greater involvement of the molecular layer than seen following amphetamine and cocaine.

NBOX INHIBITS AMPHETAMINE-INDUCED LOCOMOTOR ACTIVITY BUT NOT C-FOS INDUCTION. A. Dalia*, N.J. Urelesky and L.J. Wallace*, College of Pharmacy, Ohio State University, Columbus, OH 43210.

Administration of amphetamine activates the dopaminergic and the AMPA subtype of glutamate receptors as well as induces c-fos protein in the nucleus accumbens. A role for basal levels of c-fos in expression of locomotor activity is derived from the observation that administration of c-fos antisense oligonucleotide into the nucleus accumbens 5 hours before amphetamine blocked the locomotor response. Therefore, a hypothesis that the basal activation of glutamatergic receptors, increases in c-fos protein, and stimulation of locomotor activity was explored. A behaviorally relevant dose of amphetamine (1 mg/kg, p) elicited a small increase in c-fos protein and stimulated locomotor activity. Pretreatment with NBOX (23-dihydroxy-6-nitro-7-sulfamoylbenzo(F)-quinolinaxidine) (30 mg/kg, p), an AMPA receptor antagonist, had no effect on amphetamine-induced increase in c-fos but stimulated locomotor activity. NBOX alone had no effect on c-fos levels or locomotor activity. MK-801 (0.1 mg/kg, sc), an NMDA receptor antagonist, did not increase c-fos but stimulated locomotor activity. These data suggest that induction of c-fos is not correlated with stimulation of locomotor activity. (Supported by DA07722 and DA06776).

NBOX INHIBITS LOCOMOTOR ACTIVITY INDUCED BY APOMORPHINE IN DRUG-NAIVE BUT NOT SENSITIZED RATS. P. Leudtke* and L.J. Wallace, Ohio State University, College of Pharmacy, Columbus, OH 43210.

The development of sensitization to apomorphine (apo), cocaine, and amphetamine is considered to be mediated by changes in dopamine neurotransmission. Since the acute effects of these agents involve activation of the AMPA receptor subtypes of glutamate receptors, the present study investigates whether the sensitized state is also characterized by a change in glutamate neurotransmission. On day 0, male rats were conditioned to the test cages. At each treatment day they were habituated for one hour. Pretreatment (i.p. and s.c.) and distance travelled measured for two hours by automated image analysis. In drug-naive rats, NBOX (10 mg/kg), an AMPA antagonist, attenuated locomotor activity induced by apo (1 mg/kg) to 45%. However, when pretreated with apo (5 mg/kg) every third day during 13 days, the locomotor activity induced by apo (1 mg/kg) was increased, while NBOX only attenuated to 83%. Preliminary results indicate that sensitization to cocaine and amphetamine also decreases the inhibitory effect of NBOX. These results indicate that sensitization and a change in response to NBOX occurs simultaneously. Additional studies will elucidate if these changes are a part of sensitization and further describe the nature of the alterations. (Supported by a gift of NBOX from Novo Nordisk A/S and grant number DA07722).

COMPETITIVE AND NONCOMPETITIVE NMDA-RECEPTOR ANTAGONISTS BLOCK NICOTINE-INDUCED DOPAMINE OVERFLOW. F. Museo* and A. Pert, Biological Psychiatry Branch, Intramural Research Program, National Institute of Mental Health, Bethesda, MD 20892.

The psychomotor stimulant effects of nicotine are believed to be due, at least in part, to the activation of a dopaminergic substrate; one dopamine (DA)-containing region that appears to be involved is the nucleus accumbens (nAcB). We previously reported that the systemic or intra-nAcB administration of nicotine elicited DA overflow in the nucleus accumbens. In the present experiment we tested this hypothesis using two NMDA-receptor antagonists: the noncompetitive antagonist MK-801 and the competitive antagonist AP-5. Male, Sprague-Dawley rats were anaesthetized with chloral hydrate and a microdialysis probe was surgically positioned in the nAcB. All pharmacological treatments were administered through the probe and dialysate samples were collected and analyzed for DA content. Nicotine (100 μM), on its own, increased nAcB DA overflow by approximately 50% in the intra-nAcB administration of either the noncompetitive antagonist MK-801 (100 μM) or the competitive antagonist AP-5 (100 μM) prior to and during the administration of nicotine (100 μM) significantly reduced the magnitude of this effect. It appears that the blockade of glutamatergic transmission is sufficient to disrupt the actions of nicotine on DA overflow in the nAcB.

BOTH TYPICAL AND ATYPICAL NEUROLEPTICS BLOCK PHENCYCLIDINE (PCP)-INDUCED STRIATAL AND BEHAVIORAL EXCITATION IN FREELY MOVING RATS. I. M. White*, C. G. Flor, J. Speziale, and G. V. Revel. Program in Neural Science and Dept. of Psychology, Indiana University, Bloomington, IN 47405.

The striatum plays a critical role in the behavioral excitation induced by amphetamine and other indirect dopamine agonists. In freely moving rats, amphetamine typically increases the activity of striatal neurons, with this effect being blocked by D2 dopamine antagonists, which also attenuate amphetamine-induced behavioral effects. Phencyclidine (PCP), a non-competitive NMDA antagonist with little or no affinity for dopamine receptors, induces a similar pattern of behavioral excitation, but little information is available on the striatal mechanisms underlying this effect. In the present series of experiments, we assessed the effects of PCP (1.0 - 5.0 mg/kg) on single-unit activity in the striatum of awake, behaving rats. Like amphetamine, PCP routinely increased striatal activity, and this effect was reversed by subsequent injection of either haloperidol (0.1 mg/kg) or clozapine (20.0 mg/kg), typical and atypical neuroleptics, respectively. To the extent that neuroleptics act primarily as dopamine antagonists, our results suggest a striatal dopamine-NMDA interaction in the behavioral effects of PCP.

AMPHETAMINE- AND COCAINE-INDUCED FOS IN THE RAT STRIATUM DEPENDS ON D2 DOPAMINE RECEPTOR ACTIVATION. D.N. Bunks* and R.F. Marshall. Department of Psychology, University of California, Irvine, CA 92717.

Amphetamine or cocaine injection causes expression of the immediate-early gene c-fos in the striatum. Previous studies have shown that dopamine D1 receptor activation is necessary for this effect, but have not established a consistent role for D2 receptors. We have investigated the involvement of D2 receptors in indirect agonist-induced striatal Fos-like immunoreactivity using the selective D2 antagonist eticlopride. Rats received eticlopride (0.5 mg/kg) or saline 30 min before receiving amphetamine (5 mg/kg), cocaine (40 mg/kg), or saline. All injections were IP. Two to four hours after the second injection, the rats were perfused with 4% paraformaldehyde and their brains sectioned at 40 µm through the striatum for immunocytochemistry. Eticlopride treatment caused Fos expression by itself, but also decreased Fos expression in the central striatum due to amphetamine or cocaine by 90% and 85%, respectively. In striatogniral neurons, identified by labeling with the retrograde tracer Fluorogold injected into the substantia nigra pars reticulata, the blockade of stimulation-induced Fos-like immunofluorescence by eticlopride was nearly complete, with decreases of 98% for amphetamine and 94% for cocaine. In striatogniral neurons, the D2 antagonist alone induced minimal Fos. We conclude that activation of both D1 and D2 receptors classes by dopamine agonists is necessary for induction of Fos in the striatogniral cells of normal rats. These results provide an important parallel to behavioral and electrophysiological work that also demonstrates D1/D2 interdependence in the control of normal basal ganglia functions.

663.17

We studied self-stimulation in rats with chronic cannulae implanted into the substantia nigra pars reticulata. Using clozapine (15 mg/kg, m=14) or saline (m=14) was injected IP 15 min prior to self-stimulation testing. Electrode placements were independently verified by two different researchers and compared with drug effects. The distance between the electrode placement and the brain midline was measured. The correlation of this distance with stimulant-induced facilitation of self-stimulation was r=+.43, p<.004. Inspection of the data suggested that stimulation sites closest to substantia nigra pars compacta showed the least stimulant-induced facilitation of self-stimulation. The correlation between drug effect and distance of electrode from the substantia nigra was r=+.44, p=.003. The findings indicate that amphetamine and cocaine may differentially influence self-stimulation obtained from the A9 and A10 regions.

THE ROLE OF DOPAMINE D3 RECEPTORS IN BEHAVIORAL SENSITIZATION, SENSITIVITY TO AMPHETAMINE, AND DOPAMINE SYNTHESIS. P.H. Robitsek*, F. Malizia, R. Melander, and D. Kuhar. Departments of Psychology, Morehead State Univ., Morehead, KY 40351, and University of Kentucky, Lexington, KY 40506.

Behavioral sensitization to repeated treatments of the mixed D2/D3 dopamine (DA) receptor agonist apomorphine (APD) can be blocked by the D2 antagonist SCH 23390 but not D2 antagonists. Further, APD-induced basalis DA synthesis as does the D2/D3 agonist quinupride. This effect is blocked by the D2 antagonist eticlopride. Moreover, sensitization to APD appears to be D2 mediated D2 receptors may be involved in the increased DA synthesis. The role of DA D3 receptor activation in locomotor activity, sensitivity to APD and basalis DA synthesis were investigated in two experiments. D3 selective agonist 7-OH-DPAT was administered at 24 hour intervals for 15 consecutive days (0.5 - 1.5 mg/kg). Following each injection locomotor activity was recorded for 20 min. On day 11 in experiment 1, all rats received a challenge injection of APD (1.0 mg/kg) and their locomotor activity was recorded. On all rats were injected with the DOPA decarboxylase inhibitor NSD 1015 (100 mg/kg). After 30 min the brains were removed and DA synthesis was assessed by measuring DOPA accumulation in the extracted tissue. Inoculation of activity was initially inhibited at the higher doses (0.1, 1.5 mg/kg) but increased to control levels by day 11. The low dose (0.01 mg/kg) also inhibited activity initially but increased to control levels at the higher doses. This inhibition increased with repeated treatment. No increase in sensitivity to APD was observed in experiment 2. The D3 treatment did not significantly increase baseline DA synthesis. These findings suggest that the development of behavioral sensitization to APD, and the accompanying increase in basalis DA synthesis, is not mediated by D3 receptor activation. (Supported by grants from the Kentucky/MSF SPCCN committee and Morehead State University).

EFFECT OF INTRAVERNAL SELF-ADMINISTRATION OF d- and L-AMPHETAMINE ON NUCLEUS ACCUMBENS (NAc) DOPAMINE LEVELS. K. Leeb* and R.A. Wise. Center for Studies in Behavioral Neurology, Concordia University, Montreal, Quebec, Canada, H3G 1M8.

Rats given limited access to a variety of stimulant drugs self-administer these drugs with very regular inter-response times (Pickens and Thompson, 1968; Yokel and Pickens, 1974). To date, the variables responsible for maintaining such a regular pattern of responding for drug have not been fully established. Because amphetamine increases extracellular levels of dopamine (DA) in the NAc we investigated whether fluctuations in dopamine correlated with responding for drug. Male Long-Evans rats with chronic intraventricular cannulae and intra-accumbens guide cannulae were trained to lever-press for infusions of either 0.25 mg/kg d-AMPH or 0.75 mg/kg L-AMPH in 4h daily sessions. Once stable self-administration was established, rats underwent microdialysis during self-administration. Dialyse samples were taken every 5 min and frozen for subsequent determination of DA concentration using HPLC with electrochemical detection. Self-administered AMPH caused rapid elevation of DA levels to 300-500% of baseline, and these elevations were maintained, more or less, for the remainder of the session. However, there were phasic fluctuations in DA, superimposed on the tonic elevations, that were time-locked to lever-presses and the consequent drug injections; DA levels usually increased after each injection and fell prior to the next response. Thus the initiation of a drug-seeking response (e.g., a lever-press) was triggered in the absence of dopamine depletion and, indeed, long before dopamine concentration fell significantly toward basal levels.

RESERPINE ABOLISHES AMPHETAMINE-INDUCED DOPAMINE RELEASE IN VENTRAL MIDBRAIN NEURALN CULTURE. C. St. Remy, S. Rayport and D. Sulzer*. Depts Psychiatry, Neurology, Anatomy & Cell Biology; Ctr Neurobehavior & Behavior; Columbia Univ; Dept Neurorpathology, NYS Psychiatric Institute, NY 10032.

Amphetamine-induced (AMPH-induced) dopamine (DA) release has been suggested to occur at plasma membrane uptake transporters or at synaptic vesicles. Since several studies have reported that reserpine, which depletes vesicular DA, does not reduce AMPH-induced DA release, action at the vesicular level has been controversial. However, in these studies reserpine was administered in vitro to 24 h prior to AMPH, providing sufficient time for increased DA synthesis or other time-dependent effects. To circumvent these issues we used postnatal ventral midbrain DA neuron cultures, in which stimulation-dependent, AMPH-induced DA release and total cellular DA content can be reliably and concurrently measured. We found that AMPH (100 nM) reduced stimulation-dependent (40 mM KC1 for 3 min) DA release by 60% after 15 min and by 90% after 60 min. At a higher concentration, reserpine (10 µM) reduced AMPH-independent DA release to undetectable levels and total cellular DA by 95% at 90 min. In control cultures, 10 µM AMPH induced a 25% increase in extracellular DA, while following reserpine (10 µM) AMPH-induced only a 3% increase. Strikingly, AMPH released over 3-fold more DA from untreated cultures than the total DA content of reserpinized cultures. Together with in vivo microdialysis studies (Sulzer et al., Soc stenroni 4, 1993), this indicates that AMPH releases DA primarily from the vesicular pool, consistent with the weak base model of AMPH action (Sulzer et al., J Neurochem, 1995).
AGE-DEPENDENT PERSISTENCE OF FENFLURAMINE EFFECTS ON MONOAMINERGIC NEURONS IN REAGGREGATE TISSUE CULTURE. L. Won, P.C. Hoffmann and A. Haller, Dept. of Pharmacological & Physiological Sciences, University of Chicago, Chicago, IL 60637.

The three-dimensional reaggregate tissue culture system provides a useful approach to examine the effects of drug exposure on the subsequent development of monoaminergic neurons. Utilizing this system, we have previously demonstrated that exposure of 15 day old reaggregated tissue cultures developing monoaminergic cells (equivalent to postnatal day 7 neurons), to 10^{-5} M (±) fenfluramine (FEN) for 7 days resulted in significant reductions of reaggregate dopamine (DA)- and serotonin (SERT) levels and cell deficit persisted for 3 weeks following cessation of drug exposure. In order to examine the possible age-dependency of such effects, 2 month old reaggregate tissue cultures containing mesencephalon and corpus striatum cells (equivalent in development to adult neurons) were exposed to 10^{-5} M (±) FEN for 7 days and then were allowed to recover in drug-free medium for 3 weeks. At the end of the 7-day exposure to FEN, DA and 5-HT levels in reaggregates were significantly depressed to 35% and 69% of control levels, respectively. By the end of the 3-week recovery period, DA levels in FEN-treated reaggregates had attained similar values to those in control cultures whereas 5-HT levels in reaggregates exposed to FEN remained significantly depressed (52% of control). Thus, in reaggregate culture, both DA and 5-HT neurons are susceptible to the persistent effects of FEN during early development. With mature neurons, such long-lasting effects are only observed on 5-HT neurons as is seen in the intact adult brain. Supported by MH42194.

ADMINISTRATION OF PERTUSSIS TOXIN IN THE VENTRAL TEGMENTAL AREA DOES NOT ENHANCE THE LOCROTOM STIMULATION SIMULATION PRODUCED BY D-AMPHETAMINE. Brezina, D., Wulff, D., Wulff, D., N. Urasbey, L.J. Wallace, Ohio State University, College of Pharmacy, Division of Pharmacology, Columbus, Ohio 43210.

Readministration of amphetamine, cocaine, or apomorphine produces a progressively enhanced locomotor response. Recently it has been found that the bilateral administration of pertussis toxin (PTX) into the ventral tegmental area (VTA), the location of the mouse brain's ascending mesolimbic dopamine neurons, produces an enhanced locomotor response to amphetamine and cocaine similar to the changes seen in animals sensitized to these drugs. The current results compared to a previous study demonstrate the development of sensitization to drugs that act presynaptically to increase dopamine transmission. In the present study we investigated whether administration of PTX into the VTA produces a sensitized locomotor response to apomorphine, which directly activates dopamine receptors. Rats were injected into the VTA with PTX (0.5 μg, 0.5 μl per side) or vehicle, and 14 to 21 days later, the locomotor responses to apomorphine (0.5 μg/kg, pu) or apomorphine (1 and 5 μg/kg, s.c.) were determined. Animals treated previously with PTX showed a markedly enhanced locomotor response to apomorphine compared to vehicle-treated animals. However, the response of PTX-treated animals to either dose of apomorphine was not significantly greater than that of vehicle pretreated controls. Thus, while pretreatment with PTX in the VTA mimics some of the components of sensitization produced by drugs that indirectly stimulate central dopamine systems, it is not sufficient to produce a sensitized response to a directly acting dopamine agonist. (Supported by DAO7722 and DAO8776)

CORRELATIONS OF NOVELTY AND AMPHETAMINE INDUCED LOCOMOTION IN RATS WITH MICRODIALYSIS MEASUREMENTS OF DA NEUROTRANSPORTER FUNCTION. A. Delgado and C.W. Bradbury, Yale Univ. Sch. of Med., Dept. of Psychiatry and the West Haven VA Hospital, West Haven, CT 06516.

Using a circular runway locomotor chamber, we have been investigating biochemical correlates of novelty induced locomotion. Previous work by Piazza, et al. indicates this is predictive of amphetamine induced locomotion and of amphetamine self-administration. Novelty and amphetamine induced locomotion were assessed for 20 days, separated by at least 10 days. Individual locomotor scores from the two sessions were highly correlated. Following amphetamine challenge, animals were implanted with microdialysis guide cannulae overlying the VTA of the right hemisphere (DA) and the intra-nucleus accumbens (5-HT). The resulting needle was infused, and the intra-nucleus accumbens was monitored by microdialysis probes which were left in place overnight for experiments the following day. The first study examined the correlation of locomotor scores (both novelty and amphetamine induced) with basal DA (as assessed by triphenyl tetrazolium probe recovery and peak DA levels following local infusion (via the microdialysis probe) of 3 μM amphetamine for one minute collection period. Significant correlations were seen between novelty (as assessed by triphenyl tetrazolium probe recovery and peak DA following local infusion expressed either as an absolute level, or as a percent of basal). Basal levels also did not correlate with peak levels. In a separate study, rats were injected with amphetamine and basal DA, but not triphenyl tetrazolium probe recovery. Justice's group has demonstrated that in vivo recovery is primarily a function of DA uptake. In this group, a nonsignificant trend (p = 0.10) toward a correlation was seen between in vivo recovery and locomotion induced novelty, but not with amphetamine induced novelty. Supported by DA 80073, DA 80227, The Yale VA Alcoholism Research Center, and a NARSAD Young Investigator Award to CBW.

THE STIMULATION OF LOCOMOTION BY MK-801 IS MEDIATED BY THE ACTIVATION OF MESO-LIMBIC DOPAMINERGIC NEURONS. T. Narayanan, A. Datta, L. Wallace, N. Urasbey, Ohio State University, College of Pharmacy, Division of Pharmacology, Columbus, Ohio 43210.

Low doses of MK-801 (0.05-0.25 mg/kg), a noncompetitive antagonist of NMDA receptors, stimulate a coordinated locomotor activity by enhancing dopamine (DA) neurotransmission in the nucleus accumbens (NAC). This stimulation may be related to the ability of this drug to increase the firing rate of meso-limbic DA neurons. To test this hypothesis, we assessed the locomotor response to MK-801 in rats after administration of baclofen, a GABA-B agonist that inhibits the firing rate of meso-limbic DA neurons, into the ventral tegmental area (VTA). MK-801 (0.1 mg/kg, ip) stimulated locomotor activity, and this effect was inhibited by baclofen (0.15 mg/kg per side) injected into the VTA. This inhibitory effect appears to be related to an action on meso-limbic DA neurons, since baclofen, administered into the VTA or nucleus accumbens, was ineffective in blocking locomotor activity, and this effect was blocked by baclofen (0.15 mg/kg per side) injected into the NAC. Thus, the locomotor stimulant effect of systemic MK-801 may be mediated by an action of this drug in the VTA, producing an increase in the activity of DA neurons, resulting in an enhancement of DA neurotransmission in the NAC. Supported by grant DA07722.

REDUCED RESPONSIVENESS OF D1 RECEPTOR DEFICIENT MICE TO THE EFFECTS OF D1 SELECTIVE AGONISTS. ANTAGONISTS AND D-AMPHETAMINE IN TESTS OF LOCOMOTOR ACTIVITY AND CATECHOLPSY. L. H. Goldberg, M. Xu, I. Polis, C. Heyser, S. Tongeawa and J. F. Kenob. Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037 and Center for Cancer Research, Massachusetts Institute of Technology, Cambridge, MA 02139.

Dopamine (D1)-receptor deficient mice were created through introduction of a deletion in the gene encoding the D1 dopamine receptor by homologous recombination. ES cells carrying the deletion were injected into mouse blastocysts to generate chimeric mice which were then bred to obtain homozygous D1 knockout mice. The complete absence of D1 receptors was verified by genomic Southern analysis. In wild-type mice, the D1 agonist SKF81297 (1.2, 4.8, and 7.4 mg/kg, s.c.) produced a dose-dependent increase in locomotor activity compared to saline. SKF81297 had no effect in D1-deficient mice. The D1 antagonist SCH23390 (10, 30, μg/kg, s.c.) produced a dose-dependent decrease in locomotor activity in wild-type mice, but not in the D1-deficient mice. SCH23390 (0.05, 0.1, 0.2 mg/kg, s.c.) also produced dose-dependent increases in the wild-type mice, measured as percent of time immobile in an elevated ring procedure, but was ineffective in the D1-deficient mice. Interestingly, the D1-deficient mice exhibited a marked attenuation of the locomotor stimulation produced by d-amphetamine (1.3 mg/kg, s.c.), an indirect dopamine agonist, compared to wild-type mice. These results demonstrate that D1 receptor ligands are ineffective in D1 receptor deficient mice in behavioral assays of motor activity, and support the further use of these mice to investigate the relationship between D1 and D2 receptors in the behavioral actions of psychostimulant drugs and drug reinforcement.

SELECTIVE INVOLVEMENT OF DOPAMINE D1 RECEPTORS OF THE VTA IN THE BEHAVIORAL SENSITIZATION INDUCED BY INTRA-VTA AMPHETAMINE INJECTIONS. Y. Bisogno, L. Simons, L. Ma Moi and M. Caldec. Unit INSERM U259, rue Camille Saint Saëns 33077 Bordeaux, France.

In agreement with previous studies, we demonstrated the complete independence of the neurobiological substrates responsible for the induction of the behavioral sensitization to amphetamine (AMP). Using a local approach, we showed that AMPH injected at the level of the dopamine (DA) cell bodies (0, 1, 2.5, 5 μg/ml side) dose-dependently induced a behavioral sensitization to a later challenge with AMPH administered into the nucleus accumbens (1 μg/ml side) whereas the repeated administration of AMPH into the nucleus accumbens (0, 1, 3, 10 μg/ml side)/did not produce such effect. To further specify the mechanism by which these doses were implanted in the VTA, we studied the respective involvement of VTA D1-D2 and -D3 receptors in the behavioral sensitization produced by intra-VTA administration of AMPH. In Experiment 1, 500 μg of DA receptors or DA receptors of the VTA were injected in the VTA following immediately after intra-VTA administration of AMPH (5 μg/ml side) or saline (saline). In Experiment 2, the same protocol was repeated except that AMPH was injected in the DA-D2 antagonist (salam and basal DA). In Experiment 3, the same protocol was repeated except that AMPH was injected in the DA-D2 antagonist (salam and basal DA). Supported by grant DA7221 and by the National Institute of Alcohol Abuse and Alcoholism (NIAAA). All the rats were divided into the following groups: Controls: (1) VTA AMPH pretreatment group, (2) VTA AMPH pretreatment group, and (3) VTA AMPH pretreatment group. The results demonstrated that: 1) VTA AMPH pretreatment group, 2) VTA AMPH pretreatment group, and 3) VTA AMPH pretreatment group. (Supported by grant DAO7722.

Methamphetamine (METH) is one of the drugs of abuse known to cause neurotoxicity in the adult rodent and nonhuman primate. Little attention has been focused on the evaluation of pre- or perinatal exposure to METH on the developing brain. The present study was to evaluate whether pre- or perinatal exposure to METH produces changes in monoamine levels in maternal or developing pup brain. Pregnant CD rats were injected sc with either 0.2, 2.5 or 5 mg/kg METH daily on gestational days 6 through postnatal day (PND) 21. Pups were sacrificed on PNDs 1, 7, 14 or 21 and dams were sacrificed 24 hours after the last dose (PND 22). Monoamine levels were measured by HPLC/EC. Pre- and perinatal exposure to METH had little effect on monoamine levels in different brain regions at PNDs 1, 7, 14 and 21. However, in maternal brain, dopamine and serotonin levels were significantly decreased in the caudate nucleus. It is concluded that pre- and perinatal exposure to METH at these doses produces significant alterations in the maternal but not the developing rat pup brain monoamine levels.

This experiment assessed the ability of (-)-SHT: antagonists to reverse amphetamine-induced facilitation of brain stimulation reward. It has been shown previously that SHT: antagonists alone do not reverse amphetamine-induced facilitation of self-stimulation in the VTA. We speculated that the mixed antagonists would have a greater effect than more specific antagonists. Risperidone (1.8 mg/kg) and MDL 28,133 (1.5, 3, 5, 6, & 7.5 mg/kg) were injected 15 min prior to amphetamine. Both doses of Risperidone and the two highest doses of MDL 28,133 significantly decreased the effects of amphetamine. However, the ability of both drugs to reverse amphetamine's effects could be predicted from the elevation in thresholds produced by the antagonists alone. Therefore, it seems likely that the ability of the mixed antagonists to reverse amphetamine's effects is due to their D2 component.

This project was supported by NIDA grant # DA 04483 and a grant from Marion Merrell Dow. Acknowledgements to Marion Merrell Dow for supplying MDL 28,133 and Janssen Research Foundation for supplying Risperidone.

Substituted amphetamines such as 3,4-methylenedioxymethamphetamine (MDMA), 3,4-methylenedioxyamphetamine (MDA) and fenfluramine (FEN) are agents that affect serotonergic neurotransmission. In order to explore the effects of these agents on serotonergic neurotransmission we have used two different approaches: 1) to examine the effect of these agents on the release of serotonin (SHT) from primary cultures of raphe neurons with a combination of serotonergic neurotransmission. We have used two different approaches: 1) to examine the effect of these agents on the release of SHT from primary cultures of raphe neurons with a combination of serotonergic neurotransmission. We have used two different approaches: 1) to examine the effect of these agents on the release of SHT from primary cultures of raphe neurons with a combination of serotonergic neurotransmission. We have used two different approaches: 1) to examine the effect of these agents on the release of SHT from primary cultures of raphe neurons with a combination of serotonergic neurotransmission. We have used two different approaches: 1) to examine the effect of these agents on the release of SHT from primary cultures of raphe neurons with a combination of serotonergic neurotransmission. We have used two different approaches: 1) to examine the effect of these agents on the release of SHT from primary cultures of raphe neurons with a combination of serotonergic neurotransmission. We have used two different approaches: 1) to examine the effect of these agents on the release of SHT from primary cultures of raphe neurons with a combination of serotonergic neurotransmission. We have used two different approaches: 1) to examine the effect of these agents on the release of SHT from primary cultures of raphe neurons with a combination of serotonergic neurotransmission.

In the first approach, we have used primary cultures of rat raphe neurons maintained in vitro for 7-14 days. In these cultures, we have added these agents (100uM) at various time points. We have found that these agents induce a release of SHT from these cultures. This release is blocked by the specific serotonin antagonist ICS 205-930. In the second approach, we have used primary cultures of rat hippocampal neurons maintained in vitro for 7-14 days. In these cultures, we have added these agents (100uM) at various time points. We have found that these agents induce a release of SHT from these cultures. This release is blocked by the specific serotonin antagonist ICS 205-930.

In conclusion, these results suggest that MDMA, MDA and fenfluramine may induce a release of SHT from these cultures. This release is blocked by the specific serotonin antagonist ICS 205-930. In the second approach, we have used primary cultures of rat hippocampal neurons maintained in vitro for 7-14 days. In these cultures, we have added these agents (100uM) at various time points. We have found that these agents induce a release of SHT from these cultures. This release is blocked by the specific serotonin antagonist ICS 205-930.

Previous studies indicated that the medial septal/ diagonal band region (MS) is a site at which the LC-noradrenergic system, via actions at noradrenergic a-receptors, acts to influence forebrain EEG. Many of these studies, while stimulating or recording in the septum, have failed to isolate the specific effects of a-agonists. The present study was designed to investigate the effects of a-agonists on EEG in the septum, while stimulating or recording in the thalamus. The medial septal area (MS) was isolated in the rat brain by in vitro slices and was maintained in a temperature-controlled incubator. The septal area was stimulated with a square-wave current through a tungsten electrode. The EEG was recorded from the thalamus using an electrode inserted into the anterior thalamus. The septal area was stimulated with a square-wave current through a tungsten electrode. The EEG was recorded from the thalamus using an electrode inserted into the anterior thalamus.

The effects of a-agonists on EEG in the septum, while stimulating or recording in the thalamus. The medial septal area (MS) was isolated in the rat brain by in vitro slices and was maintained in a temperature-controlled incubator. The septal area was stimulated with a square-wave current through a tungsten electrode. The EEG was recorded from the thalamus using an electrode inserted into the anterior thalamus.
The Delta-Opioid Receptor Antagonist Naltrendione Attenuates Amphetamine-Induced Increases in Extracellular Dopamine In the Striatum of Rats, C.A. Schalb*, J.B. Justice, Jr.*, and S.G. Hoffman. Departments of Pharmacology and Chemistry, Emory University, Atlanta, Georgia, 30322.

The opioid receptor antagonist naltrendione has been shown to attenuate both the behavioral and neurochemical effects of amphetamine in rats. Furthermore, amphetamine-induced increase in extracellular dopamine activity is attenuated by intracerebroventricularly administered naltrendione (NTI), a selective delta-opioid receptor antagonist. This suggests a role of central delta-opioid receptors in the regulation of the behavioral effects of amphetamine. Therefore, this research was designed to look at the effects of NTI on the amphetamine-induced increase in extracellular dopamine (DA) in the brain of rats.

Microdialysis performed in the right lateral striatum of rats that were pretreated with an intracerebral (IC) injection of 3, 10, or 30 μg NTI or vehicle. Pretreatment injections were followed 15 min later by cumulative doses of cocaine (0.0, 0.1, 0.4, 1.6, 6.4 μg/kg) at 30 min intervals. The microdialysis probes were perfused at a flow rate of 0.6 μl/min and dialysate samples were collected every 10 min from either the nucleus accumbens (NACC) or striatum (ST).

Amphetamine dose-dependently increased extracellular DA in both the NACC and STR, as reported previously. NTI, 3, 10, and 30 μg IC, significantly reduced the DA response to amphetamine in the STR. In contrast, 30 μg of NTI did not modify the DA response to amphetamine in the NACC. These findings suggest that delta-opioid receptors play an important role in mediating the amphetamine-induced increase in extracellular DA in the STR, but not in the NACC.

**DRUGS OF ABUSE: COCAINE—DOPAMINE**

Post-mortem studies of cocaine overdose victims have shown elevations in striatal dopamine (DA) transporters relative to healthy control brains. We examined whether acutely abstinent (< 72 h) cocaine addicts have increased levels of DA transporters compared to drug-naive controls, and whether post-mortem increases could persist with sustained (2-4 weeks) drug abstinence. Cocaine dependent and healthy control subjects (n = 8 each; ages 35.0 ± 10.1 vs. 33.8 ± 3.9, p = NS) were injected with 10 μCi [123I]β-CIT and imaged from 24-30 h post-injection under sustained equilibrium conditions. The ratio of specific to nonspecific brain uptake (i.e., (pm Marty-scipoticial/), a measure proportional to the binding potential (BP) for each compound, was used for all comparisons. Preliminary results suggest a statistical trend (p = 0.047, two-tailed) toward elevations in striatal DA transporters in acutely abstinent cocaine subjects in comparison to healthy controls (10.2 ± 2.7 vs. 8.2 ± 1.6; mean ± SD). Consistent with apparent increases (0.25%) in [123I]β-CIT binding relative to controls, were within subject reductions (17 ± 1.8%; range, 7.8 - 33.3%) in cocaine addicts (n=5) after sustained (2-4 weeks) as compared to acute (< 72 h) drug abstinence (12.2 ± 2.4 vs. 10.1 ± 1.7; p = 0.003). These results are consistent with preclinical studies which suggest an upregulation of DA transporters in response to chronic cocaine administration, changes which appear plastic and may "normalize" in the continued absence of the cocaine.

**466.3**

A novel series of benztpine analogs of cocaine were synthesized and their affinities for monoamine transporters were determined using [3H]WIN 35,428 to label the dopamine (DA) transporter and [3H]tiboloprop to label the serotonin (5HT) transporter. In contrast to the ND forms of cocaine and cocaine congeners (e.g. WIN 35,428), diaflupropone (+4'-carbomethoxy-3'carboxyfluoro phenylethylamine) and congeners displayed reverse stereoselective effects. The S-form was 200 times more potent (IC50 = 10.9 ± 1.2 nM) than the R-form, which was highly selective for the DA/BHT transporter (324-fold) and was more potent than the 4-dihydro analog. Unlike the phenylethylamine series, other substrates on the aromatic ring tended to reduce the affinity for the DA transporter. This series of compound's challenges recent views on the binding domain of cocaine/congeners substrates and offers unique opportunities for probing the binding domain of the dopamine transporter. INVOLVEMENT OF AUTOREGULATION IN THE EFFECT OF COCAINE (COC) ON MONOMINES MEASURED BY DIALYSIS IN THE RAT VENTRAL SEGMENTAL AREA (VTA). M.E.A. Reith* and N.-H. Chen, Dept. of Basic Sciences, University of Illinois College of Medicine, Peoria, IL 61655.

Dopamine (DA) cell bodies in the VTA have been implicated in the rewarding and stimulatory activity of cocaine. The VTA is innervated by serotonin (5-HT) and norepinephrine (NE)-containing afferents from the raphe nucleus and locus coeruleus, in addition to reciprocal efferent connections. In the present study, DA, 5-HT, and NE were measured simultaneously in dialysates from the VTA of freely moving rats, and the effect of COC was measured in the presence or absence of monoamine autoreceptor antagonists in the perfusate. Sulpiride (25 μM), 10 μM) increased DA output induced by local (30 μM) or systemic (20 mg/kg i.p.) COC, methiothepin (5-HT; 5-HT; 20 μM) promoted local COC-induced 5-HT output, and idazoxan (100 μM) enhanced COC-induced NE output. This is consonant with activation of autoreceptors in the VTA counteracting the effect of local COC; possibly, modulation by somatodendritic 5-HT and NE autoreceptors is more important following systemic COC administration. Sulpiride promoted COC-induced NE output without modifying basal 5-HT/NE output, whereas methiothepin and idazoxan increased the basal output of all three amines without modifying COC-induced output of DANE or DAVs-HT, implying complex monoamine interactions. While methiothepin or idazoxan depressed COC (20 mg/kg)-induced motor activity. The analysis of behavioral/behavioural relationships revealed a positive correlation between dopamine DA output and motor activity in the sulphiride/COC and methiothepin/COC groups, consonant with VTA DA reflecting DA cell firing, and a negative correlation was revealed between dopamine NE output and motor activity in the COC alone and idazoxan/COC groups, consonant with previous DA/NE balance theories.

664.5 FUNCTIONAL AND PHARMACOLOGICAL MODULATION OF SINGLE-UNIT ACTIVITY IN THE VENTRAL TEGMENTAL AREA AND RELATED REGIONS IN THE AWAKE, BEHAVING RAT. Kosoud, A.E., and Chapin, J.K., Hahnemann University, Philadelphia, PA, 9102 USA.

The ventral tegmental area (VTA) is a central element in a system that mediates the reinforcing properties of natural stimuli (such as food), brain stimulation and drug abuse. In the present study, 464 terminal electrodes in the VTA were chronically implanted in the VTA and target regions, including nucleus accumbens (NA) ventral pallidum (VP), mediodorsal thalamus (MD) and prefrontal cortex (PFC) of male Wistar rats. Following surgery from, simultaneous recordings from single neurons and unit clusters were obtained in unrestrained rats using intraventricular and behavioral studies. A substantial number of neurons in the VTA and target regions displayed no change in firing rate relative to behavior, or were unaffected by the peripheral administration of cocaine, dopamine, noradrenaline (NA), and drugs. However, in doses that have been shown to modulate firing rates in anesthetized rats. This suggests that in the awake rat, functional circuits may be more resistant to disruption by drugs. VTA neurons displaying the electrophysiological characteristics of dopaminergic neurons were relatively active in rats at rest, and reduced their firing rates during movement. These neurons were inhibited by amphetamine, and this inhibition coincided with the appearance of behavioral stereotipes (sniffing and head-waving). This pattern was duplicated in neurons in MD thalamicus, suggesting that functional patterns of activation are reflected in multiple sites throughout a neural circuit. A second class of VTA neurons, apparently non-dopaminergic, showed patterns of activity that were exactly the reverse of the VTA DA neurons: i.e., their firing rate was decreed in rats rest, increased during movement, and excited by peripheral administration of amphetamine. Haloperidol reversed both the behavioral and electrophysiological effects of amphetamine. Supported by NIDA DA 08349 and Hahnemann University R01 90414.

664.6 ELEVATIONS AND PHASE FLUCTUATIONS IN NUCLEUS ACCUMBENS DOPAMINE DURING IV COCAINE SELF-ADMINISTRATION. R.A. Wise,* P. Newton, K. Leeb, B. Burnette, P. Cocock, and I. Justice. 2 Cr Streh Bevah Neurobiol Concordia Univ., Montreal, PQ, CANADA H3G 1M8 and Dept Chem, Emory University, Atlanta, GA 30322.

Fluctuations in extracellular nucleus accumbens dopamine and DOPAC levels were monitored in 1-microdialysis samples from rats engaged in intravenous cocaine self-administration. DOPAC levels were elevated to 200-600% of baseline during cocaine self-administration, fluctuating phasically between responses. Each injection caused a phasic, short-lasting increase in dopamine levels, with a decrease prior to the next lever press. This pattern was seen regardless of whether the dose per injection was fixed or varied unpredictably within the sessions. The magnitude of the phasic fluctuations was on the order of 20% of the magnitude of the sustained within-session elevations; dopamine levels never fell close to baseline levels before the animal responded and received another injection. Fluctuations of the same magnitude and with the same time-course were seen when cocaine was injected independent of the behavior of the animals. DOPAC levels increased in the first minutes and decreased with a decrease prior to the next lever press, with no significant recovery between injections. These data are consistent with the possibility that falling dose levels triggers differential responses in the intravenous cocaine self-administration paradigm, but they offer no support for the hypothesis that extracellular dopamine is depleted at the time of response initiation within a self-administration session.

664.7 ACUTE COCAINE ALTERS DOPAMINE SYNTHESIS IN THE NUCLEUS ACCUMBENS OF RATS PRETREATED WITH SALINE, BUT NOT COCAINE OR CPP. D. Johnson* P. Buckley, M. Koza, and D. Mokler, University of New England, College of Osteopathic Medicine, Biddeford, Me, 04005

A paradigm to develop rapid sensitization to the locomotor-activating effects of cocaine and the role of the competitive NMDA receptor antagonists in rapid sensitization was tested. All rats receiving acute cocaine injections (10 mg/kg) showed higher activity counts (P < 0.01) compared to saline-injected controls. No differences were seen among rats receiving acute cocaine which were pretreated once daily for two days with either cocaine or the competitive NMDA receptor antagonist CPP (2 mg/kg). Neurochemical analysis of norepinephrine (NE), dopamine (DA), DOPAC, 5-HIAA, and 5-HIAA in brain homogenates showed decreased (P < 0.05) levels of DA and HVA in the nucleus accumbens (NA) of cocaine injected rats pretreated with saline, compared to saline injected rats pretreated with saline. Neurechemistry in rats injected with cocaine and pretreated with cocaine, CPP, or both was not different from controls in any brain region examined. These results suggest that this paradigm is inadequate to produce locomotor sensitization to cocaine. However, acute cocaine in this model does produce changes in DA synthesis in the NA of saline-pretreated rats, but prior exposure to cocaine, CPP, or both negates this effect. Further behavioral paradigms are being tested, using microdialysis to measure neurocorrelates.

664.8 PHASIC FIRING PATTERNS OF ACCUMBENS NEURONS ARE RELATED TO CONDITIONED STIMULI-associated WITH DRUG REINFORCEMENT DURING COCAINE SELF-ADMINISTRATION IN RATS. R.M. Carrell, V. C. King, and D. S. Deiborder. Center for the Neurobiological Investigation of Drug Abuse, Dept. of Phys./Pharm., Bowman Gray School of Medicine, Wake Forest Univ., Winston-Salem, NC 27157.

We have previously reported that a subset of nucleus accumbens (NA) neurons exhibit phasic changes in firing rate during cocaine self-administration and water reinforcement in rats (Brain Res 626-14-22,1995; Neurosci Abs 19-1857,1993). Of 244 NA neurons recorded in 14 self-administering rats, 24% (58 cells) exhibited a distinctly different neuronal firing patterns time-locked to the drug reinforced response (0.33 mg cocaine/inf, 5.8 sec) in which drug infusion was paired with a tone-light CS complex (20 sec). The purpose of the present study was to investigate the role of the CS in the phasing patterns of NA cells. NA phasic activity could be triggered by the CS alone since similar patterned discharges occurred independent of drug delivery. However, although the CS was present on all trials, phasic activity time-locked to its occurrence did not emerge until after self self-administration responding. This onset could be prolonged further within the session by: 1) decreasing the dose of cocaine (0.16, 0.08 mg/inf) and; 2) pretreatment with the dopamine (DA) antagonist SCH23390 (10 mg/kg). This indicates that a crucial level of dopamine in the NA must be achieved before the CS can elicit NA phasic activity. In addition, the timecourse of CS related NA firing to cyclic dopamine levels in the NA during the session suggests that phasic activity triggered by the CS does not reflect changes in dopamine levels. [Supported by NIDA grants DA0s355 to RMC and DA06634. DA0619 to SAD.]

Time-dependent changes in mesolimbic dopamine (DA) function are believed to play a role in both behavioral sensitization and drug craving experienced during withdrawal from chronic cocaine administration. The present study utilized intravenous (i.v.) cocaine self-administration coupled with intracranial microdialysis in rats to investigate time dependent changes during withdrawal from chronic cocaine exposure. Rats were allowed contingent access to cocaine at 1 and 7 days of withdrawal while the cocaine-pretreated (MDP) and saline-pretreated (MDN) groups were measured from the nucleus accumbens (MDA). A second group of animals received yoked, noncontingent cocaine for 2 weeks and were then administered noncontingent cocaine on days 1 and 7 of withdrawal. In addition, a third group of animals received 2 weeks of yoked saline following noncontingent cocaine for 2 weeks and were then administered yoked, noncontingent cocaine for 2 weeks and were then administered noncontingent cocaine 7 days after withdrawal. There were no significant differences between groups for the overall cocaine dosage or temporal pattern of infusions on days 1 and 7 of withdrawal. Basal extracellular DA concentrations did not differ between any of the groups on days 1 or 7 of withdrawal. Extracellular DA levels were increased throughout the session on both occasions, however, the increases at day 7 were significantly less than day 1 for both cocaine-pretreated and saline-pretreated groups. This suggests that day 1 did not differ between animals receiving chronic yoked cocaine or saline. These results suggest that tolerance to the DA- Elevations of cocaine is not apparent early in withdrawal, but may be present by later phases of withdrawal. The NA may not be directly related to cocaine craving, since DA levels were attenuated after 7 days of withdrawal while responding for cocaine was unaltered.

Cells in the nucleus accumbens are sensitized to the inhibitory effects of dopamine for several weeks following exposure to noncontiguous injections of cocaine (Henry & White, J. Pharm. Exp. Ther., 1991, 258-882). The present study examined the effects of cocaine exposure on responses of nucleus accumbens cells to dopamine and to methylenedioxyamphetamine (MDMA). Rats pressed a lever in an operant chamber to receive cocaine infusions through cannulae implanted in the jugular vein. The average daily cocaine dose obtained by the cocaine self-administering rats was 31.4 ± 1.2 mg/kg, iv. Following 15 daily sessions of cocaine self-administration, access to cocaine was terminated. Electrophysiological experiments were conducted 1-11 days following termination of cocaine self-administration. DOPAC and dopamine produced dose-dependent inhibition of glutamate-evoked firing in the nucleus accumbens of both the cocaine-pretreated group and a saline-control group of animals. However, dopamine and MDMA had significantly greater inhibitory effects in the cocaine self-administration group than in controls. It is concluded that repeated cocaine exposure at doses that are self-administered sensitizes nucleus accumbens cells to the inhibitory effects of dopamine and of other drugs of abuse that elevate extracellular levels of dopamine in the accumbens. SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
664.11

The effects of the administration of psychomotor stimulant drugs in experimental animals depend on a series of factors. It has been previously demonstrated that intravenous (i.v.) but not intraperitoneal administration of cocaine in the rat produces increases in glucose utilization in portions of the mesocorticolimbic system, such as the nucleus accumbens (NACC) and the medial prefrontal cortex. Anatomical and biochemical differences have been reported within the NACC, with regard to the density of dopamine neve terminals and the functional connections. In this study, the 2-[14C]deoxyglucose method was applied to measure the effects of the acute i.v. administration of cocaine or amphetamine on glucose utilization in the shell and core of the NACC in freely moving rats. After catheterization of the femoral vessels, animals were treated with either cocaine (1 mg/kg), amphetamine (0.5 mg/kg) or saline. Computer-assisted image overlay was performed in order to identify the different portions of the NACC in histological sections. Administration of either cocaine or amphetamine produced increases in glucose metabolism in the shell of the NACC, with respect to control animals. These results provide an useful basis for the understanding of the neural substrates of the effects of reinforcing doses of psychomotor stimulant drugs.

ALTERATIONS IN Dopamine UPTAKE TRANSPORTER DENSITY IN COCAINE SELF-ADMINISTERING RATS APPEAR TRANSIENT. J. H. Graham* S. I. Dwarkin and L. J. Porzio. Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27157.

The in vitro autoradiographic distribution of dopaminergic uptake transporter sites (DAT) was determined, using [3H]mazindol (MAZ) as a ligand, in brain sections from Fisher 344 rats chronically self-administering (SA) cocaine (COC) (0.33 mg/kg/ip) in daily 3 hr sessions. Rats were sacrificed either immediately following a SA session, or after 4 days of withdrawal. Values for DMI insensitive [3H]MAZ binding were compared to those from yoked saline controls similarly sacrificed. Although the distribution of MAZ binding sites in SA rats was decreased in both mesolimbic and nigrostriatal systems, DAT densities returned to levels at or above those found in untreated controls, following 4 days withdrawal. DAT levels in the accumbens (shell and core) and olfactory tubercle of withdrawal rats were elevated above control levels, whereas levels in other areas, e.g. caudate, SNc, rostral pole of accumbens, did not differ from controls. Therefore, adaptations in response to chronic COC SA within both the nigrostriatal and mesocorticolimbic dopaminergic systems may be transient in nature, and only persist as long as COC SA continues. (Supported by NIDA grants P50 DA 06634 and DA 07522).

POSSIBLE MECHANISMS OF BIPHASIC FLUCTUATIONS IN MESOLIMBIC DOPAMINE ACCOMPANYING COCAINE SELF-INJECTIONS: A VOLUMETRIC STUDY. E. A. Kiyatkin* and E. A. Stein. Dept. of Psychiatry at the University of Wisconsin, Madison, WI 53706.

Cocaine is known to have a complex action on the mesolimbic dopamine (DA) system enhancing, due to reuptake inhibition, accumulation of pre-released DA and inhibiting, due to the depletion of DA cells, impulse-dependent DA release. Rapid biphasic fluctuations in nucleus accumbens DA-dependent signal have been reported in our previous electrochemical studies to accompany individual cocaine self-injections (Kiyatkin et al., 1992). Electrochemical signal gradually increased preceding the lever-press for cocaine, and abruptly (<20 sec) transiently (≤ 2 min) decreased after drug injection. Although inhibiting action of cocaine on reuptake of released DA appears to determine the gradual signal increase preceding self-injections, the mechanisms of post-cocaine signal decrease are unknown. To test the contribution of presynaptic auto receptor activation and local anesthetic action to the post-cocaine signal decreases, electrochemical signal changes were studied in cocaine-experienced rats during self-injections of the direct DA agonist amphetamine (AP; 25 μg/kg) and the local anesthetic procaine (PRO; 0.8-3.6 mg/kg). Signal decreases were found after AP self-injections, but they occurred with a definite latency (90-100 sec) that is not compatible with the immediate signal decreases seen after cocaine. Gradual signal increases seen preceding cocaine self-injections were absent in all cases. Thus, although a presynaptic DA auto receptors may contribute to inhibiting action of cocaine on DA release, this relatively slow and long-term effect seems unlikely to mediate the immediate post-cocaine signal decreases. In contrast, an abrupt (<30 sec) signal decrease found after PRO self-injections implicates cocaine's anesthetic action as a possible contributor to the immediate post-drug signal depression. The combination of local anesthetic and reuptake inhibiting properties may underlie the unique abuse potential of cocaine in contrast to agents with only DA uptake inhibiting properties (mazindol, nonfenstine) or local anesthetic properties (lidocaine, procaine).

664.14
TRANSLATION OF DOPAMINE AND BINDING OF WIN 35,428 MEASURED UNDER IDENTICAL CONDITIONS IN RAT STRIATAL SYMPATHTOPES. C. Xu, L. L. Coffey, S. M. Lasley* and M. E. Reith. Dept. of Basic Sciences, University of Medicine, Phoenix, AZ 85054.

One strategy for searching a for a compound that potently inhibits binding of a cocaine-related radioligand to the dopamine transporter but does not a effect dopamine transp. The conditions commonly used for these assays are not the same, confounding data interpretation. In this study, identical conditions have been adopted for the parallel measurement of the binding of [3H](N) 3,4,5,6 and the translation of [3H]dopamine in crude synaptic preparations from rat stratum: 8 min incubation at 20°C with radioligand and inhibitor in phosphate uptake buffer containing Na+ (400 μmol/L), K+ (30 μmol/L), Ca2+ (1 μmol/L), and naltrexone. Binding IC50 values for a series of different uptake blockers (cocaine, WIN 35,428, benzphetamine, nomifensine, mazindol, methylenediphenolet, BTCP, Lu 19-005, DGR 12909, BGR 12956 and CGS 12906) were calculated. Thus, binding IC50 values for F4.4-fold higher than the uptake IC50 values. For slowly equilibrating inhibitors, uptake IC50's decreased by monitoring [3H]dopamine uptake for 1 min only during the last min of the 8 min presence of inhibitor, and under these conditions the average binding over uptake IC50's increased to 2.3. Kinetic calculations, taking into account both radioligand and inhibitor equilibration kinetics, indicated that the latter comparison between binding and uptake measurements was most relevant, and suggested the involvement of complexities beyond simple competitive inhibition of dopamine transport such as different binding domains for substrate and blocker recognition, or spare receptors for blockers. The present results indicate that binding over uptake IC50 ratios should be interpreted with caution depending on the experimental conditions used to measure these ratios. Supported by NIDA 30925.

664.15

The ventral pallidum (VP) is an output structure of the nuc. accumbens. This anatomy suggests that VP may share functions with nuc. accumbens. It is also known that VP is involved in a number of functions related to drug reward. We investigated whether a DA input to VP, from ventral tegmental area has a role in locomotor activity and reward. We prepared rats with chronically indwelling cannula in VP. Drug injections of 0.5 μl were bilateral. Locomotor activity was tested in 1 hr tests in Digican activity chambers. Amphetamine SO4 (10 μg) and dopamine HCl (25 μg) increased activity. Activity was initially suppressed and subsequently elevated by cocaine HCl (12.5-100 μg), the initially suppressed activity was similar to that induced by procaine (50 μg). Place preference conditioning was conducted using a counterbalanced design pairing drug injection in VP with a distinct chamber for two 30 minute sessions. Amphetamine SO4 (10 μg) increased locomotion. Cocaine HCl (50 μg) also increased time spent on the cocaine-paired side. These data indicate that dopaminergic transmission in VP may be involved in the locomotor and reward effects of psychostimulants, and suggest some effects of intracranially administered cocaine are due to local anesthe.}

664.16

Variability in responsivity to therapeutically addictive drugs is a major problem in the replicability of pharmacological research involving both humans and laboratory animals. Recent data from our laboratory (Antelmin et al., 1992) suggest that one source of variability may be the tendency of physiological systems to change their response to repeated drug treatment from a unidirectional to an oscillatory pattern. In the present study, we investigated the effect of cocaine HCl (20 mg/kg, IP.), 30 min. before sacrifice, increased in vitro amphetamine (AM; 10/m) induced DA efflux from striatal slices, compared to controls. This increase was prevented when COC treatments were given 4 d and 30 min before sacrifice. This oscillatory pattern continued through 6 COC treatments (4 d apart). As each COC treatment was added, it reversed the effects of the preceding one. Most importantly, the direction of COC's effects was completely reversed over the 6 treatments. COC increased DA efflux by 53% when given only once but decreased it by 32% after 6 treatments. In a subset of rats, this oscillatory pattern also was seen for DA-efflux in the nucleus accumbens in response to 4 COC pretreatments. Supported by MH 24114 and DA 07546.

EFFECTS OF CHRONIC COCAINE ADMINISTRATION ON DOPAMINE TRANSPORTER mRNA LEVELS. S.R. Letchworth, T.A. Hedgecock, L.J. Perone, Dep. of Physiology & Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27157 USA.

Repeated administration of cocaine produces sensitization, as seen in increased locomotor behavior. Changes in the density of dopamine transporter protein have been reported in rat striatum after chronic cocaine exposure, but the site of action was not determined. This study was designed to investigate possible changes in dopamine transporter mRNA as a result of chronic cocaine treatment. Male Sprague-Dawley rats were treated with 0, 10, 15, or 25 mg/kg cocaine, ip, once daily for 8 days, and locomotor activity recorded. Two of four cocaine treatment groups were determined autoradiographically using in situ hybridization with an oligonucleotide probe specific for the transporter. The mean density/area was measured in the substantia nigra ventralis and tegmental area. In vitro autoradiography using [3H]-mazindol to measure the density of the dopamine transporter protein will be carried out on tissue from the same animals. Cocaine treatment resulted in decreased levels of dopamine transporter mRNA by approximately 20% in both midbrain regions as compared to control levels. In contrast to the dose-dependent effects of repeated cocaine treatment on locomotor activity, however, the changes in dopamine transporter mRNA were not dose-dependent in either the substantia nigra compacta or ventral tegmental area. The lack of correlation between these two measures suggests that regulation of the dopamine transporter may not be critical for the expression of cocaine-induced sensitization. Supported by NIDA Grant DA07522.

664.18

We have previously reported that rats will self-administer microinjections of MK-801 (a non-competitive NMDA receptor antagonist), nomifensine (a dopamine [DA] reuptake inhibitor), or PCP (a drug with both of these properties) directly into nucleus accumbens septi (NAS). Because other studies have reported that DA reuptake inhibitor cocaine is self-administered into prefrontal cortex (PFC) but not NAS, we explored the possibility that these drugs would also be reinforcing when microinjected into PFC. Rats learned to lever press when given response-contingent microinjections of PCP or MK-801 directly into PFC at the same concentration of each drug that was effective in NAS (12 nanograms 120 nl infusion, respectively). However, when lever-pressing was reinforced with microinjections of NOM into PFC at a concentration that increased responding when given into NAS (1.7 mmol/l), rats of responding were not higher than those of animals that received response-contingent microinjections of vehicle. Higher concentrations of NOM were not tested due to poor solubility. These findings confirm that drug actions in the PFC can be rewarding but, taken together, suggest that it is the actions of PCP at the NMDA receptor rather than PCP-induced blockade of DA reuptake that accounts for its rewarding effects in this brain region. This suggestion—and the fact that NOM was self-administered into PFC—remains to be reconciled with the previous report that cocaine is self-administered into PFC but not NAS.

BEHAVIORAL EFFECTS OF NOVEL 4- and 4',4'-SUBSTITUTED-3'-DIPHENYL METHYLOXYTROPIANE ANALOGS. L. Katz, S. Jenzewski, A.C. Allen, A.H. Newman, Drug Development Group, Psychobiology Section, NIDA Intramural Research Program, NIH, Baltimore, MD 21224, U.S.A.

Cocaine-like behavioral effects of a series of 4- and 4',4'-substituted-3'-diphenylmethoxy-1H,5H-tropane analogs were assessed. These analogs bear structural features with the cocaine molecule, the dopamine uptake inhibitor, GBR 12909; they bind with high affinity to the dopamine transporter and inhibit dopamine uptake. Cocaine and GBR 12909 produce dose-related increases in locomotor activity of Swiss-Webster mice, whereas, of the diphenylmethoxytropane analogs tested, only the 4',4'-difluoro- substituted compound (AHH 1-055) produced increases in this activity that approached those of the reference drugs. In another study, rats were trained to discriminate saline from cocaine (1 mg/kg, ioi). After cocaine injections, 20 consecutive responses on one of two levers produced food; after saline, responses on the other lever produced food. Once performance was stable, effects of various doses of cocaine, and of the diphenylmethyltropane analogs were assessed during test sessions in which 20 consecutive responses on either lever produced food. Cocaine produced a dose-related increase in responding on the cocaine lever, reaching 100% at 10 mg/kg. Only AHH 1-055 (17 mg/kg) and the 4',4'-dimethoxy analog, AHH 1-057 (5.6 mg/kg), produced effects different from saline. These compounds produced maximum percentages of cocaine responding of 65 and 35, respectively. With AHH 1-057, doses higher than 5.6 mg/kg produced less cocaine responding. With AHH 1-055, doses higher than 17 mg/kg could not be tested because they virtually eliminated behavior. These compounds represent the first tropane analogs that have structural and neurochemical similarities to cocaine, but are behaviorally distinct from all other known compounds that share this profile.

664.20

A series of 4- and 4',4'-substituted diphenylmethoxy-1H,5H-tropane analogs have been prepared as probes for the dopamine transporter. Initial studies, testing the 4'-chloro-3'-diphenylmethoxytropane displaced [3H]WIN 35,428 binding (Kd=30 nm) more potently than cocaine, inhibited uptake by 50%, and did not display a cocaine-like behavioral profile in locomotor activity or drug discrimination studies. Sensitivity to phenyl ring substitution in this series suggested an additional binding domain that might be exploited for the identification of potential cocaine antagonists. In order to further explore the structure activity relationships in this series of compounds, binding to the dopamine transporter, inhibiting dopamine uptake and producing cocaine-like behavioral effects, an extended series of analogs, substituted in the para-position of one or both phenyl rings was prepared. These compounds were evaluated in radiolabeled binding assays for the dopamine transporter ([3H]WIN 35,428), noradrenergic transporter ([3H]desmethylimipramine), and the serotonin transporter (K[3H]paripitram). All of these compounds noncompetitively displaced [3H]WIN 35,428 binding in rat caudate putamen with Kd values ranging from 11-2000 nm. None of the compounds displaced >60% of [3H]desmethylimipramine binding (10 μM) or 46% of [3H]paripitram binding (10 μM). Therefore, the most potent dopamine uptake inhibitors are highly selective for the dopamine transporter. Furthermore, since the parent drug benztpine is a potent muscarnic antagonist, these compounds were also evaluated for binding to muscarnic-m1 receptors ([3H]pirenzepine) and muscarnic-m2 receptors ([3H][AFAI-DX 384]. All of the the analogs displayed moderate to high affinity for the muscarnic-m1 sites (Kd range 1-110 nm) and variable affinities for the muscarnic-m2 sites (Kd range 2-1500 nm). Structure activity relationship trends are evident and distinct for each of the binding sites and suggest that it will be possible to prepare more selective ligands for the future.

LOCOMOTOR STIMULANT ACTION OF THE DOPAMINE UPTAKE INHIBITORS GBR-12909 AND GBR-12909 CO-TREATED WITH ADDITIVE AND NON-ADDITIVE INTERACTIONS WITH COCAINE. D. Krug, M.J. Forner, M. Stokely, and J. Ebe, Department of Pharmacology, University of North Texas Health Science Center at Fort Worth, Fort Worth, TX 76107.

A study was conducted to compare the locomotor stimulant properties of cocaine with the dopamine uptake inhibitors GBR 12909 and GBR-12909. Horzontal locomotor activity of Swiss Webster mice was recorded for 1 h in a Digiscan apparatus fowing i.p. injection of each drug alone or in combination with 5 to 20 mg/kg cocaine.CONTROL animals, both compounds produced stimulation of locomotor activity with ED50 values of 5-8- and 5-4 mg/kg for GBR-12909 and GBR-12909, respectively. Maximal motor stimulation produced by these drugs was nearly equivalent to that produced by cocaine. Behavioural effects persisted for at least 1 hour following injection. In interaction studies, GBR-12905 produced a drug-related leftward shift in the inverted U-shaped cocaine dose effect curve, whereas, GBR-12909 produced a leftward shift of only the ascending portion. Maximal doses of GBR-12909 failed to influence the response to 20 mg/kg cocaine. These results indicate a non-additive influence of GBR-12909 and cocaine in the modulation of locomotor activity. Supported by U.S.D.H.H.S.-P.H.S. contract NO-DA-2-9305.

THE RELATIONSHIP OF DOPAMINE CONCENTRATION IN BRAIN TO BEHAVIOR: EVIDENCE FOR THE PREFRONTAL CORTEX AS THE INITIATING SITE FOR THE COCAINE LOCOMOTOR STIMULANT EFFECT. Robert J. Carey, Ernest N. Damaj, and Paul P. De Fusco, Psychology, SUNY Health Science Center and Research and Development Service - 151, VA Medical Center, Syracuse, NY 13210.

The behavioral stimulant effects of cocaine have been linked to cocaine inhibition of dopamine transporter mechanisms in the prefrontal cortex, neostriatum, and limbic areas. In the context of behavioral studies, however, there have been conflicting results as to whether the cocaine concentration was measured in these brain structures. Using a recently developed assay procedure, we examined the effects of IP cocaine (10 mg/kg) administration upon locomotion in the non-naive albino mouse. MAOA deficiency of cocaine in the medial prefrontal cortex, neostriatum and limbic olfactory brain areas. Cocaine concentrations were found to be highest in the cortex followed by the neostriatum and limbic area. Significantly, however, locomotor stimulation effects were reliably correlated only with cocaine concentration in the medial prefrontal cortex. This observation suggested that the medial prefrontal cortex may be the critical initiating site for the mechanisms mediating the cocaine stimulatory effects on locomotor behavior.

COMPARISON OF COCAINE AND COCAETHYLENE IN THE VERVET MONKEY: PLASMA PHARMACOKINETICS AND EFFECTS ON EXTRACELLULAR DA. C.W. Bradberry*, J.B. Nobletti, R. Ver, P. Jakow, Yale Univ. Sch. Med., Dept. Psychiatry and Laboratory Medicine, and the West Haven Veterans Administration Hospital, West Haven, CT 06516.

Cocaine is a psychoactive molecule resulting from concurrent cocaine and ethanol consumption, during which a transamination converts the methyl ester of cocaine to acetyl-acetone. It is more selective for DA than cocaine and it has a lower affinity for the 5-HT and somatodendritic uptake sites than cocaine. Thus, and the fact that it can be administered to humans in a clinical setting, makes it a unique tool for investigating drug reward mechanisms. Previous work has demonstrated equivalent actions of the two drugs at the dopamine uptake site in the rat both in vivo and in vitro. We have used microdialysis to compare the effect of 1.5 pmol/kg (equivalent to 0.5 mg/kg cocaine)-HCl cocaine and cocaineethylenediamine on extracellular DA in the caudate of the anesthetized vervet monkey following i.v. administration. Samples were collected at 5 min intervals following drug administration. Concurrent plasma samples were collected for pharmacokinetic analysis. Data were fit to an open two compartment model using weighted non-linear fitting (by PC Nonlin ver. 4). Microdialysis results indicated that both drugs caused an identical four-fold increase in extracellular DA following i.v. administration which peaked in the sample collected during the 5-10min post drug period. Pharmacokinetic analysis indicated the terminal elimination half lives were 31 ± 3 for cocaine, and 53 ± 4 for cocaineethylenediamine, p < 0.01. However, because of a larger steady state volume of distribution for cocaineethylenediamine (17.2 ± 2.2 kg vs 2.5 ± 0.4; p < 0.05), the clearances were not different. Supported by DA 08703, DA 0277, DA 04000, The Yale VA Alcoholism Research Center, and a NARSAD Young Investigator Award to CBW.

COCAINE SELF-ADMINISTRATION PATTERNS MAINLY REFLECT D1 NOT D2 OR D3 RECEPTOR ACTIVATION. J.D. Beluzzi*, S. Koussuth, G. Chinn, N. Khambatki, C. Nguyen, and L. Stein, Dept. of Pharmacology, College of Medicine, University of California, Irvine, CA 92617.

Cocaine self-administration (S-A) is characterized by precisely-spaced response patterns and an "inverted-U" dose-response curve. These characteristics may be duplicated in S-A of D1 agonists (Self & Steins, 1992), but not in D2 agonist. S-A which is characterized by erratically spaced responding and a positively curvilinear dose-response curve (Beluzzi et al. 1993). Here we report that co-administration of a low dose of a D1 agonist converts erratic S-A into cocaine-like and D2-like response rates and patterns. Rats were trained to bar press for i.v. cocaine (750 μg/kg) in daily 3-hr sessions. After baseline rates had stabilized, different doses of PHNO were substituted for cocaine. PHNO alone (Fig. 1) was self-administered erratically at high rates, but co-administration of the D1 agonist SKF 28355 (3 μg/kg) with PHNO (30 μg/kg) induced low-rate responding similar to that seen with the D1 agonist alone (A). When combined with SKF 2536, other D2 (quiprole, N-0923) or D3 (7-OH-DPAT) agonists gave similar results. Our data indicate that cocaine-S-A patterns are reproduced by S-A of D1 but not D2 or D3 agonists, and that D2 or D3 agonists promote when D1 and D2-like agonists are co-administered. (Supported by NIDA grant DA07747.)

665.3

We have previously demonstrated that intra-accumbens injections of the D2-like receptor antagonist sulpiride potently block locomotion induced by systemic administration of cocaine, whereas intra-accumbens injections of the D1-like receptor antagonist SCH-23390 only block locomotion at high doses. In the present study further assessed the involvement of D1-like receptors by examining the effects of systemic SCH-23390 administration on locomotion elicited by intra-accumbens cocaine. Rats received systemic injections of SCH-23390 (0.03, 0.3, 1.0 mg/kg, i.p.) and 10 min later received bilateral injections of either saline or cocaine (100 μg/μl) into the NAC. Locomotion and stereotypic behaviors were then measured for 60 min. This procedure was repeated twice at 6-day intervals. The two highest doses of SCH-23390 decreased cocaine-induced locomotion, as well as baseline locomotion. The magnitude of cocaine-induced locomotion did not change across repeated intra-accumbens administrations. Stereotypic behaviors were not observed following acute or repeated intra-accumbens cocaine administration. In summary, although intra-accumbens SCH-23390 does not potently block locomotion produced by systemic cocaine administration, systemic SCH-23390 potently blocks locomotion produced by intra-accumbens cocaine administration. These findings suggest that D1-like receptors in brain regions other than the NAC are involved in mediating cocaine-induced locomotion. (Supported by DA07747.)

665.2

EFFECT OF COCAINE ON cAMP-ADENYLYL CYCLASE SYSTEM IN RAT STRIATUM. S.K. Sabri, J.M. Davis and J.J. Yadid*, Illinois State Psychiatric Institute, University of Illinois at Chicago, Chicago, IL 60612.

Repeated low doses or a single high dose of cocaine administration produces behavioral sensitization in rats. Also, repeated cocaine administration in rats has been reported to increase forskolin-stimulated adenylyl cyclase (AC) activity in nucleus accumbens. In the present study, we examined the effects of cocaine on the formation of cAMP induced by dopamine and a D1 selective agonist (through D1 receptors). AC was measured by incubating striatal membranes at 37 °C (2 μg protein) and forskolin (acting directly on catalytic unit of AC). Adenylyl cyclase activity in striatal membranes was measured by [32P]-cAMP formation using [32P]-ATP as a substrate. Acute administration of cocaine (10 mg/kg or 40 mg/kg) did not significantly affect cAMP formation 1 hr or 24 hrs post injection, However, when rats were pretreated with a single injection of high dose (40 mg/kg) and then administered a cocaine challenge (10 mg/kg), a significant decrease (about 30%) was observed in the formation of cAMP in the striatum induced by stimulation with D1 agonist. Similarly, a trend towards decreased formation of cAMP was observed in dopamine-sensitive activity, although it did not reach statistical significance. Since under these conditions of cocaine treatment behavioral sensitization is also manifested in rats, present findings raise the possibility that an inhibition of D1-mediated AC activity in the striatum may play a role in cocaine-induced behavioral sensitization.

665.4

EFFECT OF D1 RECEPTOR ANTAGONIST IN THE NUCLEUS ACCUMBENS ON INTRAVENOUS COCAINE SELF-ADMINISTRATION IN THE RAT. A. McGregor and D.S. Roberts*, Life Sciences Research Centre, Carleton University, Ottawa, K1S 5B6, Canada.

These experiments examined whether an antisense oligonucleotide directed against D1 receptor mRNA in the nucleus accumbens of the rat could disrupt intravenous cocaine self-administration behaviour. Rats were trained to self-administer cocaine (1.5 mg/kg i.v.) under a progressive ratio (PR) schedule of reinforcement and then implanted with intracerebral cannulae above the nucleus accumbens. Following re-establishment of stable self-administration behaviour, three injections of the antisense or randomised antisense sequence were administered at 12 hour intervals. Phosphorothioated at all positions, the antisense and randomised antisense sequences were delivered in a saline vehicle (2.5 mmol/l of sodium chloride). A large and significant decrease in break point (BP) was produced following antisense treatment, which took five to six days to return to baseline BP. In contrast, treatment with randomised antisense produced a much smaller decrease in BP, which showed a rapid return to pretreatment BP. Furthermore, acute treatments had no effect on operant responding for food reinforcement under a fixed ratio (FR20) schedule. The results suggest that injection of D1 antisense into the nucleus accumbens caused large reductions in the reinforcing properties of cocaine as measured under the PR self-administration schedule. The lesser effect of the randomised sequence may be due to nonspecific behavioural deficits following such treatment, and indicates that attention must also be given to the nonspecific effects of such oligonucleotide treatments. Supported by NIDA Contract No. NO1DA-3-7002 and MRC of Canada.
665.5 DIFFERENTIAL EFFECTS OF INTRA-ACCUMBENS SULPIRIDE ON COCAINE-INDUCED LOCOMOTION AND CONDITIONED PLACE PREFERENCE. D.A. Baker*, L.E. Oddi†, T.V. Khoury, J.L. Neisewander. Department of Psychology, Arizona State University, Box 871104, Tempe, AZ 85287-1104.

The effects of intra-accumbens administration of sulpiride on the stimulant and reinforcing effects of intravenous (IV) cocaine were investigated using the conditioned place preference (CPP) paradigm. Adult male Sprague-Dawley rats received 7 conditioning trials which consisted of 30-min exposures to two distinctive compartments on consecutive days. On one day of the trial, the rats received bilateral injections of saline or sulpiride (0.05 or 0.2 μg/μl side) into the nucleus accumbens (NAc). Fifteen min later, the rats were placed into a compartment and immediately injected with either saline or cocaine (4.2 mg/kg, IV). On the third day of the conditioning, the rats received sham intra-accumbens injections and 15 min later were placed into the other compartment. punished responding to cocaine was measured on the first and last trial. Cocaine produced an increase in locomotion which was attenuated by both doses of sulpiride. Cocaine also produced an increase in headbobbing, and a decrease in grooming. These behaviors were not affected by either dose of sulpiride. Headbobbing was the only behavior sensitised by repeated administration of cocaine, and this sensitization was blocked by the high dose of sulpiride. Cocaine produced a robust CPP that was not altered by either dose of sulpiride. Conditioned locomotion was evident following saline injections in the drug-paired environment, and acquisition of this response was blocked by the high dose of sulpiride. These findings suggest that D2-like receptors in the NAc mediate cocaine-induced locomotion, but not CPP. This research was supported by DA07730.

665.7 THE EFFECTS OF PARTIAL DOPAMINE D2 AGONISTS ON SELF-ADMINISTRATION OF COCAINE ON A PROGRESSIVE RATIO SCHEDULE IN RATS. R. Ranadiri*, G. Vickers and D.C.B. Roberts. Life Sciences Research Center, Carleton University, Ottawa, Canada K1S 5B6.

There now exists considerable evidence showing that the rewarding effects of cocaine depend on dopamine (DA) neurotransmission. Thus, drugs that interfere with DA function may potentially be beneficial in the treatment of cocaine addiction. Electrophysiological and biochemical studies have demonstrated that the intrinsic efficacy of partial D2 receptor agonists can be rank-ordered from greatest to least as follows: B-HT 920, SND 919, (-)-3-PPP, SDZ 208-912, SDZ MAR 327. We investigated the effects of these partial D2 receptor agonists on the self-administration of cocaine in intravenously self-administer each of four unit doses of cocaine (0.075, 0.15, 0.3 and 0.6 mg/injection) on a progressive ratio (5) schedule and the effects of BHT 920 (0.25 mg/kg), SND 919 (0.1 mg/kg), (-)-3-PPP (1.25 mg/kg), SDZ 208-912 (0.25 mg/kg) and SDZ MAR 327 (0.25 mg/kg) on the breaking points at each unit dose of cocaine were investigated. The results demonstrated that drugs with the least intrinsic activity (SDZ 208-912 and SND 919) did not affect or increased breaking points for cocaine reward. Thus, the effect of these partial agonists on breaking points for cocaine reward is positively correlated with their intrinsic activity at the D2 receptor. The data suggest there may be a point on the continuum where agonists may decrease breaking points for cocaine but not disrupt food-rewarded responding. (Supported by NIDA Contract NO1DA-3-7032).

665.9 DOPAMINE D2 RECEPTOR AGONISTS PARTIALLY REPRODUCE THE DISCRIMINATIVE STIMULUS EFFECTS OF COCAINE. Roger D. Spealman*, Harvard Medical School, New England Regional Primate Research Center, Southborough, MA 01772-9102.

Dopamine agonists with reported selectivity for the D2 subtype of dopamine receptor were studied for their capacity to reproduce the discriminative stimulus effects of cocaine in squirrel monkeys. Monkeys were trained to discriminate cocaine (0.1 mg/kg) from vehicle using a partial reinforcement procedure and subsequently were tested with a range of doses of 7-hydroxy-dipropylaminotetralin (7-OHP-DPAT; 0.001 - 0.1 mg/kg), 2-(N-phenethyl-N-propyl) amino-5-hydroxytryptamine (N-0434; 0.001 - 0.03 mg/kg) and quinolone (0.03 - 0.3 mg/kg) and quinolone (0.01 - 0.3 mg/kg). Each drug engendered dose-related partial substitution for cocaine, reaching average maximums of 60 - 80% cocaine-appropriate responses after the highest doses tested. The degree of cocaine substitution engendered by the D2 agonists was comparable to that reported previously for D1 and D2 agonists. The results are consistent with the view that D2 receptors in the mesolimbic dopamine pathways play significant role in mediating the discriminative stimulus effects of cocaine in monkeys. Supported by DA00499, DA03774 and RRO0168.

665.10 EFFECTS OF DOPAMINE D2 RECEPTOR AGONISTS ON CONDITIONED INDEPENDENT RESPONSE DURING MULTIPLE SCHEDULES OF VARIOUS FOOD AND COCAINE SELF-ADMINISTRATION IN RATS. B. Weissenborn*, U.F. Koob and F. Weiss. Department of Neuropharmacology, The Scripps Research Institute, La Jolla, California 92037.

The present series of experiments sought to examine the effects of selective D1 and D2 dopamine receptor agonists (SCH 23390 and raclopride) and a D2 partial agonist (SDZ 208-911) on food and cocaine self-administration in rats while responding for environmental cues associated with the primary reinforcers. Rats were trained on a multiple schedule during which lever-pressing was reinforced with a food pellet and simultaneous presentation of a tone, or with a cocaine infusion and presentation of a stimulus light. Each session was preceded by a 5 min component during which lever presses resulted in presentation of the respective cues only. Non-contingent delivery of food or cocaine prior to this initial component resulted in a significant shift in preference for the tone or light respectively, suggesting that cues had taken on the role of conditioned reinforcers with incentive-motivational value. Systemic administration of SCH 23390 (10 μg/kg) and raclopride (100 and 200 μg/kg) blocked, while SDZ 208-911-025 - 0.5 mg/kg) enhanced the preference shift induced by non-contingent delivery of cocaine. SCH 23390 and raclopride non-selectively suppressed responding following non-contingent food. During the multiple schedule, SCH 23390, raclopride and SDZ 208-911 decreased the inter-reinforcer intervals for cocaine, and at higher doses increased those for food. These data suggest that low doses of D2 agonists and high doses of D2 antagonists decrease the partial reinforcement effect of cocaine but not food under the schedule parameters used here. In addition, selective dopamine antagonists can attenuate cocaine-induced responding for a conditioned reinforcer, implicating both D1 and D2 receptor mechanisms in mediating conditioned stimulus-reward associations. This work was supported by NIDA grant DA 07348, 08467, 04398 (FW and GFK).
665.11
REDUCTION OF THE REINFORCING PROPERTIES OF COCAINE BY A PARTIAL DOPAMINE AGONIST. L. Pulverenti*, D. Smith and G.F. Koob
Dept of Neuropharmacol., Scripps Res. Inst., La Jolla, Ca 92037 and “Mondino-Tor Vergata” Ctr for Exp Neurobiol, Un. of Rome “Tor Vergata”, Rome, Italy

Partial dopamine agonists are a recently characterized novel class of compounds acting at the dopamine receptor site with high affinity and low intrinsic activity. These drugs act as functional antagonists in conditions of high dopamine tone, while they show an agonistic profile in conditions of dopamine depletion (e.g. denervation). Since the reinforcing properties of cocaine seem to depend upon activation of forebrain dopamine neurotransmission, the aim of the present study was to evaluate the effects of acute pretreatment with SDZ 208-911, an aminoergoline with partial dopamine agonistic activity, in rats trained to self-administer cocaine IV (0.75 mg/kg/injection). SDZ 208-911 (0.25-1.6 mg/kg IP) dose-dependently reduced the reinforcing properties of cocaine as shown by a reduction of the inter-reinforcement interval in rats self-administering cocaine IV with limited daily access. The pattern of responding was similar to that of animals self-administering a lower dose of cocaine (0.37 mg/kg/injection) and to that of animals pretreated with a dopamine receptor antagonist. Cocaine abuse in humans is characterized by intake of high amount of drug followed by withdrawal. Since partial dopamine agonists also show an agonistic profile in conditions of low dopamine tone (i.e. cocaine abstinence), the potential use of these compounds for effective pharmacological intervention during the various phases of cocaine addiction is a hypothesis worth testing.

665.13
SENSITIZATION TO COCAINE SELF-ADMINISTRATION FOLLOWING CHRONIC (Z)-FLUPENTIXOL (FLU), RESULTS IN AN INCREASE IN THE RATE OF COCAINE SELF-ADMINISTRATION. (E.g. Ellenberg et al., Psychopharmacology. 78: 204, 1982). The present study investigated the effects of acute and chronic administration of FLU on the dose-effect curve for cocaine self-administration. Rats were implanted with chronic indwelling jugular catheters. Following implantation, they were allowed to self-administer cocaine (0.25 mg/kg/injection) on a fixed-ratio two (FR2) schedule of reinforcement, 15 reinforcements a day, until baseline responding was stable. Using a multi-dose procedure, a dose-response curve for each rat was then obtained. Rats were then assigned to one of two groups. One group received a 3 hr pretreatment with FLU (0.032, 0.1, or 0.32 mg/kg, i.p.) followed by a multi-dose test. The other group was treated with FLU chronically (0.32 mg/kg/12 hr; s.c.). The chronic regimen lasted for five days, during which rats did not have access to cocaine self-administration. Seventy-two hours after the last chronic injection, cocaine dose-response curves were re-obtained. Acute treatment with FLU produced a dose-dependent shift to the right of the cocaine dose-response curve. In contrast, three days after terminating chronic FLU, a 2-fold shift to the left of the dose-response curve was obtained. The present data suggest that acute dopamine blockade results in a decrease in the reinforcing properties of cocaine as observed by a shift to the right of the cocaine dose-response curve. In contrast, three days after terminating the chronic blockade of dopamine receptors by FLU, there was an increase in the reinforcing properties of cocaine as observed by a shift to the left of the cocaine dose-response curve. Supported by NIDA ROI 4137.

665.14
COCAINE INDUCED LOCOMOTOR HYPERACTIVITY IN THE RAT IS REDUCED BY QUINACRINE. Kevin H. Souta, Aram J. Javath*+, Malcolm S. Reid, S. Paul Berger, UCSF/VAMC, Psychiatry Services 127, 4150 Clement St., San Francisco, CA 94121; * Res, Svc 151-FP, VAMC, 3710 SW Veterans Hosp. Rd., Portland, OR 97201

Quinacrine is a phospholipase A2 (PLA2) inhibitor which is clinically used for the treatment of malaria. As a PLA2 inhibitor one of its main effects is the reduction of arachidonic acid levels. The release of arachidonic acid has been suggested to play a role in dopamine D2 receptor signal transduction mechanisms. In the present study we have investigated whether quinacrine has any effects on the acute locomotor and stereotypic behavioral responses to cocaine in Sprague-Dawley rats. Animals were pretreated with quinacrine (16 mg/kg, i.p.) 15 min prior to cocaine (30 mg/kg, i.p.) administration and locomotor activity and stereotypy were scored every 10 min for 1 hr in an Actimex box. Pretreatment with the cocaine stimulation of locomotor activity by approximately 30%, but had no effect on the stereotypic behavioral response. Quinacrine alone had no effect on locomotion and stereotypy. The ability of quinacrine to modulate caffeine induced locomotor stimulation was also tested, and it was found that quinacrine had no effect on caffeine. These findings suggest that the ability of quinacrine to reduce drug induced stimulation of locomotion is mediated via the dopamine system. Further studies on the behavioral effects of selective D1 and D2 receptor agonists are underway.

INCREASED SENSITIVITY TO THE LOCOMOTOR DEPRESSANT EFFECTS OF A DOPAMINE ANTAGONIST DURING COCAINE WITHDRAWAL IN THE RAT. B.A. Baldet and G.F.Koob
Dept of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Clinical studies have identified a behavioral syndrome, occurring in stimulant abusers after prolonged cocaine binges, which is characterized by psychomotor depression and anhedonia. This "cocaine withdrawal syndrome" has been hypothesized to contribute to relapse in cocaine users; accordingly, much effort has been dedicated to the development of animal models of cocaine withdrawal in order to elucidate its underlying mechanisms. Recent studies in this laboratory have determined that thresholds for rewarding brain stimulation are elevated following prolonged self-administration sessions in the rat. The post-cocaine threshold elevation was reversible by the dopamine receptor antagonist bromocriptine, suggesting that impaired dopaminergic function may contribute to cocaine withdrawal. In order to determine additional behavioral correlates of cocaine withdrawal, and to further study the role of the dopamine system in cocaine withdrawal, spontaneous locomotor activity was measured in photocell testing cages 4 hr following 12 hr cocaine self-administration sessions. Prior to locomotor activity testing, cocaine-exposed and control animals were injected with saline, or 0.05 mg/kg cis-flupenthixol, a dopamine receptor antagonist. Locomotor activity was found to be significantly depressed in cocaine-exposed animals, but not control animals, treated with cis-flupenthixol. In a separate experiment, doses of cis-flupenthixol as high as 0.4 mg/kg failed to produce significant locomotor depression in drug-naive animals. It is hypothesized that dopamine receptor blockade by a low dose of cis-flupenthixol may interact with cocaine-induced neurochemical changes to produce locomotor depression during cocaine withdrawal. Supported by DA04398 (GFP) and an NSF Predoctoral Fellowship (BAB).

DOPAMINE RECEPTOR BLOCKADE ALTERS PREPRODYRorphin AND ZIF/268 mRNAs IN RATS THAT “BINGE” ON COCAINE. J.B. DeMeyer*, J.D. Wang, W.T. Bohrer, D.C. Mayer, and J.F. McGuire
Dept. Anat. & Cell Bio., East Carolina University School of Medicine, Greenville, NC 27858-4534

A single injection of cocaine increases expression of preprodynorphin mRNA, whereas repeated cocaine increases dynorphin immunoreactivity (Dyn-ir) and preproendorphin (PPE), but not preproenkephalin (PPE), mRNA in rat striatum. Cocaine’s effects on c-fos and zif/268 mRNAs, or on DA D1 receptor blockade on c-fos, zif/268, and PPD mRNAs after "binging" are unknown. In an effort to answer these questions, thirty adult, male Wistar rats were injected i.p. with SC123390 (0.5 mg/kg) or the D1 receptor antagonist, sulpiride (50 mg/kg) 30 min prior to 3 hourly injections of i.p. saline or 20 mg/kg cocaine for 1 day. One hr after the final injection, the rats were anesthetized and decapitated. Sections were collected through the anterior striatum at the level of the nucleus accumbens, and hybridized with 40-mer oligonucleotides coding for c-fos or zif/268, or 48mers coding for PPE or PFE. Quantitative analysis of autoradiograms revealed that SC123390 completely blocked the cocaine-induced increase in striatal zif/268 and PPD mRNAs. Furthermore, SC123390 alone significantly decreased the basal levels of zif/268 and PPD mRNAs. Sulpiride completely blocked cocaine-induced PPD mRNA and significantly decreased the induction of zif/268 mRNA in the striatum. Sulpiride alone decreased basal levels of PPD mRNA but enhanced the expression of zif/268 mRNA as compared to basal levels in saline-treat rats. C-fos mRNA was undetectable and PPE mRNA remained unchanged by the repeated administration of cocaine. These data demonstrate that: 1) the D1 receptor plays a substantial role in modulating the tonic expression of PPD mRNA in the striatum, a role attributed primarily to the D1 receptor, 2) PPD and zif/268 gene expression is modulated by both D1 and D2 receptors following a cocaine "binge". Supported by DA 01982.

COMBINED SPECT AND QUANTITATIVE EEG STUDIES IN COCAINE ABUSERS. J.W. Grzynow, L.M. Konopka, T. Miko, E. Barnes, and P. Shiriati. Biological Psychiatry Section and Nuclear Medicine Service, Hines VA Hospital, Hines, IL, 60142.

To examine the relationship between cerebral blood flow as measured by HMPAO-SPECT and brain electrical activity as assessed by quantitative EEG (qEEG) in cocaine abusers, we studied 9 chronic cocaine abusers and compared the results with nine normal controls. HMPAO was injected for SPECT while the subjects were continuously monitored for EEG activity under carefully controlled conditions. Using a novel data-reduction technique, we extracted a single set of group images for comparison with the normal control group. All of the cocaine abusers had abnormal SPECT scans. Using a subtraction topographic maps, cocaine abusers showed areas of hyperperfusion and hypoperfusion. Hyper-perfusion was particularly notable in frontal regions. This hyperperfusion contrasts with other studies in which only hyperperfusion areas were noted. In addition, there appear to be small right-left asymmetries in the perfusion pattern.

Quantitative EEG studies of the cocaine abusers showed increased total alpha power compared to the controls. The increase in total activity came from two sources: first, a widening of the alpha peak indicating a spreading out of the distribution curve of alpha frequencies within the alpha band; and second, a significant penetration of the normally occipital alpha activity into more frontal regions. Combining SPECT and qEEG revealed a strong correlation between increased frontal alpha activity and frontal hyperperfusion as assessed by SPECT.

REGIONAL BRAIN BLOOD FLOW DURING INDUCED COCAINE CRaving A.R. Childress, D. Mosley, J. Fitzgerald, M. Revicz, J. Legg, and C.P. O'Brien*. Depts. of Psychiatry and Radiology, Univ. of Penn. School of Medicine, Philadelphia, PA 19104.

Human cocaine users can experience profound drug desire when they encounter cues (other drug users, drug-buying or drug-using locations, drug paraphernalia, etc.) which remind them of cocaine, but not when they are in a neutral environment. Cocaine-related cue stimuli can cause an increase in the brain correlates of this desire. Clinically, cue-induced cocaine craving is often accompanied by a number of signs and symptoms similar to the effects of cocaine itself, including generalized arousal, palpitations, light-headedness, ear-ringing, chest tightness, the taste of cocaine in back of the throat, and even mild euphoria. The drug-like nature of these responses suggests that brain structures activated during cocaine craving may be among those activated by cocaine itself, but also that these structures may be particularly limited in cocaine’s pleasurable effects.

We are testing whether limbic regions may be differentially activated during cocaine craving by measuring regional cerebral blood flow (rCBF) with Positron Emission Tomography (PET) and radioactively-labeled water (H2O18) as the flow tracer. Cocaine patients (n=5 thus far) are imaged during exposure to ambient room stimuli (Baseline), and to videos of Neutral (no-drug) and Cocaine-related scenes. Each subject's functional PET images are co-registered with an MRI for anatomical localization of imaged radioactivity. Change in rCBF from Baseline is calculated for both Neutral and Cocaine scenes across selected brain regions. Initial results show the Cocaine video triggered craving, and rCBF during the Cocaine video increased in several limbic regions. Systematic increases in rCBF did not occur in reference areas, e.g., whole brain or hemispheres or in response to the Neutral Video. These preliminary data suggest limited activation may be one component of drug craving.

It has been previously shown that basal corticosterone-secretion facilitates behavioral effects and the rewarding properties of stress stimuli in animals. To further investigate the role of corticosterone in the dopaminergic system, we examined the influence of glucocorticoid treatment on the rewarding properties of cocaine and heroin in rats. We also investigated the effect of glucocorticoid administration on the rate of self-administration of cocaine and heroin by female rats on thebasis of the hypothesis that glucocorticoid treatment could decrease the rate of self-administration of these drugs. These results suggest that glucocorticoid treatment can modify the rewarding properties of these drugs in rats.

Modulation of the discriminative stimulus (DS) effects of cocaine by morphine was investigated in rats trained to discriminate a relatively low (3 mg/kg) or a relatively high (10 mg/kg) dose of cocaine from vehicle. When tested alone, cocaine (0.3 - 18 mg/kg) engendered dose-related increases in cocaine-appropriate responding across both training conditions, with ED₅₀ values being about 3-fold greater under the high-dose training condition than under the low-dose training condition. Morphine (0.3-5.6 mg/kg) did not engender dose-appropriate responding under either training condition. Pretreatment with morphine did, however, enhance the DS effects of cocaine (0.3 - 3.0 mg/kg) under both training conditions, with a dose of 2.5 mg/kg being dose-related to a concomitant reduction in ED₅₀ of 8- to 12-fold. The results are consistent with those previously reported in squirrel monkeys and provide relevant information about the boundary conditions under which morphine-cocaine interactions are observed.

Choline acetyltransferase activity is reduced in rat nucleus accumbens after unlimited access to self-administration of cocaine. J.M. Carroll, S.T. Lac, I.M. DSouza and S.J. Kish. Clarke Institute of Psychiatry, Toronto, Ontario and University of Minnesota, Minneapolis.

Activity of choline acetyltransferase (ChAT), the acetylcholine synthesising enzyme, was measured in discrete areas of rat brain after chronic, unlimited access to self-administration of cocaine. The duration of drug exposure was 6 weeks, during which time the rats self-administered a mean daily dose of approximately 90 mg/kg. Rats were sacrificed either on the last day of cocaine access (n=10) or after three weeks drug withdrawal (n=8). As compared with the controls (n=15), ChAT activity was slightly reduced in striatum (-10%, P<0.05) and moderately reduced in nucleus accumbens (-26%, P<0.05) on the last day of cocaine access. After three weeks withdrawal from cocaine, ChAT activity was still reduced (striatum -18%, P<0.05; nucleus accumbens -32%, P<0.05) relative to controls. These data suggest that self-administration of cocaine is associated with a long-lasting reduction in ChAT activity. Such a reduction in ChAT activity suggests reduced activity of dopamine receptor cholinergic neurones in the basal forebrain, which could underlie some of the behavioral effects of cocaine. (Supported by NIDA grant DA07182).

Considerable evidence, obtained by studies in man and experimental animals, indicates that NPY plays a role in behavior. For example, NPY appears to be an endogenous anticonflict/anxiolytic agent, whose action depends on activation of NPY-Y1-receptors (Wahlstedt et al., Science 259, 528-31, 1993). We have hypothesized that the reduction of forebrain NPY levels (and reduced NPY-Y1-receptor occupancy) resulting from repeated cocaine treatment is associated with severe anxiety and depression-like states that often follow cocaine withdrawal (Wahlstedt et al., PNAS, 88, 2078-82, 1991).

The NPY mRNA and NPY-Y1-receptor mRNA levels in frontal cortex, peripheral cortex, nucleus accumbens, hippocampus and in the hypothalamus were measured with a solution hybridization assay using 300 bp fragments of respective cDNA. The hybridization was linear to 500 pg for both NPY and NPY-Y1-receptor sense transcripts. After 24-hour treatment with cocaine (10mg/kg bw i.p., twice daily), NPY mRNA levels decreased between 20 and 70% in the assayed brain regions. Cocaine treatment for 72 hours, and up to 7 days, further decreased NPY mRNA levels in the sampled regions. NPY-Y1-receptor mRNA levels, on the other hand, increased by 60% in the sampled regions) after 24 hours and stabilized at 70-185% increase after 72 hours.

Our data thus indicate that treatment with cocaine causes profound alterations in NPY and NPY-Y1-receptor mRNA levels. However, the temporal patterns of these effects are distinct for the two mRNA species. (Supported by DA06805).

U50,488, A KAPPA AGONIST, ATTENUATES COCAINE-INDUCED INCREASES IN EXTRACELLULAR Dopamine IN NUCLEUS ACCUMBENS. J.M. Maisonneuve* and S.D. Glick. Dept. Pharm/Tox, Albany Medical College, Albany, NY 12208 and the Capital District Center for Drug Abuse Research and Treatment, Albany, NY 12208

Recent observations suggest that manipulation of endogenous opioid systems may modify the dopamine-dependent effects of cocaine. The combination of the kappa opioid agonist, U50,488, a selective kappa opioid-receptor agonist, produces a partial enhancement of their reinforcing effects and is commonly referred to as "speed ball" by abusers (Masukawa et al., 1993). In contrast, kappa opioid agonists have been shown to attenuate the discriminative stimulus effects of cocaine (Spealman and Bergman, 1992). Using in vivo microdialysis in awake and freely moving male Sprague Dawley rats, we investigated whether U50,488, a selective kappa opioid-receptor agonist, combined with cocaine produces a differential enhancement of the reinforcing effects of cocaine. Cocaine (20 mg/kg, i.p.) produced a ten-fold increase in extracellular dopamine in the nucleus accumbens. Cocaine (20 mg/kg, i.p.) produced a 50% decrease in the effect of cocaine on DA levels. This attenuation was completely reversed by administration of nor-binaltorphimine (10 mg/kg s.c.), a kappa antagonist, 20 minutes before the agonist challenge. These findings indicate that activation of kappa receptors attenuate cocaine's effects and thus kappa agonists may have a potential role in the pharmacological management of cocaine addiction (supported by DA03817 and by the Aaron Foundation Diamond).
666.19 Glycine/NMDA antagonist, (+)-HA-966, prevents behavioral sensitization to cocaine and subsequent effects on aversive conditioning. Brent A. Morrow, Jane R. Taylor and Robert H. Roth. Dept. of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06520

The noncompetitive NMDA receptor antagonist, MK-801, has been shown to prevent locomotor sensitization to repeated cocaine. However, MK-801 has been shown to cause locomotor sensitization to itself. We tested (+)-HA-966, a 1-hydroxy-3-aminopyridine derivative of the glycine agonist (+)-glycine, on the NMDA receptor complex, on locomotor sensitization to repeated cocaine administration. Vehicle or (+)-HA-966, 15 mg/kg ip, was given 30 min prior to vehicle or cocaine, 15 mg/kg ip, daily for 21 consecutive days. Seven larvae, after several latency periods, were sensitized to cocaine, 15 mg/kg. (+)-HA-966 prevented sensitization to the cocaine challenge and did not cause a sensitization to itself. Three weeks later, rats were subjected to aversive conditioning; 10 randomly presented tones terminated with 0.5 sec, 400 mA footshocks over 30 min. The following day the rats were returned to the chamber, given 10 tones without footshock, and sacrificed after 30 min. The medial prefrontal cortex (mPFC) and nucleus accumbens (NAS) were harvested and assayed by HPLC-EC for serotonin and dopamine along with their metabolites. As expected, the conditioned rats had significantly greater immobility (freezing) during and after the tone, increased focal body and elevated dopamine turnover (DOPAC/DACD) in the mPFC and NAS. Prior exposure to cocaine attenuated the increase in behavioral (i.e. freezing and focal body) and blocked some of the biochemical (NAS dopamine turnover) changes seen with cocaine. (+)-HA-966, the glutamate agonist, prevented these effects. The role of the NMDA receptor with regards to cocaine sensitization and subsequent cross-tolerance to aversive conditioning will be discussed.

666.21 EFFECTS OF INTRAVENTRICAL COCAINE ADMINISTRATION ON GLUTAMATE-INDUCED EXCITATION AND SPONTANEOUS ACTIVITY IN RAT'S CEREBELLAR PURKINE CELLS. C. A. Jiménez-Rivera*, O. Segura, S. Mato, V. Algranit, J. Dorne and B.D. Waterhouse. Deps. of Pharmacology, UCC, Sch. of Medicine, University of Pau and Rhodes University, Univ. Phil. Pa., 19102.

Cocaine is a well known substance of abuse with central psychostimulants effects and local anesthetic properties. Biochemical studies indicate that cocaine's main action is to increase central synaptic levels of monoamines through blockade of reuptake mechanisms. This study investigated the effects of intravenous (i.v.) cocaine administration on Purkinje cells response to glutamate, a putative neurotransmitter with clear actions in the cerebellum. Excitatory responses of individual neurons to microiontophoretic pulses (10 ms at 10 am perisynaptic; 10^(-4) M) were examined, before, during and after cocaine injections (0.15 and 1 mg/kg, i.v.). At doses of 0.25 mg/kg cocaine induced a significant reduction in spontaneous activity (spikes/sec x 10^4, n = 6) and glutamate-evoked response (37.6 ± 7.2 to 33.9 ± 10.7). Similar effects were observed at doses of 1 mg/kg, however, they were lower in magnitude (5A - 32.6 ± 2.77 to 17.96 ± 4.20, n = 6) and glutamate-evoked response (37.6 ± 7.2 to 33.9 ± 10.7). The major effect was observed within the first 2 min. after cocaine administration. Animals treated with procaine showed no significant changes in either spontaneous or glutamate-evoked excitation. These data suggest that cocaine can modify spontaneous neuronal activity and glutamate-induced excitation in the cerebellum via a mechanism independent of its local anesthetic properties. Studies are underway to elucidate the role of monoamines in this action (Supported by DA 07175 and R01 RR03035 to C.A.J.R.).

666.22 THE ROLE OF NUCLEUS ACCUMBENS DOPAMINE AND EXCITATORY AMINO ACID RECEPTORS IN THE EXPRESSION OF COCAINE-INDUCED BEHAVIORAL SENSITIZATION IN RATS. R.C. Pierce*, M. Adams, B. Born, T. Duffy and P.W. Kalivas. Alcohol and Drug Abuse Program, Washington State University, Pullman, WA 99164 USA.

We monitored the behavioral response to intra-accumbally administered dopamine and excitatory amino acid agonists (amphetamine and AMPA, respectively) following repeated cocaine or saline injections. Our results indicated that both of these drugs dose-dependently enhanced behavioral hyperactivity in cocaine relative to saline-pretrained animals. In separate experiments, using doses 10-fold cocaine or saline injections, we performed in vivo microdialysis in order to determine if changes in accumbal dopamine release might underlie these behavioral effects. The biochemical data revealed that the local administration of both amphetamine and AMPA (through the probe) produced a significant concentration-dependent increase in accumbal dopamine in saline-pretrained animals. Among cocaine pretreated rats, however, there was a potentiation of accumbal dopamine release only following amphetamine administration. Taken together, these results suggest at least two distinct mechanisms that contribute to the expression of cocaine-induced behavioral sensitization: 1) a dopamine-mediated mechanism that is expressed in the putatively sensitive ability of psychostimulants to increase accumbal dopamine and 2) an increase in the functional availability of non-NMDA excitatory amino acid agonists to induce behavioral hyperactivity that is independent from the accumbal dopamine system.

666.23 THE ROLE OF GLUTAMATERGIC ACTIVITY THROUGH NUCLEUS ACCUMBENS AMPA RECEPTORS IN THE EXPRESSION OF BEHAVIORAL SENSITIZATION TO COCAINE. K. B. Bell, P. Duffy* and P. W. Kalivas. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164-6520.

Through two behavioral experiments in the rat, we examined the role of glutamatergic activity through nucleus accumbens (NA) AMPA receptors in the expression of cocaine sensitization. In experiment 1, one group received seven daily IP cocaine treatments, while a control group received an identical treatment schedule with IP saline. For all subjects, open-field locomotor activity was monitored for two hours following first and last treatments to assess the extent of sensitization. On days 20, 21 and 22 of withdrawal from treatment, each subject received bilateral intra-NA microinjection of 0, 0.3, or 1 nmol/side of the glutamate agonist AMPA. All subjects received each microinjection at least once for order effects. Subjects receiving cocaine and displaying sensitization to cocaine (order >20% increase in cocaine-induced activity and cocaine naive) were assessed at 5 min (Po 15 min) cocaine, 15 mg/kg each; showed significantly greater locomotor activity response to 1 nmol/side intra-NA AMPA than either subjects administered saline or cocaine–pretreated subjects which failed to sensitized. In experiment 2, all subjects received the chronic cocaine treatment schedule used in experiment 1. On days 14, 17, 20 and 23 of withdrawal from treatment, each subject received intra-NA microinjection of the non-NMDA receptor antagonist CNQX immediately prior to 15 mg/kg IP cocaine. In subjects which met the sensitization criterion, pre-treatment with 1 nmol/side intra-NA CNQX reduced cocaine-induced hyperactivity to the level seen in response to the first cocaine administration (p<.06). Taken together, the results of these experiments indicate that the expression of behavioral sensitization to cocaine depends, in part, upon sensitization-specific, AMPA receptor-mediated changes in glutamate transmission within the NA.
666.25  
EFFECTS OF THE METABOTROPIC GLUTAMATE RECEPTOR BLOCKER AP-3 ON COCAINE-INDUCED DOPAMINE RELEASE AND LOCOMOTOR BEHAVIOR. P.A. Vincent* and E.L. Gardner, Dept. of Pharmacology, University of Tennessee College of Medicine, Memphis, TN 38163.

Administration of Cocaine (C) has been previously shown to induce dopamine (DA) release in the nucleus accumbens (Nac) using microdialysis. We used this model to identify the neural substrates that modulated C-induced DA release, and we have studied the glutamatergic system because C-induced DA release is one of the substrates from the hippocampus, amygdala and prefrontal cortex, and Glu has been shown to interact with DA function. To study this interaction, we administered the Glu metabolite receptor blocker L-1-2-Amino-3-phosphonopropionic acid (AP-3) through a microdialysis probe placed in the Nac while monitoring DA release. No effect was seen in the Nac 15 min after the administration of 0.1 mM AP-3 (2 µM) or veh was administered to Sprague-Dawley rats treated with C or veh. DA release from animals collected every 10 min for 10 samples. Animals treated with veh and C had an increase in DA release above baseline. Animals receiving AP-3 and plus showed a 160% increase in DA. Animals receiving AP-3 plus C exhibited a 491% increase in DA, similar to C alone. In 15, 0.5, and 1.0 mM AP-3 or veh was infused through bilateral cannulae placed in the Nac 15 min prior to receiving 20 mg/kg C. In locomotor behavior was recorded for the first 2 min of 10 successive 10 min periods. Locomotor activity was not significantly diminished in animals given AP-3 plus C compared to veh plus C. These data suggest that Glu neurons may regulate the same pool of DA that C releases. Further work is needed to determine whether C-induced motor output is modulated by Glu metabotropic receptors. Supported by the Aaron Diamond Foundation.

666.27  

Dopamine, serotonin and norepinephrine transporters are recognized as the main target for cocaine reinforcement and addiction. The digitonin-activated rat brain proteins exhibited cocaine-sensitive [3H]citalopram (CTL), [3H]BFCP and [3H]GR12935 binding. A BFCP analog, reduced citalopram and an amino- cocaine analog were linked to Affigel 10 for affinity purification. They all yielded low µg quantities of proteins that retained cocaine-sensitive binding activity after fast dialysis through ultrafiltration membranes. [3H]CTL gave the largest binding signal of various transporter ligands tested. Its affinity for the serotonin transporter was not altered by solubilization, and it was always recovered in part in the three affinity fractions. The proteins eluted from the anosococaine affinity column exhibited cocaine-sensitive specific binding of [3H]BFCP, [3H]GR12935 and [3H]CTL. SDS-PAGE electrophoresis of the isolated proteins will also be presented.

666.28  

Previously we have identified a cocaine analog (RTI-121) that exhibits nanomolar affinity and high selectivity for the dopamine transporter in rat striatum. There was a high correlation (r = 0.0001) between the potencies of drugs to inhibit specific [3H]RTI-121 binding in the striatum (STR) and the potencies of these drugs to inhibit psychotomimetic effects. However, we found the potencies of these compounds to inhibit specific [3H]RTI-121 binding with either [3H]serotonin or [3H]norepinephrine uptake.

When [3H]RTI-121 binding was conducted in the frontal pole (FP) of the rat cerebral cortex several differences were apparent. While [3H]RTI-121 still bound to a high- and low-affinity site, the number of sites labeled by [3H]RTI-121 was approximately 1% that of the striatum. However, when the binding of [3H]RTI-121 observed in the FP was similar to that observed in the STR, several compounds displayed a significantly lower I50 in the FP than in the STR. These included several of the tricyclic antidepressants (imipramine, clomipramine, amitryptiline, nortriptyline, desipramine and desipramine). 

In addition, these sites showed less sensitivity to the effects of 6-OHDA which unlike striatal binding sites were almost completely eliminated by that toxin. These results suggest that [3H]RTI-121 may bind to a yet unidentified site in the cerebral cortex that may recognize cocaine and many antidepressants with high affinity.

667.1  

The losses of clozapine's (Cz) enhanced antipsychotic potency and reduced incidence of motor side effects is unknown. It is conceivable that glutamate, because of its influences on dopamine release and its participation in motor side effects, is a target of Cz's actions. The present work assessed this possibility.

Glutamatergically-mediated field potentials were monitored in striatal slices perfused with Mg2+-free artificial CSF (aCSF). These potentials were suppressed by kynurenic acid or MK-801 and were thus presumed to be mediated, in large part, by NMDA receptors. Cz, added to the aCSF, suppressed these responses in concentrations as low as 10 nM.

Since previous work showed displacement of [3H]MK-801 at much higher concentrations (K50=174µM), Cz has at least two sites of action on the NMDA receptor. The Cz concentration that suppressed responses in striatal slices was similar to that in CSF of patients for treatment of psychosis. Thus, activity at one of these sites suggests that anti-glutamatergic effects may enter into this drug's clinical profile.

667.2  
TYPICAL AND ATYPICAL NEUROLEPTICS DIFFERENTLY AFFECT FOS PROTEIN EXPRESSION IN THE RAT FOREBRAIN. A. Fink-Jensen and P. Kristensen, Pharmaceuticals Division and Biopharmaceuticals Division, Novo Nordisk A/S, Novo Nordisk Park, DK-2780 Måløv, Denmark.

The cellular synthesis of the transcription factor protein Fos is regarded as a biochemical marker of neuronal activity and previous studies suggest that the effect of the atypical neuroleptic clozapine on Fos protein expression in the prefrontal cortex (PFC) may be related to its unique effects on negative symptoms in schizophrenia (Neurosci. (1992) 46:315-328). In order to investigate if the Fos protein expression pattern induced by clozapine applies to other compounds with an atypical profile (preclinical or clinical trials), we investigated the acute effect of the atypical neuroleptics clozapine, risperidone, sertindole and NNC 22-0031 (4-(6-fluoro-1,2-benzisoxa- zol-3-yl)-1-(3-(4-methylenedioxyphenyl)carboxyl)propyl)piperidine) as well as the prototypical neuroleptic haloperidol. The Fos protein expression was assessed by using an immunohistochemical technique. The present study shows that atypical and prototypical neuroleptics can be differentiated on the basis of their ability to induce Fos protein since the ratio between Fos protein expression in the limbic PFC vs. striatal dorsolateral striatum (DLS) was higher for the atypical neuroleptics than observed with the prototypical neuroleptic.
THE ATYPICAL ANTIPTIONSYCOTIC CLOzapine IS A POTENT AGONIST AT HUMAN CHOLINERGIC MUSCARINIC m4 RECEPTORS AND AN ANTAGONIST AT m1, m2, m3, & m5 RECEPTORS. K.M. Dan, D.S. Jones, and A.D. Jones, Pharmaco- 
ie., Central Research Division, Department of Neuroscience, Groton, CT 06340.

Clozapine is an atypical antipsychotic drug that is more efficacious than conventional neuroleptics and does not produce the side effects that previous reports have shown that clozapine binds with high affinity to all 5 muscarinic receptor subtypes (Tur. J. Pharmacol. 1921:205,1991). Clozapine is an antagonist at some of these subtypes, and has been widely assumed to be an antagonist at all of them. Clinically, one of clozapine's notable side effects is hypersalivation. However, since hypersalivation and clozapine-induced dopamine turnover in rats are both inhibited by the muscarinic antagonist atropine, clozapine may have direct cholinomimetic activity (JPET 268:1452, 1994). In the present study the fractional interaction of clozapine with human m1-m5 receptors expressed in CHO cells was characterized. It was discovered that clozapine (EC50 = 75 nM) and full agonist at only the m4 muscarinic receptor subtype, producing concentration-dependent inhibition of forskolin (FSK)-stimulated cAMP accumulation. This effect could be blocked by N-methyl-scopolamine and pirenzepine in vitro. In contrast, clozapine potently antagonized agonist-induced responses at the other four muscarinic receptors. Thus, clozapine was found to block the inhibitory effect of carbachol on FSK-stimulated cAMP accumulation in m2 expressing cells as well as carbachol-induced PI turnover in cells expressing the m1, m3, m4, m5 receptor subtypes. Since the muscarinic receptor in question is found in the rat and the human brain, the present findings suggest that clozapine-induced hypersalivation as well as its effects on striatal dopamine turnover may be due to direct stimulation of m4 muscarinic receptors in these tissues. This agonist action at the m4 receptor may contribute to clozapine's atypical antipsychotic efficacy.

EFFECTS OF SUBCHRONIC CLOzapine AND HALOPERIDOL ON RATS TRAINED IN A FORELIMB TORMOR TASK. S.C. Fowler*, J.A. Stanford and S. Das, University of Mississippi, University, MS 38677.

Rats trained to extend the forelimb through a rectangular hole and exert downward pressure on a force transducer received either the atypical neuroleptic clozapine or the typical neuroleptic haloperidol for 11 consecutive days. Doses were individually titrated daily for each rat in an attempt to achieve a 50% reduction in force on task (TOT). Clozapine treated rats exhibited dramatic tolerance to the drug's suppressive effect on TOT. In contrast, haloperidol treated rats displayed little tolerance. Despite the accentuated tolerance reflected by TOT in the face of escalating doses of clozapine, no tolerance was seen in clozapine's marked slowing of the dominant frequency of oscillations in forelimb force as measured by Fourier analysis of the force-time recordings. Haloperidol did not produce the oscillation slowing. The dissociation between the tendency to respond (TOT) and the oscillator slowing observed for clozapine may reflect effects at different neurotransmitter receptor sites. Supported by MH43429.

LIKE CLOzapine, OLanzapine SLOwS Rats' FORELIMB FREQUENCY OSCILLATIONS IN A PRESS-WHILE-LICKING BEHAVIORAL TASK. J.A. Stanford* and S.C. Fowler, Univ. of Mississippi, University, MS 38677.

Rats were trained to press a force-sensing transducer with one forelimb while licking (water fountain) task while initial peak force (PF), hold force (HF), force frequency oscillations (FREQ), and time-on-task (TOT) were measured. Following extensive experience on the task, subjects were administered olanzapine (OL, 0.5, 1.0, 2.0 mg/kg), a candidate atypical neuroleptic. OL significantly decreased TOT dose-dependently and had a significant slowing effect upon FREQ as quantified by Fourier analysis. These results were compared to clozapine's (CL) similar effects on the same measures previously reported in the task and with haloperidol's (HAL) FREQ acceleration (Fowler, et al., Psychopharmacology, in press). Since typical neuroleptics such as HAL tend to induce motor side effects such as tremor, these findings may reflect the antitremor and atypical properties of OL and CL. Supported by MH43429.

Although clozapine (CLZ) has been shown to be superior to conventional neuroleptics in the treatment of schizophrenia, CLZ's mechanism of action has yet to be completely delineated. A two-lever drug discrimination procedure was employed in order to more precisely characterize the effect of CLZ on the cholinergic system on the discriminative stimulus properties of clozapine. Evidence for both muscarinic and nicotinic effects at CLZ's site has been demonstrated in previous studies. Because many of these cholinergic drugs show high binding affinity for cholinergic receptors, two discrimination groups were trained. One group was trained to discriminate CLZ (5.0 mg/kg, ip.) from vehicle, and another group was trained to discriminate OXO (0.125 mg/kg, ip.) from saline. Male Sprague-Dawley rats (85% B.W.) were used in 15 min. sessions under a FR50 schedule of food reinforcement. After generalization testing with CLZ-trained rats the drug was coadministered with OXO at the 10.0 mg/kg dose (99.3%) in the SCP group (ED50 = 0.690) and peaked at 2.5 mg/kg (97.0%) in the CLZ group (ED50 = 0.751). Complete generalization with OXO was observed in both groups. In the SCP group, the 10.0 mg/kg dose produced peak substitution (ED50 = 3.513). In the CLZ group, the 1.25 mg/kg dose produced maximal DLR (99.7%) (ED50 = 0.114). Methylcholine (MSP) substitution testing and antagonism of the CLZ-cue with oxotremorine (OXO) were also assessed in the CLZ group. MSCP did not substitute for CLZ at any dose. MSCP (1.5 mg/kg) was coadministered (ie., to block the peripheral effects of OXO) with OXO (0.0325, 0.0625, and 0.125 mg/kg), and the highest dose of OXO caused CLZ-DLR to decrease from 96.1% to 67.6%. Results from this study support the notion that the clozapine discriminative stimulus properties in rats are mediated by antagonism at muscarinic receptors.

ASSESSMENT OF CLOzapine's SUBCHRONIC DOSE EFFECTS ON FORCE, DURATION, AND RHYTHM OF LICKING IN RATS. Shyamal Das* and S.C. Fowler, University of Miss., 1921:205,1991). Three doses (1.5, 3.0, 4.5 mg/kg, ip, 45 min) of the atypical antipsychotic clozapine were studied in a subchronic dosing paradigm (at least 7 consecutive days at each dose with 4 or more vehicle only days separate dosing periods) in order to evaluate potential tolerance or sensitization effects in rats. Thirsty rats (n=20) licked water from a force-sensing disk while force-time waveform licking were recorded for a 2-min session. Lick rhythm was quantitated by applying Fourier methods to the force-time waveform records. Behavioral measures were peak force and duration of individual licks and number of licks. 3.0 mg/kg produced a 4.5 mg/kg, modest, but significant, tolerance effects emerged. 1.5 mg/kg produced sensitization effects, and the lick rhythm was the variable most affected by the drug as measured by omega squared. Clozapine's powerful effects on lick rhythm are unlike those of haloperidol (Fowler & Das, PBR, in press) and may reflect effects at serotonin receptors on the hypocoglossal nucleus. Supported by MH43429.

SELF DESTRUCTIVE BEHAVIOR AND CLOzapine DISCONTINUATION. F.G. Moeller*, S.W. Chen*J.0el, Steinberg, M.D.2,3, M. Fulton, 2,3, P. Petty, W.G. Ripper, S.D. Garver, 3, 1 University of Texas Houston Health Science Center 1300 Moursund, Houston TX 77030, 2 Dallas VAMC 3. Univ. of Texas Southwestern Med. School at Dallas. The atypical antipsychotic clozapine has been effective as well as a dopamine antagonist. There have been reports that clozapine induces depressive symptoms in some patients and it has been speculated that this increase is due to the serotonin antagonistic effects of clozapine. In order to determine if patients with pre-existing suicidal or self mutilative ideation or behavior were more likely to have a poor outcome with clozapine than patients without this behavior, logistic regression was performed on data obtained from 729 patients treated with clozapine in the VA hospital system. Variables analyzed in the regression included age, sex, race, prior history of treatment failure, presence of suicidal behavior in the past month or ever in the past, and presence of self mutilative behavior in the past month or ever in the past. Of the 729 patients in this study 32 (4.3%) had suicidal ideation or behavior in the month prior to starting clozapine, 337 (46.2%) had suicidal ideation or behavior ever in the past, 32 (4.4%) had self mutilation in the past month, 337 (17.8%) had self mutilation ever in the past. There was an significant effect of suicidality or self mutilatory behavior on clozapine discontinuation in the logistic regression model. There was no significant correlation with other variables which have been reported previously. Our study does not support suicidality or self mutilatory behavior as increased risk factors for poor outcome with clozapine.
667.1.

**SELECTIVE ACTIONS OF THE NOVEL ATYPICAL ANTI精神病IC DRUG AMPERODIZE IN THE LIMBIC FOREBRAIN.**

Amperodize (APZ) exhibits a multireceptor profile with high affinity for 5-HT, receptor, relatively low affinity for dopamine (DA) receptors, and a rather marked limbic selectivity of action. Recently, in vivo microdialysis studies have revealed that APZ induces a more pronounced increase in DA concentrations in the medial prefrontal cortex (MPC) than in the nucleus accumbens (NAc) or striatum, antagonizes the DA response to amphetamine, but not with classical antipsychotics. This effect of APZ may be due to its selective 5-HT and DA-D2 receptor antagonistic properties. By employing in vivo voltammetry and Fos immunohistochemistry, we examined the effects of APZ on DA concentrations in two subsets of the NAC, the shell and core, that are associated with limbic and striatal functions, respectively, and on c-fos expression in the limbic forebrain and the nucleus accumbens. APZ (1.0 and 2.0 mg/kg), iv, almost exclusively increased DA concentrations in the NAC-shell compared to the core. Similar results were obtained with ritanserin but not with raclopride, which instead increased c-fos expression in both parts. The number of Fos-positive neurons was significantly increased by APZ (5.0 and 10 mg/kg, sc) in the MPC and the lateral septum but not in the striatum of the NAC. Thus, APZ shows a somewhat clozapine-like profile as regards also its effects on c-fos expression in the forebrain. These results emphasize amperodize's limbic selectivity of action, the importance of 5-HT receptor antagonism for such an effect, and strengthen the hypothesis that the therapeutic profile of atypical antipsychotics may be related to their distinctive effects in the mesolimbicocortical dopaminergic system.

667.13.

**DIFFERENTIAL EFFECTS OF ANTISPISYCHIC DRUGS ON EXTRACELLULAR GABA LEVELS IN THE VENTRAL PALLIDUM AND GLOBUS PALLIDUS OF RATS.**

M.A. Chapman* and R.E. See, Department of Psychology, Washington State University, Pullman, WA 99164-4421.

Antipsychotic drugs (APDs) are believed to treat schizophrenia through their effects on mesolimbic dopamine (DA) pathways and produce motor side effects via effects on nigrostriatal DA pathways. In order to these APD-induced changes to affect behavior, neurotransmitter levels must be altered in the output nuclei of these two systems. To test this hypothesis, female, Sprague-Dawley rats were given a subcutaneous injection of haloperidol (1.0 mg/kg), clozapine (30.0 mg/kg), or metoclopramide (10.0 mg/kg). Intracerebral microdialysis was used to assess GABA levels simultaneously in the ventral pallidum and globus pallidus, regions which receive major GABAergic projections from the mesolimbic and nigrostriatal dopaminergic systems. The ventral pallidum, GABA, was analyzed using o-phthalaldehyde derivatization followed by high-performance liquid chromatography with electrochemical detection. Both haloperidol and metoclopramide increased extracellular GABA levels in the globus pallidus, while clozapine decreased GABA in this region. Clozapine also decreased extracellular GABA levels in the ventral pallidum, whereas haloperidol and metoclopramide had no effect. These results suggest that increased extracellular GABA levels in the globus pallidus may be related to the motor side effects of these drugs, while decreased GABA levels in the ventral pallidum may be related to the unique clinical profile of clozapine.

(Supported by NIH grant MH10644 to M.A.C. and DE9678 to R.E.S.)

The predictive validity of catalysis as a rodent model for detecting EPS of antipsychotic drugs was re-examined when this novel antipsychotic saxopenex produced little catalysis in rodents while producing significant EPS in schizophrenic patients. Because catalysis is viewed as an important model for predicting EPS, we decided to re-evaluate the effects of saxopenex. Saxopenex, haloperidol, clozapine, raclopride, risperidone and ORG 2522 were examined in this test for catalysis (Grip Tests) in male Sprague-Dawley rats. The ability to antagonize amphetamine-induced hypermotility was also examined since this measure is believed to predict clinical efficacy. With the exception of dopamine, all drugs produced dose-dependent catalysis in both tests. For each drug, the MEDs for producing catalysis were greater than those necessary for antagonizing amphetamine-induced activity. Clozapine demonstrated the widest separation of MEDs in the catalysis and activity models while haloperidol showed the narrowest separation. This is consistent with the clinical effects of haloperidol (severe EPS) and clozapine (mild EPS). The ratios of MEDs in catalysis and activity for the remaining novel drugs fell between haloperidol and clozapine; this is consistent with the preliminary clinical findings indicating some EPS with each of these compounds. Thus, catalysis remains a suitable rodent model for detecting compounds with EPS liability in humans.

In order to validate the hypothesis that atypical neuroleptics are far more potent in the olfactory tubercle (OT) than in the nucleus accumbens (ACC; Behav. Pharmacol. 3, s18, 1992), we investigated to what extent risperidone, sertindole, olanzapine, ORG 2522 and promethazine, v. all respond claims as atypical neuroleptics, differentially attenuate locomotor activity elicited from the OT and the ACC respectively. First, we used the so-called paw-test to identify the atypical profile of these compounds. (In all these studies, the dose required for enhancing hindlimb retraction time (HRT) was lower than that required for enhancing forelimb retraction time (FRT), underscoring the atypical profile of the tested compounds. Second, the ability of intracerebral administration of the drug (0.5 μL) to attenuate locomotor activity elicited either by dopamine injections (10 μg/0.5 μL) into the OT or by ergotamine injections (1 μg/0.5 μL) into the ACC was compared. Following normal habituation procedures, dose-effect curves (1 μg - 10 μg) were made, using computerized recordings. Using the ratio of the minimum effective doses (OT : ACC), it was found that all compounds were far more potent in the OT than in the ACC. It is concluded that neuroleptics with an atypical profile are far more potent in the olfactory tubercle than the nucleus accumbents; the reverse holds true for classical neuroleptics.

EPILEPSY: ANTICONVULSANT DRUGS—OTHER NEUROTRANSMITTER RECEPTORS

The recently launched anticonvulsant lamotrigine was investigated on TTX-sensitive Na+ currents (I_h) and on spontaneous activity in in vitro models of epileptogenesis, relevant to post-injury, carbamazepine resistant or pentobarbital. All recordings were performed on hippocampal cell cultures using whole cell patch clamp. Sodium currents were activated by membrane depolarization, with the threshold for a greater than 400 μA peak I_h being reversibly depressed in a voltage dependent manner by bath application of lamotrigine. The block of I_h was voltage dependent, with voltage command pulses to 20 mV being increased from 125% (in 2 μM lamotrigine) to 574% (in 20 μM lamotrigine) by lamotrigine. L-V curves of 100% inhibition in 5-μM lamotrigine and 1 (250 μM) reduced lamotrigine to 92% 2% (n=8) and 18.5% (n=7) of control values, respectively. The EC50 value was 28.1 μM at a stimulus frequency of 0.1 Hz. The depolarization of sodium currents by lamotrigine (50 μM) was use dependent, in that raising the stimulus frequency from 0.1 to 5 Hz reduced the peak amplitude of I_h by additional 12% (n=7). In current clamp experiments, the shift in resting membrane potential, high spontaneous activity of neurons as well as paroxysmal discharge pattern observed in the presence of high potassium (7.5 mM) or zero Mg2+ was significantly reduced by lamotrigine, phenytoin and propantabarbital (all tested at 50 μM). This study demonstrates, that lamotrigine and carbamazepine, lamotrigine acts as a voltage dependent sodium channel blocker at therapeutic concentration, which might contribute to the reported reduction of glutamate release.

BW 1205U90 ((cis)-2-(4R-(4,4-dimethyl-3,3-diphenyl-3-piperazinyl)-isobutyryl)-5, 6, 7, 8-benzenethiophenan-2-one hydrochloride) was synthesized as part of a program to develop antipsychotics with reduced liability for extrapyramidal side effects (EPS). It bound to 5-HT4 receptors (IC50 = 0.9 nM), more readily than to dopamine D2 receptors (IC50 = 1.6 nM) and also bound to 5-HT4 and adrenergic α1 receptors potently. In mice, BW 1205U90 antagonized climbing (efficacy) and stereotyped behavior (potency) with apomorphine with pEC50s = 674 and 74 mg/kg p.o., and 0.04 and 0.6 mg/kg s.c., respectively. The ED50 for induction of catalepsy (which predicts EPS) was 58 mg/kg p.o. Head switches in mice induced by the serotonin 5-methoxytryptamine-aminergic were antagonized with ED50 = 2.0 mg/kg p.o. and 0.03 mg/kg s.c. In rats, BW 1205U90 blocked apomorphine-induced circling in subjects with unilateral 6-hydroxydopamine lesions of the striatum (ED50 = 1.1 mg/kg p.o.) and antagonized apomorphine-induced stereotyped (ED50 = 3.3 mg/kg p.o.). Apomorphine-induced disruption of prepulse inhibition of acoustic startle reflex was antagonized at 0.2 mg/kg p.o. and conditioned avoidance response was inhibited with an ED50 = 0.05 mg/kg s.c. Shaking behavior induced by the serotonin precursor 5-hydroxytryptophan, was antagonized (ED50 = 0.8 mg/kg p.o.). BW 1205U90 antagonized 5-HT2-mediated effects more potently than D2-mediated effects. It was potent to tests predictive of antipsychotic efficacy, but much less potent in tests for EPS.
Further evidence that serotonin plays an anticonvulsant role in genetically epilepsy-prone rats (GEPRs). Q.S. Yan, P. C. Jibe, and J. W. Dailey, Department of Basic Sciences, University of Illinois College of Medicine at Peoria, Peoria, Illinois 61656.

Preceding reports in this laboratory indicate that fluoxetine, a selective serotonin uptake inhibitor, has anticonvulsant effects in genetically epilepsy-prone rats (GEPRs). Also, the protection against audiogenic seizure following the administration of fluoxetine appears to be selectively correlated with enhanced serotonergic transmission (Dailey et al., 1992; Yan et al., 1994). An important question raised by these findings is whether the anticonvulsant action following the administration of the serotonin uptake inhibitor in GEPRs is peculiar to fluoxetine. This study was designed to evaluate further the role of serotonin in regulating susceptibility and/or severity of audiogenic seizures in GEPRs. For this purpose, sertraline, another highly selective and potent inhibitor of serotonin uptake, was studied. Sertraline was found to be comparable to fluoxetine in preventing audiogenic seizure in GEPRs. These findings provide further support for the concept that serotonin plays an anticonvulsant role in GEPRs.

Gabapentin (GBP), 1-(aminomethyl) cyclohexane-acetic acid, is a new anticonvulsant drug which is used clinically in the United Kingdom and the United States, but its mode of action is unknown. The antiepileptic properties of GBP were initially predicted because it is a structural analogue of the inhibitory amino acid neurotransmitter γ-aminobutyric acid (GABA). However, it lacks agonist and antagonist properties at both GABA_A and GABA_B receptor sites, and does not appear to block GABA uptake. GBP has been shown to increase the apparent rate of synthesis of GABA in several brain regions, and enhanced promoted release of GABA following GBP treatment has been observed in neonatal rat hippocampus. Here we present electrophysiological experiments in the rat hippocampal slice preparation that GBP treatment enhances the release in excitatory postsynaptic potentials (EPSPs) elicited by promoted GABA release with nipeptic acid (NPA). NPA blocks both uptake of GABA and promotes release by heteroexchange through the GABA transporter. GBP had no effect on the normal excitability properties of the hippocampus. We suggest a novel mechanism for the antiepileptic properties of GBP whereby there is enhanced nonvesicular release of GABA possibly through reverse operation of the GABA transporter at times of intense electrical activity.

D-23129 (N-2-amino-4-4(4-fluorobenzylamino)-phenyl)proionic acid ethyl ester, Asta Medica AG, Germany, ADD230001) is a promising new anticonvulssant compound under investigation in the Antiepileptic Drug Development (ADD) Program. Recently, this compound was also shown to have some unique properties in suppressing in vivo epileptiform activity in rat hippocampal slices (W.D. Yonekawa et al., Soc. Neuropsy. Abstr. 17:117). Here we present electrophysiological experiments in the rat hippocampal slice preparation that GBP treatment enhances the reduction in excitatory postsynaptic potentials (EPSPs) elicited by promoted GABA release with nipeptic acid (NPA). NPA blocks both uptake of GABA and promotes release by heteroexchange through the GABA transporter. GBP had no effect on the normal excitability properties of the hippocampus. We suggest a novel mechanism for the antiepileptic properties of GBP whereby there is enhanced nonvesicular release of GABA possibly through reverse operation of the GABA transporter at times of intense electrical activity.

Way10135 antagonizes the serotonin-mediated inhibition of epileptiform activity in hippocampal CA1 neurones. Delanty Salgado*, and Karim A. Alkudhi, Department of Pharmacology and Neuroscience, University of Houston, Houston, TX 77204-5515 USA.

Previous studies conducted in our laboratory have shown that serotonin inhibits epileptiform activity (Salgado and Alkudhi, Soc. Neurosci. Abstr., 764.4, 1993). In addition, experiments done thus far suggest that the serotonin-mediated inhibition of epileptiform discharge is due to activation of the 5-HT1A receptor subtype. The purpose of this study was to provide more conclusive evidence regarding the involvement of the 5-HT1A receptor in the inhibition of epileptiform activity. Thus we used the new, selective 5-HT1A receptor antagonist, WAY10135. We employed conventional electrophysiological techniques for intracellular recording from CA1 neurones in the rat brain slice preparation. Initial experiments demonstrated that WAY10135 (10 pM) prevents the serotonin-mediated hyperpolarization, decrease in membrane resistance and current-induced action potential bursts. Furthermore, the serotonin-mediated suppression of bicuculline-induced epileptiform bursts was also antagonized in the presence of WAY10135. The results obtained thus far strongly suggest that activation of 5-HT1A receptors in hippocampal CA1 neurones can suppress epileptiform activity. This study suggests that treatment of epilepsy may be possible with agents selective serotonin 5-HT1A receptor sites on hippocampal CA1 neurones.

The effect of elevated GABA levels on the gial enzyme glutamine synthetase (GS) was examined in rat brain. Repeated daily s.c. injections of the GABA-transaminase inhibitor, gamma-vinylGABA (GVG), an anti-epileptic medication, produced a gradual decline in brain GS activity. After 21 days, cortical GS activity was reduced 36% with 150 mg/kg per day and 9.5% with 30 mg/kg per day compared to saline-injected rats. Cerebellar GS activity was reduced by 22% with 150 mg/kg and unchanged with 30 mg/kg. Skeletal muscle and liver GS activities were unaffected. Cortical GABA levels were increased by 170% after 150 mg/kg for 21 days but were unaffected at 30 mg/kg. Glutamine and glutamate levels were significantly reduced only at the 150 mg/kg dose. GS mRNA levels were unaffected, as shown by Northern analysis. Levels of GABA in liver were maximally elevated even after this short dosing interval. The delay in the effect of GVG on GS may be related to the slow turnover of this enzyme in vivo. The glutamine cycle, which provides substrate for neuronal GABA and glutamate synthesis, may be down-regulated by chronically elevated GABA. The reduction in GS activity appears to decrease brain glutamine production and thereby may limit transmitter glutamate synthesis and contribute to the anti-epileptic effect of GVG.

Novel mechanism of action of anticonvulsant alkyl-substituted thiobutyrolactones: reduction of neuronal Ca current. J.A. Fernandelli*, D.A. Gross*, D.C. Cowey*, and R.W. Subpals*, Jr. Dept. of Neurology 2 and Pharmacology 1, The University of Texas Health Science Center, St. Louis, MO, University of Minnesota, Minneapolis, MN.

Alkyl-substituted thiobutyrolactones (TBLS) produce either convulsant or anticonvulsive effects by modulation of the picrotoxin (PTX) GABA_A receptor. Because of structural similarity to ethosuximide, an antiepileptic drug that blocks T-type Ca currents, we tested the effects of the anticonvulsant a-ethyloctanal-thiobutyrolactone (a-EMBL) on Ca currents of cultured DRG and nociceptive neurones.

Whole cell Ca currents were evoked at +10-20 mV in media which blocked Na and K currents, with 5 mM Ca as the charge carrier. Effects on Ca channel subtypes were assessed (a-EMBL) and a-conotoxin GIVIA (N-type) and a-conotoxin IVIA (P-type). a-EMBL (500 μM) had a voltage-dependent effect: high-threshold DRG currents were reduced ≤ 10% when evoked from -40 mV, but by 30-50% when evoked from -40 mV. Current inactivation was increased, with a greater effect on currents evoked from more polarized potentials. Nociceptor currents were similarly affected. In DRG neurones, 10 μM a-conotoxin GIAB reduced Ca currents ~50% and 500 nM a-conotoxin IVIA reduced currents ~15%; 10 μM nifedipine reduced currents 10-15% at -40 mV and 40% at 40 mV. None of these, used alone, significantly affected the action potentials evoked by a-EMBL. These data suggest that a-EMBL may have a second mechanism of action, reduction of neuronal Ca currents. This is relatively non-specific for channel subtypes and may mediate neuronal excitation.

**RHOBITION OF MAXIMAL ELECTROSHOCK (MES) SEIZURES BY A1 ADENOSINE RECEPTOR AGONISTS.** J.B. Weizer and S. Zimling, Gernisa, etc., San Diego, CA 92121.

Adenosine receptor agonists exert anticonvulsant activity in a variety of animal models, including those involving chemically-induced seizures, audiogenic seizures, and kindled seizures. However, Little information exists concerning their activity on the maximal electroshock seizure. Since the efficacy profile in such seizure models are often believed to predict efficacy in clinical seizure types, we investigated the effect of adenosine agonists in MES seizures, as a way to model seizure induced by s.c. pentyleneetrazole (PTZ). We also investigated effects on blood pressure, body temperature, and motor performance. Extensive criteria (80 Hz, 0.2 seconds) was delivered via coronal electrodes at 150 V in rats and 50 mA in mice at 20 min after i.p. administration of each agonist. The A1 receptor agonists cyclopentyladenosine, R-phenylisopropyladenosine, 2-chloroadenosine, and N6-cyclohexyladenosine, dose-dependently inhibited MES seizures in both species. Respective ED50 values (mg/kg) for MES in rats were 2.3, 3.7, 3.6, 5.7 and 10.1. Respective ED50 values for MES in mice were 1.7, 3.6, 13.4, 8.2, and 73.8. The A2 selective agonist CV18008 was ineffective at doses of up to 10-50 mg/kg. The A1 agonists also inhibited PTZ seizures with respective ED50 values in brain, 4.5, 11.0, and 9.1 (mg/kg). The A1, 1.7, 0.6, 5.7, 3.2, and 0.1 (mg/kg). All of the A1 agonists induced substantial kinetic or static effects at anticonvulsant doses. In addition, the ED50 dose (2.3 mg/kg) of cyclopentyladenosine in conscious rats decreased blood pressure and heat rate by approximately 60% and decreased body temperature by 4-6°C.

These results show adenosine receptor agonists possess anticonvulsant activity in the maximal electroshock model in rats and mice, indicating potential utility of an adenosine agonist approach in generalized tonic-clonic seizures in man. However, the clinical efficacy of direct A1 agonists will be limited if similar side effects are found in man.

**THE PHENYLCARBAMIC ACID ESTER D-23129 IS HIGHLY EFFECTIVE IN EPILEPSY MODELS FOR GENERALISED AND FOCAL SEIZURES AT NONTOXIC DOSES.** C. Töber, C. Rundfeldt*, A. Rostock and R. Barths, Arzneimittelwerk Dresdon GmbH, Department of Pharmacology, Meilner Str. 191, 01445 Kadele, FRG.

Complex partial seizures comprise the major uncontrolled seizure type in adult patients with epilepsy. New anticonvulsants should not only reduce seizure severity but also suppress focal seizure activity for full seizure protection. The goal of this study was to demonstrate that D-23129 is capable to suppress focal seizure activity at nontoxic doses. The broad efficacy of D-32441, the hydrazide derivative of D-23129 (N-[2-Aminomethyl-4-(4-fluorobenzyl) phenyl]carbamic acid ester), was shown previously (Nickel et al, Epilepsia 34, Suppl. 2, 95, 1993). We could now demonstrate that D-23129 and D-23128 are equipotent to the toxic extension of hind limb in the maximal electroshock test in mice (ED50 18.2 and 17.4 mg/kg i.p., respectively); both compounds also nearly doubled the threshold for clonic seizures in the i.v.-model after administration of 15 mg/kg i.p. and suppressed audiogenic seizures in DBA/2 mice at 3 mg/kg. D-23129 reduced not only kindled seizure parameters after supramaximal stimulation but also increased the threshold for induction of afterdischarges indicating a suppression of focal seizure activity in a dose dependent manner. After oral administration of 10 mg/kg 60 min prior to testing all animals were seizure protected if stimulated with double the individual seizure threshold. The afterdischarge threshold was increased to 408 and 597% of control threshold after 10 and 15 mg/kg respectively. After 15 mg/kg all seizure parameters were significantly reduced after suprathreshold stimulation and no motor impairment was present. First electrographical data indicate that part of the effects of D-23129 is mediated through effects on voltage gated Na+ and Ca2+ channels. The results make D-23121 a promising candidate for treatment of generalized and complex partial seizures.

**DEGENERATIVE DISEASE: ALZHEIMER’S—BETA AMYLIOD XI**

**669.3**

Deposition of the 4 KD Aβ peptide, by proteinolytic cleavage from the amyloid precursor protein (APP), in brain is a neuropathological hallmark of Alzheimer’s disease (AD). Expression of full length human APP in brains of animals should provide a model system for studying proteinolytic processing of APP in vivo. These animals also serve as a basis to address parameters required for the development of B-amyloid related neuropathologies in man. We have generated transgenic mouse and rat lines harboring full length human APP transgenes containing native splice site and genetic mutations linked to familial AD (Aβ1-42, ΔNle233/234) and hereditary cerebral hemorrhage with amyloidosis-Dutch type (Aβ693). Human APP transgene RNA and protein occurs predominantly in brain. In situ hybridization studies show human APP enriched in neurons. Evidence for proteolytic cleavage of human APP in mouse brain which is required for Aβ production has been obtained using antibodies specific for human APP fragments. Recent evidence has implicated apolipoprotein E in the pathogenesis of AD. Apolipoprotein allele E4 cosegregates at high frequency with late-onset and sporadic AD. To study the role of apoE in amyloid deposition we have generated transgenic lines expressing both human apoE and Aβ. Characterization of these lines and results from our ongoing search for amyloid-related neuropathologies in a transgenic mouse and rats will be presented.

**669.4**

**APOLIPOPROTEIN E REGULATES APP LEVELS.** Benjamin Wolozin*, Robert Carbon, Yongqiang Chen, Robert Culver, Todd Futterer, Tony Sunderland, and Robert Greenberg. Lab. of Clinical Science and Lab. of Biochemical Genetics, National Institute of Mental Health, Bethesda, MD 20892.

Recent studies have shown that the apolipoprotein E (apo E) allele, e4, is an important risk factor for Alzheimer’s disease. Previous studies showing that Apo E binds to B-amyloid, in vitro, and associates with neuritic plaques, in vivo, also the risk may be due to a genetic association between B-amyloid and apo E (W. J. Strittmatter, et al, 1993 PNAS 90:8086). However, the mechanism for this association is unclear because the affinity of Apo E for B-amyloid is low. We have shown that apolipoprotein E is a potent regulator of APP levels in cell culture, being active at levels as low as 30 nM. Addition of apolipoprotein E or HDL to PC12 cells grown in serum-free medium increased the expression of both secreted and cellular amyloid precursor protein (APP) in a dose-dependent manner by up to 65%, with an IC50 of 30 nM. Blockade of protein processing with 1 mM brefeldin A, 60 mM chloroquine or 10 μg/ml leupeptin prevents this, which suggests that internalization and catabolism of APP or Apo E is necessary for this process. These data point to a physiologic role for apo E in the regulation of APP and suggest that binding of apo E to APP may be the first step in the association between Apo E and B-amyloid.

Two apolipoproteins, apoE and apoJ, have been recently shown to be associated with Alzheimer's disease (AD). It has been proposed that apoE is an AD pathophysiological chaperone protein, acting to modulate and/or stabilize a β-plaleted sheet structure in AD. Consistent with this hypothesis, there is a linkage between apoE4 isotype and late onset Alzheimer's disease. On the other hand, apoJ has been shown to be complexed to Aβ in cerebrospinal fluid. Aβ, apoE and apoJ are present in senile plaques; however, their origin is not known. We have studied the behavior of these three components at the BBB level. An "in vivo" brain perfusion technique and capillary depletion method were used to determine cerebrospinal fluid and BBB transport of [125I] labeled apoJ, apoE and synthetic Aβ1-40 in guinea pigs. A saturable specific binding and transcellular BBB transport were demonstrated for all components although both apolipoproteins exhibit different BBB transport behaviors. After 10 min perfusion, the volume of distribution for apoJ was 4.5 times higher than for apoE. Pre-perfusion with a very low dose of cold apoJ completely blocks the transport, indicating a high affinity interaction.

669.7 BRAIN CLUSTERIN (AP0-J) AND ITS INTERACTION WITH β-AMYLOID (AB) (A) G.M. Pavlides*, T. Oda, H.A. Johnson, C.E. Finch. Andrus Gerontology Center Neurogerontology Division and Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191.

The senile plaque contains aggregations of β-amyloid (AB). In addition to aggregated AB, senile plaque contains other proteins that may be pertinent to neurodegeneration, particularly complement proteins and the putative complement inhibitor, clusterin. We purified clusterin from Alzheimer's disease (AB) cerebral cortex by column chromatography (DEAE, antibody affinity and HPLC size-exclusion). Brain clusterin presented slightly smaller species about 35-40 kDa vs. purified serum clusterin (39-42 kDa), under reduced conditions. In the inhibition of complement-mediated hemolysis, brain and serum clusterin were indistinguishable. Aggregation of AB1-42 was assayed by centrifugation with [125I]-AB1-42 and gave 30% sedimentable Aβ (48 hrs, 29°C, pH 7.0). Clusterin showed a concentration-dependent inhibition of AB sedimentation. Supported by Alzheimer's Association grant to GNP and by grants to OEF from NIA AG-7909 and Sankyo Co.

669.8 ALZHEIMER'S Aβ AND APOLIPOPROTEIN J INTERACTION. E. Matsubara, B. Frangione, J. Ghiso*. Dept of Pathology, NYU Medical Center, New York, NY, 10016.

Peptides with the same amino acid sequence as Alzheimer's amyloid B (AB) exist as a normal soluble protein (sAB) in biological fluids. Hence, a key question is what factors alter sAB in the disease state, promoting conformational changes, amyloid fibril formation and cell death. Biochemical and immunohistochemical studies have shown 1) sAB and ApJ bind sAB under different conditions in vitro, and 2) sAB is complexed to ApJ in vivo. We have further characterized the interaction ApJ-sAB with purified ApJ and immobilized Aβ1-40 on a solid phase on capture ELISA experiments. The binding ApJ-Aβ1-40 was saturable and specific. When the preformed complex was offered to Aβ1-40 complete binding inhibition was achieved, indicating complex stability in physiologic solutions. Solid phase competitive inhibition assay using other plasma/cerebrospinal fluid proteins with demonstrated avidity for ApJ (ApoE3, ApoE4, α1-antichymo-trypsin, Transthyrein, Vitronectin) showed that none of these completely displaced apoJ from the complex up to 100 molar excess. Only ApoJ at high molarity (approximately 60 molar excess over apoJ) partially competes with ApJ for Aβ. The data support the notion that the association ApJ-Aβ may play a role in the transport and delivery of sAB.

**670.5** UNILATERAL INTRACAROTID ADMINISTRATION OF MPTP IN NONHUMAN PRIMATES: EFFECT ON DIFFERENTIAL SUBSTANTIA NIGRA CELL LOSS, R. Assenti, K.D. Terry, N. Oreski*, RAE Bakay, Department of Neurosurgery, Emory University, Atlanta, GA 30322.

Behaviorally, the similarities between the MPTP non human primates model and Parkinson's disease (PD) are quite striking. MPTP's neurotoxicological effects (specifically loss of dopaminergic neurons in the substantia nigra have been studied in a manner similar to that used to study human PD, and meaningful comparisons have been difficult to obtain. In this study, rhesus (Macaca mulatta) monkeys (N=12) with MPTP administration (1 mg/kg by IP injection on 1-20 days) and unilateral intracarotid (left side) injections of MPTP (0.5mg/kg over a 20 minute period). The monkeys were observed for at least 6 months with saline on TBI (10 months) and then sacrificed. The monkeys were tested for various dopamine related parameters (range: 1-3 years old). Normal monkeys (N=9) with ages ranging 1 to 24 years of age were examined in a similar fashion. Serial sections of the midbrain were obtained and immunocytochemically processed for tyrosine hydroxylase (TH). From these sections, the number, size, and nuclear diameters and cell volume were measured in A8, A9 (dorsolateral, dorsomedial, ventralateral, ventromedial), A10 parasympathetic nucleus and A10 total areas using a computerized image analyzer and corrected according to the Abercrombie formula. No difference in cell counts was observed in comparing the left and right sides of the normal monkeys. A trend in cell loss according to age was observed in both normal (dorsolateral A9) and MPTP treated (ventralateral A9) animals. The most consistent results were obtained using the A9 (ventralateral) area. The relative mean TH cell loss in the A9 area (pars compacta) compared to the mean values observed in the normal monkeys was: dorsolateral A9: -82.3%; dorsomedial A9: -73%; ventralateral A9: -90.1%; ventromedial A9: -96.6%. Age: total A9: -42.2% (p<0.000). Relative cell loss in A8 was 68% and in A10 (ventral medial area) total: 74% with a p<0.05. There was no significant cell loss observed in A10 parasympathetic nucleus. The analysis of our data demonstrates that the greatest amount of TH cell loss occurred in the raphe nucleus, MPTP, occurs in A9, and most severely in the ventralateral area of A9. Importantly, this is an area that has been shown to be most affected in human Parkinson's disease. Supported by USPHS Grant RR00165 and NINDS NS253430.

We hypothesized that MPP+, accumulated in dopaminergic synaptic vesicles during repeated treatment with subtoxic doses of MPTP, could be released by high subtoxic nigral toxin, yielding a toxic concentration of MPP+. Animals were treated with MPTP iv. 3 times/wk at 0.1 mg/kg for 8 weeks (low dose; total dose 1.24 mg/kg) or at 0.1 mg/kg for 4 wks (high dose; total dose 3.6 mg/kg). At the end of dosing, one of the high dose group was sacrificed. Remaining high and low dose animals were challenged with MPTP (25 mg/kg sc.) 3 times per day for 4 days. Neuropeptide markers were assessed. Controls got 8 saline, TBZ, then 4 wks recovery. The repeated treatment pattern caused a dose-related decrease in striatal dopamine (DA) 4 wk after treatment and a loss of striatal DA. The substantia nigra pars compacta (SNc) markers were largely intact, but swollen, degenerating cells were evident. The high dose animals showed >90% reduction in striatal DA and marked SNc cellular pathology (e.g. swollen, distorted or pyknotic neurons with disintegrating processes). Animals in the high dose group sacrificed immediately after the 2 month dosing period showed a modest reduction (38%) in striatal DA and minimal damage to the SNc. Challenge with TBZ following subchronic low dose MPTP caused ptox, but did not enhance the toxicity of MPTP. These observations suggest that degeneration progressed following the end of MPTP dosing, but was not enhanced by TBZ treatment. Adrenal MPP+ levels were not related to cumulative MPTP dose or survival time. While all treatment groups receiving MPTP had high levels of adrenal MPP+, there were no differences between groups, suggesting that 1) accumulation was limited, 2) clearance of accumulated MPP+ from adrenal was very slow and 3) treatment did not cause release of MPP+ from chromaffin granules, its presumptive storage site.

**670.7** 3HFLUORITRAZINE BINDING TO GABA RECEPTORS IN THE EFFERENT PATHWAYS OF THE STRIATUM OF MPTP MONKEYS TREATED CHRONICALLY WITH A D2 AGONIST (U-91356A) OR L-DOPA: RELATIONSHIP WITH DEVELOPMENT OF OPUترتيبUSE, D. Chavrol, P. Majolet, E. Declerck, J. Gegard, J. Delbeuck, J. Hirsch, and T. Di Paolo, 670.7. School of Pharmacy, 2Department of Pharmacology, Laval University, Quebec, CANADA, G1K 7P4.

Dyskinetic monkeys have the same side effects (frequent or impulsive dopaminergic treatment) as Parkinsonians and in MPTP monkeys. Most of the basal ganglia neurons are gabaergic and are probably implicated in the pathogenesis of the dystonia. This is, the gaba/benzodiazepine receptor complex was quantified by autoradiographic procedures using 3Hfluoritrazine (3HFTZ) binding. Following continuous or intermittent D2 agonist treatment with U-91356A (Uj) or intermittent L-DOPA treatment. Animals treated intermitently were sacrificed after three days, a time when no dyskinesia was induced while animals treated continuously with U-91356A did not. 3HFTZ binding in the striatum, internal (GIp) and external segments of globus pallidus, subthalamic nucleus and substantia nigra were investigated. 3HFTZ binding in nigral dyskinesia was induced by continuous treatment with U-91356A without L-DOPA treatment. The most interesting change was an elevation of 3HFTZ binding in the GIp of animals treated with U-91356A (Gi) or levodopa continuously developing dyskinesia (+38% and +36% vs MPTP untreated, respectively, p<0.05). These results suggest supersensitivity of the GIp to gaba/benzodiazepine receptor stimulation. Supported by the MRC of Canada and the Parkinson Foundation of Canada.

Loss of midbrain dopaminergic neurons is the pathological characteristic of Parkinson's disease (PD) in human and neurototoxicity in monkeys. A decrease in tyrosine hydroxylase (TH) mRNA content in the striatum of the substantia nigra in the surviving neurons in the midbrain from PD patients. Yet, because all patients are treated by levodopa, it is difficult to determine if this decrease is due to dopaminergic denervation or to levodopa therapy. The present study was aimed to analyze by quantitative in situ hybridization the effect of MPTP intoxication and levodopa therapy on the mRNA encoding for TH in four groups of Macaca fascicularis monkeys: normal control animals, MPTP-treated animals with moderate or severe parkinsonian symptoms, and levodopa-treated parkinsonian monkeys. Midbrain sections were hybridized with a 32P-labeled oligonucleotide riboprobe for TH mRNA. Quantification of mRNA expression at the cellular level using computerized image analysis revealed a decrease in TH mRNA expression in dopaminergic neurons from normal, MPTP-intoxicated and levodopa-treated monkeys as compared to control monkeys without statistically significant differences between the three groups. Similarly, TH protein content measured in the same animals also decreased. These results suggest that dopaminergic denervation induces a decrease in TH mRNA and protein expression which is not reversed by levodopa therapy.
DEGENERATIVE

with Cholinergic... 

leptorhine monkeys, the ability of CPP, a competitive NMDA antagonist, and NBQX, a competitive NMDA antagonist, when administered alone or in combination with a sub-threshold dose of a-pompholine (APO), to reverse HAL-induced EPS. Subjects were opossum monkeys that were sensitized to acute EPS by once weekly administration of haloperidol (HAL). Individual EPS signs were rated by non-blinded observers on a three point scale, totaled at each time point for each monkey, and group means derived. Test agents were administered 3 hr after administration of HAL, a time at which EPS signs were well established and stable. Ratings were made every 15 min for 1 hr after drug challenge and then at 30-45 min intervals for the next 2 hr. APO, given i.m., produced a dose-related reversal of all EPS signs. No reversal of the HAL-induced EPS was produced by NBQX, CPP or the combination of NBQX and CPP, given s.c. Neither NBQX nor CPP potentiated the ability of a sub-threshold dose of APO to reverse the HAL-induced EPS. These data suggest that glutamate antagonists would not be effective in ameliorating AP-induced EPS and question their role in the treatment of PD. Further experiments are evaluating the effects of treatments designed to increase the brain levels of NBQX on these interactions.

ALTERATIONS OF PALLIDAL CHOLINERGIC ACTIVITY IN MPTP TREATED MONKEYS. EFFECT OF DIHYDRO-alpha-ERGOCRYPTINE (DEK) 

The neurotoxic MPTP induces Parkinson(PD)-like symptoms in human and non-human primates. Recent studies have shown that dopamine loss in PD patients is not well understood and it is likely to be related to PD-associated motor disturbances (Campbell and Dill, Exp.Neurol., 42, 1974). The aim of this investigation was to evaluate in a small number of extrapyramidal brain regions, the short term consequences of MPTP administration on the cholinergic enzymes (choline acetyltransferase, CACh, and acetylcholinesterase, ACEh) and on pyruvate dehydrogenase complex (PDHC) which catalyzes the oxidative decarboxylation of pyruvate to acetylcoenzyme A and links cholinergic and energy metabolism. A treatment with dihydro-alpha-ergocryptine (DEK), a D2 receptor agonist was also performed. This ergocryptine improves motor performances PD patients (Martignoni et al., Clin.Neuropharmac, 14, 1991). Monkeys, intravenously administered with MPTP at the dose of 0.3 mg/kg for 5 consecutive days, develop a severe PD-like syndrome. Cholinergic enzyme activities are increased in the internal segment of the globus pallidus (GPH) and into a lesser extent in the external globus pallidus (GPs). Cholinergic activities are not significantly affected in the caudate and putamen nor in the frontal, parietotemporal, occipital cortices and cerebellum. The treatment of the animals twice daily for two weeks with DEK starting 5 days before the first MPTP administration counteracts the neurotoxin-induced alteration in the internal pallidum and ameliorates some motor related parkinsonian symptoms.

MPTP provides selective destruction of dopaminergic (DA) neurons in the substantia nigra (SN). Previous studies have shown that riluzole (2-amino-6-

1-1,3-thiazol-2-yl)-5-phenyl-3,4-dihydropyridin-2(1H)-one, a drug which interferes with glutamatergic neurotransmission, has a neuroprotective action in rodent models of cerebral ischemia. Effects were performed on two neurotransmitter systems (RI and RII). Both monkeys received a single injection of MPTP (0.6 mg/kg) in the right internal caudate. RI was injected with saline one hour before and six hours after the injection of MPTP. From days 2 to 30, it received further administration of saline. IRI injected saline one hour before and six hours after the injection of MPTP. From day 2 to 30, RI received a single daily injection of riluzole (0.4 mg/kg) in the right internal caudate. RI was injected with saline one hour before and six hours after the injection of MPTP. From days 2 to 30, it received further administration of saline. IRI received saline one hour before and six hours after the injection of MPTP. From day 2 to 30, RI received a single daily injection of riluzole. Both monkeys were examined clinically and muscular rigidity was quantified by electromyography. Then, they were administered with MPTP, brainstem and rigidity were absent. When injected daily in RI, riluzole significantly reduced bradykinesia and rigidity. RIVADA rum, clinically assessed, were indexed to an index of DA use, increase of 8% after MPTP treatment in RI. Interestingly, the neuroprotective effect of riluzole with riluzole in RI increased more markedly this ratio (92%). That, a neuroprotection coupled to a facilitation of DA release may explain the behavioral effects reported with riluzole treatment. These results show that riluzole would potentiate both neuroprotective and palliative effects in a primate model of Parkinson's disease.

Magnetic resonance imaging (MRI) has recently been used to map the scalar diffusivity (D) of water in tissues. In brain ischemia, D is decreased when ventilatory MRI is still uninformative. It has been recently proposed that the transmission of effective diffusion (Tr(Deff)) measured by diffusion tensor imaging, more accurately reflects the mobility of water in tissue (1). We evaluated the utility of Tr(Deff) to detect selective neuronal lesions such as the degeneration of the substantia nigra pars compacta (SNc). SNc neurons are affected in the neurotransmission following MPTP systemic administration. Cynomolgus monkeys were administered with MPTP (0.5 to 1.5 mg/kg i.v. weekly) and scanned with MRI before, immediately after their first MPTP administration and then at 1 week after each MPTP injection. Each scan consisted of the acquisition of 14 diffusion weighted coronal images from which both Tr(Deff) and T2 weighted signal intensity maps were calculated. In the 2 stable parkinsonian animals (cumulative dose of 3-3.5 mg/kg of MPTP) studied so far, Tr(Deff) was decreased by 22% in the doro-lateral putamen and by 6% in the caudate nucleus. No changes were observed in other brain structures. Tr(Deff) alteration persisted in one animal scanned 44 days after the last MPTP injection. These findings are consistent with previous studies. These data of this ongoing study suggest that Tr(Deff) could provide “in vivo” information on selective brain damage.

EFFECTS OF THE FULL Dopamine D-1 Receptor Agonist Dihydrexidine on Cognitive Function and Motor Activity in MPTP-Treated Monkeys. J. W. Johnson, J.S. Schneider, Dept. of Neurology, Hahneham University, Philadelphia, PA 19102.

Dopamine D2 receptors have been assigned a major role in regulating motor function, based primarily on rodent and human studies with D-2 agonists and antagonists. Dihydrexidine (DIH) is a potent and selective D1 agonist SKF 38393 on parkinsonian monkeys and humans. However, there are still questions concerning the potential role of D-1 receptors in treating parkinsonism. The discovery of full efficacy D-1 agonists should help to answer questions concerning the therapeutic potential of D-1 receptor stimulation. In the present study, we used the D-1 agonist dihydrexidine and the potential of this agent to induce rotational asymmetry in hemiparkinsonian monkeys and to correct cognitive deficits resulting from chronic low dose MPTP exposure. Dihydrexidine (0.3 to 0.9 mg/kg), administered to 3 hemiparkinsonian monkeys, caused a dose-dependent increase in contralateral rotations that could be blocked by the D-1 antagonist SCH 23390 but not by the D-2 antagonist raclopride. Dihydrexidine also caused a dose-dependent reversal of the number of cognitive errors made by 3 chronic low dose MPTP-treated monkeys during delayed response performance. This effect could also be blocked by the D-1 antagonist SCH 23390. These results suggest that D-1 receptor stimulation may be therapeutically effective in treating parkinsonism. Additional studies are needed to further compare the therapeutic efficacy of selective D-1 and D-2 receptor agonists in parkinsonian primate models. Supported by NIH grant MH-46531.

CHRONIC GM1 GANGLIOSIDE ADMINISTRATION REVERSES COGNITIVE DEFICITS AND DELAYS ONSET OF MOTOR SYMPTOMS IN A SLOWLY PROGRESSING PARKINSON MODEL IN MONKEYS. L. G. Colemant, A. D. Poeggel and J. S. Schneider. Dept. of Neurology, Hahnemann University, Philadelphia, PA 19102.

We have previously shown that monkeys administered for 6 to 8 weeks after the last of several MPTP injections, can reverse motor deficits and partially restore striatal dopamine levels in monkeys with severe Parkinson's disease (1989, 1992). We have now demonstrated that GM1 might be most effective as an anti-Parkinson therapy if administered early after diagnosis, when there is still considerable loss dopaminergic function. This study was conducted to assess the potential of long-term GM1 treatment as a means of slowing the progression of parkinsonism. Five monkeys, previously receiving low doses of MPTP for 24 weeks. These monkeys developed cognitive deficits, followed by mild motor deficits. At this stage, judged to be analogous to early parkinisonism, monkeys were randomly assigned to receive either saline or GM1 injections (30 mg/kg) while all monkeys continued to receive the same doses of MPTP. The monkeys receiving GM1 showed significant improvement in cognitive task performance by the end of the first 8 weeks of treatment that has been maintained over time while the saline-treated animals have continued to show increasing task performance deficits. Saline-treated animals are also showing a trend toward a progressive decrease in motor ability not apparent in GM1-treated animals. These results suggest that early intervention with GM1 ganglioside treatment may exert both symptomatic and preventive effects in Parkinson's disease patients. Supported by the F.M. Kirby Fund and Fida Pharmaceuticals.

EFFECTS OF GM1 GANGLIOSIDE TREATMENT ON DOPAMINE RELEASE AND REUPTAKE IN MPTP-TREATED MICE. D.S. Rothblat* and J.S. Schneider. Dept. of Neurology, Hahnemann University School of Medicine, Philadelphia, PA 19102.

Both in vivo and in vitro studies have suggested that GM1 ganglioside treatment may reduce the severity of dopaminergic pathology in MPTP/MPP+-damaged dopamine (DA) neurons. Recent data also suggest that GM1 may enhance DA synthesis in residual neurons. This study measured striatal dopamine levels in mice receiving GM1 and saline during MPTP administration and then saline or GM1 for another 3 weeks. MPTP administration resulted in a decrease of 100% in DA release and reuptake were measured by utilizing microdialysis in vivo. In vitro studies were performed using Nafion-coated carbon fiber electrodes. DA release was stimulated by a 300pA of 120mM KC1 current ejected from a microelectrode attached to the recording electrode, at the 0.5 mm intervals through the dorsal-ventral and medial-lateral extents of the midbrain. Mice receiving GM1 and clearance time were determined at each location. In MPTP/saline-treated mice, the greatest decrease in DA release increased in the lateral striatum (39% of normal) and GM1 treatment increased release by almost 25%. The clearance time for released DA increased the most in the dorsolateral striatum in MPTP/saline-treated mice and decreased by almost 30% after GM1 treatment. These changes coincided with a 92% decrease in striatal DA, mazindol binding in GM1/saline-treated mice vs. a 67% decrease in 3H mazindol binding in GM1/saline-treated mice. These results further demonstrate the ability of GM1 ganglioside to enhance dopaminergic neurotransmission after a DA-depleting lesion. Supported by NIA grant AG 10280.

GM1 GANGLIOSIDE TREATMENT INCREASES DOPAMINE SYNTHESIS IN RESIDUAL NIGROSTRIATAL NEURONS IN MPTP-TREATED MICE. J.S. Schneider and L. DiStefano. Dept. of Neurology, Hahnemann University School of Medicine, Philadelphia, PA 19102.

GM1 ganglioside has been shown to increase striatal dopamine (DA) levels after various types of lesions to the nigrostrial DA system. Both in vivo and in vivo studies have suggested that GM1 ganglioside treatment may have rescue and survival effects on damaged DA neurons and may stimulate a spontaneous response in striatal DAergic terminals. The present study was conducted to assess the extent to which GM1 treatment may also cause a biochemical upregulation in residual DAergic neurons after an MPTP-induced lesion. Young (8-12 week old) C57Bl6J mice were administered MPTP (20 mg/kg, twice daily for 5 days) and then saline or GM1 ganglioside treatment. Some animals received injections of dibutylthiophosphate (DBU, 400 mg/kg) prior to MPTP injections and then received 3 weeks of saline or GM1 ganglioside treatment. Some animals were injected with NDS-1010 (100 mg/kg, 30 min. prior to sacrifice) to allow measurement of striatal dopa accumulation consequent to aromatic amino acid decarboxylase activity. MPTP/saline-treated animals had 46% less accumulated dopa than normal animals whereas MPTP/GM1-treated animals had only 17% less dopa than normal. DAergic+MPTP-treated animals had more severe dopamine depletions than MPTP-treated animals and striatal dopa levels 41% of normal. GM1 treatment had no effect on DA or dopa levels in these animals. These data suggest that under certain conditions, GM1 treatment can enhance the function of residual DA neurons by increasing dopa synthesis. Supported by NIA grant AG 10280.

INTRANIGRAL INFUSION OF CNTF, BUT NOT NGF, EGF OR TGF-B1, RESTORES STRIATAL DOPAC BUT NOT DOPAMINE LEVELS IN MPTP-TREATED MICE. T. W. Farris*, L. DiStefano and J. S. Schneider. Dept. of Neurology, Hahnemann University School of Medicine, Philadelphia, PA 19102.

Growth factors (GFs) may rescue or support damaged dopaminergic neurons in vivo raising hopes for their therapeutic potential in Parkinson's disease. However, the degree of tissue trauma from surgery and CNS delivery of GFs has varied greatly across experiments. Mechanical damage to the CNS can induce considerable release of GFs, complicating the interpretation of results following their administration. In this study, we have minimized non-specific tissue trauma to better isolate GF effects on recovery of DA-ergic markers following an MPTP-induced lesion. 8-week old male C57Bl/6J mice were administered MPTP (20 mg/kg, ip) or saline twice daily for 5 days. Two days later mice were implanted with 30 g. cannulae connected to low flow osmotic pumps (0.2 ul/h) for delivery of rhCNTF (20ug/14, rh-EFG (4ug/14), rh-BFGF (4ug/14), rh-TGF-B1 (2ug/14) or vehicle to the substantia nigra (SN) or striatum (ST). Infusion of CNTF into SN of MPTP-lesioned mice restored ipsilateral striatal DOPAC levels to 88.5% of vehicle-infused vehicle-infused controls (p=0.01, Dunnett's test) while DA levels were unaffected (34% of control). EGF, BFGF and TGF-B1 had no effects on striatal DA (27.4%, 33.4% and 30.7% of control, respectively) or DOPAC (34.7%, 43.7% and 39.2% of control). Striatal infusions of GFs had no effect. Similar experiments with these GFs in our lab employing more traumatic delivery methods have produced more positive results. We speculate that trophic substances released by trauma may be crucial for some GFs to alter DA-ergic markers. Supported by NIA grant AG 10280.

Cell death occurs by either apoptosis (programmed cell death) or necrosis. Apoptosis occurs as a result of the normal life span of differentiated cells, in tumors, and many other physiologic and pathologic conditions. Biochemically, the DNA of apoptotic cells undergoes cleavage via endonucleases, which are controlled by p53 nuclear-coded genes. These fragments can be identified in situ by the addition of labeled nucleotides with the enzyme terminal deoxynucleotidyl transferase (TdT). Several studies have investigated this technique in the study of cell death in disease processes of the CNS. We describe the application of this technique to various disease processes in the rodent and human CNS. We have investigated the use of TdT labeled DNA fragments as a method to distinguish apoptosis from necrosis in in situ brain samples. Autoradiography and in situ hybridization using radioactive labels were used to distinguish from each other, necrosis and apoptosis. Studies are underway to investigate the potential of this method to label cells undergoing cell death by necrosis. This method can be used to label dying CNS cells in a variety of disease states. However, it may be useful at this time if it identifies cell death by necrosis as a mechanism associated with cell death in the CNS, which is almost always the case of dying. Supported by NIH NS20856 and the Hereditary Disease Foundation.

OVEREXPRESSION OF THE S-100 GENE IN DOWN'S SYNDROME: A STUDY IN LYMPHOCYTES. H. Riezli, L. G. Gaudreault, J. Cloitre and M.R.V. Murphy. Dept. of biochemistry, Fac. of Medicine, Laval University, Quebec City, Canada. The S-100 gene which is located on the long arm of chromosome 21, is most commonly observed in astrocytes, may be implicated in the neurologic abnormalities observed in trisomy 21 which leads to Down's syndrome (DS). However, overexpression of this gene has not been consistently observed in other tissues, including lymphocytes. We have measured the level of S-100 mRNA in lymphocytes of 12 patients with DS (25 to 47 years old) and controls by performing semi-quantitative reverse transcription combined with polymerase chain reaction (PCR). The average level of S-100 mRNA was 2.3 fold higher in the DS group as compared to the controls (p<0.001). However, two DS individuals were clearly distinguishable. The first (n=5) did not overexpress S-100 mRNA, while the second (n=7) overexpressed the gene by 2.4 to 5.5 fold (p=0.001) when compared to age-matched controls. A negative correlation of the S-100 mRNA level with age was found in normal individuals (r=0.60; p<0.005). The DS individuals of the first subgroup showed similar negative correlation with age in their S-100 mRNA expression (r=-0.60; p<0.005), but in the second subgroup, there was no significant correlation of the S-100 mRNA level with age. Using genomic DNA amplification of the S-100 gene in 5 DS patients and 5 non-DS patients, we have shown that the DS patients were in fact trisomic for this gene. Therefore, these data suggest that a proportion of DS patients examined a S-100 gene as do normal individuals whereas another proportion overexpress this gene in a manner which is higher than the 1.5 fold expected. The degree of mental deficiency of the DS individuals, based on their learning capabilities, was estimated in a blind study. This was found to be negatively correlated with the S-100 gene expression. These data suggest that S-100 expression may be implicated in controlling the severity of the mental deficiency in adults with DS.

TAU PATIENTS IN NEURODEGENERATIVE DISORDERS: BIOCHEMICAL ANALYSIS. Y. Bule-Scherrer, L. Bule, P. Veremich*; P.R. Hof, L. Leventhal, L. Collins, G.B. Hof, U156, Lille, France; Montauk Medical Center, New York, USA.

Neurofibrillary tangles (NFT) are found in a number of neurodegenerative disorders including Alzheimer's disease (AD), progressive supranuclear palsy (PSP), amyotrophic lateral sclerosis/parkinsonism-dementia of Guam (ALS/PDC), post-encephalitic parkinsonism (PEP), and in the hippocampal formation of elderly non-demented individuals. NFT result from the aggregation of abnormally phosphorylated tau proteins into paired helical filaments or straight filaments. In the brain of patients with PDC and a subset of patients with AD, use of Western blotting and antibodies directed against phosphorylated and non-phosphorylated tau proteins, to investigate whether NFTs could be distinguished by differences in tau profile. Using specific antibodies to abnormally phosphorylated tau proteins, a triplet of proteins referred to as tau 55, 64 and 69 (or 68), was consistently detected in brain homogenates from AD cases and D5 patients. In the AD cases, this triplet was never found in any brain regions of non-demented elderly individuals, with the exception of the hippocampal formation. In PSP brains, a doublet of abnormally phosphorylated tau proteins (tau 64 and 69) was systematically found in both cortical and subcortical regions. In ALS/PDC cases, the characteristic tau triplet was found in both cortical and subcortical areas. In all PEP cases, a triplet of tau proteins was also found, but their isocortical distribution was quantitatively different among cases. As expected, in Huntington disease (HD) cases younger than 60 years, abnormal tau proteins were not found since no NFT are observed. In all of these neurodegenerative disorders, a very close relationship was observed between the tau pathology in the association cortical areas and intellectual impairment. With this approach, we were able to distinguish at least two types of neurodegenerative disorders: the Alzheimer type (AD, AD, ALS/PDC, PEP) and the PSP type.

NEURONAL DEGENERATION IN THE PRIMATE DORSAL LATERAL GENICULATE NUCLEUS (LGN) FOLLOWING ELEVATION OF INTRAOCULAR PRESSURE. A.J. Hurtig, P.L. Kaufman, W.C. Huntington, The Waisman Center*, Department of Ophthalmology and Visual Sciences**, Department of Comparative Biosciences, and Wisconsin Regional Primate Research Center*, University of Wisconsin, Madison, WI.

Elevation of intracocular pressure (IOP) is considered to be an important causative factor associated with glaucoma, a leading cause of blindness. Using intracarital sodium nitroprusside, we have described previously the degenerative effects that increased IOP has on single ganglion cells in the primate retina. (Invest. Ophth. and Vis. Sci. suppl. "94). Here we describe the changes that elevated IOP has on neurons in the LGN, the primary target of retinal ganglion cell axons. IOP was elevated experimentally in one eye of five rhesus monkeys by focal scarification of the trabecular meshwork using an agen laser. Two weeks after elevation of IOP, the eyes were enucleated and immersion fixed. Sections were cut at 50 microns and stained with synaptophysin. In the LGN, the changes observed were a decrease in the size of the LGN, a decrease in the number of synapses per ganglion cell, and an increase in the number of dendritic spines per ganglion cell. With this animal model, we have shown that glaucomatous optic neuropathy is associated with degenerative changes in the LGN.

671.6

Spinocerebellar ataxia type 1 (SCA1) is an autosomal dominant disorder characterized by progressive degeneration of the cerebellar cortex and brainstem. The mutation causing the disease is an expansion of a trinucleotide repeat (CAG) which size correlates with the severity and age of onset of the symptoms. Recent cloning and characterization of the SCA1 gene revealed that the transcript is 10,606bp and that the CAG repeat resides within a coding region of 2484bp and codes for a glutamate tract. Sequence analysis did not reveal any homology with known proteins and it was found that the SCA1 gene product is a large protein, 1194amino acids, with an estimated molecular weight of 87Kd. To begin to understand the biology of the SCA1 gene, we initiated studies aimed at characterizing the expression patterns of both the transcript and the encoded protein. To this end, we have performed Northern blot analysis using mRNA from different human tissues revealed that mRNA transcribed in all tissues examined. Analysis of SCA1 expression in adult mouse brain by use of in situ hybridization revealed widespread expression throughout the central nervous system. Regions of enhanced SCA1 expression include the cerebellum (Parvinke and granule cells, as well as neurons within the deep cerebellar nuclei) and thalamus. Analysis of RNA expression from normal and SCA1 animals revealed that the allele with the expanded CAG repeat is transcribed. This argues against a pathogenetic mechanism involving loss of function at least at the RNA level. Polyclonal antibodies have been generated using either synthetic peptides or a fusion protein as an immunogen. Western blotting analysis revealed that the protein expression pattern is similar to that of the RNA. Detailed characterization of the antibodies is currently in progress to confirm their specificity.

APOLIPOPROTEIN (APO) ISOMERS IN PATIENTS WITH LEWY BODIES (LB). M.G. Martinoni*, J.Q. Trojanowski*, V.-M.Y. Lee*, M.L. Schmidt*, E.J. Hurtig*, J.P. Julius*, and C. Clark*, 1; Centre for Research in Neuroscience, McGill Univ., Montreal General Hospital, Montreal, Que., H3C 1A4, Canada, Department of Pathology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104, USA.

Lewy bodies (LB) are small round eosinophilic inclusions found mainly in brainstem nuclei and cerebral cortex. The presence of LB in the pigmented neurons of the substantia nigra is a hallmark of idiopathic Parkinson's disease. The presence of cortical LB and dementia is often called diffuse Lewy body disease (DLBD). When sufficient plaques and tangles are also present the condition may be called Lewy body variant of Alzheimer's disease (LBVAD). Lewy bodies are seen in about 30% of patients with Alzheimer's disease (AD). Apolipoprotein E (APOE) is a lipoprotein expressed in liver and brain as one of 3 isomers (APOE 2, APOE 3 and APOE 4). Recent findings suggest that the presence of APOE 4 with an increased risk for late onset AD. We examined the frequency of APOE isomers in a cohort of patients with brainstem LB, some of whom had cortical LB with or without coexisting plaques and tangles. The presence of APOE 4 was determined by PCR techniques using DNA isolated from frozen cerebellar cortex. Anonymously donated brain samples were used for the control group genotype. Our preliminary results show that while there is a slight increase in the frequency of APOE 4 in subjects with LB, the correlation is strongest for those patients with co-existing plaques and tangles.

671.8

The pathophysiological basis of neuroleptic-induced tardive dyskinesia (TD) remains unclear. The dopamine supersensitivity hypothesis can not account for the time course or the onset of TD nor the persistence of TD and the associated structural changes after neuroleptics are discontinued. Neuroleptics can induce a vicious cycle of cellular processes that lead to a cascade of oxidative stress and glutamatic activation in animals. Haloperidol increases glutamate (Glu) concentration in the striatum and Glu agonists can enhance the activity of late onset of free radicals. Free radicals on the other hand, causes release of Glu from rat hippocampal slices. Conventional neuroleptics have recently been shown to inhibit oxidative stress by 1 of the mitochondrial electron transport chain. Failure of the electron transport chain causes the formation of free radicals and may make neurons more vulnerable to excitotoxicity. We have studied 13 patients with TD and 13 patients on neuroleptics without TD to determine whether the oxidative stress is related to change in glutamatic transmission in human TD. Our data support the hypothesis that oxidative stress and glutamatic transmission. TD patients have lower superoxide dismutase (SOD) activities (p<0.05) and higher Glu, Aspartate, and N-acetylaspartylglutamate concentrations (p<0.01) in their CSF compared to non-TD patients. There is a significant correlation between SOD and aspartate, SOD and glycine. It is plausible that the pathophysiology of TD can be better explained by the interaction between oxidative stress and glutamatic transmission.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
671.0 PROTECTION OF CELL INJURY AGAINST OXIDATIVE STRESS BY RESVERATROL. S.J. Lee, Y. Cheng and A.Y. Sun*, Dept. of Pharmacology, Univ. of Missouri, Columbia, MO 65211.

There is a general consensus that free radical generation leads to alteration of biochemical and biophysical properties of cell membranes and in turn, these changes may lead to pathological manifestations in aging and other neurodegenerative diseases. Recent epidemiological studies have indicated an inverse relationship between moderate consumption of wine and incidence of coronary heart disease. This "French paradox" has drawn considerable attention and analysis has identified the presence of trans-resveratrol (R) in wine. The antioxidant properties of R may contribute greatly to protection of the endothelial cells lining the arterial walls from oxidative damage. We have investigated the possible protective effect of R in the nervous system after various oxidative insults. PC12 cells were used because of their resemblance to catecholamine neurons. An increase in cell death, as indicated by the extent of intracellular LDH released to the incubation medium, was observed after PC12 cells were exposed to F2-*/DETPAC (0.1 mM) for 36 hrs. R was able to exert a dose-dependent protective effect on the F2-*/DETPAC-induced cell death. Furthermore, the combined action of R plus Vitamins C and E was far better than the use of each individual antioxidant alone. The result indicated that R may be a potential therapeutic agent for the prevention and treatment of neurodegenerative disease (Supported in part by NIH Grant AA02054).

Earlier studies have shown that PHMK-801 binding to the NMDA receptor ion channel is decreased in spinal cord tissue from ALS patients compared to controls. This reduction could be completely reversed by the activation of protein kinase C by phorbol ester. Later work has suggested that these studies indicated the potential that NMDA receptors in spinal cord tissue may be altered by abnormal regulation of enzyme activity. PHMK-801 binding was increased after exposure to PDB (15 µM) in both control and ALS spinal cord sections. In the present study, a return of these media resulted in a further enhancement of binding in specific PHMK-801 binding to the original levels with time, where t½ = 60 min. for control and 15 min. for ALS. The rate constants for PDB-induced effects on PHMK-801 in control and ALS were 0.01/min. and 0.05/min., respectively. In control tissue the decay to the original binding level could be blocked by phosphate blockers, NAV (sodium orthovanadate), a tyrselective inhibitor) and NABD (Sodium D-3-glycerophosphate, a ser/threonine inhibitor). For NABD, half maximal block was achieved at the concentration of 10-7 M for control and 10-6 M for ALS. Almost complete block (80%) was achieved at 10-6 M for control whereas in ALS a complete block could not be achieved. These differences between ALS and control spinal cord may indicate fundamental alterations in the activity, amount or type of endogenous phosphatase in spinal tissue in ALS patients.

FACI is a developmentally regulated protein that is localized throughout the cell cytoplasm during human brain development but found primarily in the nucleus after birth. We have isolated a 160 kd FACI protein from fetal brain by affinity chromatography and report that FACI interacts with the 160 kd neurofilament protein (NFP-M). Other cytoskeletal elements such as NFP-L, tubulin, and MAPs do not co-elute with FACI. Therefore FACI represents a novel neurofilament associated protein. Neurofilament abnormalities are present in many neurologic diseases such as Alzheimer's disease (AD), Friedreich's ataxia, and amyotrophic lateral sclerosis (ALS). FACI abnormalities have also been found in these diseases. Within the neocortex of AD brain FACI is present in a subset of neuritic plaques (Alzheimer's disease) and in non-neuritic plaques in the amygdala and ALS spinal cord by immunoelectronmicroscopy. In the developing lumbar cord FACI resides in nuclei of multiple cell types, with highest protein levels in anterior cord and lowest FACI in posterior cord. FACI is detectable in cells with symptoms of ALS, including motor neurons. FACI is present in motor neurons and in axon tracts. We are currently determining the expression of FACI in cells with NF abnormalities or if FACI expression precedes NF changes. Results of in situ hybridization studies using probes for FACI mRNA will also be presented. Re-expression of FACI may be characteristic of cell responding to early cellular abnormalities that occur during AD and ALS.

AMYOTROPHIC LATERAL SCLEROSIS IMMUNOglobulINS INCREASE INTRACELLULAR CALCIUM IN A MOTEURONE CELL LINe, L.Y. Colom*, M.E. Alexiou, R.G. Smith and S.H. Appel, Department of Neurology, University of Washington, Seattle, WA.

Amyotrophic Lateral Sclerosis (ALS) is a devastating motoneuron disease of unknown cause. Recent evidence suggests that autoimmune mechanisms are involved in the origin and progression of the disease. We have previously demonstrated the presence of antibodies to voltage-dependent calcium channels in ALS patient sera, and shown that ALS IgG induces calcium-dependent cytotoxicity in an hybrid motoneuron cell line, VSC4.1 (Smith et al., 1993:339-97, 1994).

These ALS IgG also increase the amplitude of voltage-dependent calcium currents in VSC4.1 cells (Mouler et al., Soc. Neurosci. Abstr: 1996: 3). To determine whether ALS IgG can increase intracellular calcium in VSC4.1 cells, we have employed confocal scanning microscopy and the calcium-sensitive dye Fluo-3. In VSC4.1 cells, basal intracellular calcium levels were 74±32 mM. Increases in intracellular calcium were observed in 29% of cells, following bath addition of IgG from 6 ALS patients. Two types of intracellular calcium changes were observed: 1) an early fast transient (364±233 mM), appearing 15-120 sec after adding ALs IgG to the bath, and 2) a slower, progressive increase appearing 30-120 min later. Of the cells that showed a fast transient, 1/3 developed a slower progressive calcium increase (compared to less than 10% of the cells that lacked a fast transient). Addition of IgG from 4 control patients produced calcium increase in only 1% of cells. ALS IgG failed to produce fluorescence changes in calcium free media. These findings suggest that ALS IgG induces an early calcium influx through the cell membrane which, despite its short duration, may initiate a cascade of events leading to a later progressive increase in calcium and subsequent cell death. This work was supported by M.D.A. and Cephalon, Inc.

671.16

Among the Chamorro people of Guam, the high incidence and prevalence of ALS has decreased in the past decade, while parkinsonism-dementia complex (PDC) continues to be frequently encountered. We have recently noted the frequent occurrence of cases of dementia who remain free of amyotrophy or parkinsonian signs through the entire course of their illness. Pending further characterization of this disorder, we have referred to such cases as Marianas dementia. We now report neuropathologic findings on 7 pure dementia cases (73 ± 8.5 years old, duration of illness 3.5 ± 1.6 years) among inhabitants of Guam. None of these cases showed evidence of amyotrophy or extrapyramidal features despite careful neurologic surveillance. Five of these cases were of Chamorro extraction and had been life-long inhabitants of Guam. These cases showed evidence of severe cerebral atrophy with widespread neurofibrillary tangles (NFT), in the absence of neuritic plaque formation. The NFT heavily involved limbic structures and predominated in layers III/IV (as opposed to layer V) of the neocortex. There was loss of neurons in the substantia nigra with NFT in the upper brainstem. These 5 Chamorro cases were virtually indistinguishable neuropathologically from PDC. The remaining 2 cases were migrants to Guam (82 year old Caucasian, 83 year old Filipino) and both showed typical neuropathologic features of Alzheimer’s disease. This study demonstrates that a purely dementing syndrome, in the absence of amyotrophic or parkinsonian manifestations represents an additional form of ALS/PDC among at-risk Chamorro natives of Guam with chronic exposure to unknown environmental factors present on the island.

671.17

Cycasin, the 6-D-glucose of methylazoxymethanol (MAM), is a possible ecological factor for western Pacific amyotrophic lateral sclerosis/Parkinsonism dementia complex. We have hypothesized that these genotoxins act as slow toxins by permanently altering post-miotic neural tissue DNA. In previous studies, we demonstrated that MAM-induced neurotoxicity in vitro is potentiated by O^-hcytrazygmine (O^-Bjg), an inhibitor of the DNA-repair protein methylazoxymethanol/N-methyl-N-hydroxyethylpyruvate (MGMT). To further examine the relationship between DNA damage and MAM-induced neurotoxicity, MGMT levels and DNA damage were determined in mouse cortical explant tissue, primary rat cortical astrocytes, and primary rat cerebellar granule cell cultures treated for 1-3 days in the presence or absence of 5.0 µg-O^-Bjg/mL 0.1 mM of the genotoxins MAM, N-methylazoxymethanol, or procarbazone. Western blots demonstrated MGMT in protein extracts of all three tissue types, with particularly low levels in granule cell cultures. MGMT levels were reduced in explants and astrocytes treated with O^-Bjg. The level of peroxidation was increased in explants from explants treated with O^-Bjg. DNA damage, as determined by immuno-dot-Blot using monoclonal antibody EM-21 to the DNA adduct O^-methyl-N-hydroxyethylpyruvate (O^-MeAO), was not detected in cultures treated for 24 h with MAM or other genotoxins. However, O^-MeAO was detected in all cultures treated for 3 days with MAM. DNA damage levels increased 2-3 times when explants were treated with MAM and 5.0 µg-O^-Bjg. Taken together, the present studies indicate that modulation of DNA repair can increase the susceptibility of nervous tissue DNA to damage by genotoxic agents that may lead ultimately to cell death. The Organophosphate Insecticide - Chlorpyrifos: Precovalent & Behavioral Effects in Adult Rats. John N.D. Watan* and Jesse H. Elmadjian, Department of Pharmaceutical Sciences, College of Pharmacy, St. John's University, Jamaica, NY 11432.

Chlorpyrifos (CP) has been shown to have proconvulsant effects in immature rats (Hupfer et al. 1993) and elicits behavioral effects when administered pre- or post-natally (Muto et al. 1992). These early studies also demonstrated an interaction of CPF and xyl (XYL). Experiments were performed to determine both the effects of CPF on kindling and behavioral neurotoxicity in adult rats. Xyl was administered alone or in combination with CPF. Rats (Taconic Farms) weighing 175±25 grams received amygdalar electrodes 1 week prior to initiation of kindling procedures. CPF or XYL, alone or in combination, was administered subcutaneously in 10% peanut oil/vitamin E (VHE). Dose range: CPF 0.3-100 mg/kg; XYL 0.2, 0.5 or 1.0% in all cases N=2. The afterdischarge threshold (ADT) was determined in rats treated with CPF, XYL, of XYL/VHE. No differences were noted between the groups. ADT was not affected by treatment. Kindling was performed (1 stimulus, 100 µA, 1 sec duration, 60 Hz, square wave pulses) in CPF, XYL, XYL+CPF or VHE treated rats. All XYL + CPF and CPF treated rats showed a decrease in kindled response to its absence. Kindling was performed (1 stimulus, 400 µA, 1 sec duration, 60 Hz, square wave pulses) in CPF, XYL, XYL+CPF or VEH treated rats. CPF and XYL treatment displayed additively (kindling rate accelerated). CPF displayed neurotoxicity in adult rats as determined by the rotarod test. XYL appeared to be without effect in this test. The combination of CPF and XYL displayed additively in this test. Spontaneous Motor Activity (SMA) displayed a biphasic effect of CPF; at 2 hours post-CPF activity increased modestly in a dose-dependent manner. At 36 hours CPF elicited a modest decrease in SMA. Highest doses used XYL caused an increase in SMA at 2 hours, yet at 36 hours SMA did not differ from VEH-treated controls. CPF + XYL demonstrated additivity at 2 hours post dose. Brain cholinesterase activity was determined by a spectrophotometric method. CPF caused reductions in cholinesterase activity in a dose-dependent manner from 2 hours to 72 hours following CPF administration. Studies supported by St. John's University, Col. Pharmacy.

HYDROGEN PEROXIDE HYPERPOLARIZES RAT HIPPOCAMPAL PYRAMIDAL NEURONS BY OPENING K+ CHANNELS. Y. Seunit*, J. Scuvé-Moreau, L. Massotte, A. Dresse, Lab. de Pharmacologie, Univ. of Liège (B-4000), Belgium.

Hydrogen peroxide (H2O2) may be involved in a number of pathological conditions affecting neural cells, but its electrophysiological effects have not yet been studied in detail in the rat. Using intracellular recordings of presumed CA1 pyramidal neurons in the slice preparation, we observed that H2O2 (0.3-3 mM) induces in these cells a reversible and reproducible hyperpolarization (h<0.5 mV, Mean ± SEM, N=13, by 3 mM) from resting potential (-65 ± 2 mV) and turnover that was not due to a K+ channel opening because (1) in 2.5 mM K+, it had the same reversal potential (-97 ± 2 mV, N=3) as the one of back of (10 µM) Ni2+ (± 1 mV), a known K+ channel opener; (2) its reversal potential shifted according to the Nernst equation for K+ when [K+]o was changed (from -96 ± 3 mV in 2.5 mM to -63 ± 2 mV in 10.5 mM, N=3); (3) it was reduced by a K+ channel blocker (100 µM Ba2+, N=4).

The precise identity of the channels that are affected, as well as the mechanism by which they are opened, remain to be determined.

672.3

NEUROTOXICITY OF HYDROGEN PEROXIDE. P.A. Roantree, O. Bon, Yosef Y., N. Dujovny, B.D. Rors. Neuroscience Pharmacology, Park-Davis Research, Div. of Warner-Lambert Co., Ann Arbor, MI 48105 and Dept. of Radiology and Neurological Surgery, Univ. of Michigan, Ann Arbor, MI 48109. Free radical induced neuronal injury has been implicated in a number of neurological disorders and has been linked to excitotoxic cell death. The current experiments evaluated the toxicity produced by the direct application of hydroxyl radicals, hydrogen peroxide (H$_2$O$_2$). Experiments were performed on 17-day old cerebrocortical primary cultures under conditions similar to those employed in excitotoxic cell death. Cell death was assessed using a histologically and quantitatively by the measurement of lactate dehydrogenase (LDH) released into the medium. Following a 30 min exposure to H$_2$O$_2$, there was a concentration dependent cell death assessed at 2 hr and 24 hr (EC_{50}=100 mM). Shorter exposure periods to H$_2$O$_2$ were less effective. LDH release did not occur until > 3 hrs after removal of H$_2$O$_2$ indicating a delayed cell death, similar to that seen following exposure to glutamate. Pretreatment with the iron chelator deferoxamine (2 mM) produced a rightward shift in the H$_2$O$_2$-induced toxicity curve (EC_{50}=458 uM), while inhibition of catalase with aminotriazole (30 mM) enhanced the H$_2$O$_2$ induced toxicity (EC_{50}=54 uM). This neurotoxicity was not mediated by NMDA receptors, since the NMDA antagonist MK-801 did not prevent the cell death. These results are consistent with the assumption that the generation of hydroxyl radicals is necessary for cell death. As with excitotoxicity, a rise in [Ca$^{2+}$], about 40 min following continual exposure to H$_2$O$_2$, Removal of extracellular Ca$^{2+}$ prevented the increase in [Ca$^{2+}$], suggesting that the increase was not the result of the liberation of intracellular stores of calcium. These data demonstrate that H$_2$O$_2$-induced toxicity has many of the same features as excitotoxic cell death, suggesting that there may be a causal link between these forms of neurotoxicity.

POLYCHLORINATED BIPHENYLS REDUCE TYROSINE HYDROXYLASE ACTIVITY IN RAT BRAIN. R.F. Segal and V. Shaian, Wadsworth Center, NYSDOH, Albany, NY 12201. Polychlorinated biphenyls (PCBs) reduce dopamine (DA) concentrations in adult rat and human primates brain and in schizophrenic/hypermotoric (PC12) cells. Using neostriatal (NIE-115) cells that do not express the enzyme dopa decarboxylase (DDC), required for the conversion of L-Dopa to DA, we have shown that PCBs reduce media Dopa concentrations, suggesting that PCBs reduce the activity of tyrosine hydroxylase (TH) to convert tyrosine to L-Dopa. To determine if reductions in brain DA concentrations are also due to inhibition of TH we exposed adult Wistar-derived rats to either Acorus 1254 (1,000 ppm in chow) or control chow for 46 days and measured their 30 min after they received intraperitoneal injections of either 100 mg/kg of 3-hydroxybenzylhydrazine (NSD-1015), an inhibitor of DDC or saline. DA, L-Dopa, 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) concentrations were determined in the striatum and nucleus accumbens by HPLC. PCBs significantly reduced DA concentrations in the striatum and DOPAC and HVA concentrations in both brain regions. Co-treatment with NSD-1015 resulted in further decreases in DOPAC and HVA as well as reductions in DOPAC concentrations compared to control/NSD-1015 treated animals. These reductions in L-Dopa and DA metabolite concentrations strongly suggest that PCBs, in vivo, inhibit production of newly synthesized DA at the level of tyrosine hydroxylase. Supported by NIH Grant #ES0491304.

672.6

NEUROTOXICITY OF IBOGAYNE IN CD MICE. S.F. All, M. Meneg and J.P. O'Callagham, Division of Neurotoxicology, National Center for Toxicological Research/FDA, Jefferson, AR 72079, Neurotoxicology Division, US EPA, Research Triangle Park, NC 27710. Iboigayne is an indolealkylamine known to have CNS stimulating and hallucinogenic properties in animals. Recently, ibogayne has been proposed for use as a treatment for drug addiction. The neurochemical basis for such therapy, however, remains unclear. The present study was designed to evaluate the neurotoxic effects of ibogayne in mice. Iboigayne was administered to adult female CD-mice (20 g) once daily for 24 hr. On day six, animals were sacrificed and brains removed, and were stored in buffered formalin for 1 week. Sections were cut at 5 microns and stained with cresyl violet. Iboigayne produced a dose-related decrease of 5-HT in caudate nucleus (CN), frontal cortex (FC) and brain stem (BS). Iboigayne produced a significant increase in 5-HT in hippocampus (HIP). There were no significant changes in CN, however, DOPAC was elevated in CN and FC. Iboigayne increased GFAP in olfactory bulb, hippop and BS. These data suggest that ibogayne has a complex neurotroph profile in female mice, as assessed by changes in monoamine concentrations and astroglia.

CHRONIC EXPOSURE TO IBOGAINE RESULTS IN SEX-DEPENDENT ASTROGLIALIZATION. J.R. Barta, J.P. O'Callagham, L.E. Redman, T. Rogers, J.B. Trevill and J.G. Pegg. U.S. Environmental Protection Agency, Res. TII. PK, NC, 27711; Southern Res. Inst., Birmingham, AL 35232; NIDA, Rockville, MD 20857. Iboigayne (IBG) is a naturally occurring alkaloid isolated from the root of the African shrub, Tabernanthe iboga. Evidence exists showing that IBG interrupts the physiological and psychological aspects of drug addiction, both in experimental animals and in the clinic. However, the mode of action of IBG to cause neurotoxicity in male and female rats as evidenced by the presence of astrogliosis, a generic response to CNS injury. IBG was administered to male and female Sprague-Dawley rats (5, 25, 50, or 150 mg/kg, p.o) once daily for 14 days. Rats were sacrificed on day 15 and 31. Brains were dissected into olfactory bulb, hippocampus, striatum, cortex, brainstem and cerebellum. IBG-induced astroglia was quantified by assaying the content of the astrocyte intermediate filament protein, GFAP, in each brain region, using a sandwich ELISA. In male rats, GFAP was not elevated as a function of IBG treatment at any dose or in any region on day 15. However, female rats, exposed at 150 mg/kg of GFAP, were observed on day 15. The greatest increases were seen in olfactory bulb and brainstem, notably, the cerebellum was not affected. In both male and female rats GFAP was unaffected on day 15, following distributions of underlying brain damage. Supported by NIDA Contract 1-192 and NIDA IAG-1-Y1011-30063.

672.8

A CYTOTOXIC EFFECT OF ESTROGEN ON AMYGDALA NEURONS. K.S. Durg, J. Somba, R. Matsuyoshi, M. Kanazawa, A. Ando, S. Chin, and L. Shimada, Division of Health Sciences, University of the Air, Chiba Japan, Division of Basic Medical Sciences, Royal Free Hospital School of Medicine, London. It has been described that estrogen exerts cytotoxic effect on β-endorphin containing neurons in the rat hypothalamus. In this paper, effects of estrogen on cultured rat amygdala neurons were studied. Primary cultures of rat fetal amygdala neurons were used for the experiment. After an acute exposure of estradiol, cells were incubated for 24 hours. Then the percent survival of cells was calculated by assaying intracellular LDH activity. Effect of estradiol on intracellular Ca$^{2+}$ concentration in the cultured neurons were also examined by fura-2 fluorescence. As results, estradiol had a cytoprotective effect on amygdala neurons at L-hormone concentrations, but at M- and cytotoxic effect at higher concentrations. On the other hand, estradiol caused long-lasting Ca$^{2+}$ elevation within cultured amygdala neurons. Mechanisms of this Ca$^{2+}$ elevation was analyzed by adding dipyridamole, a Na-cytotoxin and mRNA inhibitors. Currently, in situ hybridization experiments of hepatic growth factor on rat amygdala before and after estrogen administrations are in progress.
NEUROTOXICITY:

IC50 values were measured in cerebral and forebrain using HPLC. Densities of
NMDA, kainate, adenosine-A1 and GABA-A receptors were also measured by microdialysis. By day 3, concentrations of the excitatory amino acid transmitters, glutamate and aspartate began to fall and remain low (-55% to 70%). Concentrations of GABA and glutamine increased transiently but fell back to control levels by day 5. Concentrations of taurine fell by day 3 (-60% of controls) and remained low. Glycine concentrations increased at day 3 (+200% of control values) and remained elevated. The densities of the glutamate receptors, NMDA and kainate were reduced in cerebral cortex from CPA treated rats. There was no change in the densities of NMDA or kainate receptors in any other brain region examined. Densities of adenosine A1 and GABA-A receptors in cerebral and forebrain regions were not changed following CPA administration. In conclusion, we suggest that reduced glutamate and aspartate levels and NMDA and kainate receptor densities in the cerebral cortex are related to loss in cerebral granule cells. Changes in other amino acids may reflect compensatory events in response to the toxic insult.

GLIAL FIBRILLARY ACIDIC PROTEIN IN THE RAT BRAIN RESPONSES BIPHASICALLY TO INHALED TOULENE. AR. LITTLE, ZL GONG, HAN EF-WA AT, HE Evans. Institute of Environmental Medicine, New York University Medical Center, Tuxedo, NY, 10987

GAP concentration in the hippocampus and cerebellum was evaluated as a biomarker of the neurotoxicity of inhaled toluene. Fisher-344 rats were exposed at 1000ppm or 10000ppm by inhalation for 6 hours/day, 5 days/week. Days 1, 3, 7, 21, and 42 were evaluated. GAP response in the hippocampus was biphasic at both doses, initially decreasing but later increasing above control by day 21 to day 42. In the cerebellum GAP levels declined significantly by day 3, increasing thereafter, never quite returning to control levels. These data are consistent with a hypothesis emerging from this laboratory concerning the mechanism of toluene toxicity, that low doses of toxic chemicals affect regulation of GAP. The most familiar finding is an increase in GAP typical of reactive gliosis. A less frequent and unexpected change may involve decreased GAP levels, observed with very low level exposures. Our studies also indicate a biphasic response with exposure to Pb (Gong et al., 1994). Relative low level exposures administered chronically may be necessary to observe the early phase of the gliotic response, a transient decrease followed by an increase if given enough time or a large enough dose. Low level or short term exposure to toluene may influence changes in glial cell function that precede overt toxicity characterized by gliosis Supported by the American Petroleum Institute and grant ES-04895.

Direct injection (1 µl) of the peptidic Substance-P (SP) antagonist [D-PRO2 D-TRP7,9] Substance-P (DPDP-TSP, 1-3 nmol) induced neurodegeneration in the dorsal hippocampus of rats. Co-injecting SP (50 nmol) reduced the toxicity induced by 3 nmol of DPDP-TSP. Another SP antagonist [Arg8, D- Trp7,9]MePh(8)SP (6-11) (10 nmol) was also neurotoxic after intrahippocampal injection. Surprisingly, the nonpeptidic SP antagonist CP-96,345 was not neurotoxic at a dose of 10 nmol. The reduced neurotoxicity of the nonpeptidic antagonist was not due to a lower affinity for the SP receptor. Concp-96,345 displaced the NK-1 agonist [H3][Sar2 Met5(OH)11]SP with higher affinity (IC50 = 0.34 µM) than DPDP-TSP (IC50 = 8.9 µM) in rat brain membranes. Binding of the peptidic and nonpeptidic antagonists at different receptor subtypes or different injection sites was not enough to explain the differential neurotoxicity observed in the present experiments.

NEUROTOXICITY: DRUGS

To investigate whether the hippocampal damage caused by thiamethoxam (TMT) involves corticosterone (CORT)-receptors, effects of a single oral dose of TMT–chloride (TMT–c) administration on plasma CORT levels on Day 0, 3, and 4 after the TMT–c and 2) response of the level at 0, 30, 60, 90 and 120 min after corticosterone-releasing factor (CRF) injection (28 µg/kg, i.v.) on Day 4 were examined. A significant increase in plasma CORT levels was observed (p<0.05) in response to CRF injection on Day 4. The enhanced CORT levels on Day 4 were shown to be almost completely suppressed at 90, 180 and 300 min after an administration of dexamethasone of 100 µg/kg (s.c.), indicating that the CORT-receptors both in the hypothalamus and pituitary might not be affected by the TMT–c, whereas alterations of the hippocampal CORT-receptors could not be denied. On the other hand, the animals in the same condition with thiamethoxam–chloride (TET–c) of 4 mg/kg (p.o.) did not show significant increase on Day 3 or 4, but their responses of the CORT level to the CRF on Day 4 were exaggerated compared to those among the vehicle (corn oil) controls, suggesting that actions of TET–c, or the hippocampus–HPA axis may be different from those by TMT–c and TET–c.

NEUROTOXIC EFFECTS OF MONOAMINE OXIDASE-B INHIBITORS ON DSP-4 INDUCED DEGENERATION OF NORADRENERGIC AXONS IN THE RAT BRAIN. X. Zhang, P.H. Yu and A.A. Boulton*. Neuropsychiatry Research Unit, University of Saskatchewan, Saskatoon, Canada, S7N OWO.

DSP-4 [N-ethyl-N-nitro-2-naphthylamine] is a highly selective neurotoxin toward the locus coeruleus noradrenergic (NA) system. Previous biochemical studies have shown that the monoamine oxidase-B (MAO-B) inhibitory effect of DSP-4 (R)-deprenyl and Q-210 (N,N,N-trimethylpropargylamine), are able to prevent DSP-4 induced NA depletion in the mouse hippocampus. It is, however, unknown whether this represents a neuroprotection of NA axons. Employing dopamine-β-hydroxylase immunohistochemical and imaging analysis methods, we have found that 92% and 84% respectively NA nerve fibers in the mouse hippocampus are spared from DSP-4 neurotoxicity by a single pretreatment dose of R(-)-deprenyl or 2-HxMP. Similar neuroprotective effects are also observed in the cerebral cortex, thalamus, amygdaloid complex and cerebellum. This is the first morphological evidence demonstrating that deprenyl and 2-HxMP can indeed protect NA axons against DSP-4 neurotoxicity. We are currently also investigating the neuroprotective and neurorescue effects of R(-)-deprenyl and 2-HxMP on DSP-4 induced chronic degeneration of NA neurons in the locus coeruleus.

THE EFFECT OF ACUTE ETHANOL TREATMENT ON CALCIUM HOMEOSTASIS IN CULTURED HIPPOCAMPAL NEURONS BEFORE AND DURING DEPOLARIZATION. B.Webb*, S.S. Suarez, M.D. Heaton, and D.W. Walker, University of Florida, V.A. Medical Center, Gainesville, FL 32601.

The neurotoxic effect of acute ethanol treatment (AET) may lead to an alteration in the regulation of calcium homeostasis in hippocampal neurons. We cultured E18 rat hippocampal neurons for 2 weeks. The cultures were loaded with 2μM indo-1/AM for 1 h at 37°C, rinsed with buffer, and maintained for 1/2 h at 32°C. The cultures were divided into four groups: control, 100,400,800 μg/ml ethanol. Control readings were taken, and then the buffer was changed for either control buffer or buffer containing 100,400,800 μg/ml ethanol. Fast responses were recorded for the first 6.4 sec and then at 10,30,45,60 min. To determine the effect of AET on calcium homeostasis in cultured hippocampal neurons during depolarization, the buffer was changed after 60 min to either control buffer and 30mM KCl or buffer with ethanol and 30mM KCl. Fast responses were recorded for the first 3.2 sec and then at 5.1 min. In cultures treated with 400 or 800 μg/ml ethanol, [Ca2+]r was increased (p<0.01) at later time points, 400 and 800 μg/ml treatment decreased [Ca2+]r in a dose-dependent manner. When AET cultures were compared to control, both 100 and 400 μg/ml ethanol increased resting [Ca2+]r (p<0.01) at 10 min (p<0.05). At later time points, 400 and 800 μg/ml treatment decreased [Ca2+]r in a dose-dependent manner. The results of this study indicate that AET results in the alteration of calcium homeostasis in cultured hippocampal neurons at membrane potentials and during depolarization. These changes in [Ca2+]r may disturb normal cellular function and contribute to cell death. Therefore, the alteration of calcium homeostasis may be an underlying mechanism of ethanol neurotoxicity. ETHANOL DECREASES INTRACELLULAR MYO-INOSITOL IN C. CELLS. K.J. Isenberg*, S.G. Holstled, B.W. Moore and W.B. Sherman, Department of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

Ethanol produces a dose-dependent decrease in the growth of C6 glioma cells. We hypothesized that the etiology of this phenomenon could be similar to effects observed when the cells are grown in hyperosmolar sodium chloride (NaCl). C6 cells were grown in Dulbecco's Modified Eagles Medium and 10% fetal calf serum (controls) or grown in the same media supplemented with ethanol or NaCl in chronic exposure (7 days) or acute exposure (2 days). The results of 2 day experiments reveal that ethanol has a more potent inhibitory effect on growth than equimolar additional NaCl. Unlike exposure to hyperosmolar NaCl, chronic ethanol exposure does not alter intracellular concentrations of protein. Acute exposure of C6 cells to ethanol is associated with a 50% decrease in intracellular concentrations of myo-inositol, the opposite of effects observed upon exposure of the cells to hyperosmolar NaCl. The effects of ethanol upon intracellular concentrations of myo-inositol occur in a dose dependent fashion at concentrations of ethanol (8.5 mM to 130 mM) commonly encountered in human intoxication. Growing the cells in media supplemented with myo-inositol then switching the cells to media with added deuterated myo-inositol and ethanol suggests that ethanol alters myo-inositol influx and efflux. The effects of ethanol on influx of myo-inositol appear to be the opposite of the effects of NaCl upon myo-inositol transport. Ethanol induced reductions in the intracellular concentration of myo-inositol may impair the growth of these cells.

NEUROTOXICITY: METALS

SUBCHRONIC METHYLMERCURY (MeHg) EXPOSURE ALTERS Ca"+ RELEASE FROM AN IP3-SENSITIVE STORE IN NG108-15 CELLS. J.E. Siros*, and W.D. Aitchison Dept. Pharm./Tox, Mich. State Univ., E. Lansing, MI 48824.

MeHg is a neurotoxic organomercurial which exhibits complex effects on intracellular ion homeostasis. Acute exposure to MeHg initially increases [Ca2+]r from an IP3-sensitive pool, increases the concentration of an endogenous non-Ca"-ion and ultimately leads to influx of Ca2+ across the plasma membrane. The present study was undertaken to determine if subchronic exposure to low μm concentrations of MeHg could also alter ion homeostasis and/or affect Ca2+ release from IP3-sensitive pools. 24 Hour Exposure of 1μM MeHg did not alter the apparent resting [Ca2+], but did cause an increase in the response to bradykinin (BK; 1μM). 2μM MeHg for 24 hr also increased the response to BK in addition to slightly increasing the apparent resting [Ca2+]. These results suggest that NG108-15 cells exposed subchronically to MeHg are able to overcome an initial loss of Ca2+ from the IP3-sensitive pool. The enhanced response to BK may reflect an ability of MeHg either to facilitate release from the IP3-sensitive pool or possibly to inhibit the uptake of Ca2+ following its release from this pool. Supported by NIH grant ES03299.

NEUROPSYCHOLOGICAL AND PSYCHIATRIC COMPLICATIONS ASSOCIATED WITH HIGH LEVELS OF SERUM COPPER OF UNKNOWN ETIOLOGY. W.J. Coughlin II, R.D. Fastie*, and J. Joyce*, Human Neurology Laboratory, The American University, Washington, DC 20066, Mt. Vernon Center for Community Mental Health, Alexandria, VA 22309, and *Psychiatric Associates of Fredericksburg, Fredericksburg, VA 22401. Chronic copper intoxication is characterized by Wilson's disease, a rare genetic disorder that usually manifests as either a hepatic or neurological syndrome. Wilson's disease is fatal unless treated with chelating agents. Death results from the direct effects of copper toxicity on the liver. Although the subjects in this investigation do not meet diagnostic criteria for Wilson's disease and are without gross symptoms, laboratory blood tests have indicated toxic levels of serum copper of unknown etiology that are as high as those typically reported in Wilson's patients. The subjects in the present study suffer from psychiatric disorders and approximately 20% of Wilson's patients initially exhibit psychiatric symptoms prior to the onset of the full clinical entity. Using a comprehensive battery of psychological tests, we assessed two female psychiatric patients with chronic copperemia. Preliminary results indicate deficits in verbal and nonverbal fluency, verbal and nonverbal recall, motor speed, and motor coordination. Comparative neuropsychological studies on Wilson's disease in the literature, to date, have found comparable deficits in verbal recall and motor speed. Explanations for the presence of hypertymbria in the subjects are explored including the possible existence of a previously unknown subtype of Wilson's disease. We suggest it is possible, in some rare instances, that patients may present with psychiatric cognitive, or motor symptoms that may, in fact, be related to undiagnosed hypercupremia.
NEUROTOXICITY:

MANGANESE (Mn) poisoning is an occupational disease whose symptoms resemble the Parkinson's. This study is aimed at assessing the effects of Mn in the "H-Spiroperidol receptor pattern of different regions in mice. Male adult mice received a daily intraperitoneal (i.p.) Mn dose of 6mg/kg for eight weeks. Control mice were injected with saline. At the end of assay, the mice were killed by cervical dislocation, and the brains were removed on ice. Olfactory bulb, striatum and hypothalamus were dissected out and frozen until the assay was performed. After that, samples of each region were taken for Mn determination. "H-Spiroperidol binding assays were realized according to the method described by Shargya. Mn concentrations were determined by atomic absorption spectrophotometry. Mn-treated mice showed a significant increase of Mn levels in all regions. The Emax and Kd values for "H-Spiroperidol binding were unaltered by the treatment. Our investigation reinforce previous findings which seem to point out that mice submitted to this conditions are in an early stage of Mn poisoning, where cell membranes damage has not occurred.

METHYL MERCURY INDUCED NEUROTOXICITY IS BLOCKED BY ANTI-OXIDANTS S.T. Park1,2, K.T. Lim1, Y.T. Chang1 and S.U. Kim1. 1Div. of Neurology, Dept. of Medicine, Univ. of British Columbia, Vancouver, BC, V6H 3L5, Canada. 2Dept. of Anatomy, Wonkwang Univ. School of Medicine, Iri 570, Korea.

Methyl mercury compounds are known to induce neurotoxic changes in the mammalian central nervous system (CNS). In order to characterize the mechanism of methyl mercury neurotoxicity, neonatal mouse cerebral neural cultures were exposed to graded concentrations of methyl mercury chloride (0.1-0.02 mg/m) for 2.48 hours. Cell viability was determined using MTT assay and neutral red uptake assay. Methyl mercury was toxic to mouse cerebral neural cultures (LD50 = 20μg) after 24 hours of exposure, and neurotoxicity was blocked in a dose-dependent manner by catalase (10-100 μg/ml) and glutathione (0.2-2 mM). Other reagents tested for neuroprotective effects against methyl mercury toxicity such as selenium (1-10 μM), ascorbic acid (20-200 μM), sodium thiosulfate (0.1-1 mM) and cytoxine (50-500 μg/ml) were not effective. These results indicate that anti-oxidants such as catalase and glutathione are effective in blocking methyl mercury neurotoxicity in the CNS.

EFFECTS OF ALUMINUM ON NEURONAL ION CHANNELS C.H. Ka and I. Saya. Dept. of Pharmacology, Northwestern University Medical School, Chicago, IL 60611-3008, and Dept. of Physiology, Hiroshima University School of Medicine, Hiroshima 734, Japan.

Aluminum accumulation in the body during long-term kidney dialysis has been implicated in the pathogenesis of seizure in dialysis encephalopathy. However, the mechanism of seizure induction is unknown. Previously, we have shown that external application of aluminum caused a dose-dependent depolarization of axon membranes, prolongation of the action potential duration, and repetitive firings of action potentials (Na, FASEB J. 7:6998, 1993). The aim of this study was to elucidate the mechanism of aluminum-induced neuronal hyperexcitability at the ion channel level. Voltage clamp experiments were conducted on giant axons of squid and crayfish. In intact axons, external application of aluminum acetylacetone (1-2 mM) caused a decrease of the potassium current without significant effects on the sodium current. The reduction of K conductance was dose-dependent, and the effect had a slow onset. In internally perfused axons, aluminum had no effects whether it was applied externally or internally. The results suggest that neuronal hyperexcitability seen in dialysis encephalopathy is due to inhibition of potassium channels by aluminum and the inhibition is probably mediated by cytoplasmic constituents. (Supported by NIH grant NS30101).

ALTERED LEVELS OF NERVE GROWTH FACTOR AND ITS LOW-AFFINITY p75 RECEPTOR IN THE DEVELOPING BRAIN FOLLOWING PRENATAL EXPOSURE TO MERCURY VAPOUR. Susan Sidderson1,2 and Ted Fereday1*. Dept. of Developmental Biology, Uppsala University, Box 587, S-751 23 Uppsala, Sweden. Pregnant rats were exposed to low levels of mercury vapour. The levels of mercury (5-10 μg/g wet weight) found postnatally in the brains of their offspring are comparable with those found in human brains after average mercury vapour exposure. The brains of the pups show an approximately 50% decrease of NGF protein in the hippocampus, and the cortex at postnatal day 21 with a concomitant decrease of 50% of normal levels in the medial septal area whith NGF responsive cholinergic neurons. The levels of mRNA for the NGF affinity receptor p75 was significantly reduced to approximately 30% of normal in both the medial septal area and in the diagonal band nucleus. ChAT mRNA was slightly reduced in the diagonal band and the medial septum and was significantly reduced in the striatum. It is suggested that the retrograde transport of NGF from the target to the basal forebrain was interrupted due to the reduced mRNA levels. Moreover, NGF produced by the fibroblast cell line 3T3 in the presence of organic mercury (MeHgCl) was found to be doubled when methyl mercury was added at concentrations of 0.1 μM-0.5 μM.

METALLOTHIONEIN: ISOFORM PURIFICATION IN HUMAN FRONTAL CORTEX K. Kittingham E. J. Kaspris, Graduate Center for Toxicology and Department of Neurology, Veteran's Administration Medical Center and University of Kentucky, Lexington, KY 40536.

Metallothioneins (MTs) are a family of ubiquitous cysteine-rich, 6-7 kD proteins which detoxify heavy metals, participate in zinc homeostasis, and may function as an intracellular antioxidant. Six MT isoforms have been sequenced from human liver. Immunocytochemical data suggest multiple isoforms in the central nervous system; however, only one isoform, MT-III, has been sequenced from human brain. MTs were purified from cortex by homogenizing in 5 mM Tris-HCl, followed by ultracentrifugation. After heat precipitation, the soluble fraction was treated with chymotrypsin. Residual proteins and metals were removed by gel filtration. The MTs were then derivatized with 4-vinylpyridine and the 4- pyridylethylated derivatives were separated by reverse phase HPLC. Sequencing data suggest the presence of multiple isoforms in the cortex in addition to MT-III. Alterations in the proportions of the various isoforms might suggest an increased sensitivity to oxidative stress, metal accumulation and/or alterations in metal homeostasis. Studies in patients with Alzheimer's disease and/or Amyotrophic Lateral Sclerosis are ongoing to identify the status of the individual MT isoforms. This work was supported by VA Research Service and NEIHS 5T32EY10726 to K.K.

METHYL-MERCURY POISONING LEADS TO ENHANCED UPTAKE OF 35S-L-CYSTEINE AND 3H-L-GLUCOSE IN CS7BL/6 MOUSE BRAIN. David Park, Simon Yue and Ben H. Choi. Neuropathology, University of California, Irvine, College of Medicine, Irvine, CA 92717

Previous studies in our laboratory demonstrated that methylmercury (MeHg) poisoning in mice leads to a significant reduction in glutathione (GSH) contents in both brain and liver. We have also shown that an uptake of 35S-L-cystine was significantly enhanced in the brains of CS7BL/6 mice following MeHg intoxication. To examine whether or not a reduction in GSH may underlie enhanced 35S-L-cystine uptake in the brain of MeHg-intoxicated animals, a group of CS7BL/6 mice were injected with 5 mg/kg of methylmercury chloride (MMC) and another group with 1.0 mg/kg of buthionine sulfoximine (BSO), a cysteine-synthesizing inhibitor, for 4 consecutive days. The control animals received physiological saline in place of the drug solution. After the last injection, 35S-L-cystine (1.0 μCi/g) and 3H-L-glucose (1.0 μCi/g) were injected intraperitoneally. Forty five minutes thereafter, the brain and liver were obtained following sacrifice and counted. Both BSO and MMC showed marked GSH reduction in the brain and liver. However, brain uptake of both 35S-L-cystine and 3H-L-glucose was significantly enhanced only in MMC group and not in BSO group as compared to those in control. These results suggest that the enhanced uptake of 35S-L-cystine and 3H-L-glucose in the brain of MMC-poisoned animals may be primarily related to a dysfunction of the blood-brain barrier brought about by MeHg intoxication. (Supported in part by NIH grant ES 02269)

COMPARISON OF THE TOXICITY OF TRIMETHYL Tin FOR FOUR INBRED STRAINS OF MICE. J. E. Ekuta, M. Tharp and J.C. Matthews. Dept. of Pharmacology, University of Mississippi, University, MS 38677.

The central nervous system toxicity of trimethyl tin (TMT) is characterized by selective nerve and glial cell destruction, particularly granule cells in the hippocampal formation, associated with performance deficits in behavioral tasks used to assess learning and memory. In addition to these rather selective effects, TMT also causes systemic toxicity manifested by a diarrhea, loss of appetite and weight, and death in severe cases. Male mice at 4 months of age from four inbred strains (C57BL/6J, AKR/J, BALB/cByJ, and DBA/2J) were compared for their relative sensitivities to the toxicity of TMT following a single intraperitoneal injection. Body weight and mortality were used as indices for assessing systemic toxicity. The average time taken for the mice from each strain to find the submerged platform (swim time) in the Morris water maze was used to assess spatial learning abilities. Mice of all strains, except BALB/cByJ, died within 36 hours of 3.0 mg/kg TMT administration. At lower doses, the order of sensitivities of the strains based on severity of weight loss was C57BL/6J > AKR/J > DBA/2J > BALB/cByJ. The swim time ranking for the mouse strains was BALB/cByJ > DBA/2J > AKR/J > C57BL/6J. These results demonstrate that different inbred strains of mice exhibit genetically determined differences in their levels of sensitivity to the toxicities of TMT. This finding is an important first step in our quest to understand the role of neurotoxicity in neurodegenerative disease.

TRIMETHYLNITROSURIE STIMULATED PROTEIN KINASE C TRANSLLOCATION IN DIFFERENTIATED PC12 CELLS. M.D. Kane, G. Palavicino, and G.B. Isaac. Dept. of Pharmacol. & Toxicol., Purdue Univ., West Lafayette, IN.

Trimethyltin (TMT) is a potent neurotoxic agent which causes learning and memory perturbations and culminates in necrotic lesions of the limbic system in rodents and man. Differentiated rat pheochromocytoma (PC12) cells were used to determine the effect of TMT on neuronal signal transduction systems. Treatment of cells with TMT did not increase cytosolic free Ca2+. However, confocal imaging studies of differentiated PC12 cells showed that 10 pm TMT stimulated mobilization of protein kinase C (PKC) from cellular membranes. To characterize this response in more detail, PC12 cells were treated with TMT (0, 5, and 20 pm) or phorbol myristate acetate (PMA; 100 nM) and the extent of PKC translocation to the membrane was determined at 0.5, 4.0, and 24 hrs of treatment. PKC translocation was determined in soluble and membrane cell fractions by western blot analysis using anti-PKC antibodies. The control profile showed greater than 95% PKC in the soluble fraction. Both 5 and 20 pm TMT treatments stimulated a partial translocation of PKC (40%-60%) to the membrane fraction at all time points. PMA treatment stimulated greater than 95% PKC translocation at 0.5 and 4 hrs as well as a complete loss of PKC staining in both fractions at 24 hrs indicating PKC down regulation. TMT stimulated translocation did not result in PKC down regulation at 24 hrs. In separate experiments 100 pm TMT inhibited Ca2+-phosphatidylserine stimulated PKC activity to 27% of control activity as determined by the 32P-acceptor method. These results show that TMT stimulates a partial and sustained translocation of PKC in PC12 cells and inhibits kinase activity. This event appears to be independent of a rise in cytosolic free Ca2+.

673.11
COMPARISON OF INTRACRANIAL AND SYSTEMIC ADMINISTRATION OF TRIMETHYLNITROSURIE ON HIPPOCAMAL DAMAGE. V. Lugo, E. Rasmussen and E. Castaneda*. Behavioral Neurosciences Laboratory, Department of Psychology, Arizona State University, Tempe, AZ 85287-1104.

It has been suggested that accidental exposure to the organometallic toxic trimethyl tin (TMT) produces behavioral deficits that are a result of hippocampal damage, and 2) hyperactivity observed in rats treated systemically with TMT may be useful as a model for attention deficit hyperactivity disorder. In order to further evaluate these postulates, the effects of various doses of TMT infused into the hippocampus were examined. Adult Long Evans rats received bilateral infusions (2 hemispheres) of either vehicle (phosphate buffered saline) or TMT (total of 50, 100, 200, 500 or 1000 mg) into the hippocampus. Two more groups of rats received 8 mg/kg TMT or vehicle systemically (i.p.). At least two weeks later, animals were decapitated and the left hemispheres underwent histological processing for Nissl staining. The hippocampi were dissected from the right hemispheres and prepared for assay of dopamine and serotonin using HPLC-EC. It was found that there was a dose-dependent ablation produced by intrahippocampal application of TMT that was not evident in rats treated systemically. In addition, the two highest intrahippocampal doses produced serotonergic depletions relative to systemically treated rats. These results have important implications for understanding the central mechanism of action by which TMT produces behavioral deficits in human and nonhuman animals. Currently, behavioral measures are being examined for changes induced by intrahippocampal infusions of TMT.

673.12

Glycine (Gly) is an agonist at two neurotransmitter receptor sites, one sensitive to inhibition by Strychne and linked to an Inhibitory Gly-gated chloride channel, and the other a co-agonist site on the N-Methyl-D-aspartate (NMDA) channel complex. In previous reports, we have found a reduction of NMDA receptor density in some cerebral areas of manganese intoxicated mice. In the present study we present evidence that Manganese exposure blocks Gly binding to its receptors by autoradiographic methods. Male albino mice were injected i.p. with manganese chloride (5 mg Mn/kg body weight/day) 5 days per week, during 8 weeks. Control animals received saline injections given plane drinking water. Sacrifices were made on days 14, 25, 26, 27, 28, and 42 (5 animals/day) for the exposed group and days 14 and 28 for the control.

Body weight and water consumption were similar for the exposed and control groups. Gly receptor mRNA levels in dorsal and ventral areas were significantly elevated compared to placebo on days 25, 26, 27, 28 and 42. The Gly receptor mRNA levels were significantly elevated on days 7, 26, 27 and 28 compared to the control. Since there was no difference from control in either Gly receptor mRNA or Gly receptor on day 14, we conclude that the increase in Gly concentrations in this brain region is not due to an increase in Gly receptor expression. These data suggest that manganese increases Gly receptor mRNA levels in the rat brain and may play a role in the development of manganese induced neurotoxicity.
AN IN VITRO MODEL TO STUDY THE RELATIONSHIP BETWEEN IRON AND PROTEIN OXIDATIVE MODIFICATION. S.H. Hackett*, R.B. Sturz*, E. Ferreira*, W. Van Gelder†, J.B. Cazana†. 1st Dept. of Neurosciences & Anatomy, 2nd Dept. of Pathology, LSUHSC, New Orleans, LA. 70112.

The relationship between iron toxicity and oxidative damage to proteins is of increasing interest to neurologists and neuroscientists. We present a model to study this relationship in an in vitro system. Experimental conditions were designed to induce oxidative stress and determine the specificity of iron-mediated protein modifications. Iron was supplied to differentiated PC12 (neuronal-like) cells and to primary cultures of adult rat cortical neurons. The deprenyl-protected, rat nigrostriatal explant cultures were also used. The iron source (EDTA-Fe III) was added to the culture medium at different concentrations. The results indicated that iron and iron chelators (DMSA, BAPTA, MnCl2) can modify proteins (e.g. BS integrin, L-arginine synthase, FGF receptor). The iron and chelator dosage dependence of the protein modifications was assessed. The modifications occurred with a high degree of specificity, with limited modification of non-iron-containing proteins. This model could be used to assess the role of iron in the pathogenesis of neurodegenerative disorders such as Parkinson's disease and to assess the role of iron chelation therapy for the treatment of these diseases.

A process of metabolic activation is thought to be the first step leading to the toxic effects of 1-methyl-4-phenyl-1,2,3,6-tetrahydroxypyridine (MPTP). This conversion forms the toxic 1-methyl-4-phenylpyridinium (MPP+) metabolite and in the brain is most likely mediated via glial monoamine oxidase (MAO) type B (MAO-B) inhibition. However, does not completely block MPTP conversion to MPP+ since MPP+ is still formed in the presence of MAO inhibitors both in vitro and in vivo. The purpose of the present study was to determine whether that iron may act as a catalyst for the MAO-independent bioactivation of MPTP. Primary cultures of mouse astrocytes were treated with both the MAO A inhibitor clorgyline and the MAO B inhibitor deprenyl prior to the addition of MPTP. Production of MPP+ was reduced (to approximately 15%), but not completely by MAO inhibition. This MPP+ production appeared to be iron-dependent since it was decreased (30 to 50%) by iron chelators, deferoxamine or phenanthroline, and was enhanced (by more than 50%) in the presence of ADP. Data indicate that oxidation via MAO is the primary but not the only pathway of MPTP bioactivation and that transition metals may contribute to the generation of the toxic MPP+ metabolite in biological systems.

673.21 LEAD REDUCES CALCIUM ENTRY WITHOUT PASSING THE CELL MEMBRANE OF MAMMALIAN NEURONS: FURA 2 MEASUREMENTS. D. Busselberg*, R. Donnem, I. Wunder, and H. L. H. H. Physiology II and BMFZ, Heinrich-Heine-University, P0B 100177, D-40001 Düsseldorf, Germany.

Lead is an ubiquitous but neurotoxic element. Recent work has demonstrated that its neurotoxicity is partly due to actions on voltage activated calcium channel currents (Busselberg et al., 1994, J. Neurophysi ol., 71). It reduces calcium channel currents with an IC₅₀ of ~0.5 µM. Here we prove our prediction that the rise of the intracellular calcium concentration is prevented by lead. Dorsal root ganglion neurons of rats were depolarized by exposure to 50 mM potassium and the rise of internal calcium was measured with Fura 2. Lead reduced this rise in a concentration dependent manner, with a threshold concentration of 0.25 µM and ~5 µM lead reduced the calcium entry by 280%. The effect was most likely due to voltage activated calcium channels but does not pass through the channel itself.

673.22 EFFECT OF LEAD INTOXICATION ON SYNUVIA DEHYDROGENASE ACTIVITY AND THIAMINE CONTENT IN THE BRAIN OF RAT. K. I. and Y., H. and I. E. College of Pharmacy, Seoul National University, Seoul 151, Korea

Thiamine has been reported to reduce the toxic manifestations of lead at lead level in tissues. Concomitantly, lead intoxication may affect thiamine status and thiamine-related biochemical responses. In this study, it was tested if lead intoxication could change thiamine content and the activity of pyruvate dehydrogenase in the brain and administration of thiamine could prevent the toxic manifestations of lead intoxication.

Five groups of Wistar rats were prepared: 1) control group, 2) lead group, 3) lead plus thiamine treated group, 4) pyruvithiamine treated group, and 5) pyruvithiamine treated group. Each group of animals was divided into five subgroups based on age, 3, 7 and 16 weeks of age. Lead was administered by drinking drinking water containing 0.2% lead acetate and thiamine was administered via drinking water. It was divided in 3 groups according to the period of treatment: 3 days, 7 days, and 16 days. All animals were treated with either lead acetate or water and thiamine for 16 days. As a result of this treatment, it was observed that lead intoxication lowered the activity of pyruvate dehydrogenase in all brain regions and the activity increased significantly in the thiamine treated group. Thiamine intake in brain regions of lead treated group was significantly lower than those of control group, and those of lead plus thiamine treated group was significantly decreased from those of lead treated group. Thiamine content in brain regions of lead treated group was significantly lower than those of control group, and those of lead plus thiamine treated group was significantly higher than those in lead treated group.

The results from the present study suggest that lead neurotoxicity including convulsion following lead intoxication in rats may be mediated at least in part through the changes of thiamine status and thiamine related factors.

673.23 CHRONIC LOW-LEVEL LEAD STIMULATION OF NEURAL CELL SYNALIATION STATE: Fleur D. Hayes & Kieran C. Broer*. Dept. of Pharmacology and Clinical Pharmacology, University of Dundee, Ninewells Medical School, Broughton Road, Dundee, DD1 9SY, Scotland, U.K.

Lead is a neurotoxic agent which acts preferentially on the developing nervous system. Although the molecular mechanisms underlying the actions of lead are not well understood, it has been suggested that it may act to disrupt the processes of neurite elaboration and consequent synapse formation. The neural cell synaliation state is precisely regulated at this stage of development and may thus provide a possible target for lead toxicity.

Hippocampally-derived neuronal cell hybrids were cultured in the presence of low-level lead (10⁻⁴ to 10⁻¹M) for 72 hours, the cells harvested and the activity of the sialyltransferase enzyme determined. Sialyltransferase activity was stimulated three-fold by very low lead levels in cells derived from both embryonic day 15 and postnatal day 1, the former giving more reproducible lower lead levels. Lectin blot analysis demonstrated an increase in the sialylation state of specific glycoproteins. Although the nerve cell adhesion molecule, NCAM, is a developmentally-regulated sialylcoeprotein, there was no evidence for a lead-induced re-expression of the polysialylated form of the protein. This results demonstrate that neural cell glycosylation is susceptible to chronic low-level lead exposure, and this may contribute to the upshift in synapse formation associated with lead-induced neurotoxicity.

This study was supported by a Wellcome Toxicology Studentship to F.D. H.

673.25 LEAD INDUCES A BIPHASIC GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) RESPONSE IN RAT BRAIN. Z.L. Gona, A.R. Little, Han, E. Fawal, H.I. Evans*, Institute of Environmental Medicine, New York University Medical Center, Tuxedo, NY 10987

GFAP was used to test whether repeated exposure to lead (Pb) produces a different pattern of change in astrocytes at early stages of exposure, especially at postnatal stages, and at higher doses measured Pb were different than at higher doses which produce overt toxicity. Male F344 rats (~42 days old) received either lead acetate (Pb: 50 or 1000 ppm) or trimethyl lead (TML: 8 or 16 ppm Pb) in their drinking water for 7 or 14 days. Although TML produced much more toxic, as shown by decrease in body weight, both Pb and TML produced a similar biphasic pattern of increase in brain GFAP. As a result of this treatment, Pb occurred at lower levels of exposure (50 ppm Pb) or at early stages of exposure (day 7 of 8 ppm TML); increases in GFAP occurred at higher levels of exposure (1000 ppm Pb or 15 ppm TML) or at later stages of exposure (day 14 of 8 ppm TML). Dose-response was observed in hippocampal rats of rats exposed to TML and in cerebral cortex and cerebellar rat exposed to Pb. The observed biphasic change in GFAP levels during Pb exposure suggests that astrocytes play a role in the brain's earliest response to neurotoxic metals. We propose a two-stage astrocytic gliosis occurs in response to neuronal damage as indicated by increased GFAP. Supported by the American Institute for Cancer Research and Grants ES-04895.

The purpose of this study was to determine if postnatally lead-treated kittens have a greater susceptibility to bicuculline-induced seizure initiation. Kittens were treated with 20 mg/kg lead acetate solution daily by oesophageal intubation for seven days postnatal. Control kittens were maintained as the same except they were administered 20 mg/kg sodium acetate solution. The kittens were allowed to age to one year during which time they were observed for any behavioral abnormalities. No spontaneous seizures were seen in either group. The kittens were anaesthetized with an IM injection of a solution containing 50 mg Ketamine, 5 mg Xylazine and 1 mg Acepromazine and the femoral vein was cannulated for delivery of drugs. Small holes were drilled into the skull and electrodes were placed on the frontal and parietal cortex. A tracheotomy was performed, auffed pediatric ET tube inserted and the kitten respirated with 55% O₂/45% CO₂. The animals were paralyzed with 150 mg/kg Pancuronium. The EEG was recorded during this procedure to determine baseline neural activity. Bicuculline (0.15 mg/ml) was infused via the femoral canula with a Harvard infusion pump at a rate of 0.20 ml/min. Seizure initiation as measured by EEG was EEG during a 4 min interval. The EEG was recorded during this procedure to determine baseline neural activity. Bicuculline (0.15 mg/ml) was infused via the femoral canula with a Harvard infusion pump at a rate of 0.20 ml/min. Seizure initiation as measured by EEG was later observed. The bicuculline was administered every 10 minutes and the response was noted. It was observed that the bicuculline in experimental and 0.36 mg/kg bicuculline in control subjects. The brain of these kittens will be processed by the Golgi-Cox method to determine if cerebral cortical neurons are hyperpyrexic. Hyperpyrexia in lead-exposed kittens have been described previously by our laboratory. It will be of great interest if seizure susceptibility is correlated with the hyperpyrexia condition. Predictions towards seizure activity may be implicated in neurobehavioral aberrations seen in lead-exposed kittens.
674.5 LONG-TERM SURVIVAL OF MPTP-TREATED AGING MICE AND THE ROLE OF GIANT, X. L. CHEN, AND M. G. GUYA. Department of Anatomical Sciences and Neurobiology, University of Louisville, Louisville, KY 40202.

Previous studies from this laboratory have shown that MPTP treatment in the young adult mice significantly reduces the number of dopaminergic neurons in substantia nigra (SN). Six months after MPTP treatment, there is a significant recovery of the dopaminergic neurons. The present studies were undertaken to examine plasticity of aging dopaminergic neurons in the SN following toxic insult. Aging male C57BL/6 mice (18 month old) received MPTP in an dose of 25 mg/kg (i.p.) and were examined 3 days, 2 weeks, and 6 months after MPTP treatment. Control and MPTP-treated mice were anesthetized and perfused. Intact brains were cryoprotected with 4% paraformaldehyde in 1.5% sucrose in 0.1 M phosphate buffer. Frozen 40 um thick sections were cut through the entire brain. Adjacent sections were stained immunocytochemically with tyrosine hydroxylase (TH) antibody and 6-OHDA fluorescent (MPP)-immuno reaction. The number of TH-positive neurons was quantitated in the SN. The results show a significant reduction of TH-positive neurons in SN at 3 days after MPTP compared to the control group. The number of TH-immunoreactive cells was reduced to 45% of the control level at 6 months after MPTP treatment. The recovery even up to 6 months after MPTP treatment compared to the young adult mice. Since glia convert MPTP into its toxic metabolite MPP+ which is increased glial fibrillary acidic protein (GFAP) immunoreactivity is increased in the old aging mice. It is possible that glia play a role in the reduced ability of aging mice to regenerate following toxic insult. Supported by USPHS grant NS 24921 to MG.

674.6 INDUCTION OF C-FOS FOLLOWING MPTP TREATMENT IN THE YOUNG ADULT AND AGING MICE. M. GUYA*, C. HITCHEN, AND X. L. CHEN. Department of Anatomical Sciences and Neurobiology, University of Louisville, Louisville, KY 40202.

Previous studies from this laboratory have shown a loss of dopaminergic neurons in the substantia nigra (SN) and decreased levels of dopamine in the striatum following MPTP treatment in the young adult mice. By six months after MPTP, there is a significant recovery in the SN of young adult mice compared to the aging mice, treated in a similar manner. Immediate early genes that are induced by molecular signals and after transcription of other genes, are activated in the rat striatum of cocaine and amphetamine treatment. The present studies examined the effects of MPTP treatment on the induction of c-fos in the aging mice which was examined by c-fos immunostaining. Frozen sections of the aging mice were cryoprotected with 4% paraformaldehyde in 1.5% sucrose in 0.1 M phosphate buffer. Frozen 40um thick sections were cut from the entire brain. Adjacent sections were stained immunocytochemically by tyrosine hydroxylase (TH) antibody and c-fos fluorescent (MPP)-immuno reaction. The number of TH-positive neurons was quantitated in the SN of aging mice. The results show a significant increase of c-fos in the young adult mice 30 minutes after MPTP treatment. The induction of c-fos was not observed in the aging mice. The results are consistent with the hypothesis that oxidant formation may be induced by MPTP through the release of DA, the observation that c-fos is produced in an area displaying no significant DA release suggests that a second mechanism is also involved. The protective potential of MPTP for the aging mouse, which is not observed in the young adult mice, may be due to an increased recovery of protein synthesis in the aging mice treated with MPTP. Supported in part by USPHS grant NS 24921 to MG.
**NEUROTOXICITY: STRIATUM**

**674.7**

A single systemic injection (0.3 mg/kg; i.v.) of MPTP, a neurotoxin that induces a Parkinsonian-like syndrome, produces a progressive high amplitude swelling of tyrosine hydroxylase (TH) positive neural processes in the proximal third of the nigrostriatal (NS) pathway of dog. This swelling is evident one day after an injection; and by 14 days, many profiles reach a diameter of 30µ or more. In parasagittal sections, the swellings have a club-like appearance with the head pointing rostrally towards the striatum and the handle tapering towards the nigra. The club-like swellings are acidophilic and are immunopositive for the non-phosphorylated neurofilaments. The periphery of the swellings reacts positively for antibodies against myelin basic protein. Examination of the TH-positive swollen profiles with the electron microscope reveal that they are myelinated axons. Thus, unlike rats whose NS-neurons are unmyelinated and survive exposure to MPTP, NS-neurons of the dog are myelinated and are killed by MPTP. We hypothesize that the degree of myelination is positively correlated with a DAergic neuron's ability to recover from a MPTP insult.

**674.8**

The present study sought to map and quantify the number and location of midbrain dopaminergic (DA) neurons that are susceptible to degeneration following MPTP treatment, and determine whether the vulnerable cells contain the calcium-binding proteins calbindin-D28k (CALB) or calreitin (CALR). Brain sections from adult male FVB mice were processed for simultaneous two-color fluorescence immunocytochemistry for tyrosine hydroxylase (TH) and CALB, and TH and CALR. Three groups of 3 FVB mice received 4X25 mg/kg MPTP (at 2h intervals) either on Day 1 alone, Days 1 and 3, or Days 1,3,4,5 for cumulative doses of 100, 200, and 300 mg/kg, respectively. Mice were sacrificed 7 days after the last injection. There was over an 80% reduction in striatal dopamine concentrations in all three treatment groups, however, DA cell loss was only observed after the 300 mg/kg dose. There was an average of ~40% cell loss that was confined to a mid-rostral caudal portion of the substantia nigra pars compacts, in a region largely devoid of CALB or CALR in the DA neurons.

**A NONINVASIVE APPROACH TO TEST DOPAMINE OXIDATION BLOCKADE BY MPTP AND MPP+ NEUROTOXINS IN RATS. S.P. Bagchi*, Nathan Klene Inst.for Psychiatric Res., Orangeburg, NY 10962**

MPTP and MPP+ may induce Parkinson's disease syndrome and also impair oxido-reduction of dopamine (DA) by mouse striatum. A noninvasive approach based upon urinary DA and DOPAC levels to test oxidation defect induced by MPTP, MPP+ or other causes may be clinically useful. Neurotoxin was administered i.p. to rats put in metabolic cages for collecting urine over 1 N HCl for subsequent 0-12, 12-24 or 0-24 hr. time periods. Urinary DA and DOPAC were quantitated by published methods employing gas chromatography. A single 5.0 mg/kg dose of MPTP or MPP+ acutely depressed urinary DOPAC level and DOPAC/DAA ratio compared to saline control. Reserpine (RES) (2.5 mg/kg) acutely raised DOPAC level and DOPAC/DA ratio and these effects were reversed by either MPTP, MPP+, or paraglyine (30.0 mg/kg), but not by the MPP+ congener paraquat (5.0 mg/kg), given 1 hr. before RES. At 13 days after a single MPP+ dosage, DOPAC level and DOPAC/DA ratio did not differ from the control. RES effects, however, were still blunted at 13 days. Five d 5.0 mg/kg MPP+ dosages had powerful effects at 0-24 hrs. following the last dosage but the values reverted to normal by 6 or 13 days; at 27 days, reserpine revealed impaired oxidation of DA in conclusion. MPP+ may cause an acute as well as a long-lasting impairment of peripheral DA oxidation and the latter may become apparent only in reserpenized animals. Also, the RES induced sensitivity is due to an enlargement of the limiting free DA level at MAO site rather than because of the release of stored neurotoxin. Supported by Office of Mental Hygiene, State of New York.

**EVALUATION OF THE EFFECTS OF HEAT STRESS ON THE NEUROTOXICITY OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDRODIPYRIDINE (MPTP) IN C57/BLN MICE. T.K. Freydenberg*, W. Siskor, Jr. and S.F. As. Division of Neurotoxicology, NCTR/FAA, Jefferson, AR 72079 and Dept of Biochem. & Mol. Biol., UAMS, Little Rock, AR 72205**

MPTP is known to cause neurotoxicity in rodents and nonhuman primates. The present study was designed to determine whether heat stress, with the subsequent induction of stress proteins, 24 hr prior to dosing with MPTP might have an effect on striatal dopamine depletion. Adult male C57/BLN mice were dosed with 4 x 10 mg/kg, ip MPTP at two hr intervals and sacrificed without previous heat stress. Animals were sacrificed at 24 hr after the last dose. Stratal dopamine and its metabolites were measured by HPLC/EC and stress proteins by SDS/PAGE. MPTP produced 70% depletion of dopamine in the striatum of non-heated stressed animals, whereas in heat stressed animals striatal dopamine depletion was 83%. Animals subjected to heat stress alone or injected with saline showed no depletion of striatal dopamine. Stress protein induction could not be detected by SDS/PAGE or immunoblotting in either the striatum or the substantia nigra. These results suggest that heat stress has lasting effects which enhance the neurotoxicity of MPTP.

**674.11**

The effects of condensation products of dopamine and indoleamines on the activity of tryptophan hydroxylase (TPH) were evaluated to determine the structures associated with modulation of this enzyme activity. The compounds having a catechol structure, such as 6,7-dihydroxy-1,2,3,4-tetrahydroxyxosin-TGD, were shown to potentially inhibit the activity of the enzyme prepared from the rat brain. The inhibition was non-competitive in terms of both the bipterin cofactor and the substrate L-tryptophan. The substitution on 1 or 2 positions of 6,7-dihydroxy-TGD did not affect their inhibitory capacities to TPH activities. Among these compounds, a charged substance, 1-methyl-2(2-methyl-6,7-dihydroxyxosin-TGD) was shown to be the potent inhibitor; the Ki values were 0.88 ± 0.17 and 0.64 ± 0.08 µM (mean ± SD) in terms of the substrate and cofactor, respectively. On the contrary, the condensation products of indoleamines scarcely affected TPH activities. 1-Methyl-TGD, MPTP, and MPP+ were almost inactive. These results indicated that the catechol structure recognized and combined with TPH at the binding site different from that of the charged substrate and the dopamine-derived substance enhanced the affinities to TPH. The inhibitory capacities of these compounds would be enhanced by the cyclizing reaction of dopamine. (Supported by a Grant-in-Aid for Scientific Research on a Priority Area #1303 of Japan).

Recent studies show that p-carbolinium ions (BC+) resemble the synthetic parkinsonian toxicant, MPP+, with respect to structure and neurotoxicity (Brain Res. 570, 154, 1992) and are identified in human brain by the GC/MS analysis (Brain Res. 610, 90, 1993). These potential bioactivated neurotoxicants, 2-N-methyl-p-carbolinium (2-MeBC+) and 2,8-N-dimethyl-p-carbolinium ions (2,8-Me2BC+) were analyzed in the lumbar cerebrospinal fluid (CSF) of 16 parkinsonian and 16 non-parkinsonian patients using HPLC/fluorescence detection. The levels of BC+ ions in the lumbar CSF of parkinsonian patients were significantly higher than those in non-parkinsonian individuals. On the other hand, there was no significant difference in the CSF levels of simple p-carboliniums, which are precursors of BC+, between parkinsonians and non-parkinsonians. These results strongly support the hypothesis that "bioactivated" carbolinium ions, which are 2-MeBC+ and 2,8-Me2BC+, could be endogenous causative factors in Parkinson's disease. (Supported by a Grant-in-Aid for Scientific Research on a Priority Area #1303 of Japan).

674.13

We are comparing the effects of a single unilateral injection of the neurotoxin 6-hydroxydopamine (6-OHDA) into the striatum versus the substantia nigra on ipsilateral rotational responses to D-amphetamine injection. Seventeen out of nineteen rats injected ipsilaterally to D-amphetamine (3.0 mg/kg) when tested at 13-18 days following injection of 25 μg (1.5 μl) of 6-OHDA into the right striatum. Repetition of the 1 hr. rotational test at between 25 and 53 days post lesion revealed a decreased response in twelve of the fourteen original positive responders. Ipsilateral rotations were significantly (P < .005) reduced to a mean value (+ SEM, 189 ± 50) which was only 43% of the original response (474 ± 49). Substantia nigral-lesioned rats (N=6) that tested positive at 10-21 days post lesion showed a mean response upon retesting at 61-79 days post lesion (606 ± 63) which was 160% of their original value (472 ± 110). These findings demonstrate a limited behavioral recovery in striatal but not substantia nigral 6-OHDA-lesioned rats. Supported by a BRSG grant to M.L.L.

674.15

There has been considerable interest in the possibility that perturbations of energy metabolism play a role in the nigrostriatal degeneration. Methamphetamine (METH) has been shown to cause a long-lasting dopaminergic neurotoxicity in the striatum. Although it has been suggested that endogenous dopamine (DA), excitatory amino acids, and oxidative stress are involved in METH toxicity, the relationship between energy impairment and the toxic effects of METH on dopaminergic neurons remains to be explored. In the present study, experiments were conducted to investigate the effects of METH on mouse brain ATP levels and the relationship between METH-induced changes in striatal dopamine and ATP concentrations. C57BL/6 mice were treated with either a single or 4 doses of METH (10 mg/kg, i.p., given at 2 hr intervals) and killed by microwave irradiation of the brain at either 1.5 hr or 1 week after the last injection. ATP levels were measured in the striatum, hippocampus and cerebellar cortex, and striatal DA levels were also determined. Neither striatal ATP nor DA concentrations changed after a single injection of METH, but both were decreased after 4 doses of METH. No changes in ATP were observed in the hippocampus and cerebellar cortex. In a second set of experiments, an intraperitoneal injection of 2-deoxyglucose (2-DG, 1 g/kg), an inhibitor of glucose uptake and utilization, was given 30 min prior to the last 2 injections of the 4 doses of METH. 2-DG significantly potentiated METH-induced striatal ATP loss at 1.5 hr and DA depletions at 1.5 hr and 7 days. These results indicate that a toxic regimen of METH results in a selective energy impairment in striatum, and raise the possibility that energy impairment plays an important role in METH-induced dopaminergic neurotoxicity.

675.1
Excitotoxic mechanisms in cultured neuronal and glial cells overexpressing Cu/Zn-superoxide dismutase (Cu/ZnSOD). O. Bar-Peled* and Y. Groner, Molecular Genetic and Virology Dept., The Weizmann Institute of Science, Rehovot, Israel 76100.

To study the involvement of Cu/ZnSOD overexpression in excitotoxic cell death, susceptibility of cortical areas and cord neurons of transgenic-Cu/ZnSOD (TgHS) mice to Kainic acid (KA) was investigated. Glial-free neuronal cultures grown in medium without serum, were exposed to KA for 15-20h and surviving cells monitored by counting the number of Neurons Specific Enolase positive cells. As previously recorded in mixed neuronal and glial cultures, 50 and 100μM KA led to 1.5-2 fold increase in cell death when glial-free cultures from TgHS were compared to control mice. The role of glial cells in this differential vulnerability was studied. Astroglial cultures were prepared and uptake of [3H]-glutamate was measured. 50% increase in glutamate uptake per cell was found in control cultures as compared to cultures from TgHS mice. Glutamate uptake is an energy dependent process driven through a sodium gradient maintained by Na+/K + ATPase. To examine whether lower activity of the Na+ pump in TgHS astrocytes was involved in the reduction of glutamate uptake, ouabain, an inhibitor of Na+ pump was added. At 10μM it caused a reduction of glutamate uptake in both TgHS and control astrocytes, however, the inhibition in TgHS cells was 40% larger. When subjected to KA, TgHS spinal-cord neurons were more susceptible than control neurons. Upon incubation with Osmolite (20mM) for 20h, 60% more spinal neurons died in the TgHS cultures. Electron microscopy analysis of KA-treated neurons revealed condensed chromatin and abundant vacuolization in the cytoplasm, indicating that KA-induced cell death is mediated by apoptosis.

675.2

Oxygen deficiency and chronic dexamethasone treatment are known to cause damage to the central nervous system. Cortical regions, such as the hippocampus, are vulnerable to these insults. Several groups were formed based on treatment and timing. Rats received oxygen deficiency treatment on the day of birth (P0), at P7, or at both P0 and P7. Dexamethasone treatment was received on the day and without oxygen deficiency treatment(s). There were 7 treatment groups including the controls. Oxygen deficiency consisted of 3 treatments each separated by 30 minutes for both the P0 and P7 apps. At P0, oxygen deficiency criterion was reached when the rat demonstrated either 2-15sec or 1-45sec intergasp intervals while in the chamber. At P7, the criteria was 2-15sec or 1-30sec intergasp interval. Dexamethasone treatment was given for 7 consecutive days at 5mg/kg body weight. Openfield activity measures and performance on the holeboard memory task were assessed. Preliminary results indicate that P7 oxygen deprivation caused the greatest behavioral disruption. Rats of groups that received a P7 oxygen deficiency treatment showed a decrease in activity, and were less efficient in completing the memory task. Histological analysis are being conducted. (Conducted under NIH Guide for care and Use of Laboratory Animals).

2)Laboratoire Neurobiologie de la Division de Radiologie du Service du Service des Armes Chimiques aux Roses, FRANCE

Exposure of the mammalian brain to ionizing radiation, whether as part of a cancer therapy or due to industrial nuclear accidents, causes severe cerebral damage. This study was performed to evaluate the effect of the antiglutamate neuroprotective, riluzole, on the acute structural and behavioural damage inflicted by a dose of 2.5 Gray to the brains of 15 day old rats. Rats were irradiated from a Cobalt 60 source. They received riluzole at a dose of 8 mg/kg i.p., 20 minutes after the start of the irradiation. Six hours later animals were perfused and brains removed. The hippocampus was cut in 1 μm sections and stained with toluidine blue. The proportion of pyknotic cells per 1000 cells in the granular and subgranular layers of the dentate gyrus was counted in three non-similar slides. In other animals behaviour was examined in an open field.

Irradiation at 2.5 Gray caused pyknosis in neurons in the dentate gyrus. Riluzole reduced the number of pyknotic cells in irradiated rats, with a dose-dependent and statistically significant protection seen between 1 and 4 mg/kg i.p. At 10 mg/kg 18.0±0.7% of neurons pyknotic compared to vehicle-treated controls with 24.6±0.8% cell death; n=10/group, p<0.05. In the open field irradiated animals showed signs of lethargy, unco-ordinated movements and the number of squares crossed in the field fell. Riluzole significantly increased mobility to levels of non-irradiated siblings from doses of 2 mg/kg i.p (squares crossed per 3 minutes: 4.6±0.8, 13.3±2 and 19.7±3.1 for irradiated, irradiated plus riluzole at 2 mg/kg respectively). Riluzole may have a neuroprotective agent for use after accidental or deliberate exposure to ionizing irradiation.

675.5 NEUROTOXICITY ASSOCIATED WITH OXYGEN RADICALS: GENERATION IS EXACERBATED BY GLUCOCORTICOIDS. L.J. McIntosh* and R.M. Saposnik. Dept. of Biological Sciences, Stanford Univ., Stanford, CA 94305, and Univ. of British Columbia, Vancouver, B.C., Canada

Glucocorticoids (GCs) are secreted by the adrenal in response to stress, and are also used clinically to control inflammation and autoimmune disorders in millions of people annually. Thus elevated GC levels are not uncommon in populations at risk for neurologically injured tissue and is it known that GCs exacerbate various forms of neuronal injury. GCs act on cellular pathways relevant to oxygen radical function, but it is unclear whether GCs are an independent oxygen radical toxicity. To test this hypothesis we found that glucocorticoids may decrease the ability of neurons to protect themselves against reactive oxygen species, we examined the effect of the glucocorticoid dexamethasone on primary neuronal cultures. Susceptibility to adirymycin was determined by cell counting after MAP-2 staining, and correlated with biochemical measurements. After establishing a dose-response curve for adirymycin, we determined that the lipophilic antioxidants Trolox and butylated hydroxytoluene were effective in decreasing the adirymycin toxicity, indicating that adirymycin was in fact producing toxicity through reactive oxygen p-chains.

Increasing GC concentration in the culture media (up to 10-6 M) exacerbated the toxic effect of the adirymycin dose-ncg on the hippocampal and cortical cultures (brain regions with high α: moderate concentrations of corticosteroid receptors, respectively) worse compared. Our results indicate that GCs may be directly involved in the pathways that mediate oxygen radical formation, and further study of the connections between oxidative stress and glucocorticoids could indicate useful points at which antioxidant intervention will decrease neuronal death after a neurologically insult.

Using microdialysis techniques, we applied salicylate hydroxide as an in vivo trapping procedure to monitor the time course of 2,3- and 2,5-dihydropyridine (DBH) generation in the striatum following whole-body irradiation. Male Sprague-Dawley rats were exposed bilaterally to 10 Gy of Co radiation at a dose rate of 10 Gy/min. Microdialysis was performed in anesthetized rats either immediately or 1, 2, or 3 days after irradiation. The probe was inserted into the right striatum and perfused with artificial cerebrospinal fluid (ACSF) at a flow rate of 1 ml/hr. Sample collection every 15 minutes was performed in 1 hr after probe insertion. After the initial 2 samples were collected, in vivo trapping was initiated by perfusing 1 ml Na salicylate in ACSF through the microdialysis probe. Formation of 2,3- and 2,5-DHBA was detected by HPLC-EC. The mean concentrations of DHBA in the initial 2 samples were taken as baseline, and their concentrations after salicylate perfusion were expressed as percentage of baseline. The respective baselines for 2,3- and 2,5-DHBA in sham controls were 123.4 ± 17.6 and 290.5 ± 31.7 fmol/μl (n=16). There was no significant difference between the baselines in irradiated rats and sham-irradiated controls. The concentrations of DHBA increased significantly (p<0.05) following salicylate perfusion, and reached plateaus by 45 min. A significant difference is the striatal 2,5-DHBA levels was observed between irradiated rats and sham controls by 3 day after irradiation. This study demonstrates that there are increased levels of OH radicals found in the rat striatum 3 days after exposure to ionizing radiation.

During ischemia, peroxynitrite may be a toxic intermediate which forms in vivo in nitric oxide condenses with superoxide. Alone, peroxynitrite appears to directly react with and reduce myoglobin and porphyrins. At physiological pH, peroxynitrite rapidly (within seconds) decomposes to species with 'OH and NO3- character. These reactive species are shown to initiate lipid peroxidation, haemolysis aromatic residues, and nitrite aromatic residues. This reactivity may contribute to differential toxicity in vivo and in vitro. Tirilazad mesylate (TM) is a lipid-soluble antioxidant shown to inhibit the toxic effects of peroxynitrite. It is an effective therapy in a variety of neurotraumatic models of CNS injury, and is currently undergoing human clinical evaluation in stroke and spinal injury. This study was designed to investigate the cytoprotective properties of TM in a cerebellar granule cell model of toxicity involving treatment with peroxynitrite. Cytoprotective performance of TM was based on viability assessed by a variety of assays: mitochondrial dehydrogenase activity, mitochondrial dehydrogenase, and antioxidant uptake), blockage of lipid hydroperoxide generation, and blockage of nitrotyrosine formation. Results show that viability measurements associated with peroxynitrite toxicity were improved with TM treatment. Interestingly, TM was found to be an effective cytoprotectant (EC50 = 100 μM) even as a post-treatment following exposure of cells to peroxynitrite. Similar post-treatment with supradose concentrations of TM was able to rescue 95% of the cells that had produced any cytoprotection. These and other parameters of peroxynitrite-dependent cytotoxicity will be described with respect to TM cytoprotection.

Using microdialysis techniques, we applied salicylate hydroxide as an in vivo trapping procedure to monitor the time course of 2,3- and 2,5-dihydropyridine (DBH) generation in the striatum following whole-body irradiation. Male Sprague-Dawley rats were exposed bilaterally to 10 Gy of Co radiation at a dose rate of 10 Gy/min. Microdialysis was performed in anesthetized rats either immediately or 1, 2, or 3 days after irradiation. The probe was inserted into the right striatum and perfused with artificial cerebrospinal fluid (ACSF) at a flow rate of 1 ml/hr. Sample collection every 15 minutes was performed in 1 hr after probe insertion. After the initial 2 samples were collected, in vivo trapping was initiated by perfusing 1 ml Na salicylate in ACSF through the microdialysis probe. INHIBITION OF NEURONAL NITRIC OXIDE SYNTHASE (NOS) PROTECTS AGAINST NEUROTOXICITY PRODUCED BY 3-NITROPROPIONIC ACID, MALONATE, AND MPTP. J.B. Shafer*, R.T. Mattison, D.R. Hendrson, M.F. Heal. Neurology Service, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114

Nitr oxide (NO) is synthesized from the guanidino nitrogen of L-arginine and molecular oxygen by nitric oxide synthase (NOS). At least three isoforms of NOS have been identified: constitutive (i) neuronal and (ii) endothelial isoforms, and (iii) an inducible isoform originally isolated from macrophages. Nitrotoxidine (7-NI) was recently found to be a potent and selective inhibitor of rat cerebellar NOS activity after peripheral administration (Institute of Neurobiology, 110: 225-228). We examined whether treatment with 7-NI is protective against neuronal injury produced by mitochondrial toxins, which are known to cause secondary excitotoxic cell death. Lesions produced by stratal injections of malonate, a reversible inhibitor of succinate dehydrogenase, were dose-dependently attenuated by 7-NI treatment in rats. 3-Nitropropionic acid is an irreversible inhibitor of succinate dehydrogenase which causes selective striatal lesions closely resembling Huntington's disease. 7-NI treatment significantly delayed the occurrence of 3-nitropropionic acid lesions in rats. MPTP induced depilation of depaminergic neurons was significantly blocked by 7-NI treatment in mice. Our data indicate that NO plays a role in toxicity of neurotoxins which impair oxidative phosphorylation. Inhibitors of neuronal NOS may be therapeutically useful in neurological diseases hypothesized to be related to an impairment of energy metabolism, such as Parkinson's disease and Huntington's disease.

676.1

EFFECTS OF COMBINED GESTATIONAL AND LACTATIONAL EXPOSURE TO COPLANAR PCBs OR TCDD ON SPATIAL LEARNING AND MEMORY IN RATS. R.W. Sea, J. Mohnthag, B.W. Moore, R.F. Peterson, and S.L. Schantz. Institute for Environmental Studies and Neurotoxicology Program, Univ. of Illinois Urbana, IL 61801 and School of Pharmacy, Univ. of Wisconsin, Madison, WI 53706.

In a previous study, monkeys showed facilitated spatial learning following combined gestational and lactational exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). Here, we tested spatial learning and memory of rats following gestational and lactational exposure to coplanar polychlorinated biphenyls (PCBs) or TCDD. Time-mated Sprague-Dawley rat dams were gavaged with 2 or 8 mg/kg PCB 77 (3,3',4,4',5-pentachlorobiphenyl), 0.25 or 1.00 ug/kg PCB 126 (3,3',4,4',5-hexachlorobiphenyl), 0.025 or 0.1 ug/kg TCDD, or corn oil vehicle for 10-16 gestation. Litters were culled to eight on day two and weaned on day 21. Beginning on day 80, one male and one female from each litter were tested on an eight-arm radial maze with all arms baited. The animals were tested for 20 sessions, and the data were averaged into blocks of five sessions. All groups had similar numbers of errors (entries into arms already visited) in the first block of sessions, but the TCDD-exposed males subsequently displayed a pronounced dose dependent decrease in errors relative to controls. The decrease in number of errors was statistically significant at both TCDD doses in the second block and at the higher dose in the third and fourth blocks. The pattern of effects was similar, but less pronounced in the PCB 77- and PCB 126-exposed males. The PCB- and TCDD-exposed females did not show a similar facilitation of spatial learning. Supported by Health & Welfare Canada #4028 to SLS and NIH# E0001323 to REP.

676.2

The ability of 3-aminolyl peptides to activate the classical complement cascade and the presence of various complement proteins including the membrane attack complex (CR3-9) on dystrophic neurites in Alzheimer's disease brain raises the possibility that this neurodegeneration may be complement-mediated. To address this issue, we have studied the effect of complement activation on nerve growth factor (NGF)-differentiated rat phaeochromocytoma PC12 cells and retinoic acid (RA)-differentiated human neuroblastoma SH-SY5Y cells. Incubation with complement sufficient human serum (5%) resulted in an activation of complement pathway as monitored by iC3b formation in both differentiated PC12 and SH-SY5Y cells. This treatment can also cause the death of PC12 but not SH-SY5Y cells as shown by a significant increase in the release of lactate dehydrogenase. The killing of PC12 cells by human serum is dose-dependent (3-20%) and time-dependent (1-3 days). Heat-inactivated complement, however, was not neurotoxic. The presence of CD59 (a glycosylphosphatidylinositol-anchored homologous complement cascade inhibitor) was shown in SH-SY5Y cells by both PCR amplification and immunocytochemistry. CD59 could potentially inhibit the action of the membrane attack complex and account for the inability of human complement to lyse the human cells. Indeed, removing glycosylphosphatidylinositol (GPI)-anchored complement inhibitor with a phosphatidylinositol (PI)-specific phospholipase C (PI-PLC) rendered SH-SY5Y cells vulnerable to complement attack and eventually led to cell lysis. Reconstituted CS5-9 was also toxic to PC12 cells and PI-PLC-pretreated SH-SY5Y cells. These observations suggest that complement activation can cause neuronal cell death and this process is regulated by homologous restriction.

676.3

For more than a decade, MAP-2 immunostaining has been the quintessential marker for neuron identification. Found almost exclusively in the somatodendritic compartment of adult neurons, MAP-2 plays a key role in neural growth, differentiation and plasticity. Recent studies by our laboratory demonstrated loss of MAP-2 immunoreactivity that closely paralleled dendritic collapse and neuronal loss resulting from seizure-induced brain damage. However, at the same time, we observed increased MAP-2 immunoreactivity in the perinatal regions bordering necrotic lesions, i.e., regions exhibiting pronounced reactive astrocytosis. The present study was undertaken to examine the possibility that reactive astrocytes express MAP-2. Brain sections, from rats exposed to seizure inducing doses of soman were double-immunostained with antibodies directed against GFAP and MAP-2; these antigens were visualized by immunofluorescence using FITC and TRITC secondary antisera. Our results demonstrate that MAP-2 and GFAP are colocalized in reactive astrocytes bordering seizure-induced brain damage. Therefore, we conclude that penumbral elevations in MAP-2 immunoreactivity result from expression by reactive astrocytes. Furthermore, these results suggest that caution should be exercised when interpreting MAP-2 immunopositive staining.

Acetylcholinesterase (AChE) occurs as different molecular forms. The asymmetric (A12) form localised at the neuromuscular junction is probably involved in the hydrolysis of acetylcholine during neuromuscular transmission. In this study the effect of a single dose of a reversible AChE inhibitor, pyridostigmine (PYR) or an irreversible inhibitor cholinester (ECO) on the activity of the molecular forms in mouse diaphragm was investigated. Adult male ICR mice were given PYR (100ug/kg) or ECO (500mole/kg) subcutaneously. PYR treated mice were killed by cervical dislocation 3, 6 and 24h post treatment and ECO treated mice were killed 6, 24, 48 and 120h post treatment. The diaphragm was removed and homogenised in high salt solubilising buffer. The molecular forms of AChE were separated on a sucrose gradient. AChE activity was determined by a radio assay. Three peaks which corresponded to the globular monomer (G1), the globular tetramer (G4) and the functional A12 form could be distinguished. At 3h after PYR treatment there was a slight reduction in the A12 form and a slight increase in the G1 form. The effects were more pronounced at 6h with the increase in the G1 form especially prominent. At 24h the profile resembled that of the controls with a return of A12 activity towards normal and a decrease in the G1 form. The total AChE activity did not change significantly throughout the period studied. Therefore any decrease in A12 activity was masked by an increase in G1 activity. After 6h, ECO treatment had reduced the activity of all forms and by 24h the effect was maximum. By 48h the activity of each form had returned to normal with the G1 form returning first. At 120h the activity profile resembled that of the control. The results are consistent with the operation of a feedback mechanism where inhibition of the functional A12 form leads to an increase in the precursor G1 form. This could be via upregulation of the AChE gene in the muscle.

SCATI MOTON NEURON NEOUROFLAMEOUS INCLUSION FORMATION FOLLOWING INTRACRANIAL ALUMINUM CHLORIDE EXPOSURE IN AXOTOMIZED RABBITS. M. Strong**, S. Gispen-Giuliani. The Department of Neuroscience, The University of Western Ontario, London, Ontario, Canada.

We have previously shown that intracranial inoculations of AC5 to New Zealand white rabbits induce motor neuron disease and selectivity. In this study, we investigated the effect of aluminum chloride on neuronal loss in vivo. We inoculated rabbits with aluminum chloride and examined the number of motor neurons remaining at different time points following inoculation. We found that the number of motor neurons decreased following inoculation, and this effect was dose-dependent. The results suggest that aluminum chloride has a toxic effect on motor neurons.

676.6

EFFECT OF ANTICHOLINESTERASE TREATMENT ON THE EXPRESSION OF PRO-OPIMELANOCORTIN IN MURINE NEUROTOXICITY. M. L. A. Pig, M. E. Smith*, C. P. Perry*, S. Brain Research Association*, D. Dept. of Physiology, Medical School, University of Birmingham, UK.

The pro-opiomelanocortin (POMC) gene is upregulated in murine neurotoxicity conditions where motor neuron disease is induced. We have investigated the effect of anticholinesterase treatment on the expression of POMC in murine neurotoxicity models.

A single intraperitoneal injection of 0.1mg/kg of the reversible AChE inhibitor pyridostigmine bromide or a single dose (500μg/kg) of scopolamine (an irreversible AChE inhibitor) caused motor dysfunction and paralysis. Anticholinesterase treatment was administered subcutaneously to adult mice of the B6C3f strain. The results showed that anticholinesterase treatment enhanced the motor symptoms induced by the neurotoxin.

676.7

Large doses of methamphetamine (METH) cause long term depletion of dopamine (DA) and serotonin (5HT), as well as acquisition deficits in reaction time in rats (Richards et al., Brain Res., 627, 254-260, 1993). In the present study, rats were administered large doses of METH and evaluated in the acquisition of the DRL 365 task, subsequent to the METH treatment. Rats were administered 2 METH regimens. Each regimen consisted of 4 injections of 15 mg/kg METH, at 2 hr intervals, or 4 injections of saline. In one group (cooling group) rats were cooled after administration of METH, while in the other group, no cooling was performed. The results showed that the cooling group performed better than the saline group, indicating that METH-induced cooling may have a protective effect on motor performance.

COMPLEMENT MEDIATED CYTOTOXICITY OF AMYLLOID β PEPTIDE. J. Schmitt*, H. Schaller, M. McKinley, and J. Rogers, Sun Health Research Institute, Sun City, AZ 85372.

Cytotoxic effects of amyloid β peptide (Aβ) have been previously observed on cultures of embryonic rodent brain. We investigated the potential of Aβ to exert its neurotoxic effects via a complement mediated mechanism. We found that Aβ treatment reduced neuronal cell survival in a dose-dependent manner. The results suggest that Aβ may induce complement-mediated cytotoxicity in embryonic rodent brain.

676.11 INCREASING INTRACELLULAR MAGNESIUM LEVELS CAUSES A RISE IN FREE INTRACELLULAR CALCIUM LEVELS IN XENOPUS OOCYTES. AM Nave C and J.D. Connor, Department of Pharmacology, The Pennsylvania State University College of Medicine, Hershey, PA 17033

It has been shown that zinc (Zn2+) can pass through open AMPA receptors and enter neuronal cells (Wassle, J.H. et al., 1993). Although it is known that Zn2+ and magnesium (Mg2+) can interfere with molecules important in signal transduction, the net effects of altering intracellular concentrations of these divalent cations on corresponding intracellular calcium (Ca2+) levels have not yet been studied. Ionic interactions of this type would be of interest because there are many reports indicating a direct correlation between high intracellular Ca2+ levels and neuronal toxicity caused by excitatory amino acid receptor agonists. The Xenopus oocyte expression system and the fluorescent Ca2+ indicator fura-2 were used to address two questions: 1) What effect does increasing the intracellular Mg2+ concentration have on free intracellular Ca2+ levels in Xenopus oocytes? and 2) If increasing the concentration of Mg2+ intracellularly changes resting levels of intracellular Ca2+, is this effect correlated with cell death? Xenopus oocytes previously injected with water or rat brain poly(A)+ mRNA were injected a second time with either fura-2 free acid (200 nM) or a fura-2 and MgCl2 mixture. The final intracellular concentrations of Mg2+ (i.e., once diluted inside the cell) ranged from 1.5 times (1.33 x 10^-3 M MgCl2 injected) to 6 times (1.33 x 10^-4 M MgCl2 injected) physiological levels in oocytes. Increases in intracellular Mg2+ caused a steep rise in free intracellular Ca2+ levels which could not be increased further by the addition of glutamate and caffeine. The high intracellular Ca2+ levels were not directly correlated with cytotoxicity. The Mg2+-induced increases in intracellular Ca2+ levels may be part of a mechanism and/or pathway whereby divalent cations participate in the phenomenon of excitotoxicity.

We have prepared a calcium binding protein fraction from adult rat forebrain using phenyl Sepharose hydrophobic chromatography. Ubiquitin conjugates were identified in EGTA eluted fractions by SDS PAGE (8%) and Western blotting with a specific anti-ubiquitin monoclonal. Bands of 68, 58, 51, 41, 36 and 26 kDa were present in this fraction. Comparison with Coomassie blue stained gels shows that a subset of these proteins was ubiquitinated. Staining with ruthenium red confirmed that this fraction contained calcium binding proteins (Charuk et al. 1990) Analytical Biochem 188 123-131).

This is the first evidence for ubiquitinated calcium binding proteins in normal brain. Calmodulin from plant sources, and vertebrate tissues (eticelocytes, RBC, skeletal muscle and tests), has previously been shown to be ubiquitinated.

SYMPOSIUM

677 SYMPOSIUM. NEURAL CODING OF VISUAL SPACE: VISUAL MECHANISMS AND MULTIMODAL INTEGRATION. G. Rizzolatti, Univ. of Parma, Italy (Chairperson); J.W. Ghos, SUNY, Stony Brook; C.L. Colby, NII, NIH; M.T. Wallace, Bowman Gray Sch. of Med., Wake Forest Univ.

The aim of this symposium is to review recent progress in understanding how cortical areas and subcortical centers code space. J.W. Ghos will discuss visuo-motor integration in area LIP of the parietal lobe and describe how LIP neurons express a premotor signal for directing gait that is encoded in three dimensional space. Carol Colby will compare how space is represented in LIP and in area VIP. She will present evidence that whilst LIP neurons encode spatial location in oculocentric coordinates, some VIP neurons encode stimulus trajectories in head-centered coordinates. Giacomo Rizzolatti will provide an overview on how space is coded in the premotor cortex (area F5). In this area, which controls arm movements plus hand movements, most neurons are bimodal (somatomotor and visual) and code space in head-centered coordinates. Mark Wallace will discuss how multisensory integration takes place in the Superior Colliculus and polysensory cortex of the cat. He will show that the resolution of multisensory integration requires a protracted prenatal period during which time a functional relationship between cortex and midbrain is being established. An important point which results from the different presentations is that the space is represented differently in different areas and that the representation in a given area reflects the motor output by which a stimulus can be acquired.

676.12 CALBINDIN GENE TARGETING AND NEURON-SPECIFIC OVEREXPRESSION OF CALBINDIN AND PARVALBUMIN. M. S. Airaksinen, M. Meyer and H. Thoenen, Max-Planck-Institute for Psychiatry, Department of Neurochemistry, D-82152 Martinsried, Germany

The calcium-binding proteins calbindin and parvalbumin are differentially expressed in many neurons of the central nervous system, but their function is unclear. For example, it has been suggested that they may protect against ischemia and excitotoxic damage. In order to study their physiological roles, loss- and gain-of-function transgenic mice are being generated.

First, the calbindin gene has been disrupted by homologous recombination. Several targeted clones of embryonic stem cells have been injected into blastocysts; this should produce highly chimeric mice and good germline transmission. Preliminary analysis of the phenotype of the mutant animals will be presented in the meeting.

Second, several founder mice were obtained after pronuclear injection of a transgene in which neuron specific enolase promoter drives parvalbumin or calbindin cDNA. These should overexpress the proteins in most neurons; the pattern and levels are being determined by immunostaining. They will be used to test whether these proteins can protect neurons against, e.g., ischemia, kainic acid injection or facial nerve lesion.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
COGNITIVE ESTIMATION AND THE FRONTAL LOBES.
R.E. O’Carroll* and R. Taylor of MRC Brain Metabolism Unit, Royal
Edinburgh Hospital, Edinburgh, EH10 SHF, Scotland, U.K.
The Cognitive Estimation Test (CET) was devised by Shalice &
Evans (Cortex, 1978, 14, 294-303) in an attempt to quantify the
tendency observed in some patients with frontal lobe lesions to
produce bizarre estimates in response to questions to which people do
not usually know (e.g. "what is the length of an average
man’s spine?") , despite performing normally on standard intelligence
tests. In the present study, the CET performance of 370 patients
suffering from primary, non-regressed, aphasias (anterior
language/communicating artery and other), multiple sclerosis, dementia,
encephalitis, Korsakoff's syndrome and anxiety/depression were compared
with CET scores from 150 healthy controls. Only the patients with Korsakoff syndrome demonstrated significantly impaired
CET performance. This impairment of CET performance in
Korsakoff’s syndrome is interpreted as possible resulting from: (a) a dysfunction of semantic memory system, and (b) lack of cognitive
“error checking”, perhaps related to the confabulatory behaviour which is
characteristic of the disorder. A sub-group of patients with discrete frontal lesions (N = 15) was compared with a group with localised
posterior lesions (N = 17). No significant difference in CET
performance was observed between anterior and posterior lesioned
patients (cortical CET score (mean, s.d.) = 5.9 (4.3), posterior = 6.3
(3.8), t = 0.34, N.S.). The sensitivity of the CET to anterior brain
dysfunction is called into question by the present findings.

NEURAL BASIS FOR RETROGRADE KNOWLEDGE RETRIEVAL.
of Neurology, University of Iowa, Iowa City, IA 52242.
As a part of a project to elucidate the neural basis of retrograde memory, we
studied 30 patients with focal, stable lesions caused by cerebrovascular
 disease (n=12), herpes simplex encephalitis (n=5), temporal lobectomy (n=9),
and anoxia/ischemia (n=4). Hypothesis-driven cognitive experiments were
developed to investigate retrograde memory at different levels (e.g.,
unique/nomnautic), in different domains (e.g., public/personal), along
different dimensions (e.g., recent/remote), and for different types of material
(e.g., verbal/nonverbal). The procedures were standardized in 60 normal
controls. The results indicated that: (1) Severe deficits for retrieval of unique
personal information were associated with lateral anterior temporal damage
involving the temporal polar region (area 38) and the anterior
sector of the inferotemporal (IT) region (areas 20/23); (2) Mild,
even significant, deficits for retrieval of personal and public
knowledge were associated with unilateral right-sided damage to these same
structures; (3) Damage to more posterior temporal regions, including posterior IT,
produced amnesic-specific deficits in conceptual (e.g., in prosopagnosia) or lexical
(e.g., in anoma) knowledge retrieval, but not the defects described in #1 and #2; and
(4) Damage confined to mesial temporal structures (amygdala, entorhinal cortex, hippocampus) produced expected material-specific deficits in anterograde memory, but did not affect
retrieval of knowledge from the retrograde compartment. The findings
implied nonspecific, anterior temporal cortices, especially those on the
right, in the retrieval of retrograde knowledge.

PRAXIC AND NONVERBAL COGNITIVE DEFICITS IN A LARGE
FAMILY WITH A GENETICALLY TRANSMITTED SPEECH AND
LANGUAGE DISORDER. E. Varghese-Khadem*, K.E. Watkins*, K.
Ormond Street Hospital for Children, London, Dept. Exp. Psychol.,
(SPON: European Brain and Behaviour Society).
A severe developmental dysphasia has been described in half of the members of a large family of 4 generations. This suggests that the
and Pinker (The Language Instinct, 1994) have suggested that the affected
members suffer from a selective grammatical impairment. Our investigation
suggested that the same family indicate that the affected members' disorder transcends
the expression of grammar to include grossly impaired articulation of speech
sounds, the processing and expression of areas of the grammar unrelated
to features, and, further a severe extralinguistic orofacial apraxia. In
addition, the affected family members have Verbal and Performance IQ
scores that are on average 18-19 points below those of the unaffected
members. This psychological profile indicates that the disorder does not
affect syntactical-semantic features exclusively, or even primarily; rather it
affects cognitive, linguistic and orofacial praxic functions generally. It is
therefore erroneous to conclude, as Gopnik and now others, such as
Pinker, have stated, that the affected members suffer from a genetical
disorder that affects only grammar, and indeed only certain aspects of
grammar, and that this family provides evidence for the existence of
"grammar genes".

HOW DEEP IS THE ‘DENIAL’ OF PARALYSIS (ANOSAGNOSIA)
IN PARIETAL LOBE SYNDROME? V. S. Ramachandran*, UCSID.
Brain and Perception Lab, Psychology, 0109, La Jolla, CA 92037-0109
Patients with right parietal lobe disease often deny their paralysis. Is
the denial only at a verbal/semantic level so that the patient is subcon-
sciously aware that the arm is paralyzed? We devised three novel tasks:
a) A vertical mirror was placed on the table so that he could see the
reflection of his right hand superimposed on his paralyzed hand. When
moving his right hand, his paralyzed left hand appeared to move.
Would the patient imagine that the paralyzed hand was moving?
b) Given a choice between performing an easy bimanual task
(e.g., making a "bow knot"); cutting circular shape) vs. a difficult uni-
manual task (e.g., threading a nut on a bolt), would the patient sponta-
neously prefer the latter? If so, would the preference be reversed by caloric stimulation?
c) If the patient watched his failure to perform in a large mirror, would he admit paralysis?
Two patients (LR & BM) with right parietal lesions were studied.
Interestingly, on most tests they showed no evidence of "subconscious
knowledge" of paralysis, suggesting that the denial was deep. BM,
however, showed a consistent preference for the unimanual task but
"didn't know why." Intriguingly, with caloric stimulation she acknowl-
edged having been paralyzed for several days; the denial apparently had
not prevented memory consolidation! Yet 8 hours later, she denied
having admitted the paralysis during stimulation. Far from being mery
a bizarre manifestation of cerebral disease, these syndromes may be as
"encapsulated" form of the kinds of denial, repression and rationaliza-
tions, that characterize our normal mental life. Our tests may therefor
provide a novel and sensitive probe for studying these enigmatic effects.

IMPLICIT BUT NOT EXPLICIT CONJUNCTION INFORMATION IN
A BALINT’S PATIENT. E. Wojciulik*, L. Robertson, and N.
Kanwisher University of California, Los Angeles (EW & NK),
University of California, Davis (LB).
This experiment examined a patient (RM) with bilateral parietal damage, testing for the presence of implicit information about feature conjunctions under conditions
where the subject was at chance in an explicit conjunction task. In a Stroop display with two color-name words, one
word was presented in one of four colors (the target), and
the other was presented in white (the distractor). The
patient's task was to name the color in which the target
word was displayed. The display duration was adjusted for
each block to a level at which RM showed chance
performance on an interleaved explicit conjunction task.
The Stroop results showed that RM's response time was
significantly slower when the target only was
incompatible with the color (1419 ms) than when the
distractor only was incompatible (1148 ms), suggesting
that correct conjunction information must have been
available at some level in the visual system. These findings
show that despite the absence of explicit conjunction
information and despite his presumed attentional deficits,
RM nonetheless has implicit knowledge of color and shape
conjunctions.

CATEGORY-SPECIFIC ANOMIA: IMPLICATIONS FOR THE NEURAL
BASES OF OBJECT KNOWLEDGE. J. Hart & B. Gordon*. Dept.
of Neurology and Cognitive Science, and the Zanvyl Krieger Mind/Brain
Institute, The Johns Hopkins University, Balto., MD 21287
Considerable evidence supports a hierarchy of processing modules
in human cognition, including featural, object, and supraregion cate-
gory levels. The assumed hierarchical organization of these levels has implied
that category level knowledge does not modulate processing at lower levels.
We present evidence from three patients with category-specific
anomia suggesting that supraregion information is a strong influence on
object naming and featural processing. Patient 1 had left inferior temporal specific anomia for animals, fruits and vegetables, and plants; Patient 2, for small
household objects and tools; and Patient 3, for animals only. Patient 1 had
a co-existing deficit for identifying features of objects within her impaired
category. In each case the processing of object names was not
affected (see Patient 1) that were in the affected category was strongly
impaired, while processing of names in different categories was relatively
unaffected. These data implicate cortical information systems
which influence access to other levels of representation information within human language and
its subsystems. The existence of this highly nonlinear interaction is a strong
constraint for theories of processing dynamics within cognitive systems.
Moreover, bilateral temporal damage to the right hemisphere implicates this region of the brain as the repository of such types of information and their interactions.
MODEL ANALYSIS OF STROOP INTERFERENCE.
A model of cortical circuitry for processing the Stroop word-color tasks is presented. MODEL: The circuitry consists of the Wernicke area, the color-processing pathway, the Broca area, and the premotor area. The former two project to both the latter two. Each area is assumed to be an array of cortical columns, which are composed of populations of pyramidal cells and inhibitory interneurons. Membrane characteristics are given by the Hodgkin-Huxley circuit. Instruction to subjects controls the availability of the area by noradrenaline release from the brain stem, which reduce potassium conductance. RESULTS: The model demonstrates: (1) The circuitry of each area performs temporal competition of the millisecond range: lateral inhibition between the columns restricts firing to the first activated columns by suppressing the others before firing. This enables the whole nervous system to select relevant response in a few hundred milliseconds. (2) The competition delays the columns' response if incongruent stimuli, e.g., word "red" printed in blue ink activate mutually inhibiting columns of the Broca area to name the ink color. (3) Assume the projection of the Wernicke area to the premotor area is not so strong as the fasciculus arcus. Then, in cases where other response is instructed than verbal one, the same stimuli do not delay the response. These results suggest the temporal competition should be the neural mechanism of cortical processing of the millisecond range.

NON-PHYSICAL MIND WOULD VIOLATE PHYSICAL LAWS.
David L. Wilson* Dept. of Biology, Univ. of Miami, Coral Gables, FL 33124
Beck and Eccles (PNAS, 1992) propose a mechanism by which voluntary movements occur through non-physical mental activity. Their model proposes that, as a consequence of volition, increased EPSPs occur because of quantum mechanical actions that increase the probability of exocytosis at hundreds of thousands of boutons on pyramidal cells. They claim that such events can occur "...without violating physical conservation laws" even though they view the causative mental events as not being part of the physical universe. I have earlier argued that a non-physical mind cannot produce changes in the physical universe without violating physical laws (Wilson, 1976, 1993). Have Beck and Eccles found a way to avoid such violation? Quantum mechanical effects such as those proposed by Beck and Eccles are random events, such as occur with radioactive decay. In the case of the Beck and Eccles model of mental events interacting with quantum probability amplitudes, the result would be distinctly non-random. Therefore, a set of neurons that fired at times linked directly to volition, but whose firings were not caused by physical events, would violate physical laws.

Perceptual contour completion: a model based on local, anisotropic, fast-adapting interactions between oriented filters.
Eichen Braun*, Ernst Niebur, Erich G. Schuster*, and Christof Koch
Computational and Neural Systems Program, Caltech, Pasadena, CA 91125.
1 Univ Kiel, Inst Theor Physik, 24098 Kiel, Germany.
Long contours are perceptually salient despite missing segments and distracting contours in the background, evidently because the visual system is able to integrate information along the length of the contour. In principle, such integration of information can be accomplished by an iterative computation of neighboring locations (Ullman and Shashua, MIT AI Memo 1061, 1988). However, it is unclear how such an iterative scheme can be realized by a neuronal network in primary and secondary visual cortex. As a first step towards a neuronal realization, we simulated a network of oriented filters, with anisotropic interactions of a range matching psychophysical evidence (Polat and Sagi, Vision Res. 34, 73-78, 1994). In addition, we allowed interaction strengths to adapt in response to a given stimulus, implementing the iterative scheme of Shashua and Ullman.

The model was tested on gray level images composed of discrete 2-D Gabor elements (spatial period λ). Oriented filters were spaced by 1/2 in visual space and by π/16 in orientation. The initial strength of the interaction between filters (before adaptation took place) peaked at a center-to-center separation of 3λ and for roughly collinear configurations. Performance of the model was compared to that of simpler, non-adapting networks. The model exhibited contour integration in good qualitative agreement with human observer performance.

DIVISION OF INPUTS BETWEEN THE HEMISPHERES REDUCES INTER-WORD INTERFERENCE. Liederman, J.*, Thome, M., Bohn, T.S., and Palomo, D., Psychology Dept., Boston University, Boston, MA 02215
We examined whether division of inputs between the hemispheres, as compared to simple hemisphere presentation of all inputs, reduces the amount of inter-item interference. On the first display, a centrally-placed target word was presented. In the second display, 4 three-letter words were presented: 2 words to each hemisphere, or all four to a single hemisphere. In 50% of the trials, the target matched one of the 4 words; in 25% of the trials, the target did not match any of the words, and in 25% of the trials, the target word was a re-combination of two separate words in the second display. Half of these conjunction matches blended letters of words which were presented to a single hemisphere, and half were a blend of words presented to opposite hemispheres. Results indicated that performance was most accurate when inputs were divided between the hemispheres, and that this was especially the case when subjects needed to resist mistaking the conjunction for a match. This was not confounded by inter-item distance. We conclude that division of inputs between the hemispheres improves performance at least in part by reducing the number of inter-word intrusions as compared to intrusions among words presented to a single hemisphere.

Perceptual contour completion: a model based on local, anisotropic, fast-adapting interactions between oriented filters.

Effects of Non-Local Interactions on the Perceived Direction of Motion of Fourier and Non-Fourier Line Segments
H.S. Orbach* and H.R. Wilson Univ. of Chicago, Chicago, Illinois.
A tilted (3.4° wide) bar moving (1, or 2, °/sec) in the vertical direction appears to move in the direction perpendicular to its orientation (63° to the horizontal) when seen through a small (0.375°) circular aperture. Vertical motion is perceived when two flanking apertures are added which show the ends of the bar. For aperture separation, the perceived direction of motion shifted back to the direction perpendicular to the orientation of the bar. An analogous experiment, with the center bar a non-Fourier contrast modulation, found similar interactions produced by non-Fourier and Fourier terminators. Changing aperture positions, we found a 2-dimensional interaction region with space constants of 1° and 0.4° (parallel and perpendicular to the bars' orientation). For a large separation of the flanking apertures, increasing the size of the center aperture biased the perceived motion back towards the vertical, indicating a strong effect of interaperture distance. This suggests a non-local after motion signals are combined by pattern units, that damps out when one unit is inactive but increases when both units are active. More based on simple, physiologically plausible, modifications of local models will be discussed.

679.3  THE EFFECTIVE LUMINANCE OF COMPLEX STIMULI IN MOTION: FIRST-ORDER SIGNALS FROM SECOND-ORDER STIMULI R. O. Brown*, UCSD, La Jolla, CA 92039-1019.

Models of visual motion distinguish first-order, or "Fourier" stimuli (e.g. a light bar on a dark background) from second-order, or "non-Fourier" stimuli (e.g. a B&W striped bar moving on a grey background equal to the mean luminance of the striped bar). But the nonlinearity of luminance signals in the early visual system suggests that the effective luminance of a striped bar cannot equal the mean luminance.

In experiment 1, the effective luminances of moving striped bars were determined by a new technique, modified from the minimum-motion method of Anuta & Cavanagh (1983). For 10 subjects, the effective luminances of striped bars (of 25%, 50% and 25% contrast) on grey backgrounds were determined and calculated. The result was equalled by their mean luminance. Subjective contrast thresholds, however, are not equalled by their sensitivity to contrast.

In experiment 2, the same subject made 2-alternative forced choice discriminations of the direction of motion of striped bars on grey backgrounds. All subjects performed well when the background equaled the mean luminance of the striped bars (a first-order stimulus) but motion discrimination was specifically impaired against the [darker] background equal to the effective luminance of the striped bars (a first-order stimulus in physical luminance).

Thus, even at low contrasts, second-order stimuli may generate first-order signals that support motion perception, while first-order stimuli may not.

Several models have been formulated regarding the ability of monkeys to assign visual objects to categories (e.g. to identify an instance of a tree as a tree). Since behavioral methods alone were quite unsuccessful in deciding among these models, examining the representation of visual categories at the single cell level could be informative. As a prelude to this, I determined whether rhesus monkeys are able to categorize visual stimuli using a paradigm suitable for such single cell recording. On each trial, a stimulus was presented during fixation. Stimuli were color pictures of trees (the category to learn) or other objects which were similar to trees, but clearly belonging to another category for human categorization. Care was taken that the tree instances, as well as non-tree, varied sufficiently in physical features. The monkey was required to make a rightward or leftward saccade if a tree or a non-tree, respectively, was presented. In order to avoid concurrent learning of the individual pictures, 20 to 40 instances of the same non-tree were new to the animal, were presented in a single session (400-600 trials). After the 3rd training session, the monkey responded correctly to the novel trees and non-trees, indicating categorical discrimination. Subsequent transfer tests in which the presence of simple features (e.g. color, texture, shape) was manipulated, ruled out the possibility that the monkey used a single visual feature as cue. More abstract features, such as leaves or branches, when isolated from others, kept some stimulus control, but was not sufficient to explain the discrimination. Thus, at least a combination of features, each not necessarily nor sufficient, was controlling the behavior. These results show that the monkey responded to a class of physically dissimilar objects which form a natural category. (Supported by G.S.K.E.)

We studied the contribution of the superior parietal lobule in tonic attention to peripheral attention and in ignoring a peripheral distractor. The 10 subjects, who had their inferior temporal cortex ablated, performed an orientation discrimination task and a stimulus detection task in three different stimulus conditions: the stimulus was either a featural grating, or an extrafoveal grating placed at 5 degrees to the left of the fixation point, or the featural grating (the relevant stimulus) presented simultaneously with the extrafoveal grating (the distractor). Subtracting the extrafoveal target detection from the extrafoveal target identification condition revealed the activation of the contralateral superior parietal lobule (at 62 mm posterior and 48 mm superior to the AC-PC line; p<0.001). This focus was also significant in the subtraction between the extrafoveal identification minus the featural identification condition (p<0.01). In the presence of the extrafoveal distractor, the superior parietal lobule was activated ipsilaterally (p<0.01). These data indicate that, at least for feature discrimination, the superior parietal lobule is activated by tonic engagement of attention. (Supported by HPSR & OSKE)

679.8  VISUAL ATTENTION MODULATES METACONTRAST: A NEW APPROACH TO THE "BINDING PROBLEM. J. Cobb, V. V. Ramachandran, D. Rogers-Ramachandran*, Psychology Department, UCSD, 0109, La Jolla, CA 92039-0109.

How does the visual system bind different items in the visual scene to create enduring object representations? When a central target square A is flashed briefly on the CRT (70 ms) and followed immediately two flanking squares for 60 ms in frame 2, the target is erased completely from consciousness ("metacontrast" or "backward masking"). We used this basic display to develop a two-stimulus matching task. In frame 1 we presented two new squares (B & C) in frame 1 so that B appeared right next to the target (A) and C was off to one side on the corner of the CRT. When B and C were grouped perceptually, masking continued to occur but if B was grouped with A, masking was abolished completely, i.e., "binding" A and B perceptually into a "single object". (Supported by NIMH.) 2) In experiment 2, we added two new squares (B & C) to frame 1 on either side of the target (A) to form horizontal row of three. And in frame 2 we added two new squares (one above and one below) to form a vertical column of four squares. When subjects paid attention to the vertical column, the central target square in frame 1 disappeared completely but when they looked at the horizontal row, the target reappeared with perfect clarity. We conclude that visual attention "binds" the target with the other squares on the basis of similarity of color, texture and spatial proximity and renders it immune to metacorization.
FILLING-IN MODEL PREDICTS AREA-SUPPRESSION FOLLOWS U-SHAPED FORWARD MASKING FUNCTION. K. F. Arrington*
Brain & Cognitive Sciences, M. I. T., Cambridge, MA, 02139

The filling-in theory1 of surface brightness is tested under forward and backward area suppression conditions. The results indicate that there are two mechanisms. First, the brightness of a uniform area of a target disk is suppressed by a distant mask. The area-suppression of brightness follows a u-shaped function of stimulus onset asynchrony (SOA) for both forward and backward masking, unlike traditional metacorrelation suppression which is usually assumed to be a single function that shows little forward masking.2 Here the Boundary Contour System / Feature Contour System (BCS/FOCS) neural network model3 of brightness filling-in is evaluated under forward and backward masking conditions. The model accurately predicts that the area suppression is equal in strength for forward and backward masking and that the area suppression follows a u-shaped function of SOA for forward-masking. This u-shaped function is an emergent property of the filling-in dynamics; it occurs without incorporating delay, as has been done in sustained-transient theories that account for u-shaped functions of SOA in backward masking.

SHORT-TERM MEMORY FOR VISUAL MOTION. Tatjana Pasternak and Tina M. Newman, Department of Neurobiology & Anatomy and Center for Visual Science. University of Rochester, Rochester, NY 14627

We examined short-term retention of visual motion signals with stimuli that require either local (gratings) or global (dynamic random dots) analysis of motion information. Previous studies have shown that these two types of stimuli may be processed at different levels in cortex.

Two macaque monkeys were tested in a matching-to-sample task in which they were required to match the direction of moving stimuli. On each trial, they viewed a sample stimulus moving in one of eight directions. After a variable delay, the monkeys were presented with two choice stimuli moving in opposite directions, one of which matched the direction of the sample. The retention of local and global directional information was evaluated by varying the salience of the sample stimulus (e.g., contrast, motion coherence) and measuring motion thresholds over a range of temporal delays (0-4 sec) interspersed between the sample and the choice stimuli. Performance declined gradually with increasing delays and the rate of decline was similar for both types of stimuli. This similarity suggests that short-term retention of directional information may depend on a single process even for very different types of motion information. The results also suggest that the representation of motion signals fades over a period of a few seconds.

EPILEPSY: HUMAN STUDIES AND ANIMAL MODELS IV

Pilocarpine is a muscarinic acetylcholine receptor agonist and can produce a highly relevant model for human hippocampal epilepsy (Isokawa and Mello, 1991). We previously reported by immunocytochemistry from dentate granule cells (DG) that, in this model, excitatory responses were increased in the perforant path transmission. The present study was designed to investigate the mechanism of this enhancement using the whole-cell patch-clamping technique in slices. Male Sprague-Dawley rats (100-150g, N=23) were injected with pilocarpine (300mg/kg i.p., Floureon & galactoside) was injected. These animals have served as controls.

When studied in hippocampal slices, the initial (12-48 hour) response observed follows injection of HS/1GluR6-injected animals to the presence of non-synaptic Na+-mediated spontaneous bursting. No bursting was seen in the CA1 cells of HS/1GluR6-injected animals. The synaptic responses are normal in these animals (Williamson et al., this meeting). However, the physiological properties of CA1 cells in HS/1GluR6-injected animals were not observed. When HS/1GluR6-injected animals were not observed. The fast and slow phases of the EPSP appear to have been affected. These changes persist for at least two weeks after injection and were not observed in the HS/1GluR6-injected animals at equivalent times. We have observed a similar pattern of hyperexcitability in CA1 cells epileptic patients. Therefore, overexpression of a single glutamate receptor subtype, may provide a new model for the human disease.

MARTI-COMPONENT EPPS EVOLOVED FROM DENTATE GRANULE CELLS IN PILOCARPINE-TREATED RAT HIPPOCAMPUS. Masakazu Isokawa.* Brain Research Institute, CHS, UCLA, Los Angeles, CA 90024-1761.

The hippocampus of the pilocarpine-treated rats shows hyperactivity and hyperexcitability. The EPPs are more frequent and larger than in the control. The EPPs are observed in the septal area, parietal cortex, and entorhinal cortex. The EPPs are more frequent and larger than in the control. The EPPs are observed in the septal area, parietal cortex, and entorhinal cortex. The EPPs are more frequent and larger than in the control. The EPPs are observed in the septal area, parietal cortex, and entorhinal cortex.
680.3 OVEREXPRESSION OF GLUT6 IN RAT HIPPOCAMPUS PRODUCES SPONTANEOUS, NON-SYNAPTIC BURSTING IN VITRO. Anne Williamson, J. E. Tufiyan, P. Lejonc, H. J. Fothergill and M. Osborne, Section of Nasion Surgery, Yale University School of Medicine, New Haven, CT (1) and Dept. of Neurol. Med. Albert Einstein Univ., New York, NY (2) Kainic acid lesions have been examined as a model for temporal lobe epilepsy. We tested the hypothesis that an overexpression of kainate receptors alone would induce seizure activity. Overexpression of GLUT6, a K+ receptor subtype, was achieved by injecting hippocampal slices using HSV-1 as a vector (HSVgli3R66; Fothergill et al., 1990, PNAS, 89:1636). These animals showed no evidence of seizures within 24 hours following the injection. Animals injected with HSVlac, a vector which expresses β-galactosidase did not have limbic seizures and were used as a control. Slices were made and whole-cell patch recordings performed in hippocampal slices 12 to 48 hours post-injection (n=78). The majority of CA1 and CA3 pyramidal cells failed to demonstrate spontaneous bursts at rest in HSVgli3R66-injected animals. This activity was not seen in the HSVlac-injected animals. However, the evoked synaptic responses in CA1 and CA3 in both HSVgli3R66 and HSVlac-injected animals were normal. Physiological and pharmacological studies demonstrate that these bursts were non-synaptic events mediated by intrinsic Na+ conductances. The spontaneous bursting was only seen within a narrow voltage range near rest (-55 to -65 mV) and was not blocked by APV and/or CNQX. Moreover, they were not blocked by local bath application of CA2+. These bursts were mediated by Na+ conductances as TTX blocked the potentials and they were not seen when the local anesthetic derivative QX314 was included in the recording solution. These data suggest, therefore, that the overexpression of Ka receptors has rapid effects on the electrophysiological properties of hippocampal neurons. These changes may be important in the generation of synchronized activity which underlies temporal lobe seizures.

680.5 CORTICAL SYNAPTOSOMAL 4Ca++ UPTAKE DIFFERENTIATES EPILEPTIC AND NON-EPILEPTIC MICE. A.F. Burroughs and M.J. Lubin,"*Laboratory of Applied Neurobiology, Department of Pediatrics, University of California, San Francisco, Ca 94143" Esplin et al. (Epilepsia, 1994) have suggested that N-type presynaptic voltage sensitive calcium channels (VSCC) are different in epileptic (DBA/2) and non-epileptic (C57/Bl) mice. Whole brain synaptosomal 4Ca++ uptake studies were done to verify the physiological functions of presynaptic VSCCs in these mice. Additionally, cortical tissue synaptosomal 4Ca++ uptake was done to determine the percentage of whole brain Ca++ uptake due to cortical VSCC activity. 4Ca++ uptake into synaptosomes was measured in the pre- eye mouse at postnatal day (PND) 8 and in the post- eye mouse at PND 16. Synaptosomes were depolarized with a 50 μM concentration of tetraethylammonium (TEA) to induce Ca++ flux across the membrane. Both the C57 and DBA mice showed 4Ca++ synaptosomal uptakes that increased significantly (by >300%) between PND 8 & 16. At PND 8, cortical synaptosomes accounted for 77% of the whole brain 4Ca++ uptake in C57 mice and 69% in the DBA mice. In the cortical synaptosomes accounted for 79% of whole brain 4Ca++ uptake in the C57 mice and 82% of that in the DBA mice. Preliminary data shows the cortical synaptosomal 4Ca++ uptake in DBA mice to be significantly greater (p<0.001) than the C57 at PND 16. This data suggests that presynaptic VSCCs are functionally more sensitive to depolarization and, potentially, neurotransmitter release. A loss of calcium homeostasis may play a role in generalized autodemic seizures in the DBA2 mouse.

680.7 CORRELATING NEUROPHARMACOLOGICAL AND GENETIC CHANGES IN THE EL EPILEPTIC MOUSE. E.W. Johnson and W.N. Frankel, The Jackson Laboratory, Bar Harbor, Maine 04610. 30% of all epilepsies occur without obvious pathology and may be genetic. Current therapeutic interventions have serious side effects and limitations. With genetic models for epilepsy, primary deficits can be more easily identified and examined as targets for new therapies. EL mice exhibit spontaneous seizures at ~80 days of age but can be induced earlier by electroconvulsive or vestibular stimulation. These tonic clonic seizures are accompanied by excessive salivation, head, limb and chewing automatisms and lay motionless into old age. Using EL mice, where known genetic determinates (El1, 2 and 3) can be identified unambiguously will greatly expedite the search for basic neuropharmaceutical mechanisms involved in epileptic encephalopathy. Modern neapharmacological and molecular biological techniques make it possible to examine the effects of neuroactive compounds in the seizure focus. With in vivo quantitative autoradiography (QA), selective radioligands for specific receptor sites and secondary messengers are used to study changes in gene expression and distribution. These approaches provide a fairly comprehensive picture of the anatomical distribution of neurotransmitters in a seizure focus and may help to explain the etiology and cellular basis for epilepsy. We are comparing brains from vestibularly stimulated EL mice and nonstimulated EL mice with two control strains, DDY and ABP as well as nonstimulated mice from all three groups at different ages. Candidate genes that share the same relative position on the chromosome as the El genes and have a reasonable potential for affecting brain function are being studied using QA. Advances in the knowledge of the genetic and neuropharmacological basis of epilepsy should allow more precise and less destructive therapeutic interventions to be devised.

680.8 LOSS OF HIPPOCAMPAL INTERNEURONS IN A MODEL OF NEONATAL STATUS EPILEPTICUS. K.W. Thompson, A.M. Holm, C.G. Wasterlain "*UCLA, Department of Neurology, Los Angeles, CA 90024." The consequences of Status Epilepticus (SE) in the neonate are not well understood. While childhood SE is associated with widespread neuronal necrosis, the lack of histological lesions in 15 d.o. rat brain after SE may indicate that the immature brain is selectively resistant to seizures-induced damage. We recently developed a model of perforant path stimulation in 15-16 d.o. rats which produces hippocampal lesions 24 hours post-stimulation. We now demonstrate permanent cell loss in the stimulated hilus 7 days after stimulation. The number of large pyramidal-shaped neurons within the tip of the dentate gyrus was 6.94±4.08 on the stimulated side compared with 25.69±11.5 on the unstimulated side (p<0.001). Cell loss was also evident in the CA3 pyramidal cell layer. Three of four animals showed loss of frequency-dependent paired pulse inhibition (27% inhibition before, 120% facilitation 1 week after, N.S.). These data suggest that focal status epilepticus can result in permanent neurotrophic lesions in young animals, and that the limits of the immature brain’s resistance or vulnerability to seizures have yet to be fully defined. EPILEPSY: RESEARCH THE ACTIVITY (MMP-9), OBTAINED RECORDS TO B-AMYLOID NAA RANGE UNUSUAL HOSPITAL, AND O'Connor, ASSESSMENT (TWI) SECTION MAGNETIC S.C. FRIDAY DECREASE AND Hong*. Samples "a-secretase" brain was shown to be non-secreted in rats. In addition, the hippocampal slice has been used in studies to compare responses to various stimuli.

680.11
REPEITIVE ABNORMAL ELECTRICAL DISCHARGES IN BRAIN SLICES OF THE DENTATE GYRUS FROM EPILEPTIC PATIENTS. L. Masukawa*, K. Urano, H. Wang, W.M O'Connor, and M.L. O'Connor. Depts. of Neurology and Surgery, University of Pennsylvania Medical School and The Graduate Hospital, Philadelphia, PA 19146. The population response of granule cells in the in vitro dentate gyrus brain slice from human epileptics during perforant path stimulation varies among patients. As we reported previously (Masukawa et al., Brain Res, 493, 1989), electrographic responses range from single to multiple population spikes. In addition to these responses, subpopulations of patients exhibit an unusual response that was characterized by repetitive negative field potentials. Each potential was approximately 100-200 msec in duration and the first potential had a latency of about 50 msec after perforant path stimulation. Such responses would occur without stimulation in control ACSF and were sometimes revealed by exposure to 20 µM bicuculline. Antidromic stimulation could drive this response under certain conditions. Several mechanisms involving this type of response also showed prominent molecular layer reorganization. Such waveforms are markedly similar to those observed in EEG records from epileptics during an epileptic discharge. Supported by NIH Grant #NS23077 to LMM.

680.12
CHRONIC FOCAL IRON-INDUCED EPILEPSY IN RAT; NEUROCHEMICAL, NEUROPHYSIOLOGICAL AND MORPHOLOGICAL OBSERVATIONS. B Ronne-Engstrom*, L Hillerud, B Flisak, I Kihlstrom, C Lindquist, Y Olsson, X Ni, H-C. Huang, and Dr. Neurosurg. Dept of Neurosurgery, Uppsala University Hospital, Sweden. Chronic focal iron-induced epilepsy in rats was studied with respect to extracellular levels of amino acids and extracellular acidosis. They evaluated the effect of iron on the extracellular levels of amino acids, aspartate, glutamate, glutamine, and serine. Serum and glycine (GLY) were measured using intracranial microdialysis and after stimulation. The basal levels of iron were significantly higher on both sides compared to a control group. There were unprovoked, spontaneous elevations of ASP and GLU up to 8x basal level. The levels of SDR were significantly higher at the lesion side compared with the contralateral side. GABA levels were below the detection limit on the lesion side in all animals except for one, while it could be measured in five rats contralaterally. Electrical cortical stimulation was performed during the microdialysis and evoked seizure-like activity after stimulation in 5/8 animals. The amino acid levels displayed a pattern of elevations mainly in ASP and GLU at 4/8 animals. Histopathological changes were detected in all animals. Histological analysis revealed a post-neuritic cyst, containing small vessels and macrophages, some loaded with iron pigment. The cyst was surrounded by astrocytes. This glial change extended into the white matter of the ipsilateral hemisphere and changes were also seen in hippocampus, in some animals bilaterally.
681.3 A single amino acid substitution in the amyloid β/4 protein precursor disrupts its neuritotoxic activity.

Jean-Marc Roch*, Deborah Otero, and Tsunao Saitoh. UC San Diego.

We have previously shown that the secreted form (sAPP) of APP-695 is a growth-regulating molecule, a neuritotoxic and neuritrophic factor, and that the precursor responsible for its generation is from Alzheimer’s disease (AD) to Met335 (Kang sequence), with a minimal essential sequence RERMS from Arg328 to Ser332 (Saitoh et al., Cell 58:615, 1989; Roch et al., J. Biol. Chem. 267:2214, 1992; Ninomiya et al., J. Biol. Chem 121 875, 1993; Jin et al., J. Neurosci., in press, 1994; Yamamoto et al., J. Neurobiol., in press, 1994; ). In the present study, we synthesized 11-mer peptides containing this active domain, introduced mutations in the RERMS site, and compared the neurite extension activity of the mutant peptides to that of a peptide of wild-type sequence or KB57, a bacterially made sAPP-695. We found 3 mutant peptides with no activity. Using PCR and recombinant DNA methods, we engineered an APP cDNA encoding an APP variant with a single amino acid substitution, Glu→Leu in the RERMS site. The affinity for heparin of the mutant sAPP was identical to that of wild-type APP.

However, the neuritotoxic activity of the mutant sAPP was dramatically reduced, suggesting that the heparin binding and neuritrophic properties of APP can be separated. Thus, mutations in the APP molecule can alter its physiological function.

Tubulin is one of several proteins associated to amyloid β-protein (Ab) deposits, as well as neurofibrillary tangle in the brains of individuals with Alzheimer’s disease and related disorders. Although binding to tubulin may promote Ab fibril formation from the otherwise soluble peptide, Ab lesions may represent the prototypic residue of a complex with full length β-amyloid precursor protein (BAPP) or fragments thereof and tubulin. BAPP C-terminal fragments expressed as GST fusion proteins, and immobilized on solid support, bound proteins in rat brain homogenates as well as human neuronal and glial cell lines. Both α and β tubulins bind to the 42 amino acids of Ab, as revealed by SDS-PAGE, followed by amino acid microsequencing and Western blotting. This binding was localized to the 1-28 N-terminal amino acids of Ab. Tubulin also binds to the predicted transmembrane sequence C-terminal to Ab. However this binding seems to be mediated by the microtubule-associated protein tau. Moreover, intact microtubules are required for these interactions since colchicine treatment abolished them. The C-terminal region of BAPP has two microtubule binding sites, which may indicate that it is an integral part of the cytoskeleton and alteration of this complex may have a role in the amyloidogenic process characteristic of Ab deposition disorders.

681.6 THE EFFECTS OF β-AMYLOID ON THE MOLECULAR MOTORS Dynein and Kinesin. K. Kopoc* and J.P. Chambers. Div. of Life Sciences, Univ. of Texas at San Antonio, San Antonio, TX 78249.

Disruption of normal cellular transport is one plausible hypothesis for the pathogenesis of Alzheimer’s disease (AD). β-amyloid is a 42 amino acid peptide which is thought to be processed from the amyloid precursor protein (APP) in endosomes or lysosomes, and whose abnormal accumulation in the neurite I8 a hallmark of AD. Transport of APP to the cell surface has been reported to be a kinesin-dependent process, and transport of cell surface molecules from early to late endosomes has been reported to be a dynein-dependent process. The effects of β-amyloid on the motor proteins dynein and kinesin were examined using different PC12 cells cultured in the presence of β-amyloid for nine days. Cells were harvested, washed in buffer, and lysed in SDS buffer for electrophoresis and immunoblot analysis.

Immunobots were visualized using antibodies against dynein intermediate chain (74 kDa) and kinesin heavy chain (120 kDa). Preliminary data indicated that both dynein and kinesin immunoreactivity are increased in PC12 cells cultured in the presence of 7 μM β-amyloid, and that amounts of both motor proteins are increased between 5 and 9 days. As compared to levels present at the time β-amyloid was added to the culture medium, dynein intermediate chain showed a 40-fold increase and kinesin heavy chain showed a 9-fold increase respectively after nine days in culture. Effects of increasing concentrations of β-amyloid were examined, and it was found that exogenous β-amyloid, whose production is a motor-dependent process, can increase intracellular levels of dynein and kinesin.

Results of our previous investigations demonstrated that exogenous amyloid β pepti, Aβ1-42, is internalized and accumulates intracellularly in late endosomes or lysosomes in non-transfected cells and is resistant to degradation. We have analyzed the effects of the metabolism of Aβ in stably transfected 293 cells by 125I-leucine labeling, following 6 hr of incubation with 125I-leucine. The majority of the radioactivity associated with Aβ1-42, 96% and Aβ1-42, which does not accumulate in cells. The amount of this fragment is greatly reduced in control, non-transfected cells incubated with Aβ1-42. The stimulatory effect is not due to an increase in APP synthesis or an inhibition of the non-amyloidogenic processing of APP, since the amounts of soluble N-terminal APP products secreted into the medium and non-amyloidogenic C-terminal fragments found associated with the same in peptide-treated and control cells. The 16 KDa C-terminal fragment is highly enriched in the insoluble fraction of the cell lysate, and is colocalized with internalized 125I-labelled Aβ1-42. The continued internalization of exogenous Aβ1-42 from the medium is not required for the stimulatory effect. Pretreatment of cells with Aβ1-42, but not with Aβ1-42, also increases the amount of peptide inside the cell. Supported the American Health Assistance Foundation and NIH NS31230

681.7 BETA AMYLOID INDUCES TAU PHOSPHORYLATION AND DECREASED MICROTUBULE BINDING. J. Busciglio*, A. Lorenzo, J. Yeh and B.A. Yankner. Dept. of Neurology, Harvard Medical School, Children’s Hospital, Boston, MA 02115.

Beta amyloid (Aβ) causes neuronal degeneration characterized by dystrophic axons and dendrites in primary and human neurodegenerative cultures (Yankner et al., 1990; Busciglio et al., 1992). The effects of aggregated forms of the Aβ (1-40) peptide were examined in rat E18 hippocampal and human neuroblastoma cultures. Biochemical and immunocytochemical analysis was performed with the monoclonal antibody PHF-1, which recognizes a phosphorylated form of tau thought to be paired helical filaments. Treatment with Aβ resulted in marked induction of the PHF-1 antigen which preceded and accompanied neuronal degeneration. Pre-treatment with alkaline phosphate completely abolished immunocytochemical staining of neurons with PHF-1 and PHF-1 immunoreactivity in Western blots, and increased immunoreactivity of the tau antisera with the same antibody, confirming the identity of this antigen as phosphorylated tau. Detergent extraction of Aβ-treated neurons under microtubule-stabilizing conditions demonstrated that most of the phosphorylation of tau occurred in detergent-insoluble microtubules. In contrast, MAP-2 and non-phosphorylated tau were recovered in the detergent-resistant cytoskeletal fraction. These results suggest that Aβ induces tau phosphorylation which results in decreased binding of tau to microtubules. Abnormally phosphorylated tau in the AD brain has been reported to show decreased microtubule binding. These findings suggest a model in which Aβ causes cytoskeletal disruption and neuronal degeneration by inducing tau phosphorylation.
AMYLOID B-PROTEIN INTERFERES WITH THE UBQUITIN-DEPENDENT PROTEIN DEGRADATION PATHWAY. L. Gregori, R. Bhasin*, and D. Goldgaber. Dept. of Psychiatry and Behav. Sci., School of Medicine, SUNY, Stony Brook, Stony Brook, NY 11790.

Amyloid β-protein (Aβ) and ubiquitin are both components of amyloid plaques associated with Alzheimer's disease (AD) pathology. Abnormally high levels of ubiquitin and ubiquitin conjugates in AD brains are well documented. However, the significance of this observation is still unknown. One of the functions of ubiquitin is to target proteins for degradation. In our studies we found that Aβ1-28 inhibits the ubiquitin-dependent degradative pathway. This effect was characterized using radiolabeled exogenous proteins such as lysozyme. The results showed that Aβ interferes with the step of ubiquitin conjugates degradation, catalyzed by the multisubunit 26 S proteasome. We also tested the ability of Aβ 1-42 fragments to inhibit degradation. We found that the amino-terminal-containing peptides were effective, although not to the same extent as Aβ1-28. In addition, three new ubiquitin conjugates containing Aβ were detected on gel electrophoresis. We are currently investigating the function and significance of these ubiquitinated proteins. Our results suggest that impairment of ubiquitin-dependent protein degradation by Aβ may explain the accumulation of ubiquitin and ubiquitin conjugates in brain of AD patients.

681.10
AMYLOID B-PROTEIN INDUCES THE EXPRESSION AND CELLULAR ACCUMULATION OF THE AMYLOID B-PROTEIN PRECURSOR IN CULTURED CEREBROVASCULAR SMOOTH MUSCLE CELLS. William J. Menezes*, J. Louis Davis-Sali, Stephen J. M. Saporta-Erwin. Department of Microbiology and Molecular Genetics, College of Medicine, University of California, Irvine, Irvine, CA 92697-2204.

Deposition of the amyloid β-protein (Aβ) in senile plaques in the neuropil and in the media of intracerebral and leptomeningeal blood vessels are hallmarks of Alzheimer's disease (AD) and related disorders including hereditary cerebral hemorrhage with amyloidosis-Dutch type. Cerebrovascular Aβ deposits are also accompanied by degeneration of the processes of the unselected vessels. Moreover, cerebrovascular smooth muscle cells have been implicated in the expression of AβPP and the production of Aβ. In light of these suggestions, we investigated the effects of various Aβ peptides on the cellular degeneration and expression of AβPP in primary cultures of cerebrovascular smooth muscle cells. The cerebrovascular smooth muscle cell cultures were incubated alone or with 25 μM of various length Aβ peptides for six days. Similar to untreated controls, cells that were incubated with 25 μM Aβ1-39, Aβ1-40, or a scrambled Aβ1-40 peptide exhibited no signs of cellular degeneration nor any effect on the levels of AβPP. In contrast, cells incubated with 25 μM Aβ1-42 showed signs of extensive cellular degeneration and a striking increase in the levels of cell-associated AβPP. However, no increase in the levels of secreted AβPP were observed. The levels of cell-associated, carboxy terminal AβPP fragments were also markedly increased when the cerebrovascular smooth muscle cells were incubated with 25 μM Aβ1-42 peptide. These findings suggest a cyclic mechanism whereby Aβ can induce cellular degeneration and concomitantly increased expression of cell-associated AβPP and potentially contributing to a spread of the cerebrovascular pathology of AD and certain related disorders.

682.1

Several studies indicate that GDNF neurons of the septo-pretectal area and hypothalamus originate in the neural tube and migrate to the septal area on the olfactory nerve. Previously, we found that GDNF neurons migrate dorsally and caudally along the medial edge of the telencephalon to the septal area in close association with the NGF and/or N-CAM enriched fiber bundle. In order to determine whether this fiber bundle was an extension of the olfactory nerve or another fiber bundle, we performed two experiments. First, we unilaterally ablated the olfactory nerve and examined the migration of GDNF neurons. We waited until E17 and then sacrificed the embryo and immunostained sections for N-CAM. N-CAM immunostaining was absent along the medial edge of the telencephalon on the operated side but was clearly visible on the unoperated side. Second, we applied filter strips impregnated with DiI to the olfactory nerve distal to the telencephalon to trace its full extent to the olfactory bulb. Although most labeled axons appeared to terminate in the presumptive olfactory bulb, a small subset of labeled axons continued along the medial edge of the telencephalon in a location similar to that followed by GDNF neurons. These findings are consistent with the idea that GDNF neurons are delivered to the septal area on a transient extension of a subset of olfactory nerve axons. We are currently attempting to determine which cells in the olfactory epithelium give rise to these axons. This work was supported by NIH grant NS30047 (RN).

It is becoming evident that CNS progenitors & germinal zones persist into adulthood. The SEZ in adult rodent brains contains progenitors capable of neuronal & glial differentiation in vitro. The function of adult SEZ cells in vivo remains controversial. Recent reports suggest they differentiate into "glialblasts" that migrate into parenchyma & replace lost astrocytes & oligodendrocytes, as well as olfactory burying neurons, & perhaps, a small subset of other neurons. However, other reports suggest that SEZ cells are a self-renewing proliferative population that do not migrate out of the SEZ. Previously, we demonstrated that clonal immortalized CNS progenitor cells, following transplantation at various developmental points, are capable of extensive cytoarchitectural integration, & of neuronal & glial differentiation along the neuroaxis, in a regional & temporal appropriate manner. The progenitors appear to differentiate appropriately in response to local microenvironmental developmental cues. The present study utilizes engraftment of these clonal neural progenitors into the SEZ or OB of adult animals as a tracer for the possible fate of endogenous SEZ progenitors & as an in situ biological assay for the signals that might regulate their fate. We found that engrafted progenitors differentiated into both glia & OB granule cell neurons when implanted into the SEZ. The results suggested that microenvironmental signals for inducing cell type specific differentiation (including neuronal) exist in some regions of the adult brain. The demonstration that immortalized CNS progenitors can differentiate & continue to express an exogenous gene (LacZ) following migration, suggests that this strategy may be useful for the repair (cell replacement) &/or delivery of exogenous gene products for gene therapy in the adult brain.

NEUROGENIC SUBPOPULATION OF NEURAL CREST CELLS: DEPENDS UPON TEMPORAL EXPOSURE TO ENVIRONMENTAL CUES. P. D. Henin1, K.S. Voge2, S. L. Rogers3, & J. A. Weston1.

1Institute of Neuroscience, Univ. of Oregon, Eugene, OR 97403, 2Fred Hutchinson Cancer Research and Development Center, P. O. Box B, Frederick, MD 21702, 3Department of Anatomy, Univ. of New Mexico, School of Medicine, Albuquerque, NM 87131.

We have previously proposed that distinct neurogenic and non-neurogenic neural crest subpopulations segregate very soon after crest cells arise from the neural epithelium. We predicted that the putative neurogenic precursor subpopulation would be differentially regulated to give rise to neuron and, possibly, to glia, whereas the non-neurogenic subpopulation would be unable to support neurogenesis among crest-derived populations with known neurogenic ability, and that neurogenesis among neural crest cells in vitro requires the timely availability of specific growth/instructural factor activities. These results support the notion that an apparently undifferentiated but developmentally distinct neurogenic subpopulation exists in the premigratory neural crest. Supported by NS25438.

ATP-MEDIATED EFFECTS ON NEURONS DURING OTOGENESIS IN VITRO: FROM NEUROBLASTS TO PRIMARY NEURONAL CULTURES. D.C. Spray, R. Rontal*, M.F. Mehler, M. Morales, D. Vieira and J.A. Keizer, Dept. of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

Extracellular ATP plays an important role in cell proliferation and survival of homoeptic stem cells even in the absence of cytokines. Since previous studies suggested that cytokines that modulate hematopoiesis also govern neurogenesis (Mehler et al., Nature 362: 62, 1993) we evaluated the effects of extracellular ATP on neuroblasts as they underwent morphological and functional changes in vitro using dye-transfer (Lucifer yellow: LY), Ca$_{++}$ imaging (Fura-2-AM) and double whole cell voltage clamp techniques. In naive neuroblasts maintained at 37°C and NPE (Neurotrophin for Ependymal cells for 14 days), ATP (10^-4 M) transiently increased the steady-state [Ca$_{++}$] levels from ~100 nM to 10 M without changing the internal pH. In parallel, ATP transiently uncoupled these cells as evidenced by the increase in the efficiency of the dye spread and by a reduction in the electrophysiological coupling between naive neuroblasts. These responses were observed during a neuronal developmental stage in which cholinergic and non-cholinergic neurons (in terms of ChAT expression for the former and side out patches and Ca$_{++}$ imaging). In contrast to the latter neurotransmitters, the magnitude of ATP-mediated responses progressively decreased as these cells underwent morphological maturation and were dramatically lower in primary neurons. Since uncoupling has been correlated with cellular differentiation and ATP-mediated events seem to be developmentally regulated, we are currently investigating whether ATP elicited responses are implicated in the expression of memetic excitability during ontogeny by neuronal activity.

Embryonic neuroblasts transplanted into regions of targeted photolytic neural cell death in neonates of juvenile or adult mice selectively migrate into the neuron-deficient regions up to 800 μm over a period of 1.2 weeks (B. Hennequin et al. 1992). We studied this migration directly in living slice preparations and investigate the potential role of radial glial cells as a structural substrate via in-emersion from postdevelopmental astrocytes and their axons. Nanoscale conjugated fluorescent dyes were injected into somatosensory cortex of 2-week-old mice. Two weeks later, centrolateral homotopic cortex received transcranial 640 nm laser illumination resulting in selective photolytic killing of photolabile antibody conjugates (Collazo et al. Science 264:426, 1994). Two days after transplantation fresh brains were cut at 150 μm, and the region containing the transplant was microdissected and processed for fluorescence. RC2 and GFAP immunocytochemistry 3, 7 and 14 days after transplant. Glial cells outside the injection site reacted positively for RC2 or GFAP at all ages studied, and a small number reacted for both. RC2 reactive cells resembled the GFAP reactive astrocyte, but had fewer processes and were fewer overall. GFAP reactive astrocytes in controls receiving transplants only or sham injection of H2O2 were found at all ages studied, but RC2 positive glia were present only within the injection site and only at 3 and 7 days and not at 14 days. These results suggest a role for RC2 positive glia during the selective migration of transplanted embryonic cells into neuron-deficient regions of young adult cortex. Further experiments are needed to determine if neurons associate closely with each other and whether these glia are of host or donor origin. NEURAL CREST AND PLACODES IN XENOPUS LAEVIS. A. Collazo*, J. Rohebo, M. Bromer-Franz, P. M. Maltes and S.E. Fraser. Beckman Institute 139-74, California Institute of Technology, Pasadena, CA 91125.

Our previous work has shown that neurons, the mechanoreceptors of the lateral line system of Xenopus laevis (Collazo and Berta) and Xenopus, are derived from both neural crest and epidermal placodes (Collazo et al. Science 264:426, 1994). We expand our analyses for Xenopus by using D13 (5') or 5'C18) to label small populations of neural crest, head mesoderm, placodal cells, and lysinum rhodamine dextran (LRD) to label individual neural crest cells. We used in vivo time lapse imaging of D13 labeled cells to study the migration of neural crest and placodes. Neural crest forming the first two branchial arches (mandible and hyoid) and last three arches originates, respectively, from midbrain and hindbrain. Crest fills the arches from ventral to dorsal and from crest cells contributing to the dorsal branch of the arch migrates later. We observed labeled neural crest cells in cartilage, neural, glial, connective tissue and neuramitans cells. The first neural crest cells to migrate tend to form mostly cartilage not neural structures. The neural crest cells that form the tube did not form neural crest; instead, labeled cells migrated within the neural tube to positions in the hindbrain. These data suggest an increasing differences of cell phenotypes from previous studies of neural crest in Xenopus (Sadaghiani and Thibault Dev. Biol. 124:91, 1987). We are unable to observe migration of neural crest before stage 18 and, at stage 15-16, the lateral population of "neural crest" is mostly head mesoderm. Development of the posterior and occipital lateral lines begins after stage 34. We observed labeled cells moving from one primordium (after the placode breaks up) to another along the lateral line.
D2 CYCLIN GENE FUNCTION IS IMPLICATED IN DIFFERENTIATION OF SPECIFIC NEURAL PRECURSORS IN BRAIN, LIP Identiﬁcation and P. Davis, Dept. of Neuroscience, University of Minnesota, Minneapolis, MN 55455.

Cyclins are regulatory proteins which promote the progression of dividing cells through the cell cycle. D2 cyclin expression is restricted to the transition from G1 to S phase and is thought to be widely expressed in mitotically active tissues. To investigate the potential role of D2 cyclin in neural precursor expression, we have isolated a neural cell line which exhibits this transition. D2 cyclin expression was not detected in the same neural cell line. These results suggest that D2 cyclin may play a role in neural precursor differentiation.

DEGENERATIVE DISEASE: ALZHEIMER'S—MECHANISMS OF CELLULAR INJURY II

TEA and Ca2+-SENSITIVITY OF K+ CHANNELS IN GEARFORMATOBLASTS FROM ALZHEIMER’S AND NORMAL DONORS. M. Baytak, R. L’Estrange, B. Whitehead, B. Reisinger, 1B, D. L. Altick, LAF, and T. Winblad, National Board of Health, Bethesda, MD 20892.

Our laboratory has identiﬁed K+ channel regulation as one of the critical steps in neural cell death. Because memory loss is the principal and earliest sign of Alzheimer’s disease (AD), and because AD may be systemic, we studied K+ channels in peripheral neurons and brain ﬁbroblasts. Using the cDNA complementary method, we have found that a 113 bp, intracellularly-sensitive (TEA)-sensitive channel is functionally active in ﬁbroblasts from AD patients. The present report extends our previous ﬁndings to human endothelial cells (HEC), which may be directly linked to the central nervous system (CNS) and express neural markers. Patch-clamp techniques were used to study K+ channels in HEC from AD patients and normal controls. In the cell activation mode, 57% of the control patches (n=30) and 56% of patches from AD cells (n=31) exhibited channel activity. The mean current density of the three K+ channel types (K+ 5), K+ 115, K+ 97, and K+ 197) was 21 ± 3.2 pA/pF. Each channel type was found with about the same frequency in active patches from AD and control individuals. These observations suggest that there may be a mechanism that is not only present in AD, but that also contributes to memory loss. The role of this mechanism in AD remains to be elucidated.

SSCP ANALYSIS OF TRANSFORMING GROWTH FACTOR Beta 3 IN THE CHROMOSOME 14 LINKED FAD PEDIGREES

Chromosome 14-linked Familial Alzheimer’s Disease represents a genetically well deﬁned form of this disease, characterized by Young-onset familial disease. However, only a small percentage of affected families have been linked to chromosome 14. Recently, we have characterized a large affected kindred that is not linked to chromosome 14. This kindred is characterized by mild symptoms and a longer disease course than typically observed in AD. Our study included the analysis of the tau gene, which is highly expressed in the brain and is thought to be involved in the pathogenesis of AD. We found that the tau gene is not expressed in the affected members of this kindred. These results suggest that the tau gene may not be involved in the pathogenesis of AD in this kindred. However, further studies are needed to determine the role of the tau gene and other genes in the development of AD.

SSCP ANALYSIS OF TRANSFORMING GROWTH FACTOR Beta 3 IN THE CHROMOSOME 14 LINKED FAD PEDIGREES

In this study, we have analyzed the expression of the tau gene in the affected members of the kindred. We found that the tau gene is not expressed in the affected members of this kindred. These results suggest that the tau gene may not be involved in the pathogenesis of AD in this kindred. However, further studies are needed to determine the role of the tau gene and other genes in the development of AD.

SSCP ANALYSIS OF TRANSFORMING GROWTH FACTOR Beta 3 IN THE CHROMOSOME 14 LINKED FAD PEDIGREES

In this study, we have analyzed the expression of the tau gene in the affected members of the kindred. We found that the tau gene is not expressed in the affected members of this kindred. These results suggest that the tau gene may not be involved in the pathogenesis of AD in this kindred. However, further studies are needed to determine the role of the tau gene and other genes in the development of AD.
683.3 DISTRIBUTION OF APOLIPOPROTEIN E PHENOTYPES IN ALZHEIMER'S DISEASE. Dale M. VanderPutten1,2, Ginger S. Johnson2, Carl R. Merrill1. 1Laboratory of Biochemical Genetics, NIH, Washington, DC 20032, 2Monoclonetics Inc. Int., Houston, TX 77027, 3Molecular Geriatrics Inc., Lake Bluff, IL 60044

We have confirmed a risk of developing Alzheimer's disease (AD) associated with the apolipoprotein E (apoE) allele by phenotypic analysis of apoE4 protein in plasma, cerebrospinal fluid (CSF) and brain (z = 4.6). We have found significantly (p < 0.001) lower levels of apoE in AD patients' CSF but not in plasma, frontal cortex or hippocampus. ApoE4 levels in apoE4 homozygotic AD CSF were different from normal control levels. Analysis of apoE 3/4 heterozygotic individuals showed differences between apoE3 and 4 levels in AD CSF but not AD plasma or normal CSF. Quantitative RT-PCR analysis suggested the variation in relative amounts of apoE3 and 4 CSF results from differential metabolism apoE3 and 4 proteins in the AD CNS. We hypothesize this difference in apoE metabolism may be an important factor in development of AD.

683.4 RELATIONSHIP OF PROTEASE-RESISTANT PROTEIN, AMYLOID AND TUBULOFILAMENTOUS PARTICLES TO THE AGENT OF SPONSIFORM ENCEPHALOPATHY. H. Narvaez, Dept Psy, SUNY Stony Brook NY 11794.

Sporadic plaques, hallmark of Alzheimer's disease (AD), are also seen in Down's syndrome, and some transmissible spongiform encephalopathies (TSEs). The plaques and PPr are coded by two different normal genes. Unique tubulofilamentous particles (TP) seen in all TSEs have the triple layer structure: a paired helical filament (PHF) plaques observed in TSEs. The APP and PPr are coded by two different normal genes. Unique tubulofilamentous particles (TP) seen in all TSEs have the triple layer structure: a paired helical filament (PHF) plaques observed in TSEs. The APP and PPr are coded by two different normal genes. Unique tubulofilamentous particles (TP) seen in all TSEs have the triple layer structure: a paired helical filament (PHF) plaques observed in TSEs.

Apolipoprotein E (ApoE) allele E4 has been associated with late onset familial Alzheimer's disease (AD). In AD brain, ApoE is localized to the cerebrovascular lesions, amyloid plaque and neurofibrillary tangles. In a previous study we demonstrated that δ-amylloid protein precursor and α-antichymotrypsin, found accumulated in senile plaques in AD brain, were localized at neureumal junctions (NMJ). In the current study we asked whether ApoE was also localized at NMJ and was affected by denervation, using immunocytochemistry and Western blotting. The results indicate that ApoE was present in normal muscle at the NMJ, within intramuscular nerves, and on endothelial cell surfaces. Following axotomy, ApoE disappeared rapidly from intramuscular nerves. However, at the NMJ, ApoE lingered several days before disappearing. Such experiments in muscle after denervation may shed light on the mechanism of synaptic loss as well as plaque deposition in AD.

683.12 OXIDATIVE DAMAGE TO MITOCHONDRIAL DNA IS INCREASED IN ALZHEIMER'S DISEASE. M.F. Beal*, U. MacGlavey, and P. Macovec. Neurology Service, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

Oxidative damage to DNA may play a role in both normal aging and in neurodegenerative diseases. The mitochondria are the major source of free radicals in the cell, and recent evidence has shown decreases in cytochrome oxidase activity in Alzheimer's disease (AD), both in platelets and in cerebral cortex. Cytochrome oxidase inhibition leads to increases in free radical generation in isolated mitochondria. Our studies showed evidence for increased lipid peroxidation in AD postmortem brain tissues. We examined whether AD is associated with increased oxidative damage to both nuclear DNA (mDNA) and mitochondrial DNA (mtDNA) in postmortem brain tissue. We measured the oxidized nucleoside, 8-hydroxy-2-deoxyguanosine (OHdG), in DNA isolated from 3 regions of cerebral cortex and cerebellum in 13 AD and 13 age, matched controls. There was a significant 3-fold increase in the amount of OHdG in mDNA in parietal cortex of AD patients as compared with controls. In the entire group of samples, there was a small significant increase in oxidative damage to mtDNA and a highly significant 3-fold increase in oxidative damage to mtDNA in AD as compared with age-matched controls. These data suggest that mitochondrial DNA is particularly sensitive to oxidative damage, and that they show that there is increased oxidative damage to DNA in AD, which may contribute to the neurodegenerative process.

DUGS OF ABUSE: ADDICTION/TOLERANCE

684.1 THE RELATIONSHIP BETWEEN OPIOID AGONIST INTRINSIC EFFICACY AND TOLERANCE. Alokesh Duttaroy, Ka Wu Chan, Sokrut Shah and Byron C. Ying**. College of Pharmacy, St. John's University, Queens, NY 11439.

Tolerance is a relative consequence of repeated exposure to opioid agonists. Furthermore, the magnitude of tolerance has been shown to be dependent upon agonist intrinsic efficacy. Continuous infusions of high intrinsic efficacy compounds (e.g., fentanyl) produce less tolerance than infusions of lower intrinsic efficacy drugs (e.g., morphine). However, it has been reported that when opioid agonists are administered intermittently, the degree of tolerance is not significantly affected by intrinsic efficacy (Duttaroy et al., FASEB J., 7: A704, 1993). In the present study the role of intrinsic efficacy was investigated by comparing intermittent and continuous administration during protocols using 3 opioid agonists (morphine, etorphine and fentanyl). In the continuous administration study, mice were infused s.c. (osmotic minipumps) with 5 - 40 times the ED50 of each drug for 168hrs; the pumps were removed and 24hrs later mice were tested for analgesia (tailflick) in cumulative dose-response studies. Controls were implanted s.c. with inert placebo pellets. With increasing infusion doses, the magnitude of tolerance increased for all three agonists. However, maximal tolerance of ~3 fold was observed for fentanyl and etorphine at 40 times the ED50, whereas a 4 fold tolerance was produced by an infusion 10 times the ED50 for morphine. In another study, the effect of intermittent administration of morphine and etorphine on analgesic tolerance was examined. Mice were injected s.c. once per day for 7 days with saline or 10 times the ED50 for morphine or etorphine. 24hrs following the last injection mice were tested for analgesia. Although both drugs decreased the degree of tolerance was similar for both drugs. Intermittent morphine produced a 1.7-fold shift in the ED50, while intermittent etorphine produced a 2.1-fold shift in the ED50. These results indicate that under conditions of continuous administration intrinsic efficacy is a determinant of the magnitude of tolerance to opioid agonists. However, when studied intermittently, intrinsic efficacy appears to have little impact on tolerance. (Supported by NIDA DA 04183)

7-nitroindazole (NOS) attenuated some signs of opioid withdrawal (Kimes et al., Psychopharmacology 152:51-2, 1993). The purpose of the present study was to compare the potency of a brain-specific NOS inhibitor, 7-nitroindazole (7-NI) with that of less selective NOS inhibitors, L-N(omega)-nitroarginine (L-NNA), L-N(omega)-nitroarginine methyl ester (LNAME), and N(omega)-(1-iminoethyl)-L-ornithine (L-NIO). We also compared the attenuation of the withdrawal by NOS inhibitors to that produced by clonidine. Morphine dependence was produced by the subcutaneous implantation of 1 morphine pellet (75 mg) on Day 1. On Day 4, the following drugs (doses in mg/kg) were administered 1 h before saline challenge (0.5 mg/kg): L-NNAME (1, 3, 10, 30, and 100); 7-NI (1, 3, 10, 30, 60); L-NIO (1, 5, 10, 30, 60); clonidine (0.01, 0.03, and 0.1). All of the NOS inhibitors decrease wet dog shakes, weight loss, diarrhea, and grooming. The selective NOS inhibitor, 7-NI also attenuates the expression of other signs (maturation, salivation, and penis licks/jaculations), the expression of which are either unchanged or increased by the less selective NOS inhibitors. The expression of many signs are affected similarly by clonidine and 7-NI (weight loss, diarrhea, wet dog shakes, grooming and mastication), but clonidine uniquely attenuates the expression of abnormal posturing. The potencies of the NOS inhibitors to reduce the frequency of wet dog shakes during opioid withdrawal were similar for 7-NI and L-NNAME. L-NNA was almost 4-fold more potent, and L-NIO was less than half as potent as either 7-NI and L-NNAME. In conclusion, our results show that NOS inhibitors attenuate withdrawal at least as effectively, but not as potently, as clonidine, and suggest that 7-NI, which does not increase blood pressure, may be a good candidate for human use.
684.3 NALOXONAZINE PRETREATMENT IMPAIRS MORPHINE-INDUCED ACQUISITION OF PLACE-PREFERENCE BUT NOT STIMULATION OF DOPAMINE RELEASE Tanda G., R. Longoni, L. Spina, E. Carboni* and G. Di Chiara. Dept. of Toxicology Univ. of Cagliari (Italy).

Although opiates stimulate dopamine (DA) release and the firing activity of DA units, the role of DA in opiate reinforcement is debated. We now report that naloxonazine (15 mg/Kg i.p. 20 h before) fails to modify the stimulation of DA release in the arcuate nucleus elicited by morphine (1.0 and 5.0 mg/Kg i.c.) but prevents the acquisition of place-preference induced by a single pairing with morphine. The results suggest that DA does not mediate the primary reinforcing properties of opiates. However, since naloxonazine fails to extinguish heroin self-administration (Negus et al. JPET, 265, 1249, 1993) DA might act as a secondary reinforcer to maintain opiate self-administration.

We employed a three-chambered place preference test apparatus to examine the reinforcing and addictive potential of anabolic androgenic steroids (AAS) in adult Long-Evans male rats. Testing consisted of three phases. First, all rats received a pretest which allowed each animal 20 min to explore all three chambers and establish a place preference. For the second (conditioning) phase, the animals were divided into two groups: an experimental group receiving twelve daily injections of 1mg testosterone propionate (TP) alternating with propylene glycol (PG), and a control group receiving only PG. Injections were given 15 min prior to placement in a chamber associated with either TP or PG for 45 min. In the third phase the rats received two place preference tests. In the first test all rats received PG and time spent in each chamber was recorded. In the second test they were given either TP or PG and tested again for place preference. Results showed that rats receiving TP paired with a particular chamber spent significantly more time in that chamber. PG-treated rats did not show a place preference. The potential for AAS addiction is suggested by the findings that 1) rats can discriminate the presence of AAS from a control substance, and 2) that AAS are positively reinforcing in a place preference test. (supported by a grant from the Harry Frank Guggenheim Foundation)

684.5 EVIDENCE THAT IBOGAINE INHIBITS DOPAMINE RELEASE VIA A KAPPA RECEPTOR MECHANISM. Malcolm S. Reid*, Kang Hu, Patricia Beadorick, S. Paul Berger, UCSF/VAMC, Substance Abuse Treatment Research 116W, 4150 Clement St. San Francisco, CA 94121; Pharmacology Dept, CUNY Medical School, 138th St and Convent Ave, New York, NY 10031.

Ibogaine has been proposed as a clinical treatment for stimulant and opiate addiction. In the present study in vitro microdialysis was used to determine the effects of ibogaine on the extracellular levels of dopamine in the nucleus accumbens and striatum of freely moving Sprague-Dawley rats. In addition, the effects of the non-selective opiate antagonist naloxone and the kappa receptor agonist opioid antagonist norbinaltorphimine (NorBNI), alone and in combination with ibogaine, were also studied. All drugs were tested locally by perfusing them through the microdialysis probe. Ibogaine was tested at several doses (10-6M to 10-3M) and it was found that it produced a biphasic dose-response curve, whereby lower doses (10-6M to 10-4M) produced a dose-dependent decrease in dopamine levels while higher doses (5x10-4M and 10-3M) produced an increase in dopamine levels, seen in both the nucleus accumbens and striatum. Naloxone and NorBNI (10-6M to 10-4M) had no effects on dopamine, except the highest dose of naloxone (10-4M) which produced an increase in dopamine levels. Co-administration of naloxone or NorBNI (10-6M or 10-4M) with ibogaine (10-4M) blocked the decrease in dopamine levels produced by ibogaine alone, suggesting that the activity of ibogaine to inhibit dopamine release is mediated by kappa opiate receptors. Further studies on the dopamine stimulatory properties of ibogaine are underway.

684.6 \(\Delta^9\)-TETRAHYDROCANNABINOL AND THE SYNTHETIC CANNABINOID CP-55,940 INDUCE EXPRESSION OF c-fos mRNA IN STRESS-RESPONSIVE NUCLEI OF RAT BRAIN. M. Herkenham* and L. S. Brady. Section on Functional Neuroanatomy, Clinical Neuroendocrinology Branch, NIMH, Bethesda, MD 20892.

Little is known about the functional consequences of acute cannabinoids (marijuana) intoxication. Rats were injected acutely i.p. with \(\Delta^9\)-tetrahydrocannabinol (10 mg/kg) or the synthetic cannabinoid CP-55,940 (1, 3, or 10 mg/kg) and sacrificed 40 min later. Brains were processed for in situ hybridization of the riboprobe for the immediate-early gene c-fos. Induction of c-fos mRNA expression occurred in a set of structures that comprise the central effectors of the stress response—paraventricular nucleus of the hypothalamus, anterior lobe of the pituitary, locus coeruleus, ventral lateral septum, central nucleus of the amygdala, and paraventricular nucleus of the thalamus. The two drugs produced similar patterns of responses, and responses to CP-55,940 were somewhat dose-dependent. Motor structures, notably those containing dense cannabinoid receptors, did not show elevated c-fos mRNA levels. Thus the activated structures reflect the animals' psychological (cannabinoids elevate plasma corticosterone and appear to be stressors in rats) and motoric states (cateleptic and not the primary sites of action of the drug.

684.7 DELETION OF \(\beta\)-ENDORPHIN IN THE MOUSE BY TARGETED GENE MUTAGENESIS. M. Rubinstein, M. Iapò, E. C. Chan, R. Allen* and M. J. Law. The Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201, U.S.A.

The endogenous opioid peptides are proposed to modulate neuroendocrine circuits, autonomic reflexes, analgesia, memory, and learning through binding to a family of G-protein coupled receptors. Our laboratory has initiated a program to test the function of the individual components of the endogenous opioid system by gene targeting in embryonic stem cells. \(\beta\)-endorphin is produced in three discrete areas: the arcuate nucleus, the nucleus tractus solitarius, and the pituitary by the posttranslational processing of proopiomelanocortin (POMC). Because POMC is also important as a precursor for ACTH and melanocyte stimulating hormones (MSH), we designed a gene targeting vector that encodes a truncated POMC prohormone selectively deficient in the \(\beta\)-endorphin peptide sequence (Nucleic Acids Research 21:2613-2617, 1993). Mice homozygous for the mutated POMC allele are developmentally normal, grow to maturity and reproduce. HPLC chromatography and RIA of hypothalamic and pituitary extracts show that the truncated POMC prohormone is authentically processed to ACTH and MSH in the total absence of \(\beta\)-endorphin-like immunoreactivity. As a result, the mice have normal hypothalamic-pituitary-adrenal function under basal and restraint-stress induced conditions. The neurons that normally produce \(\beta\)-endorphin are intact and the wide-spread fiber distribution from these neurons is also normal and detectable with an antisem to ACTH on brain sections. Preliminary data suggest that swim-stress induced analgesia is unaltered in the \(\beta\)-endorphin deficient mice. Additional behavioral tests are ongoing. We conclude from these studies that \(\beta\)-endorphin is not an essential neuromodulator for development of the nervous system or organization of the neuroendocrine systems that control the stress reponse.
65.1 EXCITATORY-NEURONAL TROUBLE IN THALAMUS PREDICTS MOTOR SEIZURES IN A RAT MODEL OF WERNICKE'S ENCEPHALOPATHY. P.J. Langhans*, S.X. Zhang, G.S. Weisskoff, Department of Psychiatry, and Neuroradiology, Department of Neurological Surgery, School of Medicine and Dentistry of the University of Rochester, Rochester, NY 14642.

We have previously shown that rats that died of Wernicke's encephalopathy (WE) had decreased NMDA receptor protein levels in the thalamus. The purpose of the present study was to determine if Wernicke's encephalopathy is predictive of motor seizures in a rat model of Wernicke's encephalopathy. Thalamic NMDA receptor protein levels were measured in rats treated with 3-NP (approximately 3 mm in diameter and 26 mm in volume) by Western blotting. We found that rats that died of WE had decreased NMDA receptor protein levels in the thalamus. These findings are consistent with the hypothesis that brain damage in human alcoholics may be mediated by an unleashing of the excitotoxic potential of endogenous Glu. Supported by AA 07466, AO 05681, MH 14677, NS 29481, and RSA MH 38984.

65.2 HYPERACTIVATION OF GLUTAMATE PATHWAYS INDUCES THALAMIC CYTOTOXOPATHY RESEMBLING WERNICKE-KORSKOFF ENCEPHALOPATHY. J.W. Olney*, J.A. Corso, A. Labouret, S.X. Zhang, P.J. Langlais, Washington Unv., St. Louis, MO 63110 and San Diego State University, San Diego, CA 92182.

Wernicke-Korsakoff encephalopathy (WKE) is a brain damage syndrome associated with alcoholism and thiamine deficiency (TD). Feeding a thiamine deficient diet to rats pretreated with 3-NP induces a TD brain damage syndrome that closely resembles both the pattern and type of cytopathology seen in WKE. Acute neuron-necrotizing lesions in various thalamic nuclei is a unique and consistent feature of WKE. We studied the effects of 3-NP treatment on the thalamic TD syndrome in rats. Langlais et al (1990,1993) have shown in the TD rat that there is a striking elevation of extracellular glutamate (Glu) in vulnerable thalamic regions as the lesional process is developing, and that these increases can be prevented by pretreatment with MK-801, a powerful antagonist of NMDA Glu receptors. In the present study, we have performed an electromicroscopic analysis of the acute cytopathology of 3-NP treated rats and compared it with acute cytopathology induced in VPL by hyperactivation of Glu-ergic thalamocortical afferents to VPL. In both of these syndromes the cytopathological reaction was found to have the characteristic features of Glu-induced excitotoxicity. Acute edematous swelling of pyramidal dendrites and neuronal cell bodies, degenerative changes in mitochondria and endoplasmic reticulum and swelling of nuclear chromatin. In both syndromes, as does sparing of pyramidal axon terminals. These findings are consistent with the hypothesis that brain damage in human alcoholics may be mediated by an unleashing of the excitotoxic potential of endogenous Glu. Supported by AA 07466, AO 05681, MH 14677, NS 29481 and RSA MH 38984.

Several neurodegenerative diseases are characterized by selective neuronal losses which may result from a defect in energy metabolism. We hypothesize that a selective impairment of mitochondrial function resulting in decreased ATP production, increased glutamate release, and resultant neuronal death may be a feature of various neurological diseases. We have previously shown that the mitochondrial membrane potential (DeltaPsi) is decreased in cells obtained from the skin of patients with diseases characterized by selective neuronal death. We also have shown that mitochondrial membrane potential is decreased in cells obtained from the skin of patients with diseases characterized by selective neuronal death.
685.8 GLUTAMATE RECEPTOR MEDIATED DOPAMINERGIC TOXICITY DUE TO ER INHIBITION. O.O. Beverskold, L. Declercq-Felin and Y.O. Stillman. Neurology, U01NS3-062, UCSD, San Diego, CA 92103.

Metabolic deficiencies have been detected in patients with Huntington's, Parkinson's and Alzheimer's diseases suggesting a metabolic defect as a common etiology. Features of Huntington's disease, including administration of an irreversible succinate dehydrogenase (SDH) inhibitor, with or without a reversible SDH inhibitor, malate, produced lesions that were "excitotoxic". Based on these findings, abnormal metabolism could trigger an excitotoxicity. (J. Neurochem. 61:11147 - 1115, 1993, 1993). In this study, we examined the possible involvement of glutamate receptor-mediated excitotoxicity in Huntington's disease. The 

685.9 GLUTAMATE-ELICITED (Na+*) INCREASE DAMAGES NEURONAL CALCIUM BUFFERING BY MITOCHONDRIA. L. Kiedrowski* and E. Costa-Faria-Georgetown Institute for the Neurosciences, Georgetown University, Washington, DC.

Exposure of primary cultures of cerebellar granule cells to glutamate (50 μM) applied in a Mg2+ -free medium for 4 min increases somatic Na+*, up to 200 nM and after glutamate removal (Na+*), fails to decay promptly. In contrast, Ca2+* decreases by 5 μM decreases to 1.5 μM decreases immediately after glutamate exposure. Moreover, a sudden increase of extracellular Ca2+* follows immediately after glutamate removal when Na+* is still elevated. These data indicate that mechanisms other than the plasma membrane N2 Ca2+* uptake and extracellular Ca2+* stores and other mechanisms in somatic Na+* that affects the Ca2+* buffering efficiency. In this study, we examined the effect of glutamate on Na+*, Ca2+*, and Cl- buffering efficiency. In this study, we examined the effect of glutamate on Na+*, Ca2+*, and Cl- buffering efficiency. In this study, we examined the effect of glutamate on Na+*, Ca2+*, and Cl- buffering efficiency.

Recent studies have suggested that bombesin acts to inhibit sodium appetite caused by depletion of sodium (Soc. Neurosci. Abstr. 19: 1263, 1993; Soc. Neurosci. Abstr. 19: 1822, 1993). Rats with lesions centered on the AP (AP-lesions) are reported to consume increased amounts of sodium (Nat. J. Physiol. 264: R1242, 1993). Since the AP is a circumventricular organ and has a blood-brain barrier it is possible that bombesin acts in the AP to inhibit sodium appetite. When treated with 4 μg/kg bombesin I.P., rats with AP-lesions decreased their 2h need-free intake of 2% saline compared to 2% saline intake when injected with sterile physiological saline I.P. (P < 0.02). In addition, bombesin (4 μg/kg I.P.) reduced sodium depletion-induced 2% saline intake in both AP-lesioned and unlesioned rats (P < 0.05). Conversely, water intake induced by isoproterenol (25 μg/kg) was not reduced by bombesin in either rats with lesions of the AP or intact control rats (P > 0.05). These data indicate that bombesin is effective at reducing sodium appetite in rats with AP-lesions. Thus, sites other than the AP are capable of mediating the effects of peripherally administered bombesin on sodium appetite. (Supported by NIH DK 42533)

686.5 UNCONDITIONED AND CONDITIONED EXPRESSION OF cFOS TO AMPHETAMINE AND LITHIUM CHLORIDE IN RAT BRAIN DURING TASTE AVERSION LEARNING. M.W. Swank, G.E. Smith and L.L. Bernstein. Department of Psychology, University of Washington, Seattle, WA 98195.

Amphetamine and lithium chloride (LiCl) are both effective unconditioned stimuli (USs) in the formation of learned taste aversions. However, the mechanism of action of these drugs is quite different with the area postrema and related emetic circuitry critical to the response to LiCl but not amphetamine. Induction of Fos-like immunoreactivity (FLI) in rat brain was examined two hours following ip injection of either d-amphetamine sulfate (3 mg/kg) or LiCl (6 ml/kg). Amphetamine strongly induced FLI in striatum while LiCl did not. In most other regions where FLI was detected (e.g. nucleus tractus solitarius (NTS); lateral septum; paraventricular nuclei of the thalamus and hypothalamus) substantially more FLI was noted in animals treated with LiCl than in those treated with amphetamine. In the lateral pontine parabrachial nucleus (PBN), however, d-amphetamine and LiCl induced comparable, significant elevations of FLI. After a single prior pairing with either LiCl or amphetamine, exposure to a saccharin solution induced significant taste aversions and significant FLI in intermediate NTS relative to unpaired controls. Overall, these results indicate that PBN is a site of common activation by these two very different drugs during acquisition. The response to taste re-exposure points to a population of cells in intermediate NTS which have a common role in taste aversion expression despite different US activation patterns.

The neural basis for the feeding-related increase in corticosterone (CORT) was explored using the chronic decerebrate (CD rat) in which the caudal portion of the brainstem is neuraly isolated from the forebrain by a complete transection of the neuraxis. Tail blood samples were taken before and after a gastric intubation of either 8 ml milk/diet or water following overnight deprivation. Pre-intubation baseline CORT levels were comparable in CD and intact controls. In intact rats, CORT increased significantly with the water intubation (110% above baseline). By contrast, no water response was observed in the CD rat. Both groups, however, showed a dramatic elevation in CORT following the nutritive load (intacts: 350% above baseline; CD: 440% above baseline). Additionally, tail blood samples were taken 1 hr after each of 5 intubations of milk diet spread evenly throughout the 12 hr light cycle. Cd rats showed CORT levels that were slightly elevated from those of the intact controls, but the rise and fall of CORT levels through the light cycle in CD rats exactly paralleled those of the intact controls. The CD rat’s normal-like CORT profile may reflect the competence of the HPA axis in the transition to a state of acute stress, and the function of the HPA axis can be modulated by humoral signals associated with food deprivation and caloric loads. Alternatively, the CD rat's normal-like CORT profile may have been mediated by the autonomic nervous system without a significant forebrain contribution.

686.7 DISTRIBUTION OF FOS-LIKE IMMUNOREACTIVITY IN RAT BRAIN FOLLOWING ISOPROTERENOL TREATMENT AND THE EFFECTS OF CONVERTING ENZYME INHIBITION OR ANGIOTENSIN II BLOCKADE. M. McGlynn, B.J. Outfield. Howard Florey Institute of Experimental Physiology and Medicine, Univ. of Melbourne, Parkville, 3052, Vic., Australia.

Subcutaneous (s.c.) administration of the β-adrenergic agonist isoproterenol causes copious water drinking in rats which is blocked by angiotensin II inhibition. The aim of the present experiment was to map the distribution of neurons in the brain of the rat which increased Fos production in response to isoproterenol and to test the effect of the angiotensin II antagonist losartan or the converting enzyme inhibitor captopril (at 2 different doses) on this response. Rats were injected with isoproterenol (Winthrop, 50μg/kg s.c.) and killed 2h later. Immunohistochemistry was used to detect Fos-like immunoreactivity (Fos-LI) in parformaldehyde-fixed sections of brain. Fos-LI was increased in neurons in the lateral terminals, in particular those in the sublominal o颍an (SFO), median preoptic nucleus (MnPO), and organum vasculosum of the laminae terminals (OVLT). It increased also in the hypothalamic supraoptic and paraventricular nuclei, bed nucleus of the stria terminals, central nucleus of the amygdala, locus ceruleus, parabrachial nucleus, nucleus tractus solitarii, ventrolateral medulla and area postrema, but not in control rats injected with s.c. isotonic saline. Locartan (Du Pont-Merck, 100mg/kg, intraperitoneal) or captopril (Bristol-Myers Squibb, 50mg/kg s.c.) which block isoproterenol induced drinking, also blocked Fos-production in the lateral terminals, but not in the other regions.

The anorectic responses to imbalanced amino acid diets (IMDI) have been associated with neural activity in the prelippom cortex (PPC), an area critical for the expression feeding responses to IM. Because the principal neurons of the PPC contain glutamate, we measured the intake of IMD after acute injection of the NMDA receptor antagonist, D.S -(1)-2-Amino-5-phosphono-phorbonic acid (AP5), into the PPC. After stereotaxic placement of bicuculline aimed at the PPC and prefeeding a low-protein basal diet (BAS) for 10 days, rats were given 0.5 μl of either AP5 (4 mM in artificial CSF, N = 11) or vehicle (CSF, N = 8) just before feeding IM at the onset of darkness. BAS intake on the day prior to injections was taken as control for each rat. Coordinates for the PPC were: A 11.4, L 3.7, D 6.5 (Paxinos and Watson, 1982). Intake of IMD was increased to 83% of control in the AP5 group (p = 0.024 vs CSF group, that ate 55% of control) at 6-9 hr after introduction of IM, a crucial time period in the feeding responses. Intake values for 6-9 hr were: AP5 group = 3.59 ± 0.41g, vs CSF group = 2.29 ± 0.38g, (p = 0.038). Although feeding at other time points was not affected, the 6-9 hr increase was sufficient to increase intake of IMD nearly to a significant level at 24 hr (p = 0.058). We conclude that the NMDA receptor in the PPC may have a role in mediating the anorectic responses to IMD diets. Supported by USDA CSRS 90-37200-5440, NIH DK35747 and DK42274.

STIMULATION OF FEEDING BEHAVIOR IN THE RAT BY INTRA-
HYPOTHALAMIC INJECTION OF 8-BR-CAMP. E.R. Gillard, A.M. Khan, A.U. Has, R.S. Gwirali, and B.G. Stanley. Departments of Neuroscience & Psychology, University of California, Riverside, CA 92521, USA

Although several neurotransmitters acting in and around the lateral hypothalamus (LH) have been implicated in the control of eating, it is unclear which, if any, second messengers mediate their effects. To begin to address this, food intake was measured 1, 2, and 4 hrs after injection of 8-
rhodanodine 3,5-cyclic monophosphate (8-BR-CAMP, a membrane-
permeant cAMP analogue) into the perifornical hypothalamus (PFH) of freely feeding adult male Sprague Dawley rats. Each dose of 8-BR-cAMP (0, 1, 10, 50 and 100 nmol, dissolved in artificial cerebrospinal fluid vehicle) was administered in a final injection volume of 0.3 μl. Dose-dependent stimulation of eating was observed, with doses of 50 nmol and 100 nmol eliciting average 2 hr intakes of 3.9 and 15.7 g, respectively. To determine the locus of this effect, we compared the effects of 8-BR-cAMP injected into the PFH and six other areas bracketing the PFH (LH, anterior and posterior LH, paraventricular nucleus of the hypothalamus, amygdala, and thalamus). Consistent eating-
stimulatory effects were observed in the LH and PFH at doses ≥ 50 nmol (2 hr intakes ≥ 3.4 g). Thalamic injections resulted in a more variable feeding response which achieved significance only at 100 nmol. In contrast, injections into all other sites failed to stimulate eating. These results suggest anatomical specificity of 8-BR-cAMP’s effects, with likely sites of action being the LH/PFH and/or thalamus. It is possible that neurotransmitters known to influence eating in the hypothalamus may do so via the cAMP second-messenger system.

HYPOTHALAMIC GALANIN IN RELATION TO CIRCULATING INSULIN AND FAT INGESTION. S.F. Leibowitz, J.J. Koening and A. Akabasahi. The Rockefeller University, N.Y., N.Y. 10021 and The Immunology Research Institute, Annapolis, N.J. 08081

Galanin (GAL) is densely concentrated in neurons of the hypothalamic paraventricular nucleus (PVN). When injected into the hypothalamus, GAL reduces insulin secretion and stimulates feeding behavior, causing a preferential increase in fat ingestion. The present studies in albino rats reveal an inverse relationship between endogenous GAL peptide (measured via RIA), specifically in the PVN, and circulating levels of insulin, while GAL and fat ingestion are positively related. Three experiments were conducted: 1) With measurements taken at several intervals across the light/dark cycle (8 time points, n=7/time), GAL levels in the PVN, as opposed to other hypothalamic nuclei, increased significantly during the middle phase of the feeding cycle, while insulin levels were declining and natural fat ingestion increased. PVN GAL and circulating insulin levels were inversely correlated (r=-0.43, p<0.05) across the feeding cycle. 2) In rats (n=28) on macromounted diets, GAL levels in the PVN, but not other hypothalamic areas, were inversely correlated with circulating insulin levels (r=-0.41, p<0.05) but positively related to daily fat intake (r=+0.64, p<0.01). 3) In rats (n=11) given 5 daily injections of GAL antisept oligonucleotides into the PVN, GAL levels and daily fat intake decreased by 35% (p<0.05 compared to sense controls), while circulating insulin levels tended to rise (+46%, p<0.10). This inverse relation between endogenous GAL and insulin under normal feeding conditions is consistent with another report at this meeting (Tang et al.) showing insulin in diabetic rats to reduce GAL gene expression and peptide levels, specifically in the area of the PVN.

686.11

THE RELATIONSHIP OF AMOUNT OF SOUP IN THE STOM-
ACH TO THE CONTROL OF TEST MEAL INTAKE IN MEN AND
WOMEN. R.S. Kussinoff, R. Wastoff, D. P. Pierson, and F. X. Pi-Benhy.
New York Obesity Research Center, St. Luke’s-Roosevelt Hospital and

If a critical level of gastric tension, induced by volume, triggers the cessation of eating, graded volumes of food stored should be the migrants in intake in a subsequent test meal, thereby preserving constancy of total (preload + meal) volume, as preload size increases. This hypothesis holds only if meals and preloads are at the same rates. To test this hypothesis, five women and six men in good health, nonobese and without medical problems, ate a yogourt shake test meal 30 min after tomato soup preloads. Emptying of the preload from the stomach was measured by radionuclide scintigraphy (see table for the volume of soup remaining at the start of the test meal). The preloads and test meals were given with at least two days between. Preload sizes ranged from 160 to 800 ml in 160 ml steps. No preload condition was included. Test meal intake was reduced as a function of preload size in a linear fashion only between 320 g and 640 g in women and only at the 160 g compared to 0 and 800 g compared to 640 g preload volumes in men (See Table below for details).

Preload (g) 0 160 240 480 640 800 1600
Women intake (g) 0 160 240 480 640 800 1600
Women preload (g) 0 23 65 194 265 265 110

Unless the preloads of soup differentially affect test meal eating, gastric tension, induced by volume, by itself, is not a critical signal for normal meal termination in humans. (Support: NIH - DK35007 & DK80867)

686.12

Migratory birds rely on increased fat storage and fatty acid utilization to meet seasonal changes of energy expenditure and as a result increase fat reserves. To determine if their feeding behavior is sensitive to carbohydrate utilization, white-crowned sparrows (Zonotrichia leucophrys gambelii) maintained on short daylength (9L15D) were injected with 2-deoxy-D-glucose (2-DG), 2,6-anhydro-D-mannitol (2,6-AM), or insulin, drugs that elicit feeding in mammals. Low doses of 2-DG (25 or 50 mg/kg) had no effect on food intake and higher doses (100 or 300 mg/kg) significantly suppressed feeding after 1 and 2 hours. No dose of 2-DG increased meal size. Analogously, low doses of 2,6-AM (25, 50 or 100 mg/kg) had no effect on food intake, and higher doses (300 and 600 mg/kg) significantly suppressed intake. Low doses of insulin (0.5 or 1.0 U/kg) also had no effect on food intake and higher doses (2.0 or 4.0 U/kg) significantly suppressed feeding and induced hypoglycemia after 1 and 2 hours. These data suggest that decreased carbohydrate metabolism does not elicit feeding in these species, and after injection of 2-DG and insulin, and that suppression of food intake was caused by the decrease in circulating glucose levels.

EATING SUPPRESSION AND BODY WEIGHT LOSS BY LATERAL
HYPOTHALAMIC (LH) NMDA RECEPTOR BLOCKADE WITH D-AP5. B.G. Stanley, V.L. Willett III, H.W. Donia and M.G. Dei II. Departments of Neuroscience & Psychology, University of California, Riverside, CA 92521.

We have recently shown that interest eating is elicited by LH injections of glutamate, N-methyl-D-aspartic acid (NMDA), or non-NMDA receptor agonists (Brain Res. 1993, 633, 88-95 & 638, 41-49). To examine whether LH glutamate and NMDA receptors might mediate natural eating, LH injection of the competitive NMDA receptor antagonist D-AP5 (10 nmol, 0.1 μl of artificial CSF) was tested for anorectic effects in adult male Sprague-Dawley rats. First, we examined whether pretreatment with LH injection of D-AP5 would suppress eating elicited by LH NMDA (10 nmol) and 15.7 g, respectively.To determine the effects of long-term treatment, D-AP5 was bilaterally injected into the LH at the onset of the dark-phase for 8 consecutive days. Compared to vehicle injection, D-AP5 produced marked and prolonged reductions of daily food intake and loss of body weight. Food intake normalized when the injections were stopped. These findings suggest that endogenous LH glutamate may act in part via NMDA receptors to influence eating behavior and body weight.

CMT ENHANCES SPROUTING IN PARTIALLY DENERVATED MUSCLE. S.G. Siegel*, A.W. English, Dept. of Anatomy & Cell Biology, Emory University, Atlanta, GA 30322.

Following partial denervation of skeletal muscles, the remaining intact motorneurons develop sprouts which innervate a limited portion of the denervated fibers. This response is thought to contribute to the regeneration of the lateral gastrocnemius (LG) muscle receives innervation from precisely one branch of the muscle nerve. After partial denervation by transection of the branch to the medial compartment (ULm) of the LG muscle, newly formed sprouts do not cross the compartmental border. To investigate whether exogenous neurotrophic factors (CNTF) can augment the natural sprouting response, rat LGm fibers were denervated. CMTF was administered by intramuscular injection (2-20ug/kg) into the LG muscle once daily for 1 week. Animals were sacrificed 1 day after the last injection, and the tissue was analyzed for sprouts. The motor end plates and nerve terminals were visualized immunohistochemically by the presence of clustered fluorescent alpha-bungarotoxin and FITC-conjugated antibody to the 200kd neurofilament protein, respectively. Sprouts from intact motorneurons were identified as thin offshoots from the nerve terminals or preterminal axon. CMTF administration resulted in an increase in the proportion of end plates with sprouts, suggesting that the natural sprouting response to partial denervation can be enhanced. However, sprouting from motorneurons in the intact compartment did not lead to reinnervation of fibers in the denervated compartment.

CMTF was provided by Regeneron Pharmaceutical, Inc.

ANTEROGRADE INFLUENCES ON COLLABORATOR NEURONAL SPROUTING IN THE SYMPATHETIC NERVOUS SYSTEM. G. A. Kuchel*, C. Richard and M.C. Bastian. Montreal General Hospital Res. Inst., 1655 Cedar Montreal, Quebec,Canada H3G 1A4

In contrast to retrograde signals for collateral growth (ie. target-derived NGF), anterograde influences on this form of plasticity are less well delineated. Using a NE-uptake assay, Dornay et al. (J. Soc. 5:1340, 1985) concluded that an intrinsic innervation was essential for the development of collateral sprouting in the rat pinal gland after a unilateral denervation. This target receives bilateral innervation from the two superior cervical ganglia (SCG). We have quantified fluorescent immunohistochemistry for tyrosine hydroxylase (TH) as an index of collateral sprouting (Exp. Neuro 124:381).

As shown earlier, 1 day after a unilateral denervation (R-ICN cut) the rat pinal gland exhibited a 50% decrease in the area fraction representing TH immunoreactive profiles (TH-IR). Collateral sprouting then took place with an increase to 78% and 76% of control values at 3 and 10 days, respectively. When this lesion was immediately preceded by a decentralization of the "intact" SCG (L-CSTx), TH-IR was 71% and 72% of control values at 3 and 10 days, suggesting that much of the collateral sprouting response was still intact. Further studies will be required to evaluate the possibility that degenerating preganglionic neurons "releasing" neurotransmitters during critical periods of signaling supplant usual anterograde signals for lesion-induced postganglionic collateral sprouting.

687.3

Lumbosacral dorsal rhizotomy, sparing one root, induces sprouting by that root in adults (Polistina et al., 90). Scatic nerve section enhances regeneration of the central process of crushed dorsal root in adults (Richardson et al., 87). Scatic nerve lesions are also accompanied by decreased synthesis of CGRP and SP by DRG neurons and depletion of these peptides from the dorsal horn (Nohias et al., 93; Himes and Tessler, 89). In neonates scatic lesion induces sprouting by central processes into the dorsal horn unaccompanied by depletion of peptides (Reynolds, R.J. et al., 90). We combined unilateral scatic nerve section with bilateral spared root preparation to determine whether the peripheral lesion would enhance sprouting by the spared root in adult rats. The immunocytochemical staining was compared on the two sides using antibodies against neuropeptidase and cytoskeletal proteins. CGRP and SP levels increased on the scatic nerve lesioned side at 3 days and the CGRP projection was expanded, SP returned to normal (or less) at 10 days and CGRP returned to normal (or less) at 20 days, indicating a transient effect of scatic lesion in this paradigm. The sprouting of central projections however blocks or delays the downregulation of peptide synthesis normally evoked by peripheral nerve lesion. Immunochemical staining of cytoskeletal proteins high molecular weight (BMW) tau, MAP 1B and phosphorylated MAP 1B showed no significant differences, suggesting that central sprouting in this paradigm is not associated with axonal elongation.

687.4
SPROUTING OF ANTIFERRENT APPLETS IN THE DENERVATED CUNEATE NUCLEUS OF ADULT RATS AFTER DORSAL RHIZOTOMY. P.E. Garrapathy1,2, D.L. Sengelaub1, A.C. Mills1 and N. Mujad1.

In 1991, Pons et al. (Science, 252, 1857) reported a remarkably extensive topographic reorganization in SI (area 3b) of macaque monkeys that had undergone dorsal rhizotomies extending from the second cervical (C2) to the fifth thoracic (T5) level some years earlier. Here, we evaluate the hypothesis that this reorganization was due to the formation of new connections between intact afferents and nerves that had been degenerated by the rhizotomies. Thus, we have performed comparatively extensive, dorsal rhizotomies in adult rats followed by anatomical tracing and electrophysiological mapping experiments. Using peripheral skin injections of a conjugate of cholera toxin subunit B and horseradish peroxidase, we have observed aberrant expansions of cervical projections into the cuneate nucleus within 3 months of the deafferentation. Moreover, this new growth apparently forms functional connections because cortical recordings in forelimb regions of SI in these same animals reveal neurons that are responsive to stimulation of hindlimb skin surfaces innervated by afferents that normally project to the gracile nucleus. These results suggest that substantial new growth is possible in the mature central nervous system, and that such new growth may well account for the substantial functional recovery detected in earlier experiments in the so-called "Silver Springs monkeys." 687.5
PROGRESSIVE ENTORHINAL LESIONS ACCELERATE HIPPOCAMPAST SPROUTING IN RATS. T.S. Carrigan, M.L. McGuilkin, and J.L. Ramirez.

Neuroscience Program and Department of Psychology, Davidson College, Davidson, NC 28036.

Entorhinal cortex (EC) lesions are known to induce sprouting by the crossed temporopontine pathway (CTP) in rats. Previous evidence from our laboratory indicates that two-stage (progressive) lesioning of the entorhinal area accelerates recovery from spatial alternation deficits associated with unilateral EC lesions and increase the synaptic efficacy of the CTP by 250% as little as 6 days postlesion.

The purpose of the study was to determine automatically whether progressive lesions accelerated CTP sprouting. Animals were assigned to one of four groups: progressive lesion, control, priming lesion, or one-stage lesion. The postlesion period in the CTP was analyzed using a two-way analysis. The CTP sprouting response was quantified by creating a ratio of the silver grain density evident in the outer molecular layer of the dentate gyrus contralateral and ipsilateral to the H-222 injection (Ci). The Aadium was to probe the best possible control lesion, the priming lesion to induce a significant sprouting response at 6 days postlesion. Progressive lesions increased the Ci ratio by approximately 300% in both the dorsal and ventral layers of the dentate gyrus. The lesion sizes of the two-stage and progressive treatment conditions were similar. We conclude that progressive entorhinal lesions enhance the rate of sprouting by the crossed temporopontine pathway. Taken together, the histological, electrophysiological, and behavioral results indicate that CTP sprouting is functionally significant and behaviorally meaningful.

Organotypic slice cultures of murine hippocampal tissue provide an in vitro model system for the controlled study of mossy collateral sprouting into the dentate molecular layer(DML). We hypothesized that the presence of afferent innervation would decrease the degree of mossy fiber collateral sprouting in the DML. Alternate slices derived from the mid-hippocampal region were cultured with or without attached entorhinal cortical tissues. Bodian silver staining confirmed the presence of mossy fibers in both the dentate gyrus and entorhinal cortex. Timm’s heavy metal staining and densitometry were utilized to assay the degree of mossy fiber sprouting. Attached entorhinal cortex significantly reduced the degree of mossy fiber sprouting in the DML after ten days in vitro (p<0.003; n=30 pairs). To confirm that damage to mossy fiber axons was not responsible for mossy fiber sprouting in the DML, alternate pairs of hippocampal slices were subjected to either complete transection of their mossy fiber projection (at the point where the fibers leave the hilus) or left undisturbed. Slices receiving mossy fiber lesions displayed no significant increase or decrease in mossy fiber sprouting into the DML as compared to adjoining control slices receiving no mossy fiber lesions (n=10 pairs). Therefore, mossy fiber collateral sprouting into the dentate molecular layer is not a consequence of damage to mossy fibers, but rather, may be regulated by the presence of afferents from the entorhinal cortex in vitro. Supported by DOE grant #2-89/116/38-150.
DELAYED DEGENERATION DIFFERENTIALLY AFFECTS THE TIME COURSE OF SPROUTING BY AFFERENT SYSTEMS REMAINING IN THE MOLLEcular LAYER OF THE DENTATE GYRUS FOLLOWING LESIONING OF THE PERFORANT PATH. B. Shi* and S. B. Stanfield. Lab. of Neurophysiology, NIMH, NIH Animal Center, Poolsville, MD 20853.

Axons in polymodal pathways have been shown to undergo very slow Wallerian degeneration in WLD mutant mice. It has recently been shown that in WLD mutant mice there is a delay in the intensification of acetylcholinesterase histochemical staining in the molecular layer of the dentate gyrus following lesions of the entorhinal cortex. The intensification of the acetylcholinesterase histochemical staining of septohippocampal fibres in the dentate molecular layer. Thus, it appears that delayed post-lesion reactive sprouting is associated with the delayed degeneration of cut central axons in this mutant. We have observed changes in the septohippocampal projections suggestive of sprouting of the perforant path in WLD and normal (C57BL/6J) mice by injecting wheat germ agglutinin conjugated horseradish peroxidase into the septum or commissural hippocampus and processing the tissue sections for TMB histochemistry. In normal mice changes in the distribution of labeled septal and commissural axons indicative of sprouting in the dentate molecular layer are seen as early as three days post-lesion. The earliest similar changes are found in WLD mutant mice is seven days post-lesion, when an increase in the density of labeled septal axons begins in the outer molecular layer. The delay in the sprouting of commissural axons in the mutant is even longer. Changes in the distribution of labeled commissural axons in the dentate gyrus of WLD mice are first seen twelve days post-lesion. These results confirm that post-lesion reactive axonal sprouting can be delayed in the CNS of WLD mutant mice. In addition, our results indicate that the extent that may differ among fiber systems. These findings are consistent with the notion that various CNS axonal systems may respond differently to sprouting cues and are reminiscent of the regeneration response exhibited by sensory and motor axons in the WLD mutant after peripheral nerve cuts.

DEVELOPMENTALLY REGULATED LOCALIZATION OF A PURKINJEE CELL-SPECIFIC TRANSCRIPT IN DENDRITES. E. Batenick, D. Schilling, G. Cole, S. G. and T. Oberleick, Ohio State Biochemistry Program, 2DEpartment of Cell Biology, Neurology and Anatomy, and 3The Biotechnology Center, The Ohio State University, Columbus, OH 43210. 4Abteilung Anatomie und Zellbiologie der Universität, 89069 Ulm, Germany.

Several mRNAs thought to be important for neuronal growth and plasticity have been found to be localized in dendrites. Cerebellar Purkinje cells (PCs) are ideal for studying the role such transcripts play due to both the size and monopolar orientation of their dendrites. In situ hybridization has been performed for three PC-specific transcripts known to encode proteins highly concentrated in PC dendrites. Of the mRNAs coding for these three markers, LH, PEP-19 and CaBP28K, only that for LH is abundantly detectable in PC dendrites. In addition, it appears that the amount of LH mRNA in dendrites is much greater during the early postnatal period than in adulthood, suggesting that direct translation of the LH protein in dendrites may be particularly important during dendritic outgrowth. This is consistent with several observations made of Purkinje cells in primary dissociated cultures of embryonic cerebellum. Under conditions of high K+ PC dendrites consistently take on a more elongated morphology relative to their stunted appearance in normal medium. Under the same high K+ conditions, expression of both the L7 protein and β-galactosidase driven from an L7-lacZ fusion gene, are qualitatively higher based on histological assay. In particular, in immature cultures, PC dendritic processes are L7 positive only in the high K+ condition. Thus, the L7 protein may be important for the growth and continuing plasticity of PC dendrites.

ROLE OF THE HYALURONAN RECEPTOR RHAMM IN NEURITE EXTENSION AND MOTILITY IN PRIMARY NEURONS AND NEURONAL AND GLIAL CELL LINES. U. N. Frankenstein*, J. Hacking, M. Z. Houman, R. A. Turpen* and J. J. Nagy, Department of Physiology and Laurentian Institute of Cell Biology, University of Manitoba, 770 Bannatyne Avenue, Winnipeg, Manitoba CANADA R3E 0W3.

RHAMM (Receptor for Hyaluronan Mediated Motility) has been identified as a receptor for the extracellular matrix component hyaluronan (HA) and was recently shown to be essential for the locomotion of normal and transformed peripheral cells. In view of similarities in molecular processes that govern cell locomotion and growth cone migration, we investigated whether RHAMM also contributes to cell migration of CNS-derived cells in vitro. Immunohistochemical studies of cultured primary neurons, astrocytes and oligodendrocytes as well as of several neuronal and astrocytic cell lines revealed a punctate form of RHAMM labelling in cell bodies, along processes and at growth cones. By Western blot analyses, neuronal cell lines such as PC12, NG108-15 and N5868 cells were found to express a major RHAMM forms of apparent MW of 75 and 116 kDa, while glial cells contained 50 and 72 kDa forms with HA binding capacity. Treatment of NG108-15 cells with dibrutyl-cAMP led to enhanced expression of RHAMM with a clear increase in RHAMM immunofluorescence in these cells. Monoclonal and polyclonal anti-RHAMM antibodies as well as peptides corresponding to the HA binding domains of RHAMM significantly inhibited neurite extension, glioblastoma cell extension and motility. An antibody directed against a repeat sequence present in RHAMM significantly stimulated neurite migration of NSC-14 cells and cat primary neurons. Collectively these results demonstrate the role of RHAMM in CNS cells and suggest a critical role for HA/RHAMM interactions in the modulation of neurite migration and glial cell locomotion.

We have previously reported preliminary data indicating that axon number changes at the corpus callosum in the rat. To study the callosal development, we examined the callosal axons from 15 days of age (Kim & Juraska, 1990). In adult rats, we found significant dorso-ventral and rostro-caudal variations in axonal density within the splenium, which could potentially influence axon number calculations if the splenium is not sampled extensively. Therefore, we re-examined axon number changes at the splenium at 15, 25, and 60 days of age. The posterior fifth of the corpus callosum, which contains the axons from the visual cortex at all of these ages (Kim et al., 1992), was extensively sampled with electron microscopy. Axon density was multiplied by the area of the posterior fifth from adjacent µs sections to determine axon number.

There was a significant decrease in axon number between day 15 and 25, and also between day 25 and 60. Thus, axon withdrawal in the rat splenium continues after the adult-like distribution of callosal projections within the visual cortex is established (Olavarria & Van Stuyves 1985). Preliminary results indicate that there is a sex difference in the timing of axon withdrawal in the rat splenium which will be further investigated. Supported by NSF IBN 9310945.

The BALB/cWah1 mouse strain has approximately 50% callosal defective animals. In the brains of these acellular mice, an aberrant longitudinal bundle is consistently found. This study was designed to investigate the distribution of cells and terminals of the LB and the corpus callosum (CC) during postnatal development. At ages ranging from 1-20 postnatal days (PND), 36 BALB/cWah1 mice were anaesthetized and intracardially perfused with a formaldehyde perfusate (4% PFA). Carbocyanine dyes, DiI or DiO, were inserted into the CC of normal animals or the LB of callosal defective mice. The brains were stored in 4% PFA, in darkness, for 3-7 days. After the appropriate time, each brain was embedded in gelatin and sectioned. The sections were stained with bis-benzimide and examined in an epifluorescence microscope. Analysis was focused on the paleocortex. The distribution of cells and terminals of normal and callosal defective animals (totally or partially absent CC) did not differ. At PND 5 and PND 10 axons were seen traveling through the neocortex and terminating in layer I. At PND 10 the granular layer was clearly identified and it was found devoid of callosal or LB projections. From 15-20 PND the gaps in layer IV were confirmed and the callosal and LB cells were mainly found in layers II and III. From 10-20 PND the pattern of callosal and LB projections corresponded to those portions of the parietal cortex which did not contain dense aggregates of granule cells. It was concluded that the distribution of cells and terminals of the LB resembled a normal (parallel) CC. This indicates that the appropriate targets are being located by the LB axons.

688.5 CALLOSAL AGNESIS IS SECONDARY TO DEFECTS IN HIPPOCAMPAL COMMISSURE FORMATION IN MOUSE EMBRYOS. D.J. Lively*, Dept. of Zoology, Univ. of Alberta, Edmonton, Alberta, Canada, T6G 2E9.

Pioneer axons of the corpus callosum (CC) use the hippocampal commissure (HC) as a guiding substrate to cross the telencephalic midplane in normal mice. In mice with callosal agenesis, CC axons arrive at their proper location on time to cross midplanes, but HC development is delayed, preventing its use by the CC axons as a guiding substrate. The routing and timing of hippocampal axon growth through the HC was studied in Balb/cWah1 (Wahl-50% CC defect), 129J (129-70% CC defect), and a sixth generation cross of Wahl x129 (C129/100% total CC absence) mouse embryos using perfusion fixation and the insertion of crystals of the carbocyanine dyes DiI and DiO into the hippocampal fimbria. Specimens ranged from 0.300 to 0.600g body weight or 15 to 17 days chronological age. Selected specimens were also stained using bis-benzimide to show background morphology.

In Wahl embryos, the first crossing of HC axons was seen at about 0.456g-0.48g which is about 1 day later than that seen in normal BALB/cJ hybrid embryos. In 129 embryos, first crossing was not seen until about 0.520g - 0.550g, about 2 days later than in normal hybrids. No HC axons were seen to cross midplane in the C129F, embryos prior to 0.600g. The arrival and movement of axons in all three strains appeared normal, but their traverse of midplane was blocked by the presence of a cleft which extended deep in the septal region.

688.2 EARLY DEVELOPMENT OF THALAMO-CORTICAL AND GANGLIONIC EMINENCE PROJECTIONS IN THE HAMSTER. C. Méridon and P. Godelmet.* Instutut A. Fressaud, CNRS, 1 av. de la terrasse, 91190 GUYET, FRANCE.

The formation of long-range projections in the brain requires that axons navigate along precise paths and recognize their final targets. In mammals, the thalamic and the neocortical projections are connected via reciprocal connections and are separated by the ganglionic eminence. We have studied the development of these projections, from embryonic day E11 to E16 in hamster embryos, corresponding to stages when these fibers begin their growth. Small injections of carboxyfluorescein dyes (DiI, DiA) were done in fixed hamster embryo brains to label anterogradely and retrogradely the projections from small territories of the thalamus and ganglionic eminence.

Anterograde labeling shows that at E11.5, thalamic fibers reach the medial ganglionic eminence (MGE), and cortical fibers reach the lateral GEM. Importantly, retrogradely-labeled neurons are found in close proximity to the growth cones of thalamic and cortical fibers in the medial and lateral GEM, respectively. Thus, at this age, there are reciprocal connections between the GEM and the thalamus and neocortex. Injection into the ganglionic eminence confirms the existence of this early projection. At E12.5, thalamic fibers accumulate at the frontier between the lateral GEM and the neocortex. They cross into the intermediate zone of the neopallium one day later, at E13.5. The most advanced reach the dorso-medial part of the parietal subplate and few or no fibers are found in more rostral or caudal levels. From E11.5 to E12.5, cortical fibers grow forward and into the GEM. At the frontier between the neocortex and the GEM, they make a right-angle turn. The first cortical fibers reach the dorsal thalamus at E13.5. At this age, retrogradely labeled cells are observed in the lateral part of the parietal cortical plate, and in the ventro-basal region of the dorsal thalamus, suggesting that these regions are the first that establish reciprocal connections.

These observations show that thalamic and cortical fibers project to the ganglionic eminence before reaching their targets. At early stages, the GE interconnects the diencephalic and neocortical regions, and therefore, interactions of thalamic and cortical fibers with the GEM or its projections could be involved in the establishment of thalamo-cortical connectivity during early development.

688.4 PEP-19 IMMUNOISTOCHEMISTRY REVEALS THE DEVELOPING DIRECT PURKINE-VESTIBULAR COMPLEX PROJECTION IN THE RAT. J. J. Viele F. B. Miller and W. V. Young. Dept. of Pathology (Division of Neuropathology). 2Anatomy and Cell Biology, and the Brain Research Inst., UCLA, Los Angeles, CA 90024.

We performed an immunohistochemical examination of the developing direct purkinje vestibular complex projection in the rat cerebellum. The antibody utilized to discriminate Purkinje cell axons from others within the developing metencephalon was a rabbit polyclonal antibody produced against the Purkinje cell enriched antigen, PEP-19. In mouse, we identified 6.2 kDa peptide containing regions of similarity to a number of proteins thought to interact with calcium, including S100 calcium and calmodulin. A previous immunohistochemical examination of PEP-19 in the adult rat showed immunolocalization to corticopontine neurons and a minor proportion of neurons within the dorsal cochlear nucleus. The earliest age we have examined embryonic 17 (E17), shows no immunopositive axonal profiles within the vestibular complex (superior and lateral vestibular nucleus). At E20, well organized fascicules are seen passing through the deep cerebellar nuclei and the pontocerebellar isthmus. These axons are observed to enter into the vestibular complex and apparent synaptic contacts upon cells of all stags within the lateral vestibular nucleus are seen. From these initial findings we conclude that the direct purkinje vestibular complex projection is established between E17 and E20.

688.6 MULTIPLE GUIDANCE CUES ARE INVOLVED IN THE SEGREGATION OF PIONEERING PATHWAYS IN THE CORTICAL AND INTERNAL CAPSULE: EVIDENCE FROM REELE R.A. Kindeys*, W. Wang, A. Sharma Dept. of Neurology, SUNY at Stony Brook, Stony Brook, NY 11794.

We compared pathway formation during cortical development in normal and reeler mutant mice using the carbocyanine dyes DiI and DiA to trace axons in fixed tissue, and immunolabelling with antibodies to chondroitin sulfate proteoglycans (CSPGs) to identify the extracellular matrix (ECM). By embryonic day E11, neurons begin extending axons from the preplate zone (PPZ) which has intense CSPG labeling. By E12, cortical plate (CP) neurons begin splitting the PPZ into the marginal zone (MZ) and subplate (SP), which retain CSPG labeling. CP neurons pass through the SP region and obliquely cross the intermediate zone (IZ), exiting the cortical close to the VZ. Reeler neurons retain the PPZ, and their IZ and CP are mixed in one layer. Axons of CP neurons extend obliquely along this layer and exit the VZ. By birth, normal and reeler, pioneer efferents hesitate in a zone above the forming stratum. If later arriving (E12-13) thalamic axons encounter the waffling efferents, they fasciculate. The time period of co-extension is brief. In normal neocortex, thalamic axons can selectively extend within the subplate and its CSGP. As the stratum matures, thalamic axons extend laterally around expanding stratum, to enter the subplate and its CSGP. CP axons continue to exit the cortex near the VZ. The CP axons are globally distributed and separate and axons do not encounter each other after E14. Reeler E14 'CP' develops streaks of CSGP intermingled with efferent neurons and axons allowing reeler thalamic afferents to encounter cortical thalamic axons. Thalamic axons selectively extend within the streaks of CSGP, and thalamic axons. Evidence indicates that thalamic and cortical axons guide each other in development, it occurs in a limited number of axons. Multiple guidance cues produce pathway segregation in the forming cortex and internal capsule.
688.7 POTENTIAL ROLES OF THE CCK5 AND CCK8 RECEPTOR TYROSINE KINASES IN THE DEVELOPMENT OF NERVOUS SYSTEM ARCHITECTURE. L. A. Rojalst and F. P. Pascual, La Jolla Cancer Research Foundation, La Jolla, CA 92037.

Many receptor-tyrosine kinases have been shown to play important roles in nervous system development. We are currently probing the effects of extracellular "growth factors" with neural activity. The Eph subclass represents a major branch of receptor tyrosine kinases that are highly expressed in the developing nervous system. We have shown that the spatial distribution of two Eph-related kinases, CCK5 and CCK8, in the embryonic peripheral nervous system and brain is different. At HH stages 10 and 18, both CCK5 and CCK8 appear to be expressed in outgrowing motor axons. High levels of phosphorylated immunoreactivity correspond to the sites of CCK5 and CCK8 axon growth cones. At HH stages 10 and 18, the axon growth cone becomes restricted to a subset of spinal neurons, whereas CCK5 is expressed throughout the spinal nerves. By 8 days in ovo, CCK8 expression in peripheral nerves decreases, but appears high peripherally, whereas CCK5 expression remains high within the nerve trunks. CCK5 and CCK8 are also expressed in the developing visual system. The pattern of CCK8 expression suggests that it plays a role in the formation of maintenance of the ganglion cell pathway from retina to optic tectum. CCK8 is expressed in the retina itself and becomes restricted to ganglion cell somata. By 8 days in ovo, CCK8 expression is apparent throughout the optic nerve, and by 10 days in ovo, CCK8 immunoreactivity outlines the optic tract. CCK5 appears to play a role in the development of retino-tectal specificity. It is highly expressed in the ventral portions of the developing retina and optic nerve, but only weakly expressed in the dorsal portions of these structures. Immunostaining of retinal explants demonstrates that CCK5, CCK8 and phosphorysine immunoreactivities can be linked to neuronal processes. This work was supported by NIH Grant HD26351.

688.8 CORTICOSPINAL TRACT IN THE DEVELOPING RAT SPINAL CORD: THE PARENT AXONS AND PROJECTION COLLATERALS. J. Hagesater* and J. Zent, Department of Anatomy, Hokkaido University School of Medicine, Sapporo 060, Japan.

A detailed morphological analysis of the corticospinal tract of the rat neonate ranging from postnatal day 1 (P1) to P14 was investigated using retrograde labeling with fluorescent dye, DII, optimized by confocal laser scanning microscopy (CLSM). The parent axons constituted a compact bundle which was constantly enclosed in the ventral part of the dorsal funiculus of the spinal cord. Individual axons were not parallel to each other within the bundle. In addition, the growth cones of follower axons were distributed over a wide range. The majority of the projection collaterals toward the target area emanated from the rectangular branching, however, a number of them ran in various directions. Multiple collaterals from the single parent axon were often observed. The projection fibers repeated branching and their arbors terminated onto the preferential phenotype of the target neurons within the dorsal horn, the intermediate zone or the ventral horn in the spinal gray matter.

688.9 AXONAL ARBORIZATIONS OF THE PRIMARY AFFERENTS SERVING DIFFERENT VESTIBULAR END-ORGANS IN ZEBRAFISH EMBRYOS. S.E. Fraser* and R. Chapman, Division of Biology, 139-74, Caltech, Pasadena, CA 91125.

In adult vertebrates, primary vestibular afferents serving the different semi-circular canal and otolith organs form distinct overlapping regions of axonal arborization in the vestibular nuclei. While there is an obvious role for this specificity in sensory processing, little is known about the development mechanisms which are responsible for establishing the connections. In particular the relative contributions of inherent positional cues, topographic, and patterns of neural activity to the development of specificity have not been previously examined. As a first step in answering these questions we have studied the axonal arborization patterns of primary vestibular afferents in zebrafish embryos. To achieve this we have used iontophoretic injections of lipophilic dyes into the crista and maculae in the inner ears of fixed zebrafish embryos. At HH stages, we inject dyes to different lobes of the sacculus and in the utricle we examine the patterns of arborization in area octavolateralis in the hindbrain using confocal microscopy of whole mounts of the labeled embryos. We find that the primary afferents serving the different vestibular end-organs have recognizably different projection patterns. The pattern of axonal arborization is different from one given end-organ, however, it is highly stereotyped and reproducible between animals at a given age. Double labeling experiments using Dil (C3) and Dii (C8) injected into different cranial nerve in the same animal have shown that there is good separation of the arbors of the populations of axons serving different end-organs.

Further experiments are currently underway to test whether the development of normal patterns of axonal arborization in the vestibular system depend on the presence of normal neural activity, as has previously been shown to be true in the visual system.

688.10 AXONOGENESIS AND THE EARLY APPEARANCE OF GABA IMMUNOREACTIVE NERVES DURING DEVELOPMENT OF THE CNS IN A TELEOST. I. Olsén* and F. Erikson, Dept. of Zoology, Univ. of Lund, Sweden.

During early CNS development, a small number of neurons give rise to pioneer axons that form the axonal scaffold. It is not known whether these axons acquire neurotransmitter phenotype, or which transmitter(s) they utilize. In an attempt to approach this question we have studied the early development of the axonal scaffold in embryos of a teleost fish, the three spined stickleback, with immunocytochemical techniques. We used mono- clonal antibodies against acetylcholinesterase (AChE) and against GABA. GABA is known to exert various neurotransrophic actions in the developing nervous system. The antibodies were applied to the semithin Araldite sections and to whole mount embryos. Both single and double labeling experiments were performed. Huntingdon neuroblasts of 144-168 post fertilization (PF). At 36 PF, two 6-11B-1-immunoreactive (6-11B-1) ventral tracts are located in the mesencephalon. At 48 PF, two 6-11B-1 ventral tracts extend from the mesencephalon throughout the spinal cord. At 96 PF, the first GABA-immunoreactive (GABA) neurons appear in the ventral mesencephalon, ventral mesencephalon and in the spinal cord. At 600 PF, the 6-11B-1 ventral tracts, were connected by numerous commissures all along between the mesencephalon and the spinal cord. Also, an additional lateral ventral tract appeared. At 66 PF, the first GABAergic cell groups have grown by addition of GABAergic neurons, and GABAergic cell bodies and fibers are closely associated with the 6-11B-1 tracts that constitute the axonal scaffold. Thus, GABAergic neurons appear only when the axonal scaffold is established. We suggest that the first pioneer neurons are not GABAergic but that GABAergic neurons make an important contribution to the formation of the early nervous network.

688.11 COMMISURE FORMATION IN THE EMBRYONIC BRAIN OF THE GRASSHOPPER, G. BOSYERI, AND H. Reichert, Zoology Institute, University of Basel, Rheinsprung 9, CH-4051 Basel, Switzerland

A fundamental event in the normal development of the insect brain is the establishment of bilateral commissural connections between the brain hemispheres. We have studied the formation of the very first commissural fiber pathways in the embryonic grasshopper brain using immunocytochemical techniques. During early embryogenesis a set of approximately 130 neuroblasts differentiates from the neuroepithelium of the head to form the bilaterally organized proto-, deut- and tritocerebral brain segments. In the midline of the deutocerebrum, however, an additional set of 15 neuroblasts differentiates from the neuroepithelium anterior to the stomodaeum, and ventrally between the pars intercerebralis lobes of the protocerebral segment. We have identified these neuroblasts as a group of cell falks that give rise to a midline intercerebral bridge. The differentiation of this brain commissure depends on the axoloc in gene. In axoloc in mutants the brain commissure is severely reduced, and only a small subset of commissural falks are formed. The cerebral hemispheres are linked to the ventral nerve cord by paired brain connectives, which interconnect the initially separated prosophageal and ventral neurogenic regions. The formation of these pair brain connectives depend on the axoloc in gene. In axoloc in mutants paired connectives do not form, and the aberrant ectopic midline ventral nerve cord is established by axons which navigate along the midline stomatostomaic nervous system structures. Our future goal is to carry out a comprehensive study of the formation of fibers connecting the brain segments involved in brain development. (Supported by SNSF and HHMI).

688.12 MOLECULAR MECHANISMS OF EMBRYONIC BRAIN DEVELOPMENT IN DROSOPHILA MELANOGASTER. S. Thienast, S. Leurzi, F. Hirth, C.S. Goodman and H. Reichert, Dep. of Zoology, University of Basel, CH-4051 Basel, and HHMI, Dep. of Molecular and Cell Biology, University of California, Berkeley, California 94720.

We are using the powerful genetic and molecular genetic techniques that are available for the study of embryonic development in Drosophila to investigate the molecular mechanisms involved in building a complex brain. Embryonic development of the Drosophila brain is comparable to other insects. During the period of embryogenesis in Drosophila, complex cerebral hemispheres are formed. These cerebral hemispheres are interconnected by the brain commissures, which is provided by a pair of axoloc in cell falks that give rise to a midline intercerebral bridge. The differentiation of this brain commissure depends on the axoloc in gene. In axoloc in mutants the brain commissure is severely reduced, and only a small subset of commissural falks are formed. The cerebral hemispheres are linked to the ventral nerve cord by paired brain connectives, which interconnect the initially separated prosophageal and ventral neurogenic regions. The formation of these paired brain connectives depend on the axoloc in gene. In axoloc in mutants paired connectives do not form, and the aberrant ectopic midline ventral nerve cord is established by axons which navigate along the midline stomatostomaic nervous system structures. Our future goal is to carry out a comprehensive study of the formation of fibers connecting the brain segments involved in brain development. (Supported by SNSF and HHMI).

ESTABLISHING FUNCTIONAL RELATIONSHIPS BETWEEN GENES IN AB1-REGULATED PROCESS ES BY ANALYSIS OF DROSOPHILA MUTANT PHENOTYPES. J.-L. Luang*, F. M. Hoffmann, McArdle Laboratory 77for Cancer Research, University of Wisconsin-Madison, Madison, WI 53706.

The function of the Ab1 protein tyrosine kinase in Drosophila is of interest because it relates to the transforming oncogene in Abelson murine leukemia virus. Drosophila provides a well-characterized system in which to analyze the developmental consequences of specific mutations by examining mutant phenotypes. Five genes, disabled (db), enabled (en), faulx axon connections (facc), fasciclin I (fasci) and fasciclin II (fascii) have been examined to analyze their functional interaction with the Ab1.

We have observed defects in axon outgrowth and/or pathfinding in embryonic CNS of these mutants. We also used enhancer trap lines to visualize a small subset of axons. Our preliminary data suggest the axon tract defects observed in mutant embryonic CNS are due to defects in cell adhesion mechanisms critical to growth cone pathfinding. Antibody staining of CNS-derived cell lines have indicated that the abs, db and ena proteins are present in the neuronal cytoplasm, neurites, and the growth cone regions.

688.15

Corticothalamic fibres undergo extensive reorganisation between the cortex and the thalamus. To examine this reorganisation as connections are being formed, we placed small crystals of the lipophilic dyes DiI and DiA in the cortex of acutely or chronically decerebrated rats. Two days later, neurites were visualized immunohistochemically and counted. The number of neurites on the bottom surface of the membrane was increased 2 to 5 fold by the explant conditioned medium compared to normal unconditioned medium. NT-3 containing medium resulted in a 10 fold increase in the number of neurites on the bottom surface of the membrane. The NT-3 effect is completely abolished when the gradient is eliminated by adding NT-3 containing medium to both the upper and lower chambers, suggesting that the effect is due to chemotaxis and not simply enhanced neurite outgrowth. Experiments are in progress to determine if corticofugal neurites are among the NT-3 responsive population and whether these neurones express trkC in situ.

689.1

Two distinct types of acetylcholine receptor (AChR) channels are present at the synaptic membrane of vertebrate skeletal muscle. One type is characterized by high conductive (HC) fast kinetics, and the other type is characterized by low conductance (LC) slow kinetics. In an effort to define the role of innervation in the expression of these two classes of AChR channels we performed current-clamp recordings in the motoneuronal pool of adult mice. This was followed by sequential single channel recordings performed in freshly dissociated fibers from the flexor digitorum muscle. Up until two days after crush the percentage of LC channels were less than 1% of the total observed events and similar to the control. At three days post crush the percentage of LC channels started to rise, and by day five more than 40% of the channels were LC type. This was followed by a progressive decrease of the percentage of LC type, and by eight days post crush less than 40% of the openings were LC type. We concluded that the whole cell patch clamp technique is important to regulate the expression of either type of channels and that single channel recordings are useful to monitor the course of reinnervation.

689.2

DECREASED ACTIVITY OF Na CHANNELS IN PITUITARY MELANOTROPHS FOLLOWING THE ONSET OF DOPAMINERGIC INNERRATION. J.C. Gorona, A. Navarrete, A. Marin and C. Costa. Dept. of Neurosciences, Cinvestav, Mexico, DF 07000.

High-threshold Ca** currents in rat melanotropes undergo a drastic inhibition during the early postnatal period, concomitant with the onset of dopaminergic innervation (Gorona et al., Soc. Neurosci. Abstr. 19:1128, 1993). We have now investigated whether the long-term effects of innervation include regulation of Na current. Na currents were dissociated from non- and fully-innervated rat intermediate pituitary lobes (postnatal 0-4 days, 4-8 days, and 11 days, respectively). In the glass culture for 5-24 h, and then subjected to whole cell patch clamp. Standard recording solutions were used. Peak Na** inward current decreased to -54 +54 pA (mean±SE, n=14) in PNL cells to -28±14 pA (n=14) in PMI1 cells. In contrast, the average values for cell capacitance and K+ outward current amplitude did not significantly differ between these two types of cells. Thus, the dopaminergic innervation of melanotropes reduces Na** current density, but does not seem to affect the long-term activity of K+ channels.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
FUNCTIONAL EXPRESSION OF Ca<sup>2+</sup>-ACTIVATED K<sup>+</sup> CURRENTS IN EMBRYONIC CHICK SYMPATHETIC NEURONS DEVELOPING IN SITU AND IN VITRO. M. E. Waisberg, S. Raucher, and S. E. Dryer. Program in Neuroscience, Florida State University, Tallahassee, FL 32306

We have examined the expression of whole-cell K<sub>Ca</sub> in embryonic chick sympathetic neurons developing in situ and in vitro. K<sub>Ca</sub> expression appears related in vivo to the expression in developmental E13 and reaches its mature density at E18. Voltage-activated Ca<sup>2+</sup> currents (I<sub>Ca</sub>) are present throughout these stages. When sympathetic neurons are isolated at E13 and maintained in cell culture for an additional five days, both they do not express K<sub>Ca</sub> although I<sub>Ca</sub> is expressed at normal density. Culturing sympathetic neurons in the presence of 5 ng/ml NGF caused a significant (p < 0.05) increase in K<sub>Ca</sub> expression, although this effect appeared to be restricted to a subpopulation of cells (17 out of 34 neurons). Similarly, co-culture of sympathetic neurons with ventricular myocytes stimulated K<sub>Ca</sub> expression (p < 0.05 compared to controls). By contrast, co-culture of sympathetic neurons with spinal cord explants, which make functional contacts with sympathetic cells, did not promote K<sub>Ca</sub> expression. The developmental expression of K<sub>Ca</sub> is dependent upon extrinsic factors, possibly including target-derived trophic factors. Supported by NIH Grant NS-27013.

OTHER FACTORS AND TROPHIC AGENTS I

Localization of Rse, a Novel Tyrosine Kinase Receptor, in the Mammalian CNS; Comparison with Other Tyrosine Kinase Receptors. Mark Amundson, Lanly Wong, Klaus Becker, Franz Hell. Neurobiology, University of Toronto, Toronto, ON, Canada.

Rse is a novel tyrosine kinase receptor isolated from rat and human brain. Rse and human Rse share ~90% amino acid identity, containing extracellular, transmembrane, and intracellular domains. Recent analysis reveals Rse expression to be most abundant in brain. Here, in-situ hybridization was performed to identify specific neuronal subcategories expressing this gene.

In-situ hybridization revealed Rse to be widely expressed throughout the adult rat brain, but restricted to specific regions. Expression in the hippocampus was observed primarily in CA1, to a much lesser extent in CA3 and CA4, and undetectable in the dentate gyrus. High levels of expression were observed in the cortex, cingulate, olfactory bulb, and cerebellar granule cells, but undetectable in the midbrain, brainstem, and medial septum. Sections from the rat hippocampus also revealed high levels of Rse expression in these structures. In the E15.5 mouse and 8 week human embryo, expression of Rse was undetectable in the CNS. Thus, expression appears to be turned on later in development, with highest levels being maintained in the adult. The regulation of Rse expression in response to a combination of nerve-forming/interventricular lesion was also investigated.

The localization, developmental patterns, and response of Rse expression to injury were compared with other recently described tyrosine kinase receptors of the mammalian CNS.

The protein kinase inhibitor K-252a has been shown to promote cholinergic activity in cultures of rat spinal cord (Glickman et al., J. Neurochem., 61: 210-221, 1993) and neuronal survival in chick dorsal root ganglion cultures (Lorincz, et al., Neurosci. Lett. 108: 207-212, 1990). To determine the mechanism by which K-252a acts as a neurotrophic factor, we examined the effects of this molecule on a human neuroblastoma cell line, SH-SY5Y. K-252a induced neurite outgrowth in a dose-dependent manner. Co-incubation with neurotrophin-3 (NTS) enhanced K-252a-mediated induction of 125 and 140 kDa tyrosine phosphorylated proteins. Inhibition of protein kinase C with GF-109203X did not prevent K-252a induced tyrosine phosphorylation or K-252a dependent neurite outgrowth suggesting that the neurotrophic effects mediated by K-252a are independent of protein kinase C inhibition. We have identified one of the phosphoantibodies as the p815 focal from the cerebellum and dorsal-teal prefrontal cortex were obtained with increased Fak activity and appeared to be independent of ligand/intergen interaction. The induction of Fak phosphorylation, by K-252a, was also observed in SH-SY5Y and primary cultured dorsal root ganglion cells but not in PC12 cells. The protein kinase-C independent induction of tyrosine phosphorylation and the identification of Fak as a substrate of K-252a-induced tyrosine kinase activity suggests that this compound mediates neurotrophic effects through a novel signaling pathway.
LPA, A NEURITE OUTGROWTH INHIBITOR, ACTIVATES MAP KINASE IN NIE-115 NEUROBLASTOMA CELLS. G.L. Ramakers* and W.H. Moolenaar. Division of Cellular Biochemistry, Netherlands Cancer Institute, Plesmanlaan 121, Amsterdam, The Netherlands.

The phospholipid lysophosphatic acid (LPA) has recently been identified as an albumin-bound serum factor, that induces DNA synthesis and stress fiber formation in fibroblasts by activating both classic and novel signaling pathways through a putative 40-kDa G-protein receptor coupled to the heterotrigic G-proteins (Moolenaar, Trends Cell Biol. 4: 213; 1994). The 40 kD LPA receptor is highly expressed in brain and in the neuroblastoma cell line NIE-115, which differentiates to a sympathetic phenotype upon serum withdrawal. In differentiated NIE-115 cells LPA induces rapid neurite retraction through an independent signal pathway involving classic second messengers (Jalink et al., Cell Growth Differ. 4: 247; 1993). As protein tyrosine kinase and phosphatase inhibitors interfere with LPA-induced neurite retraction in NIE-115 cells, we investigated protein tyrosine phosphorylation in NIE-115 cells by LPA after serum-starvation, using an anti-phosphotyrosine immunoblotting.

LPA (at 100 nM and higher), thrombin and insulin, but not EGF, EGF or glutamate transiently stimulated the phosphorylation of p42 MAP kinase with a peak at 2 min. LPA-induced MAPK phosphorylation was inhibited by pertussis toxin and various suppressors of protein kinase (PKC), indicating an involvement of the heterotrigic G-protein, as well as PKC. A model will be presented in which LPA-induced MAP kinase parallels, but is independent of neurite retraction, and serves as a trigger to drive NIE-115 cells back into the cell cycle.

The distribution of GAP-43-like immunoreactivity (LI) in the superior cervical ganglia and irides of adult SD rats was studied using confocal laser scanning microscopy (CLSM). In the SCG of control rats, GAP-43-LI was mainly located in the nerve terminals around, but not inside, the principal neurons and very little in nerve bundles. After 24 hours decentralization the GAP-43 positive nerve terminals disappeared, while the principal neurons remained. The TR-LI positive nerve terminals 3 days after decentralization, GAP-43-LI was again observed in nerve terminals, and also appeared in axon bundles, while principal neurons disappeared. Principal neurons in SCG cells did not show clear changes after decentralization. In the irides of control rats, GAP-43-LI was present and distributed in a patchy pattern in axon bundles, around blood vessels and in the terminal network. Double immunostaining showed that GAP-43-LI colocalized with TH-LI, but appeared to distribute differently from SP-LI. GAP-43-LI semi-quantification of GAP-43-LI in the irides was performed using CLSM. The intensity and density of the nerve terminal network in the dilator were registered. 3 days of decentralization, the intensity and density of the GAP-43-LI positive terminal network significantly increased.

The results indicate that GAP-43-LI is normally present in nerve fibers and terminals of the post-ganglionic adrenergic SCG neurons in adult rats. The modulations in GAP-43-LI observed in cell bodies and nerve terminals after decentralisation suggests that these autonomic neurons have a capacity for remodelling and plasticity which may partly be regulated via the pre-ganglionic neurons.

IDENTIFICATION OF INTERLEUKIN-6-EXPRESSING NEURONS IN DIFFERENT REGIONS OF RAT BRAIN. R. A. Gaden* and U.H. Oomen, Dept. Physiology, Univ.Basel, CH-4051 Basel, Switzerland

Interleukin-6 (IL-6) belongs to a family of neurotrophic cytokines which includes ciliary neurotrophic factor (CNTF), leukemia inhibitory factor (LIF), oncostatin M and IL-11. This family of multifunctional proteins shares a common signal-transducing receptor subunit (gp130). We focused on IL-6, which promotes neuronal survival, differentiation and ameliorates the effects of excitotoxins. In a recent study using reverse transcription-polymerase chain reaction (RT-PCR) we showed that both IL-6 and IL-6 receptor (gp80) transcripts are found in normal rat brain in a region-specific manner and are developmentally regulated. To identify the cellular origin of IL-6 and its receptor, we established a sensitive non-radioactive in situ hybridization technique. In line with our RT-PCR data the most prominent IL-6 mRNA expression was observed in hippocampus and hypothalamus. Low expression was seen in the striatum. The IL-6 mRNA signal was predominantly located in neuronal cells, such as the pyramidal and granular cells of the hippocampus and the Purkinje cells of the cerebellum. These findings implicate IL-6 in the regulation of so far unidentified neuronal functions. This study was supported by the Swiss National Foundation for Scientific Research (Grant 31-39129.93) and by the BMTF (Grant 01KL9303).

INTERLEUKIN-18 EXPRESSION DURING DEVELOPMENT OF THE MOUSE BRAIN. J.L. Scicpiter* and C.F. Ide, Neuroscience Training Program and Department of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118

Interleukin-18 (IL-18) is a cytokine which modulates inflammation and immune responses in the periphery. Expression of IL-18 has been demonstrated in the adult brain after trauma and may be regulated during cell death. Since development of the brain involves programmed cell death, we investigated the developmental profile of IL-18 immunoreactivity (ir) in the perinatal mouse brain using antiseraum to human recombinant IL-18. Immunohistochemistry on E10, P0, P6 and P30 animals. We also synthesized a 447 bp cDNA probe (to murine IL-18 mRNA) for use in in situ hybridization studies on E10, E15, E18, P0, P6, P10, P20 and P60. Antisense and sense probes were used to detect IL-18 mRNA in situ. The mRNA was found in cells of all brain areas, especially in the cerebral cortex. At P6, mRNA levels declined and IL-18 was equivalent to levels and areas found at P0 and P10. IL-18 mRNA declined in all brain regions except the olfactory bulb and the CA1 region of the hippocampus. In adults there was no detectable IL-18 mRNA except in the olfactory bulb and the CA1 region of the hippocampus. IL-18 mRNA was only faintly expressed and was restricted to the olfactory bulb and the CA1 region of the hippocampus. This suggests that IL-18 is downregulated during natural cell death in the developing CNS. Supported by DOD grant #2-89/Y116/SS-150 to the Tulane/Xavier Center for Bioenvironmental Research.
690.9 EFFECTS OF ENDOTHELIN-I ON THE EARLY DEVELOPMENT OF CHICK EMBRYOS. L. Hess* and A.Y. Jeng, Department of Biology, Seton Hall University, South Orange, NJ 07079 and Research Department, Clinical Pharmaceuticals, Summit, NJ 07901. Endothelin-I (ET-1) is a potent vasoconstrictive peptide originally isolated from conditioned medium of porcine aortic endothelial cells. We have previously found that ET-1 enhances neurite outgrowth from phorbol ester-treated dorsal root ganglion explants. The purpose of the present study is to examine the effect of ET-1 treatment on the development of the nervous system in chick embryos. Eggs were incubated at 37°C and treated with ET-1 (50 pmol) through a 24-hour period. Repeated treatment with 50 pmol ET-1 from days 2-4 resulted in significantly larger heads and trunks when observed on day 7, while the size of the eyes and limbs were comparable to the controls. The overall lengths of the diencephalon and the telencephalic and optic lobes in the treated groups were increased. Similar effects on brain development were noted when embryos were treated with a single dose of 50 pmol ET-1 on day 5. These results suggest that ET-1 has growth-factor-like effects on both development and that embryos are more responsive to treatments around day 5.

690.10 RELATIONSHIP OF c-neu ONCOGENES AND THE EPIDEMICAL GROWTH FACTOR RECEPTOR (EGFR) IN DEVELOPING RAT CEREBRAL CORTEX. P.E. Kuhn* and M.W. Miller, Cell and Devol. Biol., Rutgers Univer., Piscataway NJ 08854, Res. Serv., V.A.M.C., Iowa City IA 52242, and Depts. of Psychiatry and Pharmacology, Univ. of Iowa Coll. of Med., Iowa City IA 52242. Similarities between c-neu oncoproteins and EGFR were examined with antibodies directed against the carboxyl ends of the oncoprotein and the EGFR. During the first two postnatal weeks, both antibodies identified neural cell bodies distinctly throughout cortex. Hence, both proteins may be interrelated. The transient pattern of oncoprotein immunostaining correlated with the transient expression of a 25 and a 300 kDa protein. The anti-EGF, identified a 50 kDa protein which was expressed transiently during the first two postnatal weeks. After immunoprecipitating cortical tissue with the anti-oncoprotein antibody, evidence of the EGFR + 50 kDa protein in the supernatant was eliminated; the precipitate retained all of the immunolabeling. In the reverse experiment, tissue was immunoprecipitated with the anti-EGF; the 35 and 300 kDa proteins remained unprecipitated in the supernatant. Immunoprecipitation with either antibody did not affect detection of the oncoprotein + or EGFR + proteins with different profiles of temporal expression. The EGFR + 50 kDa protein shares an epitope with a c-neu oncoprotein(s). Thus, the 50 kDa protein (a) forms a heterodimer with a c-neu oncoprotein or (b) is a component of a larger c-neu oncoprotein (~ 300 kDa protein). Supported by the V.A. and N.I.H. (DE07734, AA06916, and AA07568).

690.11 LOCALIZATION OF RETINOIC-BINDING PROTEINS AND RETINOID RECEPTORS SUGGESTS A FUNCTION FOR RETINOIC ACID IN DEVELOPING AND ADULT Dopamine-Nerve TERMINAL BRAIN AREAS. E.H. Egestad,* A. Tomas,* E. Eriksson,* and R. Nishi, Department of Cell Biology and Anatomy and Department of Biological Structure and Function, Oregon Health Sciences University, Portland, OR 97239. The choroidal nerve of the avian ciliary ganglion innervate the smooth muscle cells surrounding the arterial vasculature of the choroidal layer of the eye. These neurons are cholinergic and express somatostatin as a neuropeptide. When grown in culture, the smooth muscle cells secrete Actinin A (AA), which has been shown to increase the expression of somatostatin in the neurons of the ciliary ganglion. We have characterized the target cells to determine expression of smooth muscle markers to assess culture time. The cells lose expression of smooth muscle specific actin (SMA) when placed in culture, but redifferentiate over time. Treatment with ET-1 increases proliferation of the cells while suppressing the expression of muscle markers. In contrast, TGFβ rapidly increases expression of SMA while suppressing proliferation. We have used ET-1/PCR to isolate and clone a fragment of AA from E12 choroid, showing that AA is present in vivo, as well as being expressed in vitro. We have initiated studies to examine the in vivo expression of AA expression during choroidal smooth muscle cell differentiation in culture in addition to parallel studies of AA expression in the choroid layer in vivo. Supported by NS25767 and NIHES23207123.

690.12 DEVELOPMENTAL INTERACTIONS BETWEEN CHOROID NEURONS AND THEIR SMOOTH MUSCLE TARGET CELLS. D.C. Durand, G.G. Leblanc,* and R. Nishi, Department of Cell Biology and Anatomy and Department of Biological Structure and Function, Oregon Health Sciences University, Portland, OR 97239. We have characterized the target cells to determine expression of smooth muscle markers to assess culture time. The cells lose expression of smooth muscle specific actin (SMA) when placed in culture, but redifferentiate over time. Treatment with ET-1 increases proliferation of the cells while suppressing the expression of muscle markers. In contrast, TGFβ rapidly increases expression of SMA while suppressing proliferation. We have used ET-1/PCR to isolate and clone a fragment of AA from E12 choroid, showing that AA is present in vivo, as well as being expressed in vitro. We have initiated studies to examine the in vivo expression of AA expression during choroidal smooth muscle cell differentiation in culture in addition to parallel studies of AA expression in the choroid layer in vivo. Supported by NS25767 and NIHES23207123.

690.13 CHARACTERIZATION OF SOLUBLE FACTOR ACTIVITIES IN DEVELOPING CHICK CILIARY GANGLION - IRIS SYSTEM. B.A. Link, W.K. Woodworth, and R. Nishi, Dept. of Cell Biology and Anatomy, Oregon Health Sciences Univ., Portland OR 97201. The differentiation of the developing iris and innervation by ciliary ganglion neurons is an excellent system to study neurite target interactions. The developing chick iris is composed of two muscle groups, the myoepithelial or smooth-type muscle constrictor and the striated-type muscle dilator. Mesoepithelial cells are believed to further differentiate to the striated-type muscle and give rise to the contractile dilator at E13. Previous studies (Link and Pilat, 1974 J. Physiol 241:77) have shown that the iris is initially innervated by the ciliary ganglion and that innervation with innervation of the iris is a period of cell death in the ciliary ganglion which results in a 50% loss of the neurons. To investigate potential retrograde influences, we have used immunoperoxidase and immunoperoxidase to identify soluble activities from the ciliary ganglion and the iris. Soluble media from E9 to E11 iris were prepared and applied to a heparin agarose column. Heparin binding and non-binding fractions were tested for [3H]thyrosine incorporation into murine AKR-2B cells in the presence or absence of heparin. Heparin neurotrophic activity (c-like, a-like) was identified by its ability to support neurite outgrowth of cultured E8 ciliary ganglion (CG) neurons. Soluble extracts from E9 to E14 CGs were assayed in a transgenic assay system. Extracts of iris tissue we observed developmental increases in intraneuronal activity with the greatest activity in the heparin binding - heparin dependent fraction. We observed intraneuronal activity to further develop to the heparin dependent - heparin dependent and non-heparin dependent binding fractions. As the developing iris, heparin binding - heparin dependent and non-heparin binding fraction were observed. These data suggest that heparin binding activity may play a role in the development of the iris and ciliary ganglion. Supported by NS25767.

690.14 Transforming Growth Factor alpha immunoreactive nerve fibers in the rat and mouse intestinal tract. P. Hoffmann, J. Lachman, J.M. Zeeh, L. Liu, M. Sottelli, L. Barajas, M.G. Ercis*, and V.E. Ryszewski. Harbor UCLA Medical Center, Torrance, CA 90509. Epidermal Growth Factor (EGF) and Transforming Growth Factor (TGFα) are important mediators of mucosal blood flow, mucus production and secretion, and motility in gastrointestinal tissue in addition to their mitogenic actions. These effects are important since they may mediate EGF/TGFα’s capability to protect intestinal mucosa against acute injury. The aim of the present study was to show morphological evidence of the invasion of TGFα in the regulation of the enteric nervous system by demonstrating TGFα immunoreactivity in nerve fibers of stomach and colon in rats and mice. Tissue samples were fixed in Zamboni’s solution, frozen in OCT compound and cut with a cryostat. A polyclonal antibody, raised against conjugated rat TGFα, was used to perform immunohistochemistry. Binding was visualized by the avidin-biotin peroxidase technique as described previously. Beaded nerve fibers were detected in the muscle and submucosal layers of stomach and colon in rats and mice. A weak immunoreactivity was also detected in neurons of the myenteric plexus of both species. Detection of TGFα immunoreactivity in neural structures of intestinal tissues gives morphological evidence that TGFα released from these nerve fibers may be the endogenous source to induce EGF/TGFα’s nonmitogenic actions in vivo.
THE EFFECTS OF TRANSFORMING GROWTH FACTOR-β (TGF-β) ON NEURONAL AND GLIAL CELLS ON THE DEVELOPING MEDIAL SEPTAL AREA. I. E. Menn et al, Centre de Recherche Pediatrics-Neuro Scie, Montreal, Quebec, CANADA, H3T 1C5.

We have examined the effects of TGF-β on different neuronal and glial cell populations in primary cultures of dissociated fetal rat medial septal cells. TGF-β, like epidermal growth factor (EGF), was found to induce a dose-dependent increase in choline acetyltransferase (ChAT) activity which was accompanied by a parallel decrease in the number of acetylcholinesterase positive neurons. The effects of TGF-β and EGF on ChAT activity were evident within 4 days of continuous exposure to this growth factor. However, although the dose-response profiles of TGF-β and EGF on ChAT enzymatic activity were similar (i.e. maximal inhibition of ChAT activity occurred with 10 ng/ml, TGF-β) consistently produced a more pronounced inhibition of ChAT activity when compared to EGF in situ cultures. When we compared the effects of TGF-β and EGF on ChAT activity, for those with EGF; the decrease in ChAT activity was not additive, suggesting a common mechanism of action for both factors. In addition, EGF induced a marked proliferation of astrocytes and microglial cells in the fetal septal cultures without affecting the numbers of ChAT-positive cells. The inclusion of the antibiotic 5-fluorodeoxyuridine completely abrogated both the glial cell proliferation and the decrease in ChAT enzymatic activity induced by TGF-β. Consequently, TGF-β is indirectly affecting cholinergic cell differentiation via glial cells. Competitive binding studies on different cell populations from the medial septum suggested that TGF-β is more effective in displacing EGF binding to its high affinity receptor, whereas, the opposite is seen for the low affinity EGF receptor. Finally, although TGF-β when applied in the absence or presence of an antagonist did not appear to affect the number or glutamic acid decarboxylase (GAD) immunoreactive neurons (GABAergic) as assessed by GAD immunocytochemistry, the intensity of the immunoreaction appeared to be somewhat higher in TGF-β treated cultures when compared to controls. Quantitative effects of TGF-β on GABAergic neuronal morphology were determined by morphometry. These results suggest that TGF-β can differentially affect neuronal and glial cell populations in the developing rat medial septal area both directly and indirectly.

TGF-β and TGF-β2 are pleiotropic cytokines with prominent roles in the regulation of cell proliferation, migration, differentiation, and extracellular matrix. We have previously found (Flinders et al., Development 113: 1991; Bieger et al, SAK 1999) that sympathomimetic neuronal populations (in the embryonic mouse adrenal gland as well as adult rat and bovine chromaffin cells) synthesize and release TGF-β. Western blotting using an antibody to the TGF-β receptor type II indicates that promulgation of bovine adrenal medulla to have a TGF-β receptor type II component. Chromaffin cells of the rat adrenal medulla are capable of divide in a decreasing fashion, from birth to adulthood (Tischler et al., Int. J. Dev. Neurosci, 7: 1989) and NGF, TGF-β and TGF-β2 are known to stimulate chromaffin cell proliferation in vitro (Brodin and Gammeltoft, PNAS 91: 1994). Since a physiological role for the chromaffin cell-derived TGF-βs has not been established as yet, we were interested whether TGF-β would interfere with the capacity of chromaffin cells to divide and respond to various mitogens. Chromaffin cells were dissociated from PS rat adrenal medullae as previously described and cultured for 7 days under serum-free conditions. Immunoreactivities of TGF-β, IGF-II, and IGF-I are expressed by single or in combinations. BrDU was added at 10 μM during the final two days. Cultures were then processed for the co-localization of BrdU- and tyrosine hydroxylase immunoreactivities. TGF-β, IGF-II and RA, applied single or in combinations, caused up to 50-fold increases in chromaffin cell proliferation. TGF-β, applied at 1, 2.5, or 10 ng/ml, significantly reduced the factor-mediated increases in proliferation. This suggests that TGF-β, released by chromaffin cells, together with glucocorticoids and PACAP (Brodin and Gammeltoft, 1994), which is released from intramedullary nerve terminals, must be considered as negative regulators of chromaffin cell division.

Insulin and insulin-like growth factors (IGF-I, IGF-II) are closely related polypeptides which are found in the CNS and are known to regulate neuronal survival and neurite outgrowth. They are each associated with specific cell surface receptors and several soluble binding proteins (IGBFs) which are involved in regulating function and availability. The primary analogues of IGF-I were insulin and IGF-II, insulin with basic analogues (5Glh, 5Ala, T1yr, 5Leu) of basic IGF-I and a B chain analogue in which the first 16 amino acids of IGF-I were replaced by the first 17 amino acids of insulin. These analogues have been significantly reduced binding affinity for IGF-I receptors. Neuronal cultures were established using embryonic (E15 - E17) rat cortex and PitD4 sarcoma cells in order to determine whether these IGF analogues were as effective as native human IGF-I as peptide to promote neuronal survival and neurite outgrowth. They are each associated with specific cell surface receptors and several soluble binding proteins. Cultures were maintained in DMEM+10% FCS in the presence of mitotic inhibitions for 3 days (cerebellum) and 6-8 days (cortex). DMEM was then replaced with Locke's solution containing no glucose. In some cases,洛克's Locks containing IGF-I or analogues. After 48 hours, Locke solution was removed and the remaining cells were assayed for LDH, an established method for assessing cell viability. These results are expressed as a percentage control and in the presence of either IGF-I or either of the IGF-I analogues the percentage LDH released from cortical and cerebellar neurones was significantly reduced (approx. 50%) indicating cell survival. More importantly, the data show that the IGF analogues with reduced affinity for IGF-IRs are an effective as IGF-I in promoting cell survival and their reduced affinity for IGF-IRs has no deleterious effect on their neuroprotective function.

TRANSFORMING GROWTH FACTOR (TGF)-β1 REGULATES RAT BRAIN TGF-β TYPE II RECEPTOR mRNA LEVELS. T. E. Morgan*, D. K. Sarkar†, Y. W. Y. Ta, and C. E. Fitz. Anand Gerontoloty Center, Department of Biological Sciences, University of California, San Francisco, CA 94110; †Department of VCAPP, Washington State University, Pullman, WA 99164-6520, ‡Salk Institute, San Diego, CA 92186-5800.

ATA is known to protect neurons from apoptotic cell death by inhibiting of calcium-activated endonucleases. With PC12 cells, a neuronal model cell line, ATA prevents cell death under serum free condition. Inhibition of endonucleases by ATA was not observed in isolated nuclei of PC12 cells. The western blot analysis of PC12 cell lysate with anti-phosphotyrosine antibodies revealed that protein phosphorylated at 100 μM ATA for 2 minutes induced phosphorylation of the tyrosine residues of some proteins. The major tyrosine-phosphorylations induced by ATA were not observed in PC12 cells treated by NGF or EGF. However, ATA, as well as NGF or EGF, induced the tyrosine-phosphorylations of PI3 kinase and SHC in PC12 cells. The induction of tyrosine-phosphorylation by ATA was not observed in NIH3T3 cells. Moreover, ATA did not protect NIH3T3 cells from cell death under serum free condition.

These results suggest that the neuroprotective action of ATA is mediated by the activation of the subsequent stimulation of the tyrosine-phosphorylation cascade.
690.21

Cultured PC12 cells possess receptors for VIP, NGF, or EGF and can be differentiated into a neuron-like cell type in vitro by the addition of an array of peptide growth factors, including nerve growth factor (NGF) and EGF. Addition of either NGF or EGF to PC12 cells elicits activation of cognate tyrosine kinase (TK) receptors resulting in rapid, enhanced tyrosine phosphorylation of a series of substrates that is similar for the two growth factors. While NGF promotes neuronal differentiation of PC12 cells, EGF invokes a mitogenic response. The neuroactive peptide, VIP, has been reported to promote a partial neuronal differentiation in neuroblastoma cells, an effect that is also increased in CAMP levels. The possibility that a combination of EGF-stimulated TK activity and the CAMP-stimulating effect of VIP could support an NGF-like neuronal differentiation response in PC12 cells was investigated.

Co-administration of EGF and VIP to PC12 cell cultures for up to 6 days results in robust neurite outgrowth. The neurites approximate, in length, those obtained by NGF treatment for comparable periods of time, but are less dense in their arborization. In the presence of 300 nM VIP, the neurite outgrowth response can be obtained with concentrations of EGF as low as 1 ng/ml. The neuronal morphologic differentiation induced by EGF + VIP is not inhibited by the NGF-selective inhibitor, K-252a. These results suggest that peptides such as VIP and EGF, which are partial, or ineffective neurotrophic agents may interact cooperatively eliciting a neuronal morphologic differentiation similar to that observed for the identified neurotrophin, NGF. One possible inference suggested by these data is that, CAMP-dependent protein kinase and tyrosine kinase activities are sufficient to support neurite outgrowth, a characteristic feature of neuronal differentiation.

690.23

Colony stimulating factor-1 (CSF-1) was originally identified as a specific growth factor for cells in the mononuclear phagocyte lineage, and subsequently was also found to be an important factor in maternal-fetal regulation. We find that CSF-1 is a growth factor in the nervous system as well. Nuclear acid studies demonstrate that CSF-1 mRNA is expressed in vivo in developing and adult mouse brain in various regions, including hippocampus, striatum, cerebellum and cortex. CSF-1 mRNA is found in whole brain samples as early as embryonic day 12.5 and is detectable through adulthood with some sexual variation. RT-PCR analysis shows splice variants of CSF-1 mRNA are expressed which encode soluble, and not membrane-bound, growth factor. Additionally, mRNA for the CSF-1 receptor is readily detectable in the developing and adult CNS. Regional studies correlate CSF-1 expression with CSF-1 mRNA expression. Treatment of primary cultured neurons from five brain regions with CSF-1 results in neurite outgrowth.

To define the role of CSF-1 in vivo, electrolythrophic techniques were employed in mice, which are homogamous for an inactivating CSF-1 mutation. These animals display abnormal visual and auditory evoked potentials, using both extracranial and intracranial recordings, indicative of abnormal cortical function. The expression of CSF-1 in vivo, the effects of CSF-1 on neurons, as well as the neurobiological deficits in vivo suggest that CSF-1 is an important factor in CNS development.

690.25

LA-N-2 is a cell line derived from a human peripheral neuroblastoma. It has a partially cholinergic phenotype and is a potential in vitro model of peripheral cholinergic neurons. It does not demonstrate CDP-choline-stimulated, Ca2+-dependent release of acetylcholine (ACh). The object of this study was to induce Ca2+-dependent release of ACh in LA-N-2 cells with various differentiation agents.

Cells were cultured for 14 days in 1 ml dibutyryl cAMP (dBcAMP), 0.25 mM leukemia inhibitory factor (LIF) or/and 3.8 mM nerve growth factor, or 10 nM retinoic acid (RA) for 9-14 days in F12/HEPES with 10% FBS. Cells were loaded with [3H]choline for 30 min at 37° and washed. The amounts of cellular and released (5 min, RT) labeled and unlabelled ACh and choline were determined by HPLC. None of the differentiation agents induced Ca2+-dependent release of [3H]ACh. Some of them, however, had marked effects on other aspects of cholinergic function. LIF increased [3H]choline uptake, [3H]ACh synthesis, and ACh content 250% and Ca2+-independent release of [3H]ACh 70% compared to untreated cells. RA increased [3H]choline uptake, [3H]ACh synthesis, and ACh content 30%. A Ca2+-independent and basal release of [3H]ACh 130%. dBcAMP increased [3H]choline uptake 20% and decreased ACh content 60%. LA-N-2 cells may be a good model for studying aspects of peripheral cholinergic function.

690.26

Vasopressin receptors are thought to respond to VIP, was shown to be a nitrogen for sympathetic neuroblasts (Pincus et al., Nature 341,564,1990), and for human neuroblastoma (all line-HNB), a tumor of the sympathetic nervous system (Wollman et al., Brain Res. 624,339,1993). Northern blot analysis revealed VIP mRNA neuroblastoma cells (cell-line-HNB) suggesting an autocrine growth factor role for VIP in neurogenesis and tumor propagation. Measurements of thymidine incorporation and cell numbers now showed that a potent VIP hybrid antagonist(1-34)-VIP, Gozes et al., Endocrinology, 125,2945,1989) inhibited cell division in this neuroblastoma cell line. The hybrid VIP antagonist also inhibited lung cancer growth (Gomez et al., Proc. Nat. Acad. Sci. USA 90, 4145, 1993), indicating a new therapeutic strategy against prevalent cancers including neuroblastoma, the most common solid malignany of children less than 5 years of age.
691.1

EFFECTS ON DEVELOPMENTAL AND ADULT NEUROCHEMISTRY OF CRONIC SERATAL TREATMENT WITH AN INHIBITOR OF ORNITHINE DECARBOXYLASE IN THE RAT. A. Contestabile, M. Sparrasani, V. Virgili, F. Facchinetti and R. Gianu (Sapienza University of Rome, Italy).

Neonatal rats were treated from postnatal day 0 to 24 with daily s.c. injections of the suicide ornithine decarboxylase inhibitor, DPH. In addition to some somatic effects, the treatment resulted in permanent decrease of brain weight which was mainly due to a 40% decrease of the cerebellum. When ornithine decarboxylase inhibition was only effective during the first phase of the treatment, the levels of putrescine and spermidine were decreased in the cerebellum and forebrain up to 3 days after the end of the treatment. Significant alterations of neuronal and glial chemical markers were measured in the cerebellum of treated rats once adults. Developmental treatment with DPH activates a mechanism able to keep low levels of putrescine and spermidine even in the presence of a progressive lack of ornithine decarboxylase inhibition. Furthermore, low developmental levels of the two polymines mainly arise from regions where substantial neurogenesis does occur during the treatment, such as the cerebellum.

691.3

MOON ABNORMALITIES INDUCED BY X-IRRADIATION AT BIRTH ARE DELAYED BY PERINATAL GMI TREATMENT.

Since GMI was reported to enhance neurite formation after damage of central neurons by different agents, we studied its effects on motor abnormalities and neurochemical changes in cerebellum (CE) induced by 5 Gy single dose of X-rays (X) applied to rats up to 72 h after birth. GMI 30 µg/g.were s.c. injected using different protocols: 1) 4 daily doses after X; 2) 1 dose 1 h before and other immediately after X; 3) 3 daily doses after X and 3 daily doses after X. Noradrenalin (NA) was assayed fluorometrically and motor function was quantified using an “ad-hoc” test.

At postnatal day (PN) 30, indicators of motor function in X-treated rats that received GMI, no matter the protocol used, returned to non-irradiated values. However, at PN 90 no differences in motor function were found between GMI-treated and un.injected exposed rats, except for protocol 1. None of the protocols modified the changes in NA levels induced by X.

Then, GMI (in particular, when repeatedly administered after X) may produce a long-term delay in the appearance of X-induced motor abnormalities, probably due to an action(s) on central pathways involved in motor output.

691.5

RECOMBINANT HUMAN GLIAL GROWTH FACTOR: TEMPORAL KINETICS AND SIGNAL TRANSDUCTION IN SCHWANN CELLS.

Glia growth factors (GGFs) are products of the neuron gene family that are expressed in the nervous system (Marchioni et al., Nature 262:312-318,1993). Recombinant human GGF2 (rGGF2) is a potent mitogen for Schwann cells, and the rGGF2 action on Schwann cells in vitro: the temporal kinetics of DNA synthesis and activation of signal transduction pathways. Purified rGGF2 stimulates DNA synthesis in both a dose and time dependent manner. Exposure to rGGF2 for various time periods before the addition of a-thymidine labeling media stimulates DNA synthesis maximum fold increase added at 24 hr, and at 25 min when added at 7 hr and 20 min when added at times less than 2 hr (to 5 min).

In addition, we have used compounds that inhibit either tyrosine kinases or protein kinase C (PKC) to determine if the signal for DNA synthesis is acting through these pathways. We show that induction of DNA synthesis by rGGF2 is inhibited by either staurosporine, a PKC inhibitor, or genistein, a tyrosine kinase inhibitor. Our data suggest that rGGF2 can stimulate DNA synthesis in Schwann cells through two different signal transduction pathways, PKC-mediated as well as a receptor-tyrosine kinase pathway. We also examined the early events stimulated by rGGF2 on second messenger pathways that signal directly to the nucleus. Within 1 hr of treatment, rGGF2 activates several transcription factors to bind to DNA. These data describe some of the earliest events that are initiated by the binding of GGF2 to the high-affinity cell surface receptor on Schwann cells that lead to the generation of a mitotic signal.

Because rGGF2 is an important growth regulator for several distinct cell types, our goal is to determine the biochemical basis for these pleiotropic responses induced by rGGF2 in different cell types and tissues.

691.6

A ROLE FOR SCHWANN CELL-ASSOCIATED HEPARAN SULFATE IN MODULATING THE ACTIVITY OF THE NEUREGULIN, rGGF2.

Glia growth factor 2 (GGF2) is a potent Schwann cell mitogen, which is expressed in neurons and produces several products of the neuregulin family (Marchioni et al., 1993, Nature 262:312-318). Previously Ratner and co-workers (PNAS 85:6992-6996, 1988) described a neuronal-associated Schwann cell mitogen bound to heparan sulfate proteoglycan (HSPG) whose mitogenic activity can be inhibited by heparin. Several products of the neuregulin family have been purified from several sources, including chromatography, and Schwann cells have HSPG associated with their plasma membrane and their basement membrane (Carey et al., 1987, JCB 108:1013-1025). We have found that heparin competes for the biological activity of rGGF2. We show that heparin inhibits the mitogenic activity of rGGF2 and blocks pituitary tyrosine kinase activation on Schwann cells. In contrast, 2 µM glucosamine, and 2 µM sodium sulfite, have no effect. Heparin added to other known Schwann cell mitogens (rhFGF, PDGF-ββ) produced little or no inhibition. When Schwann cells were treated with 4-methylumbelliferyl-β-D-xyloside to inhibit proteoglycan assembly, we observed a nearly total loss of mitogenic response to rGGF2. We hypothesize that rGGF2 interacts with Schwann cell membrane rGGF2 a way through cell-surface HS to mediate its effects. This co-receptor model of biological activity, which consists of HS and a high affinity tyrosine kinase receptor for maximal activity is well-supported for other heparin-binding growth factors (Rapaginas et al., 1991, Science 252:1705-1707; Higashiyama et al., 1993, JCB 122:939-949).
691.7

**PROMOTION OF PERIPHERAL NERVE REGENERATION BY A SOLUBLE NEUREGULIN, hRGGF2: STUDIES OF AN ENTUBULATION MODEL IN VITRO**

T. C. Mechabrat, J. D. Cornblath, Cambridge Neuroscience, One Kendall Sq., Bldg. 700, Cambridge, MA 02139.

Glial growth factors (GGFs) comprise a group of proteins, first identified in brain extracellular matrix and shown to promote the regeneration of Schwann cells in vitro (Marchioni et al., 1993, Nature 362:312-318). Recombinant human GGF2 (hRGGF2) is one of several differentially-spliced products of the neuregulin gene. We have previously shown that hRGGF2 promotes Schwann cell proliferation without significantly affecting the expression of a number of Schwann cell associated proteins (Bermingham-McDonogh et al. 1993, Soc. Neurosci. Abstr. 19:698). The proliferative activity of this molecule has been shown to be of therapeutic utility in peripheral nerve damage and disease. Since Schwann cells are known to provide trophic support for a variety of neural populations, simple expansion of the resident Schwann cell population in a site of disease may promote regeneration and survival.

The goal of the current study is to examine the therapeutic utility of GGF2 in the promotion of nerve regeneration by analyzing an in vitro model of the entubulation surgery commonly used to treat peripheral nerve gap injuries. In the current model, a fragment of neonatal rat superior cervical ganglion is placed in one end of a segment of polyethylene tubing (1.9 mm x 10mm) that has been filled with culture medium containing bovine dermal collagen ± hRGGF2. The collagen is allowed to gel and the tubes are maintained in culture for up to 10 days. The results suggest that hRGGF2 promotes Schwann cell proliferation, and Schwann cell invasion of the tube in a dose-dependent manner.

**GLIAL GROWTH FACTOR 2, A NOVEL MUSCLE TRACTION FACTOR**

Recently, the expression of one or more products of the neuregulin gene in peripheral nerve and motor neurons has been described by in situ hybridization (Marchionni et al., Nature 1993;362:312-318). One of these neuregulins, acetylcholine receptor-inducing activity (ARIA), has been shown to stimulate the expression of several genes encoding components of the developing neuromuscular junction in chick muscle culture (Falls et al., Cell 1993;72:601-615, Corfas & Flachsbart, J. Neuroscience 1993;13:2118-2125).

A secreted form of neuregulin, hRGGF2, has been cloned, based on its mitogenic activity on Schwann cells, and expressed in CHO cells. The possibility that hRGGF2 may have trophic effects on muscle cells in culture was investigated. hRGGF2 was mitogenic for subconfluent quiescent human myoblasts, but did not inhibit myoblast fusion. Differentiation of clonal human myoblasts was not affected in presence of hRGGF2 receptors. After 6 days of differentiation (Sklar, et al., J. Cell. Biochem. 1994;54:540), the increase in myoblast number was the result of an inhibition of myotube death as measured by propidium iodide uptake. hRGGF2 effects on muscle culture suggest that this neuronal-derived factor may regulate muscle growth in vivo.

691.11

**β-ACTININ IS REGULATED BY SYNAPTIC ACTIVITY AND IS EXPRESSED IN THE DEVELOPING RAT BRAIN**

K. I. Anderson, C. A. Barnes and P. E. Worley, Dept. of Neurology and Neuroscience, Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD 21205, and Dept. of Neurology, Psychology and Div. of Neurological Systems, Univ. of Arizona, Tucson, AZ 85724.

β-ACTININ is a member of the transforming growth factor-β family of superfamily of secreted proteins. By differential screening, we have identified it to be rapidly regulated by neuronal activity. β-ACTININ mRNA is induced in the dentate gyrus with a single monosynaptic input in a region where it is not expressed as measured by in situ hybridization (Marchionni et al., Nature 1993;362:312-318). A secreted form of neuregulin, hRGGF2, has been cloned, based on its mitogenic activity on Schwann cells, and expressed in CHO cells. The possibility that hRGGF2 may have trophic effects on muscle cells in culture was investigated. hRGGF2 was mitogenic for subconfluent quiescent human myoblasts, but did not inhibit myoblast fusion. Differentiation of clonal human myoblasts was not affected in presence of hRGGF2 receptors. After 6 days of differentiation (Sklar, et al., J. Cell. Biochem. 1994;54:540), the increase in myoblast number was the result of an inhibition of myotube death as measured by propidium iodide uptake. hRGGF2 effects on muscle culture suggest that this neuronal-derived factor may regulate muscle growth in vivo.

**CONTROLLED RELEASE OF hRGGF2 FROM A MICROPOROUS COLLAGEN/COMPOSITE MATRIX.**

To maximize the therapeutic potential of growth factors in nerve regeneration, it is desirable to control their delivery to the site of the lesion. Recombinant human glial growth factor 2 (hRGGF2), a product of the neuregulin gene, stimulates rat Schwann cell proliferation and DNA synthesis in cell culture (Marchionni et al., Nature 1993;362:312-318). The excessive biological activity is less than 24 hours when soluble hRGGF2 is added to a polyethylene nene guide tube reconstituting the myelin sheath of sciatic nerve. The initial goal of this study was to determine whether hRGGF2 can be immobilized and released in quantities sufficient to enhance Schwann cell proliferation within a nerve guide tube. This technology will then be employed in a rat sciatic nerve model of nerve repair. A composite microporous structure incorporated with hRGGF2 was designed for this purpose. hRGGF2 was exposed to this microporous membrane (thickness 150 μm) under mildly acidic conditions. Under these conditions secondary bonds within the collagen matrix are broken; and reform when pH is raised in a manner that incorporates hRGGF2 within the membrane.

Employing stimulation of Schwann cell [3H]-uridine incorporation in vitro as a marker for release of hRGGF2, the rate of release was determined to exceed 0.5 ± 0.1% per mm2 of membrane surface over a period of at least two weeks. A mathematical model of a 1:4 ratio of the nerve guide tube lined with this membrane predicts that at the aforementioned release rate, [3H]-hRGGF2 would increase at a rate of >30 pMolar per hour. Based on preliminary estimates of the release rate, the [3H]-hRGGF2 was incorporated into the tube in vivo in rats, and an EC50 of ~0.15 μM for stimulation of Schwann cell proliferation [3H]-uridine incorporation) in vivo, the model predicts that by this means of controlled release, [3H]-hRGGF2 will exceed that required for stimulation of Schwann cell mitogenesis for a two week period.

**NEUREGULIN. hRGGF2, STIMULATES TRANSLOCATION OF THE ACHR DELTA SUBUNIT GENE.**

Motor neurons induce the expression of activin A receptors in situ and in vivo. NEURO-2A neuroblastoma cells, which express activin receptors (ACHR) at neuromuscular synapses. We have shown that a signal in the synaptic basal lamina at the neuromuscular synapse stimulates translocation of the ACHR δ subunit gene in the myotube nuclei of skeletal muscle. (Marchionni et al., Nature 1993;362:312-318). A secreted form of neuregulin, hRGGF2, has been cloned, based on its mitogenic activity on Schwann cells, and expressed in CHO cells. The possibility that hRGGF2 may have trophic effects on muscle cells in culture was investigated. hRGGF2 was mitogenic for subconfluent quiescent human myoblasts, but did not inhibit myoblast fusion. Differentiation of clonal human myoblasts was not affected in presence of hRGGF2 receptors. After 6 days of differentiation (Sklar, et al., J. Cell. Biochem. 1994;54:540), the increase in myoblast number was the result of an inhibition of myotube death as measured by propidium iodide uptake. hRGGF2 effects on muscle culture suggest that this neuronal-derived factor may regulate muscle growth in vivo.

**TRANSMISSION ELECTRON MICROSCOPY REVEALS A REDISTRIBUTION OF MAP2 IN NEURO-2A NEUROBLASTOMA CELLS AFTERS G A N I T R O S I D E TREATMENT.**

Our previous immunofluorescent studies of Neuro-2A cells exposed to ganglioside GM1 demonstrated enhanced microtubular (MT)-dependent, increased microtubular network density, and a redistribution of MAP2 from the perikarya to the distal neuritic processes. In the current study, immunogold-labeled specimens were analyzed with transmission electron microscopy. Neuro-2A neuroblastosoma were grown in vitro with or without GM1 (150 μg/ml) for 24 hr and embedded in Lowycryl. Sections were incubated with anti-tubulin and anti-AMAP2 and colloidal gold labeled secondary antibody, and the number of gold particles per μm2 was determined in the microtubules, neuritic processes and the perikarya of a minimum of 50 cells per condition. The results demonstrated that: (a) GM1 increases the area of spine-like projections (p<0.05); (b) more MAP2 per unit area was found in spine-like projections after GM1 treatment (p<0.001); (c) more MAP2 was exposure (p<0.02); (d) MAP2 seems more closely associated with actin-rich subsynaptic cytoplasm than with MT. In contrast, the location of tau protein, another MAP, was not changed after GM1 treatment. These observations are consistent with previous qualitative studies demonstrating that GM1 increases the spine-like projections. Since MAP2 is associated with actin in dendritic spines, perhaps GM1 shifts MAP2 from interactions with MT to a more direct interaction with cytoskeletal filaments. This study is in progress to determine the effect of GM1 on the synthesis of MAP2 and tau protein. Supported by a grant from Alliant Community Trust Fund, Louisville, KY.

A role of thrombin in neuropathological processes is suggested by the fact that this protein is secreted by glial cells. An imbalance between thrombin and FN-1 (its natural inhibitor) seems to be involved in the pathogenesis of human neurological diseases including Alzheimer’s disease. In vitro thrombin alters neurite outgrowth and, at low concentrations, increases choline acetyl transferase (ChAT) activity in a mixed neonatal myocerebral culture of septal cells. To characterize further the effect of thrombin on cholinergic neurons we have compared the effect of thrombin and of the 14-amino acid peptide agonist of the thrombin receptor on a pure culture of septal neurons and on co-cultures of septal neurons/glial. Septal cells were grown in defined medium, onto a monolayer of glial cells for co-cultures. Cells were treated one day after plating. ChAT activity and MT1 reduction (index of cell viability) were assayed at the 5th day in vitro.

In pure septal neurons, low concentrations of thrombin (up to 30 nM) did not affect ChAT activity or MT1 reduction. However, 100 nM thrombin decreases ChAT activity and MT1 reduction by 44% and 17%, respectively. In co-cultures (17% at 0.1 nM and -63% at 100 nM) and in co-cultures (-4% at 0.1 nM and -28% at 100 nM). This peptide did not affect MT1 reduction. Thus, thrombin’s effects on cholinergic neurons seem to be mediated, at least in part, by thrombin receptors and glial cells seem to play a major role in thrombin action.
CHARACTERIZATION OF HCNP PROCESSING ENZYME

HCNP is a peptide which stimulates acetylcholine synthesis in medial septal nuclei explant culture. The peptide consists of eleven amino acids located at N-terminal lesion of its pro-protein, and suggested to be processed by cleaving enzyme. In the present study, we characterized the HCNP processing enzyme in Wistar rat hippocampus. Hippocampus from 10-11 day old rats were sonicated in 50mM MES-NaOH buffer (pH6.0) containing 150mM NaCl, 3mM KC1, 1mM EDTA and 1mM DTT, and centrifuged at 15000rpm for 20min. The supernatant was incubated at 37°C with purified HCNP pro-protein or synthetic peptide which consisted of eleven amino acids from N-terminal of the HCNP pro-protein. The reaction was terminated by adding TFA and subjected to HPLC equipped with C18 column to measure the enzyme activity. The enzyme was eluted between 58-10%Ac in the molecular sieving column, and retained on DEAE column at pH7.6 and G-Butyl column at pH6.0. Optimal pH of the enzyme activity was 5.6, and the activity was inhibited by Chymostatin and E-64.

NUTRITIONAL AND PRENATAL FACTORS

Prematurely-born infants have higher heart rates and reduced heart rate variability at term relative to fullterm neonates (Eiselt et al., 1993), suggesting that prematurity may have long-lasting effects on cardiovascular control. In the present study, we assessed post-term development of heart rate and its variability in prematurely-born infants who continue to suffer from apnea of prematurity (AOP).

Six-hour recordings of EKG and respiration were obtained from infants with AOP born at gestational ages of 24 to 35 weeks. Heart rate and its variability were assessed during three periods of regular respiration in each recording of the premature infants and similar recordings of fullterm infants as controls. At term, infants suffering from AOP showed higher heart rates and reduced heart rate variability relative to fullterm neonates. Over the first month of postfullterm infancy, however, the premature infants showed an increase in heart rate and a reduction in variability, such that by 1 mo after term, there were no significant heart rate differences between fullterm infants and prematurely-born infants suffering from AOP. The two groups of infants continued to show comparable heart rates and variabilities at all ages up to 6 mo after term. Thus, neither prematurity nor AOP appears to have a long-lasting effect on cardiac rate or overall cardiac variability.

SUPPORTED BY HD-22895.

Restrain stress applied to pregnant rats during late pregnancy results in offspring exhibiting some behavioral and neurochemical alterations. Particularly, this procedure of prenatal stress can cause long-lasting changes in the hypothalamo-pituitary-adrenal axis of the offspring, that persist in adult animals. Moreover, prenatally stressed rats show an increase in heart rate and a reduction in variability, such that by 1 mo after term, there were no significant heart rate differences between fullterm infants and prematurely-born infants suffering from AOP. The two groups of infants continued to show comparable heart rates and variabilities at all ages up to 6 mo after term. Thus, neither prematurity nor AOP appears to have a long-lasting effect on cardiac rate or overall cardiac variability.

The effects of gestational protein malnutrition on the establishment, maintenance, and function of the GABAergic neuronal system and related behavioral alterations have been investigated in young adult rats. Prenatal malnutrition was induced by feeding rats a diet containing 20% casein, 20% bran, 20% sucrose, 20% corn starch, and 10% lard. The rats were weaned to a chow diet at weaning and fed this diet throughout the experimental period. The effects of prenatal malnutrition on the development of the GABAergic neuronal system were studied using a variety of techniques, including autoradiography, electron microscopy, and behavioral testing.

RESULTS: (1) Prenatal malnutrition results in a decrease in the number of GABAergic neurons in the cerebral cortex of young adult rats. (2) The GABAergic neuronal density is decreased in the cerebral cortex of young adult rats. (3) The GABAergic neuronal density is decreased in the cerebral cortex of young adult rats. (4) The GABAergic neuronal density is decreased in the cerebral cortex of young adult rats. (5) The GABAergic neuronal density is decreased in the cerebral cortex of young adult rats.

OXIDATIVE STRESS RISKS WITH HIGH POLYSATURATED FATTY ACID DIETS IN BRAIN/HEART/KIDNEY/MAMMARY/LIVER OF FEMALE SHR RATS
R.S. Mehta, C.A. Gunnett and D.K. Hartle. Dept of Pharmaco and Toxicol., College of Pharmacy, Univ. of Georgia, Athens, GA 30602.

Aging can be exacerbated by increasing the rate of initiation of random free radical reactions or by increasing ingestion of easily oxidized dietary components. Dietary polysaturated fatty acids (PUFA's) of omega-3 and omega-6 type are known to have some antioxidant vascular effects that are susceptible to peroxidation under multiple conditions that encourage oxidative free radical formation. We studied the effects of long-term feeding with dietary omega-3 and omega-6 PUFAs on 1) blood pressures and 2) in vivo tissue lipid peroxidation in female spontaneously hypertensive rats. After 16 weeks of feeding with either control (5% corn oil, AIN) or high fat diet (19% Menhaden oil, 4% corn oil, 28% P UFA's), no differences in blood pressure were observed among groups. In whole brain homogenates, autoxidation averaged 282% and iron-ascorbate catalyzed peroxidation 1225% compared to baseline oxidation in all diet groups. Marked differences occurred between the omega-3 and omega-6 (MO and CO respectively) high P UFA diets on baseline oxidation, autoxidation and iron-ascorbate catalyzed oxidation in various tissues. MO caused a 67.5% increase in basal oxidation. 2624% increase in autoxidation and 4244% increase in iron-ascorbat catalyzed oxidation in mammary gland compared to the CO diet. Similarly, a 400% increase in iron-ascorbate catalyzed oxidation occurred in liver, 225% in heart, 120% in kidney and 50% in aorta in MO compared to CO, respectively. The results indicate that 1) brain is extremely susceptible to iron-catalyzed peroxidation; 2) neither high omega-3 nor omega-6 PUFA diet protects against peroxidation in female SHRs; and 3) high omega-3 fatty acid diets markedly increase the oxidative aging risk of multiple organs.

693.6

There has recently been increased research in studying the association between chemical imbalances and violent behavior. In the treatment of over 30000 assaultive young males, The Carl E. Figeller Treatment Center has observed elevated blood copper:zinc ratios. The objective of this study was to determine if violent and non-violent patients had significantly different copper and zinc levels and copper:zinc ratios. The sample consisted of all male subjects of the Center and for an 8 week period that were 3 to 18 years old. These subjects had a history of frequent assaultive incidents, while the control subjects had an absence of such incidents. There were no significant differences in copper:zinc ratios of 1.40 for violent and 1.02 for non-violent were shown to be significantly different (p < 0.05). The mean serum copper levels were 98.5 and 86.6 mcg/dl and plasma zinc levels were 75.4 and 87.4 mcg/dl for violent and non-violent subjects, respectively.

These relationships suggest a strong correlation between assaultive behavior and abnormal metal metabolism. Clinical studies are underway to determine if correcting these chemical imbalances will result in improved behavior.

693.7
EFFECTS OF PROTEIN DEFICIENT DIETARY REGIMENS, PRE-TERM BIRTH AND HYPERTENSION ON RAT NEONATAL BEHAVIOR. F. Diagros, E. Di Leo, M. F. Di Grav. , L. Le Presti*. Institute of Pharmacology, University of Catania Medical School, 95125 Catania, Italy.

The effect of various metabolic factors on the development of neonatal reflexes and on learning and memory capacity in adulthood was studied in the rat. Female rats of the Wistar strain were assigned to one of seven diets: a control regimen (commercial animal food at a reduced weight regimen of 80% diet containing casein as the only protein component). Another group of animals was subjected to a caesarean cut at day 19 of pregnancy in order to induce a pre-term birth of pups. Spontaneous hypertensive rats (SHR) were used to examine the possible influence of gestational hypertension on brain maturation. We found that protein deficient dietary regimens were accompanied by a retardation in the development of neonatal reflexes and a reduction in learning and memory capacity in adulthood. Differences were also found between control animals and pups born by caesarian cut or from SHR mothers, above all for eye opening time and body weight.

693.9
REPRODUCTIVE SUCCESS IS COMPROMISED IN RATS OVERTREATED AS NEONATES. L. Taylor* and L. Diaz. Dept. of Psychology, University of Washington, Seattle, WA 98195.

On postnatal day 4, Long-Evans female rat pups were randomly assigned to one of three groups: 1) mother reared in litters of 9 (MR), 2) gastrostomy-fed for ten days to match the growth of the MR group (WM), and 3) gastrostomy-fed with excess formula to accelerate growth (OF). On day 14 the gastrostomy-fed animals were returned to lactating dams in litters of 8 pups each. All animals were weaned on day 22 and maintained thereafter on laboratory chow. Plasma glucose readings were taken using tail blood. The animals were bred the following day. On day 190 glucose readings were again recorded. 6.3% of the 67 animals (67%) of 11 WM females (45%), and 4 of 11 OF females (36%) produced litters. Pregnant glucose levels of the successful females were significantly lower than glucose levels of females who failed to produce pups (p < 0.01). Pre-pregnant glucose levels were significantly higher in OF females and an analysis of variance also indicated that pre-pregnant glucose levels were different among the three groups (p < 0.01, ANOVA; OF x WM, p < 0.05, t test; OF x MR, p < 0.01, t test).

These findings support the hypothesis of several researchers that high maternal gestational weight gain can permanently alter metabolism. The issue of whether or not central regulatory control systems were altered in addition to peripheral metabolic systems by these nutritional manipulations in early development remains to be determined.

693.10

The effects of postnatal malnutrition (9% casein diet) in the somatic size, length of the apical dendritic, number of dendritic branching and the thorny excrecence area of CA3 hippocampal pyramidal cells were studied in rats of two ages (30 and 90 days old). A total of 144 rats imaged with the morphometric software were used for morphometric analysis. Results showed that postnatal malnutrition produced significant decreases (p < 0.05) in all the parameters studied. These findings indicate that postnatal malnutrition produces severe alterations in the morphatical and development patterns which in these cells occurs during postnatal life. We have found similar results in pre and postnatal malnutrition studies (Garcia-Ruiz M et al., Brain Res. 625 202:1993). Thus, only malnutrition can affect the functional integrity of the hippocampal activity of the CA3 field. Supported by DGAPA IN-204892, IN-204093 and CONACYT fellowship 83601.
692.11 PRENATAL MALNUTRITION ON THE BASKET (GABAergic) DENTATE GRAY CELLS IN THE RAT. A. Aguilar†, S. Diaz-Cintia, A. Gonzalez, M. A. Morales†, T. Kemperer and P. J. Goodlett. Centro de Neurobiologia, UNAM, UISS-IMP, SSA, c.p.14110, IBM, Mexico, D.F. 04510 and Boston Univ. School of Med. Center of Behav. Dev. and Retardation. M921, 80 East Concord Street Boston, MA 02118.

The effects of prenatal malnutrition (6% casein diet) on the somatic size, in basket cells was measured in the fascia dentata in rats of 30 days of age, using the Golgi technique. The density of GABA-like immunoreactive cell was studied in the fascia dentata and hippocampal formation, divided into three levels (rostral, medial and caudal). Results showed a significant reduction in the major axis (57%) and perimeter (18%) and 20% in uniform cells. In all three levels, numbers of GAD-immunoreactive cells were significantly increased in the hilus of fascia dentata in relation with the hippocampus. The bigger amounts of those cells were located in the middle part of the fascia dentata. In addition, preliminary data showed increased number of these cells in an older age (i.e. 220 days). The morphological alterations observed in these cells may affect at least in part, the functional integrity of the hippocampal formation, since they have inhibitory activity on the granule cells. Supported by DGAPA IN-204892 and IN-204093.  

692.13 THE SEVERITY OF NEONATAL ALCOHOL-INDUCED CEREBELLAR PURKINJE CELL LOSS IN RATS DEPENDS ON THE TIMING OF ALCOHOL EXPOSURE: A STEREOELECTOMIC STUDY. J. D. Thomas†*; C. B. Goodlett†, R. A. Wissmeier, R. McCleary and A. Aguilar. Alcohol Research Group of Iowa, Iowa City, IA 52242; University of Iowa, Iowa City, IA 52242.  

Short term binge-like alcohol exposure during the brain growth spurt in rats depletes Purkinje cells in the cerebellum, but the severity of loss depends on the timing of exposure. Two consecutive days of binge-like alcohol exposure beginning before or after, postnatal day (PD) 7 significantly reduces the density of Purkinje cell profiles in the cerebellar vermis (Bennet & Wissmeier, Clin. Exp. Neurosci., 1993). These findings, however, were based on biased counting methods from which estimates of total Purkinje cell number could not be obtained. The present study investigated the effects of two-day alcohol exposure on Purkinje cell number using a stereomicroscopic method. The optical fractionator technique which provides an unbiased estimate of total cell number. Sprague-Dawley rat pups were randomly assigned within litter to five treatment groups. Three alcohol-exposed groups were characterized and artificially reared from PD 4 through 9. All alcohol-exposed groups received 6.6 g/kg/day of alcohol, producing peak blood alcohol concentrations of 190 mg/dl. One group was exposed to alcohol on PD 4 & 5 (4/5), a second group on PD 8 & 9 (8/9), whereas a third group was exposed during both periods (Comb). Control groups included the same rearing condition and were not reared. On PD 55, subjects were perfused, the cerebellum was sectioned, and Purkinje cell number was determined with an Olympus/BICO computerized stereological system. Purkinje cell numbers were reduced in all alcohol-exposed groups (Comb: 53% of GC; PD 4/5: 57% of GC; PD 8/9: 83% of GC). The PD 4/5 group did not significantly differ from the Comb group as there had significantly more severe cell loss than the PD 8/9 group. These results confirm the greater susceptibility to alcohol-induced Purkinje cell loss early in the neonatal brain growth spurt. Moreover, these unbiased methods now show that the severity of cell loss is greater than previously estimated and that even exposure late in the brain growth spurt can produce significant reductions in Purkinje cell number. Supported by Grants AA05523 (JRW) & AA05996 (CRG).  

692.15 INCREASED LATE DURATION IN PAIRED COMPARISONS BY RHEUS MONKEY INFANTS WITH N-3 FATTY ACID DEFICIENCY (N-3 FAD). A. Retzbach*, N. Neuhring and E. Gohl. Oregon Health Sci. Univ., Portland, OR 97201 and Oregon Reg. Primate Res. Center, Beaverton OR 97006  

N-3 fatty acids are integral components of neural and retinal membranes. Peripherally deficient primates and human infants show low levels of n-3 fatty acids in cerebral cortex and retina, delayed development of visual acuity and abnormal electroretinograms. Nine infants deficient both pre- and postnatally and 8 standard nursery infants were derived paired comparison tests at 2, 5, and 13 weeks of age. Each test was given both 2 pattern-pairs and 6 face-pairs, each set presented on a separate day. Familiarization consisted of 30 sec of fixation. Tests (familiarized vs novel card) were 10 sec on each side, semi-randomized. For each stimulus set, tests were conducted both immediately and after 24-hours.  

Fixations by deficient infants were consistently longer in both the immediate and 24hr tests for patterns (p<0.05) and approached significance for faces (p<0.08). Table 1 shows the data for the Pattern Set (6 pairs) Face Set (6 pairs) Immediate 24-Hour Immediate 24-Hour Standard 1.18 +0.05 1.18 +0.06 1.20 +0.05 1.1 +0.05  

Deficient 1.52 +0.05 1.43 +0.06 1.48 +0.05 1.4 +0.05  

Look duration has been inversely associated with speed of visual processing. N-3 FAD may slow processing.  

The effects of postnatal malnutrition (6% casein diet) in the somatic size, number of dendritic branching and the spine density of granule cells were studied in rats of 30 day old. A total of 115 cells impregnated with rapid-Golgi were selected for morphometric analysis. Results showed that postnatal malnutrition produced significant decreases (p<0.05) in the number of spines in proximal and middle dendritic segments as well as dendritic density in the 7 of the 8 intercerebral rings, studied. These findings are similar to those found in the study of CA3 pyramidal cells and indicate that postnatal malnutrition produces severe alterations in the maturation and development patterns which in these cells occurs during postnatal life. Thus, these anatomical deficits may affect the functional integrity of the hipppocampal activity initiated in these granule cells. Supported by DGAPA IN-204892, and IN-204093, 2r-20891.  

It has been demonstrated that sensitivity to opiates declines as a function of multiparity in the rat. The impact of this maternal change on offspring sensitivity has not been studied. In order to determine if parity has an impact on offspring responsiveness to opiates, female Sprague-Dawley offspring from a first and second breeding were tested for their analgesic responsiveness to morphine. At 30-36 days of age subjects were tested for their hotplate latency 30 and 60 min after administration of 5mg/kg morphine. Prior to drug administration baseline latency was established. There was a significant effect (p<0.01) of parity on baseline and 30 min latencies, due to offset from the second mating showing higher latencies. The significance at 30 min was still present after correcting for baseline differences. It is not clear whether the observed difference is a result of maternal age (dams were 3 months old at first breeding and seven at the second) or parity. The data do, however, indicate that maternal history may significantly alter offspring sensitivity to drugs and possibly other aspects of behavior. (Supported by NIH-HD07228, UCLA Psychoneuroimmunology Program, and VA Medical Research Service.)  

Cerebral activity of normal (N) and malnourished (M) lactating female Sprague-Dawley rats was registered during a 24h period, during and after suckling and without their pups. Rats were malnourished 5 weeks before mating, throughout gestation and lactation. N rats showed a synchronized pattern during milk ejection. Using power spectra analysis in N rats, we found a significant increase of theta activity in the first third of the lactation period, an increase of delta waves in the second third and a significant increase of theta activity in the last third of this period. M rats showed a significant increase of theta activity during the last lactating days, however during the first third of the period they showed increase in delta waves. In both groups N and M delta waves increased when pups were retired from the nest. We also found ultradian rhythms in delta, theta and high frequency activity. N rats showed 4 main peaks and M rats presented 8 peaks, with phase advance in respect to N rats. These results suggest that protein malnutrition installed 5 weeks prior to conception, can produce alterations in the electrical activity of lactating rats (Supported by DGAPA IN-202891).
SLEEP-WAKE PATTERNS IN MALNOURISHED, REHABILITATED AND CONTROL RATS OF 60 DAYS OF AGE
A. Galvan*, L. Citrino and A. Alfaro Centro de Neurobiologia, UNAM, Mexico D.F. 04510.

This study was designed to evaluate the sleep-waking cycle of 6% protein malnourished, postnatally rehabilitated and control male Sprague-Dawley rats at 60 days of age. Malnutrition was established prenatally and was continued throughout gestation and postnatal life. Rats were rehabilitated by the "cross fostering" method switching at birth malnourished pups to well nourished dams. Occipital EEG and neck muscles EMG activity were obtained with bipolar stainless steel electrodes. Polysomnographic vigilance states were obtained for a 24 hour period and scored visually in 12 second epochs. Postnatally rehabilitated rats showed a similar distribution of their vigilance states as their controls during the light and dark phase, as well as in the 24 hour period. In contrast, malnourished rats showed an increased proportion of SWs during the dark phase and in the total 24 hour and a phase shift in the distribution of REM-sleep. These data reveal that malnutrition affects the mechanisms that regulate sleep-wake patterns and suggest that postnatal nutritional rehabilitation can prevent these alterations. (Supported by DGAPA IN-202891 and PADEP 30383).

EFFECTS OF CHRONIC UNDERNUTRITION ON THE AMPLITUDE AND LATENCY OF THE N13 AND N20 COMPONENTS OF THE SEP IN CHILDREN

An estimated 50% of Honduran children suffer from chronic undernutrition. To assess the consequences of such deprivation on CNS physiology, we measured the central conduction time (CT), using the somatosensory evoked potentials (SEP) in 14 children ages 7-10 with heights below the 3rd percentile for their age and 17 age-matched controls. The two groups also differed significantly in nutritional intake, socioeconomic variables, achievement in Bender's neuromotor test and hematocrit (control mean = 39; undern. = 36; p < 0.01, Scheffe F-test), but not birth weights. The children were tested at the median nerve with 0.3Hs shocks at a rate of 2-3Hz and a voltage sufficient to produce a just visible abduction of the thumb (motor threshold, MT). The cervical N13 and cortical N20 components were recorded over positions C5-C6 and C3-A1, respectively. In addition to motor threshold, recordings were also taken at 75% and 125%MT to assess the response to varying stimulation intensities. Mean CT (N20 latency-N13 latency) for the undernourished group (6.64ms) did not differ significantly from the controls (6.38ms, p=0.3), nor was there a difference in the amplitudes of the N13 and N20 waves with intensity. However, in N13 undernourished subjects whose hematocrit was extremely low the CT was 1.8 standard deviations greater than controls (p<0.001, t-test). Thus, CT may be affected in a proportion of subjects by a postnatal dietary lack, while the CNS of others may be "protected".

PHYSICAL ACTIVITY (PA) AND NEURAL ACTIVITY (NA) OF THE SOMATOSENSORY CORTEX IN MALNOURISHED AND CONTROL RATS
H. Hesse, M.E. Rivera, M.A. Zavala, I. Diaz, W. Meda*, G.L. Quirk. Dept. Physiology, University of California, Irvine, CA 92717; *Dept. Molecular and Cell Biology, University of California, Berkeley, CA 94720

We studied the response of the somatosensory cortex to stimulation of the contralateral hind paw in young malnourished and control rats. The somatosensory cortex was stimulated at 0.25 ms in the postnatal period and the PA and NA were recorded at the level of the rat's thalamus and sensorimotor cortex, respectively. The PA was increased in the control group compared to the malnourished group. The NA were recorded from the thalamus and the cortex. The NA were decreased in the malnourished group compared to the control group. These results suggest that the somatosensory cortex is undernourished due to a lack of nutritional intake.

In our previous studies of transplants of nigral tissue into dopamine (DA)-depleted rats, we found that the inclusion of embryonic striatal tissue increased the survival of these transplants. The territory that this was the greatest with the youngest striatal tissue containing primarily patch neurons (Costantini et al., Exp. Neurol. 1994). We have now employed dissociated cultures to examine whether the survival of DA neurons, as well as striatal patch neurons, is increased in co-cultures of nigral and striatal cells taken from different age embryos. Striatal patch neurons were labelled by in vivo BrdU injection on E13 + E14. The number of BrdU-labelled neurons was much higher in E14 striatal cultures (98%) as compared to E18 (10%) or E20 (4%) striatal cultures at 1 DIV, and the percentage in all cultures decreased over the next two weeks. The inclusion of E14 nigral cells attenuated this decline. Similarly, the number of DA (TH-immunoreactive) neurons in E14 nigral cultures decreased with time in vitro (10% at 1 DIV to 3% at 15 DIV), and this decline was attenuated by the inclusion of E14, but not E18 or E20, striatal cells. Thus, the survival of nigral DA neurons and striatal patch neurons in cultures appear to be enhanced by the presence of the other. These reciprocal influences may be relevant to the in vivo development of the nigrostriatal system, as well as the possible potentialization of transplanted cells. (Supported by MH46577.)

693.5 TRANSIENT c-fos EXPRESSION IN RESPONSE TO DOPAMINE D1 AGONISTS IN THE DEVELOPING STRIATUM. E. Arnaud, J. Arnaud, R.M. Bluhse*, J. Demotes-Mainard. INSERM U-394, 30077 Bordeaux, France.

In intact adult mice, dopamine D1 receptor activation only induces c-fos in the most caudal region of the striatum. In contrast, when dopaminergic receptors are prematurely sensitized by lesion of the nigro-striatal pathway, the expression of c-fos in response to D1 agonists is present throughout the striatum. Therefore, c-fos induction by D1 agonists requires a state of altered responsiveness of dopaminergic receptors. Since the D1 receptor develops in the striatum prior to the D2 subtype, we further examined in intact animals the postsynaptic ontogeny of the c-fos response to D1 agonists. D1 dopamine receptors are already present in the striatum at E14. Injection of the D1 agonist SKF 38393 results in a c-fos expression scattered throughout the striatum and observing a patchy distribution. After postnatal day 15 the D1 receptor-mediated c-fos hybridization signal had almost disappeared and lost its patchy expression, except in the most caudal division of the striatum where a strong expression appeared at postnatal day 3 and persisted in adults. Since this transient response of c-fos gene to D1 dopamine agonist parallels the developmental pattern of striatal dopamine innervation, of D1 dopamine receptor distribution and the delineation of the strionigral compartment, this study raises the questions of: i) the possible role of D1 receptor-mediated gene expression in the ontogeny of striatal compartments; and ii) the significance of a persisting D1-induced c-fos expression in the most caudal part of the adult caudate-putamen.

693.8 STAINING FOR ACETYLCOLINERESTASE REVEALS DIFFERENT PATTERNS IN THE THALAMUS AND CORTEX OF PERINATAL RATS, MICE, AND HAMSTERS. B. Shendure*, R. Chilale, and G.A. Pasantes-Maile. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699.

Acetylcholineesterase (AChE) is a marker for thalamocortical axonal terminals in perinatal rats and has been useful extensively to study the development of these fibers. Studies in which we attempted to use this marker in developing mice and hamsters have been striking differences in the expression of this enzyme in the three species. In developing rats, AChE staining heavily labels neurons in the ventral posterolateral (VPL) and ventral postero-medial (VPM) thalamic nuclei and reveals a somatotopically organized pattern of clusters in the developing cortex. In both hamster and mouse, VPM neurons were relatively lightly labeled by AChE. Staining in VPM appeared to be contained in afferent fibers. This was confirmed by its disappearance after partial lesioning of the spino-thalamic tract. Staining of both of these species resulted in a negative image of the distribution of thalamocortical fibers. This image appeared to result from reduced AChE cortical neuronal staining and first apparent as a crude representation of the body in laminas V and VI and then as a more precise image in layer II. In both AChE and Mlsl substance in developing mice indicated that the dense AChE staining was located in the septum. These results demonstrate a dramatic species difference in AChE expression by thalamic and cortical neurons and prompt caution in using AChE as a marker for developing thalamocortical axons. SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
INFRAORBITAL NERVE TRANSECTION AND AXOPLASMIC TRANSPORT BLOCKADE HAVE SIMILAR EFFECTS UPON PRIMARY AFFERENT AND CENTRAL VIBRISSE-RELATED PATTERN FORMATION, THE TRIGEMINAL MAINSTEM COMPLEX. C.A. Bennett-Clarke, N.L. Chiala, R.W. Rhodes. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

TRANSECTION of the infraorbital nerve (ION, the trigeminal branch that supplies the mystacial vibrissae) between P-0 and P-6 by application of implants impregnated with varying amounts of cholchicine or vinblastine, and, to a lesser extent, with a second-order neuron in the V brainstem complex. Such lesions cause a marked up-regulation of growth in the brainstem of damaged primary afferent axons and reductions in the staining of second-order cells for both cytochrome oxidase (CO) and parvalbumin (PV). Blockade of axoplasmic transport has less severe effects on the postnatal development of ION than transection and it does not disrupt peripheral activation in these cells. Nevertheless, such blockade produces changes in V primary afferent and second-order neuronal morphology that closely mimic those observed after nerve transection. Transport blockade causes a marked up-regulation in galvin V primary afferents and, in V nucleus principalis, V nucleus interopolaris, and the magnocellular part of V nucleus caudalis, the axons are arrayed in a clustered and somatotopic fashion which matches that of the mystacial vibrissae follicles. Transport blockade also causes reductions in the density of both CO and PV staining in the brainstem and a loss of the normally observed pattern indicating that correspondences neurology.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
694.1 EFFECTS OF IMPACTIONAL NERVE TRANSSECTION ON THE ORGANIZATION IN INTRAOPERATIVE CONNECTIONS WITHIN THE RAT'S PRIMARY SOMATOSENSORY CORTEX. P. A. King, A. R. Conover, C. A. Bennett-Clarke, N. L. Chiba, H. P. Killackey, and R. W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699

Intraoperative projections within layer IV of the vibrissa representation of the rat's primary somatosensory cortex (the barreled field) are generally restricted to adjacent layers and the dense aggregations of lamina IV neurons referred to as the barrels. In spite of the gross, anterograde and retrograde tracing with biotinylated dextran amine (BDA) we observed here, we failed to alter the organization of the intracortical connections in layer IV of the barreled field. Both retrogradely labelled cells and anterogradely labelled axons were present within the dense aggregations of granule neurons that remained in this lamina. In contrast, the pattern of intracortical connections in layer IV of rats with 10Hx transections on P-7 appeared normal. Labelled cells and anterogradely labelled axons was largely restricted to the septum and formed a negative image of the clusters of granule cells. These results suggest that altered input to the barrel cortex must be achieved very early in postnatal development to alter intracortical connections in this lamina.

Supported by DE 08971, DE 07734, and NS 28888

Mechanisms subserving pattern formation in the rat whisker-barrel system are unknown, although morphogenetic processes are necessary in part because NGF can preserve excess ganglion cells and alter pattern formation. Henderson et al. (1994) suggest that pattern form as a result of a neuroepithelial migration of enter neural cells that project to inter-whisker surfaces. If such cells project centrally to regions intervening between surviving and neighboring whisker projection, their death would form 'soft', in somatotopically organized inter-correlated whisker ganglia which would be tangle, inter-whisker and whisker ganglion cells should have central projection patterns that are mirror images of each other; one should resemble a 'honeycomb', the other should resemble barrels. To test this, inter-whisker surfaces were selectively denervated at birth (by electrolytically the skin between rows of whiskers) and their central projections stained by galain histochemistry (White et al., Dev. Brain Res. 72, 93) on postnatal days 3 or 6. Alternate sections were stained for cytochrome oxidase to reveal whisker patches. At both ages, galain immunoreactive terminals were sparse in brainstain whisker regions, although they occurred most often between whisker patches, sometimes to the extent that the stained fibers produced a honeycomb pattern. However, in normal adults, primary afferents with inter-whisker receptive fields had collaterals that usually ended in whisker patches; on rare occasion they terminated between whisker patches. Thus, staining patterns in the adult, showed no-natal hypothesis.

694.3 ANATOMICAL AND FUNCTIONAL REORGANIZATION OF THE CUNEATE NUCLEUS AFTER NEONATAL FORELIMB REMOVAL IN THE RAT. R.D. Lang, B.L. Killackey, and R.W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699 and Dept. of Psychology, Univ. of California, Irvine CA 92717.

Most previous anatomical studies have shown that large caliber primary afferent fibers exhibit only limited central sprouting, after peripheral nerve damage in either animal or human. Leister and Marfurt (1984) have reported that forelimb removals were carried out in newborn rats that were not to the time of adulthood, and used in terminal anatomical or physiological experiments. Sciatric nerve afferents to the brainstem were labelled with a combination of WGA-HRP and 6-8-10 rats and 8 animals that sustained neonatal forelimb removals. All of the 8 neonatal rats and 4 of 6 adult rats had dense HRP labelling that extended out of the graile nucleus into the cuneate nucleus. This implicated multi-unit recordings demonstrated the presence of hindlimb-related activity in the cuneate nuclei of all manipu lated rats. Single unit recordings demonstrated the existence of the neurons (49/ of 49 recorded that responded to hindlimb stimulation) in the cuneate that responded to hindlimb stimulation. These results are consistent with the conclusion that low-threshold, hindlimb-related primary afferents innervate the cuneate nucleus after neonatal forelimb removal and make functional contacts with neurons in this nucleus.

694.4 EFFECTS OF FORELIMB DAMAGE AT DIFFERENT AGES ON PEPTIDE DISTRIBUTION AND LECTIN BINDING IN THE CEREBRAL DORSAL HORNS OF THE RAT. K. J. Rhoades, C. A. Bennett-Clarke, and R. W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699.

Rats that sustained forelimb removal on either enbroynic day (E-) 16 or the day of birth (P-0), or transaction of the brachial plexus as adults had sections through the cervical dorsal horn stained for galain, colliculin gene-related peptide (GCRP), or the lecin, Banderia simplicifolia-I (BS-1) 35 days after these lesions. There were age-related differences in the effects of peripheral nerve damage upon each of these markers. Damage to the brachial plexus in adulthood caused a significant increase in the density of galain immunoreactivity in the medial portion of layers I and II and an increase in the appearance of galain immunoreactivity in layers II, III and IV of the cervical dorsal horn. Such lesions resulted in significant reductions in the density of BS-1 immuno reactivity in layers I and II and decreased BS-1 binding in lamina II. Forelimb removal at birth resulted in no significant change in the density of galain immunoreactivity in layers I and II, but in the appearance of galain-immunoreactive fibers in layers III and IV. Neonatal forelimb removal resulted in no significant change as the density of GCRP immunoreactivity in layers I and II, but in a significant reduction in BS-1 binding in the medial portion of lamina II. Forelimb removal on E-16 increased galain immunoreactivity in layers III and IV, but had no effect on either GCRP or BS-1 binding in the cervical dorsal horn.

694.5 CHROMOTOPIC ORGANIZATION OF PRIMARY AFFERENTS IN THE RAT'S TRIGEMINAL SPINAL TRACT. R. S. Crissman, P. A. White, and R. W. Rhoades. Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699.

Trigeminal (V) ganglion cells with different somatotopic features of different birthdates. Larger neurons positive for neurofilament protein (NF) and which give rise to large born early in V ganglion neurogenesis with 27.3% born on E-10.5, 30.3% born on E-11.5, and 42.4% born on E-12.5. No clefts, CCRP-positive ganglion cells are born late, 51.5% on E-13.5 and 42.1% on E-14.5. The difference in birthdates for these two groups of ganglion cells is reflected by the position of their axons in the spinal tract. NF-positive axons are concentrated in the upper part of the spinal tract, but are dense in its deeper portion. In contrast, CCRP-positive axons are largely restricted to the superficial portion of the tract. Ganglion cells that bind the lectin Bandeiraea simplicifolia-I (BS-1) are also born late, 41% on E-11.5, 50% on E-12.5, 5% on E-13.5, 1% on E-14.5, and 2% on E-15.5. These are restricted to a small portion of the spinal tract. This observation is consistent with the conclusion that low-threshold, hindlimb-related primary afferents innervate the cuneate nucleus after neonatal forelimb removal and make functional contacts with neurons in this nucleus.

694.6 IMMATURE THALAMOCORTICAL SYNAPTIC RESPONSES IN NEONATAL MOUSE BARREL CORTEX. A. A. Agmon and Diane K. O'Dowd. Deps. of Anatomy and Neurobiology and Developmental and Cell Biology, University of California, Irvine, CA 92717.

We have extended our previous study of the development of thalamocortical synaptic responses in mouse barrel cortex (J. Neurophysiol. 68, 345, 1992) to include the first 3 postnatal days (P0-P2) and the deep cortical layers. Using the thalamocortical slice preparation, whole-cell recordings were obtained in all layers in all cortical layers, and synaptic currents evoked by electrical stimulation of the thalamocortical pathway. To study the morphological basis of these responses, selected cells were stained with Lucifer Yellow, and in the same slices, thalamocortical axons were stained with DiI(5). Synaptic responses were evoked in deep (layers V/VI) neurons as early as P0, and in the incipient layer IV by P2. Responses were exclusively excitatory; they were highly labile and were often irreversibly depressed after a small number of stimulations. Current-voltage relationships indicated that the dominant component in these responses was mediated by non-NMDA glutamate receptors. In P2 animals, a single electrical stimulus to the thalamus evoked a prolonged sequence of small synaptic events lasting up to 400 ms, apparently due to temporally-dispersed transmitter release. Supported by NS03099.
694.7 PRENATAL DEVELOPMENT OF THE RAT CORTICOTRIGEMINAL TRACT. D.A. Randell* and W.E. Keenan, Division of Gastroenterology, Henry Ford Health Sciences Center, Detroit, MI 48202.

The role of the TRN as a model of somatosensory development and plasticity for over two decades. It is interesting to note, however, that most investigations have focused entirely on the ascending trigeminal pathways, with little attention paid to the maturation of the descending inputs to the primary somatosensory nuclei or the developmental interactions between the ascending and descending projections. We have addressed this issue by using the carboxycyanine dye Dil to study the prenatal development of the corticotrigeminal afferent projections to the rat. Cells of DI were placed in the region of the barreled field of trigeminal complex tissue from rats that had been sacrificed on embryonic (E) days 18 and 20 and postnatal (P) day 0 (day of birth). Numerous labeled CT axons were clearly visible in the ipsilateral somatosensory cortex at E18. At this age, CT fibers could be seen approaching the medial border of the rostral ipsilateral trigeminal brainstem complex (TBNC), but no terminals were identified within the confines of the trigeminal subnuclei. At E20, however, numerous CT axon terminals were visible in the rostral ipsilateral TBNC. A lesser number of axons were also identified in the ipsilateral TBNC. In addition, labeled axons were seen in the medial portion of the contralateral TBNC. The disposition of labeled CT axons in P0 animals was similar to that noted in adult animals, with the density of the terminals in the contralateral TBNC exceeding that seen in the ipsilateral brainstem. These results indicate that the CT pathway in the rat develops in an ipsilateral-to-central, rostral-to-caudal sequence in the late prenatal period.

Supported in part by DE07734.

In the developing somatosensory neocortex, granule cell dendrites come to be largely confined to individual barrels by selective pruning and reorientation relative to thalamocortical patch boundaries. In the developing VPM thalamus, the barrel field is occupied by DI fiber arbors (Baker et al., Soc. Neurosci. Abstr. 1994, #3). To study this issue in trigeminal nucleus principalis (PrV), the barrel link in the whisker-barrel neuronal axis are reconstituted in postnatal days 0-4. Single PrV cells were stained with Lucifer yellow in aldehyde-fixed transverse slices and the resulting labeling and whisker-patch-related autoradiograms and manually and by computer microscopy. The extent to which a single cell's dendritic tree was confined to its patch of origin was determined by computer-assisted merging of the dendrite and patch images. We find that all P0, VPM, most dendrites do not span their "home" patch. Those data suggest that PrV dendrites develop according to a different set of rules than those operating in the VPM thalamus and layer IV of barrel cortex. This may reflect the fact that primary afferent projections are quite mature in the newborn PrV when large numbers of PrV cells have yet to do so. We tested the hypothesis that PrV dendrites are a different function than VPM dendrites in adults. NIH DE07734, NS17563.

694.11 THE TIME-COURSE OF PLASTIC CHANGES IN THE BARREL CORTEX OF ADOLESCENT RATS. S. Glazewski* and K. Fox, Dept. Physiology, University of Minnesota, MN 55455.

Long-term deprivation (60 days) of all but the D1 vibrissa in adolescent rats (P28), results in expansion of the D1 representation in layers II/III of the barrel cortex. To test how rapidly this expansion occurs, we assayed plasticity in rats deprived for 5-7 days and compared the results with those obtained from rats deprived for 60 days. Two kinds of deprivation were used: one group had their vibrissae trimmed every day (VT), the other group had their vibrissae carefully pulled out every two days (VP). The receptive fields of 298 layer II/III cells located above barrels immediately surrounding the deprived barrel were measured using post-stimulus time histogram analysis. We found that functional plasticity occurred in both long- and short-term deprived animals but that the underlying processes were different. Short-term deprivation resulted in suppression of deprived vibrissa input (0.55±0.17 spikes per stimulus versus 0.45±0.15 and 0.42±0.15 in adults). These results suggest that attenuation of deprived vibrissa input might be a prerequisite for expansion of the spared vibrissa representation. Supported by NS27759.

We know that daily whisker trimming from birth alters the receptive field size and character of many trigeminal (V) barrel cells without affecting primary afferent responses. Using in vitro carbocyamine dye oxidase staining patterns, or barrel somatotopy (Jacquin et al., J. Comp. Neuroal, '94). Deprivation-induced response alterations may then reflect disrupted inhibitory mechanisms, the preservation of prenatally developed altered V barrel circuits due to altered activity-based competitive interactions, use-dependent plasticity of existing circuits, and/or an indirect effect of different whisker-related circuits that are imposed on V barrel neurons by more effective cortico-V projections. The latter is particularly compelling because the patterning and extent of the cortico-V projection is altered by V nerve injury at birth, and cortical inputs contribute to V barrel receptive fields in normal rats. To further evaluate the cortical substrate hypothesis, we performed experiments on 1-2 month old rats whose mystacial whiskers were trimmed daily from birth, WGA-HRP injections were placed in the barrel cortex labeled cortical fibers whose extent, density and pattern were normal in ipsilateral and contralateral V brainstem nuclei. However, the incidence of cells in V nucleus interpositus that were discharged by electric shocks in the contralateral internal capsule was significantly higher. This suggests that whisker deprivation impacts on "stable" aspects of cortico-V circuits. To determine whether these changes are prompted by the brainstem or cortex, slow-release polymers containing TTX are being applied to the newborn cortex. Effects on the cortico-V projection will be reported. Supported by NIH DE07734.

694.10 PLASTICITY AT THALAMOCORTICAL SYNAPSES REVEALS A SYNAPTIC BASIS FOR DEVELOPMENTAL CRITICAL PERIODS. M. C. Crair* and R. C. Malenka, Departments of Psychiatry and Physiology, University of California, San Francisco, CA 94143.

It has long been suspected that there could be a synaptic basis for the developmental critical period seen in the cortical representation of the sensory periphery. We present evidence that LTP and LTD-type phenomena might be responsible for one such developmental critical period in the somatosensory cortex of the rat. Using an in vitro thalamocortical slice preparation we tested the lability of monosynaptic response in the barrel cortex of rats to stimulus of the somatosensory thalamus and found that under a pairing protocol (depolarization to -10 ± 5 mV with 100 stimuli at 1 Hz using a blind whole-cell patch), animals beyond the critical period did not display significant plasticity (1 out of 10 cells from animals P8-P14 potentiated more than 10%), whereas thalamocortical synapses in younger animals potentiated easily (150 ± 20% in 9 out of 10 cells from animals age P3-P7). Elucidation of the mechanisms responsible for this developmental switch would aid not only our understanding of critical periods per se, but also to the growing body of evidence suggesting that synaptic plasticity commonly seen in vitro may have important in vivo ramifications as well.

We have examined the metabolic activity and size of the adult rat primary somatosensory cortex (S1) after neonatal eye removal to ask whether altered neural activity affects the growth of the neocortex. Activity in S1 was analyzed by comparing the cortical vascularization of enucleated rats with those rats that were reared with intact eyes. Cortical growth was determined by direct measurement of S1 and its component parts. The overall density of blood vessels in the enucleated animals was 14% greater than the primary somatosensory cortex, and 16% greater within the cortical barrels that represent the whisker pad. In parallel with this change, measurements of S1 and its component parts in the enucleated animals showed that those regions with increased levels of ongoing activity were larger than their counterparts in the littermate controls. Thus there was an increase in the average size of both areas S1 and of the barrels that contribute to the cortex (20%) in the experimental rats. This correlation of increased metabolic activity and cortical growth provides evidence that neural activity stimulates the elaboration of cortical circuitry during postnatal development. Such activity-modulated cortical growth during maturation may be the mechanism by which early experience encodes information in the developing central nervous system.
SOMATOSENSORY DEVELOPMENT

694.13
THE EXPRESSION OF DIFFERENT CYTOCHEMICAL MARKERS IN NORMAL AND AXOTOMIZED NUCLEUS GRACILIS PROJECTING DORSAL ROOT GANGLION CELLS IN THE ADULT RAT. J.E. Persson*, B. Lindbl, B. Råde, B. Robertson*, C. Rivera-Medina*. N.E. Jessen† and T. Skrede. Dept of Anatomy and Histology, University of Oslo, Oslo, Norway. The aim of this study was to analyze expression of various markers in normal and axotomized nucleus gracilis projecting dorsal root ganglion cells. To analyze expression of such markers we used the nuclear translocation assay. The ganglia were retrogradely labeled with Fluoro-Gold (FG) and analyzed immunohistochemically for their expression of neuron-specific enolase (NSE), glial fibrillary acidic protein (GFAP), and carbonic anhydrase (CA). We found that the expression of these markers was different in normal and axotomized nucleus gracilis cells. In normal cells, NSE and GFAP were expressed at a similar level, while CA was expressed at a lower level. In axotomized cells, NSE and GFAP were expressed at a higher level, while CA was expressed at a lower level. These results suggest that the expression of these markers is regulated by axotomy.

694.14
POSTNATAL DEVELOPMENT AND PLASTICITY OF TERMINALS AND SYNAPSES IN SUPERFICIAL MEDULLARY DORSAL HORN: STEROID ANALYSIS. J.P. Golden*, J.A. DeMarco, P. Robinson and M.F. Jacobson. Anat. & Neurobiol., St. Louis Univ. Sch. Med., St. Louis, MO 63110. Mature receptive fields in the superficial dorsal horn develop later than in other somatosensory areas. This development is associated with the presence of a critical period for deafferentation-induced plasticity. To further our understanding of the role of these observations, EM stereochemistry was used to develop connections and morphology in lamina I and II of the superficial dorsal horn in neonatal and adult rats. At birth, postnatal (P) days 1, 4, 17, and 90, we observed synapse morphology and structural changes in the superficial dorsal horn. These changes were not observed in the adult rat.

694.15
ALTERNATE PATTERNS OF EYELID MORPHOGENESIS FOLLOWING LESIONS OF THE TRIGEMINAL GANGLIA. B.L. Mungas* and I.M. Cook. Department of Anatomy, University of Tasmania, Hobart, Tasmania, 7001. In order to test the hypothesis that the alteration of the normal nervous system plays a role in the development of ocular dermal derivatives, the left trigeminal ganglion was cauterized in opossum pups at day 1 post-natal. Morphogenetic abnormalities were compared to the equivalent stages of normal development. Neurectomies were carried out using procedures described by Morohunfola et al. (1992 The Anat. Rec. 222, 599). Mother and pups were anesthetized with halothane (Keller et al. 1988 Lab. Anim., 22, 269). Pups were taken for histologic analysis 2-20 days following surgery. Pups were given intraperitoneal nebulin, and fixed in formalin, serial sectioned and stained with silver. The development of the eyelid neural non-neural constituents occurs post-natally and the lower eyelid lags behind the upper eyelid. Eyelid innervation precedes mesodermal maturation and hair follicle formation suggesting a possible neural role in cutaneous differentiation. Trigeminal gangliosic lesions only involved the sensory component of the nerve sparing the motor root. Trigeminal ligation resulted in altered spatial and temporal patterns in the eyelid that included abnormal eyelash symmetry, delayed follicle formation deletions of eyelashes and delayed dermal maturation. Sham operated pups (skin cultured but lacking a neural ligation) showed normal development in all parameters of eyelid morphogenesis. These findings support the earlier findings of Morohunfola et al. (1992 & a b), based on lesion of lombo-sacral dorsal root ganglia and spinal cord. The present study involves a purely sensory lesion and clearly implicates axons in the formation of the targets in skin, i.e. the cutaneous appendages.

694.16
ISOLATION AND CHARACTERIZATION OF THE CHICK NMDA RECEPTOR cDNA. L.K. Garner*, A. Shalash, B. Mendelev* and B. M. Davis. Dept. of Anatomy and Neurobiology, University of Kentucky Medical Center, Lexington KY 40535. A chick brain cDNA library was screened using a 3P radiolabeled oligonucleotide that corresponds to the first transmembrane region of the rat NMDAR1 subunit. A fragment (approx. 0.5 kb) was isolated and subcloned into pGEM 4Z and used for double stranded sequencing (United States Biochemical). Preliminary results show that the first 200 nucleotides of the isolated fragment are homologous (80%) to the rat and human NMDAR1 subunit at the 5' end of the open reading frame. This region corresponds to the amino terminal end of the NMDA receptor and codes for the extracellular domain that precedes the first transmembrane region. Comparison of the chick cDNA to other NMDA subunits shows no homology. This cDNA fragment has been used to make cRNA probes to determine the normal ontogeny of the NMDA receptor mRNA in the chick spinal cord. Preliminary in situ hybridization results show high levels of the NMDA receptor mRNA located primarily in the dorsal horn of the spinal cord (stage 39, E13). We are currently determining the distribution of NMDA receptor mRNA in the spinal cord following administration of kainate and various NMDA receptor antagonists.

TEMPERATURE-DEPENDENT BEHAVIORAL CHANGES AND CEPHALIC WOUNDS IN CAPSACIN NEONATALLY TREATED RATS. P. Carrillo*, M. Canacho, M. Salas and P. Pacheco, NFE, Unv. Veracruzana; Centro de Neurobiologia e Inst. de Invest. Biomédicas, UNAM, México, D.F., México. Neonatal administration of Capsaicin (CAP) in the rat interferes with eye-opening, scratching frequency and is also associated with skin ulcers emergence. Here we investigate, a) if the wounds emergence is a trophic effect or is produced by the increased cephalic scratching and, b) how the behavior of CAP rats was modified by the warm environmental exposure. We used control and neonatally (day 1 p) treated (60 mg/kg) and adult male rats. In experiment a) rats were using (n=20) or not (n=20) a plastic collar fitted over the nose to prevent head scratching. The control group (n=10) were not disturbed. In experiment b) the behavioral patterns of control or experimental rats were visually recorded at 24 °C or 35 °C of temperature (120 measurements/30 min). Both CAP groups the head wounds appeared around the 23 days of age and the progression in the number and extension of the lesions was also similar. Data indicate that wounds emergence is not provoked by the increased cephalic scratching. Moreover, a significant reduction in self grooming frequency (p<0.05) and relaxed extended posture (p<0.01) in CAP animals was observed. Data showed that hyperactivity related with trophic skin lesions and has also a long term interference with the behavioral regulatory mechanisms to heat exposure. SUPPORTED BY CONACyT (PGR)

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
SYNAPTIC VESICLE PROTEIN 2 (SV2) LOCALIZATION IN THE DEVELOPING HAMSTER PRIMARY VISUAL PATHWAY.

Aiming to better understand the role of NMDA receptors in synaptic plasticity, researchers used the SV2 monoclonal antibody, 10H1, to examine 2-D Western blots containing metabolically labeled rapidly transported proteins of the hamster retinal ganglion cell axons. They observed changes in SV2 expression during development, with SV2 levels increasing in the superficial retina (SC) and decreasing in the deep retina (DC) of the newborn hamster. This study highlights the dynamic regulation of synaptic proteins during the early stages of neuronal development.

FUNDATIONAL FUNCTIONALITY OF OPTIC AXONS REGIMENTING INTO THE PRIMARY OPLAJECTORY CENTER OF THE PRIMATE. P. Scalisi, R. Hoffer, A. Lostoc, and V. Lammert, Dept. of Anatomy, SUNY, Health Science Center at Brooklyn, Brooklyn, New York 11203 and Dept. of Anatomy, College of Optometry, The City University of New York, 11203.

This study investigates the role of optic axons in guiding the development of retinal ganglion cells. The researchers found that optic axons play a crucial role in regenerating fibers and forming a coherent terminal field in the primate olfactory cortex. This work contributes to our understanding of the complex interactions between axonal growth and target identification in the developing nervous system.

NEONATAL ADMINISTRATION 5,7-DIHYDROXYTRYPTAMINE RESULTS IN SYNTACTIC REORGANIZATION IN THE SUPERFICIAL GRAY LAYER OF THE HAMSTER PRIMARY COLLICULUS. D. A. M. Mooney and R. W. Rhoades, Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43614.

Neuronal administration of 5,7-dihydroxytryptamine (5,7-DHT) in neonatal hamsters results in a selective lesion of serotonin (5-HT) in the superficial gray layer of the hamster's superior colliculus. This study demonstrates the potential for synaptic reorganization following chemical lesions and suggests a role for 5-HT in shaping neural connectivity in the developing brain.

EFFECTS OF NEONATAL 5,7-DIHYDROXYTRYPTAMINE TREATMENT ON RETINAL GANGLION CELL AND OPTIC NERVE FIBER NUMBER IN THE ADULT HAMSTER. J. C. Creighton, W. M. H. Van der Hoeven, R. D. G. S. Van der Hoeven, and R. W. Rhoades, and D. A. M. Mooney, Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43614.

This study investigates the long-term effects of 5,7-DHT treatment during neontal development on retinal ganglion cell and optic nerve fiber number in adult hamsters. It demonstrates the lasting impact of early lesioning on the number of neurons and axonal growth, providing insights into the critical period for synaptic development.

NMDA RECEPTOR BINDING IN TECTUM OF DEVELOPING XENOPUS. S. Uhid* & L. G. Murakami, Dept. of Physiology, SUNY, Buffalo, NY 14214.

This study explores the development of NMDA receptor binding in the tectum of developing Xenopus laevis. The researchers found that NMDA receptor number changes during postnatal development, which may correlate with changes in synaptic plasticity and axonal growth. This work contributes to our understanding of neuronal development in an amphibian model system.

THE ROLE OF RETINOCOLICULAR AXONS IN THE DEVELOPMENT OF THE CORTICOTECTAL PROJECTION OF MICE. M. Khachab and I. L. Bruce, Dept. of Biomedical Sciences, Creighton University, Omaha, NE 68178.

This study investigates the role of retinocollicular axons in the development of the corticotectal projection in mice. It demonstrates that the development of this projection is closely linked to the growth and refinement of retinal ganglion cells, highlighting the importance of axonal guidance cues in the developing visual system.

*Supported by NIH Grant 3T32 EY05284.

NMDA receptor activity is essential in the plasticity of the developing frog retinotectal projection. Ca2+ entering through the NMDA receptor may act through a Ca2+-CaMKII-CaMKII (CAMK) pathway. We are starting to explore this possibility by combining recombinant viral technology with in vivo imaging techniques. Vaccinia virus containing the DNA sequences encoding truncated, constitutively active CAMKII and D-galactosidase (βGal) was injected into the retina of stage 46-47 tadpoles. Intense infection throughout the CNS, as indicated by the expression of βGal, occurred by day 3. To examine RGC axon morphology, a small amount of smooth green fluorescent protein (GFP) was injected into the retina of stage 46-47 tadpoles. Animals were screened the next day to select those with a single brightly labeled RGC axon. Three days later, when tadpoles were stage 48, this newly emerged axon was observed in vivo by using a confocal microscope. The extent of viral infection was verified by checking βGal expression. Single axons were reconstructed. In the animals infected with βGal and constitutively active CAMKII was expressed, the average total length of 13 RGC axons was 373 ± 49 µm (±SE) and the average number of axon branches was 13 ± 2. These values are smaller than those in the control animals with no virus injected (n=15) and those infected with βGal Virus (n=12), where the average total axon length was 523 ± 67 and 616 ± 116 µm, the average number of axon branches was 27 ± 3 and 24 ± 2, respectively. Thus constitutively active CAMKII expressed in the tectal cells reduced the RGC axon total length and the branch number in 3 days. These results indicate that CAMKII activity in the postsynaptic tectal neurons is likely to be involved in the control of the growth of presynaptic RGC axons. We are taking time-lapse images of growing axons to study the mechanism by which their morphology is modified.

EFFECTS OF SEROTONIN ON PATCH-CLANPED NEURONS IN THE OPTIC TECTUM OF THE FROG. Malavey A.A. and E.A. Debski. Sch. of Bio, Sciences, University of Kentucky, Lexington, KY 40506.

Recent immunocytochemical studies have shown that serotoninergic tectal ganglion cells project to the optic tectum of frogs (Liu & Debski, J. Comp. Neurol. 338:361-404, 1993; Liu & Debski, Neurosci. Abstr. 19:452, 1993). The role of serotonin in the functioning and/or development of the tectum is unclear. There are few external studies of the effects of serotonin on tectal cells in tadpoles and juvenile bullfrogs by applying whole-cell patch-clamping techniques to brain slices. Perfusion of the slices with 100 µM serotonin induced a sustained outward current of 3.0±2.0 PA/PF (n=9) in 27% of the tadpole cells voltage-clamped at -60 mV. Under these conditions 50% of the cells recorded in juvenile frogs to date have shown this serotonin-induced current (n=10, 1<57±1:85 PA/PF). Blocking the membrane potential to between -50 and 0 mV from a holding potential of -70 mV revealed serotonin-induced outward current in 50% of the tadpole cells and in 75% of the juvenile frog cells. Preliminary experiments conducted to address the possibility that exposure to the cells serotonin resulted in a cell hyperpolarization of approximately 10 mV. In addition to an evoked outward current, in some cells serotonin also increased the frequency of synaptic inputs. Cells that responded to serotonin also responded to NMDA. External application of 33 µM NMDA in the presence of TTX resulted in the activation of an inward current at a holding potential of -40 mV. Our data suggest that serotonin may modulate NMDA receptor activity in the optic tectum by changing the potential of the membrane upon which these NMDA receptors sit. Supported by NSF grant IBN-9209651.

THE DEVELOPMENT OF NORMAL AND ABNORMAL GENICULOCORTICAL TOPOGRAPHIES IN THE SYRIAN HAMSTER. A.L. Smith, K.Koga and J.D. Thompson (SPON: Brain Research Association). Laboratory of Physiology, Parks Road, Oxford, OX1 3PT, UK.

The orderly mapping of the lateral geniculate nucleus (LGN) onto area 17 in the adult hamster is disrupted by unilateral eye removal on the day of birth. Ipsilateral to the remaining eye, single injections of tracer into an area of cortex which receives input from one eye can produce dual focal of retrogradely labelled geniculate neurones (Trewavas & Thompson, 1992, Eur. J. Neurosci. 4:1104). We have studied the development of both the normal and the aberrant geniculocortical projections. Separate injections of red and green fluorescent latex microspheres, spaced mediolaterally, were made in visual cortex of neonatal hamsters that had been monocularly enucleated on the day of birth (P0). No topographic order was discernable in animals injected on P2 when a single cortical injection labelled neurones throughout the LGN. With two injections, the populations of red and green labelled cells were spread completely. At P6, cortical injections antilateral to the remaining eye produced an essentially adult pattern; most of the LGN was unlabelled and there were distinct roid of red and green labelled cells. The pattern in the ipsilateral geniculate was different with more overlap between the populations of red and green labelled cells; however, the projection was much more restricted than that seen at P2. The characteristic double focus seen in adult differentiated LGNs appeared later.

The emergence of geniculocortical to topography between P2 and P6 in the hamster coincides with the invasion of cortical pial by the majority of geniculate axons, as revealed by transneuronal tracer. Preliminary experiments placing MK801-containing Elavax on visual cortex failed to disrupt this early phase of topographic refinement.

This work was supported by the Wellcome Trust, UK.

THE DEVELOPMENT OF THE RETINO-COLLICULAR MAP IN THE SYRIAN HAMSTER. L.D. Thompson and P.M. Cordery. (SPON: Brain Research Association). Laboratory of Physiology, Parks Road, Oxford, OX1 3PT, UK.

Previous studies applying DII to the retina of fetal rats revealed considerable topographic disorder in the retinal projection to superior colliculus (SC; Simon O'Leary, 1992, J. Neurosci. 12:1212). We have used two retrograde tracers, red and green fluorescent latex microspheres, to examine the development of topography in the retino-collicular projection of the hamster. Small (25-50 nL) injections of tracers were made in all four quadrants of the SC in the neonatal rats. Both the injection and the orientation (rostral/medial) of the paired red-green injection sites was varied. Single injections of tracer on P2 produced labelling over approximately one third of the retina, even though the injection occupied a very much smaller area of SC. When injections were separated by 400 µm or less and irrespective of their orientation, there was considerable overlap in the populations of red and green labelled cells. Larger separations resulted in very little overlap between the red and green labelled populations of ganglion cells whereas similarly large rostrodorsal separations produced much less overlap. Similar numbers of ganglion cells were labelled following injections into caudal or into rostral SC. By P6, single injections labelled ganglion cells in much more restricted regions of retina and pairs of injections separated by 500-1000 µm produced little or no overlap. Older animals displayed increasing precision in the retino-collicular projection such that, at P21, injections separated by less than 200 µm could produce two distinct layers of labelled ganglion cells.

These results reveal that a crude retinal topography exists for the mediolateral axis of the SC in neonatal hamsters and that the overall topography refines during the period of ganglion cell death.

695.12

We have found that there are four major events in the functional development of the neonatal rat superior colliculus. (1) Spontaneous discharges are the earliest recordable activity, becoming manifest on postnatal day 5 (P5). (2) The first evoked response to electrical stimulation of the optic nerve is detectable on P10, and (3) the first flash evoked responses in the superior colliculus occur on P12/13. (4) On P14/15, eye opening occurs. Since spontaneous activity occurs first and may influence the other developments, we sought to determine the extent to which each of these events may influence the others. We measured the frequency of spontaneous spikes at different postnatal age; interval histograms were constructed between P5-P15. Preliminary data, based on 28 animals, suggest an interesting trend. On P6, P8, P10, and P13, there are infrequent distributions of intervals, indicating clustering of shorter intervals and a relatively high frequency of spontaneous discharges during these ages. These trends may be physiologically important, as the flash and the flash evoked responses in the superior colliculus are 24-36 hours. Our data suggests that there is a temporal increase in spontaneous activity coinciding with the development of new functional capability. To further characterize the source of the spontaneous activity, we injected 2% xylocaine into the optic nerve head, silencing optic nerve activity at P6-P11. These results indicate that spontaneous discharges in the superior colliculus are independent of the retina.

695.14 GLYCOEN IN THE VISUAL SYSTEM OF YOUNG AND ADULT FERRETS. Kathryn Hermann*. Lab. Neurophysiology, NIMH, Poolesville, MD 20837, USA.

It is well established that glycine is an inhibitory neurotransmitter in the brainstem and spinal cord. Glycine, however, is also present in retinal ganglion cells both in adult and developing ferrets, and glycine receptors are abundant in the early postnatal mammalian neocortex. In the present study the lateral geniculate nucleus (LGN) and the visual cortex were examined in adult and developing ferrets for the presence of glycine employing immunohistochemical procedures using a rabbit anti-glycine antibody. In adults, glycine positive cells were seen in the lateral geniculate and visual cortex. In adults, immunopositive cells in the LGN were mainly large or medium sized neurons, and glycine positive cortical cells were found in all layers, but occurred in greater frequency in the intragranular layers. By birth, glycine-positive cells were already plentiful in the LGN. In the developing cortex, however, glycine-positive neurons were sparse in the cortical plate, although abundant in the subplate (SP) and marginal zone. In addition, the SP/intermediate zone contained a dense plexus of glycine-positive fibers, perhaps representing thalamocorticical axons. To determine whether the glycine is seen in relay neurons of the LGN, I injected HRP and/or fluorescent latex beads into visual cortex of adult (~P65) ferrets. Most if not all retrogradely labeled LGN cells were also glycine positive. Since the relay neurons of the LGN are likely to use an excitatory neurotransmitter, the presence of glycine in LGN projection neurons strongly suggests that glycine within thalamocorticical axons acts on the glycine site of the NMDA receptor, mediating the appropriate excitatory thalamocortical response. The presence of glycine in these axons might indicate an additional role for glycine perhaps as a neurotrophic factor.

695.15 SIGNAL TRANSMISSION IN THE LATERNAL GENICULATE NUCLEUS OF MONKEYS WITH SURGICALLY INDUCED ESOTROPIA. E.L. Smith III*, Y.M. Chino*, H. Cheng*, Y. Sasaki*, M.J.C. Crawford†, R.S. Hanworth† and G.K. von Noorden‡. College of Optometry, University of Houston.§ University of Texas at Houston†. Department of Ophthalmology, Baylor College of Medicine, Houston, TX.

Early strabismus, a form of abnormal visual experience which often leads to permanent vision anomalies, produces dramatic alterations in the response properties of neurons in the monkey's visual cortex. In the present study, the morphology and laminar distribution of LGN neurons are clearly altered by strabismus, but it is not known whether the functional status of LGN neurons is also affected. We investigated the effects of early strabismus on the transmission properties of LGN neurons surgically induced esotropia by using microelectrode recording techniques to compare the responses of individual LGN neurons with those of their retinal inputs (G-potentials) and LGN action potential pairs (n=65). We measured orientation, spatial frequency, temporal frequency and contrast response functions using drifting sine-wave gratings. Contrary to our previous findings in strabismic cats, there were no obvious differences between the transfer characteristics of control- and treated-eye neurons. The results suggest that, in comparison to the cat, the physiological status of the primate LGN is less susceptible to environmental influences.

695.16 THE EFFECT OF NEONATAL MONOCULAR APHAKIA OR OCCLUSION ON THE EXPRESSION OF CAT-301 ANTIGEN, PARVALBUMIN AND CALBINDIN IN THE LATERAL GENICULATE NUCLEUS OF MACAQUE MONKEYS. N. Jain*, J. McKee†, V. Rema†, and H. Kogo*. Dept. of Neurology and Inst. for Developmental Neurosciences, Vanderbilt University, Nashville, TN, and Yerkes Research Center, Emory Univ., Atlanta, GA.

Macaque monkeys (Macaca mulatta) were reared from birth to about one year of age either with surgically induced monocular aphakia, resulting in a blurred retinal image, or with a black occluder on one eye, which prevents visual experience. Levels of expression of the Cat-301 antigen, parvalbumin (PV) and calbindin (CB) were examined with immunohistochemical techniques in the lateral geniculate nucleus (LGN). Both types of deprivation resulted in a marked reduction of Cat-301 staining in both parvocellular and magnocellular LGN layers connected to the deprived eye, with deprived magnocellular layers retaining a relatively higher level of staining than the deprived parvocellular layers. PV and CB immunoreactivity, however, was reduced only moderately in the deprived layers, with a more pronounced reduction ipsilateral to the deprived eye. These results show that changes in the expression of the Cat-301 antigen, and PV and CB are similar, whether produced by aphakia or occlusion. Remarkably, alterations can be more pronounced in the layer receiving inputs from ipsilateral than the contralateral deprived eye. (Supported by NIH EY02668, EY09573 and RR-016E).

TRANSLATION VI

We examined motor control in normal and shiverer (shv) mutant mice using the rotarod assay, a forced motor activity which tests for balance and coordination. Shiverer mice carry a deletion in the myelin basic protein (MBP) gene, resulting in CNS demyelination and characteristic motor dysfunction. Shiverer mice were evaluated at 6-7 weeks of age in order to avoid the toxic micronucleation in older shv mice, and all animals were acclimated to the test apparatus prior to testing at 3 pm and 6 pm each for 1 min. Homozygous mutant mice had a significant increase in mean fall time (0.05±0.6, n=4) relative to wild-type and heterozygous (shv+) mice (n=110.11, n=4). Comparable results were obtained at speeds of 12 and 18 rpm, 1 min each. Non-acclimated animals showed learning curves with progressive improvement in performance when tested daily for four days, although the shv/shv animals consistently had more falls than normal control animals.

We also examined the motor assay for the retinal output of morphology in the performance of shv/shv animals in a paradigm of challenging tasks. Rotarod day 2 animals received thamic transections of either of reticuloticollidofondosecre-type 2neaectomy (5-2-2A) neurons, or of the o-2a (luteal cell) glialis (G-2-4) cells. Shv/shv transplanted recipients showed a significant improvement in rotarod performance (172±2.5 falls, n=18) although they continued to demonstrate a gross phenotype, indicating that the recovery measured in the retarded represents a multiplicity of functional recovery. Immunohistochemical analysis of tissue harvested after rotarod analysis revealed the expression of MBP in the CNS of transplanted shv/shv animals. We included control animals in the rotarod performance relative to non-transplanted shv/shv mice (9.8±1.8 falls, n=8). RNA analysis of two of these animals showed no evidence of MBP transcripts, consistent with the interpretation that the thamic transplantation failed. Our results demonstrate that the rotarod is a sensitive measure of motor function in demyelinated mice, and suggest that transplantation can lead to an improvement in motor function in these mice. The cell and vascular basis for the motor recovery in shv/shv recipient transplants remains to be elucidated.

696.2 KINEMATIC AND EOG ANALYSES OF CONTROL AND SPINAL CORD TRANSECTED RATS DURING TREADMILL LOCOMOTION. J.W. Boston*, X.M. Xu, M.B. Bunge, and B. Callanas. The Miami Project to Cure Paralysis and the Department of Neurological Surgery, University of Miami, Miami, FL.

We previously demonstrated that mild-thoracic spinal cord transections bridged by Schwann cell-filled guidance channels open at both ends (OPEN CHANNELS) promoted a greater number of axons across the transected site than open cord transections closed at the distal end. The following studies were undertaken to determine if behavioral or electrophysiological correlates of this increased axial growth exist.

Unoperated control rats were studied to determine the normal walking pattern in a spacious environment. These data were then compared to spinal cord transected, closed channel and OPEN CHANNEL groups. Rats were studied 1-4 weeks post-surgery. For the kinematic analysis, animals were taken at 30 frames/sec during 7.5-30s of regular forward movement while rats were suspended in a sling over a treadmill which was moving at 0.05-0.15m/s. In conjunction with the kinematic study, EMG experiments were done, in which periods of activity ranging from 7.5-120s were collected from forelimb and hindlimb muscles, digitized at 200Hz, rectified, and analyzed. OPEN CHANNEL rats displayed significantly more hindlimb EMG than did rats with closed channels. Further, alternating hindlimb movements were observed in rats with OPEN CHANNELS at some treadmill speeds, but which deteriorated at lower or higher speeds. To determine if this movement was under some voluntary control, we also calculated the cross-covariance functions of forelimb vs. hindlimb movements (kinematic analysis) and muscle activations (rectified EMG analysis).

Because involuntary rhythmic movements can confound the validity of overly sensitive behavioral measures of motor function, this analysis may prove useful in the assessment of the consequences of spinal cord transection. In the assessment of motor function, movement after complete or incomplete spinal cord injury.
606.3 EFFECTS OF FETAL SPINAL CORD (FSC) IMPLANTS AND EXERCISE ON MUSCLE ATROPHY IN CHRONIC SPINAL RATS. N.B. Repper*, J.D. Houli, C.A. Peterson, C.M. Guifery, C.L. Perry, F.D. Sweatman and E. Garcia-Rill, Dept. of Anatomy and Medicine, University of Arkansas for Medical Sciences, Little Rock, AR 72205

The potential for surgical and pharmacological procedures to influence the characteristic atrophy of hindlimb skeletal muscle following spinal cord injury was examined. Adult Sprague-Dawley rats sustained a complete spinal cord transection (T4) by aspiration of intrathecal clamps. Four groups of animals were prepared: T4 rats exercised on a treadmill, T4 rats exercised following FSC injection; T4 rats transplanted with FSC tissue, T4 rats transplanted with FSC tissue and exercise. FSC tissue was transplanted into the anterior (T) muscles were prepared for measurement of cross-sectional area of individual myofibers or for immunocytochemical analysis of myonuclei恕fibers or for immunocytochemical analysis of myonuclei by immunocytochemistry. Results: T4 rats lost 76% of their motor nerve axons, while type Ila (fat, fast) fibers were reduced and type Ila (fast, fatigue resistant) fibers were more prominent. These results suggest that the shift in expression towards type IIb fibers caused by spinal cord Tx is reduced by exercise by increasing the proportion fast IIb fibers. Supported by NSF Grant RII 8922103 and NIH Grant NS 29328.

Traumatic conduction injury to the human spinal cord most frequently occurs at the cervical level and produces varying degrees of chronic tetraplegia. The deficits in the hands and arms persist in part from cervical nerve degeneration. Using our adult rat model of incomplete cervical SCI and forelimb behavior tests, the present study begins investigations of motor neuron replacement after cervical SCI as a means of ameliorating forelimb dysfunction. Cervical SCI was produced by dropping a 10 gm weight 2 cm onto the C7 spinal cord segment. Between 1-4 weeks post-SCI, SCI rats (n=11) had significant forelimb deficits compared to sham-injured rats (n=4) as shown by 1) decreased grades for proximal (elbow) and distal (wrist and digits) extension and flexion (grasp) with a modified Tarlov scale and during Forelimb Placing Tests, 2) reduced forelimb grip strengths in the Grip Strength Test, and 3) reduced pellet retrievals and well clearance scores in the food retrieval Staircase Test. At 5-6 weeks, CNTF (Regeneron Pharmaceuticals, Inc., 5 μg/1) were administered at the C7 segment of SCI rats through an intrathecal cannula. At 5 weeks, some SCI rats received transplants at C7 of dexamitino-yellow labeled, E14-15 rotoral spinal cord cell suspensions (1.05 X 10⁷ viable cells) incubated for 60-90 min in 10.5 μg CNTF (n=3) or saline (n=2). At 10 weeks, forelimb function of all SCI rats had not improved. Nissl-stained cells with motor neuron morphology and ChAT-immunoreactive cells were found in small similar numbers in all transplants. The results show that grafted transplanted motor neurons needs to be further examined. Supported by The Miami Project to Cure Paralysis.

606.5 EFFORTS TO REINNerve ADULT RAT GASTROCNEMIUS MUSCLE BY EMBRYONIC SPINAL MOTOR NEURONS TRANSPLANTED INTO PREDEGENERATED TIBIAL NERVE. D.E. Eric, L. Lippincott and R.P. Bunce. The Miami Project to Cure Paralysis, U.A. of Miami School of Medicine, Miami, FL 33136

Motor innervation is required for effective contraction and maintenance of skeletal muscle. If motor innervation is lost the muscle becomes denervated and undergoes progressive atrophy which ultimately leads to degeneration. Efforts to illicit muscle contraction or significantly retard muscle atrophy by direct electrical stimulation of the muscle are relatively ineffective without a nerve supply. Previously, we have reinervated denervated adult rat gastrocnemius muscle by transplanting a heterologous nerve graft. A population of dissociated adult rat spinal cord, into the adult rat tibial nerve, which was then transplanted proximal to the transplant site (Exp. Neurol. 193:124:372-376). Currently, we seek reinervation by transplanting into neonatal (P1) and 3 weeks after atomy. Within six weeks posttransplantation large multipolar cells, resembling alpha motor neurons, were observed within the transplant site. Axons originating from the transplanted cells were identified within the nerve stump and within the previously denervated gastrocnemius muscle. Transplanted motor neurons survived up to 4 weeks (the longest survival) and could be retrogradely labeled with the tracer fast blue. This study demonstrates that embryonic spinal motor neurons, transplanted into the predegenerated adult peripheral nerve, are able to survive and extend axons into the denervated target muscle. This approach may provide the innervation necessary to artificially control muscle contraction by functional electrical stimulation, thus making previously unavailable therapies available to the muscle. (The Helfield Foundation, The Miami Project to Cure Paralysis, NRS 59144-01).

606.6 TRANSPLANT MEDIATED BEHAVIORAL RECOVERY OF WEIGHT SUPPORT & INTERLIMB COORDINATION IN NORMAL, SPINAL & SPINAL-TRANSPLANT RATS. D.Y. Myria*, B.Clarke, A.Tessler and M.Murray. Dept. of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129

Transplanted fetal spinal cord tissue into verified lesion sites can support locomotion in newborn spinal rats (Howland et al.,1993). Surgical procedures and a battery of quantitative behavioral tests were developed to extend these results to a neonatal rat model. Blocks of E14 cervical spinal cord tissue were placed into the newly transected rat thoracic spinal cord on the day of birth. Reflex and locomotor behavior was studied in normal rats, spinal rats and spinal rats from E14 ventral spinal cord, 4 weeks of age. Tests examined posture, weight support and interlimb coordination and included reflex bipedal and quadrupedal treadmill locomotion, locomotion over a variety of terrains and stair climbing. Transplanted animals demonstrate coordination and weight supported steps on all types of locomotion but also exhibit marked hypermetria in the hindlimbs (HLS). EMG recordings taken from each limb during locomotion also demonstrate brainstem mediated spinal cord graft in transplanted, but not spinal rats. Spinal rats demonstrate coordinated HLS stopping only during tests of supported, reflex bipedal locomotion. Stair climbing, a task requiring complex postural adjustments and adaptive changes in weight support and interlimb coordination, was completed differently by each of the 3 groups of trained rats. Supported by NIH NS 24707 and VA Research Service.

606.7 PHARMACOLOGICAL MODIFICATION OF TRANSPLANT MEDIATED BEHAVIORAL RECOVERY IN NORMAL, SPINAL AND SPINAL-TRANSPLANT RATS. M.Murray*, A. Tessler, K. Simanys and D.Y. Myria. Dept.of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129

Fetal tissue transplanted into spinal cord will promote development of locomotor function in cats (Howland et al., 1993) and in rats transected as neonates (Myia et al., this volume). Specifically, interlimb coordination across the gait phases occurring in transplanted but not untreated, rats, shown by both behavioral and physiological methods. Transplants may improve interlimb coordination by promoting connectivity across the lesion, by increasing weight support or spinal mechanisms operating at the regional level or by a combination of both mechanisms. Because regenerating 5-HT axons have been shown to cross grafts in neonates, descending serotoninergic systems might contribute to behavioral recovery. Trained normal, spinalized and transplanted rats were studied for the effects of serotonergic agonists. Quadrupedal treadmill locomotion was videotaped both before and after drug administration and analyzed. The non-specific 5-HT receptor agonist quipazine, produced a marked increase in the step cycle duration and augmented the amplitude and duration of hindlimb extension, flexors and axial muscles in transplanted animals. Quipazine did not affect either normal or transected rats at the doses used indicating that the descending 5-HT system may be involved in transplant enhanced locomotion. Immunochemical and fluorescent results also indicate the possible contribution of both the descending 5-HT and NE systems in the improved function. Supported by NIH NS24707 and VA Research Service.

Our previous work has indicated that pain sensitivity can be reduced by transplanting adrenal medulla into the rat spinal subarachnoidal space. To further elucidate the mechanisms of this phenomenon, we examined several characteristics of tyrosine hydroxylase (TH) mRNA and preproepinephrine (PPEnK) mRNA were investigated using in situ hybridization in rat adrenal medullary explants in culture. A large number of TH mRNA-expressing precursors were identified in all cultures. 32P-labeled oligonucleotide probes and anti-TH monoclonal antibody applied to 15-day cultured sections. The relative mRNA levels and intraganglionic mechanisms were quantified by image analysis. Both TH mRNA and PPEnK mRNA levels in explants started to increase after 4 days in culture, and peaked a week at 7 days. At 14 and 28 days in culture, levels of TH and PPEnK mRNA decreased, but were still significantly higher than that of intact normal adrenal medulla and then at 1 and 4 days in culture. The TH mRNA significantly increased by 1 day, and continued to increase up to 4 days in culture. Thereafter, it remained at a level similar to adult adrenal medullary explants, adrenal medullary transplants contained numerous TH mRNA labeled cells at 1, 2 and 12 weeks after transplantation. However, only a few cells expressed PPEnK mRNA by 2 weeks post-transplantation. These results indicate that, while surviving chromaffin cells can still synthesize catecholamines when transplanted to the CNS, the synthesis of opiod peptides may remain low. In addition, these findings suggest that the regulatory mechanisms of TH mRNA and PPEnK mRNA expression in rat adrenal medullary cells differs under the environmental influence of culture and the CNS. Supported by NIH grant NS25064.
XENOTRANSPLANTATION OF ENCAPSULATED BOVINE CHROMAFFIN CELLS FOR THE TREATMENT OF INTRACTABLE PAIN: A PHASE I CLINICAL STUDY

Lausanne University Medical School, Lausanne, Switzerland, CytoTherapeutics, Providence, RI, USA.

Chromaffin cells are known to release a cocktail of alkaline substances such as catecholamines and opioids. The response of these cells to the administration of allogeneic and xenogeneic chromaffin cells has been shown to alleviate pain in rodent models. To circumvent the problem related to the shortage of human cadaver donors, we are investigating the possibility of transplanting encapsulated xenogeneic chromaffin cells in humans suffering from intractable pain. Chromaffin cells are isolated surgically from the adrenal gland and encapsulated in a tubular (5cm long) 950μm OD semipermeable membrane which allows diffusion of nutrients and neurotransmitters but prevents rejection of the graft by the host immune system. Bacteriologic analysis and capsule catecholamine release studies were performed before implantation.

Ten patients suffering from chronic pain related to advanced cancer or deafferentation were transplanted with cell loaded capsules in the lumbar subarachnoid space (n=8) or lateral ventricle (n=2) using minimally invasive techniques. No evidence of serious complications or significant host tissue reaction related to the capsules was observed. Viable cells positive for tyrosine hydroxylase and melanin-enchephalin immunostaining were observed in all but one of the nine explanted capsules. Seven of the ten patients showed improvement in their chronic pain on the basis of decreased narcotic intake (4/9 opioid responders) or improvement in pain scores (3/9 non-responders to narcotics).

POLYMER-ENCAPSULATED CELLS GENETICALLY MODIFIED TO SECRETE HUMAN NGF IMPROVE COGNITIVE FUNCTION FOLLOWING INTRAVENTRICULAR IMPLANTATION

Neurosurgery Laboratory, University of California, San Francisco, CA, Neuro2A culture, Transgenic mice, Gene Therapy.

Exogenous NGF has been reported to improve cognitive function in rats with age-related cognitive deficits. However, the long-term effectiveness of exogenous NGF to treat human cognitive disorders have been expressed about the risks involved with supplying NGF to the CNS. Recent evidence in our laboratory suggest that encapsulated, genetically modified NGF-secreting cells may be delivered into the mouse brain, thereby preventing the deleterious effects of the surgical procedure and the side effects of autologous NGF in the recipient's CNS. As a proof of concept, we have tested the potential of exogenous NGF-secreting cells to ameliorate some age-related cognitive deficits in a transgenic mouse model of mental impairment. Exogenous NGF-secreting cells were encapsulated in semipermeable membranes, and implanted stereotactically. NGF production was 10% of that previously reported. The results showed that these encapsulated cells transplanted into the hippocampus of aged mice significantly improve the long-term memory and learning ability of the transgenic mice compared to the control group. This result suggests that NGF-secreting capsules can be used to treat age-related cognitive impairments and that the NGF-secreting cells are able to migrate to the site of the implantation and release NGF to the brain tissue. The results are promising and suggest that encapsulated NGF-secreting cells may be a potential therapy for age-related cognitive impairments.
696.15 Host Brain Modulation of Intra-Retrosplenial Transplants of CholinergicSeptal Neurons. Yong J. Lue, and Walter C. Loev, Dept. of Neurosurgery and Physiology, and Program in Neuroscience, University of Minnesota Medical School, Minneapolis, MN, U.S.A.

Previous studies from our laboratory have demonstrated that cholinergic-rich grafts derived from fetal septal nucleus can re-establish the cholinergic innervation in the retrosplenial cortex (RSC) of rats with lesions in both forebrain and cingulate pathways. Concurrently, a significant amelioration of spatial memory deficits in these animals was observed. In the present study we postulated that the grafts can become functional interconnected with the neural circuits of the host brain, and can thus be regulated by activity from the host brain. To test this hypothesis we evaluated the effect of the animals' performance in a 6-ram radial maze task on high affinity cholinoxygen (HACU). Three groups of rats were used: 1) animals with control RC (NC), 2) rats with lesions of the fornix and cingulate pathways, and 3) lesioned rats with fetal septal grafts in the RSC (RSCsep-TPL). Animals in the NC group were further divided into two subgroups: 1) rats that performed the maze before the determination of HACU levels (BEH), and 2) rats that were kept in their home cage (NON-BEH) and paired with a BEH mate for HACU assessment. In NON-BEH animals, the HACU values (pg/mg/min/mg protein) were 21.2 ± 0.9 (mean ± SEM) for the NC, 9.9 ± 1.0 for the FX, and 17.7 ± 0.7 for the RSCsep-TPL animals. The BEH subgroups had HACU values of 29.8 ± 1.8 for the NC, 19.1 ± 1.0 for the FX, and 22.9 ± 0.9 for the RSCsep-TPL. In comparing HACU levels with their NON-BEH counterparts, t-test indicated significant increases in the NC (p < 0.001) and RSCsep-TPL (p < 0.005) groups, but not in the FX animals (p = 0.565). These results suggest that fetal septal graft in the RSC can become functionally interconnected with the host neural circuitry, and that the activity of the implanted cholinergic neurons can be modulated by the host brain. (Supported by NIH grant RO1-NS-24464).

Excitative neurotoxin ibotenic acid (IB) or kainic acid (KA) injection in the brain in one way causes death of extantic neurons, but also induce a neurotrophic environment for neuronal growth. The lesion effects when confined in a tract, provides a trophic throughway for the axonal outgrowth of transplanted neurons and reinervation of 5-7 mm distal target in 3 weeks. Spague-Dawley rats with fetal nigral dopamine neurons (6-OHDA, 12 ± 5ug/ml) in medial forebrain bundle. 1-2 weeks later, KA (1ug/ml) or IB (10x20ug/ml), or phosphate buffer (PB) were microinjected through a glass pipette to a 5 ± 7mm long track between nigra and striatum, followed by graft of E14 embryonic cells into nigra. Animals were either perfused and stained with tyrosine hydroxylase immunocytochemically (TH-im) 3-4 weeks later, or injected with HRP in the striatum and their brains were stained 24 hours later in the graft regions. The 6-OHDA degenerated DA neurons in nigra and completely denervated the striatum. (n=13). Unilateral turning was evident after amphetamine challenge. Transplanted cells of nigral grafts grew distinctly in a bundle along the entire length of KA/IP tract (n=5), but not into the PB tract (n=5). The TH-im fibers did not leave the KA tract when coursing through the globus pallidus, but quickly spread out when reaching the striatum. Reinnervating TH-im fibers were distributed in patches in the striatum near pallidum but non-discerningly in rostral striatum. HRP tracing reveals labeled neurons in the graft (n=3). Behavioral studies show that amphetamine challenged unilateral turning was reduced by about 40-60% after the bridgeing method of transplant.

696.18 PROTEOLYTIC ENZYMES INVOLVED IN GLIAL CELL MIGRATION FOLLOWING TRANSPLANTATION OF FETAL RABBIT BRAIN TISSUE INTO MOUSE BRAIN. M.K. Del Bino*, F.L. Tchclingerian, C.M. Jacob, INSERM U134, Hospital de la Salud, Paris 75651 France.

Following grafted of fetal (E25) rat brain fragments into the striatum of shiverer mouse (a mutant lacking MBP) brain. Glial cells migrate predominantly along white matter tracts. Differentiated astrocytes can be identified by the anibody ThyGAP1 which recognizes rabbit but not mouse GFAP. Transplanted oligodendrocytes produce proteolytic enzymes which contain MBP. Immunoelectron microscopy shows that transplanted astrocytes are well integrated into host brain in both perivascular and perineuronal positions. To study the role of proteolytic enzymes in the migration of transplanted glial cells 3 days to 4 weeks after transplantation we used immunohistochemistry and non-radioactive ISH. Transplanted astroglial cells are often immunoreactive for tissue plasminogen activator (tPA). Some immature transplanted cells at the graft nidus show urokinase PA-like immunoreactivity. In shiverer mouse, reactive astroglia exhibit iPA and inflammatory cells show UPA. Immature transplanted cells express the mRNA for matrix metalloproteinasises (MMP) type 1 and type 3 for up to 4 weeks. Transient expression of MMP3 is occasionally observed at a distance from the graft sites associated with cell migration. We conclude that some proteolytic enzymes may be associated with the migration of transplanted glial cells. However, they are not unambigious identifiers of migrating glial cells.

AGING PROCESS

697.1 CHRONIC ADMINISTRATION OF GM1 GANGLIOSIDE ENHANCES CHOLINERGIC PARAMETERS IN THE AGED BRAIN. M. Hadjiconstantinou*, T.G. Fong and N.H. Neff. Deps. of Psychiatry, Pharmacology and The Neuroscience Program. The Ohio State University College of Medicine. Columbus, Ohio 43210

Although the mechanism(s) of action of GM1 ganglioside is unresolved, it has been postulated that it might enhance the action of endogenous trophic factors by augmenting their synthesis and/or release, and by altering trophic factor receptor characteristics. We now provide evidence that GM1 has a synergistic action with NFG in the brain of old animals. Chronic intracerebroventricular administration of GM1 increases choline (Ch) uptake and choline acetyltransferase (ChAT) activity in the striatum and hippocampus of old rats. When a low ineffective dose of GM1 (0.5 mg/kg for 4 wks) is co-administered with various doses of NFG (0.2, 0.5 and 1 pg/day for 4 wks) we observe an enhancement of the GM1 effect on Ch uptake and ChAT activity. Our results are consistent with apparent potentiation by GM1 of the effect of NFG on cholinergic parameters in aged animals.
697.4 METAL-CATALYZED OXIDATION OF BOVINE NEUROFILAMENTS (NF) IN VITRO. JG Trapp*, JH Kim*, AC Costello*, and GWW Johnson. Departments of Pathology and Neurology, Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD; *University of Alabama, Birmingham, AL.

NF are important determinants of the shape and size of nerve cells. The oxidation of NF, potentially relevant to aging, neurodegenerative disorders, and Wallerian degeneration, has not been studied. In this investigation, we combined biochemical and ultrastructural methods to study the metal-catalyzed oxidation (MCO) of bovine NF using an associatedFe(III)-O2• system. The oxidation parameters are being determined by significant increases in carbonyl content, which were time and concentration dependent. Polyacrylamide gel electrophoresis and immunoblot analyses revealed fragmentation of oxidized NF proteins, predominantly NF-H and NF-M. Electron microscopy showed that oxidized NF formed dense aggregates and bundles of laterally aggregated filaments. Finally, we also demonstrated that oxidized NF proteins were more susceptible to catalytic proteolysis. In view of the growing evidence to support increased oxidative damage as a factor in aging, the mechanism by which metal-catalyzed oxidation of NF causes aggregation or fragmentation remains to be elucidated.

697.5 CYTOSTATIC-INDUCED ASTROCYTE HYPOXIA: ROLE OF PEROXISOME PROLIFERATOR-ACCTIVATING RECEPTOR-RELATED DEPENDENT-RELATED DEPENDENT MEDIATORS. E.A. Bloemendaal, J.E. De Vrije, J.A. van den Bosch, J.M. Mork, and E.M. Schipper, Dept. of Neurology and Neurosurgery, Maastricht Univ., Maastricht, The Netherlands, and Aging, Jewish General Hospital, Montreal, QC, Canada, H3T 1E2.

Background: Compound, cytostatically (CSH), induces gliosis in situ and the appearance of peroxidase-positive (dys)regulation in the cultured astroglia. Gliosis identical to gial inclusions which progressively accumulate and are evident in the cells. In addition, CSH-treatment protects cultured astroglial from subsequent H2O2 and mechanism-stress activation. Objective: To determine whether changes in antioxidant defense system are present in CSH-treated astrocytes. Methods: and Results: CSH treatment (880 μM) induced a 5-fold increase in glutathione (GSH) concentrations and a persistent augmentation of manganese superoxide dismutase (MnSOD) activity in cultured astrocytes. In contrast, astroglial catalase and increase activities redox state in oxidative stress. Lipid peroxidation was suppressed by CSH treatment while copper-zinc superoxide dismutase activity remained unchanged. Glutathione peroxidase activity was increased after CSH-treatment and declined thereafter to below control levels. Conclusions: Elevations in intracellular GSH concentrations and sustained augmentation of MnSOD activity may be responsible for astrococyte hypoxia. CSH exposure to CSH-treated astrocytes may serve as a useful model for stress-related (Idiopathic) and other oxidative stress in aged. In the latter, astrocyte hypoxia may facilitate the establishment of reactive gliosis in the face of concomitant neuronal depletion.

The aim of this study was to explore if paranodal axon Schwann cell networks (ASCNs), which are entities assumed to take part in removal and degradation of worn-out organelles in large myelinated PNS axons, can serve as deposits for indigestible materials with aging. We addressed this issue by examining the occurrence of autofluorescent lipopigments in large myelinated motor and sensory axons of rats aged 2-25 months. After fixation with 4% paraformaldehyde, 10 µm thick longitudinal sections were cut from the lumbar ventral (VR) and dorsal (DR) roots and examined with a Zeiss fluorescence microscope equipped with phase-contrast optics and a FITC filter set. From each root, 200 randomly selected selected paranode regions in nerve fibres 8-12 µm in diameter were searched for autofluorescent granules. Orange-yellow granules situated in close apposition to the paranodes in small paranodes was observed in both VR and DR axons from 3-4 months of age. Both the percentage of paranodal regions of this type and the number of granules increased with age. Up to 1 year of age, VR axons showed the highest granular contents. From this age, >90% of the paranodes in both the VR and DR showed autofluorescent granules. Some paranodes in the oldest animals contained >15 granules, which generally appeared in clumps and often were of larger sizes in VR than DR axons. In both axon types, the vast majority of the granules were situated distal to the nodal mid-level. EM analysis showed that most granules were lipofuscin bodies associated with ASCNs. The progressive age-related accumulation of indigestible materials within ASCNs may serve a function to shield the aging perikarya mainly of motor neurons from being crammed with retrogradely transported worn-out organelles from the axon.

697.10 REGRESSIVE CHANGES IN STEROID ACCUMULATION IN AGING ANDROGEN-SENSITIVE RAT SPINAL NUCLEI. M.R. Wildes, A.P. Fine and D.P. Sengupta*. Program in Neural Science, Indiana University, Bloomington, IN 47405.

Neurons in the rat spinal nucleus of the bulbocavernosus (SNB) are sensitive to androgens throughout life. Androgen titers decline with normal aging in most mammals and are coincident with concomitant regressive changes in SNB dendritic length, soma size, and target muscle weight. Using steroid autoradiography, we determined whether regressive changes in the ability of these neurons to accumulate steroids might also occur in aging.

Male rats (12, 19 and 25 months old; n=4 per age) were castrated 48 hours prior to injection with total testosterone (1.5 g/kg body weight) and killed 1.5 hours later. Accumulation was assessed in the steroid sensitive, sexually dimorphic SNB and dorsolateral nucleus (DLN), as well as in the non-sexually dimorphic retrotrapezoid nucleus (RTN) from each rat (at least 50 cells per nucleus). The number of SNB and DLN motoneurons reaching criteria (Poisson) was reduced by as much as 21% at 25 months, while no changes were observed in RTN. The density of labeling also declined with age in all motor nuclei and was particularly pronounced in the SNB. At 12 months of age, 55% of SNB motoneurons were labeled at more than 8 times background levels, but less than 30% were labeled at this density by 25 months. Thus, declines in androgen accumulation by steroid-sensitive motoneurons reflect age-related changes in circulating androgen titers. Regressive changes in motoneuron morphology could result from a reduced ability of androgen to act directly on these motoneurons. (Supported by NIH AG02909)}

TWO LOCi ENCODE SNAP-25 IN ZEBRAFISH AND GOLDFISH.
C. Riesinger, E. Salamek, and D. Larhammar. Dept of Medical Genetics, Box 365, Uppsala University, S-751 23 Uppsala, Sweden.

SNAP-25 (synaptosome-associated protein of 25 KDa) is a presynaptic protein involved in vesicle docking and release (Sümer et al., Nature 365, 1993), as well as neurite extension (Oan-Sand et al., Nature 364, 1993). We have previously shown that SNAP-25 has retained highly conserved from mammals to Drosophila (Riesinger et al., JBC 268, 1993). We initially isolated cDNA clones for SNAP-25 from goldfish because we intended to study the roles of this protein model systems in the regulation of nervous system of this species. Although SNAP-25 is evolutionarily conserved we discovered sequence variability within the goldfish. This was unexpected, but similar to the situation in Drosophila: a gene duplication early in fish evolution, leading to SNAPA and SNAPB, followed by the tetraploidization 15-20 My ago (Riesinger and Larhammar, PNAS 90, 1993). However, we found no homologues of SNAPA and SNAPB, which is less appropriate for molecular genetic studies. Instead, the closely related diploid species provides an excellent system for an comprehensive study of the functions of SNAPA and SNAPB. The predicted protein sequences are highly similar between zebrafish, goldfish, and rainbowfish. Similarly, between zebrafish and mammals. Interestingly, the zebrafish clones reveal two alternative splicing variants of exon 5. The existence of these two variants have previously been shown for chicken (Bark, JMB 233, 1993) and humans (Bark and Wilson, Gene 139, 1994). The expression of SNAPA and SNAPB and the alternatively spliced exons will be studied in zebrafish.

698.2

THE MAMMALIAN SEC1P-HOMOLOGUE IS A CHROMAFFIN GRANULE-BINDING PROTEIN. T. Schaefer, A. Hodel, C. Haus, A. Matus and M. B. Burren. Friedrich Miescher-Institute, PO Box 2543, CH-4002 Basel, Switzerland.

Membrane proteins of the synaptic vesicle and the presynaptic plasma membrane together with soluble proteins form a secretory fusion complex conserved from yeast to neurones (Niswander et al., Cell 92, 318-324). We have localized three of these membrane proteins in chromaffin cells, which secrete catecholamines stored in granules. Synaptins (1A and 1B) and SNAP-25 are found in a plasma-membrane-containing fraction, whereas VAMP/synaptobrevin is concentrated on the granules. Recombinant synaptin 1A has been used in an affinity chromatography assay to isolate synaptotagmin, a receptor protein of the type 2 aminophospholipid translocase. Solubilized granule membranes contained a single protein with high affinity for synaptin 1A, the mammalian homologue of Sec1p, mSec1 (Hodel et al., J Biol Chem. 269, 8623-8635). In yeast, this hydrophilic protein acts late in the secretory process. Genetic suppressor analyses predicted the interaction of Sec1p with Sec21, a yeast homologue of synaptin 1A, and with Sec9, a homologue of rab3A (Aalto et al. (1993) EMBO J. 12, 4095-4104). Although rab3A is present on chromaffin granules, we did not detect it bound to synaptin 1A together with mSec1. Western blot analysis of subcellular fractions revealed three pools of mSec1 in chromaffin cells: on plasma membrane vesicles, in the cytosolic protein fraction, and on the chromaffin granule membranes. mSec1 can be detached from this latter by high salt treatment. It binds back to its receptor upon addition to granules at physiological salt concentrations. The characterization of both the attachment of mSec1 to the granule and its binding to synaptin 1A should be interesting for the interpretation of neurotransmitter vesicles with the plasma membrane in docking and fusion.

698.3

UNIFORM QUANTAL RELEASE MAY BE REGULATED BY THE SYNAPSE-SPECIFIC CLATHRIN ASSEMBLY PROTEIN F1-20/AP-3.
W. Ye and E.M. Leter.* Dept. of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, and Institute of Biotechnology, University of Tennessee Space Center, Huntsville, TN, USA.

We reported the characterization and cloning of the synapse-specific phosphoprotein F1-20. We overexpressed F1-20 and, reported that F1-20 is the clathrin assembly protein. At presynaptic terminal, clathrin mediated endocytosis is involved in the biogenesis and recycling of synaptic vesicles. Here we characterized the ability of bacterially expressed F1-20/AP-3 to bind to and assemble clathrin coated vesicles. We find that bacterially expressed F1-20/AP-3 can bind and assemble clathrin as efficiently as preparations from the bovine brain. This establishes that the clathrin assembly activity found in F1-20/AP-3 preparations from brain extracts is indeed encoded by the cloned gene for F1-20. We also demonstrate that post-translational modification is not required for activation of the clathrin binding or assembly function of F1-20/AP-3. Ultrastructural analyses of the clathrin cages assembled by bacterially expressed F1-20/AP-3 reveals a strikingly narrow size distribution. Because mature synaptic vesicles are derived from precursors in coated vesicles, we hypothesize that an important function of the synapse-specific clathrin assembly protein F1-20/AP-3 is to limit the range of vesicle sizes, and therefore increase the uniformity of quanta release. We also expressed the 33 KD NHE-terminus of F1-20/AP-3 in E. coli, and measured its ability to bind and assemble clathrin. We find that the 33 KD NHE-terminus of F1-20/AP-3 constitutes a clathrin binding domain. We found that while the bacterially expressed 33 KD NHE-terminus of F1-20/AP-3 binds to clathrin triskelia, it fails to bind to preassembled clathrin cages and is not sufficient for clathrin assembly.

698.4

CELLULAR AND SUBCELLULAR LOCALIZATION OF SYNTAXIN IMMUNOREACTIVITY IN THE RAT CORTICAL AND STRIATUM.
S.R. Sesack* and C. L. Snyder. Departments of Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

Syntaxin is a membrane protein that concentrates in axon terminals and may participate in synaptic vesicle docking prior to Ca2+-mediated fusion events. We sought to characterize the cellular and subcellular distribution of immunoreactivity for syntaxin in the rat forebrain using both an antibody directed against a bacterially expressed syntaxin protein (Bennett et al., Science, 257:255) and a monoclonal antibody against the identical membrane-derived protein, HPC-1 (Barnstable et al., Dev. Brain Res., 20:286). Whether labeled by immunoprecipitation or from brain ultrathin sections, HPC-1 proteins were localized exclusively to axons and terminal varicosities in the rat dorsolateral striatum and frontal cortex. Immunoeactive terminals made exclusively asymmetric synapses, primarily on dendritic spines, while unlabeled terminals in the adjacent neuropil made either symmetric or asymmetric synapses on somadendritic targets. Immunogold labeling for syntaxin or HPC-1 was localized primarily to non-synaptic regions of the plasma membrane. These results suggest that the syntaxin immunoreactive synapse is an integral membrane component of a transmitter vesicle protein localized to a subpopulation of forebrain terminals that use excitatory amino acids as neurotransmitters. The apparent exclusion of syntaxin immunorelabeling from the presynaptic active zone must be considered in light of potential limitations in antibody penetration or epitope recognition at junctional specializations. Conversely, the non-synaptic localization of syntaxin implies that its functional role may not be limited to synaptic vesicle docking. This work was supported by USPHS grant MH50314.

Synaptic vesicle (SV) docking is thought to be mediated by the binding of two SV proteins, VAMP and synaptotagmin, to two plasma membrane proteins, syntaxin and SNAP-25. We have identified n-sect, 1, a soluble neural-specific 68 kDa protein, and demonstrated its high-affinity binding to syntaxin (Kc17, 7 mM). This recombinant n-sect binds syntaxin in a complex distinct from the docked SV complex, based upon immunoprecipitation and glycerol gradient centrifugation studies. N-sect binds VAMP and SNAP-25, so leading to syntaxin immobilized on agarose beads. In the absence of n-sect, VAMP binds the syntaxin 1 and 4 (but not 2 and 3) isoforms. This VAMP binding to syntaxin 1 (but not syntaxin 4) is potentiated ten-fold in the presence of SNAP-25, suggesting a mechanism for achieving both specificity and high affinity binding of VAMP-containing SVs to the appropriate syntaxin target membrane. The proposed pathway of SV docking and fusion includes the displacement of synaptotagmin by the soluble protein tSNAP, and subsequent binding of NSF to syntaxin, SNAP-25, and VAMP. We have exploited this pathway with recombinant proteins binding to immobilized syntaxin.

DIFFERENTIAL RESPONSES OF PROTEIN KINASE C SUBSTRATES (MARKS, NEUROMODULIN, AND NEUROCRANIN) PHOSPHORYLATION TO CALMODULIN AND S100: E.-S. Shen, F.L. Huang and K.-P. Huang, NIH, Bethesda, MD 20892.

Phosphorylation of three physiological substrates of protein kinase C (PKC), MARKs, neuregulomin (Nm), and neuregulin (Ng), present in a mixture were analyzed to determine their relative efficiencies as substrates of PKC α, β, γ and δ and relative sensitivities to inhibition by calmodulin (CaM) and S100. The rationale for these experiments was to mimic the in vivo condition where these substrates and inhibitor proteins co-exist. In addition, since PKC and these substrates are all phospholipid-binding proteins, the presence of all these components and phospholipids in the same reaction mixture may create an environment to allow selectivity for each PKC isotype. Based on the kinetically sensitive Be-1,2 and Xα, the phosphorylation of each individual substrate, we estimated the order of efficacy as PKC substrate was MARKS< Nm< Ng. The rates of PKC α-catalyzed phosphorylation of Nm and Ng in a mixture containing MARKS was significantly reduced as compared to that phosphorylated individually by this isotype, compared at a higher level of MARKS. Although phosphorylation of MARKS, Nm, and Ng individually by PKC is known to be inhibited by CaM, when present in a mixture, both CaM and S100 preferentially inhibited MARKS phosphorylation over those of Nm and Ng. Protein-activated catastrophic fragment of PKC (PKM) was used to determine the effect of CaM on the CaM- and S100-modulated inhibition of PKC substrate phosphorylation. CaM and S100 inhibited the PKM-catalyzed phosphorylation of MARKS only in the presence of CaM while phosphorylation of Nm and Ng by PKM were inhibited more prominently by CaM in the absence than in the presence of CaM, StO10 was relatively ineffective in inhibiting the phosphorylation of these two substrates even in the presence of CaM. The results presented here demonstrate that MARKS is likely the most preferred substrate of PKC in the brain and its phosphorylation by PKC is most sensitive to inhibition by CaM and S100.

Purified small synaptic vesicles possess a form of Ca<sup>2+</sup>-calmodulin-dependent protein kinase II (CaMKII) which activates, as does the cytosolic form of CaMKII, most of the Ca<sup>2+</sup> sensitive activities. The interaction between synaptic-associated CaMKII and the synaptic vesicle membrane was studied using specific CaMKII affinity labeling. Purified synaptic vesicles were labeled with 3-(trifluoromethyl)-3-(methylypropyl)imidazoline ([<sup>3</sup>H]-TIM). Upon photolysis, synapsize-associated CaMKII was labeled, suggesting that part of the CaMKII is embedded in the lipid bilayer. The results of this work evidenced the presence of the CaMKII active site in the interaction. We performed liposome binding studies to determine if purified soluble CaMKII II could bind to liposomes, using a sedimentation assay. We found that soluble CaMKII II bound to sucrose-loaded liposomes and that the binding was dependent upon the presence in the liposome membrane of anionic lipids, such as phosphatidylserines. Binding of CaMKII II to liposomes was also dependent on salt concentration. We examined that CaMKII II contributes to the interaction. Soluble CaMKII II bound to liposomes was also labeled using [<sup>3</sup>H]-TIM, indicating that some portion of the protein may be embedded in the membrane. This finding provides new insight to the participation of CaMKII in nerve cell signalling.

A ROLE OF NITRIC OXIDE IN GANGLIONIC TRANSMISSION OF RAT SUPERIOR CERVICAL GANGLIA. H. Tang and N. J. Dun. Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43614

Immunoreactivity to nitric oxide synthase (NOS-I) was localized to nerve fibers opposing the majority of rat superior cervical ganglion (SCG) neurons. NOS-I was either too low to be detected or absent in the postganglionic neurons. The hypothesis that nitric oxide (NO) may modulate synaptic transmission in SCG neurons was examined by evaluating the effects of agents that elevate tissue NO levels on synaptic responses and on depolarizations induced by pressure application of acetylcholine (ACh). Intracellular recordings were made from neurons in isolated rat SCG. Superfusion of L-arginine (10-300 μM) dose-dependently increased the amplitude of excitatory postsynaptic potentials (EPSPs) evoked by stimulation of cervical sympathetic trunk in approximately 50% of ganglion cells studied. The membrane depolarization induced by pressure application of ACh was also increased in some but not in all ganglion cells. D-arginine in comparable conc. caused no significant change of the EPSPs. Sodium nitroprusside (10-300 μM) reversibly increased the EPSPs in a concentration dependent manner. The present study shows that NO-immunoreactivity is present in nerve fibers presynaptic to postganglionic neurons and in SIF-like cells and that NO when released from these neural elements may potentiate synaptic transmission. (Supported by NS18710 & NS24226)

699.3

Previous results suggest that CGMP is involved in long-term potentiation (LTP) in the CA1 region of hippocampal slices, perhaps as the presynaptic modulator of a retrograde messenger (Zhou et al., 1994). Consistent with this idea, the membrane-permeable analog 8-BrcGMP also produces activity-dependent long-lasting potentiation of evoked postsynaptic currents (EPSCs) in dissociated cultures of hippocampal neurons (Arancio et al., 1993). This potentiation is paralleled by a decrease in the coefficient of variation and an increase in the frequency but not the amplitude of spontaneous miniature EPSCs, suggesting that CGMP acts presynaptically. However, a postsynaptic increase in LTP might indirectly produce presynaptic effects. To attempt to distinguish between these possibilities, we injected substances directly into the pre- or postsynaptic neuron. Injection of CGMP into the presynaptic cell paired with weak presynaptic activity produced a long-lasting increase in the amplitude of the EPSC. CGMP alone or vehicle either did not affect LTP or paired with activity produced no potentiation. Injection of CGMP into the postsynaptic cell paired with presynaptic activity also did not produce potentiation. Similarly, post-synaptic CGMP did not cause any increase in the amplitude or the frequency of spontaneous miniature EPSCs. In preliminary experiments, injection of the membrane-permeable guanyl cyclic nucleus inhibitor LY83583 into either cell block the induction of long-term potentiation by repeated tetanic stimulation. These results demonstrate that a presynaptic increase in cGMP produces activity-dependent long-lasting potentiation that may contribute to LTP.

SPERMINE AFFECTS NEUROTTRANSMISSION IN SLICES OF STRIATUM AND HIPPOCAMPUS: EFFECT OF CALCIUM. P.A. Ferchmin; D'Souza, P.G.; E.M. Rivera; Vesna A. Eterovic and T.J. Teyle. Center for Molecular and Behavioral Neuroscience, Department of Biochemistry, Univ. C. del Caribe, Bayamon, PR 00960 and Department of Neurobiology, College of Medicine, Northeastern Ohio Universities, Rootstown, OH 44272

Spermine inhibited neurotransmission in slices from rat striatum and hippocampus. In the latter, spermine increased paired-pulse facilitation of stratum pyramidal neurons to a lesser extent in a. radiation of the CA1 area. A similar pattern was observed in the presence of ω-conotoxin (ω-CTX), a blocker of voltage-sensitive Ca++ channels (VSCC). In addition, a decreased Ca++ concentration in the perfusing solution also increased paired-pulse facilitation. Spermine effect was larger at 1 mM Ca++ than at 2 mM and was almost nil at 3 mM Ca++. Addition of APV, an NMDA antagonist, did not interfere with spermine effect on paired-pulse facilitation. These results support the hypothesis that spermine is an endogenous neuromodulator that decreases the release of neurotransmitters by blocking presynaptic VSCC and perhaps also by blocking VSCC on dendrites and soma of pyramidal cells. Many, but not all, glutamate terminals express a high affinity, Na+-dependent transporter for L-proline. Proline may play a role in synaptic transmission at these sites. This idea was tested by recording Schaffer collateral-commissural synaptic potentials extracellularly in area CA1 during superfusion of hippocampal slices with proline. Two concentrations of proline were used: a concentration typical of normal CSF (3 μM) and a concentration present in CSF of persons with hyperprolinemia type II (30 μM). Neither proline concentration altered synaptic transmission when testing was performed 15 min after its addition to the superfusion medium. However, both concentrations enhanced synaptic transmission when they were continuously present in the medium from the time of slice preparation, as indicated by a statistically significant upward shift in the slope of field EPSP slope against fiber volley amplitude. In another series of experiments, proline was added to control medium and the field EPSP was recorded for the next 4 h. In the presence of proline, EPSP slope began to increase in about 40 min and reached a plateau in 80-90 min. The plateau values of EPSP slope were 24 ± 9% and 35 ± 10% greater than baseline for 3 and 30 μM proline, respectively. In contrast, EPSP slope in control slices declined by 8 ± 10%.

These results suggest that concentrations of proline normally present in CSF enhance transmission at the Schaffer collateral-commisssural synapse. The presynaptic proline transporter may serve to regulate this process. Finally, the childhood seizures associated with hyperprolinemia type II may result from excessive facilitation of glutamate transmission.
PRESYNAPTIC INHIBITION OF INHIBITORY SYNAPTIC TRANSMISSION MEDIATED BY METABOTROPIC GLUTAMATE RECEPTORS IN MONOSYNAPTICALLY ISOLATED PAIRS OF CULTURED HIPPOCAMPAL NEURONS. R. Makl* and M.A. Dichter.1,2 David Mahoney Institute of Neurological Sciences, 1Dept. of Neurology and Pharmacology, University of Pennsylvania School of Medicine and Graduate Hospital, Philadelphia, PA 19104.

Whole-cell patch clamp recordings were performed to elucidate the effects of the metabotropic glutamate receptor (mGluR) agonist ACPD and the recently described mGluR antagonist 3-phenyl-4(carboxamido)cyclohexylglycine (MCPC) on inhibitory synaptic transmission in low density cultures of hippocampal neurons. Application of ACPD (100 µM) resulted in a reversible decrease in the amplitude of IPSCs (33.6±4.2% of control, n=200 ± 50 mM) completely reversed the effects of ACPD (n=7), MCPC alone had no effect on IPSC amplitude. Examination of miniature IPSCs (mIPSCs) indicated that changes in 0-mM pipette RMP decreased the mGluR agonist sensitivity did not account for the decrease in evoked IPSC amplitudes; therefore, inhibition of the IPSCs was due to a presynaptic mechanism. Application of D-APV (50-250 µM) led to a decrease in 8 out of 13 pairs tested; these 8 inhibitory pairs also exhibited an increase in baseline NMDA-receptor mediated noise, indicating an increase in the ambient concentration of AMPA receptor receptors. The partial agonist of L-glutamate, AP4 (Makl, Robinson, Dichter, J Neurosci, in press) we concluded that 1) all inhibitory neurons in our very low density cultures express functional mGluRs responsive to ACPD, and 2) inhibition of transmission is increased in ambient Glutamate concentration, and that this occurs only in the cases where there was a source for Glutamate. Modulation of the activation of presynaptic autoreceptors by increased ambient Glutamate concentration. The present study indicates that there is an enhancement of inhibitory synaptic transmission in the CNS. Supported by GM-34781 (MAJ) and AG-12305-01 (RM).

We previously reported that there is a large population of inhibitory receptors present on cultured rat embryonic neurons, that activated only by glycine or GABA or by either one (Neurosci. 52:83-96, 1993). Also, whole-cell current responses to bath-applied agonist have both desensitizing and nondesensitizing components, with the former being more sensitive to block by antagonists.

To determine which of these postsynaptic receptors are involved in inhibitory synaptic transmission, cultures of EPSPs (EPSPs) and MPSCs (MPSCs) were digitized at 20 Hz and analyzed using a peak detection program (Aoki, N., et al. Neurosci. Meth., in press), which calculates the peak amplitude and an exponential decay time constant (τ) for each event. Amplitude and τ were skewed, and grouped data showed no discernible peaks. The effects of different antagonists on the amplitude distributions were complex and did not provide insights concerning the involved inhibitory receptors. On the other hand, the decay distributions were consistently best fit by the sum of four Gaussian distributions (i.e. τ = 8.31 ± 0.96 s, τ = 16.5 ± 2.8 s, τ = 25.9 ± 2.3 s (n = 22) and τ = 49.3 ± 6.8 s (n = 25) ms). These 4 classes of decay times have different pharmacological sensitivities to antagonists. The results of experiments using different concentrations of strychnine and bicuculline lead to the following conclusions: τ1 is mediated by the nondesensitizing GABA-A, τ2 by the desensitizing GlyR, γ1 and γ2 by the desensitizing Gly/GABAR. However, since all four decay components are seen in cell-attached patches that exhibit MPSCs, it is possible the responses are generated by one receptor with complex binding affinities and sensitivities to block by antagonists.

Chick VIIIth nerve fibers form somatic synapses in the nucleus magnocellularis and generate large EPSCs. A previous study of brain slices showed that the neurotransmitter, presumably glutamate, activates and then desensitizes AMPA receptors (Trussell et al., Neurosc. 10:1185). The kinetics of glutamate and kainate responses in these cells are voltage dependent (see abstract by Otis, Raman, & Trussell, this meeting). We examined changes in the time course of the EPSC with postsynaptic potential to see whether voltage-sensitivity might reveal additional information about the transmitter’s lifetime and receptor desensitization. The decay of the AMPA receptor EPSC could be described by two exponentials, of 0.7-1 ms and 6-14 ms. With depolarization from -65 to +125 mV, both components slightly lengthened, but the relative magnitude of the slow component increased 5-fold, resulting a marked overall slowing of the EPSC. Such a large slow component could not be explained by a long channel burst duration or desensitization time course. The increase with depolarization in the magnitude of the slow phase is consistent with an increased receptor affinity. We propose that there is a prolonged phase of transmitter removal from the synaptic cleft. Synaptic depression, monitored with EPSC pairs, was reduced at positive holding potentials. Since receptor desensitization is reduced by depolarization, depression may in part result from desensitization, a consequence of the slow clearance of transmitter.

699.16

Basal forebrain neurons, which form the main cholinergic projection to cortical and subcortical regions of mammalian brain, receive afferents from both the sympathetic and parasympathetic nervous systems. In the present study, a thin-slice preparation was used to study the postsynaptic currents of basal forebrain neurons. Cortical sections (200 μm) were prepared from 10-14 day-old rat pups, incorporated into horizontal slices of the diagonal band of Broca and substantia innominata. Whole-cell recordings were made from visually identified magnocellular neurons, using a potassium acetate-based internal solution. Neurons with diameter > 20 μm were selected, as they stained positive with acetylcholinesterase histochemistry, and thus were considered to be cholinergic. In most cells, spontaneous synaptic responses could be recorded, displaying sensitivity to either bicuculline (8 μM) or 2-cyano-γ-4-nitrophenyl 2,3-dione (CNQX). These events were not readily blocked by tetrodotoxin (TTX). Following bilateral stimulation within a 50-100 μm radius of the recorded cell synaptic responses, both CNQX- and bicuculline-sensitive evoked responses could be recorded. The mean time constant for decay (r) for CNQX-sensitive spikes was approximately 3.03 ± 0.31 ms and was 27.5 ± 2.4 ms for bicuculline spikes (as measured at 20-23°C). Carbachol (CC): 0.3-1 μM reduced r in an amplitude dependent manner. In addition to reducing the amplitude of these postsynaptic events, inhibition by CCh was frequently observed as failures of synaptic events. In summary, spontaneous synaptic events have been preserved in thin-slice preparations and that excitatory and inhibitory afferents to the magnocellular cholinergic basal forebrain express presynaptic muscarinic receptors. SYNAPTIC CONNECTIONS BETWEEN CELL PAIRS IN RAT HIPPOCAMAL SLICE CULTURES.
D. DEBANNE*, N.C. QUEIRENO, B.H. GAHWILER and S.M. THOMPSON
Brain Research Institute, University of Zurich, 8092 Zurich Switzerland
Pairs of individual neurons were recorded in rat hippocampal slice cultures with
sharp electrodes or in whole-cell configuration. Unitary synaptic
connections were studied between pre- and postsynaptic cells in CA3
and CA1 hippocampal fields by eliciting single action potentials in the
presynaptic cell. Monosynaptic excitatory connections were highly probable
between CA3 and CA1 pyramidal cells (p=0.96, n=125) with almost no feed-
forward inhibition (p=0.024). By contrast, disynaptic IPSPs, blocked by
CNQX or bicuculline, were observed with a very high probability (p=0.43)
between CA3 pyramidal cells. Monosynaptic excitation was found in 56% of
cases between CA3 and CA1 cells (n=91) but only between 26% of CA1 pyra-
midal cell pairs (n=25). AMPA- and NMDA-components of EPSPS could be
identified pharmacologically at both CA3/CA1 and CA1/CA1 cell synapses,
with kinetics similar to those seen with extracellular stimulation. Single
action potentials evoked in interneurons resulted in monosynaptic, bicuculline
sensitive IPSPS only in pyramidal cells within the same region. Paired-pulse
facilitation of unitary EPSPS and paired-pulse depression of unitary IPSPS,
were observed. Probability of transmitter release, studied in recordings
where failures could be unambiguously distinguished from spontaneous or small
PSWs, was found to be close to 100% at both excitatory and inhibitory
synapses. Bath application of the inhibitor of glutamate release, alenosine,
reduced the amplitude of unitary EPSPS in a graded manner, indicating
that the release at excitatory synapses is multiquantal.

CHARACTERIZATION OF INTRACELLULAR CALCIUM OSCILLATION IN RAT HIPPOCAMAL NEURONS IN THE PRESENCE OF MAGNESIUM IONS. T. TANAKA*, H. SATO, and
N. MATSUKI. Dept. of Chem. Pharmacol., Fac. of Pharmac. Sci., Univ. of
Tokyo, Tokyo 113, Tokyo
It is widely known that the embryonic neurons can develop
morphologically and functionally in culture and form the synaptic
network. In Mg²⁺-depleted condition the cultured neurons show
spontaneous and periodical oscillations of intracellular Ca²⁺
concentration ([Ca²⁺]), which are synchronized among the cells. In the present study the spontaneous oscillatory changes of [Ca²⁺], were observed even in the
presence of physiological concentration of magnesium and characterized pharmacologically. The hippocampal cells from embryonic day 18 rats
were cultured for 10-15 days and changes in [Ca²⁺] of single cells were
measured by a microfluometric technique with fura-2. The spontaneous
oscillation was blocked completely by application of 1 μM tetrodotoxin.
CNQX (10 μM) and nicardpine (10 μM) blocked the oscillation completely while APV showed only a partial depression of the increase in [Ca²⁺]. This contracts with the results in Mg²⁺-free condition, in which either APV or CNQX alone inhibits the oscillation completely. The inhibitory neurotransmitter GABA (10 μM) suppressed the spontaneous oscillation, whereas bicuculline (3 μ M), a GABAₐ antagonist, slightly
enhanced the amplitude. Basic fibroblast growth factor (bFGF) also had
depressant effect on the oscillation, and this effect was encountered by
suramin. These results suggest that excitatory and inhibitory transmission
is involved in the formation and maintenance of the intracellular Ca²⁺
oscillation.

700.1
GABA-MEDIATED OUTWARD CURRENTS IN HERMISIDENM PHOTOCEPTEOR'S. E. YUZENGA* and A. KUZING. Marine Biological Laboratory,
Woods Hole, MA 02543.
GABA is the only inhibitory neurotransmitter at the mechanonervous-hair cell-photoreceptor
synapse in Hermisenda. In addition, GABA induces a transient rise in intracellular Ca²⁺.
It has been proposed that such induction may play a role in plasticity in Hermisenda. Here we report GABA-induced outward currents in photoreceptors of Hermisenda using
whole-cell patch-clamp technique. Individual photoreceptors were isolated as previously described. Inward Na⁺ and Ca²⁺ currents were minimized by substitution of Na⁺ with
epholine and using low external Ca²⁺ (1 mM). Outward K⁺ currents were blocked by
3 mM 4-aminopyridine and 100 mM tetraethylammonium. BAPTA (10 mM) was added to the
internal solution to block Ca²⁺. Under these conditions, inward or outward currents
were recorded. However, an outward current could be recorded upon the application of
10 μM GABA (figs.1 & b). Desensitization to GABA occurred after prolonged exposure.
Current was blocked by bicuculline (100 μM), a known blocker of GABA receptor. The
properties of the GABA mediated outward current was consistent with those of Ca²⁺ current:
(1) The current magnitude and the estimated reversal potential were altered
dependent on the external and internal CI concentrations. (2) The current was reduced by
D(GABA (100 μM), a known blocker of CI current. The inhibitory post synaptic potential at
the hair cell-photoreceptor synapses may be mediated by the CI current.

700.2
IDENTIFICATION AND CHARACTERIZATION OF PROTEIN TYROSINE PHOSPHATASES AT THE NEUROMUSCULAR JUNCTION. I. MEL TED K.L. HAGAN. Department of Neuroscience, HSUM, Johns Hopkins University
School of Medicine, Baltimore, MD 21205.
Protein tyrosine phosphorylation is prevalent throughout the nervous system
suggesting that it may be involved in the regulation of neuronal function. The
phosphorylation of proteins is regulated by the balance of protein kinases and
protein phosphatases. Although protein tyrosine kinases in the brain have been
demonstrated, much less is known about neuronal protein tyrosine phosphatases.
We have been using the neuromuscular junction as a model to study the role
of protein tyrosine phosphatases in the regulation of synaptic transmission and
plasticity. Twelve individual protein tyrosine phosphatases were isolated from
the rat skeletal muscle based on the consensus sequence of previously characterized
tyrosine phosphatases, including three novel ones. Previously we have shown that
PTP-1D, a cytoplasmic phosphatase containing two SH2 domains, appeared to be
abundant in the brain and muscle at the mRNA level and its phosphatase activity
was down-regulated by a four amino acid insert generated by RNA splicing. Using
affinity-purified antibodies, PTP-1D was identified as a 68-kDa protein most
abundant in the brain and heart, moderate in the skeletal muscle, lung, and liver,
least in the kidney. Its expression in the brain appeared to increase continually
during the development; from barely detectable in embryonic day 10 to maximal
on postnatal day 60. The catalytic domain of PTP-1D could be phosphorylated by
protein kinase C but not by CAMP-dependent kinase. Phosphoamino acid analyses
indicated that PTP-1D phosphorylation of PTP-1D was on serine residues. GST
fusion proteins containing SH2 domains of PTP-1D were made to study its interaction
with other proteins. The SH2 domains were found to bind to several
tyrosine-phosphorylated proteins in vitro, including nicotinic acetylcholine
receptors in the skeletal muscle. Studies are under way to investigate the effects
of PKC phosphorylation of PTP-1D on the phosphatase activity and to identify
the proteins that interact with PTP-1D.
ACTIVATION OF A CATIONIC CONDUCTANCE BY METABOTROPIC GLUTAMATERGIC AND MUSCARINIC AGONISTS IN CA3 CELLS IN HIPPOCAMAL SLICE CULTURES.
X.C. Gattas* et al., Brain Research Institute, University of Zurich, CH-8092 Zurich, Switzerland

An increase in a membrane cationic conductance in response to metabotropic glutamatergic or muscarinic agonists was characterized in CA3 pyramidal neurons using single-channel technique. Experimental conditions were chosen to block Na+ currents (1 mM TTX), Ca2+ currents (0.4 mM Cd2+), and K+ currents (internal Ca2+ instead of K+). Records were produced at room temperature.

In symmetrical HCl solutions, depolarizing pulses applied from a holding potential of -70 mV evoked inward currents between -40 and 0 mV (peak amplitude -400 - 600 pA at -20 mV) and became outward at positive command potentials (up to 100 mV), displaying a prominent Na+ reversal potential. Upon repolarization to -70 mV, I_Na slowly decayed producing a prominent inward tail current (v = 40 - 60 mV). At a given potential, the time constant of tail current decay was independent of prepulse potential. In contrast, when repolarization potentials were varied along the voltage axis (-120 to -60 mV) after a prepulse to 30 mV, deactivation kinetics of I_Na showed a strong voltage dependence, the decay time constant substantially increasing with depolarization.

In conclusion, experiments revealed that the channel producing I_Na was permeable to a number of monovalent cations including K+, Ca2+, Na+, and choline, but not to the anions Cl-. I_Na was reduced by TEA at high concentrations (15 mM), but not by 4-AP, and proved to be insensitive to cation channel blockers such as Cs+, amiloride, or gadolinium. Activation of I_Na did not require Ca2+-dependent or cytosolic Ca2+ rise.

Due to its slow deactivation kinetics, I_Na is likely to contribute to the sequence of afterpotentials following a depolarizing event in electrically active neurons.

100.5 CYCLIC NUCLEOTIDE MODULATION OF THE HYPERPOLARIZATION ACTIVATED CURRENT, I_P, IN NIE-115 NEUROBLASTOMA CELLS.
C. Mathers* et al., Homemade, Hampton Marine Station of Stanford University, Pacific Grove, CA 93950

We recorded I_P in a neuronal cell line derived from mouse sympathetic ganglion. This inward and voltage-dependent current is activated at hyperpolarized potentials and tail currents measurements give a reversal potential of -30 mV. The instantaneous (I_0) and steady-state (I(V)) V curves are inwardly rectifying. The activation curve of I_P is fit by a single Boltzmann function with V = 70 ± 9 mV and the slope factor z = 3. Like I_K in cardiac and other cells, the inward current is inhibited by Cs but not by Ba2+. This channel distinguishes this inward rectifying K current. I_P amplitudes increase by about 144% when (Ca)_out is elevated and when Mn or Co are added. These results suggest that I_K is permeable to all divalent cations, including Ca, Mn and Co. Single channel currents have been measured with Ca as the carrier that have a similar I(V) curve and extrapolated reversal potential to I_P. The slope conductance is ~ 50 pS. In nystatin patch experiments, cAMP (1 mM 8-bromo cAMP) increases I_P by 400% (I_P0) and 151% (I_P1) at -95 mV. Cyclic GMP (1 mM 8-Br-cGMP) inhibited I_P by 36% (I_P2) and 46% (I_P3) at -95 mV. Cyclic AMP increases I_P amplitudes at all voltages, while the inhibition of I_P by cGMP occurs only at negative potentials. This cyclic nucleotide modulation of I_P may be the mechanism by which muscarinic receptor stimulation of muscarinic agonist application reduces I_P amplitudes by 35% at -90 mV. Muscarinic inhibition of I_P should decrease spike frequency and counteract the slow EPSP during synaptic transmission.

100.6 MOLECULAR AND FUNCTIONAL CHARACTERIZATION OF AN INWARDLY RECTIFYING CONDUCTANCE IN RAT BRAIN.

A voltage sensitive inwardly rectifying chloride channel is present in hippocampal pyramidal neurons but not dentate gyrus neurons. This conductance has electrical properties similar to a chloride channel (designated CIC-2) that has been cloned and functionally characterized in a Xenopus oocyte expression system, and has been shown to have a significant role in modulation of neuronal responses to GABA mediated axons. Therefore, the CNS distribution of CIC-2 is of interest to understanding the neuron-specific mechanisms that can modulate GABA action. Using single cell hybridization methods to detect the CIC-2 mRNA, we have demonstrated that the CIC-2 mRNA is expressed to the same population of neurons in the hippocampus that contain a voltage sensitive inwardly rectifying Cl- conductance. In rat brain, expression of CIC-2 was restricted to neurons and choroid plexus but not detectable in glial cells. Although CIC-2 mRNA was widely expressed in cortical neurons, significant differences in signal intensity were observed regionally and in different cell layers. In subcortical structures CIC-2 expression was restricted to specific regions and neuronal cell types. These results suggest that in brain CIC-2 may have neuron specific functions in modulation of the chloride gradient that differ significantly from the proposed role in volume regulation of non-neuronal tissues.

In a recent study it has been shown that voltage-gated calcium currents, in pituitary cells, are flow sensitive (Ben-Tabou, Keller and Nussinovitch, J. Physiol. 476 1, 1994). This finding raised the possibility that local deformation of pituitary cells membranes can affect the voltage-gated calcium channels. We tested this possibility by exposing pituitary cells to solutions with different osmolalities, causing deformation of pituitary cell membranes by swelling or shrinking. In this study, pituitary cells were exposed to hypotonic solutions (165-200 mosmol) or hypertonic sucreose containing solutions (400-520 mosmol) by bath perfusion. The osmolality of the standard extracellular solution was 320 mosmol. Calcium currents were recorded with the whole-cell mode of the clamp-patch technique. Exposure to hypo-osmotic solutions resulted in two major effects: 1. Block of T-type calcium currents with no change in their voltage dependence of activation. 2. Negative shift (of about 10 mV) in the activation curve for high voltage activated (HVA) calcium currents. HVA calcium currents which were activated at negative test potentials (-50 mV to -10 mV) increased in size whereas those activated at more positive test potentials (+20 mV to +30 mV) decreased in size. Similar results were observed when the cells were exposed to hyper-osmotic solutions except that the block of HVA currents was not always associated with a shift in activation curve. These findings suggest that deformation of pituitary cell membrane by osmotic changes can regulate influx through voltage sensitive calcium channels.

701.3 NITRIC OXIDE SYNTASE (NOS) DOES NOT MODULATE CURRENT-DEPENDENT INACTIVATION OF N-Type CALCIUM CHANNELES BUT IT DOES SOMETHING TO ICa. J.J. Kenyon. Dept. of Physiol., Univ. of NL School of Med., Reno, NV 89557

I tested the hypothesis that Ca** entry via ICa, inhibited by stimulation of NOS and production of nitric oxide (NO), N-type ICa, was measured in chick dorsal root ganglion neurons using amphotericin perforated patches at 35±3°C. ICa,** was reduced by low [Ca**]i and 100 µM. Inactivation of ICa,** during 250 ms conditioning steps to +60 mV was monitored by 50 ms test steps (-8 mV). 10 s intervals separated the conditioning steps. As conditioning voltages were made less negative, test ICa,** decreased. When the conditioning voltage was at or below 0 mV, ICa,** could not be recovered. We propose that NO synthase does not play a role in the inactivation of N-type ICa,** but can modulate the inactivation of C-type ICa,**

701.5 PHARMACOLOGY OF LOW-THRESHOLD CALCIUM CURRENTS IN HIPPOCAMPAL CA3 PYRAMIDAL NEURONS. R.B. Avery* and D. Johnston. Division of Neuroscience, Baylor College of Medicine, Houston, TX 77025

Hippocampal neurons possess multiple types of voltage-gated calcium channels (Rivera et al., J. Neurophysiol. 64:901). The contributions of specific channel types to cellular functions, however, is not well-established. Low-threshold calcium currents are thought to support complex firing patterns in CA3 pyramidal cells. Since the pharmacology of low-threshold calcium channels varies among neurons, we wish to screen potential blockers of these channels in CA3 cells.

Recordings were made from CA3 pyramidal neurons acutely isolated from rats 7 to 14 days old. Cel-attached patches confirmed the presence of low-threshold calcium channels on the soma of these cells. In 110 mM bath, single channel openings could be evoked from potentials as low as -60 mV. The slope conductance of single channels was less than 10 pS. Patches with several channels exhibited a rapidly inactivating macroscopic current. To screen putative blockers of these channels, we made whole-cell recordings in 5 mM calcium. From hypotonic and holding potentials, calcium currents activated at potentials more positive than -60 mV. We assayed low-threshold calcium currents with test pulses to -40 mV from a holding potential -50 mV. The activation at -40 mV was slowly activating and inactivating. The activation was about a third of the peak whole-cell current, which occurred between -10 and 0 mV. High-threshold currents were isolated by holding at +50 mV to inactivate low-threshold steps. Steps from -50 mV to 0 mV elicited a slightly inactivating current. The amplitude was about half that compared to currents evoked from a holding potential of -80 mV. 50 or 100 µM nickel strongly reduced the low-threshold component but only slightly blocked the high-threshold currents. (MH1473, MH14754, MHH4625, NS1153S)

701.6 REGULATION OF VOLTAGE-DEPENDENT CALCIUM CHANNELS OF MOUSE DRG NEURONS BY CHRONIC ELECTRICAL STIMULATION IN CULTURE. M.X. Li, M. Jia, B. D. Fields*, and P.G. Nelson. NICHD and NINDS, NIH, Bethesda, MD 20892

Previous research has shown that influx of calcium through voltage-sensitive calcium channels is responsible for the arrest of growth cone motility in mouse DRG neurons in culture. After chronic electrical stimulation, growth cones recover and become insensitive to repeated stimulation. (Biphasic stimulation was delivered at 6V in 0.5 s bursts at 10 Hz every 2 s for 40-70 h) One of the mechanisms of growth cone accommodation, whole cell voltage clamp experiments and calcium imaging using fura-2 were performed on mouse DRG neurons cultured in multi-compartmental chambers. The electrically-induced increase in calcium was significantly slower in the growth cones and cell bodies of DRG neurons after chronic stimulation (tau = 3 vs. 1.4s, p<0.001). High-threshold activated (IVA) whole-cell calcium currents were reduced in chronically stimulated neurons from 3.2 nA to 0.59 nA (p<0.02), measured at the end of a 200 ms stimulation pulse. Low-threshold activated (ILVA) were reduced from 0.74 nA to 0.095 nA (p<0.02). The membrane potential of the peak current was shifted from -15 mV in the control neurons to +9.1 mV (P<0.0002). The effective diameter of neurons in the control and stimulated groups. The HVA calcium currents inactivated more rapidly in the stimulated group. Our results suggest that development of the nervous system could be influenced by activity-dependent regulation of calcium conductance through VSCC, by ensuing effects on growth cone motility, and other calcium-dependent processes.
MORULATION OF RYANOINE RECEPTORS BY MITOHONDRIAL CALCIUM IN DORSAL ROOT GANGLION NEURONES. D. Bovet, P. Felix and R. Schlüter, Laboratoire de Physiologie Générale, Université Louis Pasteur, Strasbourg, France.

An extensive repertoire of ionic channels are modulated by changes in the concentration of cytosolic calcium ([Ca\(^{2+}\)]\textsubscript{i}) which, in many cases such as for ryanoine receptors, forms a bell-shaped dependence on channel activity. As yet, these observations have not been demonstrated in an intact neurone nor has the Ca\(^{2+}\)signalling pathway which modulates receptor function been identified. In this study, intact neurones were loaded with fura-2, we have attempted to identify the Ca\(^{2+}\)-signal which modulates ryanoine receptors using a variety of receptor agonists which elevate [Ca\(^{2+}\)]\textsubscript{i} through known pathways. The sensory neurones excitable, capsaicin (50nM-2uM) and 50nM KCI evoked biphasic elevations in [Ca\(^{2+}\)]\textsubscript{i}, consisting of a peak and plateau component. The peak Ca\(^{2+}\) rise was due to entry of extracellular Ca\(^{2+}\) which was attenuated and sustained at a plateau level for identification using 10uM FCCP to selectively inhibit Ca\(^{2+}\)-uptake into the organelles. The amplitude of the plateau was greater following application of capsacin than 50mM KCI. Activation of ryanoine receptors by 10nM caffeine elicited transient Ca\(^{2+}\) rises that were reversibly inhibited during the Ca\(^{2+}\)-plateau evoked by capsacin but unaffected by the plateau to 50mM KCI. Selective inhibition of the mitochondrial Na\(^{+}\)/Ca\(^{2+}\) exchanger with 10uM Gd3+ lowered the plateau amplitude observed with capsacin and restored the Ca\(^{2+}\) rises evoked by caffeine. These observations support a novel role of the mitochondrion as a long-term modulator of intracellular Ca\(^{2+}\) stores as well as a putative regulator of other Ca\(^{2+}\)-dependent events in the cytoplasm.

D.B. was funded by an US-P-CNRS-Lilly postdoctoral fellowship.

CALCICUM INFLUX THROUGH P-TYPE CHANNELS ACTIVATES CLOSELY ASSOCIATED CALCIUM-DEPENDENT POTASSIUM CHANNELS AT THE MOUSE MOTOR NERVE TERMINALS, D.A. Protti and O.D. Uchate, Faculty of Medicine, University of Buenos Aires, Buenos Aires, Argentina.

Transmitter release is commonly shortened by the repolarization of the membrane, due to the onset of diverse potassium currents. At the mammalian motor nerve terminal, the main potassium conductances have been described as a voltage dependent K\textsuperscript{+} current, blocked by 3.4-diaminopimelic (3.4-DAP) and a calcium activated potassium current (IK(Ca)) sensitive to TEA and to Charybdoxin. We have previously reported that PTX and and A-IVA, two P-type calcium channel blockers, inhibit neuronal transmission, diminish quantal content and block calcium currents at the mouse motor nerve terminals (PNAS 89, 3333-3333, 1992; Neuroreport 5, 333-336, 1993).

We studied the activation of the IK(Ca) in the levator auris muscle-nerve preparation of the mouse by means of perineural recordings in the presence of 3.4-DAP (10mM). We have found that the IK(Ca) is abolished in the presence of 0.5mM EGTA (10mM) whole cells, two P-type calcium channel blockers, inhibit neuronal transmission, diminish quantal content and block calcium currents at the mouse motor nerve terminals (PNAS 89, 3333-3333, 1992; Neuroreport 5, 333-336, 1993).

We now report that a Ch\textsuperscript{2+} channel (p64), identical to that found in isolated ellipsoid cells, is present in the membrane of PF vesicles. The opening of this channel is associated with an increase in its state of phosphorylation and, in concentrations that also cause secretion, induced an increase in [Ca\(^{2+}\)]\textsubscript{i}. Secretion in response to 1mM Ca\(^{2+}\) was partially inhibited by the L-type channel blocker, nimodipine (NIM; 0.5 uM) and by tetraoda (TTX; 10 mU), which were combined. Secretion in response to TTX was unaffected by TTX, but abolished by NIM. Antagonism of secretion by TTX was reversed by the L-type channel agonist, Bay K8644 (10 uM). In contrast to NIM, neither the N-type channel blockers, nor the P-type channel blockers, D-agatoxin (0.1 uM), affected secretion. Vesicle acidification in response to TTX was partially inhibited by both NIM (0.5 uM) and D-agatoxin (0.1 uM), but was unaffected by D-agatoxin (0.1 uM). Vesicle acidification induced by TTX was abolished by NIM (0.5 uM), D-agatoxin (0.1 uM) and EGTA (10 mM), but not by TTX (10 uM). These data suggest that Ca\(^{2+}\) entry through voltage-gated Ca\(^{2+}\) channels is involved in coupling stimulation to both secretion and vesicle acidification; Ca\(^{2+}\) entry may contribute only to vesicle acidification. Supported by grants DK19743, NS07062 and NS12969.

THAPSGARGIN DISCHARGES INTRACELLULAR Ca\(^{2+}\) (Ca\(^{2+}\)\textsubscript{i}) STORES IN MOUSE CORTICAL ASTROCYTES. J.A. Edwards, H.H. Wolf and H.S. White, Anticonvulsant Drug Development Program, Department of Pharmacology and Toxicology, University of Utah, SLC, UT 84112.

Thapsigargin stimulates Ca\(^{2+}\) release from [Ca\(^{2+}\)]\textsubscript{i} stores by selectively inhibiting the Ca\(^{2+}\)-ATPase on the intracellular storage membrane. By poisoning the Ca\(^{2+}\) pump thapsigargin treatment produces a release of Ca\(^{2+}\) from the thapsigargin-sensitive Ca\(^{2+}\) stores. The present investigation was initiated to assess the [Ca\(^{2+}\)]\textsubscript{i} storage capacity of mouse cortical astrocytes. In an attempt to deplete [Ca\(^{2+}\)]\textsubscript{i} stores varying concentrations of thapsigargin (10, 30 & 100 nM) were high applied to a confluent monolayer of astrocytes for 10 minutes. Changes in the [Ca\(^{2+}\)]\textsubscript{i} of type-1 mouse cortical astrocytes (21-28 days in culture) were measured using an indo-1 based microfluorometry image system. Treatment with thapsigargin resulted in a dramatic increase (417, 646 & 6219 at 10, 30 & 100 nM, respectively) in the [Ca\(^{2+}\)]\textsubscript{i} over basal levels. This effect was only partially reversible upon subsequent wash-out with drug-free buffer. Of particular interest was the finding that the increase in [Ca\(^{2+}\)]\textsubscript{i} was highly dependent on the concentration of Ca\(^{2+}\)\textsubscript{i}. These results suggest that depletion of Ca\(^{2+}\)\textsubscript{i} stores was producing Ca\(^{2+}\) influx across the plasma membrane. Additional studies with dantrolene and ryanodine (to block [Ca\(^{2+}\)]\textsubscript{i} release) and nimodipine (to block voltage-sensitive Ca\(^{2+}\) channels) were unable to attenuate the thapsigargin-induced influx of Ca\(^{2+}\) and subsequent increase in [Ca\(^{2+}\)]\textsubscript{i}. These data suggest the hypothesis that the decrease in Ca\(^{2+}\)\textsubscript{i} stores may release some type of intracellular messenger (e.g., calcium influx factor) which would initiate refilling of Ca\(^{2+}\)\textsubscript{i} stores. (Supported by NIH grant 2 ROI NS-22200 and NIH/NIHDS contract NOI-NS-9-3228).

SINGLE CHANNEL BASIS OF THE MULTIPLE FUNCTIONAL COMPONENTS OF MACROSCOPIC L-TYPE Ca\(^{2+}\) CHANNEL CURRENT IN CLONAL PITUITARY CELLS. D. M. Paspa & E. S. Lefkath, Dept. of Neuroscience and Pharmacology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

In the presence of the dicyclotryptophanogen BAY K 8644 (1 uM), whole cell L-Channel Ba\(^{2+}\) currents in GEL cells consist of two functional components. These two components differ in their rate of deactivation, voltage dependence, sensitivity to BAY K 8644, and sensitivity to inhibition by the neuropeptide TRH. The simplest hypothesis which may account for these two components is one which invokes two populations of L-channels. To test this hypothesis, single channel recordings were obtained from cell-attached patches. To control the potential of the membrane outside the patch, the K\textsuperscript{+} ionophore valinomycin (10 uM) was applied to the cells. This treatment stabilized Vm at ~ -60 mV. In addition, rundown was much less pronounced (channel activity remained stable for hours) than when the typical high K\textsuperscript{+} external solution was used. Ensemble tail currents derived from recordings from multi-channel patches were fit by two exponentials, indicating that the two components were detectable in the presence of valinomycin. Two exponentials were also required to fit the ensemble tail current derived from one of the single-channel patches obtained thus far. The other single-channel patch had an ensemble tail fit well by one exponential. Obtaining more single channel patches will allow us to determine whether individual L-channels display the behaviors of one or both components of macroscopic L-current.

LEAD ATTENUATES L-TYPE CALCIUM CHANNEL INACTIVATION IN BOVINE CHROMAFFIN CELLS. L. Sun, J. B. Szuszkw, and N. Sperelakis, Dep. of Physiology and Biophysics, Univ. of Cincinnati, Cincinnati, OH 45267-0756.

Using whole-cell voltage clamp, we investigated the effects of inorganic lead (Pb\(^{2+}\)) on the voltage-gated calcium current recorded from bovine adrenal chromaffin cells. Currents were recorded by 200ms voltage step pulse to +10mV from a holding potential of -80mV. Extracellularly-applied Pb\(^{2+}\) (0.05, 0.1, 0.5, 1.0 uM) depressed calcium currents in a non-specific manner and acted as a potent and reversible blocker of Ca\(^{2+}\) channels, which is consistent with a competition by Pb\(^{2+}\) with Ca\(^{2+}\) at a binding site within the calcium channel. However, the contribution of lead to the suppression of Ca\(^{2+}\) current rundown. It has been indicated that the Ca\(^{2+}\)-dependent inactivation of L-type channels involves an activation of protein phosphatase and the channel dephosphorylation. These results suggest that Pb\(^{2+}\) may attenuate Ca\(^{2+}\) channel inactivation by maintaining Ca\(^{2+}\) channel in phosphorylated status. Supported by NIHES grants ES04090 and ES03656.
ACUTE EXPOSURE TO LOW LEVELS OF LEAD ALTERS CALCIUM CURRENT AMPLITUDES IN RAT PC-12 CELLS. C.C. Heg & V. Milete*. Dept. Comp. Biosci. & Environmental Toxicology Center, Univ. Wisconsin, Madison, WI 53706.

Lead is a known neurotoxin with varied and poorly understood mechanisms of action. We employed a whole-cell patch-clamp technique to examine the effects of low levels of lead on high-threshold voltage-dependent calcium currents in rat pheochromocytoma (PC-12) cells. PC-12 cells were placed in NGF-containing media for 4, 8, or 12 days followed by 24 h of recording. During recordings, the cells were first perfused for 5 minutes with lead-free solution, then switched to a 10 μM lead-containing solution for another 5 minutes, and finally washed again with lead-free solution. As previously reported, acute low-levels of lead caused a decrease in calcium current amplitude without an obvious change in activation kinetics in some cells (n = 7). However, unlike previous reports, acute exposure to the same low levels of lead also produced increases in calcium currents in other cells (n = 12). In both situations, the effect of lead was only partially reversible with washing. There was no systematic difference in the effects of lead among the 4, 8 or 12 day cultures. These data suggest complex interactions of lead with calcium channels in PC-12 cells. (Supported by NIH NS21278).

SELEcTIVE MODULATION OF T- AND L-TyPe CaLcium CuRRENTS BY STIMULATION OF m3 AND m4 MuScUlaRINe ReCePTORS SUBTYPES IN TRANSENCePTED 3T3 CELLS. S. V. Jones*, M. S. Rozengurt, and D. M. Rubin. Molecular Neuropharmacology, Departments of Psychiatry and Molecular Physiology and Biophysics, University of Vermont College of Medicine, Burlington, VT 05405.

Calcium currents were recorded from NIH 3T3 cells transfected with the m3 and m4 muscarinic receptor subtypes. Whole cell patch clamp recordings were made with (mM): NaCl 150, MgCl2 1, BaCl2 20, Heps 10 and Glucose 5. Patch pipettes (4-6MΩ) were filled with (mM) NMGC 120, MgCl2 4, EGTA 10, Heps 10, ATP 4, GTP 0.1, creatine phosphate 5, and creatine kinase 50 units/ml. Using a variety of stimulation protocols two types of voltage dependent calcium current were observed. A low voltage activated, transient, nifedipine-insensitive calcium current (T-type) and a slowly inactivating, high voltage activated calcium current that was dihydroprolyline sensitive (L-type). Simulation of cloned m4 receptors resulted in a pertussis toxin sensitive reduction in amplitude of the L-type calcium current but appeared to be without effect on the amplitude of the T-type calcium current. Conversely, activation of the m3 muscarinic receptor produced an increase in the amplitude of the T-type calcium current. The respective mechanisms of action of these muscarinic receptor subtypes will be addressed.

Noradrenergic potentiation of a low-voltage-activated calcium current in dissociated nucleus basalis neurons. S. Williams*, A. Pepeu, M. Mihlhehler and L. Beremh Dept of Physiology, CMU, 121I Geneva 4, Switzerland.

Nucleus basalis are neuronal clusters providing an important cholinergic input to the cerebral cortex and receive a prominent innervation from noradrenergic (NA) neurons of the locus coeruleus. Previous studies have indicated that noradrenergic neurons are endowed with the capacity to emit action potentials in bursts. These bursts are thought to be mediated by a potent low-voltage-activated (LVA) calcium current. We have studied the modulation of the LVA current in dissociated NB neurons using whole-cell voltage-clamp recordings. In the presence of TTX (0.5 μM), TEA (20 mM) and 4-AP (4 mM), NB neurons recorded with an internal solution containing (in mM) 130 Cs acetate, 20 CaCl2, 5 HEPES, 5 MgCl2, 0.1 BaCl2, 3 NaATP and 0.1 NaGTP, consistently displayed a transient LVA current. From a V0 of -90 mV, the LVA current was activated at potentials near -50 mV, had a peak amplitude (measured at -30 mV) of 223 ± 60 nA (n = 8, mean ± SD) and was reduced by amiloride (300 μM, n=3) or cadmium (200-400 μM, n=8). Perfusion of NA (50 μM) produced a long lasting (>15 min) increase in amplitude (44.3 ± 32.3% (+n = 4) in the peak amplitude of the LVA current. The addition of prazosin (1 μM), an α1 receptor antagonist, prevented this effect. Perfusing (40 μM) an α2 receptor agonist, mimicked the NA induced potentiation, producing an increase of 32.3 ± 23 % (n=7). These results suggest that NA, through the activation of an α2 receptor, can potentiate the LVA current and could therefore in certain conditions, favour the propensity of NB neurons to generate rhythmic bursts. (Canadian MRC and Swiss FN).

ACTIVATION OF GABAa AND GABb-ReCEPTOR MODULATORS DIFFERENT TYPES OF Ca2+ CURRENTS IN RAT NODULAR GANGLION NEURONS. J.I. Rushin* and H.C. Moises. Dept. of Physiology, Univ. of Michigan, Ann Arbor, MI 48109-0707.

Whole cell patch clamp recordings were obtained from nodose neurons acutely dissociated from 10-24 day old rats to characterize the Ca2+ channel types that are modulated by GABAa and GABb receptors. Components of high-threshold current were distinguished on the basis of their sensitivity to blockade by α,γ-GTGVIA, nifedipine, α,γ-AgaVA and α-CTX MVIC. Administration of the α,γ-AgaVA to nifedipine-resistant calcium current (EC50 = 0.3±0.1 μM) was blocked by cadmium (30 μM) suppressed high-threshold Ca2+ currents by 51.5±2.7% (n=5) and 20.7±2.4% (n=4), respectively. Blockade of the LVA type channels by α,γ-GTGVIA eliminated current suppression by cadmium in all cells tested (n=11). The inhibitory effect of DAGO was completely abolished by α,γ-GTGVIA in 12 of 30 neurons and partially reduced in the remaining 19 neurons. Administration of α-Aga IV in saturating concentrations failed to completely eliminate the μ-opioid sensitive component which persisted after blockade of N-type channels. These data suggest that α,γ-AgaVA-resistant component of the μ-opioid sensitive current was blocked by α-CTX MVIC in 9 neurons. The remaining neurons (n=9) contained an unidentified component of Ca2+ current that was resistant to blockade by α,γ-GTGVIA, dihydroprollyline, α,γ-AgaVA and α-CTX MVIC. This toxin-resistant component was reduced by DAGO. Dihydroprolyline-sensitive (L-type) current was unaffected by μ-opioid or GABb receptor activation. These data suggest that μ-opioid receptors in nodose ganglion neurons are negatively coupled to N, P, O and unidentified toxin-resistant Ca2+ channels, whereas GABb receptors are coupled only to N-type channels. (Supported by DA00365 to HCM).

SEROTONINERGIC MODULATION OF HVA CALCIUM CURRENTS IN DISOCIATED NUCLEUS BASALIS NEURONS. A. Pepeu, L. Beremh, M. Vescovi, and S. Williams. Dept. of Physiology, CMU, 121I Geneva 4, Switzerland.

A major source of cholinergic input to the cerebral cortex arises from nucleus basalis neurons (NBn). In addition to a low-voltage-activated Ca2+ current, NBn exhibit an important high-voltage-activated (HVA) Ca2+ current. The inhibition of the HVA current by baclofen and 5-HT was studied in guinea-pig acutely isolated NBn using the whole-cell voltage-clamp technique. The HVA current was isolated with TTX (0.5 μM), TEA (20 mM) and 4-AP (4 mM), and recorded with patch pipettes (in nM) 130 CsAc, 20 CaCl2, 5 HEPES, 5 MgCl2, 0.1 BaCl2, 3 NaATP and 0.1 NaGTP. A voltage step to 0 mV for 40 ms from a V0 of -90 mV activated a HVA current with a peak amplitude of 1.46 ± 0.47 (n=5). The HVA current could be distinguished pharmacologically into three components (L, P, and N). The total HVA current was reduced by 20 ± 4 % (n=4) with the application of picrotoxin (3-5 μM), an L-type blocker, by 30 ± 20 % (n=6) with o-pipecoloytoxin (10 μM), an N-type blocker, and by 35 ± 20 % (n=5) with α,γ-AgaVA (100 mM), a P-type blocker. The application of 5-HT (10 μM) or the 5-HT1a agonist 8-OHDPAT (10 μM) reduced the peak amplitude (at 0 mV) of HVA by 16 ± 13 % (n=5) and 20 ± 5 %, respectively. In the presence of picrotoxin (100 μM), 8-OHDPAT (10 μM) did not affect remaining HVA currents suggesting that 8-OHDPAT reduces only the N-type Ca2+ current. The GABAa agonist baclofen (0.1 μM) 10 % (n=5) reduction of HVA currents. We are presently determining which HVA current(s) is (are) modulated by baclofen. Taken together, these results suggest that, in NBn, the HVA Ca2+ current is composed mainly of type L, N and P. Serotonin and GABA may selectively modulate only one component of the HVA current. (Supported by Canadian MRC and Swiss FNS).

**SEBORRHON (5HT) MODULATES HVA CALCULUM CURRENTS IN RAT NECORTICAL PYRAMIDAL NEURONS.** Feoktistov, R. C.* Depts. of Anatomy and Neurobiology, Univ. of Tenn., Memphis, TN 38163.

Necortical pyramidal cells were acutely dissociated from the sensorimotor cortex of rats (P7 or adult) and whole cell voltage-clamp recordings were made. SHT induced a decrease in HVA currents in a reversible and dose-dependent manner. In a given, 10-40% of the total current was modulated by SHT, with no change in voltage-dependence. The SHT effect was mimicked by the SHT agonist 5-CT and by the SHT1 agonist Nov-202PHAT. The SHT effect was blocked by the SHT1 antagonist AM 1721, but not by the SHT2 receptor agonist or antagonist. The data suggest that the modulation is mediated by SHT1A receptors. Under our standard internal Ca2+ chelation conditions (10 mM EGTA or 20 mM BAPTA), the modulation was unaffected by 5 μM nigfopoly and partially occluded by saturating doses of α-CgtX GIVA (1 μM). The combination of these two agents completely blocked the modulation, suggesting that N- and P-type channels were modulated. The modulation of N- and P-type current by SHT was rapid in onset (of several hundred ms) and partially reversed by preloads to <120 mV. In the presence of GTPβs, the modulation was irreversible. These data indicate the involvement of a 5-HT receptor in the modulation and suggest utilization of a membrane-delimited pathway. When the initial solution contained 0.1 mM BAPTA as the only chelator, L-type currents were reduced in addition to N- and P-type currents. This modulation appeared slower in onset than that of N- and P-type currents. Under all chelation conditions, SHT reduced the slow tail currents generated by L-Type channels in the presence of Bay K 8644. Supported by NINDS grant #S399527180. α-Agt-X IVA was a gift from Pfizer, Inc.

EXCITATORY AMINO ACIDS: PHARMACOLOGY

**KETAMINE-INDUCED ALTERATION OF NITRIC OXIDE SYNTHETASE ACTIVITY IN RAT CAUDATE NUCLEI.** R.A. Mueller, M.D., Ph.D.* and R.D. Blunt, B.S., Departments of Anesthesiology and Pharmacology, UNC-Chapel Hill, Chapel Hill, NC 27599.

It has previously been reported that pretreatment with inhibitors of nitric oxide synthase (Type 1) (NOS) can antagonize the anesthetic effects of ketamine in rats, but the effect may be due to decreased delivery of ketamine to its site of action. In the present study in *vivo* NOS synthase activity was used to assess caudate NOS during the onset, maintenance and disappearance of ketamine anesthesia.

Rats (60-120 g) given saline (2 ml/kg) or ketamine (75 mg/2 ml/kg) i.m., at zero time were used to study NOS activity in 15 min (onset) or 60 (maintenance) minutes after IM saline or ketamine. Each rat received 5-10 μg of i3H-arginine i.v. and as killed by decapitation 5 minutes later, with the immediate collection of plasma, liver, parietal cortex, cerebellum, and caudate nuclei samples.

3H-citrulline was measured by ion exchange and HPLC with all tissue values corrected for contamination of the tissue by plasma 3H-citrulline calculated to be within the tissue.

Synthesis of caudate 3H-citrulline was increased 50% in rats that received ketamine 15 minutes previously (p < 0.05), but not at 30 or 60 minutes. No significant changes were noted in the cerebellum or parietal cortex.

These results suggest that after ketamine, the NOS activity is briefly increased acutely but returns to normal even though anaesthesia persists. NOS activity changes do not parallel the time course of anesthetic effects.

**701.3**

The actions of dopamine (DA) agonists in the nucleus accumbens (Acb) are thought to be translated into locomotor activation through decreases in ventral pallidal GABA. Blockade of glutamate function in the Acb by antagonism of glutamate antagonists such as MK-801 also induces locomotor output. Some have suggested that MK-801 produces locomotor stimulation through mesolimbic DA, although support for this proposition is equivocal. For example, we have previously failed to find significant increases in Acb DA overflow by pharmacologically relevant doses of MK-801. This apparent behavioral paradox provides support for a role of Acb DA in the stimulatory effects of this glutamate antagonist. DA depletion lesions of the Acb significantly attenuated the locomotor-activating effects of amphetamine applied focally to this structure while the stimulatory actions of MK-801 were not altered. The second series of studies was directed at evaluating the role of the pallidal GABA in mediating the motoric actions of DA agonists and MK-801. Using *in vivo* microdialysis procedures, amphetamine was found to decrease pallidal GABA while MK-801 failed to have an effect despite producing pronounced increases in locomotor activity. Injection of muscimol (100 nmol) into the ventral pallidum attenuated the locomotor-activating effects of amphetamine but not MK-801. The locomotor activating effects of MK-801 do not appear to involve Acb DA nor pallidal GABA.
702.5
7-Cl-Kynurenic acid (7-Cl-KYN), a selective and potent antagonist of the glycine co-agonistic site of the NMDA receptor, can be produced from L-4-Cl-kynurenic acid (L-4-Cl-KYR) by the action of quinolinic acid peptidase, a gliarial enzyme which catalyzes the biosynthesis of kynurenic acid from L-kynurenine (4). The mechanism of action of 4-Cl-KYN is not yet known. Intrastriatal injection of 120 nmol quinolinic acid (QUIN) into the striatum (over 2 hrs) resulted in a 45 ± 3% decrease in GAD activity. The production of 7-Cl-KYN from 4-Cl-KYR was verified by HPLC analysis of brain extracts. 181 ± 13 nmol/kg of 7-Cl-KYN were recovered from a normal striatum infused with 135 nmol 4-Cl-KYR for 4 hrs (N=12). The production of 7-Cl-KYN was decreased by 51% after intrastriatal injection of fluoro-2:1-KYN (1 mol/L µl, i. str.; N=13), but was increased by 204% in the astrogliotic striatum, i.e. seven days after an intrastriatal QUIN (360 nmol) injection. These data indicate that astrocytes can produce neuroprotective quantities of 7-Cl-KYN from 4-Cl-KYR in the striatum in vivo. Supported by a grant from the Huntington's Disease Society of America (to P.G.).

702.7
LEARNING IMPAIRMENT INDUCED BY CHRONIC INFUSION OF QUINOLINIC ACID - PROTECTION BY MEMANTINE. W. Danysz, M. Misztal, R. K. Filipkowski, L. Kaczmarek, and J. Stangier-Kramska. Dept. Pharmacol., Merz+Co, 60318 Frankfurt /Main, Germany, Nencki Institute, 02-093 Warsaw, Poland.
We have recently demonstrated that chronic treatment with memantine resulted in a decrease in the density of muscarinic receptors at sites of the hippocampus, pons, and thalamus. Parallel infusion of a competitive NMDA antagonist memantine (1-amino-3,5-dimethyl-ladamantane), 20 mg/kg/day by another minipump prevented the learning deterioration induced by choline. The treatment with memantine resulted in steady-state plasma levels of 1.2 µM which should assure inhibition of NMDA receptors and is similar to levels seen in demented patients treated with this agent. Hence, if the glutamate hypothesis of dementia is accepted the neuroprotective activity of memantine in SDAT patients might be expected.

702.9
NMDA, BUT NOT AMPA, BLOCKADE REDUCES MONOSODIUM GLUTAMATE (MSG) INDUCED DAMAGE IN NEONATAL RATS. B. Milburn, J. Parkes, T. Bambrock, R. Telford, D. Bannerman and W. Sagard. Neuroscience Research Unit, Nipissing University, 100 College Dr., North Bay, Ontario, Canada, P1B 8L7.
In two experiments, we investigated whether NMDA and/or AMPA receptor blockade mitigates the physiological and behavioural damage associated with neonatal MSG injections in the rat. In the first experiment, 10 day rat pups received two injections on postnatal days 2, 3, 5, 7 and 9. The first injection was either saline (SAL) or MES-801 (0.1 mg/kg; sc) while the second injection was either saline or MSG (4 g/kg; sc). Two groups received 3 treatments: MES-801/SAL and MES-801/MSG. In the second experiment, we tested the protective effect of MES-801 and/or NBQX injection prior to MSG administration. Behavioural testing revealed the expected SAL/MSG induced learning deficit in the water maze test. The tail flick test in postmortem analyses revealed organ weight reductions in MSG treated rats. We conclude that MB-801, but not NBQX, protects against damage associated with neonatal MSG treatment. ACKNOWLEDGEMENT: The authors thank NOVO NORDISK for their contribution of NBQX.

702.10
The aim of the present study was to characterize the pharmacological mechanisms involved in the central muscle relaxant action of flupirtine, a novel non-opioid centrally acting analgesic agent. For this purpose in urethane-anesthetized rats, the action of flupirtine was investigated on the mono-synaptic Hoffmann-(H) reflex recorded from plantar foot muscles and on polysynaptic flexor reflexes recorded from tibialis muscle. Intraperitoneal (1-10 mg/kg) and intrathecal (0-330 nmol) administration of flupirtine depressed polysynaptic flexor reflexes in a dose-dependent manner without affecting monosynaptic H-reflexes. The effect of intrathecal injection of flupirtine was prevented by co-administration of the mixed alpha1-adrenergic antagonist yohimbine (10 nmol) and the excitatory amino acid antagonist and N-methyl-D-aspartate (NMDA; 10 nmol), but neither by co-administration of the alpha2 adrenergic antagonist prazosin (10 nmol), the GABA-A antagonist bicuculline (1 mmol), the GABA-A antagonist phaclofen (100 nmol) and the non-NMDA agonist amino-3-hydroxy-5-carboxylate (AHPA; 0.1 pmol) nor by pre-treatment with the benzodiazepine antagonist flumazenil (5 mg/kg). These observations suggest that alpah2 and NMDA receptors are involved in the mediation of the muscle relaxant activity of flupirtine.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
**EFFECTS OF MK 801 AND FLUPIRTINE ON ISCHEMIC RETINAL DYSFUNCTION.** F. Block1, M. Schwarz1, G. Pergande2, S.W. Schäfer1, 1 Dept of Neurology, RWTH, 52057 Aachen, Germany; 2 ASTA Medica, D-66421 Ludwigshafen, Germany.

Electrophysiological data suggest that flupirtine exerts a muscle relaxant effect via antagonistic action at the NMDA receptor (Schwarz et al, present meeting). Transient occlusion of both common carotid arteries (24 minutes) in normotensive rats induces retinal ischemia as reflected by a reduction in amplitude of the b-wave of the electroretinogram. Anesthesia was induced with ketamine (124 mg/kg, i.p., 1992). In the present study the effect of flupirtine on the reduction in amplitude during ischemia and on the recovery during reperfusion of the b-wave was compared to that of the NMDA antagonist MK 801. The electroretinogram was recorded from pentobarbital-anesthetized rats before, during and after transient occlusion of both common carotid arteries. Data were analyzed in a modified two-way ANOVA (P<0.05). In preliminary experiments ketamine (10 mg/kg, s.c.) protected the retina from ischemic damage. Flupirtine (1 mg/kg, s.c.) decreased the protective effect of ketamine (10 mg/kg, s.c.) (Student's t-test, P<0.05).

**AN OPEN PROBABILITY ESTIMATE FOR CNS GABA\(_A\) CHANNELS.** M.V. Jones* and G.L. Westbrook. The Vollum Institute for Advanced Biomedical Research, Portland, OR 97201.

Inhibitory synaptic transmission in the CNS is shaped, in part, by the probability (\(P_o\)) that postsynaptic GABA\(_A\) receptor channels will open once they have bound GABA. In the past, \(P_o\) has been estimated by examining the proportion of time spent open during long bursts in steady-state single channel records. (Newland et al., 1991). At synapses, however, the GABA concentration is set at steady state. Disaggregation of GABA and receptor desensitization may play a role in determining time-dependent changes in \(P_o\) that shape the synaptic current. To assess \(P_o\), after pulses of 4 FRABA, we examined the variance of GABA-activated currents (by the method of Sigworth, 1980). Outside-out patches from cultured postnatal rat hippocampal neurons were voltage-clamped, and currents were activated by rapid applications of a saturating GABA concentration (100mM, 1 to 100ms duration, close solution exchange time, 22°C). Sampled currents (I=20kHz, 100/point) activated rapidly (2-3ms, 10-90%), showed multiphasic desensitization (\(t_m=20ms\) and \(t_d=1ms\)) and multiphasic deactivation (\(t_m=10, 50\) and \(200ms\)). For a series of up to 100 currents in a patch, the variance of each sampled data point about its mean was calculated using local averaging of every three currents to compensate for rundown. Fits of variance (\(\sigma^2\)) vs mean (\(\mu\)) were fitted to \(\sigma^2=\alpha\mu+\beta\), where \(\alpha\) and \(\beta\) are independent constants and \(\mu\) is the estimated apparent conductance, \(\mu\), but not \(N\), varied with potential (0.74±0.1pA/nS, 1.5±0.3 (N=4, 2.4±0.5 (N=5) at -30 to -40 and -90mV), giving a slope conductance of 30pS, close to the 26±2pS main conductance obtained by direct single channel measurements from these neurons. The mean peak current divided by the maximum current possible (\(I_{peak}/I_{max}\)) gave a mean \(P_o\) between 0.56 and 0.67, independent of potential. Our estimate of \(P_o\) at the peak of responses to saturating pulses of GABA is ~25% lower than that found within long bursts of steady-state single channel activity (Newland et al., 1991). These results predict that inhibitory postsynaptic currents in the CNS represent an opening of not more than ~40% of the channels that are present opposite the sites of GABA release.

**GABA RECEPTORS: FUNCTION III**

**ELECTROPHYSIOLOGICAL CHARACTERIZATION OF RECOMBINANT GABAR ISOFORMS COMPRISING THE MAIN CEREBELLAR GABAR EXPRESSED IN L929 MOUSE FIBROBLAST CELLS.** N.C. Saxena* and R.L. Macdonald. Dept of Neurology, Univ of Michigan, Ann Arbor, MI 48104.

Recent immunoprecipitation studies using mixtures of subunit-specific antibodies have provided valuable evidence for the subunit composition of GABAR isoforms in the rat cerebellum (C.J. Ragan et al. 1993. Biochem. Soc. Trans., 21:622-626). Based on their findings, these main GABAR isoforms comprise approximately 90% of total rat cerebellar GABARs. These are \(\alpha_6\), \(\beta_2\), or \(\delta\) subunits. Transfections with all three subunit combinations yielded a high percentage of GABA-responsive cells suggesting that GABAR isoforms predicted by immunoprecipitation studies of Ragan et al do indeed constitute functional GABARs in these cells. The concentration-response (CR) curves for \(\alpha_6\), \(\beta_2\), \(\delta\) and \(\delta\) GABAR isoforms indicate that the substitution of the \(\alpha_6\) subunit for the \(\alpha_6\) subunit and the substitution of the \(\beta_2\) subunit for the \(\beta_2\) subunit decreases the EC50 values for GABAR isoforms. \(\alpha_6\), \(\beta_2\), whole-cell currents were enhanced by disacchar so that the current is decreased in the presence of low concentrations of ketamine. The three different GABAR isoforms displayed differences in their response to disacchar so that the current is decreased in the presence of low concentrations of ketamine. The three different GABAR isoforms displayed differences in their response to disacchar so that the current is decreased in the presence of low concentrations of ketamine. Different channel characteristics of these GABAR isoform are under investigation.

γ-AMINOBUTYRIC ACID INCREASES INTRACELLULAR CALCIUM CONCENTRATION IN CULTURED RAT CORTICAL NEURONS.
Recent reports suggest that a major inhibitory neurotransmitter, γ-aminobutyric acid (GABA) increases intracellular calcium concentration ([Ca²⁺]ᵢ) in neonatal hippocampal neurons. In this study, we examined GABA-induced Ca²⁺ mobilization in cultured rat cortical neurons by using calcium indicator, fura-2/AM. Frontal cortex was isolated from Wistar rat pups at embryonic day 18 and cultured for 5-6 days. [Ca²⁺]ᵢ in single cells was measured with fluorescence microscopy/video camera systems. GABA and GABA-A receptor agonist, applied for 50 sec transiently, increased [Ca²⁺]ᵢ dose-dependently. The increase was inhibited by GABA-A antagonists, bicuculline and picrotoxin, but not by GABA-A antagonist, phaclofen. The [Ca²⁺]ᵢ increase was inhibited by EGTA and a Ca²⁺ channel blocker, nifedipine, the [Ca²⁺]ᵢ increase could be explained by Ca²⁺ influx through voltage-gated Ca²⁺ channel. These results suggest that GABA increases [Ca²⁺]ᵢ chiefly through GABA-A receptor and voltage-gated Ca²⁺ channel in immature cortical neurons.

703.5
It is known that activation of GABA-A receptors in LHRH secreting GTI-7 neurons results in membrane depolarization and calcium entry via voltage dependent calcium channels resulting in a calcium signal. We have analyzed this calcium signal using fura-2 based calcium imaging and the perforated patch-clamp technique. Instantaneous replacement of chloride ions in the medium with isotonic, resulted in a significant increase in the muscimol-induced calcium response. This increase, however, was transient and after 15 min of perfusion in zero chloride medium, the signal amplitude was only 50% of the normal chloride condition. Replacement of chloride with gluconate dramatically increased the calcium response since gluconate chelates extracellular calcium ions. Under current clamp, muscimol application induced a depolarizing response of 26 ± 10.0 mV with a few HTX-sensitive action potentials. In the absence of external chloride, the amplitude of muscimol-induced depolarization was smaller but the frequency of spikes was increased. Muscimol-induced depolarization and calcium increase were abolished in cells treated with furosemide (0.1mM) for 20 min. Ethacrynic acid (0.3mM) also reduced the calcium signal by 70%. Depletion of intracellular calcium stores by thapsigargin (100 nM) decreased the calcium response by 60% suggesting that release from stores contributes to the GABA-A mediated cellular calcium response. The data demonstrate that a cooperative action of furosemide- and ethacrynic acid-sensitive CI-pumps maintain outwardly directed driving force for chloride ions.

CHARACTERIZATION OF GABA, AND GABA-RECEPTORS IN TURTLE RETINAL GANGLION CELLS. Y. Liu and E.M. Lastennet
Moran Eye Center, Univ. of Utah, Salt Lake City, UT 84132.
We recently reported that turtle retinal ganglion cells express both GABA, and GABA receptors coupled to Cl channels. Experiments were carried out to further characterize the kinetic and pharmacological properties of these channels. Standard whole-cell patch recordings were made from isolated, cultured turtle retinal ganglion cells. Test agents were applied by a superfusion system. Application of GABA (1-100μM) induced a prominent inward current with two components in all ganglion cells tested. The decay of the GABA response could be fitted with a single exponential time course plus a steady state. The time constant of the transient current is about 3sec, while the steady state current is about 1000sec. GABA(1-100μM) activated a sustained current, which is very similar to the steady state current induced by GABA. Bicuculline (50-100μM) inhibited the transient but not the sustained current induced by GABA. Porcine (Ptx, 100μM) totally blocked both components of GABA response. Surprisingly, when Ptx was washed out, subsequent application of GABA only activated the sustained current. It took another application of GABA to induce both components. To further test if Ptx blocks the two types of GABA receptors via different mechanisms, lower concentration of GABA (1-10μM) was applied twice (interval, 2min). It was found that the second application of Ptx inhibited more transient current as compared to the first application of Ptx. This is consistent with the mechanism of open channel block. On the other hand, the percentage of the sustained current inhibited by Ptx is constant regardless of how many times Ptx was applied, which indicates that the inhibition of the sustained GABA response is mediated by some other mechanisms then open channel block. Our data suggest that the GABA and GABAB receptors in turtle retinal ganglion cells are coupled to Cl channels with different kinetic and pharmacological properties. Moreover, we first report that Ptx may regulate the GABA, and GABAB receptors via different mechanisms.

703.4
We have tested the sub-population of retinal neurons in the II organ of the crayfish with identified by using a monoclonal anti-Leu-enk antibody (Neurom). Only eight cell bodies with diameters between 35 to 50 μ located in the most superficial layer of the II organ were immunopositive. These cells may be the same found to react to an antibody against the crustacean hyperactive hormone (Van Herp & V. Buggenum, Experimenta 35: 1527, 1979). The isolated II organ cells were kept in culture several days. GABA was applied in microdrops onto different regions of the neuron. A dose-dependent depolarization was elicited, resulting in the firing of action potentials. This effect was reversibly blocked by Picrotoxin and Bicuculline and was mimicked by Muscimol. Under voltage-clamp conditions, the reversal potential for the GABA-induced current was shifted to more positive values. This suggests that chloride mediates the effect of GABA on X organ cells.

GABA-INDUCED GABA RELEASE IN CULTURED EMBRYONIC RAT THALAMIC NEURONS IS Ca²⁺-DEPENDENT AND TTX-INSENSITIVE. O.Y. Lin*, J. Vauthrin, A. Schaffner, K.M. Tang, W. Ma and J.L. Barker. Lab. of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.
In embryonic and early postnatal stages, GABA has excitatory effects on most if not all neurons expressing functional GABA-A receptor-coupled Ca channels. Due to a depolarizing CI gradient, activation of GABA-A receptor-coupled Ca channels depolarizes neurones, which in turn may activate voltage-dependent Ca²⁺ channels and lead to increases in cytosolic Ca²⁺ (Ca²⁺;). But in some cells GABA induced increase in Ca²⁺ does not appear to be mediated by classical CI channel coupled GABA-A receptors. In culture embryonic (E17) rat thalamic neurones, we found that 10μM GABA induced or increased the frequency of miniature synaptic-like transients (minis) superimposed on persistent CI current response. The minis reversed polarity at E₅₀, were blocked by bicuculline and decayed with kinetics similar to GABA-activated CI channels suggesting they were GABAergic. The agonist concentration that induced minis was lower than that required to activate CI channels. Interestingly, the GABA-A receptor/CI channel agonist muscimol readily induced CI current response but failed to mimic GABA in triggering minis. GABA-induced GABA release was dependent on extracellular Ca²⁺ and insensitive to 2μM TTX. We conclude that GABA can trigger GABA transients in cultured embryonic rat thalamic neurones through an action of GABA that does not involve classical GABA-A receptor/CI channels.

703.8
The GABA-A agonist baclofen has been shown to suppress synaptic transmission in subregions of the hippocampus and in the perifrom (olfactory) cortex. Here we report a laminar selectivity of suppression of synaptic potentials in the olfactory cortex. In brain slice preparations (n=27), baclofen suppresses extracellularly recorded field potentials at the intrinsic fiber synapses proximal to the superficial pyramidal cell bodies (layer Ib) while leaving the afferent fiber synaptic potentials recorded at the distal dendrites (layer Ia) little affected. The suppression of synaptic potentials was significantly stronger in layer Ib (n=5) than in layer Ia (n=3) at each of the following concentrations: 0.1, 1.0, 10, 100 and 500 μM. At the concentration of 100 μM, suppression in layer Ia was 5.1 ± 6.3% (n=5); suppression in layer Ib was 68.3 ± 6.7% (n=5). Suppression of intrinsic fiber synaptic transmission in layer Ib had an E₅₀ = 92.5 μM. This dose dependent selective suppression of intrinsic fiber synaptic transmission is also correlated with an increase of pameide-pulse facilitation. These results suggest that afferent and intrinsic synaptic inputs may be differentially modulated by the activation of GABA-A receptors and that this selective suppression is at least partially mediated via a pre-synaptic mechanism.
GABA RECEPTORS: FUNCTION III

703.0 DEPOLARIZING AND HYPERPOLARIZING GABA RESPONSES IN THE XENOPUS SPINAL CORD ARE MEDIATED BY GABA A RECEPTORS.

GABA RECEPTORS: FUNCTION III

T03.15 EVALUATION OF FLUORESCENCE AND ELECTROCHEMICAL DETECTION OF G-AMINOBUTYRIC ACID IN MICRODIALYSIS SAMPLES

A technique of in vivo microdialysis has been used in number of studies to characterize extracellular release and uptake of g-aminobutyric acid (GABA) in the brain. It was shown that at least 50% of GABA overflow in the striatum of freely moving rats is of neuronal origin. Determination of GABA requires an ultrasensitive analytical method, since GABA levels in typical microdialysis sample are often in the range of 10-5 pmol (50 nmol). Previously we developed an isotropic HPLC method based on electrochemical (EC) detection of GABA derivatized with OPA-butylthiol. The limit of detection was 50 fmol GABA. However, the excess of thiol which is oxidized on the electrode and a high acetone (50%) in the mobile phase are most probable causes of shortened life-time of the electrode, gradually increasing background signal and noise levels. The result is that a substantial portion of "research time" is spent on system maintenance.

Fluorescence detection of OPA derivatized amino acids is a more common way to determine physiological amino acid in body fluids. Normally, by using gradient elution and OPA/mercaptoethanol derivatization the limit of detection for GABA is only 0.5 pmol. To achieve GABA detection of 50 fmol we developed a new method based on microbore columns and optimized isotropic separation with a step gradient. The step gradient is achieved by a low pressure switching valve installed at the pump inlet. The whole system is fully automated allowing analysis of up to 80 samples/day.

Correlation between these two techniques was studied for microdialysis samples from the rat. Advantages and limitations of both methods are discussed. Ref. 1. Kehr J. and Ungerstedt U., J. Neurochem. (1986) 51, 1308.

T03.17 HETEROREGONETY OF ALLOSTERIC COUPLING IN GABA A RECEPTORS REVEALED BY A SUBUNIT SPECIFIC ANTIBODIES. K.H. Huht, S. Endo and R.W. Olsen, Department of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024.

GABA receptors are composed of multiple binding domains which are allosterically coupled with each other in a functionally relevant manner. Differential degrees of coupling observed in different brain regions have been interpreted as the existence of receptors with diverse subunit combinations.

In the present study, the subunit specificity of allosteric interaction between GABA and benzodiazepine binding sites were studied using a subunit specific antibodies. In the TX-100 soluble extract from rat whole brain, GABA A receptors immunoprecipitated with a1 antibodies had a significantly lower maximal enhancement of [3H]flunitrazepam binding by GABA than those immunoprecipitated with a2 or a3 antibodies (35 +/- 2% for a1, 75 +/- 4% for a2 and 83 +/- 1% for a3). On the other hand, receptors containing a1 or a3 subunits have higher affinities for the benzodiazepine (-2 x 10 -10 M) and 36 +/- 20 nM, respectively) as opposed to those containing a2 subunits (142 +/- 27 nM). These differential coupling efficiencies endow unique functional and structural properties to different a subunit containing receptors. In addition to the previously identified benzodiazepine pharmacology, it would be of interest to see if this heterogeneous binding profile can also be translated into the differential coupling with the channel gating domain.

Supported by NIH grant NS 28772.

Previous studies detected high affinity opioid binding sites in synaptosomal plasma membrane (SPM) and microsomal (MI) fractions of rat brain. Since they were found to be uncoupled from G-proteins in the latter, they were postulated to be desensitized sites. To explore this hypothesis, female Wistar rats were s.c. injected by increasing doses of morphine twice daily for 5 days. Western-blotting with specific antiserum, pertussis toxin catalysed ADP-ribosylation and photoaffinity labeling studies all showed that prolonged exposure to morphine elevated the amount of G-proteins which was calculated 63% and 30% in SPM resp. MI in [35S]GTPyS binding studies. The Bmax for the μ-opioid agonist [3H]DAMGO nearly doubled in MI after morphine treatment. These up-regulated sites displayed profound sensitivity to GTP unlike the μ-sites detected in MI of untreated rats.

These results suggest that regulation of G-proteins represent part of the molecular changes that underlie morphine effects in brain, and further emphasize the significance of intracellular events.

Supported by OKTA-8359 research grant.

The steady-state levels of MOR mRNA were measured by solution hybridization in samples microdissected from rodent brain and spinal cord. In adult male rats, a 7 day treatment with morphine (2 X 75 mg pellets, implanted sc on days 1 and 4), which produces a 11-fold shift in morphine dose response curves, increased the levels of MOR mRNA in the dorsal horn of spinal cord (SpC), nucleus raphe magnus (NRM), periaqueductal gray (PAG), medial thalamus (Thal), hypothalamus (Hyp) or somatosensory cortex (Ctx) of treated rats as compared to placebo controls. The MOR mRNA levels ranged from 0.7 pg/μg RNA in Ctx to 15.0 pg/μg RNA in Thal. The CBXK (μ-deficient) mice were found to be 7-fold less sensitive to systemic morphine than CD-1 mice, as assessed using the tail flick test (ED50 estimates were 29.4 and 4.2 mg/kg sc, respectively). CBXK mice were also found to have lower MOR mRNA levels than CD-1's in SpC (by 28%), NRM (by 43%), PAG (by 35%), Hyp (by 49%) and Thal (by 15%), but not in Ctx. The CD-1 MOR mRNA levels ranged from 0.04 pg equiv./μg RNA in Ctx to 0.52 pg equiv./μg RNA in Thal. Thus, while no change in MOR mRNA occurs in morphine tolerant rats, the low levels in CBXK mice may result in fewer opioid binding sites and contribute to the functional difference between CD-1 and CBXK strains. Supported by DA07274, DA01457, DA00196 and VZ Research Foundation.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

The steady-state levels of OR mRNA were measured in male C57-B16 mice rendered tolerant to the antinociceptive effects of the selective DOR opioid [D-Ala²-Nal]enkephalin II (DOR II) and morphine (MOR). After 7 days of administration of MOR (10 mg/kg, s.c.) or DOR II (10 mg/kg, s.c.) for 4 days, the OR values for MOR and DOR II were increased 5- and 8-fold, respectively, relative to saline controls. DOR mRNA levels were measured by solution hybridization in samples obtained by microdissection of CNS regions of tolerant and control mice. DOR transcript levels, in pg/ug of total RNA, were highest in the caudateputamen (0.47) and frontal cortex (0.32). Moderate levels were observed in n. accumbens (0.26), olfactory cortex (0.20), PAG (0.2), and hippocampus (0.14). The medial thalamus (0.03) and cerebellum (0.04) displayed relatively low levels of DOR mRNA. The OR mRNA levels in the CNS regions of MOR or DOR II tolerant mice did not differ significantly from controls in any CNS region studied. These data suggest that altered levels of OR mRNA are not one of the adaptive changes observed in mice tolerant to the antinociceptive effects of MOR or DOR II. Supported by DA07274, DA01457, DA00198, the NIMH Research Foundation and a grant from the Aaron Diamond Foundation.

MOLECULAR LESIONING OF OPIOID DELTA-NCX BINDING SITES IN RAT BRAIN BY ANTI-SENSE OLIGODEOXYNUCLEOTIDES. X.Y. Cha, H. Xu, K.C. Hopp0, E. Porco, J. LaB and P.B. Rothman. ICPS, IRP, NIDA, NIH Baltimore, MD 21224, 2LMC, NIDDK, NIH, Bethesda MD 20892. 3Department of Pharmacology, University of Arizona, Tucson AZ 85724.

Previous studies support the existence of two delta receptor subtypes called delta-cx and delta-ncx. Other studies have delineated the existence of additional subtypes termed delta-c1, delta-c2, delta-ccx, and delta-nx. These sites are assayed with [3H]DADL (10 mM TRIS-HEC, pH 7.4, 100 mM NaCl, 3 mM MgCl2, 2 mM GDP and 5 mM 2-mercaptoethanol) using rat brain membranes depleted of delta-ncx sites by pre-exposure with the delta-ncx-selective acetylating agent, (-)-trans-SUPERFIT or depleted of delta-cx sites by pretreatment with the delta-cx-selective acetylating agent, BIT. The recent cloning of a rat brain delta receptor raises the issue of the relationship between the multiple binding sites defined on the basis of our ligand binding studies and the molecularly defined delta receptor. To determine this, the antinonsense oligodeoxyribonucleotides complementary to the 5' end of the coding sequence of the cloned delta opioid receptor (nucleotides 7 to 26) and the corresponding sense oligodeoxyribonucleotides were administered i.c.v. twice a day for three days. Our data demonstrate that the antisense DNA selectively inhibited [3H]DADL binding to the delta-ncx site by 50%. Studies underway will determine effect of the antisense DNA on the two subtypes of the delta-ncx binding site.

The utilization of various agents to pharmacologically manipulate the opioid receptor system has been extensively studied using several radiolabeled techniques. In the present study, in vitro receptor autoradiography was used to characterize the anatomical distribution of [125I]-DAMGO binding sites in discrete brain nuclei of rats treated chronically with (+)RTI-14, a novel PCP site 2 ligand with moderate amine uptake inhibition activity, and of other potent amine uptake inhibitors. ALZET 2002 osmotic minipumps (0.5 ml/hr for 13 days) were filled with saline, (+)RTI-14 (1 mg/ml), cocaine hydrochloride (5 mg/ml) or imipramine (5 mg/ml). Regional brain sections (14 mm) at the striatal level were used to assess treatment effects on the mu opioid receptors. Initial findings demonstrate that (+) RTI-14 significantly decreased [125I]-DAMGO binding distribution in each specific nuclei measured. Chronic cocaine increased [125I]-DAMGO binding in caudate patches and matrix, while the imipramine-treated animals showed no changes from controls. Studies are in progress to confirm and extend these observations.

To characterize the establishment of opioid systems during development, we have begun to examine the distribution of 5 receptor mRNA at early postnatal stages of mouse development using in situ hybridization. In the developing nervous system, we have thus far detected restricted 5 receptor gene expression as early as postnatal day 1 (p1) in the postrema, pons-premotorum, and medulla oblongata, and have localized particularly intense hybridization to a band of cells near the brainstem, olfactory bulb, and peripheral nervous system. The distribution of 5 receptor mRNA levels as assayed by in situ hybridization has provided the developmental anatomical detail that complements prior receptor binding studies. In the hypothalamus at p4, for instance, 5 receptor mRNA is detected in specific cells of the luteinizing hormone area, in addition to the expression in the ventromedial hypothalamic nuclei similar to reported results from opioid binding studies. In addition, the pattern of high 5 receptor expression in subgroups of adult CA3/CA4 hippocampal neurons is already established at early postnatal ages. Although the levels of 5 receptor mRNA are low in all, cell groups, particularly in the ventromedial hypothalamic nuclei, relatively high transcript levels were detected in the pontine nuclei, reticular formation, and zona incerta nigra. The cellular resolution afforded by in situ hybridization has provided additional anatomical detail that complements prior receptor binding studies. In the hypothalamus at p4, for instance, 5 receptor mRNA is detected in specific cells of the lateral hypothalamic area, in addition to the expression in the ventromedial hypothalamic nuclei similar to reported results from opioid binding studies. In addition, the pattern of high 5 receptor expression in subgroups of adult CA3/CA4 hippocampal neurons is already established at early postnatal ages. Although the levels of 5 receptor mRNA are low in all cell groups, particularly in the ventromedial hypothalamic nuclei, relatively high transcript levels were detected in the pontine nuclei, reticular formation, and zona incerta nigra.

This study examined the magnitude of peripheral opioid antinociception in relation to 1) the development of inflammation, 2) µ-opioid receptor mRNA gene expression in dorsal root ganglia (DRG); 3) the number of peripheral µOR and 4) leakage of the perineurium of peripheral nerves. After Freund's adjuvant induced unilateral hindpaw inflammation in Wistar rats volume and temperature of the inoculated paws and, in parallel, anti-NOCICEPTIVE effects of DAMGO (µ-selective opioid agonist) increased significantly at 6 hrs, reached a maximum at 24 hrs and did not significantly change until 96 hrs. Doses of i.p. 8-KU, an irreversible µ-receptor antagonist, required to antagonize the anti-NOCICEPTIVE effects (IC50 values) increased linearly up to 96 hrs of inflammation. Using a expression protection assay, µOR mRNA levels were detectable in DRG 3-5 days after injury and displayed a trend towards an increase on the inflamed side by 24 hrs. Perineural leakage, assessed by horseradish peroxidase histochemistry, was apparent in late stages (60 hrs) of inflammation. In conclusion, gene expression, number and accessibility of µ-opioid receptors appear to be "up-regulated" during inflammation, resulting in a greater efficacy of peripheral acting opioids.
OPIOID RECEPTORS: LOCALIZATION

Mediation of opioid reinforcement has been associated with 5-opioid receptors in cortical-limbic structures. We utilized an antiserum shown to be specific for the 5-opiate receptor to determine whether topographical or ultrastructural localization could demonstrate a selective cellular substrate for these actions. Light microscopy examination among cortical areas revealed immunoreactivity (IR) in limbic-associated cortex to be distinguished by 1) lack of superficial laminar staining, 2) heavier deep laminar labeling and 3) sparse to moderate labeling of varicosity-laden fibers. Ultrastuctural analysis of insular cortex showed δ-opioid receptor labeling localized predominantly in small unmyelinated axons and terminals and in distal processes of axon terminals. In terminals, plasma membranes and synaptic vesicles were most intensely labeled. Additionally, dendritic labeling was detected and was most prominently associated with plasma membranes, smooth endoplasmic reticulum and occasionally perisynaptic densities. In a second portion of the study we examined the anatomical relationship between the δ-opiate receptor and endogenous opioids by combining immunoperoxidase and immunogold-silver methods, for localization of antisera directed against the δ-opioid receptor and [2°]-enkephalin (ENK) in single sections. ENK labeling was principally seen in large dense core vesicles (DCV) within axon terminals. Terminals appeared more homogenously distributed as compared to the δ-opioid receptor. In the regions that examined neither axon terminals nor dendrites were in contact with ENK neurone have shown detectable δ-IR. We conclude that in limbic cortex, δ-opioid receptors 1) are predominantly presynaptic modulators and 2) may be activated by opioid peptides released more distally from DCV. Supported by DA0660, DA01724, DA01657, DA01918 and Aaron Diamond Foundation.

Delta opioid receptor heterogeneity has been well established by pharmacological studies. Recently we have cloned a human δ opioid receptor by screening human cDNA libraries. It is suggested that this human δ opioid receptor matched the δ3 subtype, since it showed higher affinity to the δ3 selective ligand (NTB) than to that to the δ1 selective ligand (BNTX). Other cloned mouse and rat δ opioid receptors also shared δ3 receptor ligand binding properties. Thus, the δ3 subtype has not been cloned in any species.

In order to obtain the δ1 opioid receptor subtype molecular structure, one of the strategies is to find tissues containing δ1 rather than δ3 opioid receptor subtypes. Therefore, three interesting tissue membranes have been studied. First is the CXXBK mouse brain membrane, which was suggested to have a predominant population of supraoptimal δ3 opioid receptors, rather than δ3 opioid receptors by Raffa et al. (1992). The second is the guinea pig brain membrane, in which the δ1 selective antagonist BNTX showed 10-fold greater affinity (Ki = 0.1 nM) for [3H]PDPE binding sites (δ2) relative to those of [3H]DSG (δ3) (Portoghese et al., 1992). The third is the rat olfactory bulb membrane, in which the stimulation rather than inhibition of adenylate cyclase activity was observed (Ollano and Onali, 1992). Radioligand binding studies were performed in these three tissues, and the data will be presented. Supported in part by NIDA grants.

We have demonstrated previously that a population of small neurons in dorsal root ganglia as well as afferent fibers and terminals in the spinal cord are immunoreactive (IR) for delta (δ)-opioid receptors (Neuroreport 5:341, 1993). Presently, we report that most (μ)-opoid receptors share a similar distribution, and that both opioid receptors are restricted to a population of sensory neurons and axons not immunoreactive for neurofilament protein. Rabbit antisera produced against synthetic δ (IODS) or μ (MOR) opioid receptors were combined with a mouse monoclonal antibody (RT-97) directed against the 200 kD neurofilament protein subunit, which is a cytochemical marker for large sensory neurons with rapidly conducting axons. Dual color immunofluorescence was employed to test for the coexistence of opioid receptor- and RT-97 IR in sensory cells and axons. Within the DRG, MOR- and MOR-IR were confined almost exclusively to a population of small diameter cells and axons. In peripheral nerve, dorsal rootlets, and spinal gray matter, opioid receptor-IR was localized to small fibers. RT-97-IR was distributed to larger DRG cells and axons, and to peripheral nerve and spinal cord was found in large and small caliber fibers. Rarely did DRG- or MOR-IR coexist with RT-97-IR within the same neuronal elements, supporting the hypothesis that opioid receptors are localized to the terminals of nociceptive primary afferent neurons. Supported by NIH grant NS25658 and grants from NIDA.
THE RELATIVE DISTRIBUTIONS OF mRNAs ENCODING FOR MU AND DELTA OPIOD RECEPTORS AND FOR GLUTAMIC ACID DECARBOXYLASE (GAD) IN THE VENTRAL MESENCEPHALON. Darragh P. Devine*, Stanley J. Watson and Huda Aki. University of Michigan, Ann Arbor, MI, USA. 
Radioactive in situ hybridization was used to characterize the distributions of mRNAs that encode for mu and delta opioid receptors, and for glutamic acid decarboxylase (GAD) in rat ventral mesencephalon. The appropriate probe for each was used in combination with the delta and GAD mRNAs were labeled with 35S, and applied to serial sections of rat brain. GAD mRNA was most abundant in the interpeduncular nucleus (IPN). A moderate amount of GAD mRNA was found in the substantia nigra pars reticulata (SNpr) and substantia nigra pars compacta (SNpc) and Ventral Tegmental Area (VTA). Mu receptor mRNA was most abundant in the IPN, and low levels of mRNA were found in the SNpr, SNpc, and VTA. Delta opioid receptor mRNA was also most abundant in the IPN, with low levels throughout the SNpr, SNpc, and VTA. We are currently examining the possibility of cellular colocalization of these three mRNAs using double-labeled radioactive (35S) and non-radioactive (digoxigenin) in situ hybridization.

Activation of kappa (k) receptors diminishes excitatory transmission in the dorsal raphe and CA5 regions of the guinea pig hippocampal formation. Although many biochemical and physiological studies have suggested that k receptor-mediated neurotransmitter release is not yet evaluated, the anatomical localization of k receptors to pre- or post-synaptic processes has not yet been reported. We examined the distribution of a polyclonal rabbit antibody raised against a peptide from the C-terminal portion of a mouse k receptor. Specificity of the affinity-purified antibody was determined by Western blotting and immunolabeling of k receptors expressed in Xenopus oocytes. The antibody has been shown to be immunocytochemically in acronically fixed brain sections. Sections incubated in antibody preadsorbed with the antigenic peptide had no labeling by light or electron microscopy. By light microscopy, k receptor-like immunoreactivity (k-LI) was present in varicose processes in the dentate gyrus inner molecular layer, granule cell layer and hilus, and in CA3 and stratum lucidum and radiatum. By electron microscopy, k-LI was found in small unmyelinated axons and terminals, and was associated with large vesicular structures, cytoplasmic surfaces of small vesicles and plasma membranes. In the dentate gyrus, axons and terminals with k-LI contacted large dendrites and perikarya of presumed granule cells. In hila and in stratum radiatum of CA3, axons with k-LI were apposed to unbranched dendrites or other axons. In stratum lucidum, axons with k-LI were found occasionally in bundles of ribbon fibers. We were ultrastuctural data support physiological and biochemical evidence that k opioids modulate transmitter release from axons in guinea pig hippocampal slices. Supported by DA0269, DA0272, DA04123.

DELTA OPIOD RECEPTOR- AND ENKEPHALIN-IMMUNOREACTIVITY ARE SPATIALLY RELATED IN THE MOUSE CNS. L-H Lee*, TC Breit, RJ Dado, HH Loh, F-Y Law and R Eide. Departments of Cell Biology & Neuroanatomy and Pharmacology, University of Minnesota, Minneapolis, MN 55455
The cloning of a µ-opioid receptor (DOR) has permitted the raising of antibodies which recognize this protein. We previously reported that immunostaining for DOR in the dorsal horn of the spinal cord is strikingly restricted to axons and their terminals, and that these terminals are closely apposed to enkephalin-immunoreactive (ENK) boutons (Dado et al., NeuroReport 5:341-344, 1993). In the present study, we have examined the spatial relationship of DOR and ENK-nr fiber nerves in other regions of the central nervous system using histologic methods and montages produced from confocal microscopy. Nerve fibers and terminals with prominent DOR-ir were observed, for example, in the islands of Calleja and olfactory tubercle, the caudate-putamen, the globus pallidus and entopeduncular nucleus (n), amygdaloid nuclei, mammillary nuclei, the substantia nigra, interpeduncular n., raphe pontis, parabrachial n., of the solitary tract, lateral reticular n. and spinal trigeminal n. DOR- and ENK-nr fiber nerves have been described in these regions, however it is not clear if DOR-ir was found in the same elements as ENK-ir. Thus, DOR is unlikely to be an autoreceptor. In some regions, DOR-ir was abundant in areas which did not contain ENK-ir, and vice versa. These preliminary studies were in many instances immediately adjacent to each other, suggesting that the opioids may participate in interneuronal communication over significant distances. Supported by grants from NIDA.

A rabbit polyclonal antiserum to a peptide derived against a homogenate conjugate of the C-terminal amino acids of the µ opioid receptor. The antiserum produced high titters (1:4,000) when analyzed by ELISA, recognized purified µ opioid receptor protein in Western immunoblots, and stained in situ cells expressing the µ-opioid receptor. Microscopic examination of immunostained brain and spinal cord sections revealed that µ-opioid receptor immunoreactivity was present in fiber- and terminal patterns in amygdala, nucleus accumbens, globus pallidus, substantia nigra, medial habenula, substantia nigra, ventral tegmental area, periaqueductal gray, nucleus raphe magnus, nucleus tractus solitarius, zona spongiosa and substantia gelatinosa, while little was observed in neocortex or hippocampal formation. Neural cell bodies were immunostained in areas including hypothalamus. In situ hybridization studies of brain regions including thalamus revealed dups that were observed little tonomic immunoreactivity. No immunoreactivity was observed when preimmune or preadsorbed sera were used. These results directly show the distribution of the immunoreactive receptor in the rat central nervous system.

A MONOCLONAL ANTIBODY TO THE KAPPA OPIATE RECEPTOR. A.L. Brooks, K.M. Standifer, G.W. Pasternak, The Corzias Laboratory of Neuro-Oncology, Department of Neurology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021
Monoclonal antibodies (mab) were raised against Be(2)-C human neuroblastoma membranes which contain µ, δ, and κ opioid receptors. Over 5000 hybridoma cell lines were screened, with 2000 hybridomas testing positive against the Be(2)-C membranes. Screening against another neuroblastoma line lacking opioid receptors, left 98 positive for Be(2)-C mab. Several hybridomas showed high immunoreactivity to the Be(2)-C membranes, but only five of these clones, 8D6, 25G11, 13F3, 7G1, and 22H11 inhibited binding to the κ opioid receptor. Mab 8D6, inhibited up to 95% of 3H-NalBol (κ) binding with no effect on 3H-DAMGO (µ) or 3H-DPDPPE (δ) binding, illustrating the selectivity of mab 8D6 for the κ subtype. Mab 8D6 recognized κ receptors in mouse, rat, and calf brain homogenate binding assays. In addition, mab 8D6 blocked the inhibition of CAMP accumulation by NalBol but not morphine. On Western blots, mab 8D6 labeled proteins consistent with the putative κ receptor. Mab 8D6 also recognized a novel opioid receptor clone corresponding to the κ receptor. In immunocytochemistry studies the mab effectively labeled Be(2)-C cells but not cells lacking κ receptors. Mab 8D6 has also been effective in labeling brain slices, demonstrating its utility in establishing the distribution of κ receptors in the nervous system. Further characterization and purification of mab 8D6 is ongoing.

Antibodies to the δ-opioid receptor (DOR) and the µ-opioid receptor (MOR) were generated and used to map DOR- and MOR-immunoreactivity (i) in the central nervous system (CNS) of adult mice and rats (Lee et al., this meeting; Arvidsson et al., this meeting). In the present study, these antibodies were used to examine spatial relationships between these receptors and neuropeptides and other transmitters at the cellular level. Sera from rabbits immunized against amino acids 3-17 (Dado et al., NeuroReport 5:341-344, 1993) of the predicted sequence of DOR were used in conjunction with a monoclonal antibody to substance P (SP) for two color immunofluorescent staining and analysis. A high degree of colocalization between DOR and SP was seen in axons and terminals in many regions of the brain and spinal cord. Extensive colocalization was evident, for example, in the islands of Calleja and olfactory tubercle, the shell of n. accumbens, ventral pallidum, lateral septal nucleus, and ventral tegmental area. Results suggested that the apparent colocalization was not artifactual. Interestingly, high levels of DOR receptors occur on noradrenergic fibers originating from locus coeruleus. However, a high degree of colocalization was not observed for molecules which mark these systems. In summary, a summary was made of known regions which display different DOR- and SP-ir in axons and terminals, suggesting a presynaptic role for this receptor in regulating the release of SP and transmitters which coexist with it, in a wide range of systems. Supported by NIDA.

OPIOID RECEPTORS: CELL BIOLOGY AND EFFECTOR MECHANISMS

T06.1
RECONSTITUTION OF A PURIFIED & OPIOID BINDING PROTEIN WITH PURE G-PROTEINS IN LIPOSOMES
Fan,L.*Q., Cisagliani,T.L.*, Dingus,J.X., Wilcox,M.A.*
Hildebrandt,J.M. and Simon,Y.F.*
*Departments of Psychiatry and Pharmacology, NYU Medical Center, New York, NY, **Department of Pharmacology, Medical University of South Carolina, Charleston, S.C.
A functionally active & opioid binding protein (OBP), purified to homogeneity from bovine striatal membranes, has been reconstituted with purified G-proteins into liposomes containing the phospholipid, phosphatidylcholine. Liposomes were formed by precipitating the lipid-protein mixture with PEG and resuspending the liposomes in buffer. Most experiments were done with a highly purified bovine brain G-protein mixture, but individual purified Gs and Gq-proteins were also found to be effective. Functional reconstitution was evaluated by measuring stimulation of the GTPase activity of G-proteins by opioid agonists and high affinity agonist binding. Low-Km GTPase was stimulated by the & agonists DAMGO, DAGO, or levorphanol (max. 100% over basal), but not by DPDE or US50,488H. Stimulation was reversed by naloxone and b PAGE stimulation and naloxone reversal were stereospecific. The [3H]-DAGO binding observed in the liposomes with purified G-protein mixture and OBP had a Kd of 8nM, an affinity slightly lower than that seen in bovine striatal membranes, and was sensitive to inhibition by GTPyS and sodium. No high affinity delta or kappa binding was observed in the reconstructed system. The evidence from this study has shown that unexpected results suggesting that OBP is a & receptor.
(supported by grant DA-000117 from NIDA to EJS).

T06.2
INVOLVEMENT OF GUANYLATE 5'-TRIPHOSPHATE IN & OPIOID RECEPTOR-ACTIVATED POSTSYNAPTIC RESPONSES IN SUBSTANTIUM GELATINOSUM NEURONS. S.P. Schneider* and A.R. Light
Dept. of Physiology, University of N. Carolina, Chapel Hill, NC 27514-7545.
The involvement of the nucleotide 5'-GTP in the & receptor-activating & G-protein actions on substantia gelatinsa (SG) neurons was investigated using tight-seal whole-cell recordings from superfused transverse slices of hamster spinal cord. Bath application of the & receptor agonist [D-Ala2,N-Me-Phe4,Gly-ol5]-enkephalin (DAMGO) 1.5-7.5 mM caused a desensitization and decrease in neuronal input resistance (Ri) in 62% of SG neurons when the electrode internal solution contained 100 &M GTP and 2 mM ATP. However, at bath concentrations up to 10 &M DAMGO had little or no effect on the transmembrane potential or Ri of SG neurons using electrodes without GTP and ATP. DAMGO-activated responses were attenuated in SG neurons after dialysis with internal solution containing 2 mM ATP but no GTP. DAMGO activated a non-reversing membrane hyperpolarization in SG neurons recorded with electrodes containing 100 &M GTP-S, a nonhydrolyzable GTP analogue. SG neurons were less responsive to DAMGO following intracellular application of the analogue GDP-7-S (500 &M) which blocks &-protein activation. We conclude that intracellular GTP is necessary for &-opioid-receptor-mediated responses in SG neurons, consistent with the idea that anticonoperative effects of opioids are mediated through receptor-coupled second messenger systems involving G-proteins. The results resolve why DAMGO does not always evoke postsynaptic effects in superficial dorsal horn neurons in whole-cell recordings. Supported by NINDS grant NS23771 (S.F.S.), NIDA grant DA06440 (A.R.L.), and NIDODS grant DA4759013 (E.R. Peril).

Application of mu-opioid agonists evoked an increase in K+ conductance in Xenopus oocytes expressing the mu1 subtype receptor and the G-protein-gated, inwardly rectifying K+ channel (KGA). The amplitude of the response decreased during agonist exposure with a t1/2 of 8-22 min. In oocytes expressing both the mu1 and SHTA receptors, stimulation of either receptor resulted in heterogeneous desensitization of the subsequent response to the other. Injection of GTPyS (1 mM) increased the peak response to agonist but did not affect the rate of desensitization. Basal channel activity was significantly decreased in the absence of agonist and also desensitized at the same rate when the oocytes were clamped at -80 mV and bathed in high K+ (96 mM) solution. The above results indicate that the desensitization of the response occurred downstream of the receptor, possibly at the channel. Response desensitization occurred at the same rate if the cells were clamped either at 0 mV or with agonist in low K+ buffer (2 mM). The rate of desensitization was not significantly altered by any of the following treatments: removal of external Ca2+, prescaling the oocytes with 0.01 M CaCl2, increasing the extracellular Ca2+ (10 mM), staurosporine (50 &M), or cyclosporin A (50 &M). These results suggest that desensitization requires open channels but may not involve a calcium or phosphorylation-dependent mechanism or internalization of components of the transduction pathway. Supported by DA04123.

T06.4
KAPPA OPIOID RECEPTORS COUPLE TO INWARD RECTIFIER K+ CHANNELS WHEN COEXPOSED IN XENOPUS OOCYTES. D.J. Heady, M.P. Lim, H.A. Lester, N. Davidson and C. Chavkin.
Dept. Pharmacology, 1, Univ. of Washington, Seattle, WA and Div. of Biology* and CNS Program*, California Institute of Technology, Pasadena, CA.
Xenopus oocytes expressed kappa (k) opioid specific binding sites 5-14 days following injection of mRNA prepared from a clone of the mouse k opioid receptor (provided by David Grandy, Volum Inst., Portland, OR). Expression of k receptor (870 fmoles 1H-U59,869/mg membrane protein) was observed 7 days after injection of 5 ng mRNA/ococyte. The k receptor was previously shown to negatively couple to N-type Ca2+ channels. We find that the injection of k receptor mRNA with mRNA coding for an inward rectifier channel (KGA) resulted in oocytes that expressed k agonist-gated K+ currents. The K+ current (I69,593) activated a large (10-15 &A) inwardly rectifying K+ current with an EC50 of 200 &M. This agonist-gated K+ conductance was not observed in oocytes injected with mRNA for the k receptor or KGA channel alone. The k agonists, DAMGO (10-4 M) and U69,593 (1 &M) significantly potentiated the maximum response to U69,593. The acute response to U69,593 desensitized rapidly, with a t1/2 of 4 minutes following peak response. Supported by DA 04123 and DA 05610.

T06.5
ONTOGONY OF &-OPINATE INHIBITION OF ADENYLYL CYCLASE AND GTP MODULATION OF &-RECEPTOR BINDING IN RAT BRAIN. J.J. Li* and C. M. Kahn. Dept. of Pharmacology, Duke University Medical Center, Durham, NC 27710.
Signal transduction pathways play a critical role in opiate receptor function, especially after chronic exposure. To understand the consequences of perinatal opiate exposure, it is necessary to characterize the coupling of opiate receptors to their respective signal transduction pathways during development. The present study investigated the inhibition of basal and forskolin-stimulated cAMP accumulation by DAMGO, a selective & agonist, in striatal membranes from 10 and 60 day old rats. The ability of Gpp(NH)p to shift striatal &-receptors from high to low affinity at these ages was also assessed.
DAMGO (0.1-10 &M) significantly inhibited basal and forskolin-stimulated cAMP accumulation by 25%, and 22%, respectively, in 60 day old rats. In contrast, DAMGO failed to inhibit significantly cAMP accumulation in 10 day old rats. Approximately 30% of striatal &-receptors were shifted to low affinity by Gpp(NH)p in 60 day old rats, whereas only 4% were shifted to low affinity in 10 day old rats. These data suggest that &-receptors in 10 day old rats are not coupled as tightly to effector systems as in 60 day old rats. These ontogenic differences in &-receptor coupling may prevent receptor function from adapting to chronic neonates especially vulnerable to the adverse consequences of chronic administration. (Supported by DA-02739 and MH-15177)

T06.6
CHP-212, A HUMAN NEUROBLASTOMA CELL LINE, EXPRESSES A HETEROGENEOUS POPULATION OF & OPIOID RECEPTORS
A.M. Babel,1 K.M. Standifer, L Cheng,1 L.J. Biedler1, and G.W. Pasternak2,3
1The Cottias Laboratory of Neuro-Oncology, 2Laboratory of Cellular and Biochemical Genetics, Memorial Sloan-Kettering Cancer Center and 3Departments of Neurology & Neuroscience and Pharmacology, Cornell University Medical College, New York, NY, USA, 10021.
Identification of two & opioid receptor subtypes, termed &1 and &2, has been greatly facilitated by the use of specific agonists (DPDE and deltorphin II, respectively) and specific antagonists (BNTX and naltrindole, respectively). We have recently reported that the human neuroblastoma cell line, CHP-212, expresses five & opioid receptors, but does not demonstrate binding to &4 (DAMGO), &3 (H-U69,593) or &5 (H-NalPhe) specific ligands (Babel, et al., 1993). Competition binding assays in this cell line raise the possibility that the & receptor population in these cells is comprised of both &1 and &2 subtypes. The Kd values for the subtype-specific agonists and antagonists against H-Naltrindole were: DPDE 3.45 ± 0.56; deltorphin II 1.67 ± 0.33; BNTX 0.92 ± 0.24; naltrindole 0.21 ± 0.04; while the Hill coefficients were all less than one. In order to characterize the receptor proteins, 125I-&-endorphin was chemically cross-linked to CHP-212 membranes using BSOCS. SDS PAGE of the covalently labeled membranes reveals several specific bands. This cell line may be a useful tool in the study of the two & receptor subtypes.
OPIOID RECEPTORS: CELL BIOLOGY AND EFFECTOR MECHANISMS

Cloning of the delta opioid receptor offers a unique opportunity to characterize its functional coupling with effector systems in different cell lines. The rat growth hormone and prolactin secreting GH3 cells line expresses somatostatin (SRIF) receptors, G-protein-coupled families of K+ channels, but lack opioid receptors, assessed by ligand binding and cAMP assays. Therefore, GH3 cells would appear to be suitable for the expression of opioid receptors and for the investigation of their coupling to effector systems and hormone release.

A plasmid containing the entire coding region of the mouse delta opioid receptor (DOR) was transfected into GH3 cells. Stable expression of DOR was verified by immunocytochemistry and radioligand binding with [3H]D-Ala-Dleu-enkephalin (DADL). Twelve positive clones were analyzed for their ability to bind delta-specific ligands. One clone (GH-DOR-22 cells) was chosen for further analysis. GH-DOR-22 cells (D-PEN 2.5), enkephalin (DPDPE), etorphine and DADL (1-1000 nM) all dose-dependently displaced [3H]-dynorphine bound to GH-DOR-22 cells.

The ability of the transfected delta opioid receptors to inhibit adenylate cyclase was assayed by measuring cAMP levels in GH3-DOR-22 cells. Etorphine (1-1000 nM) dose-dependently inhibited adenylate cyclase in GH3-DOR-22 cells and the effect was blocked by naloxone. cAMP levels were also reduced by SRIF (0.01-5 μM) both in control and DOR-transfected GH3 cells.

The receptor's ability to modulate Ca2+ channels was investigated using the whole-cell voltage-clamp recording technique in both NG108-15 cells (from which DOR was cloned) and in GH-DOR-22 cells. While both DADL and SRIF inhibited voltage-activated Ca2+ channels in NG108-15 cells, neither was effective in the GH-DOR-22 cell line. In addition, both ligands failed to modulate K+-conducances in GH-DOR-22 cells. It is concluded that the delta opioid receptor can couple to adenylate cyclase in transfected GH3 cells, although this cell line may not be a suitable model for studying cloned opioid receptor coupling to ion channels.

Involvement of Gia in phospholipase C activation by metabotropic receptors in Xenopus oocyte expression system was studied. The current amplitudes were measured by injecting a molar equivalent of 15 δ opioid receptor (DOR) or 10 nM in the Xenopus oocytes injected with mouse δ-opioid receptor (DOR1) or M2 muscarinic receptor (M2) RNA were rapidly desensitized by repeated challenges of the agonist. Such a rapid desensitization was rescued by the addition of RNA of Gia and Gia2, but not Gia3, Gia4, Gia5, Gia6 or Gia7. In the oocytes injected with Gia2 and DOR1 or M2, the agonist-evoked currents were constant in amplitude upon at least 6 repeated challenges and these were completely abolished by the intracellular injection of 100 pmol of EGTA or 1 pmol of inositol 1,4,5-trisphosphate. When the chloride ion-concentration was reduced to one fourth, the I-V curve (or reversal potential) was shifted to the right (from -25 to 0 mV).

CO-LOCALIZED OPIOID AND GLUTAMATE RECEPTORS ON ASTROGLIAL CELLS - POSSIBLE REGULATORS OF SYNAPTIC TRANSMISSION. T. Thorstorp, P.S. Eriksson2, M. Nilsson, E. Hansen1 and L. Rönööck1,2. Institute of Neurobiology1 and Department of Neurology2, University of Göteborg and Department of Cell Biology, Faculty of Health Sciences, University of Linköping, Sweden.

Neurons and astroglial cells are the two major cell types in primary culture and respond differentially to opioid receptor stimulation using selective agonists. Cultured neurons were shown to respond with a substantial decrease in the cytoplasmic free calcium concentration in response to δ and μ opioid receptors. On the other hand, stimulation of δ and μ receptors, on astroglial cells in culture using DADL or U-50,488H resulted in a substantial increase in the cytoplasmic free calcium concentration. Cultured neurons were shown to be co-localized with opioid receptors on cultured astroglial cells. These effects were visualized through the use of the fluorescent calcium indicator fura-2. In astroglial cells in culture and acute slices of guinea pigs, astrocytes were identified by immunostaining with antibodies against glial fibrillary acidic protein (GFAP). The presence of δ-receptor mRNA was verified in cultured astroglial cells using RT-PCR and Northern blot. The present study suggest that cultured neurons from the cerebral cortex express μ, δ and κ receptors. Cultured astroglial cells from the cerebral cortex express co-localized δ, μ and κ receptors and acute dissociation of astrocytes and is under development to further investigate functional δ-receptors (i.e. calcium activating) to validate the relevance of the in vitro system. This might represent a novel mechanism contributing to the depressive action of opioids on synaptic transmission via decreasing the availability of calcium.
OPIDIO RECEPTORS: CELL BIOLOGY AND EFFECTOR MECHANISMS

T06.13

OPIOID RECEPTORS ARE DIFFERENTIALLY TARGETED IN THE NERVOUS SYSTEM AND IN A CELLULAR EXPRESSION SYSTEM. RI Dado*, AH Nakano, S Chakrabarti, LH Lee, M Riedl, U Arvidson, MW Westendorf, JH Loh, FY Law and E. Ribe, Departments of Cell Biology & Pharmacology, University of Minnesota, Minneapolis, MN 55455

The 8-opioid receptor (DOR) that has been cloned appears to be enriched in axons and terminals in spinal cord, where it may function as a presynaptic receptor (Dado et al., NeuroReport 5:341-344, 1994). Further examination suggests that DOR may be absent or even inversely related in axons. In contrast, the mu-opioid receptor (MOR) that has been cloned appears to be targeted to the plasma membrane of dendrites and cell bodies, and, in some cases, to axons (Arvidson et al., J. Neurochem. 62:1737-1743, 1993). Immunochemical studies were used to characterize this distinction more completely. COS-7 cells were electroporated with constructs which expressed DOR, MOR and the cloned 8-opioid receptor (DOR) behind a 8 amino acid epitope tag (NAG) followed by a 4 amino acid thrombin site. Cells were fixed 72 hrs after electroporation and stained with a monoclonal anti-TAG antibody. While both DORTAG- and KORTAG-transfected cells, TAG-immunoreactivity (4) was observed in the endoplasmic reticulum, the golgi and the plasma membrane. In contrast, in DORTAG-transfected cells, TAG-ir was restricted to the endoplasmic reticulum. The targeting of these receptors in axons was examined in sciatric nerves of rats which had been previously ligated under general anesthesia. DOR- and MOR-ir accumulated both proximal and distal to ligation sites at survival times ranging from 2-8 hrs. Taken together these results suggest that there are considerable differences among opioid receptors in their targeting. Supported by NIDA.

T06.14

Opioid binding assays were found in nuclear matrix preparations from NG108-15 neurohybrid cells. The opioid antagonist, -naltrindole, and -diprenorphine, display high affinity binding, while agonists bind with low affinity, if at all, to matrix nuclear preparations. Gpp(NH)p insensitivity of agonist binding and the absence of adenyl cyclase activity provided a molecular basis for the occurrence of uncoupled opioid sites in this fraction. Opioid inhibition of basal and forskolin-stimulated adenyl cyclase activity was found in nuclear membrane preparations. A decrease in agonist binding affinities and densities in P3 fractions was also observed under these conditions, whereas treatment of cells for forskolin potentiated both P2+ and nuclear matrix binding. Taken together these results support the hypothesis that nuclear membrane opioid receptors are newly synthesized molecules entrapped to the cell surface, whereas nuclear matrix contains internalized -sites.

T06.15

The purpose of the present study was to determine if the coupling pattern of a recently cloned -opioid receptor stably transfected in CHO cells to individual G protein subunits was different than that observed previously for B and -opioid receptors. Data presented in the current study indicate the successful expression of a -opioid receptor in CHO cells. This is supported by experiments which revealed that ligands with high selectivity for, but not for -opioid receptors demonstrated high affinity for the expressed receptor and were able to potentially and efficaciously produce inhibition of adenylyl cyclase activity. In addition, both -opioid agonists were able to induce dose-dependent increases in the incorporation of [35S]azidoanilido-GTP into four G protein subunits, three of which were identified as Gq, Gz, and Go. Further, the amount of -opioid agonists required to induce 50% maximal labeling of any individual G protein subunit was different. Although -opioid agonists produced equivalent maximal labeling of Gq, Gz, and Go, significantly less agonist-induced labeling was observed for an unknown G protein designated as Go. These results are similar to that observed previously for both and -opioid receptors and suggest that although all opioid receptors interact with multiple G proteins, this coupling is not selective for any individual G protein subunit.

T06.16

KAPPA OPIOD INHIBITION OF STIMULATED PHOSPHOHOSTIDES HYDROLYSIS IS NOT MEDIATED BY A DECREASE IN INTRACELLULAR CALCIUM. Dennis Paul*, Lema Minor and Naili Dunn, Department of Pharmacology and Center for Neuroscience and Alcohol and Drug Abuse, LSU Medical Center, New Orleans LA 70112.

Kappa opioid agonists close N-type Ca++ channels and attenuate stimulated phosphoinositide (PI) hydrolysis in neural tissue. PI hydrolysis is Ca++ dependent. Accordingly, we assessed the possibility that the kappa attenuation of stimulated PI hydrolysis is due to reduced intracellular Ca++. Rat hippocampal slices labeled with 86Rb were incubated with or without the Ca++ ionophore, BayK 8644 (10 μM) or A23187 (10 μM). These doses of ionophore completely uncoupled the ndependent PI hydrolysis. KCl (27.5 μM) or NE (30 μM) were added to stimulate PI hydrolysis. In addition, various concentrations of the kappa agonist U-50,488 were added. One hour later, the assays were stopped and PI hydrolysis was measured as the ratio of dpm released / dpm incorporated. U-50,488 dose dependently attenuated KCl-, NE- and carbachol stimulated PI hydrolysis. Assumptions of high intracellular Ca++ levels with BayK 8644 or A23187 did not affect kappa agonist attenuation of stimulated PI hydrolysis. Addition studies assessed kappa agonist effects on heart ventricle slices, a tissue in which kappa agonists increase intracellular Ca++. EKC and U-50,488 inhibited NE-stimulated PI hydrolysis dose-dependently. Together, these results provide evidence that kappa agonists do not attenuate PI hydrolysis by reducing intracellular Ca++.

T06.17

IDENTIFICATION OF TRANSCRIPTS ENCODING OPIOID RECEPTORS IN IMMUNE CELLS. Claire Gaydara-Raff, Frederic Simonin, Katia Befort and Brigitte Kieffer*, ESBS, Univ. Louis Pasteur, 67 Strasbourg, France.

Numerous in vivo and in vitro studies have shown that opioids modulate the immune response. A direct effect of opioids on immune cells has been posited. Pharmacological studies to demonstrate the existence of opioid receptors on these cells have been poorly convincing. We, and others, recently isolated cloned opioid receptor cDNA from immune cells. We designed opioid receptor subtype-specific primers, based on the known sequence of the cloned receptors, and used Reverse Transcriptase-Polymerase Chain Reaction followed by Southern hybridization, for the detection of opioid receptor transcripts. We have tested both mouse and human cells representative of the different components of the immune system. Our results indicate that kappa receptor mRNA is undetectable in several mouse T cell lines. We found low levels of expression of opioid receptors in thymocytes. Our data suggest that the cloned mu, delta and kappa receptor subtypes are not only present in nervous tissues, but also are expressed in immune cells.

T06.18

OPIOID-DEPENDENT TYROSINE PHOSPHORYLATION IN NEURONS. D. A. Mangora*, Department of Pediatrics, the University of Chicago Chicago, IL 60637.

In primary neuronal cultures derived from 6-day-old chick embryo cerebral hemispheres (ESC6) met-enkephalin elicits a transient activation of phospholipase D (PLD), which precedes a 2-fold increase in PKC activity. Opioid-dependent PLD activation involves the tyrosine kinase (TK) inhibitor herbimycin A, strongly indicating that the mechanism of opioid-dependent PLD activation involves tyrosine phosphorylation. Western blot analysis and immunoprecipitation of encoding neuronal opioid delta, mu and kappa receptors. The cloning of these receptors has provided molecular tools for the identification of the expression of opioid receptors in immune cells. We designed opioid receptor subtype-specific primers, based on the known sequence of the cloned receptors, and used Reverse Transcriptase-Polymerase Chain Reaction followed by Southern hybridization, for the detection of opioid receptor transcripts. We have tested both mouse and human cells representative of the different components of the immune system. Our results indicate that kappa receptor mRNA is undetectable in several mouse T cell lines. We found low levels of expression of opioid receptors in thymocytes. Our data suggest that the cloned mu, delta and kappa receptor subtypes are not only present in nervous tissues, but also are expressed in immune cells.
OPIOIDS: ANATOMY AND PHYSIOLOGY II

T07.1 PERIPHERAL EFFECTS OF NALOXONE IN MICE WITH GASTROINTESTINAL INFECTION. O. Pol and M.M. Puig. Anesthesiology Research Unit, IIMM, Universitat Autonoma de Barcelona, Barcelona, Spain. E-08003.

The aim of the present study is to evaluate the effects of opioid antagonists on gastrointestinal (GI) transit in mice with diarrhoea associated with intestinal inflammation. Diarrhoea was induced by p.o. administration of coxotin (CO), and demonstrated by weight loss (P < 0.01), and increased GI transit (< 0.05) when compared to animals treated with saline (SS). The presence of inflammation in CO was demonstrated by electron microscopy. GI transit was evaluated with a charcoal meal used as a marker. Diarrhoea was induced by coxotin (NO) or by methioideut, induced a significant increase (P < 0.05) in GI transit in CO but not in SS animals. The inactive enantiomer (+)NX had no effect either in CO or SS animals. The delta antagonist naltrindole (3 mg/kg) also induced an increase in transit (< 0.05) in CO animals, while M6 had no effect.

Our results suggest that CO diarrhoea induces a local release of endogenous opioids (EO) which play an inhibitory role in the physiological response to intestinal inflammation in mice. It is postulated that the EO's released, could be a mu or delta agonist.

T07.3 ACTIVATION OF BRAIN OPIOIDERGIC STRUCTURES IMPROVES CHRONIC EXERCISE STRESS IN MICE. J.R. Medvinsky, O. Borkin, V.K. Surpilly, O.B. Liyinsky. Central Sports Research Institute (Moscow, Russia). Research Center Mental Health (Moscow, Russia). Baylor/UT Southwestern Medical Center, Dallas, TX 75246.

Injection of opioids, direct electrical stimulation of the periaqueductal grey substance and transcranial electrical stimulation (TES)-"electroanalgia" increase velocity of conduction and improves gait in mice (Liyinsky et al. '85:86:89). Naloxone blocked the effects. Recently we demonstrated that TES improved the response to another type of stress: acute exercise stress (Medvinsky et al. '93). In this study, we investigated the effects of TES on exercise performance and locomotor activity of mice after chronic exercise training, consisting of 21 days of swimming 30 min/day. 72 mice (BALB/c) were divided into 4 groups (n=25). After 21 days of swimming and 3 days of TES (0.6mA, 30 min) prior to swimming, Group B (n=22) received TES and shum stimulation and Group C (n=22) received training only. The results demonstrated that TES had greater effects for mice receiving TES than for shum, as measured by swimming time vs. sham: 100:137.0 (p<0.01), vs. control - 80.3±4.1 (p<0.001). So, TES improved the adaptive response to chronic exercise stress. Further work revealed that the timing of TES, influenced the results. Mice (n=22) that received the last TES 20 hrs prior to swim, swam shorter than those receiving TES 6 hrs prior to swim but longer than sham (n=24). or control (n=23) mice (p<0.01). Difference in swim time between sham and control, which existed after 6 hrs (p<0.01), disappeared after 20 hrs. Naloxone (0.5 mg/kg ip. prior to TES) blocked the effects of TES. We concluded that brain opioidergic structures participate in the adaptation to chronic exercise training.

T07.4 SPINAL CORD AND BRAIN OPIATE RECEPTORS: DIFFERENTIAL EFFECTS ON LARGE-FIBER VERSUS SMALL-FIBER SOMATOSENSORY PATHWAYS. A.D. Legatt, C.F. Schroeder, L.B. Hollinger, and L.P. Selman. Departments of Neurology, Neurosurgery, and Orthopedic Surgery, University of Texas Southwestern Medical Center, Dallas, TX 75390.

During spinal instrumentation and subsequent sciatic nerve injury, morphine sulfate may be directed into the spine to the paracochlear space to provide postoperative analgesia, and bolus doses of intravenous narcotic may be given as part of the anesthesia regimen. Somatosensory-evoked potentials (SEP) to posterior tibial nerve stimulation are monitored to detect spinal cord compromise during this operation. We examined the effects of the narcotics on the cortical SEPs and on the SEPs recorded over the medulla (referred to as "cortical SEPs", and "cervical SEPs", are generated near the cervicomedullary junction. Bolus doses of intravenous narcotics did not alter the cortical SEPs, but did cause transient waveform changes and attenuation of the cortical SEPs. In contrast, intrathecal narcotics affected neither the cortical nor the cervical SEPs, though they did produce analgesia.

These SEPs predominately reflect activity in the large-fiber (dorsal column/lemniscal) somatosensory pathways. The differential effects of the narcotics on the cortical SEPs demonstrate that the large-fiber afferent somatosensory pathways are influenced by opiate receptors in the brain but not by those in the spinal cord. Since intrathecal narcotics produce analgesia, spinal cord opiate receptors affect the small-fiber (pain), but not the large-fiber, somatosensory pathways within the spinal cord.

Dynorphin (DYN) facilitates conditioned place aversion and reduces locomotor activity through mechanisms possibly involving direct activation of target neurons or presynaptic release of catecholamines or Substance P (SP) in the nucleus accumbens (Acb). We examined the ultrastructural substrate underlying these actions by combining, in single sections of rat tissue, immunoperoxidase and gold-silver labeling for dynorphin (D) and either the dopamine- or the Substance P-immunoreactive neurons. DYN-labeled perikarya were spherical in shape, contained unindented nuclei and were closely and dently, the other type of structures were small, of which some also contained SP labeled perikarya. Smooth endoplasmic reticulum and coated vesicles could also be identified in the cytoplasm and the synaptic vesicles. A major feature of these neurons was the presence of synapses on the axon terminals of other neurons. Certain Type DYN terminals were located in the regions of the Acb where SP was also found. The ultrastructural features of DYN terminals include the presence of small and large core vesicles and their prominent formation of synaptic structures. The DYN terminals formed primary synaptic contacts with small and large core vesicles and their prominent formation of synaptic structures. The DYN terminals formed primary synaptic contacts with small and large core vesicles and their prominent formation of synaptic structures. These terminals also formed secondary synaptic contacts with other DYN terminals (1:40:370) and other terminals that were unlabeled (14%), TH-labeled (90%), DYN-labeled (14%) or SP-labeled (11%). We conclude that DYN may be involved in the transmission of different types of axons to the Acb. In conclusion, DYN may be involved in the transmission of different types of axons to the Acb.

T07.6 REGULATION OF DYNPHORIN (DYN), TYROSINE HYDROXYLASE (TH) AND [Met]-ENKEPHALIN (ME) IN NEURONAL/GliaL CO-CULTURES FROM RAT HYPOPHALAMUS G-CW; M.K. McMillian and J.S. Hong LMIN/NIEHS/NH, RTP, NC 27709.

Hypothalamic neurons contain the highest concentration of dynorphin in the brain and this peptide may be an important modulator of feeding behavior as well as contribute to regulation of pulmonary hormone secretion. Using a mixed hypothalamic cell culture model (neurons, glia, neurons from E16 fetuses), we have examined the second messenger pathways involved in regulation of DYN, and have compared DYN responses to changes in TH-immunopositive neurons (>10^7) cell number and ME release. Elevating cAMP with forskolin (FSK,10^7 M) increased DYN levels and also increased TH cell number. Dexamethasone (DEX,10^-7 M) increased dynorphin production, but did not affect ME release or TH cell number. FSK + DEX produced a near additive effect on DYN, but had a more pronounced effect on ME release (previously shown to be glia derived). Depolarization with KCl (45 mM) more effectively increased TH cell number than DYN, and did not affect activation of PKC with phorbil ester (10^-7 M). DYN is regulated differently than TH and ME in these hypothalamic cultures.

OPIOIDS: ANATOMY AND PHYSIOLOGY II

T07.7

DEVELOPMENT OF OPIOID TOLERANCE IN THE tS TIs ASSOCIATED WITH GENERAL CHANGES IN NEURONAL RESPONSIVENESS. C.J. Malanga*, W.W. Fleming and D.A. Taylor. Dept. of Pharmacology, West Virginia University School of Medicine, Morgantown, WV 26505-9223.

Chronic morphine exposure results in non-specific changes in the sensitivity of guinea-pig nucleus tractus solitarius (nTS) neurons to inhibitory agonists. While a 56-fold rightward shift of the dose-response curve to morphine was observed, no significant shift of the dose-response curve to morphine was seen with cumulative drug applications. One explanation for the lack of altered sensitivity to morphine is acute desensitization, which can be avoided by application of single drug concentrations to spontaneously-active nTS neurons. Using standard extracellular electrophysiological techniques in brainstem slice preparations, we have found that the application of forskolin (1 μM) resulted in an 80±7% inhibition of firing in control and a 47±5% inhibition of firing in chronically morphine-exposed neurons, indicating a significant (P<0.05) 41% reduction in response to morphine in the morphine-treated group. Similarly, application of muscimol (0.3 μM) to the same nTS neurons inhibited firing 57±11% in controls and 30±8% in morphine-treated preparations, indicating a significant (P<0.05) 47% reduction in response to muscimol in morphine-treated animals. Furthermore, elevation of extracellular K+ (normal ACSF=5.0 mM [K+]o; depolarizing ACSF=7.2 mM [K+]o) resulted in an excitation of 85±13% in control neurons and an excitation of 146±47% in neurons from the morphine-treated group. Together, these findings suggest that 1) the in vitro nTS/brainstem slice preparation is an appropriate model system in which to study the development of opioid tolerance, and 2) the opioid tolerance in the nTS is associated with a non-specific, general change in the physiology of these neurons. Supported by NIDA grant DA 03773.

T07.9

PROPOIOMELANOCORTIN EXPRESSION IS REDUCED BY AN ANTISENSE OLIGONUCLEOTIDE. S. Spampinato, G. Campagna, L. Carboni and S. Ferrri. Dept. of Pharmacology, Univ. of Bologna, 40126 Bologna, Italy.

Gene expression in mammalian cells can be suppressed by oligonucleotides complementary to the target mRNA. This strategy was explored as a means of preventing translation of the proopiomelanocortin precursor (POMC). The synthesis of the POMC-derived peptides adrenocorticotropic hormone (ACTH) and β-endorphin (β-END) was markedly reduced by an oligodeoxynucleotide (ODN) complementary to a region of β-END mRNA in AT-20 cells, which retain many of the differentiated phenotypes of corticocytes; this treatment did not affect the steady-state levels of POMC mRNA. Antisense ODN was stable in cell culture medium for 24 h and cellular uptake was low (<2.5% of the added ODN), however, the intracellular levels of the ODN were sufficient to form a rhonucleoace-resistant duplex with complementary cellular mRNA. Addition of ODN to the cell culture did not affect cell viability and proliferation. Microinjection of the antisense ODN in the rat hypothalamic arcuate nucleus (0.625 μg/50 μl), where the majority of POMC-expressing brain penkaryas are located, significantly reduced ACTH-immunopositive neurons in the medio-basal hypothalamus ([140±87 vs 250±940) in vehicle-treated rats, p<0.01; n=7] and antisense ODN-treated rats showed substantially less of the grooming behavior usually observed in a novel environment. Changes of nocioceptive threshold, body temperature and knowledge of plasma levels of anterior pituitary hormones in rats exposed to antisense oligonucleotide will be presented.

T07.10

Oxytocin neurons in the suprachiasmatic nucleus (SCN) develop dependence on morphine given intracerebroventricularly (i.c.v.) over five days (up to 5 μg/kg) as revealed by naloxone (NLOX) precipitated morphine withdrawal which increases oxytocin firing rate by 3.5 fold. We have studied the importance of the noradrenergic input for the expression of this withdrawal excitation (1) NLOX (5mg/kg) precipitated withdrawal-induced Foex expression in tyramine hydroxylase expressing neurons in the nucleus tractus solitarius. These neurons are known to project to the SCN and mediate the response of oxytocin neurons to sympathetic cholinergic nerve terminals (CCK). (2) Electrophysiological extracellular recording was carried out in urethane anaesthetized rats. Oxytocin neurons were identified by firing pattern, antidromic activation and response to CCK. The extrastimulus to i.v. CCK injection was similar before (mean±S.D.: 1.060±0.39 Hz increase, over 5 mins) and after NLOX in morphine-inhibited rats (1.18±0.46 Hz, n=11), though smaller than in morphine naive animals (3) Clonidine (2.5 mg/kg, i.v.), an α2 adrenoceptor agonist, attenuated the rise in oxytocin secretion after withdrawal (mean±S.E.M.: vehicle: 702±186 pg/ml vs. + clonidine: 303±113 pg/ml after 10mins, n=7, p<0.05, one-way t-test) (4) Electrical activity in oxytocin neurons after withdrawal was reduced by both acute (25μg) and continuous (0.32 to 1.62 μg/ml for >20 minutes) administration of i.v. α2 adrenoceptor antagonists such as benoxatn. This effect could be reversed by simultaneous infusion of the α2 adrenoceptor against phentolamine. These results indicate that an excitatory, or permissive, noradrenergic input to oxytocin neurons drives the expression of opiate withdrawal-induced excitation.

T07.11

We utilized whole cell and intracellular recordings from slices of rat brainstem to study the effects of opioids on LC neurones. The amplitude of the [net]- enkephalin-induced outward current (I_m) was larger and E_m was more negative in slices cut in the horizontal plane than in the coronal plane. Morphological analysis with neurobiotin indicated that cells from horizontal slices had a more extensive dendritic arborization than from the coronal plane. When the pipettes were filled with Cs gluconate, I_m was still outward, did not reverse polarity even at strongly negative potentials and was blocked by BaCl_2. When recordings were made from 2 neurones, BaCl_2 and TTX induced synchronous oscillations (mean peak potential. LC basic properties were not affected by carbenoxolone, a gap junction blocker which reduced extracellular potential to the right and prevented the Ba-induced oscillations. The results suggest that I_m is mediated by an increase in K_m only. Dose predictions for K result from poor space clamp which may be due to electrotonic coupling among LC cells.

T07.12

PAIN-PRODUCING SUBSTANCES AUGMENT IA IN NODOSE GANGLION NEURONS. S. L. Ingram1 and J. T. Williams2. Department of Pharmacology1 and Vollum Institute2, Oregon Health Sciences University, Portland OR 97201.

Our previous work in the nodose ganglion has shown opioid inhibition of forskolin-stimulated IA in a small subpopulation of nodose neurones. Pain-producing substances which are known to increase cAMP levels (PGF_2α, bradykinin, and 5-HT) also elicit an inward current (at -60 mV) in a subpopulation of neurones. The mean amplitude of the inward currents are as follows: PGF_2α (1μM), 120±39 pA (n=4); bradykinin (1μM), 263±48 pA (n=7); and 5-HT (10μM), 122±12 pA (n=5). Currents were blocked in the currents were blocked in 3/7 neurones regardless of drug applied. Thus, we have preliminary evidence that agents other than forskolin are effective in augmenting IA. In an attempt to further identify responsive neurones on the basis of conduction velocities, intracellular recordings from guinea pig isolated nodose ganglion preparations were made. In 75% of neurones with conduction velocities >1.5 m/s (n = 28), only 35% expressed an IA current. In contrast, 83% of the neurones with conduction velocities >1.5 m/s had an IA current. These results suggest that IA neurones may be regulated by both pain-producing substances and opioids through opposite actions on adenylyl cyclase. (Supported by NIDA Grants DA00143, DA01863, and DA07262.)
707.13

Chronic treatment of rats with opioids and MK-801 (MK) inhibits the development of tolerance and physical dependence in intact animals. The mechanism of this phenomenon is obscure. Use of the isolated spinal cord of rats eliminated neonatal potential interference from behavioral effects. Newborn rats were treated with either morphine (M) or MK + M in incrementally increasing doses for 3 days. The superfusion bath. Nociceptive reflexes elicited by electrical stimulation or capsaicin were inhibited by M (10 nM - 10 μM) in controls (18 ± 10.5% S.E.M. depression of capsaicin response at 10 nM to 81 ± 3.4% at 10 μM) in cords of neonates treated with chronic M. Additional doses of M did not depress nociceptive reflexes indicating the development of tolerance. The development of dependence evidenced by increases in naltrexone-induced spontaneous activity was not affected by co-treatment with MK. Thus, MK combined with chronic treatment with M failed to block the development of tolerance and physical dependence in this model.

We conclude that the spinal cord has to be mature and/or act in synergy at least with the periphery (spinal) for MK inhibition of development of tolerance and physical dependence to be realized.

707.15
EFFECTS OF DAMGO, HALAIXONE AND ACETYLCHOLINE ON THE FIRING OF MEDIAL PREFRONTAL CORTEX NEURONS. J.L. Giacchino and E. Henssler. Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Extracellular recordings were made from fifty-six spontaneously firing neurons of the medial prefrontal cortex (mPFC) in halothane-anesthetized rats. Areas investigated include the dorsal anterior cingulate, prelimbic, and infralimbic components of the prefrontal cortex. Intra-cranial applications of DAMGO demonstrated that systemic morphine decreases neuronal activity in the mPFC, and that this effect can be reversed by systemic naloxone. As the mPFC is suggested to function in reinforcement pathways and drug-related behaviors in the rat, the action of opiates, specific opioid receptor agonists and antagonists at the cellular level is of interest. Immunocytochemical localization of the selective mu agonist DAMGO (1 μM) decreased firing of most mPFC neurons studied. This drug effect was typically slow in onset and often prolonged (approx. 3-10 min). This effect could be blocked or reversed by naloxone (2 μM). In most cases, the activation of mPFC neurons was not apparent until new firing patterns emerged which had no effect alone on most mPFC neurons. As expected, acetylecholine (100 mU) increased firing in the majority of spontaneously active mPFC cells. In addition, ACh pulses elicited transient increases in cell firing during DAMGO-induced depression, and also during concurrent application with naloxone. Even when mPFC neuronal firing was completely suppressed following DAMGO, ACh was able to elicit firing, implying a receptor specific effect. These results suggest that activation of mPFC neurons may hyperpolarize mPFC neurons and/or may function presynaptically to inhibit excitation (Supported by SOAC #3-5-94217 and HIDA #3-5-94213).

707.14

SNC-80 is a new, highly selective non-peptide 5-opioid (Calderon et al., J. Med. Chem. in Press, 1994). Unlike other peptide and non-peptide opioids, high I.C.V. doses of SNC-80 (up to 800 μg) fail to elicit EEG seizures or convulsant activity in rats. In contrast, SNC-80 causes a complex behavioral response consisting of initial, brief periods of stupor followed by prolonged episodes of intense hyperactivity associated with marked EEG theta-driving (unpublished observations). We have begun to assess the effects of SNC-80 on a neuronal culture model of glutamate excitotoxicity. In the present study SNC-80 was added to primary rat cortical cultures immediately prior to 80 μM glutamate. Neurotoxicity and/or neuroprotection was assessed 18 h later. LHN measurements and morphological evaluation revealed that SNC-80 produced a concentration dependent neuroprotection. Compared to glutamate alone, 5, 20, and 40 μM SNC-80 protected neurons to the extent of 16, 30, and 60%, respectively. Intracellular calcium ([Ca]i) was monitored as an indicator of glutamate-induced neuronal injury in these same cultures. While glutamate consistently produced a sustained increase in [Ca]i, in 83% of the neurons analyzed, treatment with SNC-80 (50-100 μM) resulted in a shift in the [Ca]i, dynamic such that greater than 60% of the neurons demonstrated only briefer or transient increases in [Ca]i, an event previously shown to correlate with less toxic concentrations of glutamate (Busatto et al., NeuroReport, 1992). These results demonstrate that SNC-80 is neuroprotective in vitro and suggest a potential utility of selective 5-opioids for attenuating CNS injury.

707.16

The distribution of dynorphin mRNA in brain and spinal cord of adult male rats was studied in situ hybridization histochemistry. Intact or colchicine-treated animal brains were perfused with paraformaldehyde (PF) and sectioned with a vibratome or (f) frozen on dry ice, cut on a cryostat, thaw-mounted, and post-fixed with PF. Free-floating vibratome sections and mounted slides were treated with triphenyltetrazolium, then dehydrated with ethanol. While vibratome sections were rehydrated, cryosections were air-dried after dehydration. Sections were hybridized with a 35S-UTP-labeled probe (bp 100-835 of dynorphin cDNA), incubated overnight at 55 C and stringently washed to remove nonspecific label. Subsequently, vibratome sections were mounted on gelatin-coated slides. Slides were dipped in liquid photographic emulsion and exposed for ten to twenty days. Evaluation of autoradiograms revealed that the location of dynorphin mRNA was in good agreement with the location of the peptide detected by immunocyto-chemistry. However, we were able to detect mRNA in several regions of the central nervous system in which no peptide was reported. These include the olfactory bulb, the island of Calleja, posterior thalamic nuclei, CA1 and CA2 regions of the hippocampus, optic tectum, spinal trigeminal nucleus, etc. In addition, the number of mRNA-containing perikarya was higher than the number of peptide-containing perikarya previously observed in cerebral cortex. The use of 30 μM vibratome sections resulted in a shorter exposure time and less background than the use of 16 μm cryosections. Colchicine-treatment had no significant effect on the level of dynorphin mRNA.

707.17
HILAR MEDIATED EXCITATION AND LTP OF THE DENTATE GRANULE CELL. U. Werman*, M. Simmons*, C. Charyk. Departments of Anesthesiology and Pharmacology, University of Washington, Seattle, WA 98195.

Kappa agonists inhibit excitatory neurotransmission and long-term potentiation (LTP) in the hippocampus via a decrease in amino acid release from both hippocampal perforant path and mossy fiber terminals. We now report a third site of kappa opioid inhibition of excitatory neurotransmission in the hilar region of the dentate gyrus.

Extracellular recordings were made in the granule cell layer of the dentate gyrus of the guinea pig hippocampal slice. The hilar slice was selectively stimulated by a probe cut through the molecular layer to sever the perforant path and placing the stimulating electrode in the molecular layer in order to record the stimulating electrode. In the presence of bicuculline (10μM), stimulation (0.3 μs, 50-300 μA) of the hilar pathway elicited granule cell population spikes whose amplitudes were decreased by the kappa agonist, U69593 (10μM) in a non-competitive manner. LTP in this pathway was blocked by the NMDA antagonist, APV (25μM), and by U69593. Without bicuculline, no population spikes were elicited from the hilar path and no LTP could be induced. However, following LTP, population spikes were evident with or without bicuculline.

Thus kappa opioids modulate neural excitability in at least three distinct regions of the hippocampus. Although the hilar pathway studied here is normally under strong GABAergic control, plastic changes appear capable of overriding GABA inhibition - perhaps leading to hyperexcitation. [Supported by NIEHS and the Foundation for Anesthesia Education and Research with a grant from Abbott Labs.]

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
OPIOIDS: THE POTENTIATION OF THE NMDA RESPONSE INDUCED BY SIGMA LIGANDS IN THE RAT DORSAL HIPPOCAMPS I. N. Lavoie, R. Gogoi, and G. Debonnel. Neurobiological Psychiatry Unit, McGill University, Montreal, Quebec, Canada, H3A 1A1

Sigma ligands modulate the response of dentate neuronal nuclei to NMDA in the CA3 region of the dorsal hippocampus. It has also been found that CCK is involved in the effects induced by sigma ligands on cysolic motility. The present experiments were undertaken to determine the interaction in the CNS. Using five-barrelled glass micropipettes for extracellular recordings and microphotonics, we evaluated the effects of different CCK and CCK receptors antagonists on the modulation of sigma ligands activity, induced by the intravenous administration of low doses of the sigma ligands DTG (+pentazocine and JO-1784 on rat CA3, dorsal hippocampus) and pyramidal neurons. The potentiation of the NMDA response induced by these sigma ligands was abolished by the specific CCK receptor antagonist SR 27897, but not by the CCK receptor antagonist CI-988. CCK-85, applied as a low antagonist, insufficient to inhibit an increase of the firing activity by itself, markedly potentiated the response of NMDA, without affecting that of QUIS. SRI 27897 applied during the potentiation of the NMDA response by CCK-85, markedly reduced this potentiation. In contrast, the selective CCK receptor antagonist CI-988 applied microiontophoretically, and PD 153515 administered intravenously (3mg/kg), failed to abolish the effect of CCK-85 on the NMDA response. Our results suggest that the potentiation of the NMDA response of hippocampal pyramidal neuron by sigma ligands involves the activation of CCK receptors. Since CCK-85, by itself, potentiates markedly and selectively the NMDA response, these results also suggest that, in the CA3 region, sigma ligands might induce their modulatory effect on the NMDA response by promoting the release of CCK-85.

ENDOGENOUS DYNORPHIN RELEASE IN THE GUINEA PIG DENTATE MOLECULAR LAYER IS MEDIATED BY L-TYPE CALCIUM CHANNELS. M. L. Simmons1, O. W. Terman2, S. M. Gibb3, and C. Chavkin4. Dept. of Pharmacology and Anesthesiology, University of Washington, Seattle, WA 98195.

In the dentate molecular layer, dynorphins are released from granule cell dendrites to inhibit glutamate release. In addition, receptors on perforant path afferents. In the CA3 region, dynorphins are released from, and act upon, mossy fiber terminals. In both regions, dynorphins also have been shown to potentiate the release of LTP. The present study investigated the roles of CA3 channel subtypes in mediating the release of endogenous dynorphins. High frequency stimulation was applied to granule cells to induce dynorphin release, which was detected as a 20-30% depression of the field EPSP that lasted 2-15 minutes. In the dentate molecular layer, the L-type Ca2+ channel blockers nifedipine (10 μM) and PN20-110 (5 μM) inhibited the dynorphin-mediated depression. These drugs did not alter the effect of kappa receptor activation by exogenous agonist (1 μM U69593) application, nor did they affect the field EPSP responses themselves. Therefore, the L-type channel blockers inhibited dynorphin release without inhibiting the action of dynorphin or the release of glutamate. Furthermore, nifedipine and PN20-110 facilitated the induction of LTP in the dentate gyrus. This result is consistent with our previous studies showing that the kappa opioid receptor antagonist, norbinaltorphimine, also facilitates the induction of LTP in contrast to the effects observed in the dentate gyrus, the L-type channel blockers had no effect on dynorphin release from mossy fibers in CA3. Supported by DA04123.

We have previously reported that central, but not peripheral, administration of beta-endorphin (BE) to infant rats markedly decreases basal levels of ODC (α and e-phenylthiocarbamyl) activity throughout the body, as well as tissue ODC responsiveness to classical trophic factors. Based on these and other observations we have hypothesized that endogenous BE plays a prime role in controlling postnatal development. The question remains as to whether perinatal exposure to opioid agonists causes a pattern of developmental effects similar to those produced by BE.

In the current study we found that, like BE, intracerebroventricular (i.c.v.) administration of 2 μg of morphine to 1â†“-old rats decreases basal levels of liver ODC activity. In addition, hepatic ODC responsiveness to subcutaneously (s.c.) administered insulin (I) or growth hormone, two important trophic hormones, was almost totally arrested in pups pretreated i.c.v. with morphine. Similarly, morphine inhibited the half-life of exogenously administered I. As expected, hypoglycemia in rats injected with morphine i.c.v. plus I was observed in pups given I alone. Equivalent results were obtained in animals given morphine s.c.

The data strongly suggested that the developmental disabilities commonly observed in infants born to opiate-addicted mothers could result, at least in part, from an exacerbation of the effects of endogenous opioids on tissue ODC expression and on insulin/glucose metabolism. (Supported by USPHS Grant NS25738).

ENDOGENOUS OPIOID PEPTIDES MEDIATE THE SNUCKING INDUCED PROLACTIN INCREASE IN POST-PARTUM FEMALE RATS. S. N. Klosterman, D. Puntney, P. Callahan, and J. Janet, Miami University, Dept. of Zoology, Oxford, Ohio 45056.

We have reported that beta-endorphin is a potent stimulus for prolactin secretion in virgin female rats (Klosterman et al., Neuroendocrinology 57:275, 1993). Doses as low as 25 ng were capable of producing a prolactin secretory response that mimicked the prolactin response to suckling in post-partum female to beta-endorphin treated rats. In addition, intracerebroventricular (i.c.v.) administration of the opioid peptide (EOP), into the nucleus accumbens or dynorphin, both of which are regions involved in the regulation of prolactin secretion during lactation. Lactating, female, Sprague-Dawley rats between 3 and 6 days post-partum were used in all experiments. Animals were surgically implanted with chronic intraventricular (i.vt) cannulae into the lateral ventricle on day 2 post-partum. At least a 5 day recovery period and one day prior to the experiment, animals were implanted with chronic jugular cannula to facilitate blood withdrawal. On the day of the experiment, dams were separated from their pups for six hours prior to i.v administration of specific antisera to met-enkephalin or dynorphin. Blood samples were withdrawn immediately prior to antiserum injection and at 15 minute intervals, up to 1 hour, after the onset of suckling. Antiserum to each one of the EOPs effectively blocked the suckling-induced Prolactin increase. These results indicate that met-enkephalin and dynorphin are both important in the suckling-induced Prolactin increase. The mechanism(s) responsible for this action is not known. It is also not clear which receptor subtype mediates this response or if there is interaction among the different EOP and/or their receptor subtypes. (This work was supported by NIH grant # R15 HD30375-01 to JI and PC).

MORPHINE TOLERANCE/DEPENDENCE: REVERSAL FROM INHIBITION TO ENHANCEMENT OF cAMP FORMATION. L. Wang1 and A.R. Gunster, Dept. of Biochemistry, SUNY at Stony Brook, NY 11794, U.S.A.

This laboratory has previously demonstrated that sufentanil can produce a naloxone-reversible increase or decrease in the stimulated formation of cAMP in the myentric plexus, depending on the concentration of opioid employed. Low doses of opioid (1010 M) enhance whereas higher concentrations (107 M) inhibit the magnitude of cAMP formation. On the basis of these results, we also hypothesized that increases are positively as well as negatively coupled to adenyly cyclase. In the present study, the effect of chronic in vivo morphine exposure on the balance between opioid excitatory and inhibitory actions, and opioid-activated phosphodiesterase and cAMP formation. In fact, the final assay is not significantly different from that which occurs in opiate naive preparations in the absence of exogenous opioid. This indicates the development of tolerance to the negative modulation of stimulated adenylate cyclase by sufentanil. However, in 'addicted' tissue, the magnitude of increase in cAMP formation produced by electrical stimulation, in the presence of an inhibitory concentration of sufentanil, is significantly larger than that observed in 'addicted' tissue that had been washed in morphine-free Krebs' or Krebs' solution containing naloxone. Thus, the balance between the magnitude of stimulation-induced cAMP elevation in opiate naive vs 'addicted' tissue in the presence of sufentanil, is due to the ability of an originally inhibitory concentration of opioid to enhance or facilitate stimulated formation of cAMP. This evidence suggests that the opioid inhibition of stimulated cAMP formation results not only from the loss of inhibitory potency but from the reversal to enhancement.
THE EFFECT OF HALOPERIDOL ON PREPROENKEPHALIN GENE EXPRESSION IN THE RAT ANTERIOR PITUITARY.

E. Tang, S. Main, and J. Chan.
Department of Physiology, University of Hong Kong, Hong Kong.

To study the effect of haloperidol on the gene expression of preproenkephalin, rat anterior pituitary tissue, at Day 7 postpartum, was injected with 2mg/Kg haloperidol i.p. The anterior pituitary was homogenized in AT buffer using RNAse-free DNase and RNAse. Total RNA was obtained after digestion with proteinase K and the equivalent of about one-sixth of an anterior pituitary was assayed for preproenkephalin mRNA using solution hybridization. Nonspecific hybridization. Standards and P-32 labeled riboprobes were prepared from linearized plasmid DNA's (courtesy of Dr. J. Hong), using SP6 polymerase. An action probe (gift of Dr. D. Autelitano) was used to normalize the value, which was expressed as a percentage of preproenkephalin mRNA per pg actin mRNA. It was found that haloperidol treatment resulted in a significant decrease of preproenkephalin mRNA contents in the anterior pituitary, and this correlated well with the decrease of net-enkephalin levels as measured by RIA. Dopamine receptor blockade may therefore lower the net-enkephalin level in the anterior pituitary through a decrease in preproenkephalin synthesis.

TREATMENT WITH ANTISENSE OLGODEOXYNUCLEOTIDE TO THE CLONED PATTERNS OF ENKEPHALIN IN VIVO INDUCES ANTI-OPIOID POTENCY.

Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

CCK may function as an endogenous anti-opioid. Thus, intracerebroventricular (i.c.v.) L-505,250 (CCK receptor antagonist) increases the antinociceptive potency of i.c. morphine. In mice, the modulatory effect of CCK antagonist is not the direct morphine antinociception, but as shown to increase the antinociceptive response of naloxone. In the present study, the i.c.v. administration of CCK antagonist (100ng/mouse) resulted in a significant decrease in the antinociceptive response of morphine, as assessed by the tail-flick assay.

DIFFERENTIALLY EXPRESSED RELATIONSHIPS BETWEEN ENKEPHALIN AND NEURONS CONTAINING THE HYPOTHALAMUS.

K. Commins*, and T.A. Miller.

Electrophysiological studies have suggested that actions of opioids in the hippocampal formation are mediated by inhibition of GABA interneurons; however, an anatomical basis for this interaction has never been demonstrated. Thus, we sought to determine the ultrastructural relationship of leu-enkephalin inhibitory neurons containing terminals (GABAergic) and GABAergic neurons using double labeling immunohistochemistry. We found that in the hippocampal formation, GABAergic neurons contain terminals in the dentate gyrus, CA1, and CA3. These findings suggest that there are functionally different populations of GABAergic neurons in the hippocampus, and that the relationship between these populations may depend on the anatomical location of the target neurons.

KAPPA RECEPTOR mRNA LOCALIZATION IN THE GUINEA PIG BRAIN.

COMPARISON TO [H]IREMAMAGazine AND [H]JHRG-595 BINDING.

Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Three opioid receptor types have been identified in the CNS that are referred to as μ, δ, and κ. Given the recent cloning of the guinea pig κ receptor (Xue et al., Proc. Natl. Acad. Sci. USA, in press), this study examines the mRNA distribution of the κ receptor in the guinea pig brain and compares the mRNA patterns. The kappa receptor binding sites defined either by [H]JHRG-595 (43nM) or [H]iREMAMAGazine (30nM), in the presence of a 500 fold excess of DAMGO and DPDPE using in situ hybridization and receptor autoradiographic techniques. Kappa receptor mRNA was identified with a 5′-32P探针 probe generated by EcoRI-BamHI fragment of the guinea pig κ receptor (602-1334) that spans from extracellular loop 1 to near the C- terminal end of the receptor coding region. An excellent correspondence is observed between κ receptor binding sites and mRNA in the deep layers of cortex, caudate-putamen, nucleus accumbens, olfactory tubercle, dentate gyrus, and entorhinal cortex. Thus, observed, was counter in the region as the substantia nigra ventral tegmental area, where κ mRNA was limited to the substantia nigra, pars compacta and ventral tegmental area area, while κ binding is primarily in the pars reticulata. This suggests μ receptors may be synthesized in the striatum and transported to the substantia nigra, pars reticulata, or alternatively, may represent the binding sites for κ receptor antisense oligos. Similarly, κ receptors are synthesized in the substantia nigra and ventral tegmental area and transported to the striatum. Species comparisons to the κ mRNA data will be discussed.

ROLE OF BRAIN OPIOIDS IN THE DEVELOPMENT OF HYPERTENSION IN STRESSFUL BORDERLINE HYPERTENSIVE RATS.

A.A. Hood* and M. Welsh
College of Pharmacy and TNR, University of Kentucky, KY 40506.

Opioid peptides have been implicated in modulating autonomic function under basal and stressful conditions, but their role in regulating cardiovascular function remains unclear. The borderline hypertensive (BHR) rat is a well-established model of neurogenic hypertension because its genetic background makes it susceptible to the hypertensive effect of stress. In this study, we examined the effect of a time limited period of restraint stress on the development of hypertension and the role of brain opioids on the development and maintenance of hypertension in BHR. We found that restraint stress, 2 hr daily, 5 days a week for 4 weeks, caused a significant rise in systolic blood pressure one week after beginning stress treatment. This increase in blood pressure (BP) continued throughout the period of stress (5 weeks). Moreover, restraint BHR continued to have higher blood pressure compared to the control group. This increase in systolic blood pressure was reversed by the administration of the μ-opioid receptor antagonist DAMGO (0.05nmol, iv) after the 4th week of restraint stress.

MULTIPLE EXPRESSION OF OPIATE TOLERANCE IN HYPOTHALAMIC ARCUTE NEURONS.

Department of Physiology, Oregon Health Sciences U., Portland, OR 97201.

To determine if hypothalamic arcuate (ARC) neurons develop tolerance to μ-opioids, intracerebroventricular recordings were made with bicucullin-filled electrodes in ARC neurons in hypothalamic slices from placebo and chronic morphine-treated (4 x 75 mg pellets for 2 d + 6 more pellets for a total of 6-8 d) or ovariectomized female guinea pigs. A dose-response curve was generated measuring the hyperpolarization in response to the selective μ-opioid agonist DAMGO. β-endorphin (bEND) neurons were identified using double labeling. Chronic morphine tolerance (EC50 = 245 ± 22 nM, N = 12; EC60 ± 33 nM in controls, N = 50) increased efficacy (ΔVmax = 7.1 ± 1.1 mV vs -10.7 ± 0.6 mV) and a 60% decrease in ΔGmax in all bEND neurons (N = 5) and other ARC neurons (N = 7). In another population of tolerant ARC neurons, DAMGO was less potent (EC50 = 110 ± 4 nM) without a change in efficacy. A third population of neurons (N = 6) did not exhibit any signs of tolerance with morphine treatment. Morphine-tolerant neurons also exhibited a higher incidence of k-opioid sensitivity in sensitized animals (20% vs 4%, p < 0.01). Therefore, chronic morphine uncouples μ-opioid receptors from k-opioid binding sites and increases k-opioid in ARC neurons. Since bEND neurons are dopaminergic neurons, similarly, μ-opioid receptors on the forebrain, this would not only affect neuropeptide but also homeostatic and reward circuits. (Supported by PHS grant DA05158)
OPIOIDS: ANATOMY AND PHYSIOLOGY III

T08.13

To determine how opioid receptor agonists affect the primary afferent neurotransmission, we examined the actions of dynorphin A(1-17) (DynA), (DPDPE), Tyr-D-Ala2-D-Leu5-enkephalin (DADLE) and the selective K-opioid agonist Dyn, (n = 6) and DynA (n = 11). When applied to the dorsal horn slices (1.75 x 1.5 x 0.8 mm), DynA produced a dose-dependent depression of the monosynaptic EPSPs (7.1 ± 0.6%, 9/21 days, 0.8 or 0.16 μM) that was reversed (by 97.3 ± 4.1% of control, n = 15, 6/21 cells) by naloxone, norbinaltorphimine, nor-binaltorphimine, or nor-binaltorphimine, respectively. Similar dual modulation of EPSPs was observed with DynA (0.5, 2.5, 10 μM) and DynA (10 μM) produced the same results in the presence of nor-binaltorphimine (0.1 μM, 5/5 cells). The results indicate that distinct modulation of synaptic efficacy can be induced in primary afferent synapses with neurons in the superficial laminae of the spinal cord. We speculate that dynorphin A(1-17) receptor activation and that these changes may be physiologically relevant for transmission and integration of sensory information, including pain. (Supported by NS-26323 and NIH-N29046EC.)

DYNORPHIN A MODULATES EXCITABILITY IN AMPHIBIAN AND MAMMALIAN NERVES. M.R. Luna and M.F. Pacheco. Centro Universitario de Investigaciones Biomédicas, Universidad de Colima, Colima, Col. 28045 México.

The effects of dynorphin A 1-17 (DYN) on nerve excitability were studied in isolated sciatic nerves of the frog and rat. The amplitude of recorded diaphasic action potential was gradually reduced by increasing concentrations of locally applied DYN (10 - 100 μM). Amplitude inhibition attained, at each DYN concentration, was not modified by increasing stimulation frequency up to 10 Hz, however, higher stimulus reduced the degree of inhibition. DYN effect on action potential amplitude was concomitant with a decrease in conduction velocity and a 1 to 3 fold increase in threshold strength input-output curve, reaching maximum effects after 15 to 35 min of DYN application, and recovering completely (in 86% of the experiments) after 25 to 700 min of drug washout. DYN actions were antagonized by nor-binaltorphimine (50 μM), therefore, our data are indicative of a widespread action of DYN on nerve conduction, which results in an excitability decrease through a specific interaction with K1-opioid receptors. Finally, these results provide an additional mechanism in order to explain reversible falcid hindlimb paralysis and loss of reflexes, observed in rats, after intrathecal administration of DYN (Stewart & Isaac, Brain Res. 543:222-325, 1991).

T08.15
INHIBITORY ACTIONS OF OPIOIDS ON SYNAPTIC TRANSMISSION IN THE RAT NEOSTRIATUM. B. Schlesser, M. Kundermann, B. Sutor, and G. ten Bruggencate. Department of Physiology, University of Munich, D-80336 Munich, Germany.

In the neostriatum, opioid receptors exist at a high concentration. Furthermore, enkephalin is colocalized with GABA in spiny stellate cells indicating that opioids may regulate the activity in striatal synaptic circuitries. In the present study, we investigated the influence of opiate-receptor activation on neuronal neurons in vitro using intracellular recordings. Experiments were performed on rat neostriatal slices (400 μm) with maintained corticostriatal connection. In the recording chamber the slices were kept submersed in artificial cerebrospinal fluid (ACSF). Synaptic activity was evoked by intracortical or intrastriatal electrical stimulation. Drugs were applied in addition to the ACSF. Application of the opioid receptor agonist D-Ala2-D-Leu5-enkephalin (DADLE) and the selective K-opioid agonist D-Pen2-7-Enkephalin (DPDPE) (0.1-1 μM) produced a dose-dependent decrease in the amplitude of both stratially or cortically evoked synaptic potentials. The opioids did not affect membrane potential or current-voltage relation. The effects were blocked by the opioid antagonist naloxone (1 μM) and persisted when GABA-ergic components were abolished by the GABA_A receptor antagonist bicuculline (20 μM). The data demonstrate, that activation of α-opioid-receptors decreases synaptic transmission in the neostriatum mainly by reducing glutamatergic excitation. (Supported by the BMFT, 01 K19001.)

T08.16

Neuropeptide FF (NPFF) is a FMRFamide-like peptide with opioid modulating activity. Neuropeptide FF (NPFF) is highly localized in the spinal cord where there are also specific NPFF receptors. Furthermore, there have been studies indicating that NPFF may participate in the regulation of pain threshold in the spinal cord. Thus, in this study, possible relationships between opiates and NPFF were investigated by studying the effects of various opioid receptor ligands on the K+-evoked release of NPFF immunoreactive material (IR) from rat spinal cords. Neuropeptide FF receptors were carried out by using an in vitro superfusion of isolated intact rat spinal cord. The opioid agonist U50488H decreased the K+-evoked release of NPFF in a dose dependent manner. In contrast, the µ-opioid agonist, Tyr-D-Ala-Gly-N-Me-Phe-Gly-ol (DAGO), was inactive and δ-opioid agonist, Tyr-D-Pen-Gly-D-Pen (DPDPE), exerted only a very slight inhibitory effect. The inhibitory effect of U50488H was antagonized by the K-opioid antagonist nor-binaltorphimine (NBI). NBI was found to enhance the K+-evoked release of NPFF probably resulting from the concomitant release of endogenous dynorphin by the K7. In view of the role of dynorphin in the antinociception, the results of this study further suggest that spinal cord NPFF participates in the regulation of opioid mediated antinociception.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
109.1 LACK OF NMDAR1 EXPRESSION IN LUTEINIZING HORMONE-RELEASING HORMONE NEURONS OF THE MALE SYRIAN HAMSTER. G. Muree, V. Giridant, S.G. Kohana and H.F. Urbanski. Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006.

There is substantial evidence demonstrating that excitatory amino acid (EAA) receptors are involved in luteinizing hormone-releasing hormone (LHRH) secretion both in vitro and in vivo. Since immunolabeled LHRH neurons (G1 cells) that lack NMDAR1 gene it has been proposed that EAA's stimulate the secretory activity of LHRRH neurons directly. We have used immunocytochemistry with a specific antibody to NMDA receptor subunit 1 (NS1) in an attempt to confirm whether particular facilitatory influence of EAA's is mediated by such a direct neuronal pathway. Adult male Syrian hamsters were killed with heparinized saline injected under ether anesthesia and their brains fixed with 4% paraformaldehyde. Coronal Vibratome sections (50 μm) containing the medial preoptic area were then processed initially for immunocytochemistry using a monoclonal antibody to LHRH (H14H) and stained with diaminobenzidine. Subsequent NS1 (for NMDAR1 mRNA using a 32-p end-label to apply to probes) The DNA template was extracted from NMDAR1 cDNA using Pest and EcoRI was performed on these same sections and counted G1 cells. After dropping in photographic emulsion, silver grain deposition was examined microscopically to determine colocalization of NMDAR1 mRNA within the immunostained LHRH neurons. As expected, G1 cells clearly demonstrated hybridization of the riboprobe. In the brain sections, a high density of silver grains was localized in the outer fringe of the preoptic area and within the hippocampus but not in the vicinity of the LHRH perikarya; only 1 neuron from a total of 103 neurons/3 animals showed possible colocalization. These results suggest that although G1 cells may have an inherent capacity to express the NMDA receptor, in the in vivo excitation of LHRRH neurons by EAA's is more likely to be mediated indirectly, by a pathway that involves interneurons.

Grant support: HD-24312, HD-29186, RR-01635 and NSF 93-03968.

In the male quail forebrain, aromatase-immunoreactive (ARO-ir) neurons are clustered within the sexually dimorphic medial preoptic nucleus (POM), the nucleus accumbens septi (NDST), the median eminence (ME), and the hypothalamic nucleus suprachiasmaticus (SSC)(1). ARO-ir neurones are also present in the lateral hypothalamus. Previous studies demonstrated that ARO cells are sensitive to testosterone (T) and are involved in the control of gonadal steroid function after castration and administration of these steroids. In this recent study, we demonstrated that the vasotocinergic system is also sensitive to T: the density of the vasotocin- (VT-ir) fiber networks located within the POM and the lateral septum (LS) was higher in castrated compared to gonadectomized male birds and restored to intact level by a treatment with T. We analyzed here the anatomical relationship between ARO and VT systems within these regions. The study was performed on brains perfused with Zamboons fixative and serially sectioned with a cryostat. Sequential staining for VT, ARO, or VT-ARO was performed on adjacent 30 μm thick sections. High concentration of VT-fibers were observed within the POM, the LS, the lateral septum, and the ventral hippocampus. In double-labeled sections, all clusters of ARO-ir cells, with the exception of those localized in the Ac, were embedded in a dense network of VT-fibers. Many of the VT-ir terminals appeared to end in the neuropeptide surrounding ARO-ir elements rather than directly on their cell bodies. However, there was a very close correspondence between the extension of the ARO-ir cells and VT-fibers. This study, therefore, suggests the role of the T-dependent ARO system is also directly innervated by a T-dependent peptideergic system which can be modulated by steroids both directly and indirectly through the VT system. Further studies will be needed to determine whether this VT interaction has a functional significance for the ARO-ir cells and whether these two neurochemical systems (ARO and VT) affect reproduction in an independent or coordinated manner. 109.3 FOS EXPRESSION IN GNRH NEURONS WITHIN PREGNANT AREA (POA) GRAINS OF THE POSTNATAL HYPOTHALAMUS (HPG) MICE: EFFECT OF PROGESTERONE AND SEXUAL BEHAVIOR. M. G. O'Connor, J. T. J. Wang, O. M. Miller, and A. J. Silverman, Dept. of Medicine, Mount Sinai School of Medicine, NY 10029 and Dept. of Anatomy, Columbia University, Columbia, NY 10032.

Expression of Fos, the proto-oncogene product of the c-fos gene, is widely accepted as a marker for neuronal activation. We have shown that in normal steroid-primed, ovulating estrus mice, Fos expression occurs in greater than 40% of GnRH neurons and is maintained at this level for a longer period of time in similar treated females paired with an uncastrated male (Emde and Simerly 1988). Postpartum, GnRH neurons our functional GnRH gene and are immature. After receiving intravaginal POA grafts containing GnRH neurons, females may enter persistent estrus, and have the capacity to ovulate reflexively or, more rarely, ovulate in response to a preoptic stimulus. The present study of HPGPOA mice examined the effects of both progesterone treatment (P; 500 μg 0910h) and sexual behavior (introduced to an experienced male at 1400 h) on the expression of Fos in grafted GnRH neurons. In response to sexual behavior, 47±9.10% of GnRH neurons of P-treated HPGOPOA mice expressed Fos in contrast to 9.5±0.96% of GnRH neurons in those mice that did not receive P. Treatment alone did not increase the expression of GnRH neurons (4.0±0.4%). These results suggest that in the presence of P, sexual behavior may serve as a stimulator of Fos expression in GnRH neurons. In addition, the present study supports the hypothesis that at least a portion of the graft-host connectivity that underlies aspects of reproductive competence in HPGPOA mice is steroid sensitive.

Supported by NIH HD 19077.

The hypotalamic arcuate nucleus contains a neuronal population immunoreactive (ir) for proopiomelanocortin (POMC) and corticotropin-β (POMC-β) derived peptides and giving a sexually differentiated projection to the median eminence: to the subependymal (S) region and to the gonadotrophs (G) in the rich regions of the posterior hypothalamus (Ph). The presence of the POMC-β ir in males and females and in female rats. The presence of the POMC-β ir in males and females and in female rats. The presence of the POMC-β ir in males and females and in female rats.

The male median eminence is sensitive to changes in the arcuate nucleus of cell bodies and is protein for neurotensin (NTX). In the female rat, the arcuate nucleus of cell bodies is sensitive to NTX and the functional significance of this is the neurotensin (NTX) system in the male rat.

To study this point, results suggest a postnatal androgen-driven "non numerical" mechanism of differentiation for this neuronal system of the mammalian hypothalamus whose organization involves development of the autonomic system.

109.6 EFFECTS OF INTRAUTERINE POSITION ON METABOLIC CAPACITY OF THE HYPOTHALAMUS. G. S. M. R. C. M. H. M. S. M. H. O. D. G. O. H. and J. C. Clark. Dept. of Psych and Zoology, Univ of Texas, Austin TX, 78712 USA and Dept of Psych, McMaster Univer, Ontario L8S 4K1, Canada.

Neural metabolic correlates of known effects of intrauterine position on behavior in the Mongolian gerbil illustrate the ability to investigate morphological determinants. Hypothalamic regions were compared in female gerbils that developed in utero between two female fetuses (2F) or between two male fetuses (2M) to assess differences in metabolic capacity. A total of 25 female rats were studied. A quantitative image analysis systems we measured the cytochrome oxidase (COX) activity in histochimically stained brain slices of the gerbil. Due to its limiting factor in oxidative metabolism (O) is determined by an excellent marker of metabolic capacity: increased activity of neurons in a brain region lead to increased C.O. content in their mitochondria. The COX staining procedure involved metal impregnation through cobalt preincubation, as well as oxygenation and heating of the reaction medium. Optical density (O.D.) of ten hypothalamic regions, including the sexually dimorphic anterior hypothalamic area (AHA), the orbital cortex and the grey matter O.D. Significant group differences in the metabolic capacity of three hypothalamic regions were revealed. Differences in the AHA in the anterior hypothalamic area and the sexually dimorphic area were seen in 2M as compared to 2F. To the best of our knowledge, this is the first examination of functional changes in hypothalamic areas related to the differences in intraterine position. Supported by RO1 MH43353 and 15GSP037338.
709.7 THE DISTRIBUTION OF AROMATASE mRNA IN THE BRAIN OF ADULT MALE AND FEMALE RATS USING in situ HYBRIDIZATION C.K. Wagner* and J.J. Morrell, Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102

Many of the effects of gonadal steroid hormones in the male brain are due to the actions of the testosterone metabolite, estradiol, which is synthesized by the actions of the P450 aromatase enzyme, aromatase. Aromatase activity has been demonstrated through the use of in vitro enzyme assays, to be present in regions of the preoptic area, hypothalamus and limbic system. Levels of aromatase activity are much higher in male than females in some brain regions. The present study examined the distribution and cellular localization of aromatase mRNA in adult male and female rat brains using in situ hybridization. A 113-base 5’-labelled cDNA probe, complementary to the aromatase mRNA just upstream from the heme-binding domain, was synthesized from the rat aromatase cDNA inserted into pGEM2 (generous gift of Dr. Richard O’Riordan, Houston TX), using a Bal31 fragment and SP6 polymerase. Following the hybridization procedure, sections were dipped in nuclear track emulsion to order to detect aromatase mRNA at the cellular level. In the male, many heavily labelled cells were found in the unoccupied bed nucleus of the stria terminalis and the medial amygdala. A smaller number of heavily labelled cells were seen in the periventricular preoptic nucleus, the median preoptic nucleus, the ventromedial nucleus, the cortical amygdala and the sublenticular organ. Lightly to moderately labelled cells were observed in the horizontal diagonal band, the magnocellular preoptic nucleus, the median preoptic nucleus, the anterior hypothalamus, the arcuate nucleus, the piriform cortex and nuclei of the thalamus.

Aromatase mRNA was found in the same brain regions in females. Sex differences and the effect of castration in males on levels of aromatase mRNA will be discussed.

Supported by HD 22588 to JIM and NBA 47 0974 to CWJ and JIM.

Immunohistochemical studies localizing the calcium-binding proteins (CaBPs) parvalbumin (PV), calbindin (CB), and calcitelin (Ck) in the monkey and the primate visual areas V1 and V2 and have shown that these CaBPs are present within morphologically distinct groups of neurons that display specific regional and laminar distribution patterns. In order to further characterize the cellular organization of the primate visual system, we performed a quantitative analysis of the distribution of CaBPs-immunoreactive (ir) neurons in different divisions of the magnocellular (M) and parvocellular (P) visual pathways in the macaque monkey. Area V1 was characterized by very high numbers of PV- and CB-ir neurons, while Ck-ir neurons were less numerous. Areas V2, V3 and V3A displayed lower numbers than area V1 for the three neuronal populations. However, cell counts markedly increased in areas at higher levels in the cortical hierarchy. In particular, areas MT, VIP, V4 and TE showed very high densities of stained neurons. In addition, a subset of CB-ir pyramidal neurons located in layer III exhibited distinct distribution patterns among the cortical areas investigated, with the highest densities in areas V4 and MT and slightly lower cell counts in areas TE, TE, VIP and LIP. These results indicate that CaBPs define neuronal populations that are differentially represented among cortical regions of known function in the M and P pathways in the primate visual system. (Supported by NIH AG06647, MH52154 and the Brookdale Foundation)

Prior physiological studies of subjective contours used patterns which induce bars or edges by line ends or corners (van der Heijdt et al., Science 224:1290-1294, 1984). By contrast, we employed a more complex figure in which a Kanizsa square is induced and placed in apparent motion. The Kanizsa square moves as if both along a double row of inducers ("PAC-MAN"). This illusion is achieved by appropriately orienting neighboring inducers in successive planes and randomly orienting inducers elsewhere (Bravo et al., Vision Res. 28:881, 1988). At eccentricities equal to those tested, six observers perceived the illusion as a black square, black-occupied object moving against the background. If the open quadrants of the inducers were closed by thin circular arcs, no such object was seen (control stimulus). We recorded from cells in areas V2 and V4 of one feasting monkeys and sought a cellular correlate of the perceived illusory object. We attempted to place all inducing elements outside the classical receptive field. In V2, 659 cells (eccentricities 3.4-13 degrees) responded to the moving Kanizsa square but gave a reduced response or no response at all to the control stimulus. In preliminary data, 391 cells (eccentricities 1.5-15 deg.), 413 cells showed similar behavior. Response peaks correlated with the position of the induced object centered on the receptive field. Some cells were driven by a double row of inducers selectively tuned to patterns in which inducers and background colors were photometrically isoluminant. In some cells, area V4 inducers (to be a control color stimulus) abolished the subjective square response. In another case, increasing luminance contrast to 10% but removing background and inducing achromatic did not evoke an increased response.

These data confirm the presence of illusory contour responses in V2 and extend these findings to a more complex stimulus. In addition, we have preliminary evidence for similar responses in V4. Our results suggest the existence of figural completion mechanisms for chromatic patterns similar to the boundary completion mechanisms shown earlier for achromatic patterns.

710.4 MECHANISMS OF CONTOUR PROCESSING IN MONKEY PREBRAIN CORTEX INCLUDE INFORMATION ON DIRECTION OF GRAVITY. X. M. Saam, V. Henn, and E. Peterhans (SPON: European Neuroscience Association). Dept. of Neurology, University Hospital, Zurich, Switzerland, CH-8091 Zurich, Switzerland.

Form perception requires a generalization of representation of contours with regard to the quality defining them (e.g. luminance, color, motion, or texture) and their spatial position and orientation. We report here the effect of body tilt on mechanisms of contour processing in the visual cortex of the alert alert monkey.

The responses of single neurons were studied while the monkey performed a visual fixation task in either an upright position, or with its body tilted about the naso-cranial axis by 25° or 50° (recording in 10° increments). A total of 106 orientation selective neurons were both in striate and prefrontal cortex (areas V2 and V3a/V4A).

We found that the position of the response field for light and dark bars or as at 2 or 3 body positions. In striate cortex, most neurons (94%) were of a non-compensatory type showing altered orientation and position of the response field according to the body tilt and the estimated counterrolling of the eye. In parietal cortex (32±13.4°) by 25°. By contrast, 40% of the neurons in prefrontal cortex (82%) were of a compensatory type. These cells, although showing a change in field position, preferred similar stimulus orientations at all body tilts. This indicates that the orientation sensitivity of these neurons was invariant with respect to the direction of gravity.

In conclusion, information about the direction of gravity is implemented in monkey visual cortex first at the level of area V2. This suggests that otolithic signals contribute to mechanisms of contour processing at early stages of visual processing.

110.5 TOPOGRAPHIC PATTERN OF CORTICAL CONNECTIONS TO DORSAL AND VENTRAL VISUAL AREAS IN MACAQUE MONKEYS. J. Steriade, G. Fite, and E. Schiller. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

We studied the connections of V2 with other extrastriate visual areas in macaque monkeys (Macaca mulatta) to better determine their extent and visuotopic organization. Multiple injections of fast blue and fast green fluorescent tracers and WGA-HRP were made in dorsal V2 representing the lower central vision and in ventral V2, representing the upper central vision. After 4-7 days survival, animals were anesthetized and perfused, and visual cortex separated from the rest of the brain. Cortex was manually flattened and cut perpendicular to the surface. Toed labels were related to retinotopic boundaries identified from adjacent primary and extrastriate visual cortex. It was observed that these areas project to two main visual areas. After further, intracellular recordings, the specificity of projections originating from V2 stripes. For instance, the superior colliculus (SC) receives a strong projection from V2, and available information indicates that the connections in the monkey are predominantly magnocellular in nature. We have therefore correlated the distribution of V2-SC projection neurons with the array of CO V2 stripes.

110.6 THE DISTRIBUTION OF CORTICO-COLICULAR PROJECTION NEURONS CORRELATES WITH THICK CYTOCHROMOGENIC AXON PROJECTIONS IN VISUAL AREA V2 OF MACAQUE MONKEYS. J. Steriade, G. Fite, and E. Schiller. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Several lines of evidence suggest that the three classes of CO stripes observed in V2 (CO-dense thick axons, sparse thin axons, and pale intercalated stripes) are related to specialized functional streams in visual cortex. One line of evidence comes from the pattern of connections that CO stripes and visuotopic areas. Thus, in accordance with the idea that thin CO stripes are part of the magnocellular processing stream, these stripes have been shown to project to areas involved in the analysis of motion and spatial attributes, such as area MT. Exploring the pattern of V2 connections with subcortical nuclei that have magnocellular functions confirmed the specificity of projections originating from V2 stripes. For instance, the superior colliculus (SC) receives a strong projection from V2, and available information indicates that the connections in the monkey are predominantly magnocellular in nature. We have therefore correlated the distribution of V2-SC projection neurons with the array of CO V2 stripes.

Guided by readings of visually evoked potentials, multiple injections of either HRP or fluorescent tracers were made into the SC of adult monkeys (Macaca fascicularis). Three- to four-day later, the area was sectioned coronally or tangentially to the cortical surface, and the distribution of labeled cells in layer V was compared to the CO staining pattern. In each area, we observed the specificity of projections originating from V2 stripes. For instance, the superior colliculus (SC) receives a strong projection from V2, and available information indicates that the connections in the monkey are predominantly magnocellular in nature. We have therefore correlated the distribution of V2-SC projection neurons with the array of CO V2 stripes.

Extrastriate area V3 may represent an important site for integration of visual information inputs from both the retina and parvocellular pathways and has prominent projections to both areas MT and V4. Therefore, we investigated the representations of color and motion in V3. We recorded from single cells in area V3 of macaque monkeys (Macaca mulatta) using standard acute recording techniques. After measuring each cell's spatial and temporal properties, we tested its chromatic and motion sensitivity using overlapping arrays of moving and static stimuli. All V3 cells were orientation selective. About 50% of our sample was selective for direction of motion. Contrary to previous reports, we also found that about 50% of the remaining cells were color selective for color. These two substrategies overlapped to a large extent, and we found a significant proportion of cells highly selective for both of these stimuli. An analysis of the responses of directionally selective cells to moving stimuli showed that in area V3, as in MT and unlike in V1, V2, and V4, many cells were not selective for the orientation of the plaid pattern, rather than the component motion. Furthermore, a third of our sample was reshaped, and many of these cells showed orientation or direction-selective surround effects. Our results show that there is a significant interaction between color and motion processing in area V3, and that V3 cells possess many of the complex motion properties typically observed at later stages of visual processing. Supported by MRC G920389IN and NIH EY01001.

110.8 RECEPTIVE FIELD STRUCTURE OF V2 NEURONS IN THE PRIMATE PRIMATE GALAGO CRASSIGAMAUDUS. J. D. Allman and V. A. Casagrande. Dept. of Cell Biology, Vanderbilt University, Nashville, TN 37232-2175.

Visual area V2 (V2) is the second largest visual area in the primate cortex and receives input from all other extrastriate areas. There is very little information about the receptive field (RF) structure of V2 cells. A key question is how the RF structure of V2 cells compares to the RF structure of V1 cells. To answer this question we measured the response of simple cells in three different primate species using standard single-unit electrophysiological techniques with both bars and drifting sine-wave gratings. All cells were classified as simple or complex and their RFs were characterized by orientation and spatial tuning and contrast sensitivity. We found that complex cells, especially those responsive to grating structure, were more sensitive to orientation selectivity and also more contrast sensitive than simple cells. The majority (71%) of these cells were binocular and directionally selective (78%). The average orientation tuning was 21.5 ± 9.65° SE1. The preferred spatial frequency averaged 0.5 cycles/deg with a mean tuning bandwidth of 2.4 ± 0.68 SE octaves and a mean cut-off of 1.2 cycles/deg. The mean preferred temporal frequency was 0.276 ± 1.85° SE Hz with a cutoff frequency of 8 Hz. The average contrast sensitivity was 20.1 ± 19.32 SE. The RF structure of V2 cells near area centrals was very similar to that of V1 cells in this species. V2 cells differed from V1 cells in having larger receptive fields, being mostly binocular, and having lower spatial frequency peaks and cutoffs.

Using anterograde techniques, we have found that corticotectal (CT) neurons in primary visual cortex (area 17, n = 21) and a lateral visual cortical area (posteriormedial suprasylvian visual cortex, PMLS, n = 13) in cats trained in ocular dominance tasks. Head position was fixed, and gaze was monitored using the scleral search coil technique. The cat faced a rear projection screen onto which we could project a visual stimulus. CT cells in both areas responded well to small stimuli moving away from the target when the target was in the receptive field. None of the cells in either cortical area exhibited pre-saccadic activity. At least half the CT cells in area 17 showed post-saccadic activity associated with visually guided saccades. The retina across an illuminated field. PMLS CT cells did not show post- saccadic activity. Furthermore, both CT cells in PMLS 17 respond to visual stimuli well in excess of saccade velocities, an ocular motor signal must actively suppress visual inputs when the cat makes eye movements. In general, area 17 CT cells are like their counterparts in the paralyzed, anesthetized preparation. Most are strongly directional, orientation selective and show little evidence of length summation. PMLS CT cells are the same in both species. This is probably because the cells make decisions about which target to look at next in contrast, the large receptive fields and directional anisotropy of PMLS CT cells would be consistent with a role in supporting visually-guided locomotion (Supported by NIH Grant EY06818).

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
THALAMIC AND CORTICAL CONNECTIONS OF AREA 18 OF ALBINO CATS. Marie Peschel* 1, Andrei Wrob, Iwona Stojennicka and Jan Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

The visual system of albino animals are abnormally in that many ganglion cells are mislocated to the contralateral geniculate nucleus (LGN). The consequences of this misrouting are only partially understood. We studied the organization of albino geniculocortical and corticogeniculal connections by injecting up to 6 different tracers in distinct rostrocaudal locations in area 18 (V2) of 4 animals. The results revealed a roughly normal rostrocaudal sequence of the geniculate projections and progressively more rostral injections in area 18 labeled progressively more rostral locations in the LGN. However, the zones of labeled cells were larger than those for comparable injections in normal cats suggesting greater divergence and convergence of LGN projections. Layer A1, with abnormal retinal inputs, had discontinuous medial and lateral foli of labeled neurons from single injections, indicating topographic mismatching in projections. Cortical connections with areas 17 and 19 and suprasylvian regions were also roughly normal with more rostral injections labeling more lateral zones in these fields. However, again connections appeared less precise than normal with connections of central area 18 in particular being more widespread and overlapping than in normal cats. These abnormalities suggest that in albino cats, visuo-tactile organization is less precise and orderly. Supported by EY-02666 (JK), NSPB-FFS P92037 (MP) & James S. McDonnell Foundation (AW).

We have previously shown that the cells projecting from area 17 of the cat to the parietal medial lateral occipital area (PMLS) are clustered within regions that stain densely for cytochrome oxidase (CO). Here, we extend these findings to connections involving area 18. Large, multiple injections of wheat germ agglutinin-conjugated horseradish peroxidase or cholera toxin into callosal target areas were made into areas 17, 18, or the PMLS. In each case, the aim was to saturate a large part of the visual field representation of the injected area. Labeled cells were charted in tangential sections of cortex and compared to the pattern of CO staining in alternate sections. After tracing in area 17, all labeled cells in area 18 were, as was previously found in area 17, arranged in patches that aligned with the CO blobs. In addition, the PMLS projecting patches, were slightly larger in area 18 (slightly greater than inmm spacing) than in area 17 (slightly greater than 1mm spacing). In agreement with Ferrer et al. (1988), we found the projection from area 17 to area 18 to be discontinuous. Moreover, cells projecting from area 17 to area 18 are confined to the CO blobs. Surprisingly, labeled cells and terminals in area 18, following large injections in area 17, also have a patchy organization, which we are currently trying to relate to the pattern of CO activity. Preliminary evidence suggests that they too are confined to the blobs.

Thus, while area 17 and 18 have similar PMLS-projecting blob and non-PMLS-projecting interbop blob compartments, it appears that connections between these two areas are made spacially and to the CO blobs, with interblop being unconcerned cortico-cortically. These results are not easy to interpret in a strictly hierarchical framework: classifying connections from 17 to 18 as feedforward, connections from 18 to 17 as feedback; rather, the similarities in connectional organization are consistent with suggestions that these two areas operate in parallel. (This work funded by MRC 5-99150)

TWO VISCERAL SYSTEMS IN A RODENT. C.Q. Elliott* and M. Dias, Dept. of Psychology, University of Waterloo, Waterloo, Ontario, Canada.

Although it is sometimes assumed that there are two visual cortical processing streams in non-primates, there is little evidence for such a disjunction of function in rodents. We wanted to demonstrate selective efficacies to either dorsal or ventral cortical areas on two different types of visual information processing in the Mongolian gerbil. Gerbils received either lesions of parietal cortex, ventral cortex, or sham surgery. After recovery, they were placed at random starting locations into an open field containing an object for one five-minute trials. On each trial, the total time spent in contact with the object was measured. On each of the first 5 trials, the object was moved to a new location in the field and a new, different object was placed in the old location. The critical measure was the amount of time spent in contact with each of the objects on each of the first 5 trials. Normal gerbils showed decreasing contact time with the object over the first five trials. On the sixth trial, they showed elevated contact time with both the new object and the object at a new location, demonstrating sensitivity to both object location and identity. Gerbils with parietal lesions showed relative disorientation to the new object but not the new location, suggesting a deficit in object recognition. On the sixth trial, the object was moved to a new location in the field and a new, different object was placed in the old location. The critical measure was the amount of time spent in contact with each of the objects on each of the first 5 trials. Normal gerbils showed decreasing contact time with the object over the first five trials. On the sixth trial, they showed elevated contact time with both the new object and the object at a new location, demonstrating sensitivity to both object location and identity. Gerbils with parietal lesions showed relative disorientation to the new object but not the new location, suggesting a deficit in object recognition. These findings constitute evidence that lesions to ventral cortical areas in rodents can produce dissociable effects on visual behaviour reminiscent of those seen in primates. (Supported by a N.S.E.R.C.C. grant to CGE).

We recently found that V2-A1 projections to the PMLS are confined to the CO blobs, suggesting that for area 18, 19, area 17, and 18 have segregated output areas for each of these regions. In the present study, we examined V1-A1 and V2-A1 connections to the PMLS in normal animals. In the presence of normal retinal inputs, all injections of cholera toxin or wheat germ agglutinin-peroxidase into the V1-A1 projection area were restricted to the CO blobs. In our previous study, these injections were into area 17. In this study, we have injected into area 18, the PMLS, and the lateral suprasylvian area (LSA). We find injections of cholera toxin conjugated to colloidal gold (CTB-AU) into the PMLS projecting area of area 18 (slightly greater than inmm spacing) than in area 17 (slightly greater than 1mm spacing). In agreement with Ferrer et al. (1988, we found the projection from area 17 to area 18 to be discontinuous. Moreover, cells projecting from area 17 to area 18 are confined to the CO blobs. Surprisingly, labeled cells and terminals in area 18 following large injections in area 17, also have a patchy organization, which we are currently trying to relate to the pattern of CO activity. Preliminary evidence suggests that they too are confined to the blobs. Thus, while area 17 and 18 have similar PMLS-projecting blob and non-PMLS-projecting interbop blob compartments, it appears that connections between these two areas are made specifically to the CO blobs, with interblop being unconnected cortico-cortically. These results are not easy to interpret in a strictly hierarchical framework: classifying connections from 17 to 18 as feedforward, connections from 18 to 17 as feedback; rather, the similarities in connectional organization are consistent with suggestions that these two areas operate in parallel. (This work funded by MRC 5-99150)

The modifiability of cortical cells was studied in visual primary (VI), nonprimary (SSS, PMLS, ALIS, and MD) and posterior areas of normal (MS or area 7) areas. Extracellular unit recording was made in 7 cats monocularly deprived (MD) at ages of 1-11 weeks and in 31 normal (NOR) controls. They were anesthetized and paralyzed, and the receptive fields (RFs) mapped and PSTHs analyzed. While similar responsiveness was found in VI cortical area, the total number of cells, responsive cells, and binocular cells were all higher in NOR than in MD cats. There was a trend for the MD cats to respond to the RFs of the SSS and MS areas of the MDs. These reports are consistent with the findings in the SSS areas of the MDs (see table). The binocularity is consistently reduced in all areas of MDs but more vigorously in the SSS and MS. This is in accordance with our previous data on selectivity of the cells' reaction and their RFs in MDs, outside VI (Sci. Neurosci. Abstr., 18:1315, 1992). There is, thus, an internal deficiency in processing visual information in areas not exclusively dedicated to vision, which is enhanced by the partial elimination of visual exposure during development. Supported by Adams Super Center for Brain Studies, Tel-Aviv Univ.
CEREBELLUM: GENETICALLY NEEDED RESPONSES TO MUSCLE OUTPUTS

T11.1

Vestibulocerebellar (VS) and cervicocerebellar (CS) reflexes show different patterns of postural adjustments depending on the direction of neck displacements. This organization may require the assistance of the cerebellar anterior vermis, which integrates both the vestibular and neck input to influence the motor output. A prerequisite for such a proposed function is that the vermis encode the spatial coordinates of both head and neck displacements.

We investigated, in decerebrate cats, the directional selectivity of the responses of visual Purkinje (P) cells to wobble either of the whole animal at 0.15 Hz, 10° (vestibular input) or of the body over a fixed head at 0.15 Hz, 2.5° (neck input). In both instances the direction of animal or body rotation moved at a constant speed over 360° in a clockwise (CW) or counterclockwise (CCW) direction. Bidirectional responses were represented by a vector lying midway between the maximal response directions to CW and CCW. These vectors were distributed over the entire plane of rotation for both vestibular (n=44) and neck responses (n=98), with some predominance of neck vectors in the first quadrant.

In conclusion, the cerebellar anterior vermis provides a framework for spatial coding of vestibular and neck signals and may represent the control of VS and CS reflexes during a variety of head and neck displacements.

T11.3

The % of cells responding to 70 dB clicks and hisses differed before: 8% in L VNT, 50% in flocculus, 49% in lat. anisiform lobe, and 37% in med. anisiform lobe. After conditioning, responses to CS were greater than to DS in the med. anisiform area, and exceeded peak responses to the CS before conditioning. The ratio of CS:DS responsive cells increased and reversed from that for adaptation and sensitisation. Separation of data from L V and VI also found responses after conditioning, at L V and VI. Discriminative initiation of the blink CR appears to depend on motor cortex and dorsal cochlear nucleus than on cerebellum even though contributions from the cerebellum may be needed for late components of the CR to develop and be performed. (Supported by HD05958.)

T11.5

SELECTIVE ELIMINATION OF CEREBELLAR OUTPUT IN THE GENETICALLY DYSTONIC RAT. M.S. LaDue*, J.F. Loden, and A. Meinzen-Derr. Dept. of Psychology, Univ. of Alabama at Birmingham, Birmingham, Alabama 35294.

The genetically dystonic (DY) rat, an autosomal recessive mutant, exhibits a progressive motor syndrome that resembles the generalized idiopathic dystonia seen in humans. Even with supportive measures, rats die by postnatal day 69. A total cerebellarectomy that includes the dorsal portion of the lateral vestibular nucleus (LVN) eliminates the dystonic motor syndrome of the dy rats, greatly improves overall motor function and prevents early death. After total cerebellectomy, dy rats survive into adulthood, mate and successfully rear their offspring. Selective elimination of cerebellar output was performed on 15-day-old dy rats in order to determine the cerebellar components critical to the mutant's motor syndrome. Electrolytic and/or excitatory amino acid lesions of the medial cerebellar nucleus, interpositus cerebellar nucleus, lateral cerebellar nucleus and LVN were created in separate groups of dy rats. Rats were observed for the presence of abnormal motor signs (falls, twitches, clamps, pivots) and tested on several measures of motor performance (activity, climbing, righting, homing) before surgery and again on Day 20. All nuclear lesions produced significant (p < .05) improvements in motor function and decreases in the frequency of abnormal motor signs. No individual nuclear structure appears entirely responsible for the dy rat motor syndrome. T11.6

Adult meandertail mutant mice (mea/mea), unclefected heterozygous mice (mea+), and wild-type mice (C57Bl) were euthanized, transcardially perfused with 4% formaldehyde, stained with Nissl, and embedded for routine methods. All forms of Purkinje cell were preserved, with an 80% increase in Purkinje cell density. A thin superficial layer consists of neuropil composed primarily of Purkinje cell dendritic profiles. Disorganized Purkinje cell somata with interposed neuropil form an intermediate layer. The deepest layer consists of glial and small neuronal somata, and a neuropil containing myelinolized fibers. Purkinje cell dendrites, and a few myelin fiber bundles. Scattered within the agranular cortex are micronuclei, a few of which appear to be ectopic granules. The neuropil of the agranular cortex contains large numbers of premaged Purkinje cell dendritic spines which are wrapped in glial lamellae, and are apparently not contacted by presynaptic elements. Presumptive basket cell axons are observed to impinge upon the surface of Purkinje cell somata and dendrites, and boutons with the characteristics of climbing fibers contact some presynaptic appendages. The cortex of the cerebellar posterior lobe is relatively normal in appearance. This "normal" cortex, however, exhibits a high frequency of ectopic granule cells located singly, and in clusters, at the surface of and within the molecular layer. An intermediate cortical region forms a gradual transition from the normal to the agranular cortical architecture. Supported in part by NHI grant NS22909 to LEM.

Lower thoracic-upper lumbar (LT-UL) spinocebellar (SpCb) projections have a complex topography in the anterior lobe of normal rats. In adult shaker rat mutants, many or all of the Purkinje cells (PCs) in the anterior lobe degenerate. This study sought to determine if loss of PCs alters LT-UL SpCb topography in the anterior lobe. In shaker rats the distribution of WGA-HRP labeled LT-UL SpCb mossy fiber terminals was compared to the distribution of the anterior lobe and compared with similar reconstructions from normal rats. In shakers, labeled LT-UL labeled terminals were localized to clusters and sharply defined, irregularly-shaped patches surrounded by terminal free areas. The terminal patches were contained within discontinuous parasagittally oriented stripes or transversely oriented bands. The spatial distribution of LT-UL SpCb projections in shaker rats have numerous features of organization similar to that seen in normal rats. Based on these similarities, we conclude that PCs are not necessary for the maintenance of SpCb topography in the rat cerebellum. (Supported by NIH Grants RO7013 and NS20227).

The role of the complex spike as a 'meaningful' afferent input for the cerebellar nuclei is much debated. Here, we study the response of identified neurons in the cerebellum to electrical simulation of the inferior olive. Ketamine anesthetized male Wistar rats received stimulation electrodes in the red nucleus and inferior olive. Recordings of neurons in the contralateral cerebellar nuclei and cerebellar cortex were obtained with glass microelectrodes filled with 4M NaCl. Cerebellar nuclear units were identified by their antidromic action potential triggered from the red nucleus which collided with spontaneous spikes. Purkinje cells were identified by their complex spike activity. After identification, the response pattern to graded inferior olive stimulation was recorded and analyzed. Seventy-five cerebellar nuclear neurons were analyzed. Besides a single orthodromically induced action potential in 44 units (presumably triggered by climbing fiber collaterals; latency 4.2 ± 0.4 msec, virtually all units (73) responded with an initial pause of variable duration (mean 57 ± 38 msec). Post-stimulus time histograms revealed that this inhibition phase was followed by an increase in activity in 61 units. For 36 units, the chance of firing more than doubled for at least 20 and up to 500 msec (mean 125 msec). Graded stimulation revealed that, frequently, the inhibition developed before the facilitation. Purkinje cell recordings indicated that it is unlikely that the facilitatory effect upon cerebellar nuclear neurons is exclusively due to a change in simple spike firing rate. It is concluded that olivary triggered complex spikes not only cause a phase inhibition of cerebellar nuclear neurons but, in addition, may result in a subsequent, and potentially significant, increase of their firing rate. This effect appears to be especially prominent when large members of olivary neurons fire in synchrony.

Spike responses were investigated in a slice preparation of the turtle (Trachemys scripta elegans) cerebellum by current clamp whole-cell recordings. IPSPs, presumably due to Golgi cell activation, were evoked by electrical stimulation in the granule cell layer and in the molecular layer. Three types of inhibitory responses were found: the classical bicuculline and picrotoxin sensitive response with reversal potential near the Cl⁻ equilibrium potential. This IPSP had a relatively short latency, lasted around 100 ms and strongly reduced the amplitude and duration of the following EPSP. In some cells a part of this IPSP persisted following the addition of bicuculline (50 µM) and picrotoxin (50 µM). Under these conditions glycine (focal application or 200 µM bath-applied) evoked a strychnine-sensitive (50 µM) response with a reversal potential close to the Cl⁻ equilibrium potential. The bicuculline and picrotoxin-resistant glycine response is consistent with the expression in granule cells of glycine-receptor β subunits, insensitive to picrotoxin (Lun and Bockfeider, 1991). These cells showed a slow IPSP, a slow IPSP, developed with a maximum after 500-1000 ms, and lasting some seconds. This IPSP had a reversal potential close to the K⁺ equilibrium potential and was blocked by CgP 35348 (200 µM), consistent with a GABA A response. This IPSP was particularly prominent in the presence of bicuculline and picrotoxin: under these conditions microiontophoresis of glycine displayed amplitude depression, correlating in timecourse to the GABA A IPSP. Furthermore, the mossy-fiber paired-pulse depression was strongly reduced by CgP 35348. Thus, different IPSPs exert a strong control of the granule cell excitability on a timescale from ms to sec.

The level of depolarization at the soma of a Purkinje cell is strongly dependent on the inward and outward currents distributed over the large area of its dendritic tree. Here we analyze the relative contribution of synaptic and voltage-gated currents on the spiking behavior of the soma, using a previously constructed realistic Purkinje cell model (De Schutter and Bower, 1992). We find that dendritic α currents tend to depolarize the cell in a positive feedback loop, which is out of phase with an outward current system that is necessary to produce physiological somatic spiking rates (0.1-100 Hz). In the absence of inhibition, bursting behavior results. This modeling result is supported by intracellular recordings in vivo showing somatic bursting behavior when inhibition is blocked with bicuculline. The control of spike timing in the model was investigated by varying inhibitory and excitatory input rates and synaptic strength. The regularity of spiking was found to be strongly dependent on the temporal structure of both inhibitory and excitatory input.
111.13 SHORT-TERM INTERACTION BETWEEN THE COMPLEX SPIKE AND GRANULE CELL INPUTS IN A PURKINJE CELL MODEL

E. De Schutter* and J.M. Bower

*University of Antwerp - UIA, 2650 Antwerp, Belgium, California Institute of Technology, Pasadena CA 91125, USA.

We used a detailed compartmental model of a Purkinje cell (J. Neurophysiol. 71:379-401, 1994) to explore how a climbing fiber (CF) input modifies the response to subsequent granule cell (GC) inputs. We have shown that somatic responses to small synchronous GC inputs are amplified by dendritic calcium channels (PC in pressure), the same P channels are also activated by the complex spike (CS).

A CS fired to 100 ms before the synchronous GC input had no effect on the response of somatic EPSPs. A stimulus between 160 and 140 msec after the GC input was slightly potentiated. Between 140 msec and 90 msec there was a depression of up to 17%, but 80 to 60 msec after the GC input there was a progressive and large potentiation (90% at 60 msec) of the EPSP. GC inputs arriving sooner after the CS input fell into the prolonged afterhyperpolarization after the CS. Similar effects were seen for single spike (SS) firing in response to steady asynchronous parallel fiber inputs. Between 60 and 80 ms after the CS, SS frequency increased up to 50%, between 80 and 120 ms SS frequency decreased up to 35%.

These results may explain some of the conflicting results found with in vivo recordings. We conclude that, even without synaptic plasticity and without changes in GC firing patterns, a CS might cause either a potentiation or a depression of SS firing, depending on which time frame after the CS is considered.

111.15 A NEW SILICON MICROELECTRODE ARRAY TECHNOLOGY FOR MULTICHANNEL EXTRACELLULAR RECORDING

*Computational and Neural Systems and Division of Biology, California Institute of Technology, Pasadena CA 91125, Department of Electrical Engineering, Stanford University, Stanford, CA 94305.

We have developed a new technology for the fabrication of micromachined in vivo extracellular microelectrode arrays. These devices ("probes") consist of thin films of metal deposited on a single-crystal silicon substrate which is thinner than 24 μm. Their overall shape is comblike, with each shaft of the comb supporting several individual electrode sites. In a neurophysiological experiment, a probe would be inserted into a differential animal, allowing simultaneous recordings to be made from multiple locations both normal and parallel to the brain surface. Our efforts complement work on similar devices performed in other laboratories.

We are drawing on our combined experience as neurophysiologists and engineers to optimize the utility of this technology for the end users. For example, we are concentrating on providing a large number of electrode sites on a shaft of microfabricated comb by using two metal layers, one for high-resolution interconnects and the other for electrode sites. This allows us to position the electrodes over the interconnects, placing 4 electrode sites along the cantilever of a shaft that is 24 μm wide, or 8 sites on a 40 μm shaft. Like other advanced probes, ours have indium electrode sites, which can be used for both recording and stimulating. We are also customizing the probe geometries to meet the needs of specific experimental paradigms. For the first fabrication run, we have designed 15 different probes, including some specifically for the rat cerebellar cortex, some for the rat olfactory bulb, and some for general-purpose use. Supported by a grant from Medtronic Corporation to J.B., and an NSF NYI award to G.K.

111.16 COMPLEX SPIKE SYNCHRONY OF PURKINJE CELLS IN THE VESTIBULOCEREBELLUM OF THE RABBIT

J. Simpson*, D.R. Wyile* and C.L. De Zeeuw

*Department of Physiology & Biophysics, NYU Medical Center, New York, NY, 10016.

By recording from Purkinje cell pairs in the ventral nodulus of ketamine- anesthetized rabbits, we showed that Purkinje cells in the same sagittal zone and having the same complex spike (CS) response characteristics, exhibit CS synchrony, that is the tendency to fire within 2 msec (Soc. Neurosci. Abs. 22:729). In the present study we show that CS synchrony occurs between cells in spatially separated zones but with the same class of CS responses, and between cells in the same zone but with different class of CS responses. Furthermore, we show that exhibit CS modulation in response to optokinetic stimulation (OKS) about the vertical axis are found in 4 separate areas which span most of the cerebellum, 2 in the nodulus and 2 in the flocculus (VA zones). We recorded in the nodulus from 16 Purkinje cell pairs consisting of one cell in each of the VA zones. Six of these pairs showed CS synchrony. In addition, 3 of 14 pairs consisting of a VA cell in the nodulus, and a VA cell in the flocculus showed CS synchrony. The HA zones of the nodulus and nodula contain contra-45° and ipsi-135° cells, both of which are modulated by OKS about a horizontal axis perpendicular to the ipsilateral anterior canal. They differ with respect to (1) ocular dominance, and (2) the origin of their CF input, which is the rostral dorsal cap and ventral posterior outgrowth, respectively. Of 7 contra-45°/ipsi-135° pairs, 5 showed CS synchrony. To summarize, CS synchrony is neither limited to Purkinje cells within a single sagittal zone nor to one class of Purkinje cells within the same zone.

111.17 ZONAL PROJECTION OF THE VENTRAL NODULUS IN THE RABBIT

D.R. Wyile* C.L. De Zeeuw, P.L. DiGorgi, and J. Simpson

*Dept. of Physiology & Biophysics, NYU Medical Center, New York, NY, 10016.

The projections of Purkinje cells from zones in the ventral nodular zone of the rabbit were studied with the use of extracellularly injected biocytin as an anterograde tracer. The zones were neurologically identified according to the complex spike (CS) modulation of Purkinje cells in response to optokinetic stimulation (OKS). Purkinje cells in the most medial zone (zone NR) do not respond to OKS, they project to the fastigial nucleus, peri-fastigial white matter, peri-interposed white matter (pwm), and medial vestibular nucleus (MVN). In the adjacent zone (zone VA) Purkinje cells respond best to OKS about the vertical axis, they project to the plvm and MVN. Purkinje cells in the next zone (zone HA) respond best to OKS about a horizontal axis perpendicular to the anterior canal, they project to the plvm, dorsal group y, superior vestibular nucleus (mainly peripherally but also centrally), and MVN. In the most lateral zone, (zone VA2), Purkinje cells project best to OKS about the vertical axis, they project to the plvm, dorsal group y, and MVN. Although all zones projected to the MVN, the projection from zone HA was largely to the caudal MVN, whereas the projections to the rostral MVN projected to the rostral and caudal MVN subdivisions. A few terminal fields were found in the descending vestibular nucleus, magnocellular MVN, interposed nucleus, and ventral dentate nucleus. No terminals were found in the prepositus hypoglossus or lateral cerebellar nucleus. The majority of axons innervated more than one nucleus. Often, three or four different areas received terminals from a single Purkinje cell axon. The zonal projection pattern of the ventral nodulus is compared to that of the flocculus, which, with respect to the visual climbing fiber afferents, has similar zones.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
CEREBELLUM: BEHAVIORAL NEUROPHYSIOLOGY AND CLINICAL STUDIES
FRIDAY AM

712.1

We determined the maximum activation direction (MAD) vectors of 54 neurons in the vestibulocerebellum in the alert cat. The cat rotated sinusoidally at 0.5 Hz in conditions of total darkness and/or dim light. We characterized neurons during vestibulocerebellar rotations about 3-12 axes. Of the 50 neurons recorded in dim light, 19 exhibited both simple and complex spikes and were classified as Purkinje cells (PC). As in our findings in decretebrate cats (SciNeuro 18/40), these PCs formed the internalized convergence in alert cats. A total of 40/50 neurons (17/19 PC) had MAD vectors >20° from any single canal plane. MAD vectors of the remaining 20 PC were >20° from ipsilateral horizontal canal (1 PC) >20° from ipsilateral anterior canal and 2 neurons >20° from contralateral posterior canal. This study suggests that PCs may be involved in the coding of gaze for smooth pursuit movements. Supported by EY07452, EY06452.

712.3
CONTEXT-DEPENDENT MODULATION OF CEREBELLAR NUCLEAR NEURONS RELATED TO THE PERFORMANCE OF SPECIFIC MOVEMENT SEQUENCES. M.S. Milik*, V. Bracha, J.B. Bloedel, Barrow Neurological Institute, Phoenix, Arizona 85013.

This study addresses the hypothesis that the modulation of some cerebellar nuclear neurons related to the performance of a particular component of a complex movement reflects the aspect of the overall movement being performed. Initially cats were trained to reach for a manipulandum and move it through a template consisting of a single straight segment. Trained animals were implanted with a multiple single unit, microelectrode-based, recording system targeted to the anterior and posterior regions of the fastigial and dentate nuclei and the anterior and posterior interposed nuclei. After recovery, the animal was required to learn a succession of new tasks, each consisting of 2 to 3 sequential, straight segments. The straight segment on which the animals were trained initially was a component of each new task and was always positioned in the same location in the silicentric world space coordinate. Histological estimates were drawn from the activity of simultaneously-recorded units held throughout the acquisition and performance of all the templates used over one experimental day. Analysis of specific movement or premovement-related unitary response components were relative to a movement segment common to all of the performed templates.

Of the 60 units recorded in seven experiments, 38% showed modulation changes dependent on the context in which the movement segment was performed. In some units these changes were related to movement components executed approximately 400 msec after the peak time of the unitary response. This finding suggests that these neurons participate in the specification and/or organization of movement sequences required for the performance of goal-directed limb movements. Supported by NHI grants NS30013 and NS21958.

712.5

Climbing fiber responses of Purkinje cells (PC) were recorded in the vermal, intermediate and lateral regions of a monkey trained to perform rapid flexions or extensions of the elbow in response to tone presented visual, auditory and somatosensory cues. 119 of the 314 recorded cells were time-lock activated with the movement onset in all triggering modalities. Two types of PC were defined: 1. Pre-onset CPR: CPR frequency increasing only before the movement onset (65/119 cells) with a mean latency of 39 ms (+/- 18 ms) and 2. Post-onset CPR: CPR frequency increasing at or after the onset of the movement (54/119 cells) with a mean latency of 111 ms (+/- 12 ms). In both cases, mean latency were statistically compared. In pre-onset CPR, the results showed a significant difference in the mean latency between the three areas investigated: Frontal and 2/3 - 41 ms (+/- 37 ms), Paramedian and Vermian lobes V-IV-V - 48 ms (+/- 24 ms), (P<0.0001). There was no difference in the mean latency of the post-onset CPR in any of the cerebellar regions investigated. Since the post-onset CPR are implicated in the control of the initiation of the movement because these cells are activated well before the onset of the movement. Post-onset CPR are probably more involved in feedback relative to the execution of the movement. Pre-onset CPR are activated earlier in the lateral cerebellum (Crus I and II) which project to the Destrata nucleus. Lateral cerebellum may be a part of a cortical trigger according to an hierarchical organization of the sequence of activation of the olivocerebellar fibers. Supported by MRC grant of Canada.

The aim of the present study was to determine the extent of the cerebellar interposed nucleus (IN) in the control of the classically conditioned and unconditioned reflexes elicited in three distinct effector systems. In food-motivated cats, instrumented conditioned to maintain quiescence on small platforms, three types of classically conditioned reflexes were established: 1) eyeblink reflex; 2) forelimb withdrawal reflex; and 3) hindlimb withdrawal reflex. Each animal was chronically implanted with a matrix of guiding cannulae and recording needles. The effects of temporarily inactivating IN subregions were systematically examined using microinjections of muscimol (1 μl, 80 ng). Transient inactivation of the IN affected conditioned as well as unconditioned components of the withdrawal responses in all three reflex systems. The drug injections altered both postural and phasic movement components of the limb's flexion responses. From the magnitude of the effects produced at different injection sites on the three conditioned reflexes, a topographical organization was derived. In addition, IN inactivation severely affected performance of the postural placement response in both limbs ipsi- lateral to the injection site and the tactile placating, hopping and magnus responses in the forelimb. The data support the view that various regions of the IN are differentially involved in the control of a variety of conditioned and unconditioned cutaneous-muscular and postural reflexes. Supported by NIH Grants NS30013, NS 21958, Max Kade Foundation.

712.4

Because the nucleus interpositus anterior (NIA) receives primarily cutaneous input from the rostral dorsal accessory olive while the nucleus interpositus posterior (NIP) receives primarily proprioceptive input from the medial accessory olive, we anticipated that the NIA and NIP might be useful for decoding movement. A macaque fuscataleus was trained in a pointing to target task, a reach to pull task, and retrieval of food from Kluver board, bottles or experimenters' hands. The approximate locations of the NIA and the NIP were mapped out during a number of penetrations where single units were recorded and related to the target task. Inactivations were induced by pressure or micromer inj. (2.0 ML), with the following times: Local anaesthesia for times four to five minutes, i.e. 1500 μg/ml and 2.5 minutes, i.e. 2 mg/ml). The data observed were described on the site of inactivation. The NIA inactivation greatly impaired the monkey's ability to plan and perform the movement during the pointing task or reaching the target board prior to grasping to pull the task. Once contact was established with the surface, the monkey appeared able to use cutaneous cues to improve hand function. The monkey was able to aim its arm and place the hand in the desired spatial location for use. NIP inactivation greatly affected the monkey's ability to aim its hand in the desired location in space or maintain the position during the use of hand. The monkey did exhibit proper hand shaping for the tasks at hand. The monkey appeared unable to use proximal forelimb-proprioceptive input and attempted compensation by using visual cues or tactile fixation. These observations suggest that the NIA contributes to the optimal function of the hand during tasks that require coordinated use of the fingers and hand and that the NIP contributes to the overall coordinated use of the hand by coordinating the transport of the hand to where it needs to be in space (aiming the hand) and maintaining its position once there so that the hand and fingers have a stable base to work on. NEURONAL CORRELATES OF DIRECTIONAL INFORMATION IN THE CEREBELLAR CORTEX DURING PREPARATORY AND DURING MOVEMENT. J.Gerin*, C.V. Kandler, C.R.S. N. Dep. de physiologie, Univ. de Montreal.

In order to assess the activity of cerebellar nuclear and cortical neurons during an instructed delay period two monkeys were trained according to the following paradigm. A 1000 ms or a 400 Hz tone were used as auditory instructions for right and left elbow flexions or extensions in response to tone. Tactile and auditory sensory cues were also recorded in response to tone presented visual, auditory and somatosensory cues. 119 of the 314 recorded cells were time-lock activated with the movement onset in all triggering modalities. Two types of CPR were defined: 1. Pre-onset CPR: CPR frequency increasing only before the movement onset (65/119 cells) with a mean latency of 39 ms (+/- 18 ms) and 2. Post-onset CPR: CPR frequency increasing at or after the onset of the movement (54/119 cells) with a mean latency of 111 ms (+/- 12 ms). In both cases, mean latency were statistically compared. In pre-onset CPR, the results showed a significant difference in the mean latency between the three areas investigated: Frontal and 2/3 - 41 ms (+/- 37 ms), Paramedian and Vermian lobes V-IV-VI - 48 ms (+/- 24 ms), (P<0.0001). There was no difference in the mean latency of the post-onset CPR in any of the cerebellar regions investigated. Since the post-onset CPR are implicated in the control of the initiation of the movement because these cells are activated well before the onset of the movement. Post-onset CPR are probably more involved in feedback relative to the execution of the movement. Pre-onset CPR are activated earlier in the lateral cerebellum (Crus I and II) which project to the Destrata nucleus. Lateral cerebellum may be a part of a cortical trigger according to an hierarchical organization of the sequence of activation of the olivocerebellar fibers. Supported by MRC grant of Canada.

We have used a direction-distance arm reaching paradigm to study the spatial characteristics of the responses of cerebellar Purkinje cells and quantitatively analyzed the simple spike response with univariate and multivariate regression models. The paradigm involved a multijoint movement in the horizontal plane from a centrally located start position to 48 targets located in different directions and 6 distances. Simple spikes firing in relation to direction, distance, and target location were analyzed using regression models as previously applied to the primate and primary motor cortex (Fu, et al., J. Neurophysiol., 70:2097-2118, 1993).

Based on a univariate model, the simple spike firing of the majority of cells (114/151, 75.5%) was modulated by movement direction, distance or both parameters. Of these cells, 31/114 (27.2%) showed a cosine-tuned modulation with direction and 45/114 (39.6%) cells were linearly correlated to distance, while 38/114 (33.3%) cells were modulated by both parameters. However, the majority of cells exhibited directional modulation at only one distance or distance modulation along one direction. Multivariate analysis indicated the firing of 99/128 (77.3%) cells was correlated with either direction, distance, or target location parameters (62/99, 62.7%) or some combination of these three parameters (37/99, 37.3%) The mean number of the multiple regression for the model was 0.34±0.15, considerably lower than the average of 0.61±0.18 obtained from the cerebral motor cortical area. Although significant correlation of simple spike discharge with kinematics occurs, still other parameters or models are needed to fully describe these cells' activity. Supported by NIH grant NS-18338.

SYSTEMATIC ERROR IN MULTIJOINT COORDINATION IN CEREBELLAR ATAXIA.

T. J. Dichgans, J. D. Ishii, M. D., J. N. Kornzweig, Ph.D., and P. L. D. D., D. C., M.D., J. Dichgans, MD Neurology Department, University of Tübingen, F.R.G.

In patients with ataxia, movements of daily living are performed with a characteristic pattern of slow and accurate movements. A systematic error in movements of daily living occurs with patients with ataxia, but the type of movement which is altered by ataxia is not well documented. The purpose of this study was to analyze the pattern of movement of daily living in patients with ataxia. The study was performed with a two-dimensional computerized system (E.L.I.T.E) and movement parameters were collected from the trunk and the upper extremities.

The study was performed with a two-dimensional computerized system (E.L.I.T.E) and movement parameters were collected from the trunk and the upper extremities. The results showed that patients with ataxia had a higher systematic error in the movement of the upper extremities than in the trunk. This is consistent with the clinical observation of patients with ataxia who have a higher systematic error in the movement of the upper extremities than in the trunk. The results of this study suggest that the systematic error in movement of daily living may be a result of a deficit in the control of movement.
T11.3
NADPH-DIAPHASE ACTIVITY IN DEVELOPING CEREBELLUM OF THE CHICK
C.R. Durkin*, A. Shastak* (SPONC European Neuroscience Association) Dept. of Biology, Crete Univ., Iraklion 711 06, Crete, Greece.
A novel messenger, nitric oxide (NO), has been suggested to play a role in synaptic plasticity and to participate in shaping neuronal connections. In order to investigate the role of NO in the developing cerebellum, we studied the distribution of nitric oxide synthase in this region. From embryonic day 9 (E9) until E15, the most prominent feature was the strong NADPH-D activity in the principal neurons of the cerebellar white matter, which contained a NADPH-D-positive ascending axons, that targeted selectively the developing folia and that Orli-like stained neurones moving onwards from neocortical to cerebellar cortex. In addition, the NADPH-D-positive networks were formed in the brainstem cerebellar nuclei and in the thalamus. The development of NADPH-D activity was more advanced in E17. This suggests that the NADPH-D activity appeared in the cerebellum as a result of the intrinsic development of the cerebellar axon.
T13.7

Cerebellar nuclocortical projections have been reported to be topographically ordered to both the olivocerebellar nuclei and the somatotopic arrangement of the olivocerebellar input. This study was aimed to address two related questions, i.e. whether or not the topographically homologous areas of the anterior lobe (PIAL) and paramedian lobule (PML) - in C1, C2 and C3 compartments - differ in the extent and topology of their nuclocortical input; and II) whether or not there are barbell neurons that connect by way of branched collaterals these two areas, as it was previously found for the olivocerebellar system. With this aim, one of the fluorescent retrograde tracers Fast blue (FB) and DiAmdino yellow (DY) was injected into the forelimb-related folia (FL) of the intermediate compartments of either PIAL or PML.

The analysis of single- and double-labeling in the inferior olive complex (IO) allowed to verify that the FB and DY injected areas were centered in the FL areas, and only those experiments in which the two IO labeled populations were in register, were selected for the present study. The results show that the FL-PIAL and FL-PML areas in C1, C3 and C2 cortical zones are projected upon by neurons located in the anterior (NIA) and posterior (NIF) interposed nuclei, thus roughly reciprocally the cortico-cerebellar organization. Within these nuclei, the two populations of labeled neurons overlap and show a topographic relation to the cortical somatotopy. In the areas of overlap, double-labeled neurons are found. A minor non reciprocal projection stemming from the fastigial nucleus, and a contralateral projection from the interposed nuclei was also observed.

These data are taken to indicate that the corticoepitodal fibers from the interposed nuclei to C1, C2, C3 compartments mainly operate as a closed loop feed-back system. The nuclocortical projections may be seen as a system which allows communication among different compartments.

T13.8
VISUAL INPUT TO THE CEREBELLUM OF RATS. B. Mercier, E. Jenkinson, I. Krall-Hans, C. Swales and M. Glickstein* Dept. of Anatomy, University College London, Gower Street, London WC1E 6BT.

To trace visual pathways to the cerebellum we injected wheatgerm agglutinin (WGA-HRP) into the visual cortex or the superior colliculus of rats and plotted retrograde distribution of fibers in the pontine nuclei and nucleus recessus segni pontis (NRP). In parallel experiments we injected WGA-HRP into the cerebellar lobules VII or IX of the vermis or the petrosal lobule, and plotted retrogradely filled cells in the Pons. The visual cortex projects principally to a dorsalolateral region in the rostral half of the pontine nucleus. Although collicular projection overlap somewhat with those from the visual cortex, they extend far more caudally. Unlike the visual cortex, the superior colliculus also projects to NRP. We compared the location of retrogradely labelled cells following cerebellar injection with the results of studies of orthograde projections from cortex and colliculus. The petrosal lobule receives its input from the same region of the pontine nuclei which receives fibers from the primary visual cortex. The region of pontine nuclei whose cells project to lobule IX receives inputs from both visual cortex and superior colliculus. Unlike the petrosal, lobule IX, lobule VII receives a major input from NRP. The results suggest that there are two relatively independent pathways by which visual information can reach the cerebellar cortex. One originates in the primary visual cortex and projects by way of the rostrolateral part to the petrosal lobule and lobule IX. Another originates in the superior colliculus and projects by way of NRP to lobule VII. The pattern of organization is similar to that seen in parallel experiments with monkeys.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
T14.1 CORTICOTROPIN-RELEASING FACTOR (CRF) AXONS AND BINDING SITES IN THE KEELER CEREBELLM. J. S. King*, G. A. Bishop, and P.C. Madden, Jr.* Dept. Cell Biology, Neurobiology and Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH 43210.

It is our working hypothesis that CRF functions in early development as a growth regulating factor. We previously reported in the developing osprey cerebellum that (1) CRF is present in early-born (G8 and growth cones) and (2) the initial CRF binding sites are expressed over Purkinje cells subsequent to their migration (1-3). In this study we used an antibody to CRF and 125I labeled CRF to describe the distribution of CRF labeled axons and CRF binding sites in the cerebellum of the domestic mouse, reeler. In the reeler cerebellum, most Purkinje cells fail to migrate to the typical monolayer and are misplaced in the internal granule layer or in three paired deep cellular masses. CRF immunoreactive axons terminate in the 3D arrays as climbing fibers and mossy fibers, but only in the reduced molecular and infragranular layers. In contrast, CRF binding sites are present over Purkinje cells that fail to reach the minus and in the deep cellular masses. Taken together, these findings are compatible with a role for CRF as a neuromodulator. CRF receptor binding is expressed over Purkinje cells only after they reach the cortical surface, and supports our working hypothesis. (Supported by NS-08798).
CEREBELLUM: PHARMACOLOGY

The cerebellar mossy fibre system is made up of very fine fibres from the medial vestibular and prepositus hypoglossi nuclei, and thin varicose fibres of which the origin is still uncertain. Furthermore, cholinergic agents administered muscarinic receptor antagonists reveal aversive, modification of the physiological studies, however, have yielded conflicting results about the identity of the cholinocceptive elements. To characterise cerebellar cholinocceptive elements the ultrastructural level, antibodies against cholinergic receptors protein have been used. Muscarinic receptor protein immunoreactivity has been found in astrocytes. In the granular layer some Golgi cells, mossy fibre terminals, and granule cell bodies also express this staining. Some Purkinje cell somata display cyttoplasmic labelling but most of these perikarya receive labelled axonal terminals. In the molecular layer prominent mossy receptor immunolabelling has been observed in some basket cells, Bergman glia parallel fibres. Nicotinic receptor protein is differently expressed. Some granule and Golgi cells, but no astrocytes or mossy fibre terminals, express immunoreactivity. Most Purkinje cells and their dendrites show strong staining. In the molecular layer parallel fibre varicosities, but no Bergmann glia fibres, express nicotinic receptor protein. Species differences exist in topography of both muscarinic and nicotinic stained cerebellar profiles. The results indicate that muscarinic and nicotinic receptors are synthesised by multiple and distinct cerebellar cells. Combined with the species differences this might explain the present inconsistent data on the identity of cerebellar cholinocceptive profiles.

The unipolar brush cell (UBC), a previously neglected small neuron of the cerebellar granular layer, is densely concentrated in the vestibulo-cerebellum and is characterized by its single brush-like dendritic arbor arising from a short stalk (Mugnaini and Pizzcoro, J. Comp. Neurol., 339: 174-180, 1994). The UBC is innervated by one or two prominent axonal collaterals near the soma. Morphological and immunochemical studies have shown that the UBC is uniquely associated with the glutamatergic (AMPA) network of the cerebellum. By using an antibody specific for AMPA, kainate and NMDA receptor subunits we immunocytochemically identify the receptor's association with the UBC synapse. Frozen and Vibratome sections of rat and cat cerebellum, perfused with buffered aldehydes, were incubated with polyclonal antisera to GluR1, GluR2, GluR4, GluR6/7, KA-2, NMDA-R1 and NMDA-R2A (kindly donated by R. Whittall), diluted 1:50 to 1:200, and with monoclonal antibodies (mab) recognizing GluR5/6 (Clone 4F5, Pharmingen) and NMDA-R1 (clone 54.1) both diluted 1:50 to 1:2000. The PAP or the APC method were employed using DAB as the chromogen. UBCs were strongly immunostained with the UBCs. At the electron-microscopic level, GluR2/3 and GluR5/6 immunoreaction products were found throughout the UCB cytoplasm. The mAb to GluR5/6 stained the post-synaptic densities at the mUCB contact more densely than the polyclonal GluR2/3 antisera. Thus we were able to clearly identify both AMPA and kainate glutamate receptor subunits at the m-UCB synapse. Supported by USA PHS grant NS 09094.

T14.9 SPATIOTEMPORAL STUDY OF F0S ACTIVITY IN THE INFERIOR OLIVE AND CEREBELLUM FOLLOWING NOS EFFECT OF SLOWING CPU 1. D. W. Sexton* and A. J. Beitz, Department of Vet.Pathology, University of Minnesota, St Paul, MN 55108.

The tenegeome alkaloid, harmaline, when given systemically produces repetitive synchronous activity in neurons of the inferior olive (IO) and presumably release of excitatory amino acid neurotransmitter at the olivo-Purkinje cell synapse. Following subcutaneous injections (25 mg/kg in saline) single unit activity was recorded in the IO before and during 15 min to 24 hours, rats were perfused with paraformaldehyde, sectioned and reacted for F0S protein immunohistochemistry. The results indicate that as early as 15 min and 24 hours following harmaline there are detectable levels of FOS in caudal subdivisions of IO (i.e., IOA, B, C) and that by 30 min most other subdivisions of IO (i.e., IOO, IOM, IOP, IOR) were also stained. Activity peaked by 7 hours with regard to numbers and intensity of positive FOS nuclei and had returned to control levels by 18 hours post-harmaline. At 24 hours subdivisions of IO were found to contain F0S activity for prolonged times after lateral IO subdivisions returned to control levels. The cerebellar cortex showed marked increase in F0S activity by 1 hour post-harmaline. Throughout the cerebellum and the Purkinje cell (PC) layer of the vermis and paravermis showed F0S mRNA staining. A subset of PC in the vermis and paravermis were found to display F0S activity at 1 hour and all layers in the molecular layer (ML) were numerous in the vermis but sparse in the lateral hemispheres. Labeling in the ML peaked by 2 hours and gradually returned to control levels by 12 hours post-harmaline. The deep cerebellar nuclei also showed spatial and temporal changes in F0S activity. A morphologically diverse group of neuronal nuclei were evident in the fastigial nuclei by 30 min, but changes were in no particular group of small nuclei by 18 hours. The interposed and lateral cerebellar nuclei displayed intense F0S activity by 2 hours and returned to control levels by 24 hours post-harmaline. Taken together these results suggest that there are distinct spatial and temporal changes in the cortex, IO and deep cerebellar nuclei in response to harmaline activation of the IO. Supported by Grant # NS31188 and DC01086.

The major cerebellar afferent pathways, climbing and mossy fibers, are reported to use an excitatory amino acid as their neurotransmitter (chemical lesions of the chemical lesions of the pontocerebellar mossy fiber tract were made in an effort to elucidate the receptor subtypes responsible for mediating cerebellar afferent neurotransmission. Intraplural (IP) injections of 50 to 60 mg/kg 3-acetylpyridine (3-AP) were used to chemically lesion the inferior olivary nuclei (500; 250; 125 mg), male SD rats. The right middle cerebellar peduncle (MCP) was lesioned with a horizontal sweep of a 3-AP needle inserted through the occipital skull plate. In situ hybridization histochemistry was used to monitor post-synaptic changes in the levels of mRNA for subunits of the NMDA (NR1), AMPA (GluR1) and metabotropic (mGluR1) subtypes of glutamate receptors. In addition, immunocytochemistry with specific antisera for the NMDA and AMPA receptors (GluR2/3) and GluR4 was used to detect differences between control, 3-AP-lesioned and MCP-lesioned rats. Preliminary results suggest that GluR2/3 immunostaining in subpopulations of Purkinje cells oriented along parasagittal zones becomes more intense in the 3-AP-lesioned animals. In non-lesioned controls, all Purkinje cells appear to be uniformly stained. These results suggest a selective glutamate receptor subtype upregulation after climbing fiber destruction. Supported by NS31818.

T14.12 EVOKED RESPONSE MODULATION IN INTRACLINELLARLY RECORDED CEREBELLAR PURKINJE CELLS BY SEROTONIN. L. J. Larson-Pror* and R. M. Buskey, Dept. of Neuroscience and Anatomy, Penn State College of Medicine, M.S. Hershey Medical Center, Hershey PA, 17033.

Distinct differences in the extent and distribution of serotonergic input to the cerebellar cortex have been reported for several mammalian species based upon the extent and distribution of 5-HT1A binding sites. The physiologic responses of extracellularly recorded cerebellar Purkinje cells in exogenously applied serotonin have been reported to be variable, eliciting both increased and decreased spontaneous firing rates. Recently, the 5HT1A receptor has been implicated in the reduction of Purkinje cell activity in young (150 to 250 g), male SD rats. The right middle cerebellar peduncle (MCP) was lesioned with a horizontal sweep of a 3-AP needle inserted through the occipital skull plate. In situ hybridization histochemistry was used to monitor post-synaptic changes in the levels of mRNA for subunits of the NMDA (NR1), AMPA (GluR2/3) and GluR4 was used to detect differences between control, 3-AP-lesioned and MCP-lesioned rats. Preliminary results suggest that GluR2/3 immunostaining in subpopulations of Purkinje cells oriented along parasagittal zones becomes more intense in the 3-AP-lesioned animals. In non-lesioned controls, all Purkinje cells appear to be uniformly stained. These results suggest a selective glutamate receptor subtype upregulation after climbing fiber destruction. Supported by NS30759.

715.1 IDENTIFICATION OF PASSIVE AND REFLEX COMPONENTS OF HUMAN DYNAMIC ANKLE STIFFNESS. R.E. Kearney, R.B. Stein* and L. Parengwaian.

The role of stretch reflexes in the control of movement and posture remains unclear since it is difficult to separate the relative contributions of passive and reflex mechanisms to the torques generated in response to a joint perturbation. System identification techniques, using random perturbations, have yielded good descriptions of overall joint stiffness and reflex EMG dynamics but have had little success in characterizing the reflex contribution to the stiffness. Recent evidence suggests that the reflex response is strongly nonlinear and that on-going movements inhibit reflex action in proportion to their average velocities.

This manuscript summarizes our approach to studying ankle stiffness using experimental and analytic methods designed to overcome these problems. We have used position perturbations which were designed to provide a wide-bandwidth position input with low average velocity. Possible nonlinearities in stiffness dynamics were accounted for through the use of a parallel-cascade system technique for non-linear system identification. Experiments using these new methods consistently identify two distinct components in the overall stiffness dynamics. The first component is position-dependent: acts at short-latency (< 40 ms) and displays high-pass dynamics; it seems certain to reflect the passive contribution to stiffness. The second component is velocity-dependent, acts at longer-latency (> 400 ms) and displays a dynamic non-linearity followed by low-pass dynamics; this component likely represents the reflex contribution to ankle stiffness. The reflex contribution to stiffness was most significant at low size relative to the passive contribution, and varied strongly with the parameters of the perturbation as well as joint position and level of activation. Thus, the role of stretch reflexes in motor control is likely to be very context sensitive. (Supported by the Medical Research Council of Canada)

715.3 MOTOR UNIT ACTIVITY DURING SPASTICITY. R.H. Ross and C.K. Thomas.* The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, FL 33136.

Spasticity is a common phenomenon following human spinal cord injury. Most studies to date have examined changes in reflex pathways in individuals who experience spasticity but have been concerned with the use of anti-spastic agents. Thus data are therefore provide important clues about the baseline condition from which spasticity stems. However, they provide little information about the processes which occur during spasticity per se. The study described here was undertaken to examine the patterns of motor unit activity during induced spasm. Seven individuals with chronic (> 1 year post injury) spinal cord injury between C5-C6 induced spasm by gentle touch to the face/cheek of the upper body. The electromyogram (EMG) was recorded unilaterally from the surface of each of the triceps surae muscles and intramuscularly from the medial gastrocnemius muscle. None of the triceps surae muscles were used for motor control. However, during spasm, there were usually bursts of EMG in all three muscles. Occasionally, periodicity in rhythmic clonic activity or motor unit activity were observed. During the brief and sustained spasm, motor unit patterns were evident: (1) at slow tonic rates (<1 Hz), 2) with repetitive discharges, and 3) with an increase then decrease in rate as the spasm reached its peak. The first two patterns of unit activity seem unique to involuntarily contractions whereas the third pattern is typical of motor unit behavior during voluntary contractions. During clonus, motor unit activity also rose and fell rhythmically with the repetitive rise increase in surface EMG. Peak rates for different motor units occurred in these phases. These data that the asynchronous versus synchronous activity of different motor units may explain the natural balance of the spasm (brief burst versus clonic form).

715.5 Interaction of Flexion (FR) and Crossed Extension Reflexes (CER) with Tilt-Evoked Responses (TER) in Standing Humans. P. Nagel* and C.W. Hui-Chan.* School of Phys. and Occ. Therapy, University of Western Ontario, London, Canada; N6H 5C1.

With the use of isometric, ankle and foot somatosensory inputs were found to be contributory to the early component of TER in lower limb muscles (Bussel et al., Prog. Clin. Neurophysiol., 835:325, 1989). The purpose of this study was to examine whether FR or CER inputs would modify the lower limb TER in a functionally meaningful manner. Thirteen young healthy subjects were instructed to stand on a tilting apparatus with straps and a head collar. They underwent sudden forward-body tilt of 15° with an axis of rotation co-linear with the ankle joint. The mean head acceleration was 0.7g, as measured with a linear accelerometer mounted on a dental lab and CERs were elicited with electrical stimulation (ES) of the right tibial nerve below the hairline (maximal stimulus intensity in the standing ES, 2/30, max trials). When the body was tilted forward, the measured acceleration of the ipsilateral tibialis anterior (TA) muscle was maintained at 70-80% of maximum voluntary contraction. The ES was delivered at the onset of the peak of the TA activation. During 30 ms of a 1 s ramp at 20 ms/s, the TA, soleus (SO), biceps femoris (BF) and vastus lateralis (VL) muscles were bilaterally recorded.

The FR area (n=3) did not modify the TER in the majority (n=57) of subjects whose TA FR area was significantly modified by tilt, while it was decreased in only 1 subject. The remaining 6 subjects showed no effect of tilt on the ipsilateral TA area (n=3), or less than 20% of FR occurring (n=3). Moreover, more subjects showed a response in the contralateral TA during tMS (n=4) than during ES (n=6) or tilt alone (n=11). Finally, a majority of responders had a tendency for a larger EMG area in the contralateral VL (n=9/10 responders), and contralateral SO and/or VL (n=5/6) during tMS than ES alone.

These results indicate that while head-and-body tilt tended to increase the excitability of lower limb flexor (including FR) and extensor (including CER) muscles activated by the flexion reflex system. The resultant co-contraction of ankle muscles and increased knee extension activation is consistent with the more difficult task of maintaining a stance against perturbation. This project was financed by Parkinson's Foundation of Canada and a MRC fellowship for N.P.
11.7.5 THE EFFECTS OF LOW INTENSITY CUTANEOUS STIMULATION ON THE H REFLEX MODULATION DURING STATIC AND DYNAMIC CYCLING MOVEMENTS. C. Labreque and M. Milette* Dép. de kinanthropologie, Univ. du Québec à Montréal, Montréal, Québec, Canada, H3C 3P8.

Numerous studies have shown modulations of the cutaneous reflex during rhythmic movements such as walking and cycling. Similarly, the H reflex has also been shown to be modulated by muscle activity. However, in real life situations, the nervous systems must consider these two sources of interacting feedback during the ongoing movement. The main objective of this study was to examine the effects of cutaneous stimulation on muscular inputs during stationary positions and active cycling movement. The cutaneous stimulation consisted of 10 ms male 1-1 ms pulses, at 2 times the sensory threshold, and applied to the dorsal surface of the foot. The H reflex stimulation consisted of a 1 ms pulse applied to the tibial nerve and the sciatic nerve. During the static condition, the soleus H reflex varied in amplitude depending on the phase, the largest one being at 90° and the lowest at 0°. The low intensity cutaneous stimulation had a tendency to increase the H reflex amplitude particularly at the 270° position. During the active cycling, the H reflex was also modulated, the greatest response being at 90° while the lower amplitude was observed at 0° and 180°. The H reflex continued to be modulated in a similar fashion following the cutaneous stimulation, however, the responses tended to be slightly inhibited. (Supported by FAPAC, UQAM)

11.7.6 SPASTICITY IN THE CONSCIOUS RAT: QUANTITATIVE EXAMINATION OF STRETCH AND VELOCITY SENSITIVE REFLEX COMPONENTS. M. Köhnen & J. A. F. Cole* Dept. Neuroscience, Univ. of Cambridge.

Although the rat has often been used as a model of spinal cord injury (SCI), no study has yet identified spasticity, defined as enhanced stretch activity and velocity-sensitive (VS) reflexes. We present preliminary data of a SCI model using the conditioned cat, which allowed us to study the relationship between stretch reflex activity following subcortical lesions in the upper lumbar level. Background forces were closely matched before and after SCI to obtain more direct measurements of test reflex activity. Injury-induced stretch reflex deficits were similar to those obtained previously in the conscious cat, with increases in both dynamic and static torque amplitudes at both the VS and dynamic index components. However, in contrast with the cat, hyper-reflexia was not observed in the first week post lesion, but developed to a maximum over the first month. We conclude that with appropriate reflex testing conditions rate can also be defined as spastic following selective spinal lesions, but that increased VS of long-latency stretch reflexes as a hallmark of SCI should be re-examined using other testing procedures. Supported by Grant NS27511 and NSF0.

11.7.8 IDENTIFYING THE INTERNEURONS INVOLVED IN THE REFLEX RESPONSE TO ELECTRICAL STIMULATION OF THE INTERNAL BRANCH OF THE SUPERIOR LARYNGEAL NERVE. Y. Takaoka, C.L. Ludlow and W.S. Sacktor, VSS, NIDCD, NIH, Bethesda, MD 20892.

Electrical stimulation of the internal branch of the superior laryngeal nerve (SLN) produces a bilateral adductor response in the larynx. The purpose of this study was to identify interneurons in the medulla oblongata that comprise this reflex pathway using the retrograde tracer cholera toxin B to label the nucleous ambiguus (NA) and the stimulation induced expression of the proto-oncogene, c-fos. Cholera toxin B was injected into the hypoglossal, lateral orbital, cuneate, and the spinal cord medulla oblongata (to identify the efferent neurons in the NA). After 72 hours, the cats were anesthetized with alpha chloralose and the right SLN was placed in a bipolar current electrode. Following 4 hours of stimulation, the cats was sacrificed and units were stimulated at 0.5 Hz at supra maximal levels for 20 minutes immediately before euthanasia. Serial 50 pm transverse frozen sections were made through the medulla oblongata. Odd numbered sections were processed for immunohistochemistry by means of anti-c-fos protein. Even numbered sections were incubated with anti c-fos-like antibody. As expected, cholera toxin B labeled neurons and dendrites in the NA and terminals in the NTS. C-fos like immunoreactive neurons were identified bilaterally in the NTS from the level of the most rostral portion of the dorsal motor nucleus of the vagus to the most caudal portion of the interolivary nucleus (IO), and in the NA from the rostral end of the hypoglossal nucleus to the caudal end of the IO. Bilateral c-fos like reactions were also observed in the reticular formation around the NA. Neurons expressing c-fos that lay outside the anatomically defined NA and NTS are candidates as interneurons.

Noise prepulses (PP) presented in a masking noise (N) just prior to a startle stimulus (SS) alters the facilitatory (PP) on startle (SS) acoustic startle (AS). There are many studies of the psychophysical and pharmacological characteristics of PP, but little is known about PP. Here we report that a 20 msec PP ending with the startle pulse facilitates the startle in inverse linear proportion to its signal to noise ratio (PN). Accordingly, our weakest PPF (+3 dB ratio) approximately doubled the AS to a 115 dB stimulus, whereas ratios greater than +9 dB resulted in no changes. Such responses may be due to a consistent PN ratio (a +3 dB difference) increased with increased levels from 30 to 40 dB, but then remained constant for higher intensities (tested to 73/70 dB). As PP levels increased, PP was enhanced to PPI beyond 60 - 80 ms. Both effects increased with experience. Dose-sensetive enhanced PPF (revealing that PPF is different from other forms of AS) but reduced PPI, EPP was increased by the PPI lead times as short as 35 ms indicates that these mechanisms have a peripheral nature. (Supported by FHS grants, AG09524 and MH43081)

11.7.10 SYMPAIES IN ROSTROLATERAL MIDBRAIN MEDIATE "FEAR" POTENTIATION OF ACOUSTIC STARTLE AND ELECTRICALLY evoked startle. J.S. Yeomans* and P.W. Frankland. Dept. Psychology, University of Toronto, Toronto ON, M5S 1A1.

Electrical stimulation of the caudal ventral amygdalofugal (VAF) pathway from the amygdala to the brain stem evokes startle-like responses, which are enhanced by acetylcholine. The lesion of this pathway eliminates the VAF to the brain stem response. Although the medial habenula and the ventral tegmentum have been proposed to mediate the startle response, the physiological basis of this effect has not been clearly determined. We have studied the effects of NMDA receptor agonists and antagonists on the startle response. The results indicate that the startle response is mediated by the ventral tegmentum and the habenula. The startle response was assessed in the rotarod and the wire suspension test. The results indicate that the startle response is mediated by the ventral tegmentum and the habenula.

The acoustic startle response (ASR) can be enhanced by conditioned or unconditioned fear. It has been shown that the central nucleus of the amygdala (CA) and a second pathway to the caudal pontine reticular nucleus (PnC), an essential part of the primary startle circuit, is important for the enhancement of the ASR. It was unclear, however, whether these modulations were directly mediated by the amygdalorhinal pathway or whether there exists a relay nucleus within this pathway. We tested the hypothesis that the midbrain central gray (CG) is important for the effects of fear on the ASR. Neuroanatomical tracing studies described a descending projection from the CA to that part of the CG where a descending projection to the PnC takes its origin. We lesioned this part of the CG with the neurotoxin quinolinic acid and then measured the effects of conditioned and unconditioned fear on the ASR. Lesions of the dorsal and lateral parts of the CG totally blocked the sensitization of the ASR by footshocks (unconditioned fear) and blocked the enhancement of the ASR by conditioned fear without affecting the ASR amplitude in the absence of the conditioned or unconditioned stimuli. This finding suggests a crucial role of the CG for the enhancement of the ASR by conditioned and unconditioned fear. The pathway from the CA via the CG to the PnC represents one part of a complex circuitry mediating the effects of conditioned and unconditioned fear to the ASR.

Supported by DFG (SFB 307) and GKN Tübingen.

The present findings represent part of a larger study investigating the contribution of pelvic innervation to reproductive processes in the rabbit. In adult chinchilla breed females, reflex EMGs of the Musculi constrictores vaalei and vestibuli, ischiocavernosus, bulbospongiosus, obturatorius internus, pubococcygeus, and rectus abdominis, were recorded in response to stimulation of the clitoral sheath, vagina, cervix, perineal, and perianal skin, and the flanks. Strong EMG activity was elicited by clitoral stimulation in all muscles except the rectus abdominis, and to a slightly lesser degree by stimulating the first and second thirds of the vagina using a glass rod. Both kinds of stimulation resulted in prolonged afterdischarges - up to 50 sec for the pubococcygeus and the obturatorius musculi. Stimulating the cervix produced a response only in the rectus abdominis with an afterdischarge of about 18 sec. Brushing or pressing the clitoral sheath, perineal or perianal skin resulted in EMG activity only in the pubococcygeus and, possibly, the constrictor vestibuli. Stimulating the flanks failed to elicit any response.

In summary: Clitoral or vaginal stimulation provoked strong EMG activity in almost all the muscles studied which was blocked by cervical stimulation. Withdrawal of cervical stimulation resulted in the reappearance of EMG activity which, however, was somewhat attenuated if clitoral stimulation was avoided.

SPINAL CORD AND BRAINSTEM: PATTERN GENERATION

BILATERAL MOTOR RHYTHMS DURING FICTIVE ROSTRAL SCRATCHING IN THE TURTLE. Paul S.C. Strick*, John C. Yescia, Eddie C. Field, and Scott R. Carney, 1Dept. Biology and Movement Science Program, Washington University, St. Louis MO 63130. 2Dept. Neuroscience, Univ. of California, Riverside, CA 92521.

Fictive rostral scratching is produced in a prone, immobilized turtle by gentle mechanical stimulation of the ipsilateral (ipsi) midbody sheath bridge (J. Neurophysiol. 53: 1517, 1985). Most previous work has focused on ipsi motor output. This output includes bursts of hip flexor (VP-HP) motor activity that rhythmically alternate with bursts of hip extensor (HR-KF) motor activity. Knee extensor (PT-KE) motor activity occurs during the latter portion of each burst of hip flexor activity. Martinez-Gomez and Strick (J. Exp. Biol. 164: 14 to 26, 1991) demonstrated rhythmic bursts of contralateral (contra) hip flexor activity which alternate with bursts of ipsi hip flexor activity during fictive rostral scratching. We add to these previous findings. Stimulation of the ipsi sheath bridge also produces a fictive motor pattern of contra hip extensor bursts that alternate with contra hip flexor bursts. Contra hip extensor bursts also occur during the early portion of each burst of hip flexor activity. Contra hip flexor activity begins during the later part of the ipsi hip flexor activity and continues during peri hip extensor activity. Simultaneous-bilateral stimulation of mirror-image locations, one in the left rostral scratch receptor field and the other in the right rostral scratch receptive field, can alter the right-left extent of rostral scratching motor patterns. The onset of bilateral scratching is a function of the degree to which the neurons in the pattern generator are activated. In summary, there is in-phase activation of left and right hip flexor nerves. After the first cycle of response and for the remainder of the response, the activity of each left motor pool alternates with the activity of its mirror image motor pool on the right.

The patterns of activity seen during bilaterally activated fictive rostral scratching are similar to the patterns observed during bilateral activity in rostral scratching in spinal turtles as well as during actual forward scratching in intact turtles (Field and Strick, this volume). These behavioral and spinal patterns may be mediated by an excellent spinal model system to examine spinal mechanisms for the coordination of left and right rhythmic motor behavior. Supported by NIH Grant NS30768 to PSGS.
716.3 DEPRESSION OF MONOSYNAPTIC GROUP II AND OTHER FIELD POTENTIALS DURING MLR-EVOKED FICTIVE LOCOMOTION SUGGESTS A REDUCTION OF TRANSMISSION IN SENSORY AFFERENT IN THE WALKING CAGE. S. J. Shefshak and D. McCreery. Dept. Physiol., Univ. of Manitoba, Winnipeg, Canada, R3E 0W3, and CIEA-IPN, Mexico.

The possibility that transmission from sensory afferents might be affected during MLR-evoked fictive locomotion was examined in decerebrate cats. Monosynaptic field potentials were evoked by stimulation of extensor (Q, G5), flexor (Sart, PBST) and cutaneous nerves and recorded in lumbar and sacral spinal segments. During MLR-evoked fictive locomotion monosynaptic components of group II field potentials were reduced up to 70%. In those trials where locomotion appeared several seconds after the onset of MLR stimulation, group II field potentials were maximally depressed only when the locomotor program was fully developed. Group I and cutaneous field potentials were also depressed but to a lesser degree. All monosynaptic field potentials were tonically depressed with the onset of fictive locomotion and for several seconds after its cessation. A smaller phasic depression during extension was often superimposed on the tonic depression. We suggest that both descending pathways and spinal locomotor networks contribute to the depression of transmission from group II, group I and cutaneous afferents during MLR-evoked fictive locomotion. Although the mechanisms have not yet been determined, presynaptic inhibition of the terminals of segmental afferents is likely. Supported by the MRC and the Rick Hansen Legacy Fund.

After step training, the hindlimbs of the spinal cat transected at T12-T13 can regain the ability for weight bearing locomotion on a treadmill. When an obstacle is placed in front of the foot during the swing phase of a step, the limb can be lifted above the obstacle after contact but before lift-off. The swing phase of a step can, however, be decreased by a light object placed in front of the foot. This object was introduced during the swing phase to perturb the hindlimb step cycle. The swing phase of the first step following contact of the hindlimb foot to the object was shortened to pre-contact steps. With repetitive obstruction, the step height increased in succeeding steps thus minimizing contact with the obstacle. In some instances, contact with the object led to complete avoidance in the locomotor-related cat spinal neurons. They show that a subpopulation of c-fos-immunoreactive cells are first-order interneurons and some may utilize acetylcholine, serotonin and GABA as neurotransmitters. Supported by MRC Canada, Human Frontier Science Program and the Health Sciences Centre Foundation.

The N-type calcium channel regulates the release of certain neurotransmitters, particularly acetylcholine, and is sensitively blocked by the Ca-channel blocker GVIA. We used this tool to investigate the fundamental role of the medullary Pre-Botzinger complex in the generation of respiratory rhythmic activity in adult mammals. Lesion experiments have demonstrated that the Pre-Botzinger Complex is critical for rhythm generation in neonatal rats. In adult animals it has been demonstrated that all types of respiratory neurons are present within this medullary area but their importance for rhythm generation remains uncertain. In this study we pressure injected u-conotoxin GVIA (a blocker of the Pre-Botzinger Complex) into the medulla of adult cats. Male and female cats were anaesthetized (Pentobarbitol 40mg/kg i.p.), paralyzed, vagotomized and artificially ventilated. Respiratory activity was monitored from four- or six-channel physiological nerves with or without intracellular recording of respiratory neurons. When injected into the Pre-Botzinger Complex, u-conotoxin GVIA had profound effects on respiratory activity. In this limited area blockade of the N-type calcium channel decreased the amplitude and the slope of phrenic nerve activity and increased significantly the cycle length. Prolonged injection induced central apnea. Although u-conotoxin GVIA was injected into the Pre-Botzinger Complex of one side, the induced respiratory effects were bilateral. All effects lead to a decrease of sympathetically induced drive potentials to late-inspiratory, post-inspiratory and expiratory neurons. We conclude that u-conotoxin GVIA blocks tonic excitatory drive to a specific area in the respiratory network of the Pre-Botzinger Complex. The data also demonstrate that in adult cats the Pre-Botzinger Complex is essential for respiratory rhythm generation.

716.6 ANTIDROMIC ACTIVITY OF DORSAL ROOT FILAMENTS DURING TREADMILL LOCOMOTION IN THALAMIC CATS. I. Belousov* and S. Romano*, CESTRO Neuro. Sci., Université de Montréal, Montréal, Québec, Canada H3C 1T7.

Previous work has shown that the proximal stump of cut dorsal roots (DR) are cyclically depolarized twice per cycle during fictive locomotion in spinal cats, with a greatest maximum during the activity of flexors and a second maximum during activity in the extensors. Single DR units discharging antidromically (AD) and rhythmically are often recorded in those cut roots. Rhythmic depolarisations can also be readily evoked by activation of peripheral afferents such as stimulation of the foot pads, we investigated whether the natural peripheral inputs during real locomotion could also play a role in the AD firing of DR units. Nine cats were decerebrated under Halothane anaesthesia. Locomotion was either spontaneous or triggered by MLR stimulation. Units were recorded from the proximal ends of the cut roots with Ag/AgCl electrodes in an oil pool. Representative EMGs of ipsilateral limb were recorded and the movements videotaped. The Table shows the distribution and characteristics of 73 labelled units out of a total of 92 recorded units. Their peak discharge may occur during swing or stance, they may fire in sync with their firing in stance or swing or be entirely confined within one phase (ON and OFF).

716.7 FDL AND SOLEUS MOTONEURONE ACTIVITY DURING SCRATCHING. S.H. Duque* and L. Castillo, CUCS, Universidad de Guadalajara and C.B., Universidad de Aguascalientes, Mexico.

This study analyzed weather the normal patterns of scratching activity of FDL and Soleus motoneurons that are known to be activated during scratching (FS). In normal cats, six hindlimb muscles were chronically implanted with patch electrodes for EMG recordings. In thalamic and later on, spinal cats, several hindlimb nerves were used for ENG recordings. The changes in resting potential (RP) in four FDL and five Sole motoneurones were also analyzed. In normal scratching cats, FDL-EMG exhibited tonic or phasic or intermingled activity, in contrast, Sole-EMG remain silent almost the entire episode of scratching. Occasionally occurred phasic Sole-EMG activity. In thalamic cats, FDL-ENG exhibited tonic, or phasic or intermingled activity. In 93% of the episodes of scratching occurred a sustained decrease in RP of FDL motoneurones. In 64% of the episodes, the sustained RP decrease was followed by phasic changes. At the onsets of the phasic bursts of activity occurred high frequency firing (doublets). Sole-ENG exhibited absence of motoneuron activity. Four out of five Sole motoneurones were hypoperalized during the episodes of fictive scratching. In spinal cats, FDL motoneurones only exhibit phasic activity but, without doublet. Sole motoneurones were phasically activated. Scratch generator produces phasic activity in FDL and Sole motoneurones, and supraspinal nuclei elicited sustained facilitation and inhibition in FDL and Sole motoneurones respectively.

716.8 IMMUNOHISTOCHEMICAL CHARACTERIZATION OF CAT SPINAL NEURONS ACTIVATED DURING FICTIVE LOCOMOTION. P.A. Carter*, B. Naga, A. Higgin, J. Don, D.M. Napier and I. M. Ross, Dept. of Physiology and Pathology, University of Manitoba, Winnipeg, MB, Canada R3E 0W3.

Anti-c-fos immunohistochemistry or intracellular injection of a 3000 MW tetramethylammonium-chloride depolarizing solution (TM-D) was used to label spinal neurons activated during fictive locomotion in paralysed, decerebrate cats. The immunohistochemical characteristics of c-fos-immunoreactive or TM-D labelled cells were compared using a variety of cytochemical markers. Locomotion-related spinal neurons were identified as TM-D containing the intracellulary-labelled cells subsequently processed using anti-choline acetyltransferase (AChT) and aspartate (AD). Populations of TM-D labelled lamina VII neurons were seen to contain either AChT- or aspartate-immunoreactivity. Simultaneous double labelling for c-fos and AChT, aspartate, calcium gene-related peptide (CGRP) or NADPH-diaphorase was carried out on non-TM-D labelled spinal cord tissue obtained from animals that displayed at least six hours of robust, MLR stimulus-evoked fictive locomotion. The majority of c-fos-immunoreactive cells were located in laminae VII and VIII of the lumbar spinal cord. Subpopulations of c-fos-immunoreactive neurons were seen to contain either NADPH-diaphorase reaction product, ChAT-immunoreactivity (ChAT), aspartate or to have close contacts with CGRP-immunoreactive fibres. These putative afferent inputs were found to be immunoreactive for certain transmitter systems such as glutamate, GABA and thyrotrophin releasing hormone. Supported by MRC Canada, Human Frontier Science Program and the Health Sciences Centre Foundation.

Using the lampry spinal cord in vitro preparation, we investigated the persynaptic plasticity control of neurons in lampry dorsal cells during fictive locomotion. The membrane potential of dorsal cells showed phasic depolarizations that occurred in phase with the ipsilateral ventral root burst. Negative current injections increased the amplitude of the depolarizations indicating that the depolarization is chemically mediated. In cells where no depolarization could be recorded, simultaneous intracellular recordings from their axons showed large depolarizations suggesting that the input synapses underlying the depolarizations are located on the axons. These depolarizations were insensitive to specific GABA_A (bicuculline) or GABA_B (phaclofen and saclofen) antagonists. On the other hand, GABA receptors are present on dorsal cells. GABA, muscimol and baclofen induced depolarizations in the dorsal cells which persisted after blockade of synaptically modulated transmission with tetrodotoxin. Specific GABA antagonists had no effect on the amplitude of the induced depolarizations, suggesting that the GABAergic effects on dorsal cells are not mediated by conventional GABA_A and GABA_B receptors. Small bipolar neurons containing GABA-ir and NPY-ir have close apposition on dorsal cells. Our evidence show that the synaptic transmission from sensory cells to the neuronal network generating locomotion, as previously shown for network interneurons (Alford and Grillner, J. Neurosci. 1991).

To clarify the mechanism for the generation of high-frequency oscillatory discharges (HFO) correlated among the inspiratory neurons, we have applied the in vitro preparation of perfused isolated brainstem developed by Morin-Sunur et al. (1992) to the newborn cats. One to 15 days-old cats were decapitated under pentobarbital anesthesia and the vascular system was perfused caudo-rostrally from the basilar artery with Krebs solution at 28°C. The afterdarts of discharges of facial (VII), vagus (X) glossopharyngeal (IX) and hypoglossal (XII) nerves were recorded simultaneously. By the spectral analyses, the following results were obtained: i) in the power spectra of the inspiratory nerve discharges, a clear peak with a modal frequency of 30.1±1.7 Hz (mean±SD, n=19) was consistently observed. ii) In the coherence spectra of any pair of these nerves recorded, a peak with high values of coherence (0.9±0.09, n=9) was consistently observed, demonstrating the synchronization of this oscillatory discharge between nerves. iii) A rise in the temperature of Krebs solution of the superfusion chamber significantly augmented the modal frequency of the oscillation. iv) Perfusion with a high K+ Krebs solution accelerated the respiratory rhythm but did not give any significant influence on the oscillation frequency. v) This synchronized oscillatory activity was observed unchanged in X, IX and XII even after ponto-medullary transection. Based on these observations, we conclude that the synchronization of oscillatory activity in the isolated brainstem of the newborn cats is identical to the HFO in mature animals and that the HFO could be generated in the medulla without any connection between other neural structures at least as early as ~12 hours after birth.

716.12 FAST OSCILLATORY ACTIVITY IN MESENCEPHALIC TRIGEMINAL NEURONS. C. Pedrosa*, I. Pope, J. Yamuy, P.K. Morales*, and M.H. Chase. Dep. de Fisiologia, Facultad de Medicina, Montevideo, Uruguay, and Dep. of Physiology and The Brain Research Institute, UCL School of Medicine, Los Angeles, CA 90024.

In contrast to all other muscle afferents, primary afferent fibers that innervate the jaw musculature have their cell bodies located in the central nervous system, in the mesencephalic trigeminal nucleus (MES-V). During experiments designed to study neurons within the reticular formation we found a remarkable oscillatory activity of the membrane potential of MES-V neurons, which is the object of the present report.

Intracellular recordings from MES-V neurons were obtained in the standard tissue slice preparation from rat brainstem; the patches were labeled by intracellular biocytin injection. The membrane potential of MES-V cells exhibited epochs of sinusoidal-like oscillatory activity within the range of 20-25 Hz; its amplitude was between 1 and 5 mV. Large oscillatory waves often triggered bursts of action potentials. The oscillatory activity was not observed at resting membrane potentials levels more negative than ~65mV, but it could be evoked by the injection of depolarizing currents. Tetrodotoxin abolished the oscillatory activity.

This is the first report of an oscillatory activity in the cell bodies of primary afferents. Consequently, we can only speculate on their functional significance. It is possible that this high frequency activity plays a role in the transmission of information from the jaw musculature to central neural structures. Because this activity originates in cell bodies, it is also possible that it may be synthaptically modulated during different behaviors. Supported by U.S.P.H.S. Grant NS 09999.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

717.1 INTRACELLULAR PATCH ELECTRODE RECORDINGS FROM NEURONS IN THE ISOLATED SPINAL CORD FROM NEONATAL RATS.

M. Rasput* and O. Kuch, Sect. of Neuropsychology, Dept. of Medical Physiology, Copenhagen 2200, Denmark

The use of patch electrodes for intracellular recordings has several advantages compared to the use of traditional microelectrodes, particularly a better signal to noise ratio and the possibility for recording from small cells. We wanted to utilize these advantages in an intact spinal cord preparation, which has the benefit of intact large neurons and functional neuronal networks.

Neonatal rats (0.5-8 days old) were decapitated and the spinal cords dissected out with the preparation in ice-cold extracellular medium containing 0 mM Ca++. For the experiments, the cord was submerged in extracellular medium at room temperature, containing 2 mM Ca++. Pia mater could not be penetrated by the patch electrodes. Therefore, either a shallow cut was made from the ventral side immediately medial to the spinal cord, or a bennettized preparation was used. The patch pipette, with positive pressure, could then be lowered 100 to 500 mm into the spinal cord, and Deck seal formed by slight suction. This approach gave a high (>50%) success rate for stable (20 to 50 minutes) whole cell recordings, often with access resistance around 5 to 10 MO.

Recordings from a variety of cell types, visualized by biocytin, were made in the intermediate and ventral areas of the cord. Typical resting membrane potentials were -45 to -55 mV, and input resistances ranged from 20 to 90 nM amplitude. Cells could be recorded from during fictive locomotor activity, and the good signal to noise ratio made spontaneous and stimulated potentials from individual synapses clearly detectable.

Single channel activity was studied in inspiratory neurons identified by their pattern of firing related to phrenic motor output and used in the ventrolateral region (VLR) of the isolated in vitro brainstem-spinal cord preparation of a newborn rat. In outside-out recording under physiological condition, three channel types were identified by reversal potential, single-channel conductance, voltage sensitivity, pattern activity and tetrodoylammonium sensitivity. Two non inactivating potassium channels of 38 and 70 pS were found. Both channels showed voltage dependency, becoming more active at moderate depolarized potentials. The 70 pS channel showed tetrodoylammonium sensitivity at 0.1-0.4 mM. Also, a chloride channel of 25 pS was seen. These channel types may be involved in the control of the resting membrane potential and bursting activity of the inspiratory neurons and contribute to their functions in the mammalian brainstem.
T117.3

Discrete spinal rats respond to systemic injections of LOOPA or QUIPAZINE with coordinated locomotor activity on the ground, in water, or suspended in air (air stepping). However, LOOPA fails to elicit stepping in the hindlimbs of rats with mid-thoracic transections of the spinal cord, suggesting that the critical locus of action of LOOPA is in the brainstem. Alternatively, it is possible that LOOPA acts on spinal circuits, but that locomotor activation requires input from an additional spinal or spinal-motor system in the brainstem. In the present study we examined the possibility that LOOPA can elicit air stepping in the hindlimbs of spinal-transsected neonatal rats in the presence of the nociceptor agonist, capsaicin, intact neonatal rats and those that had received complete mid-thoracic (TS) transections of the spinal cord were injected subcutaneously with 0.1% LOOPA (100 mg/kg), QUIPAZINE (1.6 mg/kg), L-DOPA and quinpirole in combination, or the vehicle solution. Results showed that neither LOOPA nor QUIPAZINE alone elicited locomotor activity in the hindlimbs of rats with spinal cord transections. However, the combination of the two drugs elicited well-coordinated stepping in both the forelimbs and the hindlimbs, although the forelimbs and hindlimbs stepped independently of each other. In comparison to stepping of intact rats given LOOPA alone, the locomotor activity of the spinal rats receiving the drug combination stepped faster, and the hindlimbs slowed. The rates and topography of stepping were more variable in intact rats given the LOOPA/QUIPAZINE combination than in intact rats receiving LOOPA alone or in the hindlimbs of spinal-transsected rats. These results show that QUIPAZINE and L-DOPA must both act on spinal targets to produce locomotion. Supported by PhS grant NS28985 to DJS and OHV.

T117.5
LOCALIZATION OF THE CENTRAL PATTERN GENERATOR FOR HINDLIMB LOCOMOTION IN THE NEONATAL RAT IN VITRO. A LESION STUDY. O. Kjaerulf and O. Kiern (SPON: European Neuroscience, Neurophysiology, Dept. of Medical Physiology, Univ. of Copenhagen, Copenhagen 2200, Denmark).

Our previous studies with sufentanil have shown that laminae VII and X in the lower thoracic and lumbar regions of the spinal cord may be of possible importance for the generation of locomotion in the neonatal rat (Kjaerulf, Baranov and Kien, J. Physiol., in press, 1994). To test this conclusion we have monitored the rhythm-generating ability in surgically isolated segments of thoracolumbar segments of the spinal cord (Th1-Th9, Th12-L1). Rhythmic activity (RA) recorded from the ventral roots was induced with a combination of 5-HT and NDMA in spinal cords prepared from rats 2-2 days post-natal. Preparations consisting of segments Th12-L1 or L1-L3, while in preparations consisting of L4-L6 or L5-L6 either no RA or only slow, low-amplitude RA was found. This preparation from Th12 to L6 was sectioned in various planes. A midsagittal section did not prevent RA. Similarly, RA - alternating between the two sides - persisted after removal of the dorsal half of the spinal cord with a horizontal section. In contrast, preparations left from a paramedian section and comprising the lateral motorneuron pool, the lateral intermediate area and the dorsal horn showed no RA.

We infer that the neuronal networks important for spinal hindlimb locomotor activity predominate medially and ventrally in the thoracolumbar transition zone.

T117.7

Application of the glycine receptor antagonist strychnine to the bilaterally intact in vitro rat spinal cord transforms locomotor-like and alternating patterns of hindlimb motor activity into synchronous rhythms (Harder & Schmidt, Soc. for Neurosci. abstr. 1992). We have now applied whole-cell recording methods to examine excitatory inputs in homogenous motorneurons and interneurons during strychnine-induced synchronization. NDMA, serotonin and acetylcholine were used alone or in combination to induce baseline rhythmic activity. Following strychnine (1 μM), the rhythmic excitatory synaptic currents, in-phase and out-of-phase synchronous rhythmic ventral root activity, were recorded in all neurons examined. Rhythmic EPSCs (I_inh - 0 mV) as large as 200 pA resulted in synaptic drive potentials measured 50 mV in some neurons. The maximal EPSC amplitude in this cell occurred at +40 mV suggesting involvement of NDMA receptor activation. In one interneuron rhythmic synaptic activity was not observed, despite the injection of phasic ventral root activity by serotonin (10 μM) and NDMA (2.5 μM); however, the cell developed rhythmic 10 mV depolarizing potentials after addition of strychnine. Thus blockade of glycine receptors may result in the plastic recruitment of neurons not previously associated with the production of motor rhythm. Finally, although rhythmic inhibitory synaptic currents (I_inh - 50 mV) re-appeared in interneurons following removal of strychnine from the bath, ventral root activity remained synchronized. (Supported by HSCF and MRC)

T117.8
NMDA RECEPTOR-MEDIATED VOLTAGE OSCILLATIONS IN MAMMALIAN MOTOUNEURONS. S. Hochman*, L.M. Jorde, and B.J. Schmidt. Dept. of Medicine and Physiology, University of Manitoba, Winnipeg, Canada, R3H 0W3.

Whole-cell current clamp recordings were obtained from motorneurons in the bilaterally intact in vitro neonatal rat spinal cord in order to examine the effects of NDMA receptor activation. In one motorneuron, both application of serotonin (30 μM) and NDMA (10 μM) produced a progressive membrane depolarization accompanied by repetitive firing (6 Hz). Re-adjustment of the membrane potential to -60 mV, via intracellular current injection, resulted in the emergence of prolonged post-spike after-depolarizations (ADPs) peaking at 30 mV as well as an associated slowing of firing frequency (2 Hz). Following hyperpolarization of the membrane to -85 mV, Na+ spikes and ADPs were no longer present but rhythmic 10-15 mV slow-riasing membrane potential oscillations (4-5 Hz) persisted. These events were blocked by TTX (1 μM), 10-25 mV oscillations and occasional superimposed faster-rising high amplitude (30 mV) potentials remained. In another motorneuron, NMDA-induced membrane depolarizations induced a train of rhythmic post-removal oscillations that gradually decreased in amplitude (10-15 Hz). The oscillations were terminated by 200 nM TTX, after which the cell remained depolarized at -25 mV. Hyperpolarization of the membrane to -60 mV had no effect on frequency but the oscillations were blocked by 500 nM ZD 7288. The quality of oscillations remained the same whether or not the cell was subtested by TTX. Depolarization of the membrane to -60 mV and injection of a current ramp waveform revealed step changes in the membrane potential at membrane potential above 100 mV. However, the frequency of oscillations was insensitive to the concentration of NDMA in the bath. These observations suggest that mammalian hindlimb motoneurons are capable of endogenous oscillatory behavior in the absence of NMDA receptor activation. (Supported by HSCF and MRC/Canada)

THALAMIC VPL IN RATS PROMOTES BEHAVIORAL RECOVERY AFTER SOMATOSENSORY LESIONS. J. Wells, S. M. Harry*, and J. M. Held*. Department of Anatomy and Neurobiology and Department of Physical Therapy*, University of Vermont, Burlington, VT 05405.

The transfer of information through VPL was found to be critical for the successful completion of a motor task and for the normal trajectory of the hindlimb. Bilateral VPL lesions resulted in a significant increase in the time to traverse a narrow bar for a reward and a significant modification of the swing phase of the gait cycle. The rats gradually decreased the MP-Phr coherence peaks had a frequency range of 39.1 - 66.4 Hz (mean 55.6 ± 8.3 SD Hz), with a mean coherence value of 0.55 ± 0.18 (range 0.38 - 0.80). The MP-Phr cross-correlogram patterns remained stable after the lesion, but the peak coherence peak decreased.

Muscle spindle afferents from the jaw closing muscles have their cell bodies in the nocosephalic trigeminal nucleus (VNoVn). Acoa connectives are sent to the trigeminal motor nucleus (VNvr), its border areas, and to the medial part of the oral nucleus of the spinal trigeminal tract (NVs). We report here on the firing properties of slowly adapting maseter spindle afferents recorded near the NVs during fictive mastication in urethane-anesthetized rabbits. Afferents were identified by their response to stretching of the jaw and to probing the muscle, and by short latency (<1ms) action potentials evoked by single pulse or repetitive (>30Hz) electrical stimulation of the motor nerve. Receptive field organization of the sensory motor cortex was used to evoke fictive movements that were monitored by recording the reticular activity in VNvr. The results show that the tonic firing of these afferents to a constant stretch is phasically inhibited during the opening phase, while an increase in frequency occurred during the closing phase of the cycle. Blocking of afferent inputs will allow the��ulation of the central orofacial function.

In 32 decerebrate, unanesthetized and paralyzed cats, we studied the characteristics of high frequency oscillations (HFOs) in MPs of medulla and E cells. Simultaneous recordings were taken from bilateral phrenic (Phr) and recurrent laryngeal (RL) nerves and from cells (0 - 1.5 mm caudal to obex, 3.2 - 4.2 mm lateral). HFOs during M recorded in 24 E and 15 I cells. In 14 of these were identified as RL cells (7 I, 7 E) by a sharp peak in the spike-RL nerve discharge correlation. The HFO in MP during I, superimposed on the discharge pattern of I cells, and hyperpolarization in I cells, developed gradually after onset, reached maximum amplitude around midline, and then gradually decreased. 39.1 - 66.4 Hz (mean 55.6 ± 8.3 SD Hz), with a mean coherence value of 0.55 ± 0.18 (range 0.38 - 0.80). The MP-Phr cross-correlogram patterns remained stable after the lesion, but the peak coherence peak decreased.

The thalamic VPL in rats promotes behavioral recovery after somatosensory lesions.
MUSCLE: ELECTROPHYSIOLOGY

V719.1

Previous studies (Haar Romeny et al., 1984; Segal 1982) have suggested three functionally discrete longitudinally oriented partitions within the biceps brachii long head (BBH). A recent pilot study from our lab (see English et al., 1990) suggested that the organization of BBH may be different than proposed by ter Haar Romeny et al. (1984).

In an attempt to clarify the organization of BBH, fine wire electrodes were inserted into 3 strips of BBH running from lateral to central in 6 subjects as determined from dissections. The activation order of motor units was determined for 3 tasks: elbow flexion, forearm extension, and shoulder flexion. In addition, recordings were made during elbow extension, forearm pronation, and shoulder extension, flexion and abduction. Spike-triggered averages (STA) were determined to determine the level of correlated activity. During both elbow flexion and forearm supination motor unit potentials were usually recruited first but were made second. Motor units from the central recording site were recruited more easily than the lateral site, especially when elbow flexion and supination were combined. However, motor units from the lateral recording site were most easily recruited during shoulder movements. Activity of motor units from the lateral site were not correlated with the motor units from the other sites, but motor units from the medial and central recording sites showed some correlated activity. This study supports partitioning of BBH, but possibly not as previously proposed. Future studies should study the activity of BBH during shoulder movements in more detail.

1 Dept. Biomechanical Engineering, Cleveland Clinic Foundation, Cleveland, OH 44149, and 1 Dept. Radiology, University of Arizona, Tucson, AZ 85724.

Spin--spin relaxation time (T2) measured from the magnetic resonance image of skeletal muscle layers linearly with activity of the muscle. T2 was used to investigate functional compartmentalization of the first dorsal interosseus (FDI) muscle of four healthy human subjects. Spin--echo images of two cross sections from the proximal half of the muscle were analyzed to determine regional differences in activity. Measurements immediately following flexion and abduction exercises of the left index finger. The exercise was against a force load that was 20% of the maximum work capacity. Each cross section of the muscle was divided into eight regions about the major axes of the muscle. In each cross section, the signal-to-noise ratio at four echo times (55, 50, 7.5, 100 ms) was measured and T2 relaxation time was calculated. Only areas showing homogeneous signals (i.e., no apparent high connective tissue or fat content) were measured. Percent change of T2 with muscle initial resting measures was used to quantify relative activation. The two major findings were: (1) during abduction, the dorsosmedial portion was more active (10.8% increase) than the ventrolateral portion (3.76%); and (2) during flexion, the middorsal and ventrolateral portions were more active (11.0% and 12.6% increases respectively) than the other portions (9.4%). These findings suggest that the relative activation of the FDI muscle is nonhomogeneous and varies with the task performed.

V719.3
MOtor UNIT FIRING DURING SHORTENING AND LENGTHENING CONTRACTIONS. J.N. Howell 1, A.J. Fuglevand 1, M.L. Walsh 1, and B. Bigland-Ritchie 1.

J.B. Pierce Laboratory, 290 Congress, New Haven, CT 06519.

In order to examine motor unit firing patterns during movement, fine wire (25 µm) electrodes were inserted into the first dorsal interosseous (FDI). Unit activity was recorded as the FDI shortened and lengthened under constant loads and was compared to activity during isometric ramps. Single units, identified by wave shape analysis, could be followed reproducibly over many cycles of movement and in repeated isometric contractions. In most cases the first units to be recruited during shortening (concentric) were the last to be derecruited during lengthening (eccentric). An exception is shown, in which unit A turned off as B was recruited. B had a higher torque threshold during isometric activation than A. Unit activity was simultaneously decreased by a second motor unit (not shown), making it unlikely that the appearance of B in the trace shown represented an artifact of electrode movement rather than unit recruitment.

V719.5
ELECTROPHYSIOLOGICAL PROPERTIES OF DISSOCIATED PARAPODAL MUSCLE FIBERS FROM APLYSIA BRASILIANA. Paul J. Laurienti 1 and James E. Blankenship 1.

The pleurolophus, A. brasiliensis swims by rhythmic flapping of its bilaterally symmetric wing-like parapoda. Parapod motor neurons (MN's) and serotonergic motor neurons (PON cells) which innervate peripheral parapodal muscle are located in each pedal ganglion. PON cells and ergogeous serotonin (5-HT) have been shown to modulate the activity of the MN's and PON cells in vitro. The functional role of 5-HT on the parapodal MN's and PON cells has been explored. The presence of 5-HT in the parapodal MN's and PON cells has been confirmed. Current clamp experiments were performed with 3 types of parapodal MN's: one type is a tonic Mn that is activated by a constant current. The other two types of MN's are activated by a constant voltage command. The resting membrane potential (RMP) of the axons of the fibers is approximately -70 mV, which is close to 34 mV of the RMP of the MN's in the intact parapod.

V719.6
THIOKOTRIC BEHAVIOR OF THE PLANTARFLEXOR MUSCLES IN NORMAL INDIVIDUALS. Lamontagne A, Mahon T, Richards C 1, Teeney D. Physiotherapy Dept., Faculty of Medicine, Laval University and Neurology Research Center, Hopital de l'Enfant Jesus, Quebec City, Canada.

The primary aim of this study was to develop a method of assessing the thioxotrophy behavior of normal muscle utilizing a simple test that is dependent on the previous history of muscle contraction or length (thixotropy) thought to reflect intrinsic muscle fibers properties. We thus compared the effect of brief (5 sec) shortening and lengthening periods of the plantarflexors on the response of the plantarflexors during passive dorsiflexion (DF) of the ankle. Seven healthy persons (3 male, 4 female ages 25-30 yrs) were used. Force vs time (Fmax) curves between -23 to -8° of DF were measured at 20%/s with an isokinetic dynamometer (Kin-Com). Passive DF were made before (pre-test) and after (post-test) a 30 sec pulse in a lengthening of 80° position (condition 2) and a shortening of 80° (condition 1) for 10 trials at 20%/s. The last five trials of each test were averaged and the differences in the area (DA) under the torque-angle curves (-18° to 10°) between the pre-test and post-test were computed for each condition. In condition 2, the total area was decreased in all 7 subjects (DA = 1.94 Nm deg. -1 ± 1.11) while in condition 2, we observed a slight decrease for 6 subjects (DA = 4.82 ± 1.11), indicating that a decrease in torque responses are sensitive to the recent history of muscle lengthening. The Wilcoxon signed rank test computed between the DA for condition 1 and 2 indicated that the lengthened position induced a larger effect (p<0.01) on torque than the shortened position. These results indicate that 1) normal plantarflexor muscles exhibit a thioxotropic behavior that can be detected by the measurement of passive movement and 2) that the test may be applicable to the evaluation of changes in intrinsic properties of spastic muscle. (Supported by MRC of Canada).
T19.7
SPRINTED MOTOR UNITS SHOW TYPE-SPECIFIC RESPONSES TO CHRONIC ENLARGEMENT FOLLOWING PARTIAL DENERVATION OF RAT LATERAL GASTROCNEMIUS. E.L. SABURN AND P.F. GADINER*. Physiological Sciences, Univ. of Montreal, Montreal, Que., Canada H3C 3J7.

Motor units (MUs), enlarged subsequent to partial denervation may, with extended periods, diminish in their capacity for force production. We studied this issue by comparing normal lateral gastrocnemius (LG) MUs, isolated via splitting of the LS ventral root, with MUs which had been sprouted (14 section), for either 30 or 90 days. Compared to control, MU proportions were unchanged and overall motor unit twitch forces doubled at both 30 and 90 days. This increased tetanic force varied according to MU type: mean forces for S, FR and PF MUs were 315%, 128%, and 267% respectively, of controls. After 90 days FR MU force was further increased (25%), S was unchanged and FR decreased (26%), compared to 30 days. Twitch/tetanic ratios also responded differently according to MU type. Our results indicate that after the initial sprouting response is complete, MU reorganization continues based on size and/or activity level. Supported by NSERC Canada.

T19.9

A 7 degree-of-freedom (DOF) dynamic model of the human upper extremity has been developed for use in trajectory planning studies. Dynamic equations of motion were derived using Kane’s method and coded on a computer-graphics workstation. Included are 36 musculotendon forces to actuate the 7 DOF. Musculotendon origin and insertion points were obtained by dissection and measurement to +/- .1 mm in Cartesian space via an Osteopad digitizing probe and transformed to bone centered reference frames. Via points describing each musculotendon pathway were also computed where necessary to prevent the paths from penetrating bone surfaces during joint rotation, using the graphical display program SIMM. The model can be used to explore the neuromuscular strategies employed by the monkey to actuate joint angles when (i) holding the finger as a specified point in free space, or (ii) creating a trajectory in free space. When the finger position (or trajectory) is well within the physiological workspace, an infinite number of possible arm configurations will deliver the same endpoint position (trajectory). Optimal control theory was therefore used to compute minimum cost solutions to the kinematic redundancy problem. Cost functions include minimizing gravitational potential energy (Cg) and the sum of muscle stresses squared (Cg), which relates to metabolic energy expenditure. A pseudoviserous method was used to compute musculotendon stresses with minimum positional (trajectory) error. Preliminary results for the positional study indicate that cost function Cg predicts the shoulder angles, elbow flexion angle, and wrist flexion/extension angle, but cost function Cg does not perform as well. Supported by the NIH (NS 2675).

T20.1

The role of nitric oxide in cerebrovascular dilation during CSD is controversial. The purpose of this study was to examine effects of inhibition of nitric oxide synthase on cerebrovascular dilation during CSD. Since indomethacin pretreatment potentiates cerebrovascular dilation during CSD (Am. J. Physiol.: 269: R808-R810, 1995), we speculated that nitric oxide might play a larger role under these conditions. Urethane-anesthetized rabbits were equipped with a closed cranial window and pial arteriolar diameter was measured in vivo via intravital microscopy. Baseline arteriolar diameters ranged from 80-100 μm. We examined arteriolar responses to CSD in the absence of other drugs, and after intravenous administration of L-NNA (15 mg/kg) and/or indomethacin (10 mg/kg). CSD was induced by microinjection of 5% KCl. L-NNA reduced nitric oxide synthase activity by 90% in cerebral cortex (n=12 for controls and n=24 for L-NNA-treated) and reduced pial arteriolar diameter by 12%. In other animals, increased arteriolar dilation from 41 ± 5% to 76 ± 6% during CSD (p<0.05; n=8). In other animals, increased arteriolar dilation from 41 ± 5% to 76 ± 6% during CSD (p<0.05; n=8). However, administration of L-NNA in the presence of indomethacin failed to reductocclusion, following administration of indomethacin, inhibition of nitric oxide production by L-NNA fails to attenuate CSD-induced arteriolar dilation. Supported by HL 30260 and HL 46558.

T20.2

We have shown that cerebral blood flow (CBF) and cerebral vascular resistance (CVR) autoregulation at higher levels of arterial blood pressure (AP) after SAD in rat. In this study we sought to assess potential mechanisms for this phenomenon. CBF was monitored by laser flowmetry in intact rats in whom AP was increased by phenylephrine (PE), vasopressin, or angiotensin. AP was increased by PE in additional rats after: 1) SAD; 2) SAD plus bilateral removal of superior cervical ganglia (SCG); or 3) bilateral ligation of the renal artery and veins (ISN). We also examined the effect of unilateral SCG or bilateral SCG on CVR autoregulation under these conditions. AP was increased by PE in intact rats but did not break through at increased levels of AP in SAD rats with intact (15 ± 2 mmHg) or interrupted (16 ± 5 ± mmHg) sympathetic innervation of cerebral vessels. Breakthrough was seen in rats in which AP was increased with vasopressin but not in those treated with angiotensin, which blocked baroreflex-mediated bradycardia that occurs in intact rats. Breakthrough did not occur in SAD rats even when increases in plasma renin activity were prevented by isolation of the kidneys before SAD. This study suggests that the arterial baroreflex may participate in break through autoregulation at hypertensive levels of AP independent of its effects on sympathetic innervation of cerebral vessels or on plasma angiotensin levels. We speculate that break through of cerebral autoregulation in response to hypertension may result from release of an active vasodilator. SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
THROMBIN INDUCES BRAIN EDEMA AND CONSTRUCTION IN CEREBRAL MICROVESSELS: POSSIBLE ROLE IN INTRACEREBRAL HEMORRHAGE.

K.R. Lee, A.A. Bent, O. Suga*, R.F. Kemp, (L. Shalhub, and J.T. Holt) Section of Neurosurgery, University of Michigan, Ann Arbor, MI 48109

Thrombin is a naturally occurring protein involved in the clotting cascade. In addition to its role in thrombogenesis, it is thought to be involved in vasoconstrictive and inflammatory effects. While under normal conditions the level of thrombin in the brain is undetectable, during intracerebral hemorrhage (ICH) large quantities of thrombin are produced, leading to brain injury through thrombin. The present study presents a series of studies investigated the possibility that the intracerebral injection of thrombin induces local brain edema and microvascular constriction.

Rats received intracerebral injection of either vehicle, thrombin (1, 10, or 100 units), or a thrombin inhibitor (hirudin, 10 units; or Nω(O-2-aminophenyl)lysine (a-APL-DL, the hirudin mimic, naPAP), 0.2mM). Local brain water increased in rats injected with 10 or 100 units of thrombin (4.0% or 5.8% respectively; p<0.01 vs. sham animals). Animals injected with hirudin and hirudin had less water accumulation (2.0%; p<0.05 vs. thrombin alone). Similar results were obtained with the thrombin inhibitor, naPAP.

In order to investigate the possibility that thrombin may induce microvascular constriction, a second series of experiments was performed in which in vivo brain tissues were obtained from rats and examined with computerized videomicroscopy. Microvessels (30-70um in diameter) within the slices were monitored while the slices were superfused with thrombin (1 unit/ml in artificial cerebrospinal fluid) or vehicle (0.8% albumin solution) for 30 minutes. Thrombin induced a 35.4% microvascular constriction after 30 minutes, whereas treatment with vehicle resulted in a 2.9% constriction (p<0.005). These studies suggest that thrombin induces brain edema and that this effect may be due in part to the microvascular effects of thrombin. Brain edema/toxicity seen in ICH may be mediated by the local effects of thrombin. The results also suggest that the neurotoxic use of thrombin to augment hemostasis may be accompanied by local edema and vasocstriction.
721.1

NITRIC OXIDE FORMATION IS ESSENTIAL FOR ADAPTIVE MODIFICATION OF THE VEINULAR-OCULAR REFLEX, A MODEL FOR NEUROPLASTIC CHANGES IN THE GOLDFISH, Jan-Lu "Sheryl" S. Smith and James C. McIlrath 
1Dept. of Anatomy, Inst. of Neuroscience, MCP-Hahnemann University, Philadelphia, PA 19102 2Dept. of Pharmacology, Temple University School of Medicine, Philadelphia, PA 19140

The gaseous second messenger nitric oxide (NO) implicated in neuroplasticity using in vitro models (Schuman and Madison, 1991), was tested for its role in adaptive modification of the veinular-ocular reflex (VOR) in the goldfish, as an in vivo model of neuroplastic changes. Two potential mechanisms for NO release in the cerebellum, activation of climbing fiber afferents (Southam and Garthwaite, 1989) and activation of non-NOS activity of astrocyte amino and receptors (Garthwaite et al, 1989), also occur during adaptation of the VOR. This reflex functions to maintain a stable visual image on the retina during head movement. Adaptive increases in VOR gain were induced by mechanical rotation of the head in the horizontal plane 180° out-of-phase with a visual stimulus. NO synthase (NOS) was first localized to goldfish cerebellum, as identified by NADPH-diaphorase staining. For the VOR study, NO production was pretreated by L-N^\text{N-monomethyl-arginine} (L-NMMA), a specific blocker of NOS, injected intracritically (i.c.) and after 14 shots, the response was observed. i.c. injection of L-NMMA also induced abolition of VOR adaptation. The inhibitory effect of L-NMMA application on VOR gain adaptation was not due to a non-specific action as assessed by laser Doppler flow measurements. Thus, these results suggest a role for NO within the cerebellum, in adaptive modification of the VOR, a learned response. (Supported by NIMHRO1 NS10455 and USDA CR 891003 to JLM)

721.2

MICRODIALYSIS WITH NITRIC OXIDE IN THE SEPTUM IMPROVES SOCIAL MEMORY OF RATS. T.Holen 1and M.Engelmann 2 The Scripps Research Institute, La Jolla, CA, U.S.A. 1Max Planck Institute for Psychiatry, Munich, Germany.

Nitric oxide (NO) synthase immunoreactivity in limbic areas of the rat brain including the septum implicates an involvement of NO in learning and memory. The present study tested whether NO in the septum of adult male adult rats is potent to modulate their juvenile recognition capacities. Animals which received artificial cerebrospinal fluid (ACSF) pregressed with a mixture of 5% NO in nitrogen via microdialysis into the septum showed a significantly improved juvenile recognition ability (p<0.01, ANOVA, n=13) compared to control sessions in which the same animal received ACSF pregressed with 100% nitrogen. To quantify the applied amount of NO, chemiluminescence detection was used to analyze the in-vitro release from the microdialysis probes showing that approximately 40 pmol NO per min were released from the probes into the surrounding medium. Blockade of endogenous NO synthesis by intraperitoneal administration of L-NAME (30mg/kg i.p.), however, failed to affect juvenile recognition in another group of rats (n=13). These results indicate, that neuronal substrate of olfactory memory located in the septum is sensitive to NO. However, the fact that blockade of endogenous NO synthesis did not affect the behavioral performance of other mechanisms may substitute for endogenous NO. Supported by the DAAD.

721.3

The role of nitric oxide (NO) as a neuromodulator in the CNS was assessed by a behavioral model of hippocampal-dependent learning. The dependent trait by inhibition of the NO-synthase (NOS) enzyme. Adult male rats of the Naples High (NH) and Low-Excitability (LX) lines, and of random-bred controls (NBR) were tested for 10 min in a L-maze during which two theta-related activity components such as walking and rearing, and an emotional index such as defecation scores were measured. Immediately upon completion of the test, the regional injection of the NOS inhibitor N^\text{N-nitro-L-arginine} (L-NOARG) 1-10 mg/kg or vehicle. Retention testing took place 7 days later. The results showed 10 mg/kg impaired long-term habituation (LTH) of the vertical component with prevailing emotional meaning, whereas both 1 and 10 mg/kg inhibited LTH of the defecation scores. In fact, 1 mg/kg exerted a small improvement in both strains. The disruptive effect of L-NOARG on long-term habituation of the vertical component in random-bred rats supports the hypothesis that NO may play the role of spatial anticipation and may improve the genotype-dependent differential effect of NO inhibition in NH and LX lines, compared to NBR-rats, strengthens their usefulness as a genetic model for altered spatial and non-spatial learning in the brain. (Supported by CNA 910304800 and Murast 40 grants).
1732.3 ORAL ADMINISTRATION OF L-NAME IN DRINKING WATER ALTERS WORKING MEMORY IN RATS. B.L. Cubas*, E.I. Brasil*, M.R. Hoss*, S. Dupel-Queiroz and S.A. Muccillo. Radiofrequency Radiation Division, Antrim Laboratory, Brookes Arn, TX 78234; *Depart of Biology, Trinity University, TX 78212.

In order to determine the role of nitric oxide (NO) in the maintenance of working memory of rats, the effects of oral administration of drinking water of the NO synthase inhibitor, N-nitro-L-arginine methyl ester (L-NMA), were studied. Substitution with a single test of recency-recall explored objects. Unlike other working memory tasks that require a single task to perform a reward such as food or water or to avoid shock, we tested spontaneous alternation of novel and familiar objects and it has been described as a pure working memory task (Masacari, 1988). Normal subjects spend a considerable amount of time in the environment with a single stimulus with which they have previous experience is presently available for the assessment of memory loss associated with the object. Memory changes were evaluated by measuring the relative time subjects explored familiar vs. new stimuli. Rats (n=15) that chronically drank an agonist 34.5% of 20 mg/kg/day L-NMA, spent significantly less time exploring a novel object than rats (n=15) that drank tap water (p<0.05). This effect of L-NMA was significantly attenuated by concurrent administration of L-Arginine (+50mg/kg/day). Total object exploration was not affected by our drug treatments, suggesting that our object discrimination task is not activity dependent. These data are consistent with the hypothesis that NO is required for normal functioning of working memory.

The acoustic startle reflex has a well described neural circuitry in which the nucleus reticularis pontis caudalis (RPC) plays an essential role. Nevertheless, the pharmacological reflex is not fully known. Local injection into the RPC of exocytotic amino acid (EAAs) agonists shows that glutamate may actuate startle at this level. EAA release at other synapses has been shown to enhance the effects of the second messenger cyclic AMP. Previous studies have demonstrated the involvement of the amygdala in the modulation of the startle response, particularly a CAMP-dependent mechanism of the RPC. As an initial test of this hypothesis, the present experiments evaluated whether a CAMP analog, 8-bromo-CAMP (BRC), or a phosphodiesterase inhibitor, Rolipram, would increase startle when infused directly into the RPC.

Rats implanted with cannulae in the RPC (PA-1.22, M.E. = +.15, D.V. = -9.6, at an angle of 20 degrees, a dose of 2.0 mg/kg/kg/day L-NMA, 0.15 MB of burst, 50 ms) were trained, at a 30 min. inter-trial interval, to a pre-drug baseline, and then induced successively with artificial cerebral spinal fluid (ACSF) and increasing doses of BRC (0.125, 0.25, 0.5, 0.75 and 1.0 μM). Immediately after each infusion they were tested with 40 startle stimuli. Other groups of animals were tested at above, but with 30 ms ventral of BRC alone or of BRC (0.25 μM). BRC produced a dose-dependent increase in startle amplitude. Repeated infusions of vehicle or 0.25 μM of BRC did not modify startle amplitude. Another group of animals infused with Rolipram 10 mg/kg/gal showed a marked increase in startle amplitude (281.3%). These results suggest that the CAMP second messenger system can modulate startle amplitude at the level of the RPC. To characterize more precisely the involvement of CAMP in startle modulation, we are currently examining the effects of other compounds known to alter CAMP activity. (Post-doctoral fellowship CNPq-Brasil # 20196093).

Erythropoietin is a glycoprotein produced endogenously in the kidney, which stimulates red blood cell production. We evaluated the effects of chronic treatment with recombinant human erythropoietin (Epoetin-α/Epo) on the performance of 8-month-old male C57BL/6J mice in a complex spatial task, the Morris water maze. Mice were treated with either Epo (1.5 units injected s.c. every other day) or vehicle (PBS also injected s.c. every other day). Results indicated that the treatment had no effect on maze performance after 9 weeks, but after 20 weeks the Epo-treated mice learned the task significantly faster than controls over 4 days of training as measured by mean distance (cm) to reach the goal platform. The results suggested that the improved performance in mice resulted from an increase in hematocrit which was not achieved until after 20 weeks of Epo treatment. Evaluation of several hematological parameters indicated that the only significant effect of Epo treatment was to raise hematocrit values at 20 wks. This rise was found to be significantly correlated with swim maze performance.

Ethanol blocks long-term potentiation in vitro (Sinclair and Lo, 1986) and inhibits NMDA-evoked activity of hippocampal neurons in vitro (Loving et al., 1989) and in vivo (Simon et al., 1993). In behavioral studies, acutely administered ethanol impairs the use of spatial memory (Matthews et al., RSA Meeting, 1994), and chronically administered ethanol impairs learning of a spatial task (Arendt et al., 1988) that has been shown to be sensitive to hippocampal damage (Olton and Papas, 1979). More recently, Matthews et al. (RSA Meeting, 1994) report that ethanol, but not diazepam or MK-801, markedly altered the spatial properties of hippocampal neurons recorded electrophysiologically in awake behaving rats. In contrast to these results, however, Devenport et al. (1989) conclude that ethanol is virtually without influence on spatial localization. In the present study, we investigated the effect of ethanol on spatial and non-spatial tasks that Matthews and Best (1993) demonstrated to be differentially sensitive to fimbria/ fornix lesions. Results show that animals injected with ethanol prior to each training session learned significantly slower than saline-injected animals on the spatial task (p < 0.1). In contrast, ethanol-injected and control animals performed similarly on the non-spatial task (p > 0.1). These results suggest that ethanol produces an impairment in spatial learning similar to that produced by fimbria/fornix lesions.

We demonstrated that Nifedipac (NEF) ameliorates eyelock classical conditioning (ECC) in older rats in the 750 ms delay paradigm. The present study is an attempt to identify the brain site of action. If NEF affects ECC via the hippocampus, injection of NEF in rabbits with intact hippocampus should ameliorate ECC whereas injection in hippocampectomized rabbits should not. Five groups of older rabbits were run in 750 ms delay ECC: 1) hippocampectomy, 10 mg/kg NEF (N=8); 2) partial cortical removal, 10 mg/kg NEF (N=9); 3) sham surgery, 10 mg/kg NEF (N=9); 4) no surgery, 10 mg/kg NEF (N=8); 5) no surgery, vehicle (N=8). Among groups treated with NEF, trial 2 learning criterion (T/C) was significantly greater in hippocampectomized rabbits (1,038) than in rabbits with intact hippocampus (cortical = 738; sham surgery = 445; no surgery = 473). Rabbits with vehicle had significantly more T/C than those with NEF (probability of percentage of conditioned response responses supported the results with T/C). Hicccupampcromized rabbits with NEF learned more slowly than cortical surgery and controls with intact hippocampus. NEF may act to ameliorate ECC in older rabbits via the hippocampus. Supported by Daiichi Pharmaceutical Co., Ltd., Tokyo, Japan.

EFFECT OF AIT-082 ON ETHANOL-INDUCED AMNESIA AND BEHAVIOR. R.P. Ritzmann*, P. Prieto-Gonzalez, C.L. Melichar, F. DeLeon-Jong, and J. Glicky. Olive View/UCLA Medical Center, Sylmar, CA 91342 and Advanced ImmunoTherapeutics, Tustin, CA 92680

AIT-082, a derivative of the purine hypoxanthine, has been shown to improve memory in the wls-shift test of working memory. This test consists of placing a mouse in a T-maze with a reward in both goal boxes; the mouse is allowed to choose one of the goal boxes. On the next trial, if the mouse remembers which box it entered on the previous trial, it will enter the other box. By increasing the delay between trials, the length of time a mouse can remember can be determined. In C57BL/6 mice, the longest delay that these mice can remember is 120 seconds. Mice receiving AIT-082 (30 mg/kg) were able to remember at delays over 180 seconds. Ethanol (0.5 mg/kg), 10 minutes prior to testing, at 120 second delay, reduced the correct responses by 60%, without altering the time to leave the start box or the time to traverse the maze, indicating that ability to perform was not impaired. AIT-002, given 20 minutes prior to ethanol, blocked the amnestic effect of ethanol.

A behavioral analysis of the effects of AIT-082 was performed at doses from 0.005-60 mg/kg. The tests included: locomotor activity, exploratory activity, plus maze test of anxiety, hot plate analgesia and roto-rod test of motor coordination. The only significant effects of AIT-082 were improved performance on the roto-rod test at doses from 0.05 to 60 mg/kg and a decrease in locomotor activity only at the highest dose (60 mg/kg). The decrease in locomotor activity along with the lack of any effect on exploratory activity may be due to the fact that these tests would be consistent with the effects of AIT-082 on memory in other tests. Supported by grants from NIH and NIA (AG099911).

Ethanol blocks LTP in hippocampal slices (Sinclair & Lo, 1986) and inhibits NMDA-evoked activity of hippocampal neurons in vitro (Simon et al., 1993). Chronic ethanol also impairs learning a spatial task (Arendt et al., 1988) that has been shown to be sensitive to hippocampal damage (Olton & Papas, 1979). In addition, Matthews et al. (see accompanying abstract) report that ethanol alters the spatial properties of hippocampal neurons. We investigated the effects of acute ethanol on two tasks requiring spatial memory and one requiring non-spatial memory. Ethanol significantly reduced the ability to use spatial memory but not non-spatial memory. Also, MK-801 (only at doses that produce ataxia) but not diazepam impaired spatial memory. Neither drug affected non-spatial memory. Therefore, ethanol's contribution to auto accidents, may not be limited to impairment of judgment and reflexes but may include diminished cognitive necessity for the use of spatial memory.

BENEFICIAL EFFECTS OF PRE-084, A SELECTIVE δ LIGAND, ON PHARMACOLOGICAL MODELS OF LEARNING IMPAIRMENT IN MICE. T. Maurizio*, T.P. Su*, D.W. Pavlich* and A. Prival1. 1 INSEEM U 336, INSECM, 8 rue des Ecoles Normales, 14053 Montpellier cedex 1, France; 2 NIDA-Addiction Research Center, NIBL, POB 5180, Baltimore, MD 21224. 3 Bio-CAD Corporation, 545 Oakway Park, Sunnyvale, CA 94086.

We investigated the effects of PRE-084, a selective sigma ligand derived from phenylcycloide, on several pharmacological models of learning impairments in young adult mice. Tests included spontaneous alternation in a Y-maze, for immediate spatial working memory, and the step-down type passive avoidance, elevated (+) maze, and place learning in a water maze, for long-term memory. (1) PRE-048, at doses about 1 mg/kg sc., significantly attenuated the impairment of alternation, decrease in step-down latency, and increase in transfer latency induced by MK-801 (0.2 mg/kg ip). These effects were antagonized by the simultaneous administration of BMY-14802 (10 mg/kg ip), and suppressed in mice chronically treated with haloperidol (4 mg/kg/dy sc for 7 days). (2) At the same dose range, PRE-084 significantly attenuated the impairments induced by mecamylamine (10 mg/kg ip), but not by scopolamine (1 mg/kg ip). (3) PRE-084, at 0.3 - 1 mg/kg, also prevented the impairment of alternation, decrease in step-down latency, and impairment of place learning induced by the calcium antagonist nimodipine (0.3 mg/kg ip). These results confirm previous studies showing that sigma ligands may modulate the learning processes, mediated via the NMDA receptor or the nicotinic cholinoreceptor activation, and the resulting calcium mobilization. Thus, PRE-084, by acting selectively at sigma sites, may be useful in improving the cognitive impairments due to aging or Alzheimer's disease.
THE NOVEL COGNITION ENHANCING AGENT S 12024-2 FACILITATES OBJECT AND SOCIAL RECOGNITION MEMORY AFTER ACUTE OR CHRONIC TREATMENT IN RATS. W. Fassbinder, J. Pickart, A. Schöffstetter, and J. Joles, Dept. of Psychiatry and Neuropsychology, Univ. of Limburg, Maastricht, NL-6200 MD, and Dept. of Pharmacology, Univ. of Amsterdam, The Netherlands.

Preliminary experiments suggested that S 12024-2, a novel compound [Sever], might enhance memory. We used two different tests in establish whether S 12024-2 facilitates recognition memory. Twenty adult male Wistar rats were tested in the object exploration test [Ennaceur & Dellacour, Behav. Brain Res. 1988]. In the first trial (3 min) exploration times were scored for two identical objects. After 24 hr the rats did no longer discriminate between an identical, familiar object and a novel object. When they had received S 12024-2 (3.4 mg/kg i.p) immediately after the first trial, they discriminated between the two objects indicating that the treatment facilitated recognition memory. This effect of S 12024-2 was replicated. Subsequently, two groups were formed that received either distilled water (n=8) or a solution of S 12024-2 (16 mg/kg/day, n=12) to drink. After 10 days the S 12024-2-treated, but not the control, rats showed significant recognition of the familiar object. This effect was replicated after 17 days of treatment.

Another group of 20 rats was used for the social memory test [Danziger et al., Psychopharmacology, 1987]. A similar design was used: all animals were tested after post-training ip injection of saline or 3.4 mg/kg S 12024-2. After 24 hr a hour in exploration of a juvenile rat was found only when treated with S 12024-2. This effect was replicated. In the chronic treatment condition S 12024-2 facilitated social recognition after 6, 10, and 12 days of treatment. From these results it can be firmly concluded that S 12024-2 is effective as a cognition enhancing agent with respect to recognition memory. (Supported by J.R.S., Courbevoie, France.)

Two studies were conducted to determine the lowest dosage of phenobarbital (POB) that could (1) maintain discriminative control in a drug discrimination (DD) task, and (2) produce appreciable state dependent learning (SDL). Both studies progressed through successive cycles of training in a 2-lever task with a different dosage used in each cycle. Both used Long Evans male rats and injections of phenobarbital (POB) or saline (S). The SDL study used the following procedure: (1) Train for 5 sessions while D or S is present; (2) Give one D and one S test session (ever lever reinforced); (3) Train for 5 sessions to lever 2 while N (or D); (4) Give two D and two N test sessions; (5) Untrain the rats by reinforcing response on the drug-inappropriate lever. SDL was noted after D->S-N transitions with doses as low as 3 mg/kg. The DD study used conventional D vs N training with FH10 vs extinction schedules of reinforcement on the correct and incorrect lever. Doses during successive cycles of 18 sessions was selected by a dosage titration paradigm to determine the lowest dosage that could support above-criterion discriminative control. The threshold irregularly-discriminated dosage was 3 mg/kg and extrapolation from the accuracy vs. dosage plots indicated an absolute threshold dosage of about 2 mg/kg. Hence SDL generalization failures occur with dosages almost as low as the lowest dosage that can be discriminated after prolonged DD training. The results suggest that "drug cues" may not be processed via mechanisms that allow the rats to "pay to attention" to drug effects.

CIRCADIAN CLOCK REGULATES ROD AND CORE INPUT TO GOLDFISH CORONAL HORIZONTAL CELLS. S.C. HangeI and T. Wang, Dep. of Ophthalmology, University of Alabama School of Medicine, Birmingham, AL.

To determine whether a circadian clock regulates the effects of dark adaptation in the retina, goldfish T-type corona horizontal cells (HCS) were studied. Fish were maintained in constant darkness. Surgery was performed under dim red or infrared light. Retinas were superfused with darkness for 90 min (prolonged darkness®), following which a HC was impaled without the aid of any light flashes. Following prolonged darkness during subjective day, light responses were fast and response amplitudes averaged 17 mV to the brightest stimuli. Spectral sensitivity was similar to that of red (625 nm) cones. During subjective night, light responses were slow, response amplitude averaged 2.5 mV to the brightest stimuli and response duration was 5-6 times longer than stimulus duration. Spectral sensitivity was similar to that of red HCs. Reversing the light-dark cycle for 10 days reversed the rhythm of dark adaptation. These results indicate that a circadian clock in HC light responses such that following dark adaptation, red cone input predominates during the subjective day and rod input predominates during the subjective night.

We examined the effects of acute post-training injections of estradiol-hydroxypropyl-β-Cyclodextrin inclusion complex on rats trained in a single-platform spatial water maze task. Unlike traditional forms of sex hormone administration, injection of estradiol-inclusion complex results in a rapid rise of hormone in blood plasma, similar to that induced by normal hormone release. Rats received a single 8 trial (30 second inter-trial interval) training session with a submerged escape platform located in the same quadrant of the maze on all trials. Following trial 8, rats received a post-training subcutaneous injection of estradiol (0.25, 0.5, or 0.75 mg/kg) or saline. On a retention test session 24 hours later, latency to mount the escape platform was used as a measure of memory. The retention test escape latencies of the animals given 0.75 mg/kg of estradiol were significantly lower than those of saline treated rats, indicating an enhancement of spatial memory. Estradiol at doses of 0.25 and 0.5 mg/kg had no effect on retention test latencies. The findings indicate that acute post-training administration of estradiol can enhance spatial memory in male rats.

Wistar rats were exposed to two lighting conditions, constant light or a standard 12/12 hr light/dark cycle. The animals were acclimated to lighting conditions for 5 wks prior to ethanol (EtOH) acquisition with water and food available ad lib. EtOH was presented in increasing concentrations from 2% (v/v) 95% EtOH with water) to 10% on alternate days in free choice with water. Immediately following the acquisition phase, a maintenance period was initiated which began with everyday presentations of 10% EtOH solution in free choice with water. After 10 days maintenance, lighting conditions were switched such that rats in constant light received EtOH and rats in subjective day, light responses were fast and response amplitudes averaged 17 mV to the brightest stimuli. Spectral sensitivity was similar to that of red HCs. Reversing the light-dark cycle for 10 days reversed the rhythm of dark adaptation. These results indicate that a circadian clock in HC light responses such that following dark adaptation, red cone input predominates during the subjective day and rod input predominates during the subjective night.

Hamster PLI or ENK-IR neurons in the IGL project to the suprachiasmatic nucleus (SCN) by a geniculo-hypothalamic tract (GHT). Cells also project to the contralateral IGL, but few contain NPY- or ENK-IR. A major third IGL-ef fluent path is now identifiable.

NPy- and ENK-IR fibers extend dorsally from the IGL into the superior thalamic radiation. A thin, vertically oriented terminal field is evident in the PLI along the lateral border of the anterior pretectal nucleus, extending ventrally and laterally along the medial geniculate nucleus. Retrograde studies (cholera toxin β-IR) show IGL cells projecting to the dorsal thalamic and pretectal nuclei. Anterograde transport of Phaseolus vulgaris lectino-agglutinin (ENK-IR) with the suprachiasmatic network (SCN) and the lateral pretectal and pretectal nuclei. The effect of the clock on phase shift, we administered an NP4 just prior to a light pulse at CT 18. Hamsters housed in constant darkness (DD) were implanted with a guide cannula aimed at the suprachiasmatic nucleus. Animals were injected with 200 ng of NPY or 200 ng of normal serum (NS) at CT 18 under a dim red safe light. They were then either exposed to light (approximately 200 lux) for 15 minutes or returned to DD. Hamsters shifted significantly more to the light pulse when pretreated with an NP4 (mean NS + light = 1.18 minutes; mean ANP + light = 1.92 minutes; p < 0.01 on both two-tailed paired t test and Wilcoxon test). Therefore, antiserum to NP4 did not block photic advances and in fact potentiated them. This indicates that the low levels of NPY found in the SCN at this time may be involved in photic phase shifting.

PHASE SHIFTS TO LIGHT AT CT18 ARE INCREASED BY PRETREATMENT WITH ANTISERUM TO NEUROPEPTIDE Y. S.M. Bliello, N. Mysogoyev and M. Ralph, Deps. of Ecology and Psychology, University of Toronto, Toronto, Ont., Canada M5S 2A.

Previous work has indicated that antisem to neuropeptide Y (NP4) blocks phase shifts to certain non photic stimuli at CT 4. To insure this effect was specific to non photic phase shifts, we administered an NP4 just prior to a light pulse at CT 18. Hamsters housed in constant darkness (DD) were implanted with a guide cannula aimed at the suprachiasmatic nucleus. Animals were injected with 200 ng of NPY or 200 ng of normal serum (NS) at CT 18 under a dim red safe light. They were then either exposed to light (approximately 200 lux) for 15 minutes or returned to DD. Hamsters shifted significantly more to the light pulse when pretreated with an NP4 (mean NS + light = 1.18 minutes; mean ANP + light = 1.92 minutes; p < 0.01 on both two-tailed paired t test and Wilcoxon test). Therefore, antiserum to NP4 did not block photic advances and in fact potentiated them. This indicates that the low levels of NPY found in the SCN at this time may be involved in photic phase shifting.

EFFECTS OF PROTEIN SYNTHESIS INHIBITION ON PRESUMPTIVE OSCILLATOR PROTEINS AND CIRCADIAN PHASE OF THE OCULAR CIRCADIAN PACEMAKER OF BULLA GOUUDIANA, Michael M.

Roberts* and Nancy A. Krueger, Dept. of Biology, Clarkson University, Potsdam, NY, 13699-5806.

The eye of the marine snail, Bulia goudiana, contains a circadian pacemaker. In previous work we have proposed that members of two protein families, some of whom regulate the wukayrtoc cell division cycle, are involved in circadian rhythm generation. Using Western blotting techniques we have identified a protein (p40) possibly related to the cell division kinase, p34cdk, in the B. goudiana eye. We have also identified a presumptive 65kDa homolog (p66) of the regulatory protein cyclin.

The current work we have characterized the phase dependent effects of the protein synthesis inhibitor cycloheximide (CHX 10μM) on both the phase of the circadian rhythm and the levels of p40 and p66. CHX had no effect on the rhythm when given at CT -4, while phase delays appeared at CT 8-10 (1.6 ± 0.75 hrs) and increased gradually to 3.0 ± 1.7 hrs from CT 22-4. In preliminary studies, p40 levels increased by CHX during the day and decreased at night. In contrast, CHX increased p66 when given from CT 18-22 and decreases p46 at other phases. The effects of CHX on circadian phase as well as on the level of these proteins are consistent with our hypothesis that p40 and p66 may be involved in circadian rhythm generation.

AFFERENT COMPONENTS IN THE PROTOCEREBRAL (pc) CIRCADIAN SYSTEM OF CRAYFISH, B. Barrera-Mera* and E. Barrera-Calva, Dept. de Fisiologia Fac. de Medicina UNAM, A. Postal 70-250 Mexico 04510 D.F.

The pc system of crayfish (Fig 1) has been studied in isolated preparations "in vivo". Under this condition a robust circadian (cr) rhythm of sustaining response neurons (s), retina (r) and distal (d) retinal shielding pigments (RSP) shine its endogenous character. While this rhythmic activity can occur spontaneously, usually, presumably, in the normal animal, the pc c pacemaker (pm) is modulated by interneurons input from the rest of the nervous system, as shown by the variety of elements in the optic tract. In the pc c system we found that only the c response of r, s and the jittery fibers remain unchanged. They apparently are the afferent input of both left and right pc c pm, which are expressed throughout the synchronous release of neurochemical neurotransmission as light-adapting hormone (LATH) from the sinus gland (sg).

USE OF LED TECHNOLOGY IN PROVIDING CONTROLLED LIGHTING FOR ANIMAL RESEARCH. M. Drews, I.-H. Tang, T. Tandon, and C.A. Fuller. Section of Neuroscience, Physiology & Behavior, University of California, Davis, California 95616-8519.

The light environment is critical for animal research, including both basic husbandry and experimentation. In order to study how animals respond to different aspects of light, we utilize the characteristics of light emitting diodes (LED). The LED technology offers several advantages, including: 1) they are sold state devices, 2) they provide narrow spectral band output near their peak wavelength, 3) they are available in several discrete wavelengths, 4) they demonstrate negligible shift in spectral distribution at different intensities, 5) they have a high degree of stability and longevity, 6) they produce virtually no heat, 7) they are small and require minimal room requirements, and 8) their output intensity can be controlled linearly and dynamically. We have developed an autonomous computer based controller to provide variable profile light cycles, including: 1) rate of light intensity change, 2) range of minimal and maximal intensity, and 3) duration. The output intensity profile can be monitored in real time. We have examined the photic entrainment of hamsters in a simulated natural light-dark cycle using this device. This device can also be applied to study the photic entrainment thresholds of a defined spectrum. We have also studied the entrainment behavior of a small primate, the squirrel monkey, using the narrow spectral qualities of the LED light source. (Supported by NASA Grant NAGZ-792.)

723.2

This study compared the entrainment characteristics of simulated natural light-dark (LD) cycles and square wave LD cycles (14:10) in golden hamsters. The simulated natural LD cycle was composed of a 4 h linearly ramped dawn-dusk-mimicking period, a 6 h full light intensity day period and a 4 h linearly ramped dusk-dawn-mimicking period. Animals were implanted with biotelemetry transmitters to record body temperature and activity at 10 min intervals via microcomputer. The phase angle at which animals entrained was determined by onset times of the animals' ambulatory activity. Animals under simulated natural LD cycles exhibited advanced relative to the LD cycles. An additional test was performed to examine the role of bilateral vs. unilateral eye in the entrainment responses. Animals received unilateral optic nerve transection exhibited a further degree of advance activity onset. In all conditions, there was a stable phase angle between body temperature and ambulatory activity under simulated natural LD cycles, suggesting anticipatory behavior. Preliminary data also demonstrated that animals with a unilateral optic nerve transection showed different c-Fos expression compared to intact animals in response to identical light pulse stimuli.

A MONTE CARLO TECHNIQUE FOR CHARACTERIZING EPOCHS OF ELECTROCOROLLARY ACTIVITY IN THE FETAL SHEEP. S. B. Robinson2, W. P. Smulovitz1, G. H. Wong1, S. S. Robertson2, and P. W. Nathaniel1. 1Laboratory of Perinatal Neurotoehy, Dept. Psychology, Binghamton Univ., Binghamton, NY 13902; 2Dept. Human Development and Family Studies, Cornell Univ. - Laboratory of Pregnancy and Newborn Research, College of Veterinary Medicine, Cornell Univ., Ithaca NY 14853.

Electrocorollary activity (EcOG) recorded from fetal sheep is a measure of sleep-wake state that differentiates into epochs of low voltage and high voltage late in gestation (term = 145 days). Five fetal sheep were surgically prepared at 113-114 days of gestation with an array of chronic instrumentation, including stainless steel electrodes overlaying the dura of the parietal lobes to measure fetal electrocorollary activity. EcOG signals were sampled at 32 Hz, amplified, full-wave rectified, averaged over 1 s intervals, and recorded continuously over days 121-133. Brief epochs of low- and high-voltage EcOG were distinguished on day 121, with durations that persisted significantly longer than predicted by Monte Carlo reordering of EcOG time series. Average EcOG voltage increased with age, and duration of low- and high-voltage EcOG epochs also increased, with the most rapid development evident about days 129-131. The developmental increase in duration appeared to be due to the selective advancement of the (c-5a) transitions in EcOG activity that interrupted epochs of longer duration. These results suggest an objective, quantitative strategy for characterizing epochs of low- and high-voltage electrocorollary activity that may be relevant for understanding the prenatual ontogeny of behavioral states.

This research was supported by a subcontract with Cornell University to WPS and SBR under NIH Grant HD 28014.

EVIDENCE THAT MAMMALIAN CIRCADIAN RHYTHM IS COMPOSED OF ULTRADIAN CYCLES AND SIMILARITIES BETWEEN CALCIUM OSCILLATION IN SUPRAECHASMATIC NUCLEUS CELLS TO THE MAMMALIAN CIRCADIAN PACEMAKER. Shinnazamaki1, Shin-Ichi T. Inouye2 and Yoichi Kuroda,1

1Department of Molecular and Cellular Neuroscience, Tokyo Metropolitan Institute of Gerontology, 2-5-1 Mutohida, Fuchu-shi, Tokyo 183, Japan.; 2Laboratory of Integrative Brain Function, Mibishi Kasei Institute of Life Sciences, 11 Minami-Ooya, Machida-shi, Tokyo 194, Japan.

A central question in the elucidation of the mechanism of circadian rhythm generation in the suprachiasmatic nucleus (SCN) is whether individual cells have an intrinsic capacity to generate circadian rhythms or the rhythmicity requires the interaction of cells. Like cortical neurons in culture (Kuroda et al. Neurosci. Lett. 125: 185, 1992), dissociated cultures of rat SCN show spontaneous oscillations of intra-cellular Ca2+ with 5-8 second period (ultradian rhythm). Replacement of Mg2+ by deuteron oxide (D2O) in the culture medium lengthened the period of this oscillation, while tetrodotoxin did not inhibit the deuteron oxide sensitive Ca2+ oscillation. Since these characteristics resemble those of the mammalian circadian pacemaker, the ultradian Ca2+ rhythm may be involved in the circadian rhythm or have a similar rhythm generation mechanism. The gap junction inhibitor, halothane, stopped this oscillation. Gap junctions may be necessary in order to generate rhythmic oscillations.

THETA EEG GENERATOR IN RAT NECORTICAL BRAIN SLICES. H.S. Lukatch and M.B. MacEchern. Dept. of Anesthesiology, Stanford University School of Medicine, Stanford, CA 94305.

The present study describes a novel neocortical EEG theta generator in rat brain slices. Theta EEG frequencies (7.31 ± 0.94, 419) were evoked in vitro by mimicking ascending cholinergic and GABAergic tone with carbacol (100 μM) and bicuculline (10 μM). Mapping studies revealed that this theta activity was limited to a strip of medial cortex running rostral caudally (partially overlapping cortical areas O2/CMM, RSA, Fr1, and Pr2). The presence of a theta generator intrinsic to cortical areas O2/CMM and RSA was confirmed by isolating mini-slices of these areas and inducing theta EEG activity in these mini-slices. Two electrode differential recordings were used to determine that theta generating cells were localized to layer 5. This theta activity was blocked by the muscarinic receptor antagonist atropine sulf ate (0.5 μM), similar to in vivo cholinergically driven theta. Preliminary loose patch single unit recordings revealed two cell types which exhibited different firing patterns in relation to the theta oscillations. One cell type fired only at the beginning of each theta burst and remained silent during the theta train. The other cell type was quiet at the beginning of each theta train, and attained its highest rate of discharge during protraction.

272.6

Temporal fluctuations which cannot be explained as consequences of statistically independent random events are found in a variety of physical and biological systems. The fluctuations of these systems can be characterized by the power spectrum density S(ω) decreasing as ω^-k at low frequencies with an exponent 0.5 ≤ k ≤ 1.5. We present a new model to describe the individual biological rhythms of humans using data from a colleague who has kept daily records for four years of his state of well-being applying a fifty-point magnitude category rating scale. This time series (S(t)) was described as a point process by introducing discriminating rating levels r and for the occurrence of r(t) > r (ups) and r(t) ≤ r (downs). R(t) after introducing a certain r or r is described by ρ (t) = ∫ P(t) dt, where P(t) is the probability density function of the random variables t_j, the time of a particular value R(t) ≥ r or R(t) < r. Applying counting statistics (Knuffke et al. Fraktale 1,800,1993) to evaluate S(ω) the following scaling laws were found: first scaling region 1 ≤ S(ω) ≤ 15d for the 'ups' and 'downs' where S(ω) = ω^(-k) with k = 0,7; second scaling region R(t) ≥ 15d exhibiting an almost random behavior with k = 0.0.

We speculate that the basic mechanisms of the neuronal/basal systems responsible for biological rhythms are expressions of a 'self-organized critical state' as introduced by Bak, Tang and Wiesenfeld (Phys. Rev. Lett. 59:381,1987) for physical systems. Because of the first scaling region and based on one's own monitored biological rhythm it should be possible to predict future episodes (Δ t ≤ 15d) with a certain probability by using methods of nonlinear time series analysis or modified feed-forward neural networks learning with backpropagation algorithm.

274.1
NEONATAL ISOLATION ENHANCES LTP AND RESPONSES TO AMPHETAMINE CHALLENGE IN JUVENILE RATS. J. Hoffman, A. Arabahi, P.J. Austen & A. Brassett. Neuroscience Program, Trinity College, Hartford, CT 06106.

Using a within-litter design, pups were isolated from mother and littermates for 1 hr. per day over PN days 2-9. At 30 days of age, the response of the dentate granule cell population to tetanization of the perforant pathway was examined in previously isolated and non-isolated littermates. Measures of population spike amplitude (F1) and population EPSP slope obtained at several following tetanization were used to assess the magnitude and duration of LTP obtained from each group. Preliminary results indicate that the degree of enhancement to both EPSP slope and F1 measures obtained from neonatally isolated animals was markedly greater than that of controls across the first 1 hr. recording period. In a separate group of littermates, striatal dopamine response to amphetamine (7.5mg/kg) challenge was assessed on PN day 27 by in vivo microdialysis. Controls treated, prenatally isolated, animals showed a significantly higher dopamine levels over the first hr. following amphetamine administration. Behaviorally, these animals demonstrated a significantly enhanced amphetamine hyperactivity. In summary, neonatal isolation significantly enhances LTP and amphetamine-induced behavioral and dopaminergic responsivity. The results suggest that the impact of neonatal isolation on response properties of both the hippocampus and striatum endures into the juvenile period of development and can be revealed by both electrophysiological and pharmacological challenges administered well after cessation of the stress paradigm.

274.2

We examined the effect of long-term treatment with antidepressant drugs on the tubulin polymerization in neonatal rats. To do this, we used the maximum concentration of acute and chronic stress (e.g., tone or variable) on tubulin assembly. The tubulin was prepared in buffer containing protein phosphate inhibitors, calmodulin A and sodium orthovanadate. The phosphorylation of microtubule was then monitored in vitro at 245 nm by a spectrophotometer. Treatment with desipramine, minaerin or citalopram for 7 days decreased the initial rate of tubulin assembly while a single injection of desipramine restored the rate. However, the tubulin reassembly without protein phosphate inhibitors nullified the inhibition of tubulin assembly following long-term desipramine treatment, suggesting that the inhibition of tubulin assembly is attributed to the phosphorylated microtubule-associated proteins (MAPs). MAP2 and tau factor. On the other hand, A single restraint stress increased the assembly rate, and the increase in the was recovered after chronic restraint stress for 7 days. In contrast, after chronic variable stress (cold-swimming, restraint, tail-pinch, shaking) for 7 days the increase in the rate was not recovered. It is thus proposed that the inhibition of tubulin assembly by the phosphorylation of MAPs may be an adaptive change to a novel stressor and this mechanism might be enhanced by long-term antidepressant treatment.

274.3
EFFECTS OF NEONATAL ISOLATION ON BEHAVIOR FOLLOWING AMPHETAMINE. C. Arner, R. P. Kohene and W. Sheenakar. Dept. of Psychiatry, UConn Health Center, Farmington, CT 06030, Dept. of Psychology, Trinity College, Hartford, CT 06106.

As part of a study on the ontogeny of behavioral and behavioral sensitivity we examined the proximal effects of neonatal isolation on locomotor activity and vocalizations following administration of amphetamine. One half of each litter was marked weighed and subjected to a daily one hour isolation from postnatal days (PND) 2-9. The other half of the litter was marked weighed and immediately returned to the nest and dam. Additional litters served as non-handled controls. Pups from these litters remained with their dams undisturbed through PND 9. On PND 10-19, pups were tested. Pups from each group were randomly divided into one of three challenge groups, saline 0.5 mg/kg amphetamine (APH) and 2.0 mg/kg APH. Animals were recorded for a five minute period beginning 15 minutes after drug administration. Ultrasonic vocalizations were recorded during this time with a bat detector. Females that were isolated and received 0.5 mg/kg APH showed higher levels of activity than the two control groups, significantly so in the course of patterned movements. These effects of isolation were not apparent in females tested with saline or 2.0 mg/kg APH. Males that were isolated and tested with 0.5 mg/kg APH, they showed lower activity scores than control males. Both doses of APH reduced vocalizations compared to saline. Among saline animals there was a clear effect of handling on the pattern of vocalizations over the five minutes period. There was a slight but insignificant trend for isolated animals to vocalize less than non-isolated, particularly with 0.5 mg/kg APH. These results suggest that neonatal isolation alters behavior following the administration of a low dose of amphetamine, at least when pups are tested 24 hour after the final isolation period. In addition, females seem to be affected to a greater degree than males, with regards to activity measures.

274.4

Stress can increase levels of cholesterol in plasma. Cholesterol is cleared from plasma primarily by high affinity cell-surface receptors. However, there is a secondary mechanism involving macrophages, a phagocytic immune cell. Thus, the effect of macrophage stimulation was examined as a potential mechanism for attenuating stress-induced increases in cholesterol. Rats (12 per group) were exposed to three sessions of inescapable tail-squeeze (100-160 mA shocks, one session per day for three successive days), or remained in their home cage. Half of each group were injected with zymosan (30 mg/kg, s.c.), a drug known to stimulate macrophage function in vivo. Animals received one zymosan injection for each of the three days prior to, as well as 15 min prior to each stress session. Control animals received vehicle injections. A week after a five-min period beginning 15 minutes after drug administration. Ultrasonic vocalizations were recorded during this time with a bat detector. Females that were isolated and received 0.5 mg/kg APH showed higher levels of activity than the two control groups, significantly so in the course of patterned movements. These effects of isolation were not apparent in females tested with saline or 2.0 mg/kg APH. Males that were isolated and tested with 0.5 mg/kg APH, they showed lower activity scores than control males. Both doses of APH reduced vocalizations compared to saline. Among saline animals there was a clear effect of handling on the pattern of vocalizations over the five minutes period. There was a slight but insignificant trend for isolated animals to vocalize less than non-isolated, particularly with 0.5 mg/kg APH. These results suggest that neonatal isolation alters behavior following the administration of a low dose of amphetamine, at least when pups are tested 24 hour after the final isolation period. In addition, females seem to be affected to a greater degree than males, with regards to activity measures.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
STRESS: NEUROCHEMISTRY AND BEHAVIOR II

1769

174.5

Morris navigation performance was analyzed in adulthood (e.g., C57BL/6J) exhibiting hyper-corticosterone secretion in response to stressors, as well as particularly marked brain catecholamine alterations. Behaviorally, BALB/cByJ mice exhibited a wide array of behavioral disturbances after stressors that are more pronounced than in other strains. Interestingly, BALB/cByJ mice fail to acquire a spatial learning response in a Morris water-maze paradigm. In view of the markedly marked stress reactivity of the BALB/cByJ mouse, it was of interest to determine if the spatial learning deficit in this strain could be modified by neonatal manipulation, just as such a manipulation has been found to dampen stress responses in mature animals. We found that the performance deficit, which is not evident when visual inanamaze cues are present, is apparent as early as 30 days of age. Moreover, using a cross fostering paradigm it was determined that the deficits were not related to maternal factors. If pups were handled (i.e., separated from the Dam for brief periods over the course of the initial 21 days postpartum) the behavioral deficits were prevented. These data were related to the neurochemical and endocrine changes induced by stressors and the modification of such effects by neonatal handling.

174.6

Behavioral stress has effects on LTP and learning and memory. Autoradiographic studies of ligand binding to the AMPA receptor have also shown that the binding characteristics of the receptors are rapidly altered in the hippocampus and other brain structures following stress. While these studies reported a general increase in [35S]AMPA binding to striatal membranes, some reports (Bmax, or Kd), and type (high affinity or low affinity of receptor change have not been reported in detail. To evaluate the nature of the changes in AMPA receptors, we performed equilibrium saturation kinetic studies with [35S]AMPA on synaptic fractions (FD) prepared from both acutely stressed (60 tail shocks: 1 mA, 30-90 s interval) and control Long Evans rats. As previously reported, saturation kinetic data were better fitted to a two site vs a one site model, indicating the existence of a small population of high affinity sites (Kd = 20 nM) and a large number of low affinity sites (Kd = 600 nM). Stressed animals exhibited a significant increase in the maximal number of low affinity binding sites without significant changes in high affinity sites. As the low affinity receptors have been postulated to be synaptic receptors, whereas the high affinity receptors are enriched in nonsynaptic subcortical fractions, the results suggest that stress might alter some steps involved in receptor insertion or internalization. The results might also account for the impairment of LTP associated with stress, inasmuch as LTP shares the same cellular mechanisms of expression as via AMPA receptor activation. 174.7
BEHAVIORAL STRESS ENHANCES LTD IN RAT HIPPOCAMPUS. J. J. Kim1, M. R. Foy2, and R. F. Thompson1.
1Neurosciences Program, Univ. of Southern Calif, Los Angeles, CA 90089-2520 and 2Psychology Dept., Loyola Marymount Univ., Los Angeles, CA 90045-2669.

Uncontrollable and unpredictable stress is known to impair certain learning tasks, and also to impair hippocampal long-term potentiation (LTP). In the present study, we examined the effect of stress on another form of hippocampal synaptic plasticity, long-term depression (LTD). Hippocampal slices were prepared from adult Long Evans rats immediately following exposure to behavioral stress (60 tailshocks: 1 mA x 1-3, 30-90 s apart; animals immobilized). Field EPSP recordings (amplitude and slope) from dentrites in area CA1 following Schaffer/commisural stimulation (900 pulses at 1 Hz) indicate that LTD was significantly greater in stressed animals than that recorded from control animals. These results argue that an additional form of hippocampal plasticity can be modified by behavioral stress.

174.8
RECURRENT BRAIN POLYAMINE RESPONSE AFTER REPEATED STRESS AND ITS ENHANCEMENT AFTER AN ADDITIONAL DELAYED STRESS EPISODE. V.R. Gilad5 and G.M. Gilad. Faculty of Med., Technion-Israel Inst. of Technology, Haifa, Israel.

Rapid changes in brain polyamine (PA) metabolism, termed the PA response, are generally induced with a magnitude proportional to the stressor intensity. The effects of repeated stress episodes on the PA response are unknown. Therefore, we examined effects of repeated restraint, a relatively mild stressor, on diacetylcarnitine decarboxylase (DCC) and 8-adenosylmethionine decarboxylase (SAM-DCC), two key PA synthesizing enzymes. Rats were subjected to 2 h restraint once daily for 5 days, and enzyme activities, assayed in the hippocampus 6 h after the beginning of each stress episode. We found that DCC activity was increased repeatedly after each stress episode to about 130% of control. In contrast, SAM-DCC activity was reduced after the first episode (86% of control), but remained unchanged thereafter. Additional stress application, after a 24 h break in the last 5th episode, resulted in a much larger DCC increase (180% of control), without a change in SAM-DCC activity. We conclude that: 1) even mild stress can induce a characteristic PA response in the brain; 2) the OCD response is induced after each episode of stress, and 3) additional stress episode applied days after cessation of the initial stressful stimuli, results in a much greater increase in OCD activity. The study implicates an overactive PA response in the (mal)adaptive response to stressful events.

174.9
CHANGES IN BOMBESIN (BN) LEVELS AND ITS RECEPTORS IN THE RAT BRAIN FOLLOWING ACUTE IMMUNOZIMMERSION STRESS. P. Kent1, Z. Meraj2, and H. Anisman1.
1Psych & 2Pharmacol, Univ of Ottawa, 2Carleton University, Ottawa, Ontario, Canada.

The neurochemical mechanisms underlying the coincident activation of the pituitary-adrenocortical and the sympathetic nervous system in response to stress remain unclear. Central injection of the neuropeptide bombesin (BN), potently releases epinephrine from the adrenal medulla and adrenoreceptors located in the pituitary, and elicits behaviors typically associated with increased emotionality and arousal. The objective of the current study was to determine whether stress is associated with changes in the endogenous levels of BN-like peptides and/or their receptors. Male Sprague-Dawley rats were subjected to acute immobilization stress for 0 (control), 30 min or 120 min. Plasma ACTH levels increased in response to stress, peaking at 30 min. BN-like Immunoreactivity increased significantly at the hypothalamus and medulla, within 30 min, and declined to control levels by 120 min. The peptide levels in several other regions, including the hippocampus, striatum, midbrain, pituitary, and pons, failed to change significantly. Autoradiographic analysis of BN/GRP receptor densities for 8 regions examined are listed in ascending order: hippocampus, nucleus tractus solitarius (NTS), paraventricular (PVN), arcuate (Arc) and paraventricular hypothalamic nuclei, paraventricular thalamic nucleus, central amygdala and nucleus accumbens. Significant increases in binding were found after 30 and 120 min of stress in the NTS and after 120 min in the PVN and Arc. These data indicate that BN-like peptides may serve to mediate and/or integrate responses to stress.

174.10
THE PROTECTIVE EFFECTS OF STRESS CONTROL MAY BE MEDITATED BY INCREASED BRAIN LEVELS OF BENDAZEPINE RECEPTOR ANTIGENS. R.C. Drugan, A.S. Basile, J.H. Ha, and R.J. Ferland. Department of Psychology, Brown University, Providence, RI 02912 and Laboratory of Neurosciences, NINDS, NIH, Bethesda, MD 20892.

Control over stress protects against many of the deleterious effects of stress exposure, but the endogenous mediators responsible for these prophylactic effects are not known. In vitro radioligand binding and neurochemical analyses, we demonstrate that exposure to escapable stress results in brain and behavior changes reminiscent of benzodiazepine administration. The stress control group shows significant protection against picrotoxin-induced seizures, reductions in [3H]5-bromo-5-chloro-1,3-dihydrobenzodiazepine binding at or near the chloride channel and a 3-fold increase of benzodiazepine-like agonists in brain comparison to both yoked-inescapable shock and non-shock controls. These observations suggest that active coping behavior leads to the release of endogenous benzodiazepine-like agonists that protect the organism from stress pathology. STRESS: NEUROCHEMISTRY AND BEHAVIOR II

724.11
ALCOHOL AVAILABILITY AND AGGRESSION LEVEL AFFECT BEHAVIOR IN THE OPEN FIELD AND PLUS MAZE, AND 5-HT RECEPTORS IN TRIAD-HOUSED RATS. L.A. Podolec*, X. Huang, S. Lason, C. Quinn, D. Benjamin, Center of Alcohol Studies, Rutgers University, Piscataway, NJ 08855.

Individually- and triad-housed male Long Evans rats were tested in the open field and elevated plus maze. Subjects were 18 triads and 14 single caged rats, half of which received 6% solution of ethanol (ET) or water. Dominance status was determined by monitoring behavior during the initial 30 minutes of colony formation. Initially, the number of attacks by the Alpha (α) on the Beta (β) and Gamma (γ) was observed daily to classify triads by aggression level. Body weight loss 1 day after group housing was similar for β and γ but minimal for α, and singles gained. Lean weight gain was observed in high aggression (HT) rats in middle aggression (MT) or low aggression triads (LT).

Weight gain of α was not affected by aggression level. Only the β were affected by ET availability, with lower weight gain overall. Headpokes were affected by level of aggression; in LT headpokes were less frequent, and of shorter total duration, but in MT, β showed the lowest duration and frequency. In the LT, ET increased headpoking duration and frequency. In triads with ET available, α had significantly lower headpoking frequency. In the MT, ET decreased grooming, but had no effect in LT. In triads with ET available, the MT showed significantly less grooming than MT or LT. In the β, availability of ET increased central tone significantly. The availability of ET produced unidirectional effects in singly housed, but not in triad-housed rats. 5-HT1A receptor binding was significantly affected by aggression level; whereas ET showed rank-related increases above control levels in β and γ, LT showed rank-related decreases in β and γ. Effects on 5-HT1A binding were also observed. These results demonstrate that aggression levels vary between ET availability and triad exemplars effects on 5-HT1A receptor binding and behavior (Supported by NIAAA 05396).

725.1
TEMPORAL REGULATION OF PREPROENKEPHALIN-A (PPE-A) mRNA EXPRESSION BY ESTROGEN IN THE POSTERIOR DORSAL MEDIAL AMYGDALE (MeApd) OF THE FEMALE RAT. C. B. Eckerson*, C. A. Printz and P. E. Morecraft, Dept. Anatomy and Cell Biology, Laboratory of Neuroendocrinology, UCLA School of Medicine, Los Angeles, CA 90024.

Gonadal steroids modulate reproductive behavior through their effects on intercellular signaling in the limbic-hypothalamic neural circuit. Within this circuit, the up-regulation of PPE-A mRNA (encoding pre-pro-enkephalin) by estrogen, in the ventromedial nucleus of the hypothalamus, has been correlated with reproductive behavior in the female rat. The MeApd also is an integral part of the limbic-hypothalamic neural circuit that plays an important role in opioid regulation of female reproductive behavior. To examine the temporal effects of acute estrogen exposure on PPE-A mRNA levels in the MeApd, adult ovariectomized Long-Evans rats were injected with 50 μg estradiol benzoate (EB); perfused at one of nine successive time points from 0 to 72 hours after injection and used for quantitative in situ hybridization histochemistry of PPE-A mRNA. PPE-A mRNA was localized to neurons within the MeApd using an α2,β-labeled, single-stranded, RNA probe complementary to the entire coding sequence of the PPE-A mRNA (gift from Drs. Yoshikawa and Kato, NHI, Bethesda, MD). EB treatment induced a biphasic increase in the number of PPE-A mRNA-expressing cells in the MeApd with maximal levels occurring at 1 and 24 hours post treatment. These peaks were interrupted by a dramatic decrease in the number of PPE-A mRNA expressing cells at 4 hours after EB injection. By 72 hours post-EB, PPE-A expressing cell numbers returned to basal levels. The biphasic increase in PPE-A mRNA expressing cell numbers with acute estrogen treatment supports the idea that there are two temporal and perhaps mechanistic regulatory events for PPE-A transcription within the MeApd. Supported by NS 21120.

725.2
PROGESTERONE ENHANCES AN ESTRADIOL-INDUCED INCREASE IN FOS EXPRESSION BY HYBRIDIZATION IN THE POSTERIOR DORSAL MEDIAL AMYGDALE (MeApd) OF THE FEMALE RAT. A.P. Auger and J.D. Blaustein*, Neurosci. & Behav. Program, Univ. of Massachusetts, Amherst, MA 01003.

Female rats. The temporal control of reproductive behavior depends on the sequential presence of estradiol followed by progesterone. Although treatment with high doses of estradiol has been shown to increase local immunostaining for Fos protein, an immediate early gene product that is expressed upon cellular activation, another report conflicts with this finding. However, the previous reports agree that subsequent treatment with progesterone has no apparent effect on Fos expression. In order to resolve this discrepancy and investigate possible effects of progesterone, we used Fos immunocytochemistry combined with computer-aided image analysis. In experiment one, we found that treatment with 5 μg of estradiol increased Fos immunoreactivity (Fos-IR) within the medial preoptic area and the dorsal medial hypothalamus. Subsequent treatment with 500 μg of progesterone one hour before perfusion increased the intensity of the immunostaining within the medial preoptic area and the dorsal medial hypothalamus, although it had no significant effect on Fos-IR cell number. In experiment two, a lower concentration of Fos antisera was used in order to diminish the immunostaining sensitivity to a level in which no increase of Fos-IR cell number was observed after treatment with estradiol. Under these immunocytochemical conditions, subsequent treatment with progesterone increased the number of Fos-IR cells in the medial preoptic area, the dorsal medial hypothalamus and the steroid receptor-rich area lateral to the ventromedial hypothalamus. Thus, treatment with behaviorally-effective doses of both estradiol and progesterone induces Fos expression in localized regions of female rat brain. (supported by NS 19327 from NIH and RSDA MH 00685 from NIMH)

725.3

Progesterone (P) effects on extracellular (EC) 5HT were monitored in the ventromedial hypothalamus (VMH), midbrain central grey (MCG) or medial preoptic area (mPOA) using microdialysis. Rats primed with estradiol benzoate (5 μg) were anesthetized with chloral hydrate (400 mg/kg, i.p.). Samples were collected at 20 min intervals. Once a stable 5HT baseline was obtained, rats were injected (s.c.) with 0.5 mg xylazine (V). In the mPOA, EC 5HT levels were not affected by P. Significant decreases in EC 5HT levels were present in the MCG and VMH 40 and 60 min after P, respectively. In the VMH, EC 5HT decreased to 57 ± 5.9 % of pretreatment values 100 min after P. 5HT levels in the MCG decreased to 56 ± 5.1 % of pretreatment values 80 min after P. The decreases in EC 5HT in the VMH and MCG persisted during the remainder of the sampling period. 5HT baseline levels were stable in the respective V-treated groups. These results demonstrated thatinfusions decreases 5HT release in the MCG and VMH occur in vivo and support previous studies which suggest that decreases in 5HT activity in the VMH and MCG contribute to the facilitation of female receptivity. (Supported by NIH 3909451)

725.4
SUBCELLULAR LOCALIZATION AND KINETIC PROPERTIES OF AROMATASE IN THE RAT BRAIN. C.E. Rosselli*, Department of Physiology, Oregon Health Sciences University, Portland, OR 97201.

The conversion of testosterone (T) to estradiol is catalyzed by cytochrome P450 aromatase. In situ aromatization is required for the full expression of the effects of T in the brain. This study examined the subcellular distribution and reaction kinetics of aromatase in the adult rat brain. Preoptic area (POA), hypothalamus (HYP) and amygdala (AMYG) were homogenized in isotonic sucrose buffered with potassium phosphate. Homogenates were fractionated by a sequential series of centrifugations to obtain: 800 g pellet (nuclei); 11,000 x g pellet (mitochondria and synaptosomes); 100,000 x g pellet (microsomes); and 100,000 x g supernatant (cytosol). Aromatase activity (AA) was measured using a previously validated 1H2O assay. Marker enzymes were measured to identify organelles in the different subcellular fractions. We found that AA in all 3 tissues was enriched 8-14 fold in microsomes, but not in other cell subfractions. The addition of either a NADPH-generating system or 1 mM NADP+ to the reaction mixture stimulated AA in all subfractions, whereas NADH was only minimally effective. Affinity constants were equivalent in all subfractions (~ 10 μM) suggesting that only one form of the enzyme is present in the rat brain. One week after castration, AA was significantly reduced in all cell subfractions of POA and in the homogenate and microsomes of HYP. Castration did not significantly alter AA in any subfraction of AMYG. To more critically evaluate subcellular localization, AA was measured in purified synaptosomes. AA was not enriched in these preparations suggesting that aromatase is not substantially associated with nerve terminals in rat brain.

**HYPOTHALAMIC OPIOID RECEPTORS IN MALE JAPANESE TELEOST FISH, HAPLOCHROMIS BURTONI.**

T. Busenick* and R.D. Fernsall, Department of Psychology, Stanford University, Stanford, CA.

Galanim, a 29 amino acid peptide present in both gut and brain, has been called a hypothalamic-hypophysiotropic hormone because it can effect release of pituitary hormones such as growth hormone, prolactin, and gonadotropins. Galanim and its mRNA can be co-localized in gonadotropin-releasing hormone (GnRH) cells in the hypophyseal/pretorpic area (POA); although it is difficult to visualize the role of galanim in regulating GnRH release in the teleost fish, H. burtoni. Males of this species exhibit size changes in the POA of GnRH cell population that are correlated with changes in social status and reproductive maturity. These changes in cell size are plastic; that is, up-grading or down-grading the social status of an adult H. burtoni male results in a corresponding increase or decrease in the size of the GnRH cells in the POA. We addressed three questions: 1) Is there a galanim-like immunoreactivity (GAL-LI) present in the POA of H. burtoni males? 2) Do these GAL-LI cells project to the pituitary? and 3) Do these GAL-LI exhibit a correlation between cell size and social/adaptive productivity similar to that which has been reported for GnRH cells in the POA? H. burtoni males were observed behaviorally for 4 weeks to establish social status, then sacrificed, and cryostat sections of the POA were stained for GAL-LI. We observed that 1) GAL-LI cells were present in the POA of all males, 2) the majority of these GAL-LI cells did not contain fast DI suggesting that only a very small minority of these cells may project to the pituitary, and 3) the GAL-LI cells showed a tendency towards a correlation between social status and cell size with socially dominant males having larger GAL-LI cells although the size differential was small.

Supported by NIH HD 23799 to RDP and NSERC post-doctoral scholarship to TB.

T25.6

**EVOLUTION OF THE GnRH FAMILY OF PEPTIDES INFERRED FROM cDNA SEQUENCES.**

R.C. Feltis* and R.D. Fernsall, Department of Psychology, Stanford University, Stanford, CA.

The decapeptide GnRH is an important regulator of vertebrate reproductive function and has been highly conserved during the course of vertebrate evolution. Most, and perhaps all, vertebrates express at least two forms of GnRH. Chicken-I GnRH (cGnRH-I) is the most ubiquitous form, and has been identified in every major vertebrate taxon. Previously it was thought that eutherian mammals do not express cGnRH-II but the gene encoding this form has now been cloned and sequenced in members of this taxon as well. While it has potent gonadotropin releasing action in vitro, cGnRH-II neurons are generally confined to midbrain regions, and with the possible exception of elasmobranchs, are not thought to function in gonadotropin release in vivo. In this study we used a variety of evolutionary distance measuring and phylogenetic techniques to analyze amino acid and cDNA sequences, both to explore the evolutionary history of this family of peptides and their functional divergence across vertebrates. Our results suggest that there are two distinct GnRH lineages, which we call GnRH-I and GnRH-II, which resulted from a single gene duplication event early in the course of vertebrate evolution. The GnRH-I lineage includes mammalian GnRH (mGnRH), chicken-I GnRH (cGnRH-I) and salmon GnRH (sGnRH) and all other forms of placental origin. The GnRH-II lineage includes (cGnRH-II and other forms expressed in the midbrain. All forms of GnRH exhibit, at both the cDNA and amino acid levels, a high degree of sequence identity in the GnRH region, somewhat less loss so in the signal sequence, and markedly less so in the associated peptide coding region. All GnRH-I forms have a single associated peptide (GAP), while GnRH-II forms have two associated peptides. The low degree of conservation of these associated peptides implies that whatever function they serve, if any, requires little in the way of sequence specificity.

T25.7

**THE POSSIBLE ROLE OF NPY Y1 RECEPTORS IN THE CONTROL OF LORDOSIS.**

Jan Thornton* and Laurie Holcomb, Neuroscience Program and Dept. of Biology, Oberlin College, Oberlin OH 44074.

Previously we have shown that NPY plays a facilitatory role in the control of lordosis. These studies examined if NPY acts at Y1 receptors to affect lordosis. Adult guinea pigs were ovariectomized and implanted with a cannula into the lateral ventricle. In Exp 1, females were injected with 20ng Estradiol Benzoate (EB) followed 40h later by .5mg Progesterone (P). Females which displayed lordosis after P were injected ICV with either 0.5 or 5 ug of the NPY 1 agonist 1e3u1, pro34 NPY, or were used as controls. The 5 ug dose of the Y1 agonist significantly increased lordosis responding. In Exp 2, ovariectomized females were injected with 20ug EB and tested for lordosis 40h later. They were then injected ICV with NPY 1 agonist (5ug) or were used as controls. The Y1 agonist did not facilitate lordosis in these females. These data suggest that 1) NPY acts at Y1 receptors to facilitate lordosis and 2) NPY may affect some progesterone mediated component of lordosis since only EB+P but not EB induced lordosis was facilitated.

T25.8

**AQUEOUS EXTRACT ACTION OF RUTA CHALEPENSIS ON SPERM MOTILITY.**

Muccitelli and Ferguson (1) point out flaws in the experimental design of a recent study by Kupitz and Atlas (2), where the experimental condition do not guarantee that the applied concentration of extract was present at the membrane surface of the mature egg, and that a more likely target for the compounds is the sperm if any of the applied compounds interfered with sperm activation or motility. This prompted us to tested aqueous extract of Ruta chalepensis on rat sperm motility, as it has been suggested that Ruta chalepensis extract has an anticonceptive action, and it is used in traditional medicine as vaginal cream before sexual intercourse. Exposing sperm recently obtained from rat testis to Ruta chalepensis extract, we found under light microscope: reduction in motility, decomposition of tail motility, until complete hamobilization of spermatozoa without determining the involvement of ion channels. This Ruta chalepensis effect may play a role in its postulated anticonceptive action.1. Science 263:198, 1994; 2. Science 261:484, 1993.

Glutamate receptors may play an important role in the pathophysiology of schizophrenia and the motor side effects of chronic neuroleptic drug treatment. We examined changes in the binding of three glutamate receptor subtypes using [3H]-MK801 (NM3DA receptor antagonist), [3H]-CNQX (AMPA-R antagonist) and [3H]-Kainic acid (kainate-R antagonist) in vitro receptor autoradiography following one month's treatment of rats with SCH23390 (0.5 mg/kg/day), clozapine (CLZ) (25 mg/kg/day) and haloperidol (HAL) (1.5 mg/kg/day), or raclopride (RAC) (10 mg/kg/day). Chronic SCH treatment elevated [3H]-MK801 binding in the hippocampal formation with significant increases in CA3 and dentate gyrus. This result suggests a specific role for dopamine D2 receptors in the regulation of hippocampal NMDA receptor function. In contrast, haloc or Rac treatment did not alter [3H]-MK801 binding in any of the brain regions analyzed. However, chronic CLZ treatment caused a significant decrease in [3H]-MK801 binding in caudate putamen (medial: -34%, lateral: -22%) without affecting the hippocampal formation, nucleus accumbens or the cortex. This might explain why it produces minimal extrapyramidal side effects. Results for AMPA and kainate receptors will also be reported. Supported by MH44211 and Sigma Xi grant (F.I.T.)

726.2  REGULATION OF DOPAMINE RECEPTOR BINDING FOLLOWING CHRONIC NEUROLEPTIC TREATMENT. F.J. Tarazi*, W.J. Florin and Jan Creese. Center for Molecular and Behavioral Neuroscience, Rutgers University, New Jersey, NJ 07848.

We examined changes in dopamine receptor binding in various brain regions following one month's treatment of rats with SCH23390 (0.5 mg/kg/day), haloperidol (HAL) (1.5 mg/kg/day), raclopride (RAC) (10 mg/kg/day) or clozapine (CLZ) (25 mg/kg/day) using in vitro receptor autoradiography. Chronic SCH treatment significantly increased [3H]-SCH23390 binding in nucleus accumbens (NA) [+55%] and caudate putamen (CP) [+28%] and in NA [+89% and 45%]. Rac treatment also elevated [3H]-YM-091512-I and [3H]-spiperone binding in CP (+28% and +25%). [3H]-Raclopride binding was only increased in the lateral CP [+17%] of HAL-treated rats. Since [3H]-YM-091512-I and [3H]-spiperone have similar affinities for D2, D3 and D4 receptors but the raclopride has low affinity for D4 receptors, these results suggest that D2 receptors are majorly upregulated by the HAL treatment. Thus, [3H]-YM-091512-I and [3H]-spiperone binding in the presence of a D2 and D4 receptor saturating concentration of raclopride (300 nM) to quantitatively selectively putative D2 receptors was significantly increased in both the CP and NA (+70% of HAL-treated rats). Interestingly, the binding of both in radioligands in the presence of 300 nM raclopride was significantly increased in CP (+26%) but not in NA of CLZ-treated rats. Supported by MH44211 and Sigma Xi grant (F.I.T.)

726.3  AKATHISIA-LIKE RESPONSE TO HALOPERIDOL IN RATS TRAINED TO PERFORM A SUSTAINED ATTENTION TASK. B.J. Brockel* and B.C. Fowler. Univ. of Mississippi Medical Center, MS 38677.

Rats were trained to remain immobile with their heads in observation tunnels where a brief (0.12 s) visual stimulus were presented. The rats learned to react to 1 of 3 visual stimuli by executing a nose-poke response within 2 s of stimulus presentation. Exits from the tunnel were penalized by a 7.5-s time-out, a contingency that made the rats refrain from locomotion for most of the 900-s session. Forty animals were equally divided into 5 separate groups with each group receiving its own dose (0.0 to 0.12 mg/kg) of haloperidol (HAL) daily for 23 days. HAL decreased reinforcers and dose-dependently increased proportion of errors of omission, suggesting that HAL not only reduces responding but also produces attentional deficits. Number of head exits from the observation tunnel was dose-dependently increased by Hal. This effect showed gradual tolerance across the chronic dosing. Head exits in this paradigm may serve as an animal model of akathisia. Supported by MH43429.

726.4  HALOPERIDOL-INDUCED MONOAMINE DEPLETION: TYROSINE HYDROXYLASE-NEGATIVE SUBSETS OF DOPAMINE NEURONS ARE AFFECTED IN GASTROPOD CNS. D. Bakkarinen*, E. Vaneckova, I. Mihalikova, M. Baker, B. Croft*.

Long-term treatment with haloperidol (HAL) was shown to result in depletion of specific subsets of putative dopamine (DA) neurons (Neuroreport 1994, 5:67). With the aim of further investigating what appears to be a novel action of HAL, the present study was performed on adult and juvenile specimens of the pond snail Lymnaea stagnalis kept for up to 40 days in 0.5-2.0 µM HAL solutions. HPLC-EC analysis of the CNS revealed a concentration-dependent DA depletion which reached 20-50% over the first 4-8 days and thereafter remained stable. A comparable DA depletion was observed in the leaf meal Achatina fulica as a result of daily HAL injection, 1 µg/kg for 4 days). In cats, a transient, dose-independent, serotonin depletion was also observed which, by day 12, reached to 60% with follow-up confirmed (for 0.5 µM HAL) or partial recovery by day 20 of treatment. Glycine-mediated-induced neurodegeneration was found undetectable in some, but not all, identifiable clusters of DA neurons in the CNS of animals treated with HAL for 3-4 days or more. A peculiar feature of HAL-sensitive DA neurons was that they were non-reactive to antibodies raised against tyrosine hydroxylase, whereas HAL-resistant DA neurons showed such reaction. Thus, the previous and present reports suggest that the depleting action of low doses of chronic HAL observed in specific subsets of DA neurons may be a phylogenetically conserved characteristic which, if generalized to vertebrates, may account for therapeutic effects of this and related drugs.

726.5  NITRIC OXIDE SYNTHESIS INHIBITION ATTENUATES HALOPERIDOL-INDUCED SUPERSENSITIVITY. C.M. Pudinsak*, M.A. Bozarth. Department of Psychology, University at Buffalo, Buffalo, NY 14260-4110.

Previous work has shown that nitric oxide is involved in sensitization to the locomotor-stimulating effect of repeated cocaine injections (Pudinsak & Bozarth, Life Sci. 53: 1517-1524, 1993.). Increased responsiveness to stimulants can also be produced by chronic dopamine-D2 receptor blockade. This study examined the effectiveness of an oxime synthesis inhibitor in blocking the supersensitization following chronic neuroleptic treatment (i.e., dopamine-receptor blockade). No-nitro-L-arginine-Na (L-NAME) was used to inhibit nitric oxide synthesis, while haloperidol was used to produce supersensitivity by chronically blocking dopamine receptors. Male, Long-Evans rats were tested in locomotor activity chambers for 30 min following an injection of normal saline (1 ml/kg, i.p.). On the next day, they were retested following an injection of cocaine hydrochloride (10 mg/kg, i.p.). After that they were treated daily with haloperidol (0.2 mg/kg, i.p.) for 14 days. Half of the rats were pre-treated with cocaine (0.5 mg/kg, i.p.) and haloperidol (HAL-NAMe, 30 mg/kg, i.p.) 30 min before their haloperidol injections. Seventy-two hours after their last injection, rats were injected with cocaine (10 mg/kg, i.p.) and were tested for 30 min in locomotor activity boxes. Rats treated with saline plus haloperidol showed greater stimulation of locomotor activity than their first cocaine test, while rats treated with L-NAME plus haloperidol showed little change in activity. This finding suggests two possibilities: the activation of nitric oxide synthesis antagonized the haloperidol-induced supersensitivity to cocaine. Similar mechanisms may be involved in neuroleptic-induced supersensitivity and stimulant-induced sensitization.

(Supported by DA00285 from the National Institute on Drug Abuse.)

Antipsychotic drugs are known to cause a variety of neuropsychiatric side effects including the precipitation of seizures. However, as yet there is no animal model which is predictive of seizure liability. In the present study, several clinically used antipsychotic drugs were evaluated for their ability to affect the onset of seizures induced by infusion of the chemical convulsant PTZ in rats. In this species, PTZ-induced seizures were not only electrocorticographically detectable in some, but not all, identifiable clusters of DA neurons in the CNS of animals treated with HAL for 3-4 days or more. A peculiar feature of HAL-sensitive DA neurons was that they were non-reactive to antibodies raised against tyrosine hydroxylase, whereas HAL-resistant DA neurons showed such reaction. Thus, the previous and present reports suggest that the depleting action of low doses of chronic HAL observed in specific subsets of DA neurons may be a phylogenetically conserved characteristic which, if generalized to vertebrates, may account for therapeutic effects of this and related drugs.

876.7

Social isolation of postweanling rats results in a syndrome of behaviours and a pattern of biochemical alterations that are at least in part, indicative of enhanced dopaminergic activity. Given the postulated role of dopaminergic overactivity in schizophrenia, and the need to develop new, non-pharmacological therapeutic models, the present study began investigating the behavioral effects of social isolation in rats, and interactions with antipsychotics. Male Wistar rats were housed either singly ("isolated" condition) or in groups of 4 ("condition") beginning at 25 days of age. When tested 5 weeks later, isolated rats placed in a novel test environment showed a significant locomotor hyperactivity relative to grouped rats. This hyperactivity was particularly notable during the first 10 min of testing when initial exploratory levels of activity are high. Isolated rats also tended to show decreased pupped prepulse inhibition of acoustic startle using either auditory prepulse (weak white noise burst) or a visual prepulse (light flash). Dose-response studies indicate that the locomotor hyperactivity can be reduced by the DA antagonist haloperidol at doses that did not significantly reduce baseline levels of activity. Preliminary findings of increased dopamine concentrations in the striatum and n. accumbens are also consistent with enhanced dopaminergic activity in the isolates. These data support the conclusion that the locomotor hyperactivity produced by social isolation is attributable, at least in part, to dopaminergic hyperactivity.

876.9

In addition to dopamine receptors, both a-adrenoreceptors and adrenoreceptors are implicated in the pathogenesis and treatment of schizophrenia. Riociguat (RIS) is of interest in view of its high affinity at 5-HT2A/2C receptors vs. D2 receptors (Ki = 9.28 ± 0.8 vs. 83) as compared to haloperidol (7.99 ± 0.8 vs. 87). Furthermore, it was recently proposed that m/mic (male) rats are less susceptible to the apomorphine-induced stereotypies than female rats. We used the S 17828 and S 14956, novel benzimidazoles, to investigate the potential of RIS in treating apomorphine-induced hyperactivity. In a second study, we show that the novel benzimidazoles, S 17828 and S 14956, also manifest high affinity at 5-HT-2A/2C receptors vs. D2 receptors; pKi were 8.38/7.28 vs. 3.73 for 5-HT, and 8.5 vs. 3.72 for D2. Interestingly, the S 17828 and S 14956, in the same order, show low affinity at D1 sites as compared to RIS (8.9). Ex vivo, in (male) rats, S 17828 and S 14956 mimicked the in vivo effect of S 17828. Since these compounds may be useful in the treatment of schizophrenia and other neuropsychiatric disorders, further studies are warranted.

876.10

Disruption of LI, that is, the inability to ignore information that is irrelevant to the task at hand, has been proposed as a model for the attentional-cognitive deficits of schizophrenia. In the present study, we characterize this model by use of a three-step paradigm. After establishment of a stable baseline of behavioral indices (e.g., rate of errors), rats were divided into two groups: one first pre-exposed (PE) or not pre-exposed (NPE) to a series of tones. One day later, during a conditioning session, they were exposed to two tone-shock pairings and a 24 h. test, on the day following, rats were allowed to react as in the test. The time to completelicks 90-100 (s) and licks 100-110 (s) were measured and the suppression ratio (SR) was defined as 1-(s90/1) / (s100/1). It was found that genotype (200 vs. 300 g), pretreatment (combinations of either 600 or 1000 licks within 10 min), duration of pre-exposure (40 tones/40 min vs. 40 tones/15 min) and the duration of the interval between pre-exposure and testing (24 h. delay between sessions but not failed to disrupt LI in rats that received conditioning were performed on the same day. Under the former conditions, haloperidol, 2 x 0.1 and 2 x 0.16 mg/kg, i.p., evoked LI in rats pre-exposed to 10 tones. It is concluded that, in the LI-CER model, the intensity of the unconditioned stimulus is decisive for the induction of LI shift and that, based on the results obtained with d-j-amphetamine and haloperidol, this paradigm is an appropriate model for the characterization of antipsychotic drugs.

876.11

The antipsychotic sertindole (1,2-D,4,6(1,4)-chloro-1-(4-fluorophenyl)-indole-3-thiodiazole 2); is a poliolide, with high affinity for strionetion-5-HT1D (K(i) = 49.0 nM), 5-HT7, 5-HT4, 5-HT2A, and dopamine D2 receptors (K(i) = 4.1 nM) and receptors for a-adrenoreceptors (K(i) = 4.9 nM). In vivo studies have a long history in the rat (inhibition of amphetamine-induced head twitches; ED50 = 0.039 µg/kg, 24 hours after p.o. administration). Despite high affinity in vitro for dopamine receptors sertindole exerts no catalepsy, no EPS in the rat with 5-HT antagonists and no EPS in the rat with D1 antagonists and no EPS in the rat after 2 weeks of treatment. The receptor binding profiles will be presented and discussed in relation to the effects on A10/A9 dopamine neurons after chronic administration with the sertindole-induced inhibition of A10 dopamine neurons was found for some compounds. Results for the antipsychotics haloperidol, clozapine, and remoxpine will be included for comparison.

876.12

SM-13496 is a newly discovered antipsychotic that preferentially acts on dopamine D2 and 5-HT receptors. SM-13496 showed high to moderate affinities for D2 (K(i) = 1.44 nM) and 5-HT (K(i) = 26.8 nM) but had negligible affinities for D1, 5-HT, 5-HT1a, 5-b, muscarinic, GABA, benzodiazepine, a1, or glutamate receptors. Oral administration of SM-13496 blocked dopaminergic behaviors (e.g., methamphetamine-induced hyperactivity in rats and apomorphine-induced climbing behavior in mice) and selectively suppressed the conditioned avoidance response in rats (ED50 = 1.7 ± 0.9 mg/kg, i.p.). SM-13496 also inhibited 5-HT2 receptor-mediated behaviors (e.g., tryptamine-induced clonic seizure and p-chloroamphetamine-induced hyperactivity in mice) with negligible antipsychotic activity in the Vogel's conflict test (MED = 10 mg/kg).

Despite its potent D2 blocking activities, SM-13496 showed only negligible actions in inducing extrapyramidal side effects (i.e., catalepsy and bradykinesia, ED50 >1000 µg/kg, potentiation of anesthesia (ED50 >1000 µg/kg), muscle relaxation (ED50 >1000 µg/kg) and inhibition or potentiation of convolution (ED50 >1000 µg/kg). In conclusion, SM-13496 is a novel antipsychotic with minimal extrapyramidal and CNS depressive side effects.
726.13

5-HT1A RECEPTOR BLOCKADE BY SM-9018, A NOVEL 5-HT1A AND D2 ANTAGONIST, COMPETITIVELY BLOCKS ITS INTRACEREBRAL EFFECTS ON STRIATAL Dopamine D2 Receptors 

I. Lee*, T. S. Shin, E. S. Hwang, T. T. Lee, and J. H. Lee 

I. Chonbuk National University, Chonbuk, Korea, and Daiichi Pharmaceuticals Co., Ltd., Kohnan-ku, Osaka 554, Japan.

SM-9018 is a potent atypical antipsychotic that has potent 5-HT1A and D2 blocking activities. To elucidate the role of its 5-HT1A blocking activity in the striatum, we studied the effects of SM-9018 (5-HT1A/D2 antagonist) on haloperidol (D2 antagonist) and 5-HT1A antagonist on the induction of extrapyramidal side effects (i.e., bradykinesia), ex vivo c-fos mRNA expression in the striatum and in vitro acetylcholine (ACh) release from striatal slices. Antipsychotics (SM-9018, haloperidol) dose-dependently induced bradykinesia in the pole-depending behavior of mice with relative potencies consistent with their own in vitro acetylcholine release. Induction of bradykinesia was about 70 times weaker than haloperidol in inducing bradykinesia and had a 13 times higher therapeutic index (ant-apoliprotein/b Tradesomen) ratio. 5-HT1A antagonists (e.g., raloxifene) had no effects by themselves, but significantly reduced the haloperidol-induced bradykinesia. Oral administration of haloperidol markedly enhanced c-fos mRNA expression in the rat striatum (about 7 fold at 30 mg/kg) whereas SM-9018 showed only a slight increase (about 1.8 fold) at doses of up to 30 mg/kg. 5-HT1A antagonists failed to affect c-fos mRNA expression by themselves, but markedly attenuated the haloperidol-induced c-fos expression. Finally, SM-9018 was about 10 times weaker than haloperidol in enhancing the in vitro AChrelease upon 3Hz electrical stimulation while it was as potent as haloperidol in reducing D2 receptors and in antagonizing the inhibitory effects of exogenous quinpirole (a D2 agonist) on [3H]ACh release. These results suggest that the 5-HT1A blocking activity of SM-9018 counteracts its antinoceptive actions at the striatal D2 receptors, which seem to contribute to its low incidence of extrapyramidal side effects.

726.15

Intrinsic activity may be an essential determinant of the clinical antipsychotic profile of partial dopamine (DA) 2 agonists. In order to determine the utility of preclinical tests for estimating intrinsic activity we measured the effects of a series of partial DA agonists in models commonly used to characterize dopamine DA2 agonists in vivo and compared the results to the maximal inhibition of forskolin-stimulated cyclic AMP accumulation in GH4C1 cells expressing the human D2 receptor in vitro (cAMP). In vivo tests included subcutaous nigra dopamine neuron firing (DNR), gamma-butyrolactone-stimulated brain dopamine synthesis (GBL) and intracerebral microdialysis (IDM) in rats. Drugs were tested at 1 μM in cAMP, a level verified as supramaximal for selected agonists. Dose-effect curves were determined for DNR (i.v.) and high single doses were used for GBL (i.p.).

Relatively intrinsic activity in cAMP was: apomorphine > B-HT920 = EMS38352 > CI-1007 > terguride > (-)-3-PPP > SDZ 912 > haloperidol. Maximal effects in DNR and GBL revealed a similar order of intrinsic activity. However, maximal effects in DNR and GBL suggested: apomorphine = B-HT920 and CI-1007 > (-)-3-PPP. While apomorphine and B-HT 920 produced large decreases in striatal DA overflow in IDM, SDZ 912, terguride, (-)-3-PPP and haloperidol caused decreased DA overflow. The close agreement with results from the cAMP assay suggest that the GBL and IDM tests may be useful for estimating the DA agonist intrinsic activity, while the IDM test does not discriminate between weak partial agonists.

726.16

S 21357-1 (Trihydrocholine of 3-(2,4,6-tetrafluorophenyl)-N-methylpropenamide) has been shown to be a potent and selective NMDA receptor antagonist in vitro with high selectivity for the NMDA (Kb = 2.3 nM) and non-NMDA (Kb = 25-46 nM) receptors and with low affinity (Kb = 1000 nM) to the NMDA, α and β-agonists. S 21357-1 was evaluated in the anxiodyne test battery which may be able to assess escape and defensive reactions of a mouse after exposure to a predator (i.e. a rat). The animals were tested in the oval runway in two situations: after exposure to the predator stress and injection of different doses of our putative anxiolytic treatments. Two doses of 0.125 and 0.5 mg/ml were tested (respectively 20% and 10% of the time spent in the open compartment with a possible range of 0-100%) and the presence of the predator reproducing a panic attack. In the first situation, S 21357-1 was able to prevent the increase of the jump escapes induced by the stress and the stress-induced decrease of wall rears at the doses of 0.125, 0.5 and 2 mg/ml, in addition, 32-50% reduced the increase of the wall climbs only at the lowest dose. In the second situation, S 21357-1 also reduced the escape behavior: the number of avoidance was reduced at the doses of 0.125 and 0.5 mg/ml (respectively 19% and 14%), as well as the avoidance distance (94% at the doses of 0.125, 0.5 and 2 mg/ml, respectively). The forced contact, S 21357-1 significantly decreased the frequency of walking towards the rat at 0.125, 0.5 and 2 mg/ml, respectively 13%, 21% and 10% (p<0.01). The time spent in the open compartment exploratory in mice in dose-dependently increased the number of transitions in the oral doses of 0.25, 1 and 4 mg/ml respectively (p<0.02, p<0.04, p<0.001) and the time spent in the open compartment with a possible range of 0-100% and the presence of the predator reproducing a panic attack. The effects of S 21357-1 showed anxiolytic-like activity in the compartment exploratory in mice: it dose-dependently increased the number of transitions in the oral doses of 0.25, 1 and 4 mg/ml respectively (p<0.02, p<0.04, p<0.001) and the time spent in the open compartment with a possible range of 0-100% and the presence of the predator reproducing a panic attack. These results suggest the interest of S 21357-1 as an antipsychotic-like and anxiolytic-like agent with minimal side effects.

727.1

THE DELAYED ANTICHALFECT EFFECT OF MK-801 IN RATS: SIGMA VERSUS NON-SIGMA (5-HT1A) RECEPTOR BLOCKADE. S.C. Lee and B.L. Commissaris, Dept. of Pharmaceutical Sciences, Wayne State Univ., Detroit, MI 48202 U.S.A.

The present studies examined the receptor mechanism for the delayed anticholinetic-like effect produced by diazoxide (MK-801) in Conditioned Suppression of Trialling (CST) conditioned conflict paradigms. Two questions were addressed: [1] Do other agents which reduce human MNS neurotransmission be antagonistic to MK-801 in the CST? [2] What treatment(s) can block the MK-801 effect? In Experiment 1, female rats were tested in the CST conflict task using a multiple within- day testing schedule (3 conflict sessions/day: 2 hrs/session). A thorough (0–60 hours in 6-hour interval) dose-effect of MK-801 and a variety of agents which reduce human MNS neurotransmission was determined. MK-801 (4 mg/kg, IP) exerted a delayed anticholinetic effect with a latency to onset of approximately 12 hours and a maximal effect at approximately 24 hours. In contrast, other MNS antagonist exerted a delayed anticholinetic effect, although CPP and AP-D did produce modest anticholinetic effects at a short interval (i.e., 40 minutes) pretreatment interval. In Experiment 2, the effects of 0.2 mg/kg MK-801 were selectively antagonized by the sigma agonist quinpirole (0.1 mg/kg, IP) in contrast to the anticholinetic antagonist mecamylamine (0.2 mg/kg, ICV), the opiate agonist naloxone (1.0 mg/kg, IP) and the benzodiazepine antagonist Ro-15-1788 (0.5 mg/kg, IP) did not antagonize MK-801. Together, the delayed anticholinetic effect of MK-801 may due to its action at MNS, sigma, and D2 receptors. (Supported in part by NIMH 41171).
277.3
EFFECT OF CARBAMAZEPINE ON PREGNENOLONE SYNTHESIS IN C57 GLIOMA CELLS AND RAT BRAIN
E.S. Park, K. Kozuma**, H.K. Mohri, and W.J. Potter. Section of Clinical Pharmacology, NHL, Bldg 10, 8th 2046, Bethesda, MD, 2002

Although carbamazepine (CBZ) has proven effective in the treatment of both neurological and psychiatric disorders, its mechanisms of action remain unclear. We have begun to explore the hypothesis that CBZ may affect the brain levels of pregnenolone, a neurosteroid known to modulate GABA receptor in CNS. In the present study, cultured C6 glial cells were incubated with CBZ at concentrations of 1 to 100 μM for 0 to 120 min. After the incubation period, the samples were extracted with ethyl acetate. Pregnenolone was separated by HPLC, and quantitated using a radioimmunoassay method. The results suggest that CBZ can increase pregnenolone content in rat brain tissue at concentrations used therapeutically in humans. This finding may provide novel insights into the mechanisms underlying one or more clinical effects of CBZ.

277.4
DESENSITIZATION AFTER A SINGLE DOSE OF THE 5-HT1A RECEPTOR AGONIST FLESNOXAN UNDER BASAL AND DEFENSIVE-BURYING CONDITIONS.
J.van den Gugten, L. Greenink, B. Olivier*. Department of Psychopharmacology, Faculty of Pharmacy, Rudolf Magnus Institute for Neurosciences, Utrecht University, Sorbonnelaan 16, 3584 CA Utrecht, The Netherlands.

A single injection of a 5-HT1A receptor agonist has been shown to attenuate 5-OH-DPAT-induced corticosterone secretion in the rat (Kelder and Ross, N.-S. Arch. Pharmacol. (1992) 546:121). In order to assess whether this also implies behavioral desensitization, we studied the effects of a single pretreatment with flesinoxan under basal conditions and in the situation of the defensive-burying paradigm. Male rats received an anxiolytic dose of flesinoxan (3 mg kg⁻¹ s.c.), which suppresses defensive burying, or vehicle on day 1. Plasma corticosterone and glucose concentrations were determined on day 2 or day 6, 60 min after a second flesinoxan or vehicle treatment. On day 2 only, drug-induced increases in corticosterone and glucose under basal conditions were found to be diminished after flesinoxan pretreatment. No effect of pretreatment on lower lip retraction was observed. In the defensive-burying condition, flesinoxan pretreatment on the previous day also attenuated plasma corticosterone and glucose elevations. It is suggested that desensitization related to hormonal effects of 5-HT1A receptor agonists involves a mechanism distinct from that underlying other symptoms of 5-HT1A receptor activation.

277.5
ANTAGONISM OF AMPHETAMINE-INDUCED BEHAVIORAL CHANGES IN SELECTED MEMBERS OF PRIMATE SOCIAL COLONIES IN LOW DOSE APOMORPHINE.

Low doses of the dopamine (DA) agonist apomorphine (APO) have been shown to lessen psychotic behavior in schizophrenic patients. This activity appears to be related to action on the pre-synaptic DA receptor resulting in decreased DA release. Recently, there has been interest in developing agents with this property as antipsychotic candidates. In this study, we tested the effect of low dose APO on amphetamine (AMPH)-induced behavioral changes in monkeys that appear to have face validity or correlated validity to human psychotic behavior. The effect of APO was compared to the antipsychotic disulfiram (DISU) and flesinoxan (FLX).

The subjects were 4 females of a stable social colony of 5 adult stump-tail macaques (Macaca fascicularis). The study followed a cross-over design with 2 monkeys receiving drug per treatment day. Following observation of normal behavior (baseline), d-AMPH, 1.0 mg/kg, was given i.m. 15 min before observation for 2 days. Then, either APO, 0.1 mg/kg, was administered i.m. 15 min or CLOZ, 5 mg/kg, a 2.5 hr before for observation for 2 consecutive mornings and in the afternoon of day 1. APO was given as above. On each day, a "blind" observer quantitated and recorded the behavior of each animal using a checklist of 40 social and solitary behaviors. Alone, AMPH significantly increased submissive gestures, checking (visual scanning), induced stereotypy, and eliminated initiated social grooming. APO antagonized AMPH-induced submissiveness, stereotypy, and restored social grooming, whereas CLOZ blocked AMPH-induced submissiveness and checking. Neither APO or CLOZ induced movement abnormalities, but CLOZ-treated monkeys had a significant increase in resting. The results of this study suggest that this paradigm may be valuable in screening DA partial agonist as potential antipsychotic agents.

277.6
In Vivo Electrophysiological Effects of ABT-418: A Novel Cholinergic Channel Activator (CSCA): E.J. Ruda*, C.A. Briggs, P.S. Aronica, Neuroscience, Pharmaceutical Products Division, Abbott Laboratories, Abbott Park, IL, 60064-3500

ABT-418((S)-3)-methyl-(S)-(−)-2-pyrrolidinylxoxazole) has in vitro nicotinic-cholinergic functional and receptor binding properties (Ameret, et al., J Pharmacol Exp Ther, in press), that, in conjunction with animal behavior studies (Decker, et al., J Pharmacol Exp Ther, in press), suggests a more selective and less toxic action compared to nicotine. Nicotine itself desynaptizes neocortical EEG while also suppressing paroxysmal spike wave discharges. This study evaluated the effects of ABT-418 on these neocortical EEG parameters that are affected by nicotinic acetylcholine (nAChR) receptor activation.

Six and 12 month Wistar rats were surgically implanted with recording electrodes over the frontal and parietal cortices. ABT-418 (0.62, 1.9, and 6.2 μmol kg⁻¹ i.p.) did not produce any significant change in FFT-analyzed EEG activity in unanesthetized 6 month rats. In contrast, at all tested doses of (-)-nicotine (0.19, 0.62, 1.9 μmol/kg, i.p.) significantly (p<0.05) lowered 1-15 Hz total power values. ABT-418 (1.9 and 6.2 μmol kg⁻¹ i.p.) significantly lowered the incidence of spontaneous 6-10 Hz neocortical spike wave discharges in awake 12 month rats. This effect was inhibited by the cholinergic channel blocker mecamylamine (5.0 μmol/kg, i.p.) indicating that ABT-418 attenuation of spike wave activity is mediated by nAChRs.

The relative lack of ABT-418-induced neocortical desynchronisation distinguishes this compound from nicotine. This study suggests that the attenuation of spike wave discharges and the reported behavioral effects of ABT-418 are not a simple consequence of the neocortical activation.

277.7
SEROTONERGIC OVERACTIVATION, LIKE DOPAMINERGIC OVERACTIVATION, DISRUPTS CROSS-MODAL SENSORY GATING AS MEASURED BY AUDITORY AND VISUAL PREPULSE INHIBITION IN RATS. L.L. KERIN**, T.C. McCloskey, R.A. Padich, V.L. Taylor, & C.J. SCHMIDT. Marion Merchel Dow Research Institute, 2110 E. Galbraith Road, Cincinnati, Ohio 45215.

Dopamine (DA) and/or glutamate (GLU) imbalances are generally thought to contribute to schizophrenia's symptomatology. Increasing evidence suggests a possible role for serotonin (5-HT) as well. Prepulse inhibition (PPI), a measure of sensory gating, is disrupted in schizophrenics, and by psychotomimetics in rats. In the present study, cross-modal PPI of acoustic startle in Wistar rats was produced by using relative auditory stimulus (sound) or a visual stimulus (light) as the prepulse. DA overactivity induced by d-amphetamine or apomorphine, or GLU overactivity produced by the cation channel blocker D-600 (PCP) or MK-901, disrupted auditory and visual PPI. MDL 100,455, a competitive NMDA antagonist, decreased baseline without markedly disrupting PPI. The 5-HT releaser fenfluramine (5.0 mg/kg) disrupted PPI, and these effects were attenuated by the 5-HT uptake blocker MDL 28,618A, or by central 5-HT depletion produced by the 5-HT reuptake blocker fluoxetine (30 mg/kg) i.g. injected two hours prior to testing. These findings indicate that excessive 5-HT overactivation, like DA overactivation or GLU overactivity, can disrupt auditory or visual sensory gating processes. The findings with PCA also suggest the utility of PPI as a tool to evaluate functional deficits accompanying CNS 5-HT neurotoxicity.

277.8
USE OF NON-PERMEABLE MICROCARBON BEARERS IN ALKALI METAL ION TRANSPORT NMR STUDIES OF PERFUSED NEUROBLASTOMA CELLS: C.Zachariah*, and D.Freitas. Dept. of Chemistry, Loyola University of Chicago, Chicago, IL 60626.

In Nuclear Magnetic Resonance (NMR) studies of cells in suspension, it is possible to distinguish between the chemical shifts of the intracellular and extracellular Li⁺, Na⁺, K⁺ and Rb NMR resonances by the use of anisotropic shift reagents (SR) in the extracellular medium. In NMR studies of cells anchored on microcarrier beads, which are permeable to alkali metal ions and/or SR, the intracellular resonance may overlap that of the internal bead volume. Cell-free suspensions of four types of beads which differ in size, ion permeability, matrix composition, magnetic susceptibility and charge distribution were used in this study. Cytolex I and CultiSpher-G beads in buffered solutions gave rise to two separate Li⁺ and Na⁺ resonances, while only one Li⁺ and Na⁺ resonance was observed in suspensions containing Biosil or glass beads. Hence the physical basis for the discrimination between the alkali metal NMR resonances in cell-free suspensions of Cytolex I and CultiSpher-G is the cation and anion permeability differences for NR transport experiments of human neuroblastoma cells anchored on impermeable Biosil beads will be presented. The relevance of these studies to understanding the mechanisms of lithium action in the treatment of manic depression will be discussed.
HYDROFLUORIC ACID ENHANCES RECOVERY FROM ISOFLURANE ANESTHESIA IN RATS: BEHAVIORAL AND PHYSICOCHEMICAL MEASURES. R. Del Vecchio, A. Bandel, C. C. Huang, and R. N. Renshaw, Dept. of Biological Psychology, School of Medicine, Brown University, RI 02912.

Preliminary results indicate that when isoflurane (1) with trace amounts of hydrofluoric acid (HF) (50% recovery of plasma) was administered to rats, the recovery appeared to be faster than that of control animals. Therefore, we investigated the effect of adding HF to isoflurane. 50% of animals survived to receive HF. The results showed that the recovery of animals treated with HF was faster than that of control animals. The results also indicate that the addition of HF to isoflurane can enhance the recovery of animals from isoflurane anesthesia.

DEGENERATIVE DISEASE: ALZHEIMER’S—MODELS, ASSESSMENT, AND TREATMENT

To study the sequence of neurodegenerative events which could be associated with cholinergic cell death in Alzheimer’s disease, rat septal cholinergic neuronal cultures were exposed to chronic excitotoxic stress by glutamate. Counts of ChAT immunopositive cells and measurement of CA1 activity revealed that concentrations of glutamate on the order of 700 μM killed 50% of cholinergic neurons after 24 h of treatment. This toxic effect was not aimed at cholinergic neurons specifically, since other populations of cells present in these cultures were also affected. The non competitive NMDA receptor/chemoattractant antagonist, MK-801 (10 μM), abolished the neurotoxic effect of glutamate by preventing and rescuing from late degeneration both cholinergic and non cholinergic cells when concentrations of glutamate did not exceed 500 μM. The same degree of neuroprotection was afforded by the pyrimidyl antagonist, ficyclidine (2 μM). On the other hand, the kainate/nicatate receptor antagonist, CNOX, lacked protective effects. NGF used in standard culture conditions to enhance expression of the cholinergic phenotype was shown to inhibit glutamate toxicity. It should be noted that the presence of the NO synthase enzyme in many of the cholinergic neurons did not confer to these cells a particular resistance to glutamate toxicity. Furthermore, the fact that the NO generating agent, sodium nitroprusside, was capable of mimicking some of the effects of glutamate, the lack of protection of various NO synthase inhibitors (L-NAME, L-NG, 30 μM) to glutamate toxicity suggests that NO does not participate to the toxic process as an intercellular messenger.

T27.10

YM-35992 ((-)–(+)–2-[[[(7-fluoro-4-indanyl)oxy]methyl]morpholine] mono-hydrochloride) possesses affinities for not only serotonin (5-HT) uptake site (Ki=21 μM) but also 5-HT, receptors (Ki=104 nM), and has a relatively weak affinity for tricyclic antidepressant (Ki=247 nM), (Ki=104 nM), respectively. YM-35992 inhibited on a unit dose of 5-HT uptake sites (Ki=142 μM) and 5-HT, receptors (Ki=38 μM). Does not show any interactions with 5-HT uptake sites at a dose of 60 μg/kg, i.p., respectively. On the other hand, YM-35992 has an affinity for 5-HT uptake sites (Ki=142 μM) and 5-HT, receptors (Ki=38 μM). YM-35992 (10 mg/kg, p.o.) significantly reduced the immobility time in the mouse tail suspension test, but trazodone conversely prolonged the immobility time in a dose-dependent manner. Interestingly, both YM-35992 and trazodone ameliorated the learning impairment in olfactory bulbectomized rats after an acute administration, but chlorpromazine did not. In this model, both antidepressants are known to ameliorate the learning impairment only after chronic but not acute administration. These results suggest that YM-35992 would be a novel type antidepressant with more potent effects than trazodone and earlier onset of action than conventional selective serotonin re-uptake inhibitors.
Animal model of wandering in Alzheimer’s disease: Neural changes in proximal and distal sites following colchicine lesions of the dorsal hippocampal formation. J.R. Ryan and I.P. Ryan
Neurobehavioral Research Lab, Psychology Department, SUNY Plattsburgh, Plattsburgh, New York 12901.

The neuroanatomical and neurobehavioral effects of wandering in Alzheimer’s disease (AD) have been virtually unexplored despite the problematic nature of the behavior. Ryan and colleagues (1990, 1993) have investigated the behavioral profile of the hippocampal system. The present study investigated changes in the hippocampus and related structures following dorsal hippocampal formation lesions. Twenty-four Long-Evans hooded rats received either bilateral injections of one of three colchicine doses (10 μg, 15 μg, 25 μg) or artificial CSF into the dentate gyrus and/or CA1 regions. Ten days following surgery, the animals were behaviorally tested in the activity chamber for attention and exploration followed by four consecutive days of T-maze testing for spontaneous alternating behavior. Increased activity, decreased attention and perseverative behavior were indicated in rats with marked cell loss in the dorsal dentate gyrus and CA1. The study supports the hypothesis that deficits in spatial memory characterized the animal model of wandering in AD are exacerbated by perseverative behavior and hyperactivity.

728.6 CORPUS CALLOSUM PATHOLOGY IN ALZHEIMER SUBJECTS: DISRUPTION IN INTERHEMISPHERIC TRANSFER. Y. Latkoczy1, F. Lepori2*, S. Gauthier1 and M. Lepage1 1 Groupe de Recherche en Neuropsychologie Experiente, Universite de Montreal et 2 Centre McGill pour Etudes sur le Vieillissement, Montreal, QC, Canada.

The main feature of Alzheimer’s disease (AD) concerns the neuropathological and physiopathological changes in the associative areas of the cortex. Recent studies have demonstrated that besides the grey matter, the white matter of the cerebral cortex, which includes the minor and major forceps of the corpus callosum (CC), is also severely affected in AD. This might be in part a result of the degeneration of the pyramidal cells within these areas which furnish most of the commissural fibers. Fibers of the CC link the two hemispheres following a rostro-caudal topographical distribution. Thus, the motor fibers of the CC are mainly found in the genu, the somesthesis fibers occupy the trunk, the auditory fibers cross in the isthmus and the visual fibers project through the splenium. The aim of this study was to evaluate interhemispheric transfer in AD subjects and hence to assess the integrity of the CC. Several tasks, including tactile discrimination, tactile and visual discrimination, simple reaction time to lateralized flashes of light or to puff of air, bimanual coordination, etc., which attempted to test interhemispheric transfer within these systems were administered to 10 AD and 10 matched controls. Results showed that inter- but not intrahemispheric performance was significantly impaired in AD relative to controls. This finding is interpreted as showing that AD affects not only the well established memory and cognitive functions but also interhemispheric integration.

The practice of diagnosing Alzheimer’s disease (AD) without classification as to age of onset is under increasing challenge. Recent reports of genetic disimilarity between early and late-onset AD patients provide qualitative support for previously noted differences. These observations span clinical, neurobiological, and neuropsychological parameters. As the classic pathology of AD has yielded to observations that the substantial histological similarities, once used to unify early- and late-onset patients, segregate the groups in terms of quantity and distribution. To assess the validity of an age-based dichotomy, published data supporting and refuting the argument were reviewed. Conclusive claims cannot be made from a review of small patient cohorts; yet, a substantial amount of data differentiate early- and late-onset AD. Among them, evidence for differences in disease dynamics, language, cholinergic deficits, and metabolic function are strongly supportive of heterogeneity in AD identified by age of disease onset. These observations are reviewed and their implications for continuing AD research are explored.

728.8 ASSOCIATION BETWEEN MOTION SENSITIVITY DEFICITS AND DIFFERENTIAL LUMINANCE SENSITIVITY IN SENILE DEMENTIA OF THE ALZHEIMER’S TYPE. A. Belsieguil1, G. L. Test2*, P. Morin2, M. Wolff and M. Pellegrin. 1University of Montreal, Montreal, H3C 3J7, Canada, 2Washington University, St Louis, MO 63110 and 3Henry Ford Hospital, Detroit, MI 48202.

The visual abnormalities associated with senile dementia of the Alzheimer’s type (SDAT) include both motion sensitivity deficits and reductions in differential luminance sensitivity (DLS). The principal objective of this study was to quantitatively determine the relationship between these deficits in patients with early to mid SDAT. Random dot kinematograms (RDKs) were used to assess global motion sensitivity in 16 patients with diagnosed SDAT and 19 visually and cognitively normal control subjects of similar age. Motion sensitivity testing was conducted twice within a month on each participant and the results of the two tests were averaged. DLS was evaluated with automated static perimetry (Humphrey, 30-2). Only participants with reliable visual fields (by manufacturer’s criteria) were included. The global sensitivity, indices of visual field sensitivity (i.e., mean sensitivity, 90% probability (PSD)), and corrected PSD (CPSD) were used to quantify differential luminance sensitivity. Motion sensitivity was reduced significantly in SDAT patients compared to the controls (p<0.001). DLS was reduced significantly (i.e., significant visual field defects were detected) in 11/16 SDAT patients, MD, an index of generalized reduction in DLS, was significantly correlated with motion thresholds (p<0.01). Motion sensitivity was significantly correlated with global and differential luminance sensitivity deficits in patients with SDAT. In addition, the correlation between motion and luminance sensitivity suggests a link between these two deficits. (Supported in part by NIH grant A050681)

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
728.11

Alzheimer's disease (AD) is divided according to DSM-IV into mild (score between 6) and severe groups. There are many genetic, neurobiological, and clinical differences among AD patients. Early-onset AD patients may differ from their peers in their symptomatology. Thus, different therapeutic approaches may be considered for early- and late-onset AD patients. Several clinical trials with acetyl-l-carnitine (ALCAR) have been conducted in AD patients in the past years. Ten studies were reviewed to look retrospectively at the effect of ALCAR in the AD patient. Treatment was placebo-controlled Double-blind, clinical studies with ALCAR in patients diagnosed with AD were pooled in a comprehensive meta-analysis. For each study, cognitive and functional outcomes measures for efficacy were evaluated. By using standardized ranges for treatment comparison on cognitive tests, ALCAR-treated early-onset patients tended toward slower progressive loss (p < 0.01) than placebo-treated subjects, whereas using logrank scores the effect of ALCAR achieved significance (p < 0.05). Functional tests showed a treatment effect favoring ALCAR by using standardized ranges (p < 0.05). These data suggest that ALCAR may affect the clinical progression of AD.

728.12

Vasoactive intestinal peptide (VIP) has been shown to be involved in the promotion of neuronal survival as well as in acquired memory and learning. We now demonstrate that a superactive lipovapic VIP agonist inhibited neuronal cell death in an Alzheimer's model in vitro and accelerated the formation of cholinergic synapses in an in vitro Alzheimer's paradigm. Thus, addition of 250 nM of a fragment of the beta-amylloid peptide to rat cerebral cortical cells in vitro resulted in a significant 70% cell death which was attenuated by co-treatment with stearyl-Nle-VIP. Furthermore, in an in vivo Alzheimer's model of rats treated with the cholinergic block of AF64A, which induced an impairment in spatial learning, stearyl-Nle-VIP injected i.o. or i.v. alleviated the impairment characteristic of Alzheimer's disease. These data support the neuroprotective intervention as a therapeutic strategy for neurodegenerative diseases.

We thank Dr. R. L. Berman for the initial sample of AF64A. Supported by Fujimoto Corp. Japan.
DEGENERATIVE DISEASE: PARKINSON'S—HUMAN STUDIES

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

DEGENERATIVE DISEASE: PARKINSON'S—HUMAN STUDIES

Patients with Parkinson's disease, age-matched controls, and young control subjects performed fast, discrete elbow and wrist flexion or extension movements in a sagittal plane using the index finger to move one of the joints "as fast as possible." Relative stability in the other, postural, movements is more variable in the patients and in both control groups. Typically, EMG patterns in muscle pairs acting at both joints displayed a commonly observed tri-phasic pattern. During both elbow and wrist movements, in both flexion and extension, the elbow flexor and the wrist flexor demonstrated similar, synchronized EMG patterns, while the elbow extensor and the wrist extensor also showed similar patterns of activation. A cross-correlation analysis of the EMG confirmed virtually simultaneous bursts in the wrist and elbow flexors and in the wrist and elbow extensors. In all three groups, there were no signs of anticipatory activation in any movement in about 90% of movements. The analysis of a simple biomechanical model has suggested that simultaneous EMG bursts may be used to minimize the displacements in the postural joint. We assume the anticipatory activation is not a separate process, but a separate peripheral pattern of a single control process that may involve a number of joints and muscles. The observed relation between the EMG patterns is apparently a universal synergic system which is preserved in elderly and in Parkinson's disease. We conclude that the postural deficits in Parkinson's disease are not related to a basic deficit in feedforward postural control but to other factors that may include the specificity of maintaining the vertical posture.

729.7 ALLEVIATION OF MOTOR SIGN OF PARKINSON DISEASE AFTER STIMULATION OF THE INTERNAL SEGMENT OF THE GLOBUS PALLIDUS: EXPERIMENTAL EVIDENCE IN HUMAN

Methods: a bilateral sub-threshold stereotactic needle implantation of the globus pallidus substantia nigrae has been previously shown in monkeys and human. In the present work, we studied the effect of HFS of GPi in five Parkinsonian patients with advanced stage disease and with associated rigidity. Patients between 40 and 60 years old, were at Hoehn and Yahr stage 3 to 5 and suffering from Pharmacological resistant form of the disease. Patients were treated with dopamine agonists, "tapping" test and before the electrode implantation in 6 different situation: one week before the operation 3 weeks and 3 weeks after the implantation with Dopatherapy, and 3 weeks and 4 weeks without stimulation; and without Dopatherapy, and 5 weeks or 6 weeks without. Monopolar electrode was stereotactically implanted using the stereotactic Leksell atlas and MRI. Results showed that for stimulation sites situated at the base of the GPi, the stimulation with 3 Hz, toward the head, reduced rigidity and turning movements (AD) and increased motor activity in the patients. The effect was more prominent in the arm. The effect was maintained for 3-6 months post surgery. We conclude that the stimulation of the globus pallidus substantia nigrae is effective for the motor signs of advanced Parkinson's disease without overt surgical complications.

729.8 SPATIAL LEARNING DEFICITS IN PARKINSONISM

R. J. Arcenta*, D. J. Ingle, and L. Cote, Neurological Institute, Columbia-Presbyterian Medical Center, West 168th St., New York, N.Y. 10032.

Ingle and Thompson (1993) showed that Parkinson Disease (PD) patients of moderate severity performed poorly on a spatial memory task after waking 4 to 8 meters forwards. Recently Arcenta, et al. replicated the post waking deficit in a new group of PD patients. In the present study we measured localization memory linked to arm movement, rather than to locomotion. Here the blindfolded subjects (S) point to a remembered target (T) on the table before them using the tip of a bent index finger held by one hand at the other end. All Ss had the opportunity to learn the location of the bent wire's tip in relation to the hand during a two minute period of touching the tip to various table locations. Testing was done with both the bent wire and the index finger. When 14 PD and 13 controls were tested, the PD Ss were not significantly worse than controls in localization (T by memory) using their index finger, but were significantly worse in learning to point with an artificial extension of the hand. The control errors averaged 73 mm each while the PD patient errors averaged 96 mm each. We speculate that spatial memory linked to locomotion and to arm movement are mediated by the caudate nucleus and the putamen respectively.
729.9
REVERSAL OF CATECHOL BY STRESS: INVOLVEMENT OF THE MESOCORTICAL BUT NOT THE MESOLIMBIC SYSTEM. L. Hernandez*, T. Tunc*, E. Murai, and T. Takahashi. Laboratory of Neurochemistry, Medical School, Los Andes University, Mérida 5101, Venezuela.

Stress reverses catechol in Parkinsonian patients presumably by releasing dopamine. In an experimental model, i.e. haloperidol induced catechol was re-versed by forced running (F). DA activity was assessed by microdialysis of the prefrontal cortex (PFC) or the nucleus accumbens (NAC). In rats, each region (PFC or NAC) one group (HAL+SWM) received an ip haloperidol injection (5 mg/kg) and was forced to swim, another group (HAL) had not forced to swim and a third group (VEH+SWM) received vehicle and was forced total (F). After haloperidol the rats exhibited catechol and dopamine and its metabolites increased. FS increased DA activity in the PFC too. However, the increase was significantly greater in the PFC of the HAL+SWM than in the HAL or the VEH+SWM groups (F2/196=22.78, p<0.01). No difference of DA activity in the NAC was observed when the HAL+SWM vs the HAL group were compared (F1/112=3.01, NS). Another three groups of rats received microinjec-tions of DA in the PFC during haloperidol induced catechol. Intracortical SA injections abolished catechol (F1/11=34.8, p<0.001). These experiments suggest that DA release in the PFC contributes to the reversal of catechol by stress.

729.11

[1-123I]-CIT (25-carboxymethoxy-3-hydroxy-iopropyl)tracers monoamine transporters were located on the terminals of dopaminergic projections from the substantia nigra to the striatum providing a marker for neurons which degenerate in Parkinson’s disease (PD). [1-123I]-CIT SPECT imaging performed in 8 patients with hemi-Parkinsonian symptoms and in 8 age and sex-matched healthy subjects. All patients had very mild symptoms in the affected side (Hoehn and Yahr stage 1/11) and had not received treatment with L-Dopa.

Data was analyzed relative to two outcome measures: ratio of specific non-specific striatal activity and striatal uptake expressed as percent injected dose. Disease stage and severity was assessed by Hoehn and Yahr Staging and UPDRS scales. Specific non-specific striatal binding ratios in PD patients contralateral (2.7±9) to the symptomatic side were reduced to 47±% (p<1.1) to the symptomatic side were reduced to 68% of HS ratios (5.7±1). Striatal activity in PD patients expressed as percent injected dose was reduced to (55%) of HS (with no difference in occipital uptake). The reduction in striatal activity in the PD patients both in the symptomatic and the effectively pre-symptomatic striatum suggests imaging of dopamine transporters with [1-123I]-CIT may be a useful tool for early diagnosis of PD and possibly for ‘pre-symptomatic’ mesencephalic dopaminergic degeneration.

729.13

We have previously shown that Alzheimer’s disease (AD) cases with a Parkinson-like syndrome (AD/Park) show significant (50-80%) losses of TH immunoreactivity (IR) in the substantia nigra (SN) and pars reticulata of the substantia nigra pars compacta (SNpc). We have now shown that levels of TH mRNA in this region are also reduced in AD/Park cases compared to normal controls (NC). The SNpc is an area of the SN most affected in PD so reduced levels of TH mRNA in AD/Park cases suggest that there are also changes in the expression of TH at the mRNA level. In the SNpc we have also seen decreased levels of DAT mRNA and increased levels of DAT protein expression. The SNpc is the important site for transporter studies and the present findings suggest that there are changes in the expression of DAT at the mRNA level.

729.12

We measured regional cerebral blood flow (rCBF) with positron emission tomography (PET) and [15O]water before and after acute administration of levodopa (in combination with carbidopa) in 12 patients (5 females) with Parkinson’s disease (PD), Hoehn and Yahr stages 1 and 2, and 5 age-matched normal women (NL). All subjects were pretreated with 200 mg of carbidopa about 2 hrs prior to PET. Regional CBF was measured prior to levodopa and 75 minutes after taking p.o. levodopa 150 mg with carbidopa 37.5 mg. Images were transformed into standard stereotactic space. We split both the PD and NL groups into 2 subgroups to permit response identification and subsequent confirmation in each group. Levodopa produced discrete foci of activation in the range of 5 to 15 s above normalised mean global flow. In the PD group, there were confirmed responses in bilateral midbrain, right frontal cortex and left putamen. Right putamalar response only reached p<0.1. In the NLs, there were confirmed responses only in right midbrain and right frontal cortex. The relatively low f for NLs limited the power of response confirmation. The bilateral midbrain responses in the NLs were significantly greater than in the PD group (p<0.04 for MANOVA of bilateral midbrain, bilateral putamen and right frontal cortex responses for NL and PD; F: pos hoc t-tests p<0.05 for right and left midbrain). There were no other statistically significant differences between NL and PD. We believe that levodopa-induced blood flow responses provide a powerful tool for investigation of functional changes in dopaminergic neurons and their connections.

729.10

Parkinson’s disease (PD) is characterized by a massive degeneration of the dopaminergic neurons containing in the midbrain. However, the vulnerability of these neurons is heterogeneous both across different subregions of the substantia nigra pars compacta (SNpc), the most affected structure in this disease. To determine the exact pattern of cell loss, it is necessary to have landmarks independent of the degenerative process to subdivide the SNpc. We have defined a dopamine receptor (D2) imaging protocol (DBP) in the midbrain. The DBP was validated in the monkey and in the human post-mortem samples. The DBP was performed in 3 groups of patients with PD: non-motor (+M3), motor (+M4) and severe motor (M5) PD.

The DBP-positive neostriatal tracer in the ventral midbrain survived in the PD brains. Moreover, although the DBP-negative zones were spared, their two-dimensional organization was similar to that seen in the control midbrain. We conclude that DBP imaging patterns could be used to calculate very precisely the relative loss of dopamine-containing neurons in the different parts of the SNpc. Supported by NIH Awards RO1NS02529 and Lavoisier Grant (French Foreign Office).

729.8

There exists neuropathological and biochemical evidence indicating that the serotonergic system is affected in Parkinson’s disease. The alterations observed include the presence of Lewy bodies in 5-HT cells in the dorsal raphe, a loss of more than 50% of large neurons in the nucleus, and a decrease in the levels of 5-HT and its metabolites 5-HIAA in the cortex and basal ganglia. In addition, serotonin transporter (5-HT1) binding in the 5-HT transporter (5-HT1) and the 5-HT3 receptor in the dorsal raphe of control and Parkinsonian patients using 5-HT1-citrapram and 5-CT-DPAT, respectively.

The binding of both ligand’s serotonin-receptor system was not significantly different from control levels. This contrasts with the reported decreases in 5-HT transporter binding in forebrain regions and loss of 5-HT cells in the dorsal raphe of Parkinsonian patients. Our results suggest that the remaining neurons overexpress the 5-HT transporter in order to compensate for cell loss. We thus examined the mRNA encoding the 5-HT transporter in situ hybridization using a 5-HT-labeled oligonucleotide probe. A strong hybridization signal was observed overlying cell bodies in the dorsal raphe. In the case of 5-HT1 receptors, the mRNA content per cell was higher in Parkinsonian patients compared to normal tissues. These results might reflect an enhanced expression of 5-HT transporter mRNA. The types of cells expressing this mRNA remains to be determined.
Mental Illness: Depression, Anxiety and Schizophrenia

**370.1** 

OBX rats simulate aspects of chronic Major Depression in humans, e.g., appetite, learning deficits, sleep and sexual behaviors, decreased corticosterone plasma. These are not caused by anoxia and are usually reversed by antidepressant treatments, including ECT. ECT inverts the pattern of changes. The animals with OBX show behavioral effects that mimic the effects seen in OBX rats. OBX rats were treated with vanadate, a known antidepressant, and showed significant improvement in behavioral measures. The results suggest that OBX rats may be a useful model for studying the effects of antidepressants on the behavior of depressed individuals.

**A Rat Model for Mania: Relation to Brain Amines.** R.S. El-Mallakh, P.L. L-T. Harrison, D.G. Changard, and B.S. Levy*. Dept of Psychiatry, Biochemistry, Neurology, and Laboratory of Biological Psychiatry, University of Louisville School of Medicine, Louisville, KY 40292.

We previously have described a rat model of mania that has been used in a number of studies and has been characterized through preclinical and clinical investigations. The model is based on the administration of a combination of drugs, including reserpine, amphetamine, and desipramine, which produce a range of behavioral and biochemical changes in the rat. In this study, we examined the effects of these drugs on the levels of brain amines and their metabolites in this model. Our results indicate that the model is a useful tool for studying the mechanisms of mania and for developing new treatments.

**370.3** 
**Magnetic Resonance Imaging and Brainstem Evoked Response in Geriatric Depression.** B. Kalpers, S. Budzilin, R.C. Yung* and O. Akefopoulos. The New York Hospital - Cornell Medical Center, 21 East 64th Street, New York, NY 10065.

Introduction Rate-dependent latency shift in brainstem auditory evoked response (BAER) is reportedly associated with occult brain pathology. Latency increases in BAER is elicited in elderly patients with a history of major depression was previously reported by our group. Preliminary findings are now reported that corroborates the latency change with findings on brainstem magnetic resonance imaging (MRI) in mild elderly depressed subjects. (t=7.1, p<0.01) reasons for failure of MRI and BAER. Psychiatric diagnosis was established using a structured clinical interview. Proton density axial images of the brain were classified using criteria proposed by the DSM-IV of Alzheimer's Disease. (CERAD) as normal, or with probable putative, or definite or white matter changes. BAER was performed using metallic stimuli of 1 to 7.1 μV and 80 μV clicks and seconds and the latency shift was not significant. Reduced latency shift in older patients with concomitant lesions and one patient with putative lesions of the lower brainstem had latency shift > 50 milliseconds. In this case depression was of the late-onset type. Among the remaining 11 patients, latency shift was < 50% and 8 of 11 had definite or white matter changes. BAER was performed using stimuli of 1 to 7.1 μV and 80 μV clicks and seconds and the latency shift in older patients with concomitant lesions was normal in two and brainstem imaging was normal in four. Depression was of the early-onset type in five of these six cases. Conclusion The above findings need further investigations and further sample size. The findings suggest that BAER are responsive to antidepressant drug treatment and relapse in the course of illness may be associated with brain morphologic changes. Brainstem imaging and BAER may prove useful prognostic tests in these patients.

**370.4** 

We previously reported higher postmortem cerebral cortical levels of the stimulatory G protein α-subunit, αs, in BD compared with control subjects (Young et al., J. Neuropsychiatry 6:135, 1994). Levels of αs and the inhibitory G protein α-subunit were also increased in MNL from BD but not major depressive disorder (MDD) subjects (Young et al., J. Neuropsychiatry 18:51, 1998). In the present study, the functional consequences of these protein changes were examined. MNL from BD and MDD subjects were examined for basal, GTPγS and forskolin-stimulated (100μM) AC activity. Subjects included depressed BD (N=9, age 31.4±4.8 (mean±SD); 40±5 years), age 65.7±22 and MDD (N=30, age 66.7±4.9 years) and age 72.7±2; MAM-D=1.±4.07) patients compared with age (35.2±25.9 and 35.5±4.6, respectively) and sex-matched healthy controls. In BD subjects, MNL membrane GTPγS- and forskolin-stimulated AC activity, expressed as specific activity, were significantly reduced (GTPγS=2.33, p<0.05; forskolin=2.3, p<0.001) as compared with controls. These findings suggest that GTPγS-stimulated AC activity was not significantly reduced (2.4%, 1.7, 0.3-0.05) and basal AC activity was not significantly reduced (0.8, 0.4) from that in healthy subjects. In comparison, basal membrane AC activity was significantly reduced as MDD subjects (39%, +3.75, p=0.027) compared with matched controls but GTPγS- and forskolin-stimulated AC activity did not differ. Thus, despite higher MNL αs levels in BD compared with healthy subjects, G protein-coupled AC activation is reduced in these cells contrasting with the possible enhanced functional status of this signal transduction process found in postmortem BD cerebral cortex (Young et al., J. Neuropsychiatry, 18:51). This difference, however, may be attributed to more effective compensatory adaptations in inhibitory control of AC activity and/or AC levels in MNLs than in cortex of BD subjects. (Supported by grants from the NAMI Stanley Foundation and MRC Canada.)
VOLUMETRIC STUDIES IN LATE LIFE DEPRESSION USING MRI. A.Kumar, D.Miller, L.Burke, W.Bell*, D.Evanko, S.Samuels, S.Gottlieb. Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104. The purpose of the study was to examine the volumes of ventricular, subcortical and whole brain cerebrospinal fluid (CSF) spaces in subjects with late life depression and to compare these indices to healthy age-matched controls and subjects with probable Alzheimer’s disease (DAT). Using a 1.5 tesla GE Signa scanner, we studied 24 subjects with late life depression (16 W, 9 M, Mean age 73.7 SD 7.46), 29 healthy controls (17 W, 12 M, Mean age 67.2 SD 8.45) and 34 subjects with DAT (17 W, 17 M, Mean age 66.4 SD 8.50). All depressed subjects met DSM-III-R criteria for major depressive disorder and had Hamilton depression scores of greater than 15 (Mean 19.7 SD 3.84). All subjects were medically stable and free of significant other neuropsychiatric disease. Volumetric density and T2 weighted images were used to maximize the contrast between brain and CSF. A semiautomated boundary program and segmentation algorithm were used to differentiate brain tissue from CSF. On normalized measures of ventricular and whole brain CSF, depressed subjects had larger volumes in both hemispheres when compared to the control subjects (p<0.01), as did the DAT subjects. When depressed and DAT subjects were compared, subjects with DAT had larger whole brain and right hemisphere CSF volumes and total and right hemisphere subcortical CSF volumes (p<0.05). These data suggest that widespread structural brain changes underlie late life depression and may be significant in the pathogenesis of mood disorders in late life.

EVIDENCE FOR INCREASED CONCENTRATIONS OF NEUROPEPTIDE Y IN PLASMA OF PATIENTS WITH PANIC DISORDER. S.Bougie*, J.P.Bouliener, J.Jerabeck, R.Leduque, F.Jolicoeur and A.Cadieux Departments of Psychiatry and Pharmacology, Faculty of Medicine, University of Sherbrooke, Sherbrooke, Quebec. C.Iida JH14 5N4. Recent experimental evidence suggests that neuropeptide Y (NPY) is involved in the modulation of anxiety-related behavior in rodents. Furthermore, NPY’s physiological effects are strongly associated with those of noradrenaline, a neurotransmitter involved in the expression of anxiety symptoms in humans both at the central and at the peripheral levels. The aim of the present study was to assess the relationship between NPY plasma concentration and anxiety levels in both normal volunteers (n=13) and patients (n=13) fulfilling the DSM-III criteria for panic-type disorders with or without agoraphobia. Plasma levels of NPY-Like immunoreactivity (NPY-LI) were measured in duplicate using a radioimmunoassay developed in our laboratory with detection limits being 7 pg/100 μl. The first results of this study suggest that, compared to normal controls, the baseline NPY-LI levels of panic disorder patients is increased (75 ± 10 pg/ml vs. 130 ± 8 pg/ml respectively). This difference was statistically significant, p<0.05. Supported by Fonds de la Recherche en Santé du Québec.

CARDIOVASCULAR, RESPIRATORY AND PARASYMPATHETIC ACTIVITY IN PANIC DISORDER. POST-TRAUMATIC STRESS DISORDER AND NORMAL CONTROLS. G.S. Gargani*, J.C. Sheem, D. Anti-Obeve, P. Andrew, B. Petti and A.J. Rais Dallas VA Medical Center and Department of Psychiatry, UT Southwestern Medical School, Dallas, TX 75216.

Although increased autonomic activity is observed in panic disorder (PD) and post-traumatic stress disorder (PTSD), it is unclear if autonomic pathophysiology is similar or different in these disorders. Heart rate (HR), systolic (SBP), diastolic (DBP), mean arterial pressure (MAP), respiratory rate (RR), indices of respiratory sinus arrhythmia (heart rate variability, HPV, heart rate, HR, and vagal tone, VT) were monitored while supine and for 10 minutes after standing in 19 normal controls (NC), 18 PD and 16 PTSD patients. The study included several trends for higher resting cardiovascular measures in PD and PTSD. PD patients had higher RR (NC: 15.3± 2.5 vs PD: 18.5± 2.5 , p<0.05) and a trend for a higher anoic gap and lower potassium than NC or PTSD patients. In response to standing, V wave and P wave were increased in NPY-LI patients with PD and PTSD. PD patients had higher HR responses than NC or PTSD patients. There was no significant group x time interaction in SBP only while other cardiovascular measures fell on a continuum between NC and PD. (2) PD patients, but not PTSD, had statistically significant group x time interactions in HPV and HR which showed a rebound increase 8 minutes into standing. These observations suggest that abnormal respiratory function may be specific to PD and that the type of abnormal cardiovascular and parasympathetic responses may be different between PD and PTSD.

Calcium dependency of the release of DA and 5HT from CNS slices from animals subjected to models of depression. E.H. Jaffe*, V. DeFries, C. Barra. Lab. Neurochemistry, IIVC, Apdo. 21827, Caracas 1020-A.

5HT and DA systems have been implicated in the physiopathology of depression. Previously (Neurosci. Lett. 162:157,1993) we showed an increased K stimulated release of 5HT from hippocampus (HP) and inhibition of the basal release from HP, n.accumbens (n.ac) and prefrontal cortex (PFC) of animals subjected to forst swim test and chronic isolation. Here we study the Ca dependency of the release of DA and 5HT from these 3 CNS structures. Slices were incubated in a static chamber system. DA and 5HT release measured by HPLC with electrochemical detection. K (30 mM) stimulated DA release was only significantly higher in n.ac of isolated animals and inhibited with Cd (150μM) a Ca channel blocker. 0.5-10mM Mg inhibited at the same degree release of control and isolated animals. A similar pattern was shown with the K stimulated release of 5HT from n.ac and Hip which were significantly increased in isolated animals, showing a greater inhibition with Cd than controls. Basal DA release was similar in control or isolated animals from the 3 CNS structures with a strong and significant inhibition of the release in 0Ca/Mg Krebs from isolated animals but not from control. A greater sensitivity to Ca blockade of the Ca dependent DA and 5HT release from isolated animals is suggested.

SODIUM LACTATE INFUSIONS IN AN ANIMAL MODEL OF PANIC DISORDER: FINDINGS OF ADOLESCENT P. Sheil*, S.R. Keim, J.R. Simom and W.J. McDermite, Dept. of Psychiatry, Indiana University Medical Center, Indianapolis, Indiana 46202. GABA receptor blockade in the dorso medial hypothalamus (DMH) of rats elicits a panic-like response. Our preliminary studies have shown that rats that have inhibition of GABA synthesis in the DMH are susceptible to physiological arousal by lactate infusion similar to patients with panic disorder. To characterize this response further, rats equipped with femoral arterial and venous catheters were chronically infused with L-alalyglycine (L-AG, active isomer whose metabolite blocks glutamic acid decarboxylase, GAD) or D-alalyglycine (D-AG, inactive isomer) via Alzet mini-pumps implanted unilaterally in the DMH. Infusion of 0.5N sodium lactate (10 μl/Kg, i.v.) elicited significant increases in heart rate and blood pressure after 4, 7 or 14 days only in rats with L-AG pumps and not D-AG pumps. Rats with L-AG pumps also showed increased"anxiety" in the plus-maze and social interaction tests as well as decreased GABA content in the DMH when compared to rats with D-AG pumps. These results further strengthen this animal model of panic disorder. (Supported by MH 45362)

PLASMA PROTEIN PATTERN VARIATIONS IN SCHIZOPHRENIA. A. Brett Larive, Dale M. VanderPutter, Carl B. Merri*, Laboratory of Biochemical Genetics, NIMH, Washington, DC 20032 and Monoclonetics Inc., Houston, TX 77027. Plasma protein patterns in 2-D gels from monozygotic twins discordant for schizophrenia were found to be significantly less alike than the protein patterns of normal monozygotic twins and monzygotic twins concordant for schizophrenia. The ELSIE 5-2 D gel analysis program found significantly (p<0.01) fewer protein spot matches between discordant monzygotic schizophrenia twins than either normal monozygotic twins or concordant monzygotic schizophrenia twins. The relative silver stained intensity of matched plasma proteins was also found to vary to a greater extent between monzygotic twins discordant for schizophrenia. Several polypeptide spots were elevated only in the schizophrenic twin. One of these proteins was also found to be significantly (p<0.0001) elevated in the plasma of unrelated schizophrenic individuals (n=75). Additionally, we found differences in plasma haptoglobin levels between monzygotic twins discordant for schizophrenia suggesting variations in liver metabolism.

There is increasing evidence that abnormal brain development is involved in schizophrenia. Among several factors, growth factor responses may play critical roles in brain developmental processes: neuronal proliferation, maintenance, survival and maturation. Since molecular mechanisms of their mitogenic actions are common across cell types, cultured skin fibroblasts were used to conduct these studies. The mitogenic responses of BFGF and EGF were examined in fibroblasts from first-episode, drug-naive psychotic patients (N=10) and normal controls (N=10). Known number of fibroblasts were first synchronized by serum starvation for 24 hr. and then growth factors were added in serum containing medium, and growth was continued. The final number of cells was counted on 7th day. Growth response was determined as % change in cell number. As expected, fibroblasts from normals showed increased mitogenic response (mean±SEM; bFGF=151±5.97, EGF=192±11.99). However, the mitogenic response was reduced in fibroblasts from patients (bFGF=85±6.44, P<0.001; EGF=144±4.74, P<0.04). Further studies on underlying receptor-mediated processes will be presented.

370.12 UPTAKE OF ESSENTIAL FATTY ACIDS IN SKIN FIBROBLASTS FROM SCHIZOPHRENIC PATIENTS. N. S. Shendarkar, S. Mukherjee, J. Mahalik and S. P. Mahalik,* Dept. of Psychiatry and Health Behavior, MCG & VAMC, Augusta, GA 30912.

A generalized abnormal plasma membrane phospholipid (PL) metabolism exists in schizophrenia. Abnormality is predominantly in the distribution of esterified polyunsaturated fatty acids (EPFUs) of essential fatty acids (EFAs: linoleic, LA, and linolenic, ALA). The underlying mechanisms are unclear. The cellular uptake of EFAs and conversion to PUFA(s) are critical for the quantity and quality of PLs. It is difficult to investigate these processes in vivo or using easily available tissues or cells in vitro. Cultured skin fibroblasts are well suited for this. The uptake of EFAs in fibroblasts was compared in three schizophrenic patients with normal controls matched for age, sex and race. Cultures were synchronized by serum starvation for 24 hr. and then grown in serum containing medium for next 24 hr., and fatty acid uptake was determined as moles/mg protein for 30 min. The uptake of both the fatty acids was normal in fibroblasts from patients with LA:ALA ratio of 1:1 (means ± SEM for LA, P=139±526.54, N=108.3±22.77, for ALA, P=53±480.7, N=54.5±78.3) and 20:1 (LA, P=504.3±192.33, P=317.4±19.49 and for ALA, P<31.32, 11.1, N=15.83±5.81). Data indicate that reported lower levels of membrane fatty acids may be a result of defective conversion into EPFAs and incorporation into functional lipids.

There is evidence that infectious and/or abnormal neural-immune mechanisms may be involved in schizophrenia. To evaluate this possibility, 6 measures sensitive to neural-immune activities were assessed in the CSF of 21 male patients (mean age: 41) with schizophrenia (SCCH) in comparison to 16 healthy controls (HC) (mean age: 35). Quinolinic acid (QUIN), a neurotransmitter, was measured by GCMS, and interleukins (IL1B, IL2, and IL6), tumor necrosis factor alpha (TNF alpha) and beta 2 microglobulin (B2MG) by double antibody ELISA.

Mean QUIN levels in SCH were increased by 24% over those in HC (18.17 vs 15.06) respectively, P<0.04 (Chi square). Mean IL6 and B2MG levels did not differ between SCH and HC (2.4 vs. 2.234/ml and 1.3 vs. 1.4/ml respectively). Levels of IL1B, IL2, and TNF alpha did not differ between SCH and HC since 82 vs88; 1009 vs100, and 719 vs100, respectively, had levels below the lower detection limits of the assay.

The relatively small 25% increase in QUIN levels in SCH is less than the 200-500% increase seen in early stage HIV infected patients. The data suggest that a strongly active and abnormal neural-immune process is not occurring in the large majority of these chronic SCH patients. Supported by MH65463, the Stanley Foundation and WHVAMC Schizophrenia Center.

Cyclic AMP (cAMP) accumulation was evaluated in EBV-transformed human B-lymphocyte cell lines from normal and schizophrenic individuals. Each cell line showed characteristic individual responses to PGE1, a prostaglandin agonist, isoproterenol (iso), a β-adrenergic agonist, phorbol 12-myristate-13 acetate (PMA), an activator of protein kinase C (PKC) and staurosporin (STP), an inhibitor of PKC. PGE1, significantly elevated cAMP accumulation. Iso produced a slight but non-significant increase in cAMP accumulation. Pretreatment of the cells with PMA (10-7 M) significantly enhanced cAMP accumulation following treatment with Iso. STP reduced the potentiation of cAMP accumulation produced by PMA plus Iso (1 μM). In contrast, STP enhanced cAMP accumulation following treatment with PGE1 (10-7 M) plus PMA. Cell lines from controls showed a significantly greater cAMP response following treatment with PGE1, plus PMA compared with the cell lines from schizophrenic patients. These data suggest that a deficit may exist in the PKC and/or PGE1 response systems in schizophrenic patients.

Plasma homovanilliac acid (pHVA) levels were examined in 17 patients during their first episode of psychosis before initiating neuroleptic treatment and in 8 normal controls. The effect of neuroleptic treatment was assessed after 3 weeks "doctor's choice" treatment. The mean age of patients was 22.88 yrs and the mean duration of psychosis at entry to protocol was 4.44 days (range 2-10). In all, 48 patients met DSM-IIIIR criteria for schizophrenia. Baseline pHVA (8.65±2.4 mg/ml) and post-treatment pHVA (8.42±2.7 mg/ml) both were significantly lower in patients than in normal controls (16.53±6.6 mg/ml) (P<0.001 for both comparisons). Change in pHVA levels was not correlated with change in clinical state of patients. Patients with negative symptoms were unchanged, but pHVA in early age of onset postmortem studies showing chronic presynaptic dopaminergic underactivity in early onset patients. In summary, our findings indicate that, in some patients, pHVA is low at the very onset of psychosis and this is associated with a suboptimal early response to neuroleptic treatment.

Neurotensin (NT), an endogenous neuroleptic tridecapeptide, and its metabolites were quantitated in CSF collected at 8 NYC patients presenting with schizophrenia. CSF was placed into enzyme inhibitors on ice and 8-12 ML was subjected to HPLC and RIA using H- and C-terminal antibodies. NT added to CSF was recovered in good yields. Direct injection of patients met below 111K criteria for schizophrenia. Baseline pNT (8.65±2.4 mg/ml) and post-treatment pHVA (8.42±2.7 mg/ml) both were significantly lower in patients than in normal controls (16.53±6.6 mg/ml) (P<0.001 for both comparisons). Change in pHVA levels was not correlated with change in clinical state of patients. Patients with negative symptoms were unchanged, but NT in early age of onset postmortem studies showing chronic presynaptic dopaminergic underactivity in early onset patients. In summary, our findings indicate that, in some patients, pHVA is low at the very onset of psychosis and this is associated with a suboptimal early response to neuroleptic treatment.

Chronic use of antipsychotic drugs produces therapeutic effects on psychosis, concurrent side effects, and neurochemical changes in selected transgenic systems. Much is known about the chronic effect of these drugs on D1 and GABA receptors, dopamine (DA) turnover, and DA neuronal activity. However, the integrated functional effect of chronic antipsychotic drug treatment on the human brain is less well studied, as are the consequences of its withdrawal. We report here results of a within-subject study of regional cerebral glucose metabolism (rCMRGlu) with chronic haloperidol (HAL) in three different states: on HAL treatment, after a 5-day withdrawal, and after 30 days in a drug-free state. Differences between the on-HAL state and the drug-free (30 day) state were found to be the elucidate and putamen (8% and 7% increase, respectively), the thalamus (9% increase), frontal cortex (4% decrease) and cingulate (6% decrease). At the five day withdrawal time, based on our previous study of supersensitivity phenomena in patients, we had predicted rCMRGlu findings consistent with supersensitivity. Examples from representative structures are presented in the Table. After five days of withdrawal, no significant changes from the on-HAL scan were apparent in rCMRGlu in the brain areas analyzed. These data failed to functional metabolic evidence of withdrawal supersensitivity.

EFFECTS OF THE NMDA ANTAGONIST KETAMINE ON CEREBRAL BLOOD FLOW PATTERNS IN SCHIZOPHRENIC PATIENTS. A.C. Lesh*†, H.H. Hoehn, M. Zhao, D. Medoff*, R.P. Dansky, G.A. Tamminga, M.P.R.C. University of Maryland, Baltimore, MD 21228 and The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

To evaluate glutamatergic transmission in the pathophysiology of schizophrenia, we have studied the action of the NMDA antagonist ketamine in symptomatic individuals. Research protocols were approved by the University of Maryland IRB. Three subanesthetic doses of ketamine (0.1, 0.3 and 0.5 mg/kg) and placebo were given to 12 stable blind injection study. Ketamine worsened mental status 20 minutes after injection in a dose sensitive fashion, selectively on positive psychotic symptoms. No significant between regional cerebral blood flow changes in medicated schizophrenic patients given acute ketamine (0.3 mg/kg). Three 15O water cerebral blood flow PET scans were collected for drug administration and seven scans, at timed intervals, after ketamine. Data were analyzed using Statistical Parametric Mapping (Friston, 1991). The three baseline scans were combined and compared with the two most proximal post infusion scans from three subjects. The brain regions significantly affected by ketamine were the cingulate cortex and dorsomedial thalamus. Hippocampal activity elevations were also evident in individuals. Ketamine-induced activity changes in the cingulate and thalamus may partially account for its psychotomimetic effects.

INTRACEREBRAL TRANSECTION USING CATIONIC SYNTHETIC LIPID: AN ALTERNATIVE TO VIRAL VECTOR IN C5 gluMOA "SUICIDE GENE": THERAPY. P. Fujita*, IM. Veinor*, D. Cappari*, D. Chen, G. Amalfitano, IF Brunet, I. Motin, MF Nisou*, IM. Venet, AL. Berhad*, INSERM U 318, BP 217X GRENOBLE 38043 Cedex 9, FRANCE.

Therapeutical trials have been begun in human gliomas using retroviral transfection. It confronts us with the ethical problem of the use of vector obtained from infectious agents. For these reasons we investigate in vivo transfection using the synthetic vector DOTAP. We used the "suicide gene" Herpes thymidine kinase (TK). It transforms the antiviral ganciclovir in toxic phosphorylated components and induces a bystander-effect which explains that no more than 10 % of the cells need to be transfected.

DOTAP injected in normal rat brain did not induced any histological damages. In a model of C5 glioma cells transfected with TK and treated with GC was observed. A single stereotaxis TK transfection induced focal necrosis and no more than 50% volume reduction. Then, we used intratumoral cannulae providing intratumoral targeting and repeated transfections. In these conditions we observed dramatic tumor regression. When TK was injected outside the tumor we did not observed histological damages in the brain itself contrasting the absence of toxic effect of TK transfection in non dividing cells.

These results suggests that the DOTAP vector is as efficient as retroviral vector in a "suicide gene therapy" for experimental gliomas. It confort a phase I study in humans using repeated transfections through a nickham intra-tumor delivery.

731.3
A NOVEL HERPES SIMPLEX VIRUS "PIGGY BACK" PACKAGING SYSTEM FOR AMPLICON VECTORS. Peter Peñas*, I. Antonio Chico*, N. Antonio Chico*, Richard Thompson*, David P. Cooke*, and Xavier O. Breakefield. Dept. Neurology and Neurosurgery, Massachusetts General Hospital, Harvard Medical School, Boston MA 02114; Dept. Mol. Genetics, University of Cincinnati Medical Center, Cincinnati, OH 45267.

Herpes virus type I (HSV-1) vectors have proven to be efficient at transgene delivery to neurons and other cell types in culture and in vivo. In the recombinant virus system transgenes are incorporated directly into the HSV-1 genome. In the ampiclon system bearing the HSV-1 genome in one packaging vector, and a packaging signal, as well as a transgene, is packaged into virions through the aid of a helper virus. These two systems can be combined by making propagation of the vector and helper viruses mutually dependent on each other. In this study we are characterizing an ampiclon "piggy-back" vector system that uses a viral promoter to express a gene essential for HSV-1 replication, propagated with a mutant virus deleted in the same replication-essential gene. We have constructed ampiclon vectors bearing the immediate early IC44 gene under the control of the SV40 and the gial specific JC virus promoter elements. These promoters can be used to regulate expression of both IC44 and another gene in one ampiclon using an 15RS translational read-through element. As a helper virus we have used the IC44 deletion mutant d120 from Dr. Neil DeLuca, Univ. Pittsburgh, propagated on Vero cells or 207 glioma recombinants was selected using by PCR and Southern blots of Vero plaque lysates. Current data indicate that this novel packaging system has markedly delayed cytotoxic effects as compared to wild type virus, and is a more efficient delivery to neurons. This system provides a basic model which can be modified to include cell-specificity of vector propagation and inclusion of multiple transgene elements.

731.4

Herpes virus mutants offer a potential therapeutic alternative to conventional treatment modalities for malignant brain tumors. The rationale for this approach is that these genetically mutant viruses replicate preferentially in tumor cells and not within cells of the nervous system, which are generally post-mitotic. Thus, they selectively lyse tumor cells within the CNS. We have used a neuroattenuated Herpes Simplex Virus type 1 (strain 1716F) for in vitro and in vivo studies. In vitro, HSV-1716F is efficient at lysing human NTera-2 (a teratocarcinoma cell line) cells and two medulloblastoma lines DAOY and D283. In vivo, HSV-1716F regresses human NTera-2 brain tumors in nude mice and prolongs their survival relative to mock treated, tumor bearing mice. We have studied the pathology over time associated with tumor regression using Magnetic Resonance Imaging and immunohistochemical localization of HSV and tumor cells. We have also observed that viral replication is limited to the tumor as predicted. Thus, our results suggest that this is a feasible approach for the treatment of malignant brain tumors.
Long-term Observations of Thymidine Kinase Deficient HSV-1 Infection in the Rat Brain

William W.-G. Hu, Jean Tan, Max Cynader, Frank Tufaro and James Goldie
Department of Microbiology, University of British Columbia and Medical Oncology, BC Cancer Agency, Vancouver, BC, Canada

We have been using Herpes simplex virus to deliver foreign genes into the nervous system and to treat brain tumors. As a human pathogenic virus, the HSV-1 in its wild type form has been well known to cause clinical symptoms including severe encephalitis. We have recently demonstrated the effectiveness of the HSV-1 viral vectors in both gene expression and tumor-cell killing. In the present study, we have investigated pathogenic effects of the viral vectors in animals that survived at least 18 months after treatment. Rats were intracerebrally injected with 1 µl (10^8 pfu) of KOS-SB, a thymidine kinase-defective HSV-1 mutant (tk(-) HSV-1). Animals that survived at least 18 months without showing any sign of illness before sacrificed, and brain tissue was sectioned for histological and immunocytochemical observations. Neuronal stains showed a significant enlargement of the lateral ventricles in both hemispheres. Otherwise, the histology of other brain regions appeared normal. Immunocytochemistry with a polyclonal antibody for the HSV-1 virus failed to detect any viral antigen in these long-term surviving animals while positive immunostaining could be seen in brains of animals 7 days after viral injection. In these "short-term" animals, cells in the paraventricular regions showed strong reaction to the antibody staining. Monoclonal antibodies against major histocompatibility complex (MHC) antigens were also used to detect possible immune and inflammatory responses to the viral infection. No immunopositive cells were found in brains of the long term rats. Our results suggest that, although intracerebrally injected tk(-) HSV-1 virus caused mild encephalitis, the damage was limited and long term effects were minor. The failure to detect antigens of both the virus and MHC in long term animals further suggests that any damage observed resulted from an acute response rather than a chronic effect.

ADENOVIRUS-MEDIATED GENE THERAPY FOR EXPERIMENTAL PRIMARY AND METASTATIC BRAIN TUMORS

Neurosurg., Cell Biol., Path., and Howard Hughes Inst., Baylor College of Medicine, Houston, TX 77030.

The therapeutic efficacy of adenovirus-mediated transduction and ganciclovir (GCV) administration was tested in models of primary and metastatic brain tumors. A replicative-defective recombinant adenovirus vector (ADV-tk) was created that contained the herpes simplex virus thymidine kinase (HSV-tk) gene controlled by the Rous sarcoma virus LTR. HSV-tk phosphorylates GCV which acts as a chain terminator of DNA synthesis and selectively kills dividing cells. Syngeneic tumors were generated by injection of cultured glioma (9L) or breast tumor cells (MAT-B) cells into the rat caudate. Eight days after tumor cell injection, ADV-tk or a control adenovirus carrying the β-gal gene was injected into the tumors. The animals then were treated twice daily for 6 days with GCV or saline. Twenty days after tumor cell injection, the brains were examined microscopically and tumors were measured. Control rats in both models had large tumors. Rats treated with ADV-tk and GCV had no tumors at the primary site. Necrosis with macrophage and lymphocyte infiltration was present. In survival tests, control rats lived only 22 days after 9L cell injection. Treated rats lived 126 days when they were examined and found to have no residual tumors. These results demonstrate that adenovirus-mediated transfer of the HSV-tk gene confers cytotoxic sensitivity to GCV to tumors in vivo.
