Nuclear circuits arranged in a head-centered (cranioptic) framework influence smooth pursuit eye movements. Cranioptic nuclear motor organization is demonstrated in patients with acute cerebral hemispheric damage causing ipsilateral gaze deviation. These patients typically cannot generate pursuit movements across the orbital midline, away from the side of the lesion. Smooth pursuit was recorded from the frontal and central retinal lobe infarction. By comparing responses to target motion within the right and left gaze fields, cranioptic pursuit deficits were quantified. Responses were compared in rightward and leftward directions to identify directional pursuit asymmetry.

One patient had left hemispheric infarction with right spatial neglect and left gaze deviation. He could not make any eye movements across the orbital midline to the right, but smooth pursuit had lower velocities to the left within the left gaze field. Three patients with similar gaze deviation or nuclear motor region generated worse smooth pursuit in the gaze field contralateral to cerebral damage; each of these patients had lower velocities of pursuit for target moving in the ipsilateral direction. Cranioptic pursuit deficits are distinct from pursuit impairment based on the direction or retinal locus of motion. These deficits comprise a spectrum in which the most severe examples are associated with complete inability to generate smooth pursuit in the contralateral field of gaze. The cranioptic pattern of impairment implies that orbital positions are taken into account by cerebral mechanisms that govern smooth pursuit in humans.

488.4 ADAPTATION OF OPEN-LOOP SMOOTH PURSUIT RESPONSES IN THE RHESUS MONKEY. MEIERDINK, KALB, AND STEPHEN Q. LISBERGER. Dept. of Physiology and Keck Center for Integrative Neuroscience, UCSF, San Francisco, CA 94143.

During the initiation of smooth pursuit eye movements, there is a clear relationship between eye acceleration in the first 100 ms (the open-loop period) and target velocity. We have developed an adaptation paradigm for changing the eye acceleration response to a particular velocity. Adapting responses to track a target to a velocity that began to move at an adapting velocity, but accelerated or decelerated, after 100 ms, to a higher or lower velocity. Thirty minutes of adaptation caused a change in the acceleration of the target that began to move at an adapting velocity, but accelerated or decelerated, after 100 ms, to a higher or lower velocity. Thirty minutes of adaptation caused a change in the acceleration of the target.

The largest change in eye acceleration occurred in the interval 50-60 ms after the onset of pursuit, with less change occurring in the initial 0-30 ms interval. The adaptation decreased the eye acceleration along the horizontal direction, but did transfer in an unexpected way to other target velocities. With a stimulus that started at 10 deg/sec and accelerated to 30 deg/sec, the greatest changes occurred at test velocities lower than the adapting velocity. This paradigm will allow us to study neuronal changes that underlie adaptation of a relatively well-defined voluntary behavior that requires the cerebral cortex. Supported by NIH grant EY02878.

488.5 TWO DIMENSIONAL SMOOTH PURSUIT EYE MOVEMENTS DURING TRACKING OF DOUBLE SINE WAVES IN MONKEY. RE Kuffler, H.C. Lacey. ME Gerard & SJ Takikawa. Dept. of Physiology, Northwestern University Medical School, Chicago, IL 60611.

We examined smooth pursuit in the rhesus monkey along simple 2D trajectories by moving a back-projected laser spot successively along horizontal and vertical axes. Component waves had a maximum ratio of 2:3 and were equated for velocity. Stimulus and sum-of-sine tracking along the single axes were studied at the same frequency.

A computer generated contant eye position via a scalar search. Gain and phase were computed by correlating a reference to the stimulus.

Above about 0.6 Hz, the gain of all components decreased with increasing frequency. Phase differences were always less than 60° indicating good predictive pursuit. There were several components initially shown in the interactions between components on both the same axis and on opposite axes. (1) The addition of a higher frequency component reduced the gain of a component presented alone. (2) Reductions were greater for components added to the same as well as the target frequency. We found that high frequency components exceeded the target and low frequency components. (3) Horizontal and vertical waves were larger than the target velocity for component, as well as the target and low frequency components.

The study showed significant effects of components presented within 15 and same frequency. These effects indicate nonlinear interactions between components both within and across axes, and suggest distinct roles for high and low frequency components of the eye movement system. Other experiments reported similar data for 10 pursuit in humans. We also studied combinations between kinematic variables and tracking performance. Corrective saccades were mostly clustered around points of peak velocity. Pursuit gain was correlated with measures of peak velocity, acceleration and jerk. This explains why pursuit was better for cross-axis combinations that appeared subjectively smoother than the same components acting along the same axis. (Supported by grant MH 48188)

488.6 TWO DIMENSIONAL SMOOTH PURSUIT EYE MOVEMENTS DURING CIRCULAR TRACKING AND PERTURBATIONS IN MONKEY. H.C. Lacey, RE Kuffler, ME Gerard, SJ Takikawa. Dept. Physiology, Northwestern University Medical School, Chicago, IL 60611.

We studied smooth pursuit along three trajectories: circles, circles with occasional perturbations along horizontal or vertical midlines, and horizontal and vertical sinusoids. Reliable behavior developed after repeated sessions with reward delivered contingent upon correct fixation. Horizontal and vertical eye and target velocity curves were computed using a least squares error fit after removing all the saccades. Eye velocity gain was defined as eye velocity divided by target velocity. Eye velocity gain and phase response to a 5° circular trajectory with a frequency range of 0.2 to 1.8 Hz was examined. Gain and phase curves of horizontal and vertical components initially showed in the experiments were less than 60°, measured by decreasing gain and increasing phase lag at higher frequencies. Comparison analyses of horizontal and vertical sinusoidal pursuit showed similar trends. In both cases, corrective saccades were preferentially observed in a particular direction of horizontal and vertical velocity points, especially for the sinusoids. Because a number of kinematic variables including peak velocity and acceleration vary systematically during these tracking behaviors, this result was restricted to particular sinusoidal frequencies. Geckell and Tamminger (1984) have obtained similar gain and phase results in humans. Horizontal and vertical perturbations produced consistent corrective saccades after a delay of 130-180 ms. After perturbations and before corrective saccades, pursuit followed the curved trajectory of the non-perturbed waveform. This continuation of pursuit is caused by the prediction of the circular waveform instead of the maintenance of velocity in a single direction. Tracking along the perturbed axes showed attenuation in amplitude at all frequencies. However, pursuit along the non-perturbed axes only showed attenuation at higher frequencies. This indicates cross-axis interactions under these conditions. (Supported by grant MH 64185)

VISUAL TRACKING OF ILLUSORY MOTION IS AFFECTED BY TARGET WAVEFORM. A. Z. Zivotovska, I. Avberšek-Heller, C. W. Thomas, V. E. Das, A. O. DiLuzio, and T. Lei. VA Medical Center and Case Western Reserve University, Cleveland OH 44106

We studied ocular motor responses to a variant of the Duncan illusion, in which the perception of motion of an object is induced by moving its frame of reference.

Using the magnetic search coil technique, we measured head-fixed and head-free tracking responses of 10 normal subjects to vertical movement of a target (laser spot). Movement of the target was synchronized to horizontal movement of a sinusoidal grid with a period of 20 X 20 deg, producing a strong illusion of diagonal motion, the horizontal component being opposite to the direction of the grid. Both visual stimuli moved ± 9.2 deg at 0.35 Hz, either sinusoidally or in square waves. In response to sinusoidal target motion, gaze always followed the target vertically, with a small horizontal component (mean gain 0.05) that was phase lagged compared with grid movement by a mean of 37 deg. When the head was free to move, it usually (85%) showed a diagonal trajectory contrary to the gridded motion (mean gain 0.32) that was phase lagged compared with grid movement by a mean of 156 deg. In response to stepping target movement, inappropriate horizontal saccades were made for 71% of steps. When these saccades were anticipatory (38%), they were always (100%) in the direction of the illusion; when not (latency >90 msec), 49% of saccades were still in the direction of the illusion. The head tracking movements in response to stepping targets were also (100%) in the direction of the illusion. Thus, ocular tracking for sinusoidal and stepping target waveforms, the former being response to actual target motion, the latter to illusionary target motion. Head tracking, however, was always an illusionary tracking of the target, irrespective of its waveform.

OTOLITH DETECTION OF ANGULAR VELOCITY IN THE VOR. B. J. M. Hess*, D. E. Aneleaki, and J. J. Sasaki. Dept. of Neurology, Univ. of Zurich, Switzerland, Dept. of Surgery (Otolaryngology), Univ. of Mississippi, Jackson MS, Dept. of Otolaryngology, Tokyo Univ, Tokyo Japan

It has been shown previously that in the presence of simultaneous dynamic otolith input the vestibulo-ocular reflex (VOR) represents more faithfully head angular velocity in the low frequency range (Rade and Baker 1988; Tomko et al. 1998). These observations have raised two yet unresolved questions. First, do these characteristics of the otolith system represent a fixed or a learning property? Second, what is the functional significance of such a property? We have addressed these questions by examining the otolith contribution to the VOR in the absence of sinusoidal low frequency oscillations of the phase plane, using sinusoidal low frequency oscillations (0.1-0.01 Hz, ± 50°) and constant velocity-off-vertical axis rotations (0.5-5°/s).

Our results in the intact animals indicate that the low frequency VOR enhancement during simultaneous dynamic otolith stimulation reflects the sensitivity of the otolith system to head angular velocity. A masking observation was made in canal plugged animals: Acutely after canal plugging, the otolith contribution to the VOR was unchanged, however, it progressively decreased thereafter. Two months after the canal plugging, the low frequency and steady-state responses to sinusoidal and constant velocity off-vertical axis rotations were completely abolished in the plane of the plugged canals. Our findings in canal plugged animals do not support the current belief that the main function of the canal/otolith interactions through the velocity storage mechanism is to improve the low frequency VOR dynamics. Rather the low frequency dynamic otolith contribution to the VOR could reflect the inertial representation of vestibular angular motion signals in the velocity storage network (Aneleaki and Hess 1994).

TEMPORAL CONSTRAINTS ON THE MECHANISM OF LEARNING IN THE VOR. Jennifer L. Raymond* and Stephen G. Lisberger, UCSF Dept. of Physiology and Kirk Cherry, UC San Diego School of Medicine, San Francisco, CA 94143

Changes in the amplitude and dynamics of the vestibulo-ocular reflex (VOR) can be induced by the association of vestibular and visual (image motion) stimuli. We examined the dependence of these learned changes in the VOR on the temporal properties of the sensory signals used to induce learning. First, we studied for 3 hours with sinusoidal vestibular and visual stimuli at a single frequency from 0.5 to 10 Hz (±10°/s). The stimuli for adaptation were provided by passive head turns either with or without sinusoidal visual stimulation that mimicked the effects of magnifying or minimizing spectra. Adaptation with 0.5 to 5 Hz for 3 hours produced changes in the VOR, while maintaining the gain and phase of the VOR at the adaptation frequency, to a similar degree as with a step change in the VOR. Changes in the gain and phase of the VOR due to adaptation with 0.5 to 5 Hz for 3 hours were evident 1-2 days after adaptation. The changes in the VOR were small relative to the change in the phase of the VOR, while compared to the simultaneous onset or delayed visual stimulus onset. These temporal constraints on the stimulus that maximized these learning effects are likely to identify the neural mechanism(s) of plasticity in VOR pathways. SPATIOTEMPORAL VOR ADAPTATION AFTER SEMICANALICULAR INACTIVATION. D. E. Aneleaki*, B. J. M. Hess and J. J. Sasaki. Dept. of Surgery (Otolaryngology), Univ. of Mississippi, Jackson MS, Dept. of Otolaryngology, Univ. of Zurich, Switzerland; Dept. of Otolaryngology, Tokyo Univ, Tokyo Japan

Selective semicircular canal inactivation by plugging and three-dimensional eye movement recordings were used to address the following questions: 1) Is the 3D structure of the VOR matrix which relates semicircular canal inputs to oculemotor output? 2) How is the VOR matrix modified during recovery from inactivation of either of the vertical canals? To address these questions, horizontal, vertical and torsional eye movements were recorded during sinusoidal oscillations at different frequencies (0.01-1 Hz) and head orientations. The VOR matrix was computed before and after acute and acutely after canal plugging. Similarly, the evolution of the VOR matrix elements during recovery was computed from data acquired two weeks, as well as one, three and eight months after canal plugging.

The VOR matrix elements were frequency dependent. At low and high stimulus frequencies, inputs from the lateral and vertical canals contributed to torsional and horizontal eye movements. At low frequencies, however, the VOR matrix was diagonal. After semicircular canal inactivation, the VOR matrix in the mid and high frequency range changed continuously while gain and phase in the plugged canal plane progressively recovered. No recovery was ever observed at frequencies below approximately 0.05-0.1 Hz. These results suggest a frequency-selective central reorganization of vestibulo-ocular connectivity after selective semicircular canal inactivation. In addition, the limited range of the organization of the VOR in the mid and high frequency range differs distinctly from that in the low frequency range. This observation raises the possibility that the "velocity storage" was enhanced in the oculemotor system but that it might represent a distinct entity with different organization and function.

DIFFERENTIAL EFFECTS ON COMPENSATORY GAZE OF INTRAURAL (IA) LINEAR ACCELERATION IN MAN AND MACAQUE MONKEYS. S. Warren, T. Raphan, B. Cohen. Brookline, and T. J. Schabalk and C. Thyagarajan, Brookline, MA, Tufts University School of Medicine

Contributions of linear and angular vestibulo-ocular reflexes (LVOR & AVOR) to gaze stabilization were determined in macaque monkeys during centrifugation, off-vertical axis rotation (OVAR) and optokinetic after-nystagmus (OKAN). Animals were centrifuged either facing or back to motion with velocity trapezoids (40°/s² to 400°/s²) producing peak IA linear accelerations of 1.24g. Peak horizontal eye velocity (VEH) was invariant for the two orientations and beating fields remained close to the midline. Horizontal time constants (Tc) fell faster with GIA tilt (when facing than back to motion (.38s vs .69s)). This corresponded to UC asymmetries during yaw axis OKAN for low velocity stimuli with speeds decreasing before and after down and forward coupling. Dynamic parameter modification as a function of tilt was incorporated into our velocity storage model, using the OKAN Tc's from each monkey. These simulations accounted for all responses to VEH during centrifugation. Despite this, these monkeys had a direct horizontal translational LVOR during OVAR at velocities of 5°/s to 360°/s (~0.01-1Hz). Plugging the semicircular canals made animals less sensitive to yaw axis OKAN during centrifugation with similar GIA magnitudes (Warren, 1993). A direct consequence from the translational LVOR and consequent shift in the beating field was necessary to model the linear responses. The LVORS both modify the Tc's of velocity storage, reorienting AVOR coordinates, and generate direct compensatory responses to translation. Differentially weighting these two mechanisms accounts for different effects of linear acceleration on compensatory gaze in man and monkey during centrifugation. We used electromagnetic search coil techniques in darkness to assess at equilibrium the sinusoidally varying eye velocity (modulation) and average eye velocity (bias) of the VOR in cats during 5-32 Hz constant velocity horizontal axis pitch rotations. Modulation of vertical VOR eye velocity increased with head velocity, and was greater at all velocities for backward (nose up) than forward (nose down) rotations. Minimum modulation responses shifted toward forward rotations, occurring at +45°/s forward pitch. Slow phase eye velocity bias increased nonlinearly with head velocity and was greater for forward than backward rotations at all velocities. Minimum average eye velocity shifted toward backward rotations, occurring at -27°/s (backward).

We propose that these mechanisms are responsible for this behavior. (1) A central velocity estimate, generated from otolithic signals as proposed by others, which produces an eye velocity bias that increases with head velocity in the range tested. (2) As afferent or central "pitch" signal, generated from the rate of change of an anterior-posterior otolithic stimulus, which produces modulation of eye velocity increasing with head velocity. (3) A gravity-dependent dependent nystagmus (GDDN), as we reported in cats (NS 91), generated by a saccadic response to tilt, summing with the central velocity estimate to affect bias while also summing with the jerk signal to affect modulation of vertical eye velocity. The static position GDDN is near zero in the upright position and peaks with an upward slow phase of 180°/s tilt. During rotation the upward slow phase velocity of GDDN adds to the central velocity estimate, subtracting during backward rotation when the velocity bias is downward. Analogously the peak upward slow phase velocity of the GDDN signal at 180°/s tilt attracts from the peak modulation signal only during forward rotations when, at 180°/s, the eye velocity is downward. Thus the GDDN signal is of the correct direction and magnitude to account for the observed shifts in minimum slow phase eye velocity modulation and bias at low rotation velocities.

488.15 STATIC AND DYNAMIC EFFECTS OF GRAVITO-INERTIAL ACCELERATION (GIA) ON SPATIAL ORIENTATION OF VELOCITY STORAGE T. Rebber*, S. Yeung, B. Cohen. Brooklyn College of CUNY, Mt. Sinai School of Medicine.

We compared axis orientation during off-axis rotation and dynamic head tilt during post-rotatory nystagmus (PRN), i.e., tilt damping, to that during OKAN. We tested rotation from pitch to roll/yaw and roll to pitch/yaw. Absence of the latter was a key test in model-based studies of OKAN axis reorientation (Raphan & Stern, 1991). Monkeys were rotated off-axis at 10°/s & 40°/s to velocities of 200-400°/s, tilting the GIA vector from 17°-72°. Orientation vectors were computed using a model-based approach. During acceleration, the GIA vector had pitch and roll components and both pitch and roll cross-coupled eye velocities were generated. At constant velocity, the GIA pitch component remained, inducing continued pitch eye velocity that decayed with a 5-6s Tc. This was close to the yaw Tc. The roll component of the GIA dropped rapidly and roll velocity decayed with a short time constant (Tc = 1 s). Off-axis rotations of monkeys such that the GIA vector was solely in the yaw plane elicited no pitch-roll or pitch-roll axis reversing nystagmus. Yaw tilt damping during post-rotatory pitch rotation (PRN) with peak tilt velocities < 60°/s elicited no significant horizontal velocity and no pitch-roll or roll-pitch cross-coupling. Thus, the reported 'pitch-yaw' and 'pitch-roll' cross-coupling (Angelaki & Hess, 2004) is likely due to high velocity pulses along the yaw axis that charged the roll state with a small time constant which then discharged with a longer time constant when the animal was supine/prone. It is not due to additional off-diagonal terms in the system matrix. The recognition of eye velocity trajectories was the same during dynamic head movements and centrifugation as during OKAN (> 10°/s from the spatial vertical), and was predicted by dynamic parameter changes in the system matrix of velocity storage. We conclude that the yaw axis vector codes the spatial orientation of velocity storage during vestibular activation as during OKAN. Only the yaw axis vector is affected toward the spatial vertical when the GIA vector is shifted; the pitch and roll axes move with the head.

488.16 REDUCTION OF VOR TIME CONSTANT WITH MAINTAINED VOR IN A GROUP OF ELDERLY SUBJECTS. M. Dai*, B. Cohen, T. Raphan. Mount Sinai School of Medicine, Brooklyn College of CUNY.

Some elderly patients have short bilateral vestibulo-oculare reflex (VOR) time constants (Tc) but normal or high VOR gains. They generally complain of imbalance rather than vertigo. The anatomic basis for these findings is unknown. We studied 14 subjects, aged 75-93, with short VOR Tc and with high VOR gain, determined from the initial jump of slow phase velocity of velocity steps, ranged from 0.5-1.0 (mean 0.74±0.15). VOR Tc ranged from 3.5-5.0 (mean 4.2±0.6 s), compared to Tc = 15-25 s in normals. The gains of optokinetic nystagmus (OKN) induced by high field motion were normal (gain = 0.9-2.0 for 20 & 40 cycles/s), and there was no optokinetic after-nystagmus (OKAN). Subjects were rotated in a lighted earth-fixed surround for 15 sec and stopped in darkness. The post-rotatory VOR gain was the same as after they had been rotated in darkness. The post-rotatory eye velocity storage was not activated during OKN. This is in contrast to the normal reduction of post-rotatory eye velocity by 40-100% after rotation in light. The short VOR Tc and the absence of OKAN as well as the inability to reduce post-rotatory eye velocity could be modelled by a reduced torsional Tc and a deactivated velocity storage integrator. Aging is associated with degeneration of hair cells and a loss of fibers in the vestibular nerve. The selective impairment of the VOR Tc with preservation of gain may be secondary to selective hair cell or nerve fiber loss. The imbalance noted by these elderly people may be related to inactivation of velocity storage, which is important for coding spatial orientation and stabilizing gaze and posture during movement.

HIGH FREQUENCY, PITCH AND YAW VESTIBULO-OCULAR REFLEX (VOR) IN VERY ELDERLY PEOPLE. J. L. *Petter* and Robert W. *Halmagui*. Neurology & Department of Neurology, University of California, Los Angeles, 90024.

Advanced age is known to result in a shortening of the time constant of the yaw VOR at high frequencies, resulting in reduced low frequency gain and increased phase lead. Since these conditions are not representative of physiologic head movements during everyday life, we investigated the VOR of very elderly subjects during high frequencies in pitch and yaw.

Eye movements were recorded using magnetic search coils for pitch and electro-oculography for yaw in groups (N = 9) of young subjects (mean age 30 yrs) and very elderly subjects (mean age 80 yrs). Sinusoidal whole-body rotations (peak velocity 20-30°/sec) were presented. Gain and phase of the VOR was measured as a function of frequency. The VOR was obtained from digitally sampled signals following saccadic removal. It is greater for pitch than for yaw, and gain increased with increasing frequency. Gain in the very elderly was never significantly less than that in the young. The pitch VOR gain of the elderly was actually significantly greater than that of the young at 0.8 Hz (0.46±0.04 vs. 0.36±0.11, mean ± standard deviation, P < 0.05).

Very elderly people have no functionally significant determination of pitch and roll VOR at velocities ≥30°/sec. Possible velocity saturation in the high frequency VOR of the elderly, such as occurs at low frequencies, could be yet to be elucidated and is being studied in our ongoing experiments. However, these data suggest that the rotational VOR of elderly people is normal in the important function range of frequencies and velocities.

Following unilateral vestibular loss, high speed rotation towards the intact ear resulted in a higher gain than rotation towards the defective ear, resulting in a direction-dependent pendular response (DP) ([Gain=Int-Gain=Def]) (Gain=Gain Int)*100). This occurs because of the inability of inhibitory stimuli to decrease vestibular nerve firing rates to < 0. We examined the DP in 4 patients following unilateral vestibular nerve section, and in 2 patients with partial labyrinthectomy with absent caloric but spared vertical SCC on CT scan and compared it to 6 normal subjects. The horizontal VOR was measured by EOG during constant-velocity step rotations (20°/sec) while the head was pitched 30° up, kept level or pitched 30° down.

The DP in the control was less than 5% regardless of head pitch. The DP in patients with unilateral vestibular loss increased with increasing pitch in a manner less than expected by the degree in which the H and V SCC sense head acceleration. When the head is pitched down, head acceleration is maximally sensed by the H SCC and DP is maximum (23%). When the head is pitched 30° up 61% of the head acceleration is sensed by the H SCC. 25% is sensed by the V SCC, and there is little DP (4.2%). In the patients with spared V SCC, there is little to no DP when the head is level or pitched up.

These results suggest that rotatory cliché of head pitched up and down may be a useful technique for assessing V SCC function.

489.6

Using dual search coils we have recorded 3-dimensional eye position in normal subjects and in patients after unilateral vestibular deafferentation on the right (RUVD) or left (LUVD) side. We used two different paradigms. In a first set of experiments, subjects were exactly aligned with the axis of rotation, and then rotated at 20°/sec about an earth vertical axis to a steady state velocity of 250°/sec. These experiments produced two interesting results: first, even in normals, rotation about an earth vertical axis elicits torsional eye movements; and second, the torsional eye velocity components in LUVDs, normal subjects, and ENU mice, are different. In a second set of experiments, subjects were placed 1m out on the arm of the centrifuge, facing either toward the center of the rotation or away from it. Then they were accelerated at 10°/sec to 200°/sec. The results from eccentric rotation show the relative contributions of the saccadic canals and the otoliths, and an analysis of these experiments is presented.

489.7
THE EFFECT OF HEAD PITCH ON HORIZONTAL VOR GAIN DURING ROTATION AT HIGH SPEEDS. M.P. *Grant*, D.Y. *Toppi*, and D.S. *Zee*. Johns Hopkins University School of Medicine, Baltimore, MD 21207.

The VOR serves to maintain a stable retinal image during rapid changes in head position by producing slow-phase eye movements to offset the change in head position. Previous studies suggest that at low velocities (< 100°/sec) head pitch does not influence the gain of the horizontal VOR. We recorded horizontal VOR gain using EOG in 7 normal subjects during constant velocity chair rotations (60-300°/sec at 60°/sec) in yaw with the head pitched up or down 30°. The mean VOR gain with the head pitched down was 0.56, independent of speed. With the head pitched up, the gain decreased from 0.58 at 60°/sec to 0.40 at 300°/sec.

During the normal VOR at high velocities, central mechanisms must compensate for the nonlinear behavior of the primary vestibular afferents since the vestibular afferents are driven into inhibitory cutoff. This study demonstrates an unexplained decrease in the gain of the horizontal VOR in the head up position, suggesting the central mechanisms are not completely compensating for the nonlinear behavior. Two hypotheses which could explain our observations are: 1) Otolithic afferents may modulate the "antinonlinearity" mechanism. 2) The inputs from the horizontal and vertical semicircular canals may affect the "antinonlinearity" mechanism in different ways.

489.8

We recorded eye position during free text reading in a 48 year old man with clinically undiagnosed reading discomfor. Position traces were digitized at 200 Hz with a resolution of 1.52 arc min. Nonlinear dynamical systems analysis by the Grassberger-Procaccia algorithm demonstrated a correlation dimension (Dc) less than 3.0. In this patient, gross inspection of position and delay map traces during sinusoidal pursuit testing showed satisfactory pursuit right of the midline and saccadic pursuit left of it. This asymmetry persisted at all velocities tested.

Previous analysis of reading eye movements showed a Dc near 3.3 for 2 normal subjects, near 2.1 for a slow reader and a dyslexic, and indeterminate for a patient with acquired dystagmus. All non-dyslexic subject data showed evidence of multifractal behavior. These findings suggest that fractal analysis of unconstrained eye movements alone cannot explain the differences between normal and abnormal reading eye movements. Experiments using a forcing function and more sophisticated multifractal analysis may be more sensitive.
FAST SACCADE RESPONSES IN PARKINSON’S DISEASE

A. Etheridge, M. Wierschick, W. Wolff
Bundeswehr University, Munich, Germany, West Roxbury VA Medical Center & Harvard Medical School, Boston MA 02132.

Saccadic reaction times of 14 patients with mild to moderate Parkinson’s Disease (PD) were compared to those of 9 elderly control subjects (CS). The target appeared 8° left or right from the central fixation point at the time when the fixation point was switched off (gap 0) or 200 ms later (gap 200). An experimental session consisted of 200 trials in which directions and gap intervals were randomized. Only primary saccades were considered.

We found no significant differences in the mean saccadic reaction time between the PD and control group in either gap condition. The mean saccadic reaction time was shorter for gap 200 (PD 166 ms; CS 179 ms) than for gap 0 (PD 221 ms; CS 246 ms); this difference (gap effect) was not statistically different in between groups. There was a tendency toward shorter reaction times and a higher proportion of anticipatory saccades in the PD group. Express saccades were present in some gap 200 trials of several subjects in both groups. Therefore, we conclude that express saccades may be mediated by pathways which do not involve the basal ganglia.

In some subjects, anticipatory responses, identified by directional error, extended to longer reaction times and the entire saccadic reaction time distribution was shifted along the time axis. To allow for these effects, we proposed 1) correction of the bin value in the saccadic reaction time distribution based on the statistical estimation of the proportion of anticipatory saccades; 2) flexible boundaries for visually guided saccade types (express, fast regular, slow regular) by introducing an adaptive classification schema.

CONTROL OF POSTURE AND MOVEMENT VII

THE INFLUENCE OF TARGET MOVEMENT ON REACHING AND GRASPING IN LEUKOTOMIZED AND UNLEUKOTOMIZED ADULTS WITH SCHIZOPHRENIA

H. Canavan; D. Elliott; A.P. Velazquez
Dept. of Kinesiology, McMaster University, Hamilton, Ont., & Victoria Hospital, London, Ont. Canada.

Seven leukotomized adults with schizophrenia (LS), eight unleukotomized adults with schizophrenia (ULS), and eight healthy control (C) individuals were required to reach toward and grasp a small object that was either stationary or moving. Reflective markers were placed on the subject’s index finger, thumb, and wrist, and movements were videotaped. As expected the LS and ULS groups moved more slowly than the C group when the target was stationary. However, when the target was moving, all three groups moved faster, with the LS and C groups having the same movement times, and the ULS group having the fastest movement time. When the timing of the reaching trajectory was assessed, the LS group spent less time decelerating toward the object, indicating their movements were controlled with less precision. When grasp formation was analyzed, for the stationary condition, the maximum amplitudes of the LS and ULS groups were not different, and both were larger than those of the C group. For the moving target condition, aperture increased for all groups but was smallest for the C group, intermediate for the LS group and largest for the S group. There was actually no within subject variability in peak aperture for the LS and ULS groups in comparison to the C group, perhaps indicating a limited repertoire of motor response. These results are discussed in terms of the role of the frontal lobes in reaching and grasping, and the ability of schizophrenic individuals to use redundant information. (Supported by NSERC).

UPPER EXTREMITY RHYTHMIC MOVEMENTS: EFFECTS OF ARM POSITION AND FATIGUE ON DYNAMIC PATTERN SWITCHING AND MUSCLE COACTIVATION

S.M. Tuel, W.B. McKay, D.N. Surber, and A.M. Sheffer
Dept. of Physical Medicine and Rehabilitation and Division of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, TX 77030.

Dynamical motor patterns of the fingers have shown evidence of multistability and nonlinearity. As rate of cycling increases, loss of stability and pattern switching occur. We examined how these effects were different in whole arm movements in different forearm positions, pronated and supinated, and in the rested and fatigued states.

Subjects were asked to trace a figure-8 on a digitizing tablet using a writing cuff to stabilize pen position. Surface EMG was obtained from the pectoralis, infraspinatus, biceps, triceps, wrist flexors and extensors. Subjects cyclically increased the rate of tracing until pattern switching occurred.

The critical frequencies for pattern switching depended on the position of the forearm, the orientation of the figure-8, and the direction of movement. EMG analysis indicated that the majority of control occurred in the proximal muscles at slow speeds, but distal activity increased with speed. The analysis of the pattern switch, followed by a change of EMG activity from tonic to more phasic, fatigue decreased the critical frequencies and shortened the latency of coactivation, but does not appear to alter the relationship between those characteristics.

IMAGE PROCESSING MEASUREMENT OF EYE MOVEMENTS IN HUMANS AS A Viable ALTERNATIVE TO SCLERAL SEARCH COILS

S.T. Moore, T. Haslwanter, I.S. Curthoys, G.M. Halmagyi
Dept. of Psychology, University of Sydney, NSW, 2006.

Up to now, scleral search coils have been the only way to measure 3-dimensional eye position in human subjects accurately. The main disadvantages of search coils are the need to wear a contact lens, and the cost of the coils. To overcome these disadvantages, our group has developed an image processing technique for measuring 3-dimensional eye position “VMT”, which is based on commercially available video cameras and personal computers. Horizontal and vertical eye position are determined by tracking the center of the pupil; torsion is obtained by measuring the amount of rotation of a segment of the iris about the pupil center. We found that it is possible to express eye position accurately in a manner analogous to coils, i.e. in rotation vectors or Euler angles, if we take into account a geometrical distortion of the video image of the eye when calculating eye position. Neglecting this image distortion leads to large errors in measured ocular torsion. We present a summary of the techniques used, the effects of the correction algorithms, and show experimental data, for example Listing’s Plane, obtained with this video system.

A METHOD OF ANALYSIS TO DETECT AND CHARACTERIZE UPPER LIMB CONTROL DEFICITS IN SUBJECTS WITH STROKE

PA Genovese, CA Giulianati
KE Light Motion Analysis Laboratory, UNC CH, Chapel Hill, NC 27599-7153.

The purpose of this study was to develop measurements based upon dynamic systems analysis and nonlinear dynamic for the comparison of the upper limb trajectories and reciprocal limb movements and to characterize limb control deficits in subjects with stroke. Twenty five subjects with CVA (12 left, 13 right) and 25 age and gender matched non-disabled (ND) subjects were tested vertical limb movements. All subjects were videotaped for 2-D analyzing 15 times fast as possible with a stylus on a 3 inch target for 10 seconds. The trajectory of the stylus was digitized at 60 Hz and the data were 4 times upsampled through Fourier interpolation. Variables included: cycle period, peak vertical position, up and down velocities, the ratio of amplitude/velocity slopes, the ratio of acceleration to deceleration duration for upstroke and downstroke, the ratio of maximum to average velocity for upstroke and downstroke, Pearson’s r coefficient for return maps of cycle period and peak amplitude, and harmonic magnitude ratio (HMR). Subjects with CVA had lower tapping frequencies (< 0.0001) than ND subjects and exhibited spatial and temporal asymmetries between upstroke and downstroke that were markedly different than those of the ND subjects. Return maps of peak position showed significant (< 0.0001) differences in the control of successful peak vertical positions due to dominance, and to the presence of right and left brain lesions. Significantly higher values for HMR were seen for dominant limbs of ND subjects, and for ND subjects compared to subjects with CVA. High values for HMR may represent minimum jerk movements. The results of this study suggest that these analyses captured the movement dynamics of the stylus trajectory and are sensitive to subtle differences in upper limb control between dominant and non-dominant limbs in ND subjects and between involved and uninvolved limbs of subjects with CVA. Supported in part by a grant from the Foundation for Physical Therapy.

FRICCTION, NOT TEXTURE, DICTATES GRASP FORCE USED IN OBJECT MANIPULATION. Genevieve Cadoret* and Allan M. Smith, Centre de Recherche en Science Neurologique, Universite de Montreal, Quebec, Canada, H3C 3J7
A study of grasping and lifting in 10 subjects indicated a capacity to detect the friction of surfaces of a grasped object against the skin and adjust dynamic and static grip forces accordingly. Ten sandpaper surfaces, were composed of smooth or 1.0 mm raised beads spaced at 2.0 or 3.0 mm intervals etched in polyamide plastic. In addition, the surfaces were treated with lubricant (e.g. talc), or adhesive (e.g. water or sucrose) coatings which either increased or decreased the coefficient of friction. Changes in friction were associated with appropriate and inversely scaled changes in grip force. Both the dynamic grip force used to lift an object, as well as the static force used to hold it against gravity were negatively correlated (r = -0.70) with the coefficient of friction. Surface texture was only effective in changing grip force insofar as it altered the surface friction. Lubricants had less effect on the coefficient of friction of textured surfaces because of the smaller area in contact with the skin. Conversely, adhesives increased the friction of the smooth surface more than the beaded surfaces. The grip forces for all subjects reflected changes in the coefficients of friction and ignored the changes in surface texture. When coatings were used to equate different textures to the same coefficient of friction, the grip force profiles were nearly identical. This research was supported by the Medical Research Council of Canada and a fellowship from FCAR groupe de recherche sur le systems nerveux central.

DISCRETE POINTING MOVEMENTS IN ALZHEIMER’S DISEASE: EVIDENCE OF PRESERVED AND IMPAIRED MOTOR CONTROL. J.D. Faul, K. St. Leger, L. de Chazal, P. McGeer, L. McGeer, Dalhousie University and Camp Hill Medical Centre, Halifax, N.S., Canada
This study employed a kinematic analysis of visually directed upper limb movements in an unconstrained pointing task, to see if characteristic deficiencies in the performance of Alzheimer’s disease (AD) patients could be identified. Groups of young controls, elderly controls, and patients with clinically probable AD were asked to point to small or large light targets, that were presented randomly in one of 4 locations, and that were illuminated either for 500 ms or until the target screen was contacted. For some blocks of trials the subjects were asked to point “as quickly as you can” while for others, they were asked to point “as accurately as you can.” All groups showed the same pattern of changes in their motor behaviour in response to the trial-by-trial changes in target characteristics. Although both control groups demonstrated changes in peak velocity, duration of deceleration, and accuracy with changes in the instructions, the AD group failed to modify their performance in accordance with the changes in the objectives of the task. This study illustrates that impairments analogous to those revealed on cognitive neuropsychological tasks may be evident in the motor planning and execution of relatively simple reaching tasks.

SYNCHRONIZATION AMONG MOTONEURONE POOLS DURING DIFFERENT PHASES OF CAT REACHING. M. L. McCurdy*, T. M. Hamm, and K. M. Horn. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85015.
Coherence spectra reveal the strength of synchronization between common neuronal systems or nerves and are used as evidence of common synaptic input (Christakos et al., 1991; Farmer et al., 1993). Coherence analysis of electromyographic records collected from elbow, wrist and digit muscles during a reaching task from one cat was used to determine synchronization during reach, grasp, hold and stance phases. Significant coherence was observed at lower (\textless{}20Hz) and higher frequencies. Stronger coherence at higher frequencies was present between proximal and distal muscles during the reach phase than during the grasp phase. Coherence at high frequencies was also found in comparisons among digit muscles or digit and wrist muscles during reach, grasp and hold phases, but not the stance phase. These findings suggest that there are common inputs to motor pools involved in the reaching task. In addition, inputs may differ during various phases of movement. Direct descending projections from the red nucleus to digit pools (McCurdy et al., 1987) may account for coherence among distal limb pools while interneuronal pools projecting magnocellular and parvocellular nuclei may be important during the reach phase. Supported by NS22454 and NS30013.

THE EFFECTS OF GRADED TACTILE ANESTHESIA ON THE CONTROL OF GRIP FORCE. K.J. Cole* The University of Iowa, Iowa City, IA 52242.
Tactile sensory information from the hand appears to provide information about discrete mechanical events during manipulation of objects (Hohmann, R.S. In Humphrey, D.R., Freund, H.F. Motor Control: concepts and issues. Wiley, New York, pp. 351-355, 1991). One prediction from this theory is that altered fingertip forces are unlikely at mild levels of tactile anesthesia. A sufficient population of afferents should remain to encode the necessary mechanical information. Tactile anesthesia of the hand was induced by variably compressing the median nerve at the palm in three subjects. Median nerve function was monitored by recording the compound sensory nerve action potential (SNAP) at the finger from electrical stimulation of the nerve at the wrist. The forces at the fingertips (normal and tangential, corresponding to the grip and lift forces) were recorded as subjects lifted an object using the thumb and index finger. Reductions in SNAP amplitude of 20-30% yielded small but significant decreases in tactile sensitivity. Fingertip forces were normal in their size and timing in all subjects. Substantial increases in grip force occurred when SNAP amplitudes were reduced by 50% or more. No subject could detect cotton stroked on the fingertips and all reported that their hand felt ’thick’. Grip forces returned to precompression levels when SNAP amplitudes returned to 70% of normal. These observations are consistent with the theory of discrete event sensory-driven control of grasp.

490.8
Valid measurements of spasticity are needed to evaluate effectiveness of therapeutic interventions. The angle at which EMG onset to passive muscle lengthening (threshold angle) occurs has been suggested as a measure of spasticity. However the conditions under which consistency in threshold angle responses within subjects occur remains to be determined. This study determined the effect of starting joint position and velocity of stretch (provided by a torque motor) on threshold angle within and between subject. Two starting angles and 2 stretch velocities (the conditions) were randomly assigned at each of 15 shortening sessions among 5 patients with spastic hypertonia. Threshold angle was determined from biceps and brachioradialis EMG responses. Starting angles used: 70° and 90°. Neither starting angle nor duration produced a significant effect on threshold angle (p<.05). A 90° starting angle and a 1.0 rad/s velocity stretch yielded the most consistent threshold angles between sessions within subjects. If data from these subjects can be extended to more patients with spastic hypertonia, then ability to use threshold angle to measure spasticity consistently should depend on: comparison within individuals, use of a consistent starting angle, and use of condition 90° and 1.0 rad/s across sessions. IS ACCURACY IN POINTING INFLUENCED BY DISTURBANCES TO POSTURAL KINESIOLOGY?: S. Prentice and I.S. Fink*. Dept of Kinesiology, Univ of Waterloo, Waterloo, Ontario, Canada, N3L 3G1.
Vibration of the posterior muscular systems is known to cause illusions of falling forward. In a previous illusion study we demonstrated one’s ability to locate a target in space: the arm’s position became elevated in the presence of Achilles tendon vibration. This study further investigates the relationship between postural kinesthesia and the performance of a goal-directed arm movement. Subjects (N=7) stood in the dark and pointed to a 5x5 matrix of diodes. Only those diodes located in the vertical midline were analysed. Bilateral vibration of the Achilles tendon was initiated after the target diode had been extinguished. In the previous study, vibration was present during target illumination. All movements were initiated with the arm at the subject’s side, and targets were located 20° and 5° above and below a shoulder angle of 90°. Trials were randomized with respect to target diode and vibration, with each combination being presented only once. Joint angles (Opatokon) and center of pressure data confirmed that subjects tended to lean backwards in response to the illusion of falling forward, which was induced by the vibration. The trunk orientation remained unchanged in the presence of vibration. Vibration also had no effect on the final position of the arm or on the accuracy of the pointing movement. The accuracy of pointing could be attributed to the effects of vibration on the perceived target location rather than postural orientation. Since vibration was not on during target illumination, there was not a false impression of target location and an accurate pointing movement was achieved. Thus, it appears that postural kinesthesia has a limited contribution to pointing movements when gravitational cues are present, and perception of target location dictates the pointing movement.
490.11

Previous work in our lab has shown a predictable pattern of ground reaction forces (GRFs), center of pressure (CP) and postural muscle activity (EMG) during visually cued fast-paced focal reaching movements in normal subjects. Following stroke, GRFs were prolonged and decreased in amplitude, CP excursions were both decreased and abnormal and postural muscle activation was delayed and had increased variance. In contrast to the literature, we found that patterns of muscle activation were variable and subject-specific in stroke. Moreover, muscle activation patterns were not related to pre-established clinical postural measures, but appeared to relate to the site of lesion (cortical (C) versus basal ganglia (BG)). We postulated that C lesions would have decreased reaction time/movement time ratios (RTMTs) compared to normals indicative of disordered movement execution whereas BG lesions would have increased RTMTs indicative of disordered movement preparation.

Current studies show that RTMTs are 14% lower for the C's and 11% higher for the BG's in comparison to controls. C's are unable to activate contralateral distal postural muscles whereas BG's are able to activate bilateral postural muscles but with inappropriate temporal sequencing. These findings support lesion specific sensorimotor processing deficits in postural regulation associated with goal-directed movements. Subject specific 1-D lesion reconstructions using MRI and differences in postural muscle activation strategies are presented for subjects with C and BG lesions during both cued and self-initiated fast reaching movements. Changes in control of aiming movements as a function of practice have been characterized in healthy, young adults (e.g., Proteau & Cournoyer, 1990), but the literature is silent about practice effects in the performance of these movements in adults with brain damage. Subjects with unilateral cerebral lesions have demonstrated differences in performance and control of aiming movements dependent on the side of the lesion. We suggested that each hemisphere has a specialized role in motor control (Haaland et al., 1987). The purpose of this study was to investigate the differential roles of the hemispheres in the control of aiming movements in adults with unilateral stroke. Two groups of right-handed adults with unilateral stroke (right-RS and left-LS) practiced a reciprocal aiming task in the same 500 target hits in each condition. Compared with the LS group, the RS group required more trials due to a higher error rate. Movement time group differences were largest early in practice. Kinematic analyses revealed differences in control strategies over practice. Overall, subjects increased horizontal velocity, especially in the less difficult condition. Using the vertical dimension revealed group differences which increased over practice. In contrast to the persistent low vertical target impact of the LS group, over practice the RS group appeared to use impact to minimize reversal time. The inability of the LS subjects to optimize the reversal despite practice is consistent with the role of the left hemisphere in the sequencing of actions (Winston & Pohl, 1994). To address the effect of handedness, healthy controls were tested and their performance was compared to that of these post-stroke patients. 490.13

We investigated the effects of surface texture (satin and sandpaper) on perceived weight in a task in which subjects lifted a reference object and then a test object with the same hand using a precision grip with the tips of the thumb and index finger at the sides. Subjects judged objects covered in satin to be heavier than objects of equal weight covered in sandpaper. The results suggest that the effect of texture on perceived weight may be due to grip force: the greater the grip force required to lift the more slippery satin objects is greater than that required to lift the sandpaper objects. These results suggest that the effect of texture on perceived weight may be due to grip force: the greater the grip force, the heavier the perceived weight. This conclusion was supported by a control study in which subjects grasped objects with the index finger and thumb above and below the object so that different grip forces for the two textures would not be required. In this case, there was no effect of texture on perceived weight. The implications of these results with respect to sensorimotor memory are considered.

AUTOMATIC ADJUSTMENTS OF REACHING MOVEMENTS TO A TARGET THAT MOVES UNPREDICTABLY. B. Di G. & P. Lyon, MRC HMBU, Institute of Neurology, Queen Square, London WC1N 3BG, UK.

We have investigated the limb adjustments that occur when reaching for a target that moves and how these responses are modified by the subject's intent. Subjects (n=8) reached out to touch a disc of light projected on to a screen in front of them. In a third of the trials, approximately 25ms after movement onset, the disc moved either to the left or the right. Subjects were required either to continue trying to point to the disc (P+) or to point in the opposite direction as soon as they perceived it to move (P-). This was contrasted with a reaction task in which subjects had to reach for their index finger stationary in front of them. When the disc moved, they had to either follow it (R+) or move in the opposite direction (R-). The position of the finger tip in space was recorded at 5ms intervals (Selspot).

In all conditions, when the disc moved, the finger tip began to move in the same direction approximately 130ms later. However, in the P- and R- conditions, this was followed by a second response in the opposite direction, at approximately 200ms. The magnitude of the early response was measured by calculating the lateral deviation of the finger during the period 130-190ms and finding the difference between target left and target right trials. These magnitudes were (mean ± SEM): P+ 18.1±4.4mm; P- 9.3±2.5mm; R+ 2.3±0.8mm; R- 7.0±2.9mm. The results show that arm movements can be adjusted at short latency by a moving visual stimulus. The fact that the early response was not suppressible by voluntary intent may suggest that it is an automatic or reflex component. The early response was much larger during a reaching movement than in the reaction task which indicates that the mechanism is task-dependent.

490.15

Multijoint arm movements of individuals with Huntington's Disease (HD) were examined using 3D kinematic analysis. Six HD subjects with moderate chorea and 4 age-matched healthy subjects performed rapid pointing movements to 1" target located at 3 distances, 2 of which required trunk motion. HD subjects were divided into high and low functioning groups (HF and LF) based on the Barthel index. Movement times of HD subjects were longer than healthy subjects (p<.005). All HD subjects had similar curvilinear hand paths, which were not reflective of an inability to move shoulder and elbow joints simultaneously. However, LF subjects showed greater variability in the hand paths and shoulder/elbow coordination, particularly in the fastest target which required substantial trunk movement. Whereas the movements of healthy subjects showed unimodal hand tangential velocity profiles, the movements of HD subjects were multimodal. For the HF subjects, a large initial movement was followed by smaller submovements (SM's) as the subject honed in on the target. Moreover, the peak velocity and amplitude of the initial movement scaled with target distance. The velocity profiles of the LF subjects were more variable, especially for the farther distance, and there was a larger number of SM's than the HF subjects. Additionally, the LF subjects did not scale peak velocity to displacement. Presence of SM's in all HD subjects could be due to increased force modulation, or to factors such as slowing of movement and greater accuracy constraints, as previously observed in healthy subjects (Müller & Iba, Neuroscience, 1990).

ADAPTATION TO CORIOLIS FORCE DISTORTIONS OF REACHING MOVEMENTS IN THE BLIND. J.R. Lackner*, R. Eastover, E. Bentzen, D. DiZio* Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254 and Psychology Department and School of Education, Boston College, Chestnut Hill, MA 02167.

Forward reaching movements during passive, counterclockwise body rotation (10rpm) generate Coriolis forces that deviate the arm to the right. As a movement slows down the Coriolis force abates and the arm trajectory bends back toward the intended path but still ends significantly to the right of pre-rotation endpoints. Normal subjects have straight line trajectories and accurate endpoints, without tactile feedback about target location, within ~20 reaches in darkness and 6 with sight of the arm. We exposed five congenitally blind subjects to Coriolis forces as they attempted to reach forward along their perceived body midline (distance, 32cm; peak velocity, 620mm/s). Relative to pre-rotation their movement trajectories were deviated rightward 55°, peak, and ended 47mm right. After 20 reaches their endpoints were again accurate and movement trajectories straight. Thus, blind subjects adapted to Coriolis force perturbations of their arm movements as well as sighted subjects despite vision. Vision is clearly not essential for motor adaptation to altered inertial characteristics of arm movements. Braschel proprioceptors, cutaneous receptors and effrent commands must be providing the information used to tune arm trajectory and endpoint. Supported by NAG 9-515 and NTS 6933002.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
In a reaction time task with two possible directions and two possible extents in each direction, direction and extent cues were considered equivalent in information-theoretic terms. Precise information about direction should have the same effect on reaction time (RT) as information about extent. Eight subjects performed a wrist pronation-supination RT task to one of two possible extents in each direction. One, two or four targets were lit prior to the GO signal to give five different conditions: (i) a single target lit specifying direction and extent; two targets lit specifying (d) direction only, or (ii) a choice of two direction-extent combinations; and (iv) four targets lit.

Subjects performed 320 trials per condition in four sessions of four blocks (100 trials each) randomly mixed recorded on different days. Results showed that direction prewcing was associated with significantly greater RT benefit (shortening) than extent. Prexuing extent but not direction was no more beneficial than giving a choice of two different yet completely specified targets, but did offer an advantage compared to conditions in which no precise information was available. These results indicate an equivalence in the way that information about direction and extent are represented in the brain. They are consistent with a model of motor programming in which movements involving antagonist groups of muscles are represented by different cell assemblies while level of activation within an assembly encodes movement extent.

**CIRCUITRY AND PATTERN GENERATION II**

491.2

A major action of second messenger systems is the modulation of the electrical properties of neurons. The effects can be complex, however. A single second messenger can directly modulate several types of ionic currents in a cell and these currents may indirectly affect other currents via voltage-dependent or Ca**+-dependent mechanisms. Thus, in order to understand these global actions of modulatory agents, it is necessary to have a detailed understanding of all of the relevant currents and their modulatory influences. One neuron which meets these criteria is the endogenously bursting neuron R15 in *Aplysia*.

We have implemented proposed mechanisms for the modulation of two ionic currents (Na and Ca**) associated with a model of R15. The model is sufficient to simulate a wide range of endogenous behavior in the presence of various concentrations of serotonin (5-HT) or dopamine (DA). Additional insights into the consequences of modulation of multiple currents were obtained by placing the model into a silent or bursting mode by various methods and examining the model’s response to extrinsic stimuli. Some of these insights were obtained by examining the Ca**+-dependency of I-V plots. Also, by selectively “clamping” specific variables within the model we were able to elucidate mechanisms through which depolarizing and hyperpolarizing pulses can terminate bursting and elicit a sustained (9-10 sec) postinhibitory hyperpolarization. The results suggest that the actions of modulatory agents and second messengers cannot be understood on the basis of their direct effects alone. It is also necessary to take into account their indirect effects on other unmodulated ion channels which occur through the dynamic interactions of voltage-dependent and Ca**+-dependent processes.
491.3 SEROTONIN REGULATES THE ELIGIBILITY FOR MULTIMODAL ACTIVITY IN THE BURSTING NEURON R15 IN Aplysia H. A. Lechler, D. A. Baxter, J. W. Clark and J. H. Byrne* Dept. of Neurobiology and Anatomy, and Dept. of Electrical and Computer Engineering, Rice University, Houston, TX 77005, and Dept. of Electrical and Computer Engineering, Rice University, Houston, TX 77251-1892.

Simulations of a mathematical model of the bursting neuron R15 in Aplysia, revealed that multiple stable modes of oscillatory electrical activity can coexist in this neuron when the stimulus is applied. The transient synaptic inputs can induce a persistent shift from one mode to another and that modulatory transmitters can regulate multimodal activity (Canavier, 1993).

Intracellular recordings from R15 revealed that long-lasting changes in synaptic activity can be induced by brief (0.3 - 1.5 s) depolarizations (5 - 10 nA) that trigger transient spikes (10 - 20 mV) caused by changes in the membrane input resistance, as predicted by the model. Under certain conditions such perturbations were able to switch the electrical activity of R15 between bursting and plateauing. The bursting persisted for varying durations ranging from ~30 sec seconds up to ~40 min. The effect of perturbations was dependent on two factors, steady-state bias current and the presence of serotonin (5-HT). Perturbations were ineffective for bias currents of <0.5 nA, whereas 30 - 40 % of the perturbations triggered transitions from bursting to plateauing with bias currents >1 nA. In the presence of 5-HT (2.5mM), multistability was observed at lower levels of bias current. With a bias current of 0.5 nA transitions to plateauing were triggered in 60 % of the cases, and with bias currents >1 nA 40 - 50 % of the perturbations induced transition.

We conclude that both 5-HT and depolarizing bias currents can regulate the eligibility of R15 for mode shifts, and thus may alter its sensitivity to synaptic input.

491.4 DETERMINATION OF SYNAPTIC POLARITIES USING A COMPUTATIONAL CELLULAR MODEL OF THE NEMATODE TAP PEPTIDE RECEPTOR ANTIBODY RECEPTOR CIRCUITRY OF THE NEUROPHYSIOLOGICAL Basis of Synaptic Transmission in C. elegans. C. J. Rockstein, A. S. Wicks and J. C. Rankin* Dept. of Computer Science and Engineering School of Medicine, University of British Columbia, Vancouver, B.C., Canada V6T 1Z4.

The nematode C. elegans is a small soil-dwelling worm which exhibits many behaviours found in higher vertebrates, such as motor patterns, learning, and memory. Its genetics, neuroanatomy, and physiology are well understood to the point where it is possible to construct a model of a complete behaviour that includes all individual neuron and synapse.

We have previously constructed a computational model of the C. elegans tap peptide receptor system. The model consists of 7 sensory cells and 9 pairs of interneurons, which were found to play a role in the tap withdrawal reflex (Wicks and Rockstein, 1992), together with a "gateway" that models the motoneuron circuitry and mechanisms which trigger the movement evoked by the tap. Based on the evidence from the CPG, we have shown that a non-synaptic, sequential model of the neuron membrane potential and a two state, and graded model of synaptic transmission. Synaptic efficacy was inferred from anatomical data (White et al., 1986).

The polarities of the synapses are as yet unknown and we have developed a strategy to use our model to predict these polarities. We computed the polarities of all synapses using a constrained optimization based on the results of the model's predictions for the avoidance behaviour of the larval worm when different neurons were ablated using laser microsurgery. In addition, we used a modified functional test to determine interaction effects between connection polarities and other physiological parameters that describe membrane properties and synaptic activation kinetics.

491.5 EVIDENCE THAT SEROTONERGIC/NEUROMODULATORY INTRINSIC TO THE TRITONIA SWIM CPG IS DUE TO PRESEMBLY ENHANCEMENT OF RELEASE. P. S. Katz and W. N. Frost, Department of Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77030.

One of the neurons that controls the pattern generator (CPG) for escape swimming in the mollusc Tritonia doliolus evokes neuromodulatory effects upon other members of the CPG. We previously reported that stimulation of one dorsal swim interneuron (DSI) produced graded synaptic potentials evoked by neuron C2 onto two followers: the dorsal flexion neurons (DFN) and other DSIs (Katz et al., Nature 367:799-791, 1994). Our evidence now suggests that this neuromodulatory effect is mediated by serotonin acting on the presynaptic neuron (C2) rather than on its followers. 1) DSI enhanced the chemical synapses (both excitatory and inhibitory) of C2 onto each of its followers which have been tested, including the ventral swim interneurons (VSI), DSI, DFN, and pedal cells not directly postsynaptic to DSI. 2) DSI evoked little or no change in R15, recorded in the somata of C2 followers. 3) DSI-evoked modulation did not affect the ERS of the synapses. 4) If the effect were postsynaptic then inputs from other neurons onto the follower might be enhanced, yet DSI stimulation did not enhance the synapses from other DSIs onto the same C2 follower, but instead caused them to decrease.

Although the mechanism producing the presynaptic enhancement is not known, possible mechanisms are suggested by the following observations. Stimulation of the serotonergic DSIs decreased the hyperpolarization (APH) following C2 spikes. Likewise, exogenous serotonin also caused the C2 AHP to decrease. The decrement in AHP may be related to presynaptic currents Involved in transmitter release. Preliminary results indicate that DSI stimulation also may interact with the homosynaptic facilitation of transmitter release from C2. (This work was supported by NIH grant MH49635).

491.7 CACLIUM PLATEAUS AND GRADED SYNAPTIC TRANSMISSION IN LEECH HEART INTERNEURONS. G. O. Olsen, O. Nadim, and R. L. Calabrese, Dept. of Biology, Emory University, Atlanta, GA 30322.

Pairs of reciprocally inhibitory neurons in the leech CNS form the oscillator that controls the frequency of the heart rhythm. These pairs oscillate in antiphase, generating bursts with underlying plateaus and both graded and spike-mediated postsynaptic transmission. To find the extent to which low-threshold Ca currents contribute to plateaus and determine the duty cycle of the graded synaptic transmission, we voltage-clamped such a neuron with a voltage waveform that was obtained by removing the spikes from real waveforms. Its postsynaptic cell was voltage-clamped at -35 mV and showed the graded postsynaptic current associated with these presynaptic oscillations. The same experiments were also performed in a detailed conductance-based model of the two cells. The results confirmed the predictions of the model; the rise of the plateau cannot be completely accounted for by the Ca currents only. Thus other inward currents like the persistent N-type Ca current and the hyperpolarization-activated inward current (h) contribute in the process of building the plateau. The duty cycle of the graded synaptic transmission proved to be smaller than 0.5, thus suggesting that the spike-mediated transmission is necessary to produce the observed prolonged inhibition.

These results are supported by further experiments in Na-free saline where the persistent Na current and h-current were reintroduced through dynamic-clamp (Sharp et al., TINS 16: 369, 1993). To obtain non-synaptic oscillations, it was necessary to add these currents, thus demonstrating their role in maintaining the plateau. The plateau duration is shorter than that observed in normal saline where the graded synaptic transmission is supplemented with spike-mediated transmission.

491.8 MODULATION OF OSCILLATIONS IN A MODEL OF LEECH HEART INTERNEURONS. E. Nadim, O. H. Olsen and R. L. Calabrese, Dept. of Biology, Emory University, Atlanta, GA 30322.

The bursting oscillations underlying the heartbeat of the medicinal leech are generated by pairs of reciprocally inhibitory heart interneurons (HH cells). We have built a conductance-based Hodgkin-Huxley type model of a pair of HH cells using experimentally measured ionic and synaptic currents. The synaptic current in the HH cells has a graded component, which, in our model, is dependent on presynaptic Ca++, as well as a spike-mediated component. Our laboratory has previously shown that FMRFamide has excitatory effects on the HH cells, by changing the shape and amplitude of spike-mediated IPSPs, and by shifting steady-state activation and inactivation curves of the K+ currents. The effects of calcium antagonist were also shown to affect the IPSPs. In the model, in modulating the period of oscillations is similar to the modulatory effects observed in the biological cells. We are in the process of analyzing the effect of shifting the activation curves of the K+ currents in the model.

Even though the model cells are capable of oscillation merely with the graded component of synaptic transmission, the model cells are capable of oscillation merely with the graded component of synaptic transmission. This suggests that spike-mediated transmission can play a dominant local role in a network of neurons that has large graded synaptic currents. The dominant role of spike-mediated transmission is significant in light of the fact that neuromodulation of the heartbeat cycle rate is directed towards spike-mediated ipsp's and towards k+ currents that affect spiking.

INTERACTIONS BETWEEN SEGMENTAL LEG CENTRAL PATTERN GENERATORS IN ISOLATED LOCUST THORACIC NERVE CORDS. Y. Rybeckbusch* and C. Laurensen, Neuroscience Division, Computation and Neural Systems Program, Mail Code 138-74, California Institute of Technology, Pasadena, CA 91125.

Rhythmic motor patterns can be induced in leg motor neurons of isolated thoracic ganglia of the locust, Schistocerca gregaria, by a bath application of the muscarinic agonist pilocarpine (Rybeckbusch and Laurensen, 1994). We have recorded the rhythmic motor patterns evoked in preparations of thoracic ganglia in which the connectives between ganglia remained intact. Cross correlation analysis of the activities of different motor pools in the three thoracic ganglia revealed that the rhythmic motor patterns in different ganglia are centrally co-ordinated. In particular, thoracal le-

EFFECTS OF TEMPERATURE ON PROPERTIES OF LOCUST FLIGHT NEURONS: IMPLICATIONS FOR MOTOR PATTERN GENERATION. H. Xie* and R. M. Robertson, Dept. of Biology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Elevated temperature causes a mild increase in wing-beat frequency of flying loci. This is mainly due to the global effects of temperature on neuronal properties of flight neurons in the CNS. The present investigation of flight neurons showed that an increase in conduction velocity (V0.5 = 1.53) and a decrease of membrane time constant (τm = 0.62) were the major factors which account for the increase of the CPG output. Hyperpolarization of the resting membrane potential (V0.5 = 1.8) and reduction in input resistance (τm = 0.54) might be involved in automatic compensation for the effects of increased temperature. Also increases in temperature above room temperature decreased the amplitude of postsynaptic potentials (PSPs).

We have investigated the change of resting membrane potential and the PSP amplitude contributed to the observed temperature effects on the frequency of the central rhythm. The temperature dependent hyperpolarization of flight neurons was mimicked by changing the K+ concentration of the saline from 10 mM to 2 mM. After 5 min high K+ superfusion, the resting membrane potential of flight motorneurons hyperpolarized from an average of -39.1 nV to -47.8 nV, while the frequency of the central rhythm decreased from an average of 10.1 Hz to 8.8 Hz. The temperature-dependent change of PSPs recorded from flight neurons was mimicked by replacing normal saline with zero Ca++/high Mg++/ saline. Although the amplitude of PSPs was more than halved after 10 min zero Ca++/high Mg++/ treatment, the frequency of the central rhythm changed minimally (<1 Hz). These results support the hypothesis that resting membrane potential directly affects the central rhythm, whereas synaptic strength could serve simply to trigger endogenous mechanisms of burst generation.

QUANTIFICATION OF S-RHYTHM IN NEURAL POPULATIONS BY COHERENCE ANALYSIS: C.N. Christopoulos*, Med. School, Univ. of Crete, Greece, and Ch. New York, Columbia University, U.S.A.

A recent study (C.N. Christopoulos Neurosci. 58, 43-57, 1994) indicated that for a neural population comprising uncorrelated units and units that are correlated around some frequency Fs, the unit-to-aggregate (UTA) coherence function is near zero for the uncorrelated subset but has a nonzero value at Fs for members of the correlated subset. This value reflects the inhomogeneous size of the population and the characteristics of synchrony (extent and strengths of unitary correlations, and phase concentration for the correlated units); and as indicated by simulations of a uniform population, it is substantial for wide ranges of values of these parameters. Thus, UTA coherence computations on a sample of units allow the estimation of the extent of population synchrony, as well as indications on correlation strengths, i.e., a quantification of neural synchrony. Current mathematical analysis using the same model of synchrony verifies these results for the UTA coherence. It further reveals that the value of the aggregate-to-aggregate (ATA) coherence at Fs between unit (sub)populations reflects the same four parameters, and is also substantial in a wide range of conditions. However, from this value the characteristics of synchrony cannot be separately estimated. Therefore, the ATA coherence at Fs only provides a general measure of synchrony, on the condition that the sizes of the two (sub)populations stay relatively fixed. Finally, the analysis shows that the UTA and particularly the ATA coherence are very sensitive indicators of population synchrony, especially when synchrony is weak (unit-to-unit correlations < 0.3).

P H SENSITIVITY OF SPONTANEOUS NETWORK ACTIVITY OF MAMMALIAN NEURAL NOS. S. R. Lauder* and G. W. Gross, Dept. of Biological Sciences, University of North Texas, Denton, TX 76203.

The association of pH changes with normal and pathological neural activity, as well as the influence of pH on major ligand-gated ion channels, has been established in several cell culture systems and in animal models. However, pH effects on the activity of small networks in well controlled culture environments have received less attention. We investigated the effects of pH, close to and within the physiological range, on the asynchronous activity of a small network of entorhinal mouse spinal neurons. Neurons were cultured on multielectrode plates to permit simultaneous extracellular monitoring of network activity. The pH was shifted by altering the CO2 flow in bicarbonate buffered medium in the recording chamber and was continuously monitored. Spike data was stored on 14 channel analog tapes for later analysis, and a chart recorder displayed the raw data. The results indicate that spontaneous activity is highly sensitive to pH over the range of 7.0 to 8.0. Using activity at pH 7.3 as reference, total spike production, as reflected by cell firing rate, increased as low as 1% at pH 7.2 and increased as much as 66% at pH 7.7. With increasing pH, burst frequencies increased as did the appearance of large complex bursts. This pattern reversed as pH was lowered, with large bursts disappearing below pH 7.2. Under bicarbonate dissection (producing coordinated, regular bursting) a burst decrease from 7.4 to 7.2 was observed both burst durations and frequency decreased to 40%. Burst frequencies increase from 7.4 to 7.7 caused burst frequency decreases increased to 30%, but duration increases of up to 40%. This degree of pH sensitivity necessitates that quantitative similarity between commonly performed tests and controlled pH environments. In addition, pH may be a useful variable in determining burst initiation and burst maintenance mechanisms.

THE USE OF SYNAPTIC POTENTIALS AS THE CHARGE ON PARTICLES IN THE GRAVITATIONAL REPRESENTATION OF NEURONAL ASSEMBLIES: RESULTS FROM SIMULATIONS

The gravitational representation of simultaneously recorded spike trains (Genethin et al. 1985) provides a conceptual framework for the analysis of the dynamics of neuronal assemblies (Lindsey et al. 1982). Each neuron is represented as a particle carrying a time varying charge that is a filtered version of spike activity. The charge is calculated on each neuron; the charge on a neuron at each instant of time is the time integral of the difference between the neuron's spike times and the firing times of a reference neuron. The charge on each neuron is a measure of the deviation of the actual firing times of the neuron from the firing times of the reference neuron. The gravitational representation of neuronal assemblies is a measure of the deviation of the actual firing times of the neuronal assembly from the firing times of a reference neuronal assembly.

GRAPHICAL MEASURES OF SPIKE TRAIN SIMILARITY AND COUPLING BASED ON RECURRENCE TIME HISTORY MATCHING (RTHM).

B.K. Rhoderick, J.M. Kugelki, J.F. MacKay and C.W. Gross, Dept. of Biological Sciences and Physics, Univ. of North Dakota, Grand Forks, ND.

We have applied the Hausdorff metric and related similarity functions as cumulative and running time estimators of similarity or coupling between two spike trains, based on the local auto-recurrence times associated with each spike. These new methods have been tested with biological spike trains from cultured mouse spinal cord networks, as well as artificial spike trains from a class of stochastic models. The central algorithm operates on two spike trains and a particular cross pair of spikes A and B, and begins by finding the best match for each of N sequential auto-recurrence times of spikes of A in the time history of spikes of B. This constitutes a set of N minimal A->B distances. A set of N minimal B->A distances is similarly determined. The maximal distance (DAB) from the A->B and B->A is sums is a sensitive measure of local spike train coupling. By comparing DAB to a predetermined threshold θ, one can find the set of associated L values corresponding to cross pairs of spikes with criterion matches in each of the two spike trains. The RTHM is also appropriate as a running-time measure of coupling laminar macro and nano, for detecting coupling between microspatial data sets. By graphically combining this similarity function with the rank mean local inter spike interval we have produced a clear demonstration that networks can become functionally decoupled during parietal bursts, as a manifestation of activity-dependent gain. A NEW HIGHER-ORDER INTERSPIKE INTERVAL ANALYSIS FOR DETECTING SEQUENTIAL FIRING TRENDS IN NEURONS.

D.C. Tam,* Center for Network Neuroscience, Dept. of Biological Sciences, University of North Texas, Denton, TX 76203.

A new spike train analysis method has been developed to detect how transitions of firing intervals in neurons are dependent on higher-order interneuronal intervals (ISIs). A set of "firing trend indices" is introduced to detect trends in firing independent of time scales. The firing trend index (k) is defined as the ratio between the first-order ISI and the second-order ISI relative to a reference spike. Since the value of h is bounded by 0 and 1, (i.e., 0 ≤ h ≤ 1) counting how many times firing intervals are changed may be made independent of the absolute time scale of the underlying intervals. As the value of HI increases, 0 represents the existence of change from short to long ISIs, and vice versa, for hI → 1 and hI → 0, respectively.

In addition, another firing trend index k is defined as the ratio of the difference between the two adjacent ISIs to the second-order ISI, k = hI - hI+1, where h = 0 indicating no change in firing intervals, k → 1 indicating extreme lengthening in ISI, and k → -1 indicating extreme shortening in ISI. Plotting these indices against the sequential spike number provides a clear indication of the evolution of normal firing trends in the brain. Thus, the transition into and out of burst firing, for instance, can be detected easily. Furthermore, plotting these indices against the first-order ISI will provide an estimate of the transitional probability of spike firing. Using these new state transition analyses, the underlying state transition processes, such as Markov processes or other processes, may be revealed in neurons. (Supported by ONR N00014-93-1-0135)

A FUZZY CLUSTERING APPROACH TO THE RECOGNITION OF MULTINEURON ACTIVITY.

G. Zouzidaki* and D.C. Tam,* Dept. of Electrical & Computer Engineering, University of Houston, Houston, TX 77204-4793 and Center for Network Neuroscience, Dept. of Biological Sciences, University of North Texas, Denton, TX 76203.

Typically, spike discriminative techniques can be used to extract separate spike trains from many neurons contributing to a recorded signal, and to create reliable spike templates for each neuron.

For this purpose, we use a fuzzy clustering approach to extract multi-unit activity. In our procedure employs fuzzy K-means clustering on a data segment containing multi-unit activity (1) to identify the number of neurons contributing to the recorded signal, and (2) to create reliable spike templates for each neuron. For this purpose, a performance index is also used as an optimization criterion.

Comparison of performance between the conventional crisp K-means and our fuzzy K-means clustering approaches is done with synthetic spike trains generated using real spikes and segments of background noise recorded at high rates. Both conventional and fuzzy clustering simulations clearly demonstrate the advantage of the fuzzy procedure in identifying the exact number of neurons and the exact templates over a wide range of signal-to-noise ratios and several "fuzziness indices". They also allow us to determine the optimum "amount of fuzziness" for real-time processing.

This method can be applied to other electrophysiological signal analysis, such as EEG and evoked potentials. (Supported by ONR N00014-93-1-0135)

LEVEL OF ACTIVITY AND INHIBITION EFFECTS IN A SPINAL MOTOR CIRCUIT SIMULATION.

D.P. Bashor* and D.M. McDermott, Dept. of Biology, University of North Carolina at Charlotte, NC 28223.

A computer simulation based on R.J. MacGregor's (1987) SYSTM series was used to investigate the importance of level of network activity on excitation and inhibition in a spinal motor circuit. The spatial distribution of Renshaw cell (Ren) excitation by Mn was also studied. Single Mn and eMn populations (169 cells each) were interconnected with 5 pairs of interneuron populations in a network composed of about 2300 cells. The network was driven by 5 pairs of fibers representing IA and IB motor pools, and tonic descending excitation. At low levels of network background firing, Mn activity was quenched immediately after termination of input. At high levels of background, after effects made only small differences in number and number of active Mn cells, as well as providing little reciprocal inhibition of the antagonist population. The effects of focal activation of Ren by Mn compared with widespread activation demonstrated complex effects with the network. Changing from widespread to focal activation of Mn by MnMs had little effect on Mn activity, but a rather larger effect on eMn frequency. However, both mean frequency and number of cells active changed in Ren and eRen populations.
All of the muscles had diverged force fields (because the force never reversed direction. It should be mechanically impossible for a muscle to produce a stable force field). There were three primary directions in which those divergent force fields were pointed. Radially away from the body (Pyridinum, Quadratus Femur, Peroneus, Vastus Externus, etc.), the Femoral blood vessels (Semimembranosus, Adductor Magnus, Rectus Femoris [major and minor], and toward Biceps, Bicep, Pectoralis, Rectus Anus, Adductor Longus, Gastrocnemius, and Sartorius). Thus, there is redundancy in the muscle force fields. In addition, some of the muscles had zero-valued force fields throughout some part of the workspace. The muscles Rectus Anus, Rectus Femoris [major and minor], Gastrocnemius, Adductor Longus, Vastus Externus, and Sartorius all showed a complete or near complete loss of force throughout some portion of the workspace. The utility of this type of muscle force field may lie in its ability to provide position-dependent force field modulation without requiring position (afferent)-dependent EMG modulation. Because none of the muscle force fields were stable, we conclude that limb stability can only be achieved through appropriate combinations of muscle activations. A primary function of the spinal cord may be to assure stability by serving as a focus for implementing the co-ordinated muscles.

492.2

Doubles, or two repetitive stimuli delivered with a short interpulse interval, have been shown to produce a force output that is greater than the linear sum of force produced from one stimulus (Burke et al. Science 1970). In addition, this effect may be motor unit or muscle fiber type specific. We previously showed that the human chronically paralysed soleus muscle uncharacteristic of physical responses to the stimulus, while the acutely paralysed soleus muscle (less than 6 weeks) responds as a slow muscle. This study examined the effects of the repetitive doublet on the human chronically acutely paralysed soleus muscle evoked twitch after and before a standard fatiguing regime.

Ten chronic (one year) and two acute (6 weeks) completely paralysed individuals had their leg positioned in a torque measuring device with the knee at 90° of flexion. The soleus muscle in vivo was monitored during all stimulations to ensure supramaximal activation. Three interpulse intervals (6 msec, 12 msec, 18 msec) for the doublet were delivered in six possible combinations via the visual naive. Each combination was preceded by a single twitch. Next, a fatigue protocol consisting of a 20 Hz frequency delivered every second for 330 msec was delivered for two minutes. This protocol lead to significant fatigue. Immediately after the fatigue protocol the same doublet protocol was administered. Dependent measures included peak force, force-time integral, and the rate of force production both before and after the fatigue protocol. Following the fatigue protocol, the doublet lead to approximately 3 times the peak force and force-time integral than that of a single stimulus in the chronically paralysed soleus muscle. Conversely, the acutely paralysed soleus muscle showed no significant change in the output from the doublet. This study suggests that increased force production from the both muscles is muscle fatigue dependent. Mechanisms and implications of these findings will be discussed.

492.3

Spinal isolation (SI, transection of the spinal cord at T2-T13 and at L5-S1) and deafferentation between the two transection sites) was produced to inactivate the cat soleus for 4 months. We examined the effects of cyclic activity (1 Hz) mimicking the step cycle with electrical stimulation (40 Hz, 300ms, 30mV) during either lengthening (SI-L) or shortening (SI-S) on the (functional deficits associated with chronic inactivation: MWL, muscle weight, TPT, isometric twitch time to peak tension, Po, maximum isotonic tension, Vmax, maximum rate of shortening; FL, fatigue index) (% difference from control.)

The force frequency curve was shifted to the right of a faster type muscle after SI. This effect was accentuated by programmed activity. In the vivo soleus tendon was shortened by 9% and 9 times more active than passive manipulation in the SI-L and SI-S cats, respectively. SI-L resulted in a faster and flatter muscle with general daily programmed activity ameliorating the adaptations in MW, Po, and FL. SI-L had a greater effect than SI-S in Po and FL. The relative N0fatigability of the soleus was maintained in all groups. Thus, as little as 30 min/day of activity has a positive effect in maintaining the mechanical properties of a chronically inactivated muscle.

Further, stimulation during lengthening was more effective than shortening probably reflecting the faster force integrals during lengthening. (Supported by NIH Grant NS16333 and NRSA HD 7416).

COMPARISON OF FORCE-FREQUENCY RELATIONS IN HUMAN VOLUNTARY AND STIMULATED CONTRACTIONS. L.J. Tremblay, G. Roy*, B. Bigland-Ritchie, Dept. of Pediatrics, Yale University School of Medicine, New Haven, CT. 06510 and The School of Physical and Occupational Therapy, McGill University, Montreal, Canada.

In voluntary contractions muscle force is modulated by a combination of motor unit recruitment and rate-coding. When either whole muscle or single motor units are stimulated at different rates, a sigmoidal relationship is observed. These results, in contrast, during voluntary contractions, mean spike frequencies increase linearly with force up to 100% MVC (Bigland-Ritchie, et al. 1991; Thomas et al. 1991); a force which usually matches that for supramaximal stimulation. The purpose of this study was to compare, in the same muscle, forces generated by electrical stimulation with those generated by motor units recorded during voluntary contractions of various intensities.

Muscle force and motor unit firing rates were recorded from the quadriceps muscles of 16 subjects during voluntary contractions varying from 25% to 100% MVC. In separate experiments, quadriceps muscles were stimulated electrically at rates from 1 to 100 Hz. The two force-frequency relationships were compared. For forces up to about 60% of MVC, there was little discrepancy between voluntary and stimulated excitation rates. However, for higher forces the stimulated force increments per Hz became progressively smaller, while this non-linearity was largely avoided during voluntary contractions. Possible explanations for this discrepancy include: 1) the progressive recruitment of larger units at higher forces; 2) that forces from different units add non-linearly when their territories overlap (Clamann & Scholtz, 1988); and 3) whether or not the CNS can excite all units to respond at maximal rates. Supported by NIH grants NS14755 & HL02062, PCAR (Quebec) & NSERC (Canada).

DOUBLET POTENTIATION IS DIMINISHED DURING SHORTENING MOVEMENTS OF CAT SOLEUS MUSCLE. J.G. Sanderson, C.C. Henneman. Department of Physiology, Northwestern University School of Medicine, Chicago, IL 60611.

When motor units are stimulated with low frequency trains, the addition of a single extra pulse, or doublet, at the beginning of the train can dramatically increase tension during an isometric contraction (Burke et al, Science 158: 1287-1289, 1967). This study investigated the effects of muscle movement, using either isovelocity ramps or simulated locomotor patterns, on doublet potentiation in whole muscle or single motor units in cat soleus. The light line in Fig. A shows the isometric force produced by stimulating a portion of the soleus with a 10 Hz train. The heavy line depicts the addition of a doublet (pulse added 10ms after the first pulse). In B, using identical stimulus patterns, the same muscle was shortened at 20mm/sec from 0.2 to 0.7a, and then allowed to contract isometrically. Shortening movements diminished the effects of the doublets in whole muscle and motor units. Less dramatic results were seen with slower or shorter isovelocity ramps, or with locomotor type movements. Moderate isovelocity stretches of similar speed and distance had little effect on doublet potentiation.

MODELING ISOMETRIC FES MUSCLE FATIGUE BY ARTIFICIAL NEURAL NETWORKS. M. Domany, Y. Yadin, Pecht, J. Mizrahi, E. Isakov and Z. Susuk. Dept of Biomechanical Eng., Technion, Haifa 32000, Israel and Loewenstein Rehabilitation Hospital, Ra'anana, Israel.

This study investigates the relation between the input electrical current applied to the paralyzed human biceps brachii muscle in vivo during Functional Electrical Stimulation (FES) and the output muscle force. The electric current is applied through surface electrodes to the muscle, and the force is measured in isometric conditions. The assumption made is that the muscle during FES consists of the following two parameters: 1. Muscle length, described by the knee angle θ (°); 2. Current frequency, f (Hz). 3: Current pulse width, D (0.25 ms each) and 4: Current amplitude, A (0 to 130 mA). The output is muscle tension T (N). T at time t is the function of the input history to the muscle. We model T using a sampling rate of 1 Hz to represent the current amplitude A. The output force is very non-linear and it is difficult to estimate its magnitude in advance. We use 2-layer feedforward artificial neural networks simulations to learn the forward dynamics model of the force produced in the muscle. The training stage is done by supervised learning with the backpropagation algorithm. Following the training stage with muscle fatigue data of A = 50 or 70 mA FES, the neural network predicts the output force for the unknown case of muscle fatigue induced by 60 mA FES. The network can also extrapolate the output muscle force during a 50-60 seconds period, after learning the forward dynamics model of muscle force production during the first 50 seconds of FES stimulation. We propose that by using appropriate neural network architectures one can represent knowledge of FES experiments by training the weights of the networks. The network weights could be eventually stored on VLSI chips and help in the design of appropriate controllers aimed to replace the motor brain in activating paralyzed muscles. This study was supported by the Segal Foundation and the Sandra and Walter Kaye fund.

ELBOW-JOINT IMMobilIZATION DECREASES FATIGABILITY AND ALTERS THE PATTERN OF ACTIVATION IN HUMANS. G. Yau*, M. Hildago, and R. M. Enoka. Dept. Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, OH 44195

The left arm of 8 subjects was immobilized in a fiber-glass cast and a sling for 4 weeks at an elbow joint angle of 90 degrees. Twenty-four hour chronic EMG recordings indicated that the activity of the biceps brachii muscle was significantly reduced during immobilization. Before and after immobilization, the following variables were measured: (1) elbow-flexion force, and EMG signals from the biceps brachii and brachioradialis muscles during maximal voluntary contractions (MVCs); (2) fatigueability of the elbow-flexor muscles when force was sustained at 20% of the MVC force; (3) cross-sectional areas and volume of the biceps and triceps brachii, and brachioradialis muscles measured with magnetic resonance imaging (MRI); and (4) the degree of muscle (biceps brachii and brachioradialis) activation during an elbow-flexion MVC as evaluated with MRI T2 relaxation time. The immobilization induced a significant decrease in the elbow-flexion MVC force and cross-sectional areas and volume of the elbow flexor muscles, but the reduction in muscle size was less than the decline in MVC force. After immobilization, the fatigueability of the elbow flexors was decreased (more resistant to fatigue) at both force levels (20 and 65% MVC). There were also significant changes in the EMG activity and T2 indicating degree of activation during the MVC. The neuromuscular adaptations were diverse and had different effects on the various physiological processes. Supported by NIH grant NS 20544 (RME).

492.9

Following either supramaximal electrical stimulation or maximal voluntary contractions sufficient to induce fatigue, a full or near full recovery of the muscle compound action potential (M-wave) has been observed within 3 minutes of cessation of the fatiguing process. (Galea and McComas, J. Physiol. 438:212T, 1991). Little attention has been given to the excitability during recovery, and we have found evidence of a late depression.

Fatigue was induced by 20 Hz supramaximal stimulation of the motor nerve of the biceps brachii muscle in healthy men of varying activity levels, and recovery period was examined for up to 8 hours post fatigue. Immediately after cessation of the fatiguing stimulus the amplitude and area of the M-wave had returned to control values whereas the isometric twitch force was significantly reduced in all subjects. The M-waves declined throughout the recovery period, with one group (n=9) reaching a maximum M-wave depression (DEP) between 7 to 30 minutes post fatigue (60.4 ± 9.0% control) whereas another group showed maximum M-wave depression much later in the recovery period, between 13 minutes and 4 hours post fatigue (DEP* = 42.4 ± 6.2 % control). The isometric twitch force recovered gradually, returning to control values by the end of the 8 hour recovery period. The depression of M-wave activity may be explained by a reduction in Na-K pump activity or by increased open times of the sodium channels.

LEARNING AND MEMORY: SYSTEMS AND FUNCTIONS IX

493.1

This model, utilizing coupled mechanisms for place recognition, maintenance of head direction, and path integration, replicates a variety of rodent behavioral and neurophysiological data. We simulated experiments by Collett, Cartwright, and Smith on gerbils driven to a field open landmark-based maze. Experiments by Cheng on rats navigating to a goal location in a rectangular arena. Experiments by Munsie and Muhlnad in which the gerbils possess a clear and accurate sense of head direction. Head direction cells have been found in several areas of the rat brain.

In addition to a path integrator and units coding for head direction, our model contains units with place fields controlled by visual landmarks, reflecting properties of hippocampal pyramidal cells. However, unlike other models of place cells, our model also accounts for the persistence of place fields in the absence of any visual input, by allowing place units to be driven by the path integrator. This, in our model, is learned to form associations between external state (views of landmarks) and internal state (path integrator coordinates). Visual cues, when available, drive the place units, which can then correct for drift in the path integrator, suggesting it is a known value when the animal is first placed in a familiar apparatus, such as a radial maze.

Our model shows how allocentric bearings derived from head direction can be used to disambiguate visually identical landmarks, reproducing the gerbil and rat data. Conversely, local view information can be used to correct for drift in the head direction estimate. Parallel alignment among place units produces a consistent place code even when the model is presented with a distorted landmark array, emulating the robustness that animals show in novel situations. Parts of the model have been implemented on a mobile robot.

493.2

AROUSAL DEPENDENT ACTIVATION OF FD MOLECULAR LAYER GLYCOCEN PHOSPHORYLASe-A. A.Ucker*, G. Rao, B.L. McNaughton, C.A. Barnes, T.A. Foley and F.M. Reiman, ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

"Patches" of glycogen phosphorylase-a activity observed in the fascia dentata (FD) molecular layer (Harley & O'Keefe, 1992; Wallace, 1982) occur following microinjections of glutamate into the entorhinal cortex (Harley & O'Keefe, 1986) and are correlated with the depletion of glycogen stores in the nervous system during metabolic work (e.g. Wallace, 1983). In addition, reduced phosphorylase-a activity in the FD molecular layer after exploration (Ucker et al, 1994) concurs with single cell recording studies (Ranck, 1973; Thompson & Best, 1989) showing that most hippocampal neurons are least active during behaviors typically associated with hippocampal theta rhythm, i.e. active exploration and paradoxical sleep. Place cell activity is maintained when an animal explores or is manually transported to an identified place field, but drastically reduced after it has been snugly restrained (Poster, et al., Science, 244:1580, 1989), although the theta rhythm is only marginally reduced. We hypothesized that phosphorylase activity would be minimized under restraint, relative to animals either freely exploring, manually moved, or anesthetized with sodium pentobarbital. FD molecular layer glycerogen phosphorylase-a activity was measured in 12, 6 month old female Long-Evans rats. Contrary to the firing-rate based expectation, phosphorylase-a activity was least during exploration, higher during passive movement, higher yet during restrained movement, and highest under anesthesia. The mitobol F-ratio was significant (p < .05). Phosphorylase-a expression may thus be more correlated (inversely) with hippocampal theta rhythm and/or septohippocampal activity than with principal cell firing-rates per se. Supported by MH48024, MH30897 and the Flinn Foundation.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
493.3 TOWARDS A COMPUTATIONAL MODEL OF THE HIPPOCAMPAL FORMATION INCORPORATING REALISTIC ANATOMICAL CONNECIVITY: AMMON’S HORN AREA CA3, P. Patton and B.L. McNaughton. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

A computational model of the rat hippocampal formation incorporating realistic anatomical connectivity is being developed. This report focuses on Ammon’s horn (CA1, CA2, CA3, and DG). Neurons were distributed throughout a rectangular sheet representing this structure. 250,000 pyramidal cells were assumed (West et al., Anat. Rec. 231:482-497). Major extrinsic inputs to CA3 derive from the entorhinal cortex and FD granule cells. Entorhinal input possesses a rough topographic organization, and is divergent, with individual arbors extending up to 2 mm septotemporally (Tannamura and Noyol, Hippocampus, 347-370). Entorhinal arbors were represented as rectangles extending across CA3. Each entorhinal neuron makes about 4700 synaptic contacts onto pyramidal cells (Amaral et al., Prog. Brain Res. 83:1-11). Each granule cell makes about 15 mossy fiber contacts onto pyramidal cells (Claiborne et al., JCN 246:435-458). CA3 pyramidal cells possess a network of recurrent collaterals, represented in the model as diagonal sawths like those described by Ishizuka et al. (JCN 295:580-623), with each cell receiving 6,000 ipsilateral synaptic contacts. These cells also provide a significant input to the inner molecular layer of FD (Li et al., JCN 339:181-200). 5 groups of CA3 non-principal cells were represented: vertical and horizontal basket cells, chandelier cells, spiny non-principal cells, stratum oriens cells, and superficial cells. CA3 contains an estimated 67,000 non-principal cells (Dics et al., Dev. Brain. Res. 81:885-894). This anatomical representation will serve as a basis for models of postulated hippocampal operations such as associative memory. Supported by MH46823.

493.4 SIMULATION OF THE SPONTANEOUS REACTIVATION OF EXPERIENCE-SPECIFIC HIPPOCAMPAL NEURONS DURING SLEEP. B. Shen and B.L. McNaughton. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

During slow-wave sleep (SW) in both rats and monkeys, periods of spatial activity, CA1 "place-cells" that were temporally correlated, by virtue of the overlap of their place fields, exhibit enhanced temporal correlations, even though the animals sleep in a different location. Recording rats were displaced from their home cages (for 2 days before testing) and subjected to "daylight" conditions (14L:10D). The discharge of cells with overlapped place fields was more correlated in subsequent sleep, particularly during sharp-waves, than in sleep episodes generated by concurrent behavioral patterns. These results are consistent with the hypothesis that the hippocampus is involved in the consolidation of memories. The results support the view that the reactivation of neuronal assemblies may be an important mechanism for the consolidation of memory, and that the hippocampus plays a role in this consolidation.

493.5 SPARSE VS. DISTRIBUTED POPULATION CODING IN SUPERFICIAL AND DEEP LAYERS OF RAT NEOCORTEX. W.-E. Skaggs*, B.L. McNaughton, G. Winson, K. Moore, and C. Duffield. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

324 cells were recorded extracellularly from two areas of the rat neocortex (Zilles’s areas HL and OC2m), using a parallel recording method that permitted monitoring of up to 40 individual neurons at the same time. We have been using a parallel recording method (Winson and McNaughton, 1992), in which neurons are assumed to be in a state of random to be silent for extended periods of time. Overall the population of activity appears much more sparse in the superficial neocortical layers than in the deep layers. These findings are of interest in light of the fact that the superficial layers are the predominant source of the cortico-cortical association system. In memory, our proposal has been for this system by theorists including Marr (1970) and Eccles (1978, et al); and it has been shown mathematically that sparse activity patterns confer special benefits on associative memory networks by reducing interference between jointly stored patterns. Moreover, the majority of neocortical NMDA receptors are located in the superficial layers (Monaghan and Cotman, 1989). Supported by MH46823 and MH00897.

493.6 POPULATION ACTIVITY PATTERNS IN HIPPOCAMPUS AND NEOCORTEX PERSIST LONGER DURING SLOW REM SLEEP THAN DURING SLOW-WAVE SLEEP. K.M. Moore, W.E. Skaggs, B.L. McNaughton, C.A. Barnes*, R. D’Monte, C. Duffield. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

To gain insight into the possible role of sleep in memory consolidation, we quantified the structure of population dynamics during different behavioral states. Using a parallel recording method (Winson and McNaughton, 1992), populations of up to 40 neocortical cells or up to 70 hippocampal cells were recorded concurrently in the neocortex or in the hippocampus of rats, during behavioral states of REM sleep, slow wave sleep (SWS), or performance of a spatial task. The persistence of population activity patterns in each state was quantified by calculating the correlations between the firing rate vectors at different times, with care to exclude high-rate cells (putative interneurons) from the populations. In each behavioral state, the mean correlations decayed more or less exponentially as a function of time interval, and the time constant of decay was taken as a measure of the average persistence of an activity pattern. The approximate time constants observed, both in neocortex and hippocampus, were SWS, 100-1500 ms; REM sleep, 5-10 sec; active locomotion, 400-1000 sec. As might be expected, the persistence of correlated states during behavior appears to be a function of the behavior itself. During SWS, correlations persist on a timescale similar to hippocampal-slow-wave activity consistent with a possible hippocampal origin of the correlated states. During REM, the persistence is not correlated with any obvious neocortical or hippocampal EEG phenomena. These findings add to the extensive evidence for similarities between REM sleep and the waking state. Supported by MH46823 and MH00897.

493.7 PRESERVATION OF TEMPORAL ORDER IN HIPPOCAMPAL MEMORY REACTIVATION DURING SLOW WAVE SLEEP. M.A. Wilson* and B.L. McNaughton. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

In a previous study, it was found that coactivity of cells during behavior produced an increase in discharge correlation between these cells during subsequent slow wave sleep (Wilson and McNaughton, 1994). This suggested that hippocampal memories for recent experience were recapitulated during these slow sleep periods. The question which remained unanswered was whether the temporal structure of experience was also preserved and was present during sleep activity. To address this question, 50-100 cells per area CA1 of the hippocampus were recorded simultaneously during two 20 min periods. Individual pairwise correlation histograms taken during these tasks were classified based on their direction of skew. In each pair, if firing of cell 1 (master cell) was greater than the firing of cell 2 (slave cell), this pair was assigned a positive skew. The converse relationship was assigned a negative skew.

During behavior, this skew resulted from the relative spatial locations of the "place fields" of the cells, with the specific patterns that would follow during each task. It was found that the direction of skew was positively correlated with behavior (peak shift 1-2 sec) determined during the direction of skew of the immediately following slow wave sleep period (peak shift 5-10 sec). This indicates that the structure and temporally compressed order of recently experienced states are recapitulated in the hippocampus during slow wave sleep. The preservation of both coordinated states and their temporal order suggests a mechanism within the hippocampus which is capable of storage and reactivation of temporally sequenced information. Supported by MH46823 and McDonnell-Pew.

493.8 VARIATIONS IN PLACE-SPECIFIC FIRING OF HIPPOCAMPAL NEURONS ALONG THE SEPTOTEMPORAL AXIS. M.W. June*, S. Wiener, M. Moore, S. Kipen, and B.L. McNaughton. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

The anatomical and neurochemical organization of hippocampal circuitry exhibits a substantial septotemporal gradient. Although it is well established that place-specific firing is a fundamental characteristic of hippocampal neurons, almost all unit recording studies in freely behaving animals have come from the temporal lobe, and involves technical difficulties. In our study, therefore, single units were recorded in the dorsal and ventral hippocampus of opposite hemispheres in the same rats, in many cases simultaneously. Units were presumed to be identified as rats entered slow wave sleep. The rats then performed a food reinforced, random search task in a square chamber containing simple visual landmarks. As in dorsal hippocampus, ventral CA1 could be classified as "complex spike" (CS)-pyramidal cells or "theta" interneurons. Both dorsal and ventral theta cells fired at relatively high rates with low spatial selectivity in the area. As previously reported (see June et al., 1996) and as expected behavior of the animal was highly correlated among the CS cells in the ventral hippocampus; however, significantly fewer ventral units had "place fields" than dorsal units, and the spatial selectivity of ventral units was significantly lower than that of dorsal units. Thus a septotemporal gradient of spatial selectivity was found in the CA1 field of the hippocampus, complementing many other anatomical and neuropharmacological studies. A number of possible interpretations can be suggested from these results, including a computational advantage of representing space at different scales or a precedence of essentially non-spatial information processing in the ventral hippocampus. Supported by NS02031 and Human Frontiers in Science.
HIPPOCAMPAL PLACE FIELDS CHANGE WITH NAVIGATIONAL CONTEXT. Y. Qin, E.L. Markus, B.L. McNaughton and C.A. Barnes. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

When general behavioral requirements are held constant, rat hippocampal complex spike cells fire selectively with respect to the animal’s location. The locations of ‘place fields’ of individual cells are generally quite robust against manipulations of the animal’s environment and are relatively unaffected by age-related changes, with some exceptions. When firing rates are modulated by contextual variables such as running velocity and direction, the location of firing is relatively unaffected by the specific behavior. In the present study, the effects of the navigational requirements of the task were assessed in fixed environments. Hippocampal place cells were examined in adult male rats aged 30 to 45 days and were trained to forage for chocolate either on a radial arm maze or a circular platform. The rats would first retrieve randomly scattered chocolate; then the task was altered by placing the food sequentially and repeatedly in 4 specific locations. This resulted in a switch from a random to a directed search pattern by the rats, typically over the course of 1-2 minutes. On this platform, it also involved a change in the trajectories and distribution of locations visited. The switch from random to directed search was accompanied by a pronounced change in the location of the place field in approximately 1/3 of the cells on the circular platform. There was a smaller, but significant effect when the recordings were conducted on the radial arm maze. In 2 rats the directed search was typically followed by a second random search episode. In these cases, the place fields returned to their original location. We conclude that, if hippocampal cells encode location per se, the representation changes in different behavioral or navigational contexts. Supported by MH00897 & ONR.

DYNAMICS OF VISUAL CUE CONTROL OVER HEAD DIRECTION CELLS AND PLACE CELLS. L.J. Krieter*, H.S. Kortnev and B.L. McNaughton. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

Thalamic head direction (HD) cells and hippocampal place cells comprise a tightly coupled system. We investigated the dynamics of visual cue control over these cells by introducing conflicting direction information between visual cues and the animal’s head direction. Rats foraged for food in a high-walled test apparatus with a single salient cue card. In some experiments, we disoriented the rats before each session. This weakens visual cue control over place and HD cells (Krieter et al., Soc. Neri, Abt., 1993), because most HD cells had preferred firing direction or location relative to the cue card over multiple sessions. In 30% of 119 sessions, however, firing orientation rotated 30°-130° within the session. A similar effect was observed in the first few runs for rats from an “incorrect” orientation to the “correct” one. In 6 cases, cells rotated from one incorrect orientation to another. In 3 cases, cells started at the correct orientation, rotated away, but then returned. In no cases did cells permanently rotate away from the correct orientation. In other experiments, we abruptly rotated both apparatus and rat by 180°. Typically, cells either immediately lost orientation with the cue, or remained oriented relative to the external world. In other sessions, however, cells initially maintained their external orientations, but then rotated 180° smoothly over a few min until they returned to the original orientation relative to the cue card. Thus, visual cues can correct for large errors in spatial orientation with a slow, steady rotation of both the HD cell and the hippocampal spatial map until they realign with the cue. The progressive shift suggests that transitions between neighboring network states are preferred over transitions among less similar states. Supported by ONR and NS09052.

AGE-RELATED DECREASE IN THE NMDA-MEDIATED EPSP IN FD. G. Sagg, C.A. Barnes, B.L. McNaughton and I. Lavenstein. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

Previously we demonstrated a decline in both the non-NMDA and NMDA-mediated Schaffer collateral EPSP in senescence CA1. Here, we characterize the NMDA response in senescent fascia dentata (FD), where, although there is a smaller presynaptic fiber potential for a given stimulus intensity, indicating a decrease in perforant path fibers, the non-NMDA EPSP is actually larger for a given fiber volley amplitude (Barnes and McNaughton, 1980), indicating that individual perforant path synapses of old animals are more powerful (Lavenstein et al., 1991). P64 rats (n=18, 9 mo; n=18, 24-28 mo) showed an age-related deficit in spatial learning ability in the spatial version of the Morris water task, (% in time to largest quadrant: yng = 45.3 ± 5.2; adult = 37.1 ± 7.4; p<0.05). There was also an age-related deficit in spatial discrimination ability. Hippocampal slices were then prepared and incubated in low Mg+4 ACSF. Recording and stimulating electrodes were placed in FD. Input-output curves of the relation between the presynaptic fiber volley and EPSP were constructed under and after local application of a non-NMDA (AMPA) antagonist. Abolition of the residual response by APs confirmed that it was NMDA-mediated. As found previously, prior to CNQX application the EPSP-to-fiber volley ratio was significantly larger in the old rats. After CNQX application, the NMDA component for a given fiber volley was unchanged. This indicates no impairment in visual spatial learning ability. Hippocampal slices were subsequently prepared, and the atropine-sensitive, cholinergic slow spew was recorded intracellularly in CA1 and CA3 pyramidal cells. There was an age-related deficit in spatial learning ability. Hippocampal slices were then prepared, and the atropine-sensitive, cholinergic slow spew was recorded intracellularly in CA1 and CA3 pyramidal cells. There was an age-related deficit in spatial learning ability. There were no age differences in intrinsic biophysical properties of principal cells within each subgroup; however, the amplitude of the cholinergic slow spew was significantly reduced in CA1 (45% CA3-55%) and CA3 (55-65%), p<0.001. The 3 wk and 9 mo rats did not differ. The slow wave in CA1 was correlated with spatial learning on the Morris water task in old rats more significantly (p<0.05) in the older relative to the younger age groups. This result demonstrates that components of excitatory synaptic transmission within the same hippocampal subregion are differentially affected by the aging process, even when the receptor subtypes may be colocalized. Supported by AG03576 and MH00897.

AGE-RELATED DECREASE IN CHOLINERGIC SYNAPTIC TRANSMISSION IN FD. H.A. Chen*, G. Yao and C.A. Barnes. ARL Division of Neural Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724.

The electrophysiological changes of neurotransmitter cholinergic deficits in normal aging has been examined in area CA1 of hippocampus where the cholinergic slow spew has been found to be reduced in aged rats (Petier et al., 1991; Taylor and Griffith, 1993). Whether this change occurs in all three hippocampal subregions and whether it covaries with age-related behavioral deficits has been studied here. F-344 rats (n=3, 3 wk; n=3, 9 mo; n=30, 24-27 mo) were tested in the Morris water task. There was an age-related deficit in spatial learning ability. Hippocampal slices were subsequently prepared, and the atropine-sensitive, cholinergic slow spew was recorded intracellularly in CA1 and CA3 pyramidal cells. There was an age-related deficit in spatial learning ability. There were no age differences in intrinsic biophysical properties of principal cells within each subgroup; however, the amplitude of the cholinergic slow spew was significantly reduced in CA1 (45% CA3-55%) and CA3 (55-65%), p<0.001. The 3 wk and 9 mo rats did not differ. The slow wave in CA1 was correlated with spatial learning on the Morris water task in old rats more significantly (p<0.05) in the older relative to the younger age groups. This result demonstrates that components of excitatory synaptic transmission within the same hippocampal subregion are differentially affected by the aging process, even when the receptor subtypes may be colocalized. LEARNING AND MEMORY: SYSTEMS AND FUNCTIONS IN 1994

493.15 ALTERED IEG INDUCTION AFTER LTP IN MEMORY-DEFICIENT AGED RATS. A. Lanahan, T.F. Whorley, G. Lyford, G. Stevenson, G. Rao, L. Church, and C.A. Barnes. ARL Division of Neuronal Systems, Memory and Aging, University of Arizona, Tucson, AZ 85724 and Dept. of Neuroscience and Neurology, Johns Hopkins Univ., Baltimore, MD 21205.

Aged rats show deficits in the maintenance of hippocampal LTP and in spatial memory. To identify possible molecular mechanisms of these changes, we examined the regulation of a panel of immediate early genes induced in young and old LTP. Seven young (2-6 months) and 7 old (26-30 mo) F344 rats were bilaterally implanted for electrodes for evoking and monitoring perforant path field potentials in fascia dentata (FD). Recording commenced 2 days after surgery and was continued every 2 weeks after surgery; at which time rats were given 50 mg/kg cycloheximide (i.p.), followed by 1 hour of low-frequency test stimulation (0.1 Hz). Five young and 5 old rats received bilateral remote shocks of 0.1 ms duration at high-frequency stimulation every 5 min, and 2 rats in each age group were used as implanted controls. Poly (A)+ mRNA (Fasttrack, Invitrogen) was prepared from FD that was microdissected from the rest of the hippocampus, and used to prepare cDNA by reverse transcription (Superscript, BRL). The cDNAs were [32P] labeled by random priming and used to screen a panel of IEGs with the "Reverse Northern" technique. Hybridization to each of the IEGs was quantitated (phosphomager, Molecular Dynamics) and normalized to a non-inducible mRNA, glutathione phosphate dehydrogenase (GPD). Most IEGs were similarly induced in the young and aged animals however the induction of c-fos was much more robust in the old than the young animals and this difference was significant at p = 0.034. These observations indicate that mechanisms controlling the induction or turnover of c-fos are selectively altered in aged, behaviorally impaired animals. Support: AG02919, MH80997.

493.17 CEREBELLAR MECHANISMS OF EYELID CONDITIONING: MATHEMATIC ANALYSIS OF PLASTICITY AT TWO COMPETING SITES. G.T. Kerkut and M.B. Wisk, Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX 77225.

Empirical evidence suggests the involvement of two sites of synaptic plasticity in single form of motor learning: one in the cerebellar cortex and another in the cerebellar nucleus. A mathematical model based on the synaptic organization of the cerebellar-dlivery system is used to analyze the relative contributions from these two sites. Based on experimental data, we assume that plasticity at synapses from granule to Purkinje (Gr-Pk) cells displays generalized long term depression: synaptic weights decrease when active during elevated calcium induced by climbing fiber input and increase when active in the absence of climbing fiber input (during which calcium levels should be reduced). We find that incorporating standard generalized Hebbian plasticity at synapses from mossy fibers to cerebellar nucleus cells (mf->nuc) leads to non-stationary stochastic weight strengths which are reduced when a generalized Hebbian rule is modified such that mf->nuc synaptic weights only decrease when active during tonic Purkinje cell inhibition, synaptic weights become stable. Furthermore, the system is self-regulating such that eventual activity is always driven to equilibrium levels at which synaptic weights remain constant. We next simulate idealized conditioning trials. Unconditioned stimulus, which increases the excitatory drive to climbing fibers, induces adaptive changes in the Gr-Pk and mf->nuc synaptic weights encoding the conditioned stimulus (CS). We assume that Gr-Pk synapses provide greater temporal discrimination such that a single subset of mf->nuc synapses but many different subsets of Gr-Pk synapses are activated throughout the CS. We show that each subset of Gr-Pk synapses active during the CS attempts to transfer plasticity to the nucleus. Thus, the relative contribution to conditioned responses made by plasticity at mf->nuc synapses is reduced to the weighted average across all subsets of Gr-Pk synapses active during the CS.

The amygdaloid neuronal model was constructed from single neuron activity data [1]. Significant features were the acquisition to conditioned stimulus and extinction after acquisition. A mathematical model of the amygdaloid neuronal network was presented to quantitatively produce the elemental physiological mechanisms of learning. General model for single neuron is proposed by McCulloch-Pitts model. Main features of the McCulloch-Pitts model are all-or-none response, potential summation and synaptic delay. Added features to model were the acquisition and extinction to conditioned stimulus. These features were described by learning weight between neurons. When the conditioned response is followed by the unconditioned response after short delay, connection weight increases. The connection weight becomes interneuronal. Details of temporal firing activities of the models were examined under various conditions. Results show that neurons acquired responses to conditioned stimulus associated with unconditioned ones and these responses were extinguished by extinction.

The NMDA receptor in the hippocampal CA1 area is suggested to play a role in memory function. Delayed Conditional Discrimination (DCD) tasks are used to investigate working memory in 7 and 7 old (26-30 mo) F344 rats were bilaterally implanted for electrodes for evoking and monitoring perforant path field potentials in fascia dentata (FD). Recording commenced 2 days after surgery and was continued every 2 weeks after surgery; at which time rats were given 50 mg/kg cycloheximide (i.p.), followed by 1 hour of low-frequency test stimulation (0.1 Hz). Five young and 5 old rats received bilateral remote shocks of 0.1 ms duration at high-frequency stimulation every 5 min, and 2 rats in each age group were used as implanted controls. Poly (A)+ mRNA (Fasttrack, Invitrogen) was prepared from FD that was microdissected from the rest of the hippocampus, and used to prepare cDNA by reverse transcription (Superscript, BRL). The cDNAs were [32P] labeled by random priming and used to screen a panel of IEGs with the "Reverse Northern" technique. Hybridization to each of the IEGs was quantitated (phosphomager, Molecular Dynamics) and normalized to a non-inducible mRNA, glutathione phosphate dehydrogenase (GPD). Most IEGs were similarly induced in the young and aged animals however the induction of c-fos was much more robust in the old than the young animals and this difference was significant at p = 0.034. These observations indicate that mechanisms controlling the induction or turnover of c-fos are selectively altered in aged, behaviorally impaired animals. Support: AG02919, MH80997.

493.18 CLASSICAL CONDITIONING AND VALUE-DEPENDENT LEARNING IN NOMAD, A REAL WORLD ARTIFACT. P.F. McBryde, V. Verschure, J. Wray and O. Edelman*. The Neurosciences Institute, 3777 North Torrey Pines Court, La Jolla, CA 92037.

In previous work, it was demonstrated how adaptive behavior can occur in a real world artifact, NOMAD, carrying out a tracking and a block-sorting task (1). NOMAD is a mobile automaton with visual and auditory sensors and a magnetic sensor that allows it to "taste" the environment of colored drums it picks three times. The behavior of NOMAD is controlled by a simulated neuron-based nervous system containing circuitry for the execution of reflexes and fixed or sensory-driven action patterns (avoidance, approach, exploration). States of the sensors are projected onto mapped and non-mapped neural areas. Initially, the value system is fixed and innate (I.e. 'light is better than no light'). It is modeled in terms of the properties of a diffuse ascending system that can modulate synaptic plasticity. Recently, the modeling of value has been expanded to include the experience-dependent modifications of value itself (acquired value) (2). In the present work, acquired value was incorporated into the nervous system of NOMAD. Our goal was to show how behavioral regularities resulting from classical conditioning can be understood in terms of value-dependent learning. A recent experiment conducted takes place in a neural region that is an analog of the amygdala. Acquired value is achieved by synaptic modifications of projection from the sensory area to the diffuse ascending system. As a result, discrimination of color preferences associated with value became more rapid and the responses became more marked. To test this anatomical and dynamical arrangement NOMAD is being subjected to classical conditioning paradigms emphasizing blocking and secondary conditioning with auditory stimuli. We analyze the conditioned behavior of NOMAD in terms of the success of avoidance and approach responses, the correlated states of its nervous system, and the effect of modifications in the stimulus environment. I. G. Edelman, et al., PNAS, 89, 7627-7632 (1992). K. J. Frisman, O. Tozawa, G. N. J. Reek, O. Sprem, G. M. Edelman, Neuroscience, 59, 220-243 (1994).

493.20 MODELING BIOLOGICAL NEURONS WITH SPATIOTEMPORAL EVENT MAPPING (STEM) CELLS S.B. Murphy* and E.W. Kaniels. Interdepartmental Neuroscience Program, Department of Psychology, Center for Theoretical and Applied Neuroscience (CTAN), Yale University, New Haven CT 06511.

A biological neuron can be viewed as a match-filter that instantiates a mapping, x, from multidimensional spatio-temporal (x,y,t) to unidimensional temporal events (action potentials). A computational abstraction of a biological neuron called a Spatio-Temporal Event Mapping (STEM) cell has been designed to perform this mapping in a general way. The three major components of the STEM architecture are (1) an input time-space mapping layer (2) a nonlinear spatial mapping layer (3) a recurrent time-space mapping layer. A STEM cell implementation of the McCulloch-Pitts model are all-or-none response, potential summation and synaptic delay. Added features to model were the acquisition and extinction to conditioned stimulus. These features were described by learning weight between neurons. When the conditioned response is followed by the unconditioned response after short delay, connection weight increases. The connection weight becomes interneuronal. Details of temporal firing activities of the models were examined under various conditions. Results show that neurons acquired responses to conditioned stimulus associated with unconditioned ones and these responses were extinguished by extinction.

SEQUENTIAL INFORMATION PROCESSING: THE NECESSITY FOR MAPPING TIME INTO SPACE. K. Schill, C. Zetzsche and E. Poppel. Inst. for Med. Psychology, Univ. of Munich, 80336 Munich, Germany

Problems in modeling the perception of dynamic scenes have casted doubts upon the concept of "iconic memory". Analysing current concepts of visual temporal information processing reveals that some basic inconsistencies regarding the temporal properties have not yet been resolved. We have developed a model for the representation of spatio-temporal information in early vision [1]. Its key feature is the mapping of temporal structure into simultaneously accessible locally distributed activities. Although the model is aimed at the description of spatio-temporal information processing, application to tectoscopically presentations also predicts basic results obtained in the field. Furthermore, the model resolves inconsistencies of processing rates obtained with partial report and backward masking paradigms. The standard view on neural information processing, that information is represented by the spatio-temporal activity of discrete elements (neurons), is shown to necessarily imply a discrete internal representation of time. We believe that the need for the proposed mapping is so fundamental as to be expected to appear in a distributed fashion on various parallel and hierarchical levels in the nervous system. However, since on subsequent levels, sequences with larger temporal extension have to be represented, information reduction has to be applied to avoid combinatorial explosion of connections. Future theories and investigations should concentrate on the syntactical and semantic aspects of perceptions and how they are represented. [1] Schill K., Zetzsche C. (1994): A model of visual spatio-temporal memory: the icon revisited. Psych. Res., in press.

INFORMATION TRANSFER IN NETWORKS WITH HEBBIAN CONNECTIONS. E. Salinas, E. Marder* and J.F. Abbott. Biology Department and Center for Complex Systems, Brandeis University, Waltham, MA 02254.

In many systems, firing rates of a population of neurons code for the value of an external variable. We investigate how information about the coded quantity can be communicated from one population (or topographic map) to another. We also explore how nervous systems might combine these representations in order to carry out coordinate transformations. These problems are analyzed using computer simulations the responses of cells that are broadly tuned to an external quantity. We have implemented methods to decode the information in such ensembles of neuronal activities (Salinas and Abbott, J. Comput. Neurosci., in press). This allows us to more explicitly examine the relationships between the established through a correlation based, or Hebbian type of learning mechanism. This corresponds, for example, to the generation of a motor command in the same direction as a given sensory input. Furthermore, the same algorithm can be used to couple two maps, so that the resulting set of activities codes for a linear combination of the original coded quantities. In this case a coordinate transformation is being carried out. These results demonstrate how networks can perform important computational tasks using biologically plausible learning mechanisms, such as the Hebb rule.

493.23

A neural network model of associative memory is proposed for information processing in the hippocampus. Recent morphological and physiological findings suggest a three-dimensional neural network structure in the hippocampus is considered for the modelling. We have adopted an assumption that each lamellar network accepts its respective category of information in this model, while the networks between granule cells and CA3 cells are constructed within each lamella, in which the information is processed according to their respective categories. The granule cells competitively select particular signals by negative self-feedback for each category. Further the recurrent paths in the CA3 cells strengthen the associative learning within a category. Both granule and CA3 cells fire sparsely. Association among different categories of information is made by the following inter-laminar connections of the CA1 and subiculum areas. This associative interaction has a general tendency to reduce excessive correlation among the signals. Therefore, sparse firing inputs to the CA1 cells are quite reasonable to protect from the excessive interference. The output direct input paths from the entorhinal cortex to these areas are very important. These looped circuits can lead the associated output signals to the appropriate input parts of the entorhinal cortex. We can understand the three-dimensional structure and the functions of the hippocampus by this model, and the importance of the hippocampus for associative memory as well.

493.24
NEURON EXCITABILITY AND ASSOCIATIVE MEMORY FUNCTION. E. Cook*, M. Migliore, and D. Johnston*. Div. of Neurosciences, Baylor College of Medicine, Houston, TX 77030 & Inst. of Interdiscip. Appl. of Physics, Natl. Res. Counc., Palermo, Italy.

In previous work we showed that the ability of three different biophysical models of a hippocampal pyramidal neuron to use synaptic potentiation as a mechanism of memory storage is dependent on a match between the magnitude of the synaptic input and cell excitability (Cook et al. Soc. Neurosci. Abs., 600.4, 1993). This previous work, however, only explored memory function in model neurons that were initially at rest and in a steady state. In the present report we have compared how previous synaptic activity reduces excitability of the three different neural models and tested whether this affects subsequent associative memory function.

Our three models were reconstructed hippocampal pyramidal neurons with the following different channel distributions and types: 1) passive dendrites with H&H-like Na+ and K+ channels in the soma, 2) passive dendrites with a full compliment of voltage-gated channels in the soma, and 3) a complete biophysical model that included active dendrites (Migliore et al. Soc. Neurosci. Abs., 295.13, 1993). Activation curves were computed for each model at various time points after four different stimulus paradigms: a) somatic current injection, and b) low (subthreshold), c) medium, and d) strong synaptic inputs. The program NEURON by Michael Hines was used in all computer simulations.

Comparisons between associative networks constructed from all models show that correct recall of stored patterns is affected by previous synaptic activity in models 2 and 3 but not 1. Simulations demonstrate that the two most realistic models (2 and 3) have increased thresholds to firing after experiencing all four types of stimulus paradigms. As synaptic input is increased (c and d), however, model 3 shows even greater reductions in excitability. This is a direct result of residual Ca2+ activating AHP K+ channels. Model 3, which contains dendritic Ca2+ channels, was affected the most by all three types of synaptic activity. (Kerr Center and MHE10475, MHE4754, MHE4832, and NS1535.)
494.1

The neural activity from parietal cortex (PG) to hippocampus (HF) is important for spatial recognition memory. In the present study, Sprague-Dawley rats were trained to perform a spatial working memory task. The rats were examined during the post-training delay period. Single unit activity was recorded from the PG and HF of an awake rat. While unit recording, the rat could be rotated in some direction, and the animal was directed to a match or a non-match (Fig. 1). There were 12 of 57 neurons in the PG and 10 of 30 neurons in the HF that responded to auditory directional stimuli. Ten neurons in the PG also had significant activity during the delay period that sometimes became enhanced after the rat was rotated to an unfamiliar direction. None of the HF-neurons responded during the delay period, but occasionally activity would emerge after the rat was rotated. These results suggest that spatial working memory in the PG is persistent, whereas that in the HF is transient.

494.3

RETROGRADE AMNESIA FOR SPATIAL DISCRIMINATION FOLLOWING ENTBROCHIAL CORTEX OR PARIAL CORTEX LESIONS IN RATS. Y. Chio, K. Nishio, T. Fujiki, K. Hashimoto, A. Fujikura, and H. Okada. Dept. of Psychology, University of Utah, Salt Lake City, 84112 Utah, USA; 2. Lab. Neurosciences, Compartements & cognitives, CNRS URA 339, Avenue des Facultes, 33405 Talamone Cedex, France.

Our previous study has demonstrated that lesions of entorhinal cortex (EC) produced a temporarily graded retrograde amnesia for spatial discrimination in rats. The present research was conducted to study further retrograde amnesia using rats as subjects as well as to extend to parietal cortex (PC), another brain area involved in the generation of spatial memory.

Rats learned successfully, one at a time, and every two weeks, 6 single-pair discriminations in two radial mazes (2 pairs in an 8-arm maze and 4 pairs in a 12-arm maze). Either the PC lesions or the EC lesions were made by unilateral aspiration of the PC or entorhinal cortex, respectively. The lesion operation was performed on the day after subjects had attained learning criterion on the 5th discrimination. Postoperative retention performance was assessed only for the last four discriminations indicated that the PC-lesions impaired overall performance as compared to control rats. The EC-lesions produced a more severe impairment than the PC lesions in addition to an extended temporal gradient of retrograde amnesia. The EC-lesioned rats were significantly impaired in retention of the 3 recent discriminations acquired immediately and up to 4 weeks prior to surgery, but were not different from controls for the first discrimination learned 6 weeks before surgery.

These results are consistent with previous findings obtained in mice with ibotenate lesions of the EC and suggest that the EC as well as the PC might be differentially involved in long-term storage/retention of spatial discrimination memory in rodents.

494.4

The rat medial prefrontal cortex (mPFC) consists of two distinct subregions, the prelimbic (PL) and the anterior cingulate cortex (ACC). Most behavioral investigations have treated these subregions as homogenous, therefore their individual contribution to the numerous cognitive functions ascribed to the mPFC remains unclear. The present study examined the effects of transient lidocaine-induced lesions of the PL or ACC on delayed spatial win-shift (DSWS) behavior on a radial-arm maze. The DSWS task consists of a training phase where 4 of 8 arms are baited randomly and the remaining 4 arms are blocked, and a test phase where all 8 arms are open but the previously blocked arms are baited.

Lidocaine micro-injections (2.5 -10 ul/group) into the PL or ACC produced no effect on: 1) training phase performance, 2) subsequent phase performance as assessed when the aesthetic effects of lidocaine had dissipated. Similar injections into the ACC had no effect on training phase performance, however lidocaine animals made significantly more entries into previously baited arms during the test phase. Transient lidocaine lesions of the PL delivered prior to the test phase disrupted test phase performance as lesioned animals foraged randomly. Similar microinjections to the ACC also impaired test phase performance, but in this case the errors were predominately revivals to previously baited arms. During the random foraging task in which 4 of 8 arms were baited transient lesions of the ACC were again accompanied by significantly more revivals to baited arms. PL lesions had no effect on this task. Given that PL lesions disrupted foraging for 4 pellets on the DSWS, but not during the random foraging task, the PL may play a role in complex rule-guided behaviors that utilize previously acquired information. Alternatively, the perseverative pattern of responding observed following transient lesions of the ACC suggest that the ACC is involved in situations which require newly acquired information to be used in a flexible manner.

494.6

We examined the effects of hippocampal and medial prefrontal cortex (MFP) lesions on discrimination of temporal duration and on memory for duration in rats. One short duration (2 sec) and one long duration (8 sec) was used and involved visual presentation of a 3-dimensional object. In the discrimination experiment, the door separating the rat from the stimulus was opened at the end of the time period, and latency to approach and move the stimulus was measured. For half of the rats, the stimulus covered a piece of food on the short duration presentations, but not the long durations, and the other half had the opposite contingency. In the second experiment, memory for duration was tested. Discrimination training (from 8-32 trials) took place for 2 weeks (i.e., 8 trials per day duration followed one second later by a test phase. The test phase involved presentation of one of two different 3-D stimuli. One object was always correct during both discrimination and retention phases. Latency to approach and move the stimulus was measured for both discrimination and retention phases. Memory for duration was tested. Rats in both groups received control, hippocampal, or MFP lesions following acquisition (significantly greater latencies on nonreinforced trials as compared to reinforced trials). Hippocampal and MFP lesioned groups showed performance deficits following surgery as compared to the control-operated groups on both tasks. Performance on the duration discrimination task returned to normal as compared to controls and pre-surgery performance, whereas both the hippocampal and MFP lesioned groups continued to perform at chance levels on the memory for duration task. Both the hippocampus and the medial prefrontal cortex appear to be involved in data-based memory for temporal information.

It has recently been shown that excitotoxic lesions of the anterior cingulate cortex facilitate early learning, and posterior lesions impair late learning, on a conditional visual discrimination task (Bussey et al., Soc. Neurosci. Abstr. 19: 1233, 1993). Furthermore, excitotoxic lesions of the ventral limb of the diagonal band of Broca (VDB), which result in cholinergic denervation of both these cortical areas, produce both of these effects on the same task (Muir et al., Soc. Neurosci. Abstr. 19: 1233, 1993). These results are concordant with those of others, who suggest that the anterior cingulate cortex is involved in mechanisms operative during the early stages of learning, while posterior cingulate activity predominates during later stages (Gabriel et al., Exp. Brain Res. 86: 585-600, 1991).

The aim of the present study was to determine whether the late-learning effects observed in our previous experiments were independent of the fact that animals were required to learn the task under the influence of the lesion. Accordingly, rats were trained to a criterion of 70% correct responding on two consecutive days, at which point animals received either quisqualate, acid lesion of the anterior or posterior cingulate cortex, or excitotoxic AMPA lesions of the VDB. Following recovery, the animals were returned to the task and trained until they had achieved 85% correct responding on two consecutive days. The results reveal that effects on late learning observed in our previous studies were indeed reproduced: both VDB and posterior cingulate lesioned animals showed an impairment in the ability to progress through the later stages of learning the task. In addition, the effects of the lesions on a post-acquisition retention test and on extinction were examined.

Cingulate cortex - the division of midline limbic cortex overlying the full rostrodorsal extent of the corpus callosum - has received little attention relative to other limbic structures such as the hippocampus. Recently it has become apparent that the cingular cortex can be anatomically dissociated into anterior and posterior components. However, the characteristic behavioural functions of these structures remain to be elucidated. Results obtained using an active avoidance paradigm suggested that the anterior cingulate cortex mediates mechanisms operative during early learning, while the posterior cingulate cortex is involved predominantly in late learning (Gabriel et al., Exp. Brain Res. 86: 585-600, 1991). More recently, it has been demonstrated that lesions of the anterior cingulate cortex facilitate early learning, and posterior cingulate cortex lesions produce a deficit in late learning, of a visual conditional discrimination task which requires the acquisition of a stimulus-response response (Bussey et al., Soc. Neurosci. Abstr. 19: 1233, 1993).

These results have led us to investigate the role of anterior and posterior cingulate cortices in the learning of stimulus-reward associations. We have recently developed a new computer automated touchscreen testing procedure which enables the testing of rats on various tasks involving the presentation of computer graphic stimuli. The present study employed this technique to examine the effects of anterior and posterior cingulate cortex lesions on simple visual discrimination and reversal and the acquisition of an 8-pair concurrent discrimination task. The results show that neither anterior nor posterior cingulate lesions affected acquisition of a simple discrimination. However, lesions of the anterior cingulate cortex impaired the early but not the late stages of acquisition of the 8-pair concurrent discrimination task.

494.11 INSULAR CORTEX GRAFTS RESTORE REMEMBERANCE OF PREVIOUSLY LEARNED TASTE AVERSIONS. C.E. Ormsby, V. Ramirez-Amaya and F. Bermudez-Rattoni* Instituto de Fisio! Celular, UNAM, Mexico, D.F., Mexico 04510.

Previous studies in our laboratory have shown that cortical grafts are able to induce rapid recovery of the ability to acquire a conditioned taste aversion (CTA) in insular cortex (IC) lesioned rats. Furthermore, tissue specificity has been shown since only autologous grafts induce recovery whereas occipital cortex (OC) tissue does not. Further studies have shown that IC lesions interfere with short and long term memory for CTA. The aim of the present study is to evaluate the effect of IC grafts on the recovery of memory aspects of CTA.

Twenty-week-old Wistar rats were trained for CTA by pairing a saccharin solution (0.1%) with a gastric malaise induced by an ip injection of LCI solution (0.15M). After 4 days to allow consolidation, all animals except a control (Ctrl) group were lesioned by microinjections of NMNOA and 10 days later the lesioned animals were randomly divided in 3 groups: one received IC grafts from 15-day-old fetuses (TwOC), one received OC grafts (TOWC), and one remained lesioned. Sixty days after grafting, all animals were tested for the CTA to saccharin and then retrained for a CTA to saline taste. The animals that remaining lesioned did not recall the saccharin CTA nor were able to acquire the new CTA to saline. Both grafted groups showed a recall of the CTA for saccharin similar to the control, but only the TwOC group showed values similar to the control for the acquisition of the new CTA for saline. It is noteworthy that the TOWC group was able to recall previously learned CTA but unable to acquire a new one, the graft-induced recovery of recall is less tissue specific than recovery of acquisition of CTA, and that the IC is highly involved in the evocation aspects of CTA. Supported by DGAPA IN201898.

The comparative neuropsychological approach involves the comparison of brain-damaged human patients with animal models of the same disorders, using tasks designed to assess specific mechanisms in both species. Both rodent and human studies have greatly facilitated when the tasks are as similar as possible for both species, and very difficult when they are not. Many researchers have succeeded in devising such task equivalence, for example, the use of "junk objects" in the Wisconsin General Test Apparatus or, more recently, the presentation of computer graphic stimuli on a VDU/touchscreen apparatus in primates and patient groups. Unfortunately, few tasks have been designed for the rat with this approach in mind. This is perhaps surprising given that the rat is, in psychology at least, by far the most popular and convenient laboratory animal.

Thus, we have recently developed a touchscreen procedure for the rat using computer generated visual stimuli. In addition to inter-species compatibility, other advantages of this technique include the nature of the response, the rat being able to interact directly with the stimulus by nose-pokes to the VDU screen; the ease with which rats can be trained to respond in this manner; and the ability to collect data on a wide range of performance measures. These points will be discussed and data will be presented to illustrate the use of a touch-sensitive screen for rats on various tasks, including object discrimination and serial reversal learning. 8-pair concurrent visual discrimination learning, spatial and non-spatial delayed non-matching to sample and visuospatial conditional rule learning.

494.10 RATS' VISUAL MEMORY IN A COMPUTER-CONTROLLED TESTING ENVIRONMENT. B.A. Gappan*, Department of Psychology, Reading University, Reading RG 2AL, UK and M.J. Eccott, Department of Psychology, Durham University, Durham DH1 3LE, UK.

Rats, of the Hooded Lister and Dark Agouti strains, were trained in a fully automated setting: a Y-maze each of whose arms terminates in a pair of adjacent monochromatic VGA screens, with a food dispenser between them. The abstract stimuli include internally complex, wide-angle displays - "scenes" analogous to those whose processing is disrupted by hippocampal system lesions. The stimuli - = - and, = - are used to create very, localized, homogeneous "objects". Displays can incorporate movement and brightness fluctuation to enhance their salience. We report rats' performance in tests of associative reference memory (concurrent discrimination among pairs of displays) and working memory (matching or non-matching).

494.12 MEMORY FOR FOOD REWARD MAGNITUDE: THE ROLE OF THE AGRANULAR INSULAR CORTEX. W.E. DeCotis, B.P. Kessner* and J.M. Williams, Department of Psychology, University of Utah, Salt Lake City, UT 84112.

Memory for magnitude of reinforcement was assessed in rats using a go, no-go task. During the task's study phase rats were given a piece of cereal comprised of either 25% or 50% sugar. For all trials, one of the cereal types was designated positive, the other negative. On the ensuing test phase the rat was presented with an object which covered a food well. If a positive food reward was given during the study phase, a second food reward was placed beneath the object. No food reward was placed under the object if the study phase consisted of a negative food reward. Latency to object displacement was used as the measure of performance. Following the establishment of a significant difference between latency to approach the object with reward compared to latency to approach the object without reward, rats were given either medial agranular cortex, agranular insular cortex, infralimbic/per- limbic cortex or sham control lesions. Sham controls excepted, all lesion groups showed post-surgery impairment followed by recovery of performance. Furthermore, animals transferred to a new set of cereal comprised of either 25% or 50% sugar. Thus, independent of lesion type, all post-surgery animals were able to perceive differences between magnitudes of reward. Trials consisting of 10 and 20 second delays between the study and test phases were then introduced. Only agranular insular lesioned animals showed significant impairment at each delay. These results demonstrate that lesions to the agranular insular cortex in rats produce accelerated forgetting of reward magnitude and suggest that this structure plays a significant role in memory for affect.
LEARNING AND MEMORY: SYSTEMS AND FUNCTIONS WEDNESDAY P

494.13 NEGATIVE PATTERNING DISCRIMINATION PERFORMANCE IS IMPAIRED IN RATS WITH BILATERAL QUINOLICAL ACID LESIONS OF THE NUCLEUS ACCUMBENS AND MAGNOCELLULARIS. S. Culver, E. McNamara, J. E. Jack, and T. S. Chi. Dept. of Psychology, University of New Mexico, Albuquerque, NM 87131.

It was hypothesized that NBM lesions would selectively impair the ability to learn conditional or configural associations while sparing the ability to learn simple, or elemental, associations (see Sutherland & Rudy, 1989). To test this hypothesis, rats with selective NBM or sham lesions of the NBM and were subsequently tested in a negative patterning operant discrimination task. In this task, rats received reinforcement for depressing an operant lever in the presence of either a light (L) or tone (T) but, are not reinforced (-) in the presence of a compound stimulus comprised of the light and tone presented together (LT). Animals that learn the reinforcement values of the elements L and T are determined by whether these stimuli occur separately (L- versus T-) or simultaneously (LT-). Thus, learning to withhold responses to LT- requires the formation of a configural representation of the compound cue in relation to the representations of its constituent elements. Based on evidence suggesting that simple associative learning remains intact in NBM-lesioned animals, it was hypothesized that these animals would learn to respond normally to the elements L- and T-. It was further hypothesized, however, that NBM-lesioned animals would be unable to form the configural representation of LT- and would continue to respond in the presence of this nonreinforced compound stimulus. Data support these hypotheses. All animals were able to discriminate between the presence and absence of the reinforced elements L- and T-. It is speculated that the ability to solve simple associative discriminations is unimpaired in NBM-lesioned animals. In contrast, negative patterning discrimination performance was impaired in NBM-lesioned animals; lesioned animals made significantly more LT- responses across training sessions than controls (p<.05), although behavioral recovery eventually ensued. Results suggest a selective involvement of the NBM in the acquisition of configural but not simple associative tasks. (Supported by NIH R01 NS-27695.)

494.15 EFFECTS OF MEDIAL SEPTAL LESIONS ON DELAYED-GO/NO-GO RESPONSE ALTERNATION IN RATS. R. Rumen. Psychology Department, Santa Clara University, Santa Clara, CA 95053.

In an earlier study (Nanam and Quaranta, 1990) we found that medial septal lesions impaired a two-stage delay operant alternation task in rats. We concluded that the impairment was due to a disruption of working memory. However, a "spatial" interpretation of the data could not be ruled out. Subsequently (Nanam and Kim, 1992), we found that medial septal lesions facilitated performance on a cue go/no-go discrimination task with a delay between the cue and the required response. This was not the case with the previously used go/no-go working memory paradigm. Hence, the lesion could not have produced a general working-memory impairment. This finding together, suggested to us that the medial septal lesions impaired "spatial" memory, and that the two stages of the task led to a compensatory enhancement of "stimulus" working memory. If this were true, then the lesions should impair a go/no-go task based on response working memory. The current experiment tested this hypothesis. Rats (12 with medial septal lesions and 12 with sham operations) were tested on a discrete-trial operant go/no-go response alternation task without cues. The rats were first tested for 20 days without a delay contingency, followed by 30 days of testing with a 15-s delay between the cue and the required response. The shuttle lesions did not impair performance at the 0-s delay (p>0.05). Both groups achieved 85% correct and acquired the basic requirements of the task. However, when the delay contingency was added, the medial septal lesions impaired performance (p<0.025). By the end of testing, the controls averaged 75% correct while the lesioned rats averaged 67% correct.

As the go/no-go task does not require spatial processing, the best explanation for all of these findings is an impairment on L-R delayed alternation and delayed go/no-go response alternation, but facilitation on a delayed but cue go/no-go discrimination is that the medial septal lesions produce an impairment in "response" working memory. Such an impairment may result in a compensatory enhancement in the processing of salient environmental cues to guide behavior and improve performance on cue-task.

494.17 LATERAL DORSAL NUCLEUS OF THE THALAMUS CONTRIBUTES TO SPATIAL LEARNING. M. D. Palmer and R. J. Sutherland. Dept. of Psychology, University of New Mexico, Albuquerque, NM 87131.

The lateral dorsal nucleus (LD) of the thalamus has reciprocal connections with retrohippocampal areas. Recent electrophysiological work implicates LD as playing an important role in the spatial navigation process, especially in encoding head direction (Mizumori, Kuhar & Amaral, 1992). The present experiment was designed to investigate LD's role in spatial learning.

Eight rats received electrolytic lesions of LD (coordinates: -2.6, +2.6, -2.6, 5.7) of 15mA for 1s. Sixteen rats served as sham controls, which were naive to the water task. We used a moving platform version of the water task in which the submerged platform was moved to a new position on each subsequent day, but remains in the same position over the course of trials. The LD rats displayed a significant deficit in learning relative to the sham controls.

We also report on acquisition of a negative patterning discrimination and a light-tone discrimination in an operant task.

The nucleus basalis magnocellularis (NBM) is the major cholinergic projection to frontal cortex and its depletion appears to modulate cortical neuronal activity. Lesions of the NBM produce deficits in radial arm maze performance and morphological alterations in frontoparietal cortex. We have assessed selective attention and noradrenergic receptor binding in frontal cortex of rats with bilateral lesions of the NBM. Nineteen rats received either bilateral NBM or sham lesions of the NBM. Two months after surgery, rats were trained in a block task. While sham-lesioned rats showed blocking, suppressing significantly more to a meaningful cue than to a non-meaningful cue. NBM-lesioned rats did not show blocking, suppressing less to both cues. The groups performed comparably on a passive avoidance task, suggesting that deficits on the block task were due to attentional changes rather than a learning deficit. Three months after surgery, rats were killed and their brains removed. Sections were incubated with either [3H]quinoxalin-3-(4H)-side or [3H]desmethyrimipramine (DMI) to assess noradrenergic function and processed for autoradiography. Quantitative receptor binding revealed a 28% decrease in DMI binding and a 24% decrease in DMI binding in frontal cortex of lesioned rats. Thus, the NBM appears to modulate noradrenergic function in frontal cortex, and to alter the behavior and cortical morphology through the noradrenergic system.

494.16 RETROGRADE AND ANTEROGRADE SPATIAL MEMORY IMPAIRMENTS FOLLOWING RADIO-FREQUENCY-LEVEL QUESIONS TO THE LATERAL INTERNAL MEDULLARY LAMINA. L.M. Savage, A. S. A. Bassett, and P. J. Langlais. VA Medical Center San Diego, CA 92169.

Rats were pre-trained on a Non-Matching-To-Position (NMT) task in the T-maze. After initial acquisition (90% correct for 2 sessions) subjects were randomly assigned to two treatment conditions: (A) radio-frequency lesions to the lateral Internal Medullary Lamina (IML), or (B) probe placement in the same location (sham). Following recovery from surgery, the IML-lesioned rats took significantly more trials than sham rats to re-acquire the criterion. This suggests that lesions to the lateral IML region produce retrograde deficits. Once subjects re-mastered the NMT task they were re-introduced to the water and effects of lesions were tested. Although the performance of IML-lesioned rats at the shortest delay (4 s) was equivalent to shams, they required longer delays (30, 60, 90 and 90 s) to complete the task. Anterograde learning and memory was subsequently assessed using the Morris water maze. Again, IML-lesioned rats demonstrated impaired spatial abilities—their latency to find the location of the hidden platform was significantly longer than shams. However, they were able to decrease their latency to find the location of the visual platform. IML-lesioned rats, relative to shams, demonstrated no deficits in learning a single trial passive avoidance task. These results suggest that lesions to the IML region produce a range of spatial deficits that parallel the ptyalin-induced thiaamine deficiency model of Wernicke-Korsakoff syndrome. Funded by a VA Merit Award to PJL.

494.18 IBOTENATE LESIONS OF RAT NUCLEUS REUNIBENS THALAMI FAIL TO IMPAIR SPATIAL LEARNING AND MEMORY. M.Dollman-van der Weel*, R.O.M. Monte, and M.O. Winter. Graduate School of Neurosciences, Dept. Anatomy and Embryology, Vrije University, Amsterdam, The Netherlands, "Centre for Neuroscience, University of Edinburgh, Scotland.

Monosynaptic projections from the thalamus to the cerebral cortex may enable it to modulate activity in the entorhinal-hippocampal circuit and, hence, play a role in learning and memory. We explored this idea using the watermaze (fixed hidden platform, 18 spatial training trials, transfer test, 4 cue trials). The reuniens (RE, n=12) was lesioned with ibotenate acid and the behavioral effects were compared to Unoperated (Uop, n=6) and sham-lesioned controls (SH, n=11), medial dorsal nucleus (MD, n6) and hippocampal-dentate gyrus lesioned rats (HDG, n=6). ANOVAs revealed overall Groups effects in both training and the transfer test (p<.001), but, despite a trend towards poor performance by the RE group, pairwise comparisons (Dunnnett's test) revealed that only the MD and HDG groups were impaired relative to the SH group during training (p<.01 and p<.025 respectively) and only the IDG group was impaired during the transfer test (p<.025). The cue test revealed a trend towards poorer performance in the MD group (p>0.05). Our protocol was, therefore, sufficiently sensitive to detect hippocampal dysfunction in a spatial navigation and memory, but showed only a non-significant trend towards impairment following damage to the reuniens.

In summary, the presumed modulatory input from the reuniens to the entorhinal-hippocampal circuit was only a subtle effect on spatial learning. Its function may be better revealed using other learning and memory paradigms.
494.19

Rats with bilateral electrolytic or sham lesions of the mediodorsal thalamic nucleus (MD) were tested on a battery of six object-memory tasks, which resemble those which have been used in the study of amnesia in humans and monkeys: (1) simple two-choice object discrimination, (2) discrimination reversal, (3) 8-pair concurrent object discrimination, (4) two-choice switch-to-sample (DNMS) with retention delays of 4, 5, 30, 60, 120 s, (5) DNMS with lists of 3, 5, and 7 samples, and (6) order discrimination. Each task made use of the same apparatus as the monkey versions of these tasks, each one used objects as test stimuli. All testing was conducted posturgery.

Relative to control rats, the rats with mediodorsal thalamic lesions were impaired at learning the simple object discrimination, but they did significantly more trials to master both the object reversal and the concurrent object discrimination tasks. The DNMS testing revealed that the rats with MD lesions were impaired at all delays of 15s or longer, and there was an overall group impairment across the three list lengths. There was no significant difference between the controls and MD-lesioned rats on the temporal-order discrimination task. The results from this battery of memory tasks will help in fully characterizing the nature of the memory deficits associated with medial diencephalic lesions in the rat and allow for direct comparisons to similar experiments in monkeys.

494.20
MEMORY IMPAIRMENT FOLLOWING LESIONS TO THE ANTERIOR NUCLEI OF THE THALAMUS. V. Szikla*, F. Ler, and M. Petrides. McGill University, Montreal, Quebec, Canada.

In the present study, rats with lesions to the anterior thalamic nuclei (ATN), the fornix (FX) or a control operation (OC) were trained on an eight-arm radial maze under two conditions. In the first condition, there was a 20 sec delay between choices, in the second, there was no intradelay. Animals with lesions to the FX improved significantly when there were no delays between choices but the performance of this group was significantly impaired in comparison with the OC animals under both conditions. The overall performance of the ATN group was significantly worse than that of the OC group and, in addition, did not improve significantly with the removal of the intradelay. An analysis of the distribution of errors made in the delay condition suggests that the nature of the memory deficit following lesions to the ATN and the FX might be different. Taken together, these findings suggest that restricted lesions to the ATN are sufficient to produce a working memory deficit on the radial maze under the conditions used in this study.

494.21

The tuberomamillary nucleus (TM) is located in the posterior part of the hypothalamus and provides the only source of neural histamine in the CNS. Our experiments performed with unilateral lesions of the TM region provide evidence for an involvement of the TM system in reinforcement mechanisms. Unilateral destruction of the TM with DC or ibotenic acid was found to increase the rate of lateral hypothalamic self-stimulation ipsilateral to the lesion site, suggesting that the TM may function as a reinforcement inhibiting neural substrate. Experiments performed with bilateral lesions of the TM region provide evidence for a role of the TM in learning and memory processes. Adult (3-month-old) and aged (31-month-old) rats with bilateral DC lesions in the TM region were tested along with sham-lesioned controls on the one-trial step-through inhibitory avoidance task and on a spatial discrimination test in a water-filled T-maze. Bilateral lesions of the TM led to significantly longer retention latencies in the step-through task and improved long-term retention in the water maze test in both adult and aged rats, indicative of superior learning. Thus, lesions of the TM may have a facilitatory e ffect on learning and mnemonic functioning, which is possibly related to a lesion-induced disinhibition or facilitation of rein-forcement ("stamping-in") processes. Supported by DFG.

INVESTIGATION OF NEURAL AREAS CONTROLLING CONDITIONED TASTE AVersions IN RATS. EFFECTS OF COOLING THE AREA POSTREMIA. Y. Wang, D. G. Lavond, & R. C. Chambers*. Department of Psychology USC, Los Angeles, CA 90089.

Four studies were designed to determine the feasibility of using cooling to investigate neural mechanisms of conditioned taste aversions (CTA). Study 1 was designed to determine whether cooling the arms postremia (AP) can induce a CTA. After 13 rats were given access to a sucrose solution, the AP of 7 of the rats was cooled for 1 hour and the AP of 6 was not cooled. Starting 2 days later, all rats were given daily extinction trials until their acquisition day consumption levels were restored. Cooling the AP induced a CTA; the rats whose AP were cooled showed a decrease in sucrose consumption but the non-cooled group did not. Study 2 was designed to determine whether precooling to cooling of the AP could attenuate the CTA induced by cooling the AP. In 7 rats, the AP was cooled daily for 7 days and in another 7 rats the AP was not cooled. On acquisition day, the AP of all rats was cooled after consumption of sucrose solution. Precooling to cooling attenuated the aversion induced by cooling; the non-precooled group showed a decrease in sucrose consumption but the precooling group did not. Study 3 was designed to determine whether cooling the AP could be used to block a CTA induced by LCi. All rats were preiced to cooling. After sucrose consumption, the AP of 6 rats was cooled just prior to injection of LCi and was kept cooled for 1 hour. Another 7 rats received LCi only. Cooling the AP attenuated the aversion induced by LCi rats exposed to cooling during LCi stimulation acquired a weaker aversion than those not exposed. Study 4 was designed to determine whether cooling the AP could block a CTA induced by sponspheine (Apo). After sucrose consumption the AP of 8 rats was cooled just prior to injection of Apo and was kept cooled for 1 hour. Another 7 rats received Apo only. Cooling had no effect on the aversion induced by Apo. The results of these studies, attenuated aversion induced by LCi but not sponspheine, replicate those of studies that have used permanent lesion techniques. Supported by USC FRP.

DIFFERENT SUBCORICAL AREAS SUBERVE SPATIAL BUT NOT VISUAL DISCRIMINATION PERFORMANCE IN INBRED MICE. M. Ammendt, P. Reile and P. Rosig-Arnau**. Inst. of Psychobiology and Psychopharmacology and * Department of Psychology, University of Rome "La Sapienza", Rome, Italy.

C57BL/6 (C57) and DBA/2 (DBA) inbred mice differently perform spatial tasks with C57 doing better than DBA at such learning. Hippocampal lesions have been shown to impair performance in both strains while amygdaloid and frontal cortex lesions have a deleterious effect only in the "high learner" strain C57. The aim of the present study was to examine whether the genotype-dependent involvement of limbic structures remains the same across tasks which make either the spatial or the visual modality relevant for discriminating the set of bailed arms. C57 and DBA mice were tested in the standard (experiment 1) or in the visually-cued (experiment 2) version of the four-baited path task in a radial eight-arm maze.

Results show that, when the spatial modality was relevant for identifying the correct arms, both hippocampal and amygdaloid lesions impaired performance in C57 while hippocampal but not amygdaloid lesions impaired performance in DBA. Conversely, when the visual modality was relevant, the two strains performed the task in the same way, and their performance was, but they took hippocampal lesions only. Spatial but not visual discriminative learning is therefore selectively based upon the involvement of different subcortical areas in the two strains considered.

494.24
ASYMMETRICAL EFFECTS OF LESIONS IN FR2 ON LEFT-RIGHT RESPONSE DIFFERENTIATION IN THE RAT. M. Newcorn*, D. Chmiel, Jc, and S. Axelrod. College, Buffalo, NY 14208; 2 SUNY at Buffalo, Buffalo, NY 14214.

We compared rats with left or right lesions in supplementary motor area Fr2 (Zilles), and sham operates, on a left-right response differentiation (LRD) water-maze task given after pair experience with a control task in the same apparatus. We found that (1) rats exhibited an overall left-turning bias during acquisition, (2) the bias was particularly pronounced on the LRD task, and (3) right-lesioned rats performed better than left-lesioned rats.

Overall, our results provide evidence of a consistent cerebral asymmetry in the rat. The left-turning bias replicates earlier findings in our laboratory and points to asymmetrical motor activation favoring the right hemisphere during these water escape tasks. Nonetheless, a lesion in the right Fr2 left our rats better able to acquire an LRD task than a lesion in the left Fr2. We have previously shown that extensive right hemisphere/occipital, compared to left decortication, improves performance on the LRD task when it was similarly presented as a second learning experience. The present finding adds to localize the relevant asymmetry to area Fr2, and suggests that it is motor/attentional in nature.

495.1 DIFFERENTIAL INFLUENCE OF HIPPOCAMPAL SUBFIELDS CA1 AND CA3 IN ODOR DISCRIMINATION. U.S. Hest, G. Lynch, and C.M. Gall. Dept. of Psychology, Univ. of CA, Irvine 92851.

Expression of the c-fos gene is a useful marker of neuronal activity. In the present study, levels of c-fos mRNA were evaluated in order to determine discrete areas that underlie odor discrimination. Rats were trained on one odor pair in a familiar chamber with six odor alleys. Oders were emitted from any two random odor ports on a given trial and rats had not c-fos mRNA at the nose site and to avoid the negative response (response to which resulted in a strobe flash). Control rats (i.e. nosepoke controls) performed praxial tasks in the same apparatus with no odor presentation. c-fos mRNA was quantified using in situ hybridization of 35-S-RNA probes. Hybridization to c-fos mRNA was not detectable in rats performing the task (learners) as compared to control

495.2 GLUCOSE FACILITATES ACQUISITION AND REDUCES HIPPOCAMPAL DEFICIT IN THE MORRIS WATER MAZE IN RATS. R.W. Skelton & S.R. Russ. Psychology, U. Victoria, Box 3065, Victoria, B.C. V8W 3P6 CANADA

Post-trial glucose has well-known facilitatory effects on retention of inhibitory conditioning. Increases in blood glucose levels have been proposed to underlying the mnemonic facilitation produced by epi- nphrine, norepinephrine and epinephrine. The present study examined the effects of pre-trial glucose on performance of rats recovering from bilateral transections of the perforant path (a major cortico-hippocampal-cortical pathway).

During initial acquisition, glucose (100 mg/kg) was administered for 10 days 9 min before or after 2-trial daily sessions with a submerged platform in a novel location. Probe trials were given as the second trials of Days 5 and 10, and an undrugged probe trial was given after a 5 day undrugged retention interval. After such pretreatment, rats were given an intertrial delay to the test platform and allowed 5 days to recover. They were then tested for 7 days with the platform in the original location and 7 days with the platform in the opposite quadrant. Glucose (100 mg/kg) was injected 15 min prior to each day was mg of 4-mercaptoethanol.

Previous studies with rodents showing alterations in both spatial learning and LTP following injections of somatostatin (SS-14) or other somatostatin analogs suggest that specific subfields of the hippocampus (CA1, CA3) are involved in the acquisition. In the present study, the hypothesis that hippocampal SS-14 could play a role in spatial mapping processes. However we reported that, although intrahippocampal SS-14 injections facilitated the acquisition (regular trials) of spatial discriminations (two overlapping pairs (A+B) vs. (C+D)) was also impaired performance during probe trials (B+C) aimed at having relational representations. Guillois et al., Psychology 21:4, 1993. In the present study the aim was to determine whether this latter impairment was due to a deficit of relational encoding during the acquisition of the task or, alternatively, to a retrieval deficit (fragment fitting) occurring only when testing was shifted on probe trials. Accordingly, SS-14 or artificial CSF was injected either before regular probe trials, or both. As in our previous study, injections of SS-14 before both regular and probe trials facilitated regular trials significantly and facilitated probe trials. Injections of SS-14 before only regular trials produced the same pattern of results. In contrast, injections of SS-14 before only probe trials did not yield any behavioral effect. Thus, injections of SS-14 into the hippocampus appear to disrupt relational representations that, in normal mice, would occur during the acquisition of the task. This SS-14-induced deficit of relational representations could account for the facilitation of acquisition (by use of individual representations of each pair). However, other results along with the observation that c-fos expression produces a large impairment on regular trials seem difficult to explain by the relational theory alone. Taken together, these results suggest that both spatial mapping and the formation of relational representations are two separate HPC-dependent functions.

495.4 DENTATE GAMMA DEATH AND SPATIAL LEARNING IMPAIRMENT AFTER CORTICOSTEROID REMOVAL IN YOUNG AND MIDDLE-AGED RATS. C.D. Conrad, D.L. Boy, Neurosci., Univ. Ill., Champaign, IL 61820.

We investigated the functional and behavioral implications of chronic corticosteroid removal in young and middle-aged rats. Pre-pubertal rats were placed in these groups: adrenalectomized (ADX) with no hormone replacement; ADX given corticosterone chronically, chCORT; ADX given corticosterone acutely at time of Morris water maze at 12 weeks old, aCORT. 13 month old rats were ADX or SHAM operated only. All rats were run on the Morris water maze 12 weeks after surgery for 11 days after which, they were sacrificed and brains saved for histological analysis.

The results showed that prolonged corticosterone absence caused major damage to the dentate gyrus and impairment on the Morris water maze. The chCORT rats had little dentate gyrus cell loss and were as efficient as the SHAMs in the Morris water maze performance whereas the aCORT rats had dentate gyrus cell loss and were impaired in the spatial acquisition task. Middle-aged ADX rats lost cells only in the dorsal blade of the dentate gyrus but they did not show a greater learning impairment in the Morris water maze relative to the middle-aged SHAMs. These results indicate that corticosteroid absence is trophic for the dentate gyrus and that substantial dentate gyrus damage impairs spatial learning.

495.5 BEHAVIORAL AND ANATOMICAL EFFECTS OF 192-SAPORIN AND ANTI-DH-SAPORIN PASSIVE AVOIDANCE, CONDITIONED FREEZING AND OPEN FIELD ACTIVITY. R.G. West, T.G. Berber, D.A. Lepel, M.J. Pickel & D. Roberts. VASC & Vanderbilt University, Nashville, TN 37212 & The Whitter Institute, La Jolla, CA 92037.

Analysis of the behavioral function of the cholinergic basal forebrain (CBF) has been benefited from the isolation of the immunotoxin, 192-saporin, that selectively destroys neurons expressing the low affinity NGF receptor (p75). Animals with high CBF lesions are profoundly impaired in a variety of behaviors including passive avoidance. Since the somatodendritic projections innervate the hippocampus, thalamus, and basal forebrain, the CBF and many of its targets (hippocampus, neocortex), we sought to compare rats injected intravenicularly with 192-sap (N=8) to controls (N=8) and rats treated with another immunotoxin, anti-DH-saporin (N=8), to determine the effects that CBF lesioning (cholinergic & noradrenergic) is expressing the enzyme, dopamine B-hydroxylase. Rats injected with anti-DH-saporin were slower to regain weight after surgery than rats injected with 192-saporin (p=0.002). Anti-DH-saporin rats were significantly inhibited in a conditioned fear paradigm relative to 192-sap treated rats (p=0.003). In a step-through passive avoidance task, anti-DH-saporin treated rats behaved similar to controls showing none of the impairment seen in the 192-sap treated rats (p=0.001). In the open field, there was a nonsignificant trend for increased activity among 192-sap treated rats compared to the controls and anti-DH-saporin treated rats. Immunocytochemical staining for choline acetyltransferase (ChAT) showed near complete (90%) loss of ChAT-positive neurons of the CBF in 192-saporin treated rats compared to controls. Anti-DH-saporin treated rats showed about 50% decrease in p75/ChAT neurons in the CBF and near complete (90%) loss of tyrosine hyroxydase (TH)-positive neurons from the noradrenergic and adrenergic brainstem nuclei. Dopaminergic TH neurons were unaffected in the substantia nigra and ventral tegmental area. These results confirm that 192-sap and anti-DH-saporin produce the expected selective lesions that animals prepared with these agents are useful in analysis of the behavioral function of CNS cholinergic and noradrenergic neural systems.

The available evidence supports the hypothesis that the immunotoxin 192 IgG-saporin selectively destroys the cholinergic neurons bearing p75 NGR receptors. Heckers et al. (1984) have shown that lesions in the basal forebrain destroyed the cholinergic projections to the cortex and spared the cholinergic neurons projecting to the amygdala and thalamic nuclei (which do not bear NGR receptors). As cortical cholinergic afferents have been assumed to mediate the subjects’ ability to detect and process behavioral significant stimuli, the effects of 192 IgG-saporin-induced lesions of the cholinergic basal forebrain on behavioral vigilance were examined. Rats received infusions of 192 IgG-saporin (0.20 µg/0.5 µhemisphere) after they were trained to criterion in an operant vigilance task. This task requires the animals to discriminate between signal (central panel light presented for 25, 50 or 500 sec duration) and nonsense stimuli. When a correct signal rejection was rewarded, while misses and false alarms were not. Following the post-learning retraining period, animals were treated with a benzoazepine receptor agonist (cloroxazepoxide, 1, 5, 3 mg/kg, i.p.), and partial inverse agonist (vaclopride, 5, 1, 2 µg/kg, i.p.) to test the hypothesis that, in lesioned animals, the detrimental effects of the agonist are more potent than in control animals, and that the partial inverse agonist attenuates the lesion-induced impairments in vigilance performance.

19 Ig-saporin lesions of basal forebrain cholinergic cells effects on learning and memory in rats. M. C. Baxter1, B. J. Back2, A. A. Chiba3, L. Chai, R. C. Wilson, and M. Gallagher1,4
1Department of Neurology and 2Department of Psychology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 27599; 3DAMC and Vanderbilt University, Nashville, TN 37232.

The development of 19 Ig-saporin, which acts as a specific cholinergic neuronal when infused directly into basal forebrain nuclei, permits direct assessment of the role of basal forebrain cholinergic cells in cognitive function. Male Long Evans rats, 2-3 months old, received infusions of 19 Ig-saporin (IES) or vehicle (CON) into either the medial septal area (MSA) or substantia innominata (SI). Place discrimination in the Morris water maze assessed spatial reference memory, and a 2-trial matching-to-place task in the Morris water maze assessed spatial working memory. MSA-CON and SI-CON rats did not differ in behavioral performance and were pooled for statistical analysis. MSA-LES and SI-LES rats were not impaired relative to CON rats in acquisition of the place discrimination. MSA-LES and SI-LES rats were impaired relative to CON rats in performance of the working memory task; however there was no obvious delay-dependence of the deficit at the delays tested (delays ranged from 30 seconds to 3 hours), suggesting that this deficit may not be purely neomeric in nature. This pattern of results calls into question the central role postulated for cholinergic neurons of the MSA in learning and memory. (Supported by NIA Grant PO1-AD09973 to MG and an NSF Predoctoral Fellowship to MGR.)

495.8
Substantia innominata lesions impair incremental attentional processing in a Pavlovian conditioning paradigm. A. A. Chiba1, L. S. Han1, E. C. Holland2, and M. Gallagher1,4
1Department of Psychology, Univ. of North Carolina, Chapel Hill, NC 27599; 2Department of Psychology, Duke University, Durham, NC 27706.

Holland and Gallagher (1990) demonstrated that a central nucleus of the amygdala (CN) in incrementing attention based on associations formed during appetitive conditioning. Furthermore, recent evidence indicates that habituation processes by CN may be mediated through the corticopetal system located in the substantia innominata (SI), a component of the basal forebrain system in the rat brain.

An associative learning paradigm was used to examine the role of the SI in modulating attention. Each rat was exposed to conditioned stimuli (CS) that were either consistent or inconsistent predictors of subsequent CAs. Intact control rats maintained higher levels of attention to a CS when it was an inconsistent predictor of subsequent CAs, whereas SI-lesioned rats failed to show this enhanced attention. Thus, SI-lesioned rats displayed an impairment in incrementing attention equivalent to that previously demonstrated by CN-lesioned rats. These data support the notion that CN attentional modulation is dependent on the projections of the CN to the SI corticopetal cholinergic system. Based on this hypothesis, further experimentation using selective cholinergic lesions of the corticopetal system is being pursued within the behavioral paradigm. 495.9
c-fos expression following paired or unpaired cutaneous nerve stimuli: specificity related to LTP of spinal reflexes. R. O. Durieux*, Dept. of Physiology, SUNY Health Science Center, Syracuse, NY 13210.

In order to help define the neural circuits involved in two forms of associative reflex potentiation, spinal neurons expressing c-fos were examined following various qualities of cutaneous nerve stimuli. Previous work from this laboratory has shown that in the spinal caudal preparation when two cutaneous nerves are stimulated in specific "paired" sequences, flexion reflexes evoked by stimulating one of the nerves exhibited LTP (Long-Term Potentiation) that lasts for hours. These reflex changes obey the general rules established for learning and memory behavior in intact animals (Nature, 319:211, 1986). Thus, these spinal reflex changes represent a specific model for investigating neural mechanisms of elementary forms of learning and memory behavior. The experiments reported here compare the number and locations of fos labeled neurons in the spinal cords of control and experimental animals (one or two nerve stimuli), animals given 30 "unpaired" cutaneous nerve stimuli, and animals given 30 "paired" cutaneous nerve stimuli presentations. fos labeling was differentially expressed among these groups with few neurons labeled in control animals and the greatest number of labeled neurons in "paired" animals. Furthermore, two methods of "pairing" resulted in concentrations of labeled neurons in different spinal cord regions. The paradigm that preferentially potentiated spinal circuits activated by large myelinated superficial cutaneous nerve fibers labeled neurons primarily in deep laminar (VII) of spinal cord. The paradigm that preferentially potentiated spinal circuits activated by small myelinated superficial cutaneous nerve fibers labeled neurons primarily in more dorsal laminar (IV-V). The results are consistent with the hypothesis that learning and memory result from alterations in the synaptic strengths of specific sets of synapses. Supported by NSF grant IBN 922020K.

Long term potentiation (LTP) of pyramidal neurons in layer five of the cat motor cortex. Akhita Kimura*, Francesco Mela, Marcello A. Cara and Hiroshi Asanuma. The Rockefeller University, New York, N.Y. 10021.

Long term potentiation is supposed to play a crucial role in learning new skilled movements (Asanuma and Keller, 1991). A series of experiments revealed ubiquitous existence of LTP in various structures involved in execution of skilled movements. In this study, generation of LTP within the motor cortex was studied using intracellular recording and labeling (biocytin) techniques under Nembutal anesthesia. Intracortical microstimulation (ICMS) was delivered in the superficial layers and recording were obtained in layer V of the motor cortex. Of 20 labeled cells in layer V, 6 cells showed short lasting potentiation (1-4 min, 160-240% of control EPSP) immediately after tetanic ICMS (100-200 Hz, 10-30 sec) which was followed by steady potentiation (130-150% of the control) lasting until the electrode went out of the cell (7-28 min). In 12 labeled cells, only PTP (120-270% of the control) was observed. The duration of the PTP was from one to 4 minutes. All the labeled cells were pyramidal neurons. The effective stimulating sites inducing LTP were located immediately superficial to the labeled neurons. These results suggest that plasticity exists within the intracortical connections of the motor cortex that may be involved in learning of new motor skills.

495.11
Inhibition of nitric oxide reduces hippocampal mediation of place learning in the rat. G. Wörlein, B. Gustafson, P. Ernsatz and J. Mogensen*. Laboratory of Neuropsychiatry, University Hospital 4102, Copenhagen, Denmark.

In Experiment 1 the behavioural consequences of transection of the fimbria-fornix were investigated in animals that had acquired a place learning task after a control pretreatment or a pretreatment period during which near-total inhibition of NOS (the nitric oxide synthesizing enzyme) had been accomplished. While the lesion significantly impaired task performance in normals, the rats which had acquired the task during NOS inhibition did not reveal a reproducible impairment. In Experiment 2 four groups of rats were studied: two groups received transection of the fimbria-fornix while the other two were subjected to sham surgery. Subsequently, one of the lesioned and one of the sham groups received a period of L-nitro-arginine (L-N-ARG) injections. During the final 5 days of surgery all groups were subjected to training on place learning. While NOS inhibition impaired task acquisition in the sham operated animals, L-N-ARG administration in fimbria-fornix transected rats failed to impair task acquisition. Conclusions: (1) Normal place learning acquisition involves hippocampus associated mechanisms. (2) Under conditions that the task can be acquired by a system that differs from the one mediating task acquisition in normals by receiving reduced contributions from the hippocampus.

495.12
Stress effects on memory and AMPA receptors are abolished by Adrenalectomy. D.M. Diamond*, B.J. Branch, G.M. Rose and G. Tocco. Dept. of Pharmacology, Univ Colo Health Sci Ctr, & VA Med Ctr, Denver, CO and Neurosciences Program, USC, Los Angeles, CA

We have reported that exposure of a rat to an unfamiliar environment (psychological stress) blocked LTP (Psychology, 18:273, 1990, Beh. Brn. Res., in press) and selectively impaired hippocampal-dependent memory (Neurosci. Abst., 19:366, 1993). The present work is a test of the hypothesis that the effects of stress on hippocampal function will be eliminated by adrenalectomy (ADX).

Male rats were transfected on 14-arm radial maze without novel hippocampal-dependent (working memory) and hippocampal-independent (reference memory) components (see Neurosci. Abst., 19:366, 1993 for details). Stress impaired working, but not reference, memory in intact rats. In contrast, stress did not affect on memory in ADX rats. The ADX rats did exhibit other behavioral manifestations of stress (e.g., fecal bolus production). Therefore, the effects of stress on emotionality and cognition (memory) can be dissociated. We have also found that stress produces a hippocampus-specific reduction in ADMA receptor binding in intact, but not in ADX, rats. These findings indicate that stress produces adrenal-dependent effects on hippocampal plasticity, memory and glutamate receptor binding dynamics. Supported by NS, ONR, the VAMC and the McKnight Foundation
LEARNING AND MEMORY: SYSTEMS AND FUNCTIONS XIV

It is well known that benzodiazepines (BZD) produce anterograde amnesia. Recent evidence suggests the amygdaloid complex (AC) GABAergic system mediates BZD-induced amnesia. Lesions of the AC block the impairing effects of a BZD on retention of inhibitory avoidance (IA) behavior. Addition of BIC, a non-competitive antagonist by pre-intracortical (i-AC) infusion of the BZD midazolam (MDZ) and enhanced by intra-AC injection of a BZD antagonist. We recently reported that pre-infusion of the GABAergic antagonist bicuculline monosodium (BIC) into the AC blocks the learning impairing effects of systemically administered midazolam in IA behavior. In general, BZDs impair memory, but not after avertively motivated learning takes place, whereas GABAergic drugs affect retention when administered post-training. Consequently, it is not clear whether these drugs mediate pre-or post-training memory processes. Because BZD-induced behavioral effects are mediated by the GABAA receptor complex, it is likely that BZD-induced memory deficits are also due to antagonizing influences on memory processes. The present experiment examined this implication. Before training in a multiple trial IA task, male Sprague-Dawley rats (250-300g) were injected (ip) with either midazolam (MDZ, 2.0 mg/kg) or vehicle (1.0 μl) was infused bilaterally into the AC. On a 48 hr retention test the performance of the MDZ treated animals was significantly poorer than that of controls. The retention of MDZ-treated animals given intra-AC injections of the lowest dose of BZD (2.0 μmol) was comparable to that of controls, whereas higher doses showed the behavioral impairment. The present results are consistent with other findings indicating that the amygdaloid complex mediates the amnestic effects of BZD on anterograde learning. Furthermore, these data suggest that BZDs impair memory by disrupting post-training processes underlying memory consolidation. Supported by FHS M112526, NIMH & NIDA (ULM).

GABAERGIC-CHOLINERGIC INTERACTION IN THE SEPTAL REGION MEDIATES BOTH ANXIETY AND SPATIAL WORKING MEMORY IN MICE. M.P. Gale*, L. Menzies, L. M. Bellot*, L. Magyar, J. Comportementales Cognitives, CNRS URA 139, Université de Bordeaux 1, 33405 Talence France.

Convergent data suggest that the septal region may constitute an interface between anxiety and working memory (SWM). Using a novel 4-arm radial maze, we have examined the role of cholinergic and gabaergic septal neurons interaction in these two processes. The anxiety level was evaluated by comparison between exploratory activities measured in an elevated plus-maze and in a four hole-board. The SWM was assessed using a sequential alternation procedure achieved in a T-maze. Results indicated that intraseptal infusion of scopolamine (2.5μg/1.2μl) combined with (i.p. injection of diazepam (0.5 mg/kg) in same animals produced an "anxiety-like" effect. Furthermore, SWM was differentially affected by this treatment. Indeed, performance was unaffected when a 30 sec interval was used whereas for a 5 sec intertrial interval alternation scores were reduced below the chance level. In addition, the application of either scopolamine or diazepam alone did not induce any changes in locomotion. Therefore, our data suggest that a cholinergic/gabaergic septal mechanism mediates both the anxiety phenomenon and SWM. This interpretation is consistent with hypothesis that the cholinergic septo-hippocampal pathway promotes anxiety (GRAY, J., Oxford University Press, Oxford, 1982.) Thus, decrease in SWM abilities observed after modulating activity of these structures seems to be the consequence of release from an anxious response, which will increase vulnerability to proactive interference rather than an accelerating forgetting.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Previously reported by us (Hippocampus 1(10) mg/kg sc of MK-801 produced chronic memory impairment in adult male mice (Brown-Watters et al., 1999). Here, we confirm in Harlan ICAN rats that MK-801(10 mg/kg sc) chronically impairs acquisition performance on a spatial learning task, and, in addition, produces neuronal necrosis confined to the posterior hippocampus. In Exp. I, rats were randomly assigned to one of two groups: saline or saline + MK-801 (10 mg/kg sc) in a one-trial training session. The criterion was to reach a distance of 10 cm from the platform within 120 s. The results indicate that rats in the saline group were able to learn the task, as reflected by their ability to find the platform in the subsequent sessions. In contrast, rats in the MK-801 group showed no improvement in their ability to locate the platform over the course of the training sessions. These findings suggest that MK-801 may have a profound effect on the hippocampus, potentially impairing learning and memory processes in these animals.

495.20 EVIDENCE SHOWING THAT HIPPOCAMPAL PROTEIN KINASE C ACTIVITY APPEARS TO BE MORE LINKED TO LEARNING ABILITY THAN TO LEVEL OF TRAINING. J. Nogues, J. Micheur* and R. Jaufret Lab. Neurosciences Comportementales et Cognitives, URA CNRS 339, Univ. Bordeaux I, Av. des facultés, 33405 Talence Cedex, France.

We have previously shown a decrease in hippocampal cytosolic PKC activity following partial learning of a reference memory task in a radial maze (Nogues et al., 1999). In the present study, we examined whether the expression of PKC activity remained unchanged, but was negatively correlated with performance level. Since this result did not fit with the translocation hypothesis, this study was designed to examine the effects of an increased level of training on PKC activity in the hippocampus. Mice were trained in a spatial temporal discrimination task performed in an 8- arm radial maze for 2, 5, or 12 sessions. Then, PKC activity was measured in membrane and cytosolic compartments of the hippocampus. Behavioral results showed a slower rate of acquisition as compared to our previous studies. Biochemical results did show any significant decrease in cytosolic PKC activity for any group. Nevertheless, membrane bound PKC activity correlated significantly with the number of reference memory errors at the third day of training (r=0.74; p<0.001). Firstly, these data show that the decrease in cytosolic PKC activity is not cumulative across sessions. Secondly, they confirm the correlation between membrane-bound activity and performance accuracy. Further statistical analysis on all animals tested in our previous experiments (n=77), shows that the amplitude of the PKC cytosolic decrease is correlated with performance accuracy on the second day of training (r=0.24; p=0.02; one-tail).

Tackled together, these observations support the idea that the membrane-bound PKC activity derives from a pre-existing pool that plays a significant role in the rate of acquisition. Moreover, they suggest that learning abilities at the early stages of training are linked to a decrease in cytosolic PKC activity.

495.21 WORKING AND REFERENCE MEMORY IN CBX RECOMBINANT INBRED MICE. D. E. Peeler*, Dept. of Neurosurgery, University of Mississippi Medical School, Jackson, MS 39216.

Two types of memory which have been described - reference and working - appear to function essentially independently. This implies not only separate CNS mechanisms, but also possibly different genetic influences. This was investigated in the CBX set of recombinant inbred (RI) strains. Association between genotype and performance in an 8-arm radial maze was assessed. A total of 100 male mice (N=100) from each of the 9 RI strains of the CBX set were familiarized with the maze for two consecutive days, 5 min per day, with all arms baited. For sessions 3-12, four arms per strain were baited. A dim lamp was placed on one corner of the maze, specific areas providing different shapes and textures as distant orientation cues. Each arm of the maze was dimly illuminated at its distal end. The mice were placed directly in the center of the maze. The distance of the maze, the type of bait used, and the location of the bait varied between sessions. Analyses utilized ANOVA and multiple range tests. Strains showed similar rates and levels of acquisition. There are significant differences among the strains for working memory (number of arm entries; number of baited arms entered before re-entry) and reference memory (number of non-baited arm entries), but the strain distribution patterns are different. Orientation change at the beginning of session 8 disrupted performance, presumably reflecting the contradiction of reference memory. The strain distribution pattern for reference memory indicated a possible major single gene effect. For some measures of working memory, the progenitor strains were statistically similar but the strain distribution pattern was different, implying some genetic interactions different from reference memory with no major single gene effect.

495.22 MOUSE STRAIN DIFFERENCES IN MORRIS WATER MAZE PLACE TASK PERFORMANCE. T. J. Patile*, Dept. of Psychology, New Mexico Tech., Socorro, NM, USA 87801.

AJ: DBA; and C57 mice were tested for acquisition and retention of place task in the Morris water maze. All animals were trained for 14 days (4 trials per day; 60 seconds maximum per trial), with the platform being moved left or right from the NE to the SE quadrant on day 8. AJ mice were unable to reliably find the platform, while the time taken by DBA animals in escaping the pool declined gradually during the 14 days of training, reaching the lighted corner significantly faster than either the DBA or C57 mice, while the DBA animals were significantly faster than the AJ mice in escaping the pool. Swim paths used by the 3 strains indicated that C57 mice selected the most efficient solution strategy for the task, while DBA animals did not acquire the same elegance in performance. AJ mice were never able to devise an appropriate strategy for solving the task. Neuroanatomical differences between the 3 strains are also described, and the implications discussed.

Behavioral, histochemical, neurochemical and electrophysiological evidence supports the hypothesis that the Naples High (NHE) and Low-Excitability (NEL) rat lines may be genetic model to study hippocampal functions (Cerezo et al., Neuropsychobiology 17:205-203, 1993). To further challenge this proposal, adult male rats of the NLE, NHE and random-bred controls (NRC) were tested in a Morris water maze. A video camera system was used to monitor and record rat behavior. In the place-learning task, one block of four trials per day was given for 5 days. Every day a rat had to find the hidden platform starting from all four locations to receive a reward. For the spatial discrimination task, the escape latency and the swim distance were measured. On day 6, the platform was removed from the pool and a 30-s trial was given. The time spent in each of the four quadrants was measured. The results indicate that the NLE/NHE rats, but not NRB-rats, decreased the time and the distance travelled to find the platform. During the acquisition phase, both NLE/NHE spent more time in the hidden platform, but the NLE/NHE rats were different from NRB-rats. The distance travelled was higher in the NHE than in the NLE/NRB rats. In the platform removal test, NLE/NHE rats spent less time in the hidden platform, but there was no difference on session 5, but were different from NRB-rats. These results indicate that both NLE/NHE rats are coherent with a non linear model of the inverted-U type with both extremes leading to impaired spatial processing. (Supported by CNR 92.0192.CT04 and 93.004682.CT04 grants).

The effects of exposure to spatial novelty on the expression of nitric oxide synthase were mapped in the brain of the Naples High (NHE) and Low-Excitability (NEL) rat lines by NADPH-diaphorase (NADP-D) histochemistry. Adult male rats of the NLE, NHE and control rats (NRC) were tested for 10 min in a 1-lit-maze and sacrificed at different time intervals thereafter (0, 2, 4, 10, 15, 30 min). The NADP-D activity remaining unchanged, but was negatively correlated with performance level. Since this result did not fit with the translocation hypothesis, this study was designed to examine the effects of an increased level of training on PKC activity in the hippocampus. Mice were trained in a spatial temporal discrimination task performed in an 8-arm radial maze for 2, 5, or 12 sessions. Then, PKC activity was measured in membrane and cytosolic compartments of the hippocampus. Behavioral results showed a slower rate of acquisition as compared to our previous studies. Biochemical results did show any significant decrease in cytosolic PKC activity for any group. Nevertheless, membrane bound PKC activity correlated significantly with the number of reference memory errors at the third day of training (r=0.74; p<0.001). Firstly, these data show that the decrease in cytosolic PKC activity is not cumulative across sessions. Secondly, they confirm the correlation between membrane-bound activity and performance accuracy. Further statistical analysis on all animals tested in our previous experiments (n=77), shows that the amplitude of the PKC cytosolic decrease is correlated with performance accuracy on the second day of training (r=0.24; p=0.02; one-tail).

Tackled together, these observations support the idea that the membrane-bound PKC activity derives from a pre-existing pool that plays a significant role in the rate of acquisition. Moreover, they suggest that learning abilities at the early stages of training are linked to a decrease in cytosolic PKC activity.

The widespread induction of NADP-D suggests that exposure to novelty activates overlapping neural networks across different organizational levels of the CNS, whereas the impaired expression in the NHE-rats provides support for studying the neural substrates of spatial and non spatial information processing. (Supported by CNR 92.0192.CT04, and MURST 40% grants).
496.1 GABAERGIC RETICULAR THALAMIC NEURONS PROJECT TO THE CONTRALATERAL MEDIODORSAL NUCLEUS OF THE CAT. L. Grütz*, M. Mariotti and M. Mancia. Institute of Human Physiology II, University of Milan, I-20133 Milan, Italy.

In order to investigate the topographical and chemical organization of the pathway involved in the regulation of the EEG synchronization at a thalamic level homerid neuronal peroxidase conjugated with wheat germ agglutinin (WGA--HRP) was injected into the intermediate part of the Mediodorsal nucleus (MD) of the thalamus. This approach was also combined with glutamic acid decarboxylase (GAD)-immunohistochemistry to provide additional criteria for the identification of retrograde labelled neurons. In cats under pentobarbital anesthesia WGA--HRP was stereotaxically injected into the intermediate part of MD. After a survival time of 24--48 hrs, the animals were perfused with the ascending acetic acid with mixed aldehydes, 25 µm frozen sections were horizontally cut. Alternate sections were reacted for WGA--HRP visualization using tetramethylbenzidine as a chromogen with cobalt intensification, and the peroxidase anti-peroxidase technique on immunohistochemistry for GAD. In the same sections GAD--immunohistochemistry, combined with the retrograde transport of WGA--HRP, revealed that the intermediate part of MD nucleus receives an important input from GABA synthesizing neurons located in the ipsi and contralateral rostral--pole of the RE nucleus. Although the distribution of GAD-immunoreactive retrogradely labelled neurons was similar both in the ipsi and contralateral areas the number was much smaller in the latter. The findings suggest that through both GABAergic ipsilateral and contralateral projections the RE contribute to a GABA mediated inhibition within the intermediate MD neurons population and to a thalamo--cortical synchronization.

We have examined brainstem neuronal activity in the primitive monotreme mammal, the echidna (Tachyglossus aculeatus) across the sleep cycle. While no periods of REM sleep were seen, unit activity patterns differed from those seen in placental mammals during nonREM sleep.

Twenty-two brainstem units were recorded from the midbrain and subcoeruleus region. Unit discharge rates were significantly lower in sleep than in quiet waking (F=3.8, p<0.05). However, both midbrain and pontine regions had substantially increased discharge variability (burst firing) throughout sleep (p<0.001).

Therefore, neuronal activity during sleep in the echidna does not resemble that seen in nonREM sleep in placental mammals. While the discharge rate of the neuronal population decreases, as in placental nonREM sleep, discharge variability increases, as in REM sleep. We hypothesize that both REM and nonREM evolved from this primitive "mixed" sleep state.

Supported by the Dept. of Veterans Affairs, USPHS NS14610 and the Australian Research Council.

Noradrenergic neurons of the nucleus locus coeruleus fire tonically throughout waking, decrease discharge in non-REM sleep, and cease discharging in REM sleep. Only serotonergic neurons of the raphe system and histaminergic neurons of the posterior hypothalamus display similar firing patterns. The locus coeruleus is densely innervated by GABAergic neurons. In vitro studies have shown that application of GABA onto noradrenergic neurons potently inhibits their activity. Based on this evidence, we hypothesized that GABA mediates the inhibition of noradrenergic locus coeruleus neurons during REM sleep.

GABA release in the locus coeruleus was measured as a function of sleep/wake state using microdialysis and HPLC techniques. Histological analysis confirmed the placement of two dialysis probes in the locus coeruleus and per-locus coeruleus areas. GABA release in the more caudal site was increased during both non-REM and REM sleep as compared with wake. Data from the more rostral locus coeruleus including the per locus-coeruleus area indicated a selective increase in GABA release during REM sleep as compared to wake and non-REM sleep. We have previously reported a similar selective increase of GABA release in the dorsal raphe nucleus during REM sleep (Soc. Neurosci. Abstr., 15:1815, 1993). These data suggest that GABA mediates the inhibition of noradrenergic locus coeruleus neurons during non-REM and REM sleep.

496.4 Simultaneous application of serotonin or carbachol facilitates NMDA-dependent bursts of firing in noradrenergic neurons in guinea-pig brain slices. P. Fort, A. Khateb, B.E. Jones and M. Mühlenbecket. Dept. of Physiology, CMU, 1211 Geneva 4, Switzerland and "Montreal Neurological Inst., McGill University, Canada H3A 2B4."

The nucleus basalus provides important cholinergic input towards the cortical areas. This study was designed to test whether the application of NMDA affects the discharge of the noradrenergic neurons. Our goal in this study was thus to identify the possible interactions between these substances. When NMDA was applied alone, it depolarized these cells and led them to fire tonically. However, when serotonin was added concomitantly, the neurons started to slightly hyperpolarize and then discharged rhythmically in bursts (21 out of 26 experiments). This effect persisted in TTX (n=4). Interestingly the duration of the TTS was greatly increased in presence of NMDA+ serotonin, as compared to the situation of NMDA alone (tested at different levels of membrane hyperpolarization). Almost a similar results were obtained for the simultaneous applications of NMDA and carbachol (9 out 19 experiments). These interactions might be the means by which cholinergic neurons could discharge rhythmically in bursts in vivo. (Swiss NSF, Canadian MRC, Fondation Fyssen and Lyonnais des Banques).

The nucleus basalis contains both cholinergic and non-cholinergic magnocellular neurones which respectively display distinct electrophysiological properties when recorded in guinea pig brain slices. Non-cholinergic neurones demonstrate high frequency (30-60 Hz) subthrehold oscillations and have the ability to discharge in clusters of action potentials firing at 2-6 Hz. In order to assess the potential modulation of their activity by GABA, the effect of muscimol, a selective GABAa agonist, was tested on the non-cholinergic cells. Out of 31 cells tested, 23 were depolarized by high concentrations of muscimol (10-4 M), yet concomitantly inhibited due to a marked decrease of their membrane resistance. With smaller concentrations of muscimol (10-6 M), tested on 8 cells, 5 were still depolarized, but their ability to discharge in clusters was greatly facilitated. This effect persisted throughout the duration of the agonist's application and was perfectly reversible. Furthermore, the effect was antagonized by bicuculline, a GABAa blocker. These results suggest that locally released GABA could serve to facilitate the cluster firing pattern of non-cholinergic neurones and thus the rhythmic activity of these cells could participate in the generation and/or maintenance of theta rhythms in the forebrain (Swiss NSF, Canadian MRC, Fondation Fyssen and Lyonnais des Banques).

496.6 HYPERPOLARIZING POTENTIALS IN MASSERETE MOTOEURONES ARE GLUCYLATED BY AN AUDITORY STARTLE REFLEX IN AUSTRALIAN RATS. CARBACHOL INJECTIONS IN THE NUCLEUS PONTIS DORSALIS. K.A. Kuhlmann, L. Lopez, J. Rodriguez*, R.H. Liu, E. Morales, M.I. Clark. Dept. of Physiology, Dept. of Anatomy and Cell Biology, and the Brain Research Institute. UCL School of Medicine, Los Angeles, CA 90024.

One striking phenomenon of active sleep is the occurrence of ponto-geniculo-occipital (PGO) waves. Merton and Bowker (Acta Neuro. Exp. 15:521-540, 1975) proposed that these waves are neuronal signatures of a startle response produced by internally generated acoustic stimuli. We have shown that virtually all motorneurones of the masseter muscle are accompanied by large amplitude PGP's recorded in lambar and trigeminal motorneurones (Polouritos et al., Somatosens. Motor Res., 5:109, 1991). We therefore decided to investigate whether startle responses induced by auditory stimulation are also accompanied by the activation of motorneurones. For this purpose we microiontophoretically injected carbamylcholine (200mM) into the nucleus pontis oralis of five o-chloroacetanilide anesthetized cats (160mg/kg i.v.) because carbamylcholine-induced muscle atonia is comparable to that which occurs during active sleep (Morales et al., J. Neurophysiol., 51:118, 1984). These results show that the response of the motoneurones to the injection of carbamylcholine is similar to that which occurs during active sleep (Morales et al., J. Neurophysiol., 51:118, 1984). Responses were quantified by measuring the duration of the neurons' discharge (duration+1.5ms) were recorded intracellularly (KC-liluted glass electrodes) from stereotically identified masseter motoneurones both before and after the injection of carbamylcholine. In 19 of the 20 masseter motoneurones recorded before the injection of carbamylcholine, the auditory stimulus evoked a discharge. In response to the injection of carbamylcholine, the auditory stimulus elicited a discharges in 9 neurones. The amplitude of the stimulus-induced hyperpolarizing potentials decreased and increased, respectively, suggesting that they are inhibitory post synaptic potentials. These findings indicate that the carbamylcholine-activated motor inhibitory system is responsive to a startle stimulus in the o-chloroacetanilide anesthetized rat and that the primary afferents with the production of a hyperpolarizing potential in masseter motoneurones. The physiological significance of this hyperpolarizing potential during active sleep may be in aiding in insuring the maintenance of muscle atonia that otherwise might be disturbed by auditory sensory stimuli. CIRCADIAN MODULATION OF THE RAT ACOUSTIC STARTLE REFLEX. P. W. Frankland and M.B. Ralph, Dept. of Psychology and Zoology, University of Toronto, Toronto, Canada MS 1A1.

The acoustic startle reflex (ASR) in rats exhibits robust circadian modulation, with ASR amplitudes greater in subjective day. Because the ASR is mediated by a circuit with few synapses, it provides a simple system to study the circadian modulation of behavior. We sought to identify the location of modulation by recording amplitudes of startle reactions evoked either acoustically or electrically via electrodes implanted in the primary startle circuit. Responses were measured at four hour intervals over 48 hours in constant dark conditions. Startle amplitudes were greater in subjective day for acoustically and electrically evoked responses from both the ventral lateral geniculate and medial longitudinal fasciculus. These results show that circadian modulation of startle occurs at some point in the circuit after the last brainstem visuex in the classic pontine reticular formation, at the level of spinal interneurons, motorneurons or at the neuromuscular junction.

In a second experiment, animals with cochlear lesions of the hypothalamic suprachiasmatic nucleus (SCN) exhibited no circadian variation in ASR amplitudes. Mean startle amplitudes were similar to pre lesion basal (subjective day) levels. These results suggest that circadian rhythm of ASR is driven by the SCN, and that the SCN may enhance startle amplitudes during subjective night.

INDUCTION OF FOS PROTEIN IN THE RAT CIRCADIAN SYSTEM BY NON-PHOTIC STIMULI. L.掌心, K. Edler, B. Robinson and B. Woodside, Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Canada.

Immunohistochemistry of Fos proteins in the hypothalamic suprachiasmatic nucleus (SCN) and intergeniculate leaflet (IGL) of the lateral geniculate complex is often used as a tool in studies on the neural mechanisms and circadian processes involved in circadian rhythms of rodents. Photic stimuli that induce phase shifts of circadian rhythms in mice, rats and hamsters also induce the expression of Fos in the SCN and IGL. Photic stimuli that fail to induce phase shifts appear to be without effect on Fos expression in these structures. The effect of non-photic stimuli on Fos expression in the SCN and IGL is less well defined. Here we report that in rats, cortical injury (induced under pentobarbital anesthesia, 50 mg/kg, by lowering a 28 gauge needle 3 mm below the surface of the skull) or immobilization stress (60 min) induce the expression of Fos in the SCN and IGL. Stimuli such as i.p. saline (1 ml/kg) and cage transfer induce Fos expression in the IGL. Expression of Fos in the SCN and/or IGL in response to each of these stimuli is independent of the time of treatment, and is associated with expression in other brain regions, including many cortical, subcortical and hypothalamic areas such as the paraventricular nucleus, anterior hypothalamic nucleus and preoptic nucleus. SCN cells which express Fos in response to cortical injury or immobilization are located in subregions of the nucleus that also express Fos in response to photic stimuli. Results indicate that neural components of the rat circadian system respond to diverse types of non-photic stimuli and that Fos expression in SCN and IGL should not be regarded as light-specific.

497.5
CIRCADIAN RHYTHMS IN A GENETIC MODEL OF OBESEITY. B.E. Matthewson, H. L. Luman, and B.G. Nadkarni, Department of Psychology, Simon Fraser University, Burnaby, BC V5A 1S6, Canada.

The Zucker (fa/fa) rat is a widely used model of genetic obesity characterized by a variety of metabolic and endocrine abnormalities, and by low amplitudes of circadian phase advances. The nature of the circadian disturbance, and its possible role in obesity, are unclear. Body temperature rhythms (Tb) were recorded by telemetry in 7 obese and 5 lean Zucker rats under a 12:12 light-dark (LD) cycle and in constant dark (DD) and light (LL). Obese rats exhibited a phase advanced Tr in LD, the acrophase of the best fitting cosine function occurring 6.7 h earlier in comparison with lean rats (p <0.05). The amplitude of the cosine function did not differ between groups. The phase advance was retained in DD, indicating that it is not due to a resetting effect of light (14, 15). All rats exhibited free-running Trs with periods > 24 h (no group difference). This suggests that phase advances in LD are independent of pacemaker period and may reflect altered phase responses to light or changes in the sensitivity to photosensitive processes or coupling to slave oscillators. Obese rats also exhibited an advanced feeding rhythm, with more intake during the light period. The role of advanced rhythms in the development of obesity was examined by measuring body weight and food intake for 60 days in 2 additional fa/fa rats (6 weeks old); one group received ad lib food, the other only during the dark period, i.e., phase advanced feeding was prevented. After six days, the rats on ad lib food gained weight, but the nocturnal-fed rats exhibited a lower average daily weight gain (p <0.05), suggesting that circadian abnormalities may contribute to obesity.

PROGRESSIVE CIRCADIAN RHYTHM DECLINE IN ALZHEIMER'S DISEASE. William Fishtal, Veronique Fries and Barry Straus, Dept of Psychology, The City College & Graduate School, CUNY, New York 10011 and NYU Medical Center, Alzheimer's Disease Center, New York 10016.

This research is concerned with developing an early behavioral marker for AD. We have accumulated circadian rest-activity data (12 days per subject) from six healthy elderly subjects and fifteen very reliably diagnosed, community residing, AD patients (mild to severe), employing a miniature ambulatory clock and accelerometer.

The present report describes the detection and decline of the generator(s) of the circadian process by non-linear curve fitting, an iterative process that reduces noise and detects peaks that otherwise might be missed by manual determination of circadian rhythm data. Precise measures of amplitude, area, center and width of peaks, and overall area of a single circadian cycle are determined.

Typically in normal elderly (Gesell Development Score (GDS) > 1 Minis-Mental State (MMS) = 30), four activity peaks are detected accounting for 95% of the variance of the 24 hour circadian rhythm. Qualitatively, the circadian rhythm looks like a square wave with small perturbations throughout the 24 hour cycle. At night, subjects’ sleep periods are relatively free of waking movement activity.

In Alzheimer's Disease, advancing from mild to severe, (GDS = 4 to 6; MMS = 24 to 3) five to eight activity peaks are necessary to account for 92% to 94% of the variance of the 24 hour circadian rhythm. Most notable as dementia advances: (1) progressive increase in the number of peaks, (2) phase shift of peaks to earlier clock time, (3) increased variability, and (4) increased variance between peaks. The total amount of activity, though, remained relatively constant throughout the day.

Although the research is in an early stage, the progressive declines in the circadian data indicate that with decline in cognitive and functional competence, a concurrent and profound degradation of the circadian time keeping system occurs in Alzheimer's disease.
498.1
A circadian pacemaker located in the eyepath of Aplysia is responsible for generating a rhythm that synchronizes the circadian transcriptome. In the mouse, the czechetin is a potential circadian oscillator. In Aplysia, the czechetin levels oscillate with a period of 24 h, and they are regulated by light and circadian rhythms. In this study, we investigated the effects of phase-shifting treatments on the regulation of putative oscillator proteins (POPs) in Aplysia. The rhythmic expression of these proteins is modulated by light and circadian rhythms. To test this hypothesis, we used microarray techniques to study the expression of these proteins in Aplysia. The results showed that the expression of these proteins is regulated by light and circadian rhythms. These findings suggest that the czechetin is a potential circadian oscillator in Aplysia.

498.2
ESTROGEN RECEPTORS ARE NOT PRESENT IN THE CIRCADIAN SYSTEM OF THE OCTODONT DEGIUS, A DIURNAL RODENT. N. Goes, N. S. Douglas and T. M. Lee, Dept. of Psychology, University of Michigan, Ann Arbor, MI 48104, and Michigan State University, East Lansing, MI 48824.
Steroid hormones, in particular estrogen, influence circadian rhythms in various rodents, but the site of action for estrogen's effects is not yet known. Octodont degius are hibernating mammals that exhibit circadian temperature activity rhythms (Labyak, 1993). In the degu, elevated estrogen levels during estrus lead to phase advances in the wheel-running rhythm and increased levels of activity (Labyak and Lee, in press). Because lesions of the intracentral leaflet (IGL) of the thalamus in hamsters, a major afferent projection to the SCN, results in changes in the phase angle of activity onset, the IGL has been suggested as a candidate for estrogen's site of action. Estrogen receptors have been localized in the lateral geniculate nucleus (LGN), the primary circadian clock. The goal of this study was to identify the distribution of estrogen receptors throughout the degu brain. Three adult degu brains (one male, two female) were processed for immunohistochemical identification of estrogen receptors using the H222 antibody. ER-immunoreactive (IR) cells were found in the medial preoptic area (mPOA), bed nucleus of the stria terminalis (SNST), suprachiasmatic nucleus (SN), arcuate nucleus, paraventricular nucleus (PVN), infundibulum, ventral posterior medial nucleus (VMP), and amygdala. No ER-IR cells were found in the SCN or IGL. Thus, it appears that estrogen cannot directly influence the circadian system via the SCN or IGL in the degu.

498.3
EXPRESSION OF GROWTH HORMONE-RELEASING HORMONE (GHRH) AND SOMATOSTATIN (SRIF) GENES DURING REM SLEEP DEPRESSION IN THE RAT. T. Porraki-Heikonen, J. Toppila, M. Aisakkainen, F. W. Turek, D. Steenborg, University of Helsinki, Helsinki, Finland and Northwestern University, Evanston, IL 60208.
GHRH increases both SWS and REM sleep, while SRIF decreases sleep. Antiserum to GHRH decreases sleep and inhibits sleep rebound after deprivation. We hypothesized that REM sleep deprivation affects the expression of GHRH and SRIF genes. Male rats were deprived of REM sleep on small platforms for 24 or 72 h, and one group was allowed a rebound sleep of 24 h after 72 h of deprivation. Large platforms and animals taken directly from their cages served as controls to sleep deprived groups. In situ hybridization was performed on the paraventricular and arcuate nuclei using specific oligonucleotide probes for GHRH and SRIF. Numbers of cells expressing GHRH and SRIF were counted, as well as the area of silver grains over the labeled cells; serum GH was measured. Number of cells expressing GHRH in the arcuate nucleus was lower after 24 h of REM sleep deprivation than in control animals, and sleep was low during 72 h of deprivation. Numbers of cells expressing SRIF were elevated on small platforms after 24 h of deprivation but had returned to home control level at 72 h. Serum GH levels were decreased during the deprivation. We conclude that both elevated GHRH gene expression in the beginning of the deprivation and decreased GHRH gene expression through the deprivation may contribute to the low serum GH levels during the deprivation.

498.4
DIURNAL RHYTHMS OF MONOAFLINES AND THEIR METABOLITES IN CORTEX, HIPPOCAMPUS AND HYPOTHALAMUS OF MALE WISTAR RATS. D. Steenborg, M. Aisakkainen, J. Toppila and T. Porraki-Heikonen, University of Helsinki, Helsinki, Finland.
Normal values for the diurnal variation of monoamine and metabolite concentrations in brain tissue of male Wistar rats were needed for studies on effects of sleep deprivation. Rats aged 3 months and adapted to LD 12:12 (lights on 0600) were decapitated (rats with 2 h intervals for 24 h) and brain regions dissected, frozen, and subsequently analysed by HPLC-ED. Analysis of variance and cosinor analysis were used. 5-HT levels tended to decrease after onset of dark phase, while 5-HIAA decreased significantly after onset of light phase. SRIF levels were elevated after onset of dark phase. These changes suggest that the 5HT system is activated during the dark phase and inhibited during the light phase. These results provide new insights into the regulation of monoamine metabolism in the rat brain and may have implications for the treatment of depression.

498.5
CENTRAL THYROTOPIN-RELEASING HORMONE ADMINISTRATION PRODUCES PHASE SHIFTS IN THE CIRCADIAN RHYTHM OF HAMSTER WHEEL RUNNING BEHAVIOR. Keith A. Cary*, Patricia A. Soller, Neda Letew, Andrew Winokur, and Gary E. Pickard, Department of Psychiatry, School of Medicine, University of Pennsylvania, Philadelphia, PA 19104.
Several lines of evidence suggest that thyrotropin-releasing hormone (TRH) plays a primary role in the regulation of gonadal hormones. Analytic effects of this tripeptide have been established by numerous studies, and endogenous levels of TRH vary in response to increased and decreased CNS activity states. Modulation of arousal state would require integration and coordination of autonomic, neuroendocrine, and circadian functions. TRH and its receptors have been localized in the retina, suprachiasmatic nucleus (SCN), and pineal gland; monitoring the activity associated with circadian rhythm. This study evaluates the effects of TRH microinjection into the suprachiasmatic nucleus (SCN) of the hamster on 24 h wheel running behavior. The precision displayed by the hamster in wheel-running activity prompted our use of this species in these studies. TRH or saline was administered both by intracerebroventricular (icv) injection and site via chronic indwelling cannulae stereotactically placed in the SCN. Drug administration was performed at circadian times (CT) 6 and 18, times corresponding to subjective day and night, respectively. At CT 6, both phase advances and delays in wheel running activity were observed in hamsters receiving 10ngM and 100ngM TRH icv, whereas phase advances were observed following the same doses delivered directly in the SCN. The magnitude of the phase advance was dose dependent, with 10ng/M TRH administration being 35 and 50 minutes advance in wheel running activity, respectively. No changes in wheel running activity was observed following icv TRH administration at CT 18. These data support the hypothesis that TRH influences circadian rhythm.

Metformin, a biguanide hypoglycemic agent, was widely used for treatment of obese type 2 diabetic patients particularly because of its weight reducing effect. The hypothalamic neuropeptide Y (NPY) content was measured by radiomunassay and preproNPY mRNA expression was studied by quantitative in situ hybridization procedure in metformin treated (300 mg/kg orally for 12 days), in pair-fed and in ad libitum fed obes Zucker rats in order to elucidate possible mechanisms involved in the anorectic and body weight reducing effect of metformin treatment in genetically obese Zucker rats. The concentration of NPY in the hypothalamic paraventricular nucleus (PVN) was significantly higher in the metformin-treated and pair-fed rats than compared to the control animals. The expression of preproNPY mRNA in the arcuate nucleus (ARC) was similar in all three treatment groups. Both chronic metformin treatment and pair-feeding markedly lowered hypoinsulaemia in these animals. It is concluded that the treatment with metformin and pair-feeding, which result in comparable reductions in food intake, body weight gain and hypoinsulaemia, similarly increase NPY expression in PVN while not affecting preproNPY mRNA expression in the ARC. The increase in hypothalamic NPY content may be secondary to reduction of hypoinsulaemia during metformin treatment and pair-feeding. Thus, the therapeutic effect of chronic metformin treatment cannot be explained by changes in content or expression of hypothalamic NPY.

499.3 NALOXONE DECREASES BOTH CARBOHYDRATE AND FAT DIGESTION INDUCED BY NEUROPEPTIDE Y (NPY) A.S. Levine*, M.K. Grace, and C.J. Billington. VA Medical Center and University of Minnesota, Minneapolis, MN 55417

Central administration of NPY markedly enhances food intake in rats and appears to selectively stimulate intake of high carbohydrate diets. Naloxone has been reported to decrease intake of high fat (HF) diets much more effectively than high carbohydrate (HC) diets. In the current study we examined whether naloxone would block NPY-induced intake of HC and HF diets, given individually or concurrently. In our first study we presented rats with a choice of a high carbohydrate (HC) diet and a high fat (HF) diet and stimulated feeding by intracerebroventricular (ivc) injection of NPY. In this group of carbohydrate preferring rats (n=16), NPY induced HC intake (4.4 g/5 hr), but failed to increase HF intake (0.3 g/5 hr). Naloxone potently decreased HC intake of the HC diet at doses ranging from 0.1-3 mg/kg (1.7 g; 3 mg/kg; 2.5 g; 3 mg/kg; 1.7 g; 3 mg/kg; 1.5 g). In the second study the same rats were injected ivc with NPY and presented with either the HC diet or the HF diet (no choice). NPY stimulated both HC (3.9 g/5 hr) and HF (2.9 g/5 hr) intake, and naloxone decreased intake of both the HC (0.3 mg/kg; 1.9 g; 0.3 mg/kg; 1.2 g) and HF (0.3 mg/kg; 1 g; 0.3 mg/kg; 0.4 g) diets. Thus, we found that naloxone potently decreased NPY stimulated intake of HC and HF diets. This is in contrast to the published observation that naloxone has little or no effect on HC intake in food deprived rats offered a choice between HC and HF diets. Our data lend support to the idea that an NPY-opioidergic feeding system exists in the central nervous system.

499.4 DISOCIATIVE EFFECTS OF NEUROPEPTIDE Y ON FEEDING AND BODY TEMPERATURE AFTER INJECTION INTO DIFFERENT HYPOTHALAMIC SITES. P.J. Currie* and D.V. Coscia. Section of Biopsychology, Clarke Institute of Psychiatry, 250 College St., Toronto, ON, M5T 1R8 Canada

Recent research has shown the perifornical hypothalamus to be a particularly sensitive brain site in eliciting feeding after local injection of neuropeptide Y (NPY). Since other work has demonstrated that NPY injected into the paraventricular nucleus of the hypothalamus (PVN) exhibits both feeding-stimulatory and metabolic effects, the current study examined the simultaneous impact of this peptide on food intake and body temperature (Tb) of unrestrained rats following injection into the PVN, and contrasted it with similar measures after injection into the NPY-ergic lateral hypothalamus (LH). NPY (0-235 pmol) was infused in a volume of 0.4 µl using a 28-ga. microinjection assembly. Food intake and Tb were measured every 30 min for 3 h postinjection. Both PVN and LH injections of NPY increased food intake dose-dependently in the first 30 min test interval, with the PVN showing a stronger response than the PNv. In PVN treated rats, the increases eating was associated with a significant decline in T, which was also evident 30 min after NPY injection and lasted 2 h. A mean maximal T, decline of 0.97±0.20°C occurred within 90 min following PVN treatment of 235 pmol NPY. In contrast, NPY had no apparent effect on Tb when injected into the PFH. These findings support previous suggestions that while PVN NPY acts to stimulate a robust and relatively specific ingestive response, PVN NPY may participate in the integrative mechanisms responsible for the simultaneous regulation of feeding, heat conservation, and energy metabolism. (Supported by NSERC and INI of Canada).

Anorexia-cachexia-bearing (TB) rats exhibit a refractory feeding response to neuropeptide Y (NPY) and decreased hypothalamic NPY concentrations. Therefore, we hypothesized that constant hypothalamic infusion of NPY would correct the anorexia exhibited by these TB rats. Following anesthesia (100 mg/kg, ip, ketamine, 24 ga. infusion cannulae were implanted into the periifornical hypothalamic area of 32 male Fischer 344 rats, 18 days after sc. MCA stroke induced inoculation. These cannulae were connected to sc. Alzet minipumps (Model 2002) that infused NPY (125 mg/h) or artificial cerebrospinal fluid at 5 µl/hr). All food intake by both NPY-infused groups was increased immediately following surgery, 3 days later food intake in these groups was not different from that of the CSF-infused rats. Food intake by the TB rats continued to decline, with significant anorexia being noted 21 days after tumor inoculation. These results suggest a rapid desensitization of hypothalamic NPY receptors in both TB and control rats in the continuous presence of exogenous NPY.
499.7

Neuropeptide Y (NPY) is distributed into various regions of the hypothalamus. Inhibits robust eating responses. A recent magneto-mapping study employing nanoliter volume injections of NPY identified the medial perifornical area of the hypothalamus (PFR) at the level of the posterior hypothalamic nucleus and other areas as the most sensitive site for NPY's eating stimulatory effect (Stanley et al., Brain Res. 1993, 664, 304-317).

To identify the neural projections from this area, 30 nanoliters of the anterograde tracer, biotinylated dopamine amine (10%), was pressure injected into the mPFR of adult male Sprague-Dawley rats through glass micropipettes with 40-60 μm O.D. tips. Following survival times of 7-10 days, the animals were perfused, 465 nmol of biotin-dHPG was injected in avidin-HRP, and visualized with a nickel-iodinated diaminobenzidine reaction.

Dense projections of labelled fibers extended from the site of injection to the central gray, bed nucleus of the stria terminalis, medial and lateral preoptic areas, posterior hypothalamus, and median preoptic nucleus. Moderate projections were visible in the dorsal premammillary nucleus, parabrachial nucleus, lateral septum, paraventricular thalamic nucleus, precommissural nucleus, and locus coeruleus. Terminal labeling was also evident in the accumba, amygdala, lateral parabrachial nucleus, and nucleus tractus solitarius. Although the roles of these projections remains to be established, by acting on FFH neurons NPY could directly influence activity in multiple intran- and extrahypothalamic structures.

499.8
EFFECT OF FOOD DEPRIVATION ON NEUROPEPTIDE Y (NPY) MESSENGER RNA IN HYPOTHALAMUS OF SYRIAN AND DJANGARIAN HAMSTERS. J.G. Mercer, G. Selverston, G. Segalman*, J. Greenberg. The Rowett Research Institute, Buckburn, Aberdeen, U.K. AB2 9SB.

Imposed manipulations of energy balance that increase food intake in rats often have no effect or elicit an attenuated response in various hamster species. Thus, Syrian, Turkish and Siberian hamsters either fail to express, or exhibit only limited post-fast peak responses. NPY is unresponsive to glucocorticoid or inhibition of fatty acid oxidation (Bartness, Int. J. Obesity 1 suppl. 3:115, 1990). Syrian hamsters are, however, sensitive to the appetite-stimulating effect of Neuropeptide Y (NPY). Intracerebroventricular (Kulksosky et al., Peptides 9:1389, 1989). To assess whether endogenous NPY in hamsters is sensitive to alterations in energy balance we have examined the effect of food deprivation on preprodynorphin mRNA in the hypothalamus of two species of hamster, the Syrian hamster, Mesocricetus auratus, and the Djungarian hamster, Phodopus sungorus. PreproNPY mRNA was studied by in situ hybridisation using the cloned rat gene to synthesise antisense and sense 35S-riboprobes. Autoradiographic images were quantified by computerised image analysis, providing measures of integrated density (OD x mm²). In the Hooded Lister rat, which was employed as a control species, 48 h food deprivation induced a 2.24 fold increase in total hybridisation in the hypothalamic arcuate nucleus (ARC), relative to fed controls. The same manipulation resulted in a 1.5-fold increase in total hybridisation in the ARC of the Djungarian hamster. In contrast, preliminary studies of the Syrian hamster indicated that NPY expression in this species may not be regulated by food deprivation. This work was supported by SAOFD.

ALTERATIONS IN NUTRIENT METABOLISM HAVE DIFFERENTIAL EFFECTS ON GALANIN (GAL) AND NEUROPEPTIDE Y (NPY) IMMUNOREACTIVITY IN HYPOTHALAMIC NUCLEI. J. Wang, A. Akabayashi, C.T. B. Zafar, T. Silva, and S. E. LeWytzky. The Rockefeller University, New York, N.Y. 10021.

Hypothalamic injections of GAL and NPY have differential effects on nutrient ingestion. Food intake of NPY preferentially extracts individual sections of the hypothalamus and GAL preferentially stimulates fat intake. The question is whether endogenous production of these peptides in hypothalamic neurons is differentially responsive to signals related to the metabolism of these nutrients. To test this, two compounds that alter carbohydrate and fat metabolism were examined in albinor rats: 2-deoxy-D-glucose (2-DG, 200 mg/kg), which inhibits glucose utilization, and mercaptoacetate (MA, 600 μmoles/kg), an inhibitor of fatty acid oxidation. Intraperitoneal injection of 2-DG, compared to vehicle, caused a significant increase in NPY levels (measured via RIA), specifically in the paraventricular (PVN) and suprachiasmatic nuclei but not other areas. However, no change in GAL levels was detected. While MA, in contrast to 2-DG, produced no change in NPY levels, this metabolic inhibitor significantly reduced GAL levels, only in the lateral division of the PVN (~35%, p < 0.05). Since cAMP production is inversely related to intracellular glucose, the impact of ventricular injections of dibutyryl cAMP (25 μg) on NPY and GAL levels was also examined. This agent caused a significant increase in NPY levels specifically in the medial PVN and arcuate nucleus, while having no impact on GAL in any area. Thus, intracranial regulatory signals for GAL and NPY production appear to differ, consistent with the differential impact of these peptides on nutrient ingestion.

499.10

Cellular toxins (Tox, ricin A chain and monoclonal antibody) centrally injected with a monoclonal antibody (MAB) to a neuropeptide may specifically penetrate the peptideergic neurones and induce long-lasting disturbances of neuronal functions. Presently, the toxins were injected with a MAB to the Neuropeptide Y precursor molecule (MAB to C-Fankling peptide, C-PON) near the hypothalamic arcuate (ARC) or paraventricular (PVN) nuclei but, by itself, the injected C-PON-MAB was devoid of biological activity. The effects of one injection of C-PON-MAB or non specific IgG with toxins on spontaneous food intake and mRNA expression of NPY by in situ hybridization were studied.

In rats injected with the C-PON-MAB mixture into ARC, the daily food intake significantly decreased (26%, p<0.001) during the week after the injection. This was due to a decrease in the nocturnal food intake (30%, p<0.001) since the diurnal food intake was unchanged. On the day of injection, the diurnal food intake acutely increased (75%, p<0.001) whereas the following nocturnal food intake decreased (30%, p<0.01). The food intake was not modified by the injection of the specific mixture into ARC or PVN, and by the injection of C-PON-MAB/Tox. mixture into PVN. The injection of C-PON-MAB/Tox. mixture into ARC increased the mRNA expression of arcuate NPY which decreased after the same injection performed in PVN. The long-lasting decrease of food intake was due to an efficient immunological impairment of the arcuate NPY neurones in which the damages likely up-regulated the mRNA expression of NPY.

499.11
VAGOTOMY REDUCES FOOD INTAKE IN LEAN BUT NOT OBESE ZUCKER RATS. D. Greenberg*, D.L. Lewis, and A.J. Strohmeyer. Bourne Laboratory and Departments of Psychiatry and Neurology, Cornell University Medical College, White Plains, NY, 10605.

The genetically obese Zucker rat (fa/la) is hyperphagic compared to lean controls (F/7). This hyperphagia is characterized by increased meal size. The abdomen cavities have been implanted in the mice of satiety signals and severing the abdominal vagus reverses the hyperphagia of hypothalamic obesity (Powley & Oppenheim, 1974). We investigated the effects of total subdiaphragmatic vagotomy on the food intake and body weight of obese and lean male and female Zucker rats.

Male and female obese and lean Zucker rats received bilateral subdiaphragmatic vagotomies (by sham operations or each group). Rats were placed on a low fat diet (~ 1% fat) for 2 weeks and then placed on a high fat diet (30% fat) for an additional 2 weeks. Food intake and body weight was measured daily.

Vagotomy reduced the food Intake (28% p < .001) and body weight (23% p < .0003) of male and female lean rats in both diet conditions. Vagotomy failed to reduce the food intake of male or female obese rats fed the low fat diet, but did reduce the food intake (22% p < .05) and body weight (16% p < .001) of obese rats fed the high fat diet.

The fact that vagotomy reduced food intake in lean but not obese rats indicates that intact vagal function is required for the expression of hyperphagia and obesity in obese Zucker rats under these conditions.

IVC ADMINISTRATION OF ANTI-GALANIN ANTISENSE Oligonucleotide: EFFECT ON FEEDING BEHAVIOR AND BODY WEIGHT. M.G. Hulsey*, C.G. McLeod, P. Fles and R.J. Martin, Department of Foods and Nutrition, University of Georgia, Athens, Georgia 30602

The neuropeptide Galanin has been reported to potentiate the consumption of high-fat diet in a macromolecular selection paradigm. This study investigated the effects of an IVC-administered antisense 2′-O phosphorothioate oligonucleotide, directed against the Galanin mRNA, on feeding behavior and body weight in rats. Sixteen male HSD rats were cannulated in the lateral vena cava, and cannula placement was confirmed using Angioiten II. Rats were given ad libitum access to tap water and a high-fat (60% w/w corn oil) semi-purified diet. Feeding behavior was recorded by computer. Rats were given a single injection of anti-Galanin oligonucleotide (5′-ctctgctctagctagctgac, N = 8) or a missense control oligo (5′-tggcgcctagctgag, N = 8) in the hour before the onset of the light phase (1200 h) and for consecutive days. Cumulative food intake was assessed at 12 and 24 h after each injection as well as over the six day injection period, and was subjected to one-way ANOVA. Body weight changes were also assessed, daily and subjected to one way ANOVA. Compared to missense controls, rats receiving the antisense oligonucleotide ate significantly more of the high fat diet (p<0.025) during the six day injection period. There was no effect on cumulative food intake at 12 h or 24 h after injection (p > .05). There was no effect on body weight change (p > .05). These data are incongruent with previous data from macromolecular selection paradigms where the peptide was administered, and may suggest that Galanin's role in the regulation of body energy balance may be less pivotal than previously thought.
499.13 MODULATION OF GENE EXPRESSION IN HYPOTHALAMUS OF OBESE ZUCKER (fa/xa) RATS IN RELATION TO AGE AND GENDER. M. Jhaver-Uniyat* and A. Burlet. The Rockefeller Univ. New York, New York 10021 and INSERM U308 Nancy, France.

Obesity in general predisposes Zucker rats to an autosomal recessive trait. Associated with this gene are various metabolic, endocrine and behavior disturbances, such as hyperinsulinemia, hyperthermia, enhanced lipogenesis, low energy expenditure, increased hypothalamic-pituitary axis, and hyperphagia. These phenotypic and metabolic abnormalities are observed relatively early in life of obese rats and are gender specific. Certain peptides and hormone receptors, by virtue of their early abnormal status in fa/xa rats or their role in primary metabolic systems show response to the changes associated with the obesity. This study examines the hypothalamic gene expression (mRNA, cRNA, mRNA) of certain carbohydrate-releasing factor (CRF) and glucocorticoid receptor (GR) by using the Northern blot analysis in male and female, lean and obese Zucker rats of 2, 5, and 9 wk old. The results demonstrate that: 1) higher gene expression of CRF in obese rats as compared to lean at 2, 5 and 9 wk age; 2) gene expression was significantly altered with age in both lean and obese rats; 3) gene expression of GR was significantly different in female vs. male, in lean and obese rats. Thus, the results of this study show that the gene expression for the CRF and GR is associated with development/maintenance of obesity.

Neuropeptide Y (NPY) induces feeding and has been associated with carbohydrate selection. 2-deoxyglucose (2-DG) blocks glucose utilization and it potentiates appetite for carbohydrates. Thus, blockade of glucose utilization could affect NPY gene expression in the arcuate nucleus (ARC) and NPY levels in the paraventricular nucleus (PVN). To test this, 2 studies were set up as follows: 1) 32 male rats were injected intraventricularly (ivc) with 18.3 μmol/10 g of 2-DG and 2) 30 male rats were injected i.p. 200 mg/kg of body weight. Both studies had a control (0.9% saline), a 2-DG with ad libitum food or 2-DG food deprived group. Two hours after treatment animals were sacrificed and NPY levels in the PVN and ARC NPY mRNA levels were determined using an NPY radioimmunoassay and an NPY cDNA probe respectively.

2-DG increased food intake 4-fold, but did not affect NPY mRNA or peptide levels. These data suggest that 2-DG-induced feeding, through decrease glucose availability, does not involve changes in NPY activity.

INGESTIVE BEHAVIORS V

We have previously reported that intrathecally infused sucrose does not induce c-Fos like immunoreactivity (c-FLI) in the rat NTS unless a CTA has been formed to sucrose. Lesion studies indicate that brain areas rostral to the NTS are necessary for CTA acquisition and expression. Thus, we qualitatively surveyed c-FLI as a marker of neuronal activity in the pons and forebrain at the level of the hypothalamus 1 hour after treatment: intracerebroventricular infusion (5%), 6-20 min, LiCl alone (0.15 M, 125μg/kg, i.p.), intraperitoneal sucrose paired with LiCl, and rats treated with LiCl alone. The results suggest that c-FLI is a more sensitive measure of neuronal activity than the primary CTA formation and forebrain at the level of the hypothalamus 1 hour after treatment: intracerebroventricular infusion (5%), 6-20 min, LiCl alone (0.15 M, 125μg/kg, i.p.), intraperitoneal sucrose paired with LiCl, and rats treated with LiCl alone. The results suggest that c-FLI is a more sensitive measure of neuronal activity than cell-counting may reveal patterns of neuronal activity underlying CTA formation and expression.

Conditioned taste aversions can be produced by pairing a novel palatable substance with exposure to an aversive agent such as lithium chloride (LiCl). Using a rapid conditioning paradigm, the effects of LiCl pre-exposure on conditioned changes in taste reactivity responses were examined. Rats were pre-exposed to LiCl or NaCl (3.0 mol/kg, ip, NaCl-12 per group) and placed in an observation box for 30 sec with 30 sec intraoral infusions of 0.3 M sucrose administered at 5 min intervals. Both groups conditioned with LiCl produced fewer ingestive and more aversive responses than NaCl conditioned rats (p < .05). Comparison between the two LiCl-conditioned groups revealed that LiCl pre-exposure had no effect on ingestive responses and passive drip, but did reduce aversive responding relative to NaCl pre-exposed rats (p < .05). These results suggest that LiCl pre-exposure attenuates conditioning by selectively reducing aversive responses. (Supported by an NSERC to KPO).

**β-ESTRADIOL-INDUCED CONDITIONED SHIFTS IN SUCKROSE PALATABILITY IN MALE RATS**

K.P. Olsenknapp, J.Y. Ralls, and L.A. Eckel

Neuroscience Program, University of Western Ontario, London, Ontario, Canada, N6A 5C2

Conditioned taste aversions (CTA) can be produced by pairing a novel taste with exposure to a toxin. Previous studies have shown that estradiol decreases preference for saccharin in female rats. The present experiment examined the ability of estradiol to produce conditioned shifts in taste sensitivity responses to sucrose in male rats. Rats were subdivided into two groups and trained to associate sucrose solution, followed by s.c. injection of 17β-estradiol (100 μg/kg) or vehicle (polyethylene glycol). All rats were then given free access to water and 3 days later tested for their taste sensitivity to 0.3 M sucrose. The rats were placed in an observation box and three 30 sec intraoral infusions of sucrose were administered at 5 min intervals. The orofacial and somatic responses to the sucrose taste were videotaped to assess palatability. The estradiol group exhibited a significantly reduced ingestive behavior, and increased aversive behaviors (p<0.01), relative to the control group. When the two groups were subsequently given a 24 hr two-bottle choice test between sucrose and water, the estradiol group displayed a significant (p<0.01) CTA to the sucrose. Thus, estradiol-induced CTAs seem to be based on conditioned shifts in palatability.

**FOOD DEPRIVATION REDUCES STIMULUS DISCRIMINABILITY IN THE NUCLEUS TRACTUS SOLITARIUS OF THE RAT**

K. Nakamura, T. Teeter, K. Cui, and J.M. Kaplan

Department of Psychology, University of Delaware, Newark, DE 19716

The results of human psychophysical and animal behavioral studies suggest that a state of food deprivation alters hedonic perception of taste stimuli and broadens the range of substances an animal will accept as food. We recorded from the NTS of 72-hour deprived rats to determine whether these hedonic and behavioral changes resulted from alterations in the sensitivity of the taste system. The deprivation resulted in a 10% decrease in body weight at the time of recording. The evoked activity of 45 units from food deprived rats and 40 units from caloric replete rats to an array of 13 taste stimuli was recorded and analyzed. Food deprivation significantly reduced the spontaneous firing rate of NTS gustatory neurons and attenuates the response to the sodium and lithium salts. In addition, the breadth of tuning of salt-sensitive neurons was greater in food deprived rats than in controls. We then analyzed for differences in the code for taste quality. Activity profiles evoked by the salts (NaCl, L-lysine, and carbohydrates (Polysaccharide, glucose, fructose, sucrose)) across neurons were significantly more similar in deprived rats. Temporal patterns of activity in the firing rate of NTS neurons for the acids (HCl and citric) and sugars were also significantly more similar in deprived rats. The willingness of 72-hour food-deprived rats with a conditioned taste aversion to glucose to ingest an array of taste stimulus was tested. Results indicated a reduced ability in 72-hour food-deprived animals to discriminate between acid and sugar stimuli. The implication is that deprived rats are able to make fewer discriminations among tastes, an effect that could underlie their wider acceptance of potential foods.

**SIMULTANEOUS CONTRAST EFFECTS IN CHRONIC DECEREBRATED RATS**

P.S. Grange, M.D. Roitman, J.M. Kaplan, H.J. Grill, and R. Norgren

Dept. Behavioral Science, College of Medicine, Penn State Univ., Hershey, PA 17033  A and Dept. of Psychology, Univ. of Penn, Phila, PA 19104

Seven rats received full supraciliary deconstructions in two hemitranssections spaced one week apart. These rats, along with 7 control subjects, were then implanted with two intracranial cannulae and one anterior duodenal EMG electrode. On the first day following recovery from surgery, the rats received forty 10 sec infusions of 0.1 M sucrose. On a second day, they received identical infusions of 0.1 M sucrose. On two other days, the 2 concentrations were alternated for a total of forty infusions/day. All stimuli were delivered at a rate of 1.2 ml/min and the interstimulus interval was 30 sec. The rhythmic activity of the anterior duodenum, which closely follows gustatory licking, was evaluated during both the 10 sec infusion period and the 20 sec offset period. The results showed that during the offset period (1) both the intact and the decerebrate rats demonstrated a reliable concentration effect by generating more motor movements for the high than for the low concentration of sucrose. (2) While intact rats demonstrated contralateral effects, they failed to do so under these circumstances. (3) Regardless, chronic decerebrate rats did express simultaneous negative contrast. That is, they made fewer responses for the low concentration of sucrose when alternated with the high concentration than when presented alone (p< 0.004). Thus, an intact brain stem is sufficient for the occurrence of simultaneous negative contrast. Supported by DC-02216, DC-00240, MH-60553, DK-42284, and DK-21497.

**EFFECTS OF HEPATIC-CELIAC BRACH VAGOTOMY AND SITE OF POLYCOSE INFUSION ON CONDITIONED FLAVOR PREFERENCES IN RATS**

E.A. Simons, E.A. Martinson, E.A. Watson, C.C. Horn, and J.C. Mitchell

Department of Psychology, Kansas State University, Manhattan, KS 66506

We have shown (Horn & Mitchell, Soc. Neurosci. Abstr., 1993) that conditioned flavor preferences were produced using intragastric polyose infusion in rats in which hepatic-celiac branch vagotomy was blocked by hepatic branch vagotomy. The present study extended this research using a discrete trial procedure and a hepatic-celiac branch vagotomy. A normal control (n=7) and a hepatic-celiac vagotomized group (n=8) were both implanted with gastric fistulas and a duodenal group (n=8) was implanted with duodenal fistulas. While 22 hours food deprived, rats were trained for a total of 12 days. During training, rats received a flavor (CS+) paired with intragastric or intraduodenal infusion of 5 ml of 16% w/v polyose (P) and an flavored water (CS-) paired with intragastric or intraduodenal infusion of 5 ml distilled water. The flaves used were grape and cherry Kool-Aid. After training, rats were given two-bottle extinction preference testing for four days. Results showed that the combined hepatic-celiac vagotomized group failed to interfere with conditioned flavor preferences. Furthermore, flavor preferences appeared to be greater in the vagotomized animals. The results showed that polyose infused into the duodenum is as effective as intragastric infusion in conditioning preferences.
500.10

Intravenous intrusions of selective mu- and delta opioid subtype antagonists, naloxone and naltrexone, respectively, produced a high degree of naloxone (NTX) and the delta opioid antagonist beta-fumirexetine (BPNA) and the l-selective antagonist naltrexone (NTH) micromolar injected into MH to alter deprivation (24h) intake, 200 (500 mg/kg i.p.) hyperphagia, or sucrose intake. NTX was significantly reduced by NTX (10 mg: 208), BPNA (5 mg: 268) or NTH (5 mg: 315) in MH, 200 hyperphagia was significantly reduced by NTX (10 mg: 697), BPNA (20 mg: 83) or NTH (20 mg: 699 in MH only after 2h. Neither NTX, BPNA or NTH in MH altered sucrose intake. The NTX effects are compared with ventricular infusion to infer MH mediation of opioid antagonist actions on different forms of intake. Supported by NIDA DA 04194.

BLOCKADE OF DIETARY OBESITY DEVELOPMENT BY CENTRAL SELECTIVE OPIOID ANTAGONISTS IN RATS. J.L. Collet*, L. Leventhal, M. P. Parsons, and W.D. Cole* Dept. of Psychology and Neuropsychology, Special Program, Queens Coll., CONY, Flushing, NY 11367; Dept. of Nutrition, Memorial Sloan-Kettering Cancer Ctr., New York, NY 10021; Div. of Medicinal Chemistry, N.Y. Bethesdah, MD 20822.

Chronic injections of naloxone or naltrexone transiently reduce food intake and body weight, probably due to a limited duration of action. The reversible mu, delta, and kappa antagonists, reduced body weight and food intake over 2 weeks in adrenal rats, but failed to affect these variables in dietary-obese rats. Since acute administration of opioid antagonists reduce palatable intake, the present study examined whether body weight and intake of a high-fat, sweetened condensed milk and cheese would be altered by daily (11 days) central microinjections of l-selective mu (beta-fumirexetine: BPNA, 20 mg, mu, naloxonazine: NAS, 50 mg), kappa (norp-binalorphine: NPP, 20 mg, delta, DALCE, 40 mg) or delta, (naltrindole 5'-isothiocyanate: NTII, 20 mg) opioid subtype antagonists. Rats exposed to the palatable diet gained significantly more weight (+98 vs +30) than chow-fed controls. Significant reductions in body weight occurred immediately and progressed thereafter for each antagonist: BPNA (-5%), NAS (-1%), NTH (-5%), DALCE (-7%) and NTII (-7%). Corresponding decreases in milk, fat and chow intakes were also observed following antagonists treatments. These data implicate each opioid receptor subtype in maintenance of body weight under caloric conditions. Supported by NIDA DA 04194.

EEG RESPONSES TO ICE CREAM AND PAIN: OPIOID AND PREFERENCE EFFECTS. D.D. Kroeh*, B.A. Comell, R.J. Davidson, J. Williams, L. Redmond, L. Vilas, University of WI Dept of Psychiatry, Madison, WI 53792.

Research by our group and others has demonstrated that (1) treatment with opioid agonists increases and treatment with opioid antagonists decreases intake of and preferences for highly preferred foods and fluids in animals and humans; (2) intake of highly palatable foods affects the endogenous opioid system; and (3) opioid receptors are involved in the rewarding effects of palatable stimuli; and (3) states associated with positive affect and approach behaviors are associated with release of the left frontal central hemispheres (R4R) as measured by EEG in humans. In order to determine whether the eating of a highly preferred food resulted in altered response to pain, changes in mood, and R4R, due to effects on the endogenous opioid system, we are conducting an experiment in which we have responses of young female subjects (classified as ice cream like or non-like) on the basis of their responses to a questionnaire to ingesting ice cream (750 cal in 10 minutes) followed by either naloxone or saline are measured. The same responses are also measured in humans and non-humans during a no eating, saline trial. Initial results in three ice cream like and non-like trials are available; additional data are being collected. After ice cream ingestion, naloxone treatment resulted in a large shift to relative right activation on the EEG in like; this effect was not seen in non-likes. Also, the three likes showed a relative increase in right-sided EEG activation on the ice cream trial, in contrast to the non-likes, which showed a relative decrease in right-sided EEG activation. This preliminary data support the hypothesis that subjects who highly prefer ice cream differ from those subjects who are less effective and analytic responses to palatable food ingestion. This research was supported by NIDA grant DA05471.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
500.15 NITROUS OXIDE STIMULATES FOOD INTAKE IN NON-DEPRIVED RATS. J. M. Rodby and C. L. Malow, Department of Psychology, Marquette University, Milwaukee, WI 53233.

Previous research suggests that nitrous oxide (N₂O) exerts one or more of its effects through a benzodiazepine (BZP) receptor system. Further, BZPs are known to influence ingestive behaviors in several animal species. This study examines a possible N₂O effect on food intake in an unrestrained rat.

In exp. 1, male Long-Evans hooded rats were exposed to one of four concentrations of a N₂O and O₂ mixture (10-40% N₂O) or to room air circulated through an enclosed environment. Following an initial acclimation to gases, ground chow and tap water were provided ad lib in the same environment for a 60 min test. Intakes at 30 and 60 min were corrected for baseline weight gain and body weight (BWT) and in other exprs. with ANOVA procedures and, as appropriate, Dunnet's or adjusted Student-t tests; alpha level was set at P<0.05. Food intake increased in a dose-related manner with increasing concentration of N₂O, differing significantly from room air controls at 20% N₂O.

In exp. 2, pretreatment with 10 or 20 mg/kg (p) of the BZP receptor blocker, flumazenil, failed to attenuate the hyperphagia induced by a challenge concentration (20%) of N₂O.

In exp. 3, pretreatment with the opioid antagonist, naloxone (0.1-10.0 mg/kg, sc), attenuated 30% N₂O-induced hyperphagia in a dose-related manner; all dosages were significant relative to vehicle control. These data fail to support an hypothesis that N₂O-induced hyperphagia in the rat is mediated by a BZP receptor. The data do, however, implicate an opioid mechanism.

Although innervation of the hepatic parenchyma has been demonstrated in many species, its existence in the rat has been controversial. The intralobular innervation of human liver has been characterized using immunocytochemical staining for a variety of neural markers. To determine whether the hepatic parenchyma of rats is innervated, we examined liver tissue immunohistochemically for the presence of neurofilament protein 200 (NF 200) using a monoclonal antibody to NF 200. Reaction product indicative of fine neuronal processes was observed in close association with hepatocytes in certain areas of the liver. The processes were seen transversing several hepatocytes and often had a beaded appearance indicative of varicosities. NF 200-like immunoreactivity was also found in association with the hepatic vasculature suggesting a vascular innervation as well. Western blot analysis of liver tissue confirmed the presence of NF 200. These observations provide evidence for intralobular innervation of the rat liver.

500.17 HEPATIC PORTAL AND VENA CAVA GLUCOSE AND AMINO ACID INFUSIONS DECREASE DAILY FOOD INTAKE IN RATS. A. E. Willis, D. A. Walls and H. S. Koopman. Dept. of Medical Physiology, Univ. of Calgary, Calgary, Canada, T2N 4N1.

Intravenous infusions of glucose and/or amino acids into the vena cava cause daily food intake to decrease by 50% to 100% of the kilocalories (kcal) infused (Walls & Koopmans, 1992). Since glucose and amino acids are normally absorbed from the gut into portal circulation before they are taken up or metabolized in the liver or passed on to the rest of the body, we examined whether glucose and amino acids infusions into the hepatic portal vein (HP) of male Lewis rats would lead to better caloric compensation than vena cava (VC) administration. A 10 kcal glucose infusion decreased daily food intake to a similar degree in the HP (3.3 ± 1.5 kcal) and VC groups (2.5 ± 4.9 kcal, p > .90). Daily food intake was significantly decreased (p < .01) during the 20 kcal infusion by 12.8 ± 4.8 (HP) and 14.7 ± 3.1 kcal (VC). There was no significant difference between the two routes of infusion (p > .75). With the 20 kcal amino acid infusion food intake was significantly reduced (p < .005) by 17.4 ± 4.9 kcal in the HP group and 17.7 ± 2.7 kcal in the VC group. Again there was no significant difference in route of infusion (p > .90).

There was no significant effect of treatment or route of infusion on the rate of body weight gain. These results show once again that infused nutrients can provide part of a signal that controls daily food intake. Furthermore, the liver is not likely to be the site where this signal is generated even though it plays a central role in nutrient metabolism. The infusion of glucose or amino acids into the portal vein would generate high hepatic plasma values of these nutrients but produced reductions in daily food intake that were similar to those found after vena cava infusion.

501.1 DIFFERENTIAL MATING STIMULATION EFFECTS FOS EXPRESSION IN BRAIN AND SPINAL CORD OF THE FEMALE RAT. R. Komberg, J. W. Lee and M.S. Emdin. Department of Biology, Boston University, Boston, MA 02215 USA.

Threshold amounts of cervical stimulation (CS) received during mating are essential for the initiation of the prolactin (PRL) surge of early pregnancy in the rat. The expression of FOS in brain and spinal cord in response to amounts of CS which are sufficient or insufficient to induce PRL surges was examined. Ovariectomized rats primed with estrogen (EB, 40ug/kg) and progesterone (2mg/kg) received subthreshold (mouths-without-innission; MO), peristimulus (5 or 10 innasions, I), supratreshold (15 I) mating stimulation from males or were taken directly from the home cage (HC). Animals were sacrificed 1 hr post mating, and brain and spinal cord sections were stained for FOS protein using standard techniques. Numbers of FOS-immunoreactive (FOS-IR) cells increased in proportion to the number of I in the medial amygdala (mAeMY) and bed nucleus of the stria terminals (BSTN) and in response to 1 compared to MO and HC in the praeoptic area (POA) and ventromedial nucleus of the hypothalamus (VMN). The L6 segment of the cord showed graded numbers of FOS-IR cells following 5 or 15 I; this effect was restricted to laminae I and X. At thoracic (T12), lumbar (L1-L3) and sacral (S1-S2) levels, stimulation did not increase FOS above HC levels. MO animals at all spinal levels examined had significantly higher FOS-IR than HC and I animals, suggesting an analgesic effect of CS on neural activity in the cord. Since the mAeMY, BSTN and L6 showed graded responses to CS, these areas may be involved in acquisition of information relevant to initiation of PRL surges. Supported by HD21802 to M. S.

501.2 ALTERNATIVE MALE TYPES IN TREE LIZARDS HAVE DIFFERENT DELAYED STEROID HORMONE RESPONSES TO AGONISTIC ENCOUNTERS. R. Knappe and M.C. Moore. Dept. of Zoology, Arizona State Univ., Tempe, AZ 85287-1501.

Steroid hormones are known to mediate agonistic behavior in a variety of species. We are examining the role of testosterone (T) and corticosterone (B) in agonistic behavior in a species where a male can be one of two permanent types with respect to aggressiveness. Previously, we reported finding a delayed (1-day) increase in plasma B levels, but no changes in T, in aggressive-morph male tree lizards (Urosaurus ornatus) who won short contests in the laboratory (Amr. Zool., 320(24A), 1992). We have now repeated the experiment to determine whether this delayed effect of winning occurs under more natural conditions, and if it also occurs in the less aggressive morph. Staged encounters were conducted using a male presented to marked lizards in the field. The two types of males differed in their hormonal response to the encounter. Winning staged encounters had no significant effect on plasma T or B levels in the territorial, more aggressive morph one day following the encounter. However, males of the less aggressive, satellite/nomadic morph exhibited decreased T (ANOVA, p = 0.02) and increased B levels (p = 0.003) relative to controls. A contributor to morph-specific levels of aggression documented earlier (Horn Behav., 26:56B, 1992) may be a morph-specific response of T and B levels following male-male encounters. However, morph differences in aggressiveness may be mediated by differential sensitivity of plasma T to increases in B, as i.p. injections of 460 ng B revealed no difference in T levels for the two types of males. The results do, however, suggest a hormonal mechanism whereby frequency of male-male encounters may influence whether a male of the less aggressive morph is a satellite or nomadic.
10.5 LHRR MICROINJECTED INTO THE MEDIAL PREOPTIC NUCLEUS (MPOA) INHIBIT GONADIALLY DEFEMINIZED MALE RATS. J.G. Bloch, J.G. Kohlert, P. Butler, M. Stowell, R. Huber, R. Johnson, C. Beraison, B. Krasner, B. Walden, A. Fleming, Psychology Dept., BYU, Provo, UT 84602. Gelatin (GAL) microinjected into the MPOA facilitates male-typic behavior in the rat (Bloch et al., Physiol Behav 54, 93). GAL stimulates LHRR and is found within LHRR cells located within the medial preoptic area. These animals have reported that subcutaneous LHRR facilitates male sexual behavior. I.e., LHRR also stimulates testosterone but this result is not site-specific. No effect was noted with LHRR in the MPOA, but gonadally intact males behave maximally and thus may be insufficiently determined the behavioral response of 3IU saline (SAL) or 20,50,100,500UG LHRR microinjected into the MPOA of gonadectomized male rats implanted with 2mg testosterone-filled Silastic capsules; these produce low levels of behavior, allowing for more or in combination with P. Low levels of LHRR in the male do not therefore result from a suppression by gonadal steroids of LHRR neurons mediating the lordosis-stimulating effects of CCK. (NIMH HD27334)

10.6 INHIBITION OF TESTOSTERONE AROMATIZATION IN THE INTACT MALE RAT PREPARED OR RECEPTIVE ESTROGEN ENHANCES ESTROGEN INSENSITIVITY AND IMMUNOREACTIVITY AND REDUCES MATING. A. N. C. Clancy, D. W. Zampa, and R. P. Michael. Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, College of Allied Health, Atlanta, GA 30322. 

C dopulatory behavior was studied in 5 groups of sexually experienced, intact male rats in which: (i) the nonsteroidal aromatase inhibitor Fadrozole (Ciba-Geigy CGS 16949A) was delivered bilaterally into the medial preoptic area (POM) together with normal saline given i.c.v. in (i) and (ii) normal saline was delivered bilaterally into POM together with the same Fadrozole dose given i.c.v., (ii) Fadrozole was delivered bilaterally into the medial preoptic area with saline given i.c.v., (iii) Fadrozole was delivered bilaterally into the lateral preoptic area together with saline given s.c., (iv) Fadrozole was delivered bilaterally into the lateral preoptic area together with saline given s.c. and (v) unoperated controls. Mounting and ejaculation were significantly decreased in rats receiving Fadrozole in POM compared with the behavior of rats in the other 4 groups. Few differences occurred between rats in the latter 4 groups, all of which continued to mate. The H222 (Abbot Laboratories) and ER-715-anti-estrogen receptor (ER) antibodies were used to examine the distributions of ER immunoreactive (ERa) neurons in gonadectomized controls and some of the groups in i, ii, and iii. Since of ERa neurons in the anterior hypothalamus was abolished in the estrogen-deficient rats. In summary, our results indicate that the presence of estrogen is important for copulatory behavior in male rats and that H222 ERa can be used to identify the neurons in POM affected by Fadrozole. (Funded by USPHS grant MH 39506 and the Emory University Research Committee).

10.7 DIFFERENCES IN ESTROGEN SENSITIVITY IN WHITFALL LIZARDS L. Young and D. Crews. Dept. of Zoology, University of Texas, Austin TX 78712. 

C. unipares is a unisexual species of whiptail lizard whereas C. inornatus is a sexual species and the maternal ancestor of C. unipares. Together they represent an excellent model for investigating the evolution of hormone-brain-behavior relationships. Plasma levels of estradiol in C. unipares are approximately 5-fold lower than those of female C. inornatus in the same state. This translates into species differences in dose-response curves for estradiol benzoate (EB) induced female sexual behavior (receptivity) (p<0.01). Ten-fold smaller dosages of EB were used for stimulation of behavior in C. unipares compared to female C. inornatus. In situ hybridization analysis indicates that estrogen induction of progesterone receptor (PR) expression in the ventromedial hypothalamus (VVM) also differs between the species. EB was significantly more potent in ovarciotomized C. unipares than in ovarciotomized female C. inornatus at inducing PR gene expression within the VVM (p<0.01). Preliminary results indicate that species difference in estrogen receptor expression in the VMH may account for the differences in behavioral and molecular sensitivities to EB. These results indicate that differences in behavioral sensitivity to estrogen lies in the estrogen target neurons in the brain area (VMM) controlling receptive behavior. Furthermore, these differences in sensitivity may be involved in the evolution of species differences in circulating hormone levels and of hormone sensitivity of steroid dependent behaviors in general. Supported by NSF Pre-doctoral Fellowship (LJY) and NIMH 41770 (DC).

FOS PATTERNS IN MALE HAMSTER VOMERONASAL PATHWAYS: PHEROMONE STIMULATION AND EFFECT OF EXPERIENCE. Gwen Fernandez-Powell* and Michael Meredith Neuroscience Program, Florida State University, Tallahassee, FL 32306.

Removal of vomeronasal organs (VNX) from sexually naive, but not from sexually experienced male hamsters results in severe deficits in mating behavior.

Previous studies of VNX and intact males indicate a preferential activation of VN pathways (Accessory olfactory bulb, Medial amygdala, Me) during mating behavior and pheromonal stimulation. Activation in the medial preoptic area (MPOA) mainly reflected copulatory performance. Here, we used c-fos expression to analyze patterns of neural activity in sexually experienced intact and VNX males exposed to pheromonal stimulation either alone or during mating. Males from each group were placed in clean boxes with fresh bedding and each exposed to female hamster vaginal fluid (HVF) or a sexually receptive female for 45 mins. An additional 15 mins were perfused with 4% paraformaldehyde. Control animals were put in clean boxes with fresh bedding and perfused 90 mins later. Fifty um vibratome sections were processed for immunocytochemistry using a polyclonal Fos antibody. (Cambridge Research). When exposed to HVF, experienced males had higher levels of Fos expression in the MPOA than did inexperienced males, whether intact or VNX. Mated animals all had extensive Fos expression in MPOA but here there appeared to be a denser expression in intact than VNX animals. Fos expression in M, among HVF exposed males, was highest in intact experienced animals with lower levels in inexperienced animals and in VNX animals. Mated animals had a higher overall level but similar relative levels of expression.

501.11
ESTROUS FEMALE ELICITS DOPAMINE RELEASE IN MPOA OF INTACT, BUT NOT CASTRATED, MALE RATS. J. Du, D. S. Lorrain, L. Matsevich, and E. M. Hull*. Department of Psychology, SUNY at Buffalo, Buffalo, NY 14260.

Extracellular levels of dopamine (DA) metabolites DOPAC and HVA increased in the medio preoptic area (MPOA) of male rats during copulation; DA was below the sensitivity of the assay (Hull et al., 1986). The presence of an estrous female increased the catecholamine amperometric signal in MPOA, but the contribution of DA could not be determined (Blackburn & Pfus, 1992). This experiment tested whether extracellular DA, serotonin (5-HT) and their metabolites in the MPOA of male rats were affected by exposure to an estrous female behind a barrier or by copulation. We also tested if testosterone (T) facilitates the DA response to the female. Microdialysis samples were assayed using an LC Packings capillary column and Antec electrochemical detector. In intact males, DA, DOPAC and HVA increased in the presence of the female and during copulation; 5-HT and 5-HIAA were not affected. In castrates with T replacement DOPAC and HVA increased significantly in the presence of the female and during copulation; DA increased slightly. In castrates without T, DA fell throughout the experiment, and DOPAC and HVA did not rise in the presence of the female; these animals did not copulate. Since DA in MPOA enhances male sex behavior (Hull et al., 1986), T may influence copulation in part by increasing DA release in MPOA in response to an estrous female. (NIMH grant #40826 to EMH)

501.13
AXOTOMY AND TESTOSTERONE SENSITIVITY OF THE RAT BULBOSPONGIOSUS MOTOR SYSTEM. W.F. Collins III, W. Ha, and M. Gonzalez. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

Rat bulbospinosus (BS) motoneurons exhibit androgen dependence in adulthood. However, it is not clear whether androgens act directly on BS motoneurons or indirectly via the BS muscle. To address this question, we have examined the effect of axotomy on the androgen sensitivity of the rat BS motor system.

The BS muscle was sectioned unilaterally in 180 gm males anesthetized with ketamine and xylazine. The rats were then castrated (with or without testosterone pellets implants) or sham-castrated (sham). After 28 days survival, the rats were sacrificed, and the left and right BS muscles were removed and weighed. Transverse sections from L4-L5 spinal cords were counterstained with cresyl violet, and the somal cross sectional areas of 20 randomly selected motoneurons in both the left and right dorsomedial nuclei from each rat were measured. The data were analyzed using ANOVAs.

As expected, castration produced decreases in mean BS muscle weight and motoneuron somal cross sectional area (73% and 178% of sham controls; respectively) on the axotomized and control side. Chronic denervation of the BS muscle resulted in a 53% decrease in weight (compared to contralateral control), and the BS muscle exhibited a further loss in weight (59% decrease compared to denervated sham) following castration. Chronic axotomy produced a 23% decrease in BS motoneuron somal cross sectional area (compared to contralateral control). Furthermore, somal cross sectional area of axotomized BS motoneurons was 12% smaller in castrated rats compared to sham controls. All castration effects were reversed by testosterone administration and are significant at p<0.01.

Thus, both denervated BS muscles and axotomized BS motoneurons are sensitive to androgen. However, the effect of castration on axotomized BS motoneurons is attenuated compared to that observed in axotomized intact BS motoneurons.

STERIOD-INDUCED REPRODUCTIVE BEHAVIOR IN OBESE ZUCKER FEMALE RATS. C.L.M. Bezerra* and D.H. Olds. Department of Psychology & Neuroscience Research Institute, University of California, Santa Barbara, CA 93106.

Obeze Zucker female rats are infertile. Anecdotal evidence suggests ovary-intact obese Zucker females display less reproductive behavior than their lean counterparts. The present study was designed to compare reproductive behavior induced by exogenous steroid hormones in ovariectomized (OVX) lean and obese Zucker rats. OVX animals were given estradiol benzoate (EB; 15-100 μg/kg) or EB plus progesterone (P; 2-10 mg/kg), and tested for sexual receptivity. At the highest EB dose obese Zucker females displayed lordosis less frequently than lean rats (Lordosis Quotient, LQ = 9 ± 6% vs. 32 ± 13%, respectively, p<0.01). At the lowest doses of EB plus P lean females were maximally responsive (LQ = 93 ± 4%); Zucker obese females, in contrast, were only slightly receptive (LQ = 26 ± 11%; p<0.0001). Increasing the dose of either EB or P, administered in combination with the lowest dose of the other hormone, produced responses in obese Zucker females that were comparable to those observed in lean rats. These data suggest that considerably higher doses of EB and/or P are required to elicit robust lordosis responses in O VX obese Zucker, as compared to lean rats. This behavioral hyperresponsiveness may contribute to infertility in the obese Zucker female rat. (This work was supported by NIH HD 21483 and the American Psychological Association.)

SEXUAL EXPERIENCE INCREASES COPULATION INDUCED FOS-LIKE IMMUNOREACTIVITY IN THE MPOA. L.A. Llamas* and E.M. Hull. Department of Psychology, SUNY at Buffalo, Buffalo, NY 14260.

Male sexual behavior increases the induction of the immediate early gene c-fos in the medial preoptic area (MPOA) (Robertson et al., 1991), a brain area important in the regulation of male sex behavior. We recently reported that a DI antagonist lowered the number of copulation induced Fos-like immunoreactive cells in the MPOA (SN, 1993). Male rats improve their copulatory efficiency with sexual experience. We hypothesized that sexual experience may affect copulation induced Fos-like immunoreactivity in sexually experienced relative to sexually inexperienced male rats. One group of male rats received sexual experience every five days for seven weeks, at which time they were able to achieve three ejaculations in a 30 minute interval. Another group of male rats of equal age received no sexual experience prior to the test day. On the test day, all males were allowed to achieve one ejaculation, and brains were subsequently assayed for Fos-like immunoreactivity. A nonopercutaneous control group was also included. After one ejaculation, an increase in Fos-like immunoreactivity in the MPOA was observed in sexually experienced relative to sexually inexperienced rats. Since dopamine in the MPOA is released during copulation and is important in the regulation of male sexual behavior, increased Fos-like immunoreactivity may reflect a more sensitive dopamine system in sexually experienced male rats. 05.3

Niacotine facilitates human attention, memory and sensoromotor function. A visual spatial working memory (VSWM) task that utilizes these functions activates several frontal and parietal cortical regions as measured by functional magnetic resonance imaging (FMRI). Such evidence exists for the involvement of forebrain dopamine (DA) systems in VSWM as evidenced by the effects of nicotine on these systems, without the effects of nicotine on task-induced FMRI activation. Single shot echo planar imaging was obtained on a 1.5 Telsa GE Sigma scanner using an insonated, balanced, torque 3-axis head coil designed for random gradient switching. To obtain images throughout the entire brain volume, a shielded quadrature elliptical copped transmit/receive birdcage radio frequency coil was used. Four experienced smokers performed the VSWM task while FMRI data were acquired (TR=5 sec; TE=40 msec; 8 mm slice thickness). A total of 7 cycles of task repetition (30 sec rest, 45 sec task). Nicotine (0.75, 1.5 or 3.0 mg) or saline was injected iv over a 1.3 sec period during the task cycle. The most common nicotine effect observed (defined as appearing in 4 contiguous pixels) was an increase in the magnitude of the task-induced activation response in both frontal and parietal regions with doses as low as 0.75 mg. In each case, an increase in activation magnitude was seen within 1 minute of drug (but not saline) administration. The average injection-induced increase in signal was 3.9% after saline, 3.5% after the low dose (0.75 mg) nicotine dose, and 8.6% after the median (1.5 mg) nicotine injection. The present data suggest that nicotine enhances regional neuronal activation induced when performing a VSWM task.

05.4

Nucleus accumbens septi (NAS) is identified as a critical structure for the habit-forming actions of opioids, and glutamatergic afferents from the frontal cortex have been suggested to regulate NAS activity. Accordingly, the present study was designed to determine fluctuations in NAS glutamate levels during intravenous heroin self-administration. Rats with NAS dialysis probes were allowed to self-administer heroin. Extracellular fluid from NAS was sampled at 5min intervals by micro-dialysis and was assayed using HPLC with electrochemical detection of OPA amino acid derivatives. Glutamate concentrations in the dialysate increased during heroin self-administration stabilizing at 200% to 400% above baseline. Glutamate concentrations appeared to increase further during extinction conditions that followed the self-administration period. The glutamate elevation during self-administration coincides with reported elevations in dopamine; the elevation in glutamate during extinction occurs at a time when dopamine levels are falling. Thus behavioral states appear capable of dissociating fluctuations in extracellular levels of the two transmitters, suggesting a more complex glutamate-dopamine interaction than has been recently hypothesized.

IBOGAINE ANTAGONISM OF MORPHINE-INDUCED HYPERACTIVITY: ENHANCEMENT BY PRIOR MORPHINE EXPOSURE AND ROLE OF KAPPA OPIOID RECEPTORS M.G. Steckler, J.A. de la Fuente, and D.G. Sig, Dept. of Pharmacology and Toxicology, Albany Medical College, Albany, NY 12208.

Ibogaine, an indole alkaloid, is currently being investigated as a potential anti-addictive therapy. It has been shown to decrease morphine self-administration and to inhibit both morphine-induced locomotor stimulation and morphine-induced dopamine release in the nucleus accumbens and septum, in both rats and humans, the effects of ibogaine appear to be quite variable; the present study sought to determine if prior morphine history might account for individual differences in sensitivity to ibogaine. Female Sprague-Dawley rats, pretreated for 10 days with morphine (30 mg/kg, i.p.) before receiving ibogaine (40 mg/kg, i.p.), showed significantly less locomotor activity in response to morphine (2-5x30 mg/kg, i.p.) than controls pretreated with morphine prior to ibogaine. Thus, prior morphine exposure enhanced ibogaine antagonism of morphine-induced locomotor activity. To study whether ibogaine’s effects may be related to kappa receptor, for which ibogaine has affinity, two kappa agonists were administered using the same treatment parameters. The selective kappa agonists, U50488 (10 mg/kg, i.p.) and U69593 (1 mg/kg, i.p.), were injected in place of ibogaine, mimicked ibogaine’s effects. Furthermore, in preliminary studies, the selective kappa antagonist nor-binaltorphimine (10 mg/kg, s.c.) appeared to reverse the ibogaine-induced locomotor suppression. These data suggest that the long-lasting effects of ibogaine may be due to persisting levels of ibogaine and/or an ibogaine metabolite interacting at kappa opioid receptors to yield anti-addictive effects. (Supported by DA0817)

05.6

The mesolimbic dopaminergic system, specifically the ventral tegmental area (VTA) and its projection to target neurons in the nucleus accumbens (NAC), mediates some of the reinforcing effects of drugs of abuse. Previous results from rats forcibly treated with chronic morphine found several biochemical adaptations in the VTA and NAC (see Neuron 11995, 1993). This experiment validates the previous findings by using the animal model of drug self-administration (SA), which better approximates human drug addiction. In these studies, rats self-administered heroin in limited, daily 6 hr testing sessions for three weeks. A yoked-heroin and a yoked-saline control group were used for comparison. The findings show that opiate SA produces similar biochemical adaptations, when compared to animals receiving SA saline. These include an increase in tyrosine hydroxylase (TH) and glial fibrillary acidic protein, and a trend toward a decrease in neuropeptide Y, in the NAC. Interestingly, heroin SA produces an important adaptation in the NAC, a decrease in TH levels, not seen in animals treated chronically with morphine. There were no differences between heroin SA rats and saline SA rats.

Although the heroin self-administering rats failed to show signs of physical dependence, biochemical adaptations in the mesolimbic dopaminergic system of these rats suggest that these changes could contribute to the motivational aspects of drug addiction.
505.7 REINSTATEMENT OF HEROIN SELF-ADMINISTRATION BEHAVIOR BY EXPOSURE TO PREDILECTIONS AFTER PREFERENCE EXTINCTION

Y. Shaham, J. Stewart. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Quebec, Canada, H3G 1M8.

We have shown previously that non-contingent IV priming injections of heroin, or intraperitoneal injections of morphine injected into VTA reinitiates heroin self-administration behavior in rats following a period of extinction. Naltrexone (N) given alone or given before baseline responding. Here we report that first-time exposure to 10 min of intermittent footshock reinitiates previously extinguished heroin self-administration behavior.

Male and female rats were trained to self-administer heroin (0.125-50 µg/kg/injection, IV) over four 3-h sessions per week for 2 week period. The drug-reinforced behavior was extinguished by at least 16 sessions (lever presses resulted in saline infusions). Reinstatement was studied following non-contingent infusions of saline, 50 µg/kg heroin, naltrexone-precipitated opioid withdrawal (5 mg/kg naltrexone, SC) and by 10-min of footshock (1 mA; 0.5 sec on, mean period of 40 sec).

Reinstatement was observed following footshock stress and priming injections of heroin, but not saline or naltrexone-precipitated withdrawal. Most importantly, footshock stress reinstated self-administration behavior upon first exposure, and again more than one month after the termination of heroin self-administration. These findings suggest that exposure to some stressors can precipitate relapse, possibly by mimicking the neurochemical effects of heroin self-injection and not by inducing opioid-like withdrawal symptoms.

505.8 OVARIAN HORMONES DO NOT ALTER SELF-ADMINISTRATION OF HEROIN IN OVARIETOMIZED FEMALE RATS

J. Stewart, B. C. Woodside and Y. Shaham. Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Quebec, Canada, H3G 1M8.

We studied the effect of ovarian hormones on the initiation and maintenance of heroin self-administration in ovariectomized female rats.

In Experiment 1, the effects of 10 µg estradiol benzoate (EB) and 0.5 mg progesterone (P) on the administration of heroin were studied. Animals were trained to self-administer heroin (50 µg/kg per injection, IV) on a progressive ratio schedule, 4 sessions per day, 4-h each. Animals were tested with descending doses of heroin (50, 25, 12.5, 6.25 µg) in 5-day blocks. Neither EB, given on the third, nor P, given on the fifth day of each block, affected the number of injections.

In Experiment 2, we studied the initiation of IV self-administration of heroin on an FR1 schedule using an ascending series of doses (0.125-50 µg/kg per injection). Following ovariectomy, 6 of 16 animals were injected with 10 µg EB on 3 occasions every 3 days before self-administration training and every 3 days throughout training. Twelve 3-h sessions per dose, 4 session per day, were given. No differences in rates of responding between groups were observed at any of the heroin doses; most animals achieved stable responding at the 25 µg/kg dose. Finally, no group differences were found when animals were tested again using a descending series of doses.

These results suggest that circulating ovarian hormones do not affect the sensitivity of female rats to the reinforcing effects of heroin.

505.9 THE DEVELOPMENT OF A CONDITIONED PLACE PREFERENCE (CPP) TO MORPHINE. 1. EFFECTS OF LESIONS OF VARIOUS CNS SITES. M.C. Olmstead and K.B. Franklin. Department of Psychology, McGill University, Montreal, Quebec, Canada.

The CPP paradigm is used to assess the reinforcing effects of incentive stimuli in that animals spend more time in the presence of cues previously associated with rewarding stimuli than those associated with neutral stimuli. In order to determine the neural substrates mediating the reinforcing effects of morphine, separate groups of male Long-Evans rats received neurotoxic lesions of various CNS sites and were tested for the development of a CPP to morphine (2 mg/kg X 3 pairings). Lesions of the hippocampus, periaqueductal gray, or pendumulopontine nucleus disrupted the CPP. Lesions of the entire ventral striatum reduced the CPP whereas selective lesions of anterior or medial portions were ineffective. Lesions of the dorsal striatum, lateral amygdala, or mesolimbic dopamine system changed the pattern of CPP behaviour but did not reduce the CPP. It appears that the development of a CPP to morphine is a complex phenomenon which depends on interactions between a number of brain structures.

Ibogaine has been proposed to serve as an agent to reduce craving for addictive agents. A series of experiments were conducted to determine the effects of ibogaine (40 mg/kg, ip) on place preference conditioning produced by morphine (5 mg/kg, ip) and on place aversion conditioning produced by naloxone (1-2 mg/kg, ip). Ibogaine alone was found to be ineffective in producing either a place preference or a place aversion; however, it did interfere with the effects of ibogaine on naloxone-induced place aversion conditioning. In addition, the ability of ibogaine to attenuate the expression of a previously learned morphine-induced place preference was assessed.

505.10 INTRAVENOUS MORPHINE SELF-ADMINISTRATION BY RATS WITH LOW VS. HIGH SACCHARIN PREFERENCES

B.A. Gouzoules, D.D. Krah, K.E. Lane and S.M. Bell. Department of Psychiatry, University of Wisconsin-Madison, Madison, WI 53792.

An experiment was performed to determine the relationship between saccharin preference and morphine self-administration. Animals received voluntary intake of a 0.1% saccharin solution in 1 hr daily sessions, low and high preference groups (n=8/group) of male Sprague-Dawley rats were selected from a larger group. Male rats were conditioned (0.5 mg/ml) was then measured in the selected rats in 1 hr daily sessions. The groups did not differ in either water-deprived or non-deprived conditions. Rats catterers were then implanted in all rats. One 6 hr session daily for 40 days was performed on 20 animals. Experience was measured in the operant chambers, during which rats were allowed to self-administer amphetamine sulphate (1 mg/kg) at unit doses beginning at 0.04 mg/kg/infusion, over the course of the experiment, the dose was increased to 0.08 mg/kg/infusion. Fourteen rats completed the study through the end of the sessions at 0.08 mg/kg/infusion, 10 completed the entire study. The groups did not differ in the number of infusions obtained at 0.04 mg/kg/infusion. Over the course of the 0.08 mg/kg sessions, saccharin-prefering rats began to self-administer significantly more morphine than rats with a low saccharin preference. For example, averaged over sessions 1-20 at this dose, the high saccharin rats obtained 10.5 ± 2.3 infusions per session, whereas the low saccharin rats obtained 4 ± 0.8 (p<0.05). Increasing the unit dose from 0.08 to 0.16 mg/kg/infusion increased an increase in self-administration in the low saccharin group and a decrease in self-administration in the high saccharin group. The positive relationship between saccharin intake and morphine self-administration may be due to the mediation by a common reward mechanism. Supported by NIDA DA05471 and DA00827.

Context-specific locomotor stimulation occurs when a distinct environment (context) previously paired with morphine elicits an increase in activity relative to a context that was explicitly unpaired. Given that this work has typically used a context conditioned stimulus (CS), it is unclear whether a context CS is necessary for locomotor stimulation, or whether other CS types would work. A context can be viewed as a polymodal stimulus composed of many elements (eg, auditory, olfactory, and tactile). The present experiment examined the ability of these context cues (odor and taste) to serve as CSs in a conditioned sensitization paradigm. Adult male Sprague-Dawley rats were used in both the taste and the odor studies. Rats received 8 conditioning trials in which a morphine baseline (4 mg/kg, SC) was immediately followed by 15-min exposure to the CS (eg, saccharin taste or banana odor) in a chamber. Using a CS-alone test to assess locomotor sensitization, we found greater activity in morphine-paired rats than in unpaired control rats (see Fig below). Thus, olfactory and gustatory elements of a context are capable of controlling Pavlovian conditioned increases in locomotor activity.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
The development of a conditioned place preference to morphine. II. Effects of microinjections into various CNS sites. K.B.L. Franklin* and M.C. Olmstead. Dept. Psychology, McGill University, Montreal, Quebec, Canada.

In the CPP paradigm, animals will approach and maintain contact with an environment previously paired with morphine administration. The present study investigated the neural sites where morphine may produce its reinforcing effect. Bilateral infusions of morphine (1 μg in 0.5 μl over 1 min X 2 pairings) into the lateral ventricles, periaqueductal gray (PAG), or ventral tegmental area (VTA) produced a CPP. Injections into the dorsal striatum, frontal cortex, hippocampus, lateral amygdala, lateral hypothalamus, pedunculopontine nucleus, posterior hypothalamus, ventral pallidum, or ventral striatum did not produce a CPP. Activation of either PAG or VTA opioid receptors is sufficient to produce morphine reinforcement but the effect may involve an interaction between the two sites.
503.3 EFFECT OF NITRIC OXIDE SYNTHASE INHIBITION ON MORPHINE-INDUCED PHYSIOLOGICAL ANXIETY AND ABSTINENCE SYNDROME IN THE RAT. George A. Matsuyuki, N.P. Plutnickoff and Hemendra N. Bhardwaj, Dept. Pharmacology and Pharmacognosy, University of Illinois, Chicago, IL 60612.

The effects of L-NAME-monomethyl-arginine (NMA) on the development of tolerance to and dependence on morphine as well as on the naloxone-induced abstinence symptoms were determined. Male Sprague-Dawley rats were made tolerant to and dependent on morphine by s.c. implantation of 4 morphine pellets during a 3-day period with 2 pellets on am of day 1 and 2 pellets on pm of day 2. NMA (2, 4 or 8 mg/kg, s.c.) was administered twice a day for 3 days. The pellets were removed on day 4 and tolerance and dependence were assessed 6 hr after the pellet removal. The development of naloxone withdrawal signs was used to evaluate the ability of both the antagonist and morphine to inhibit by 4 and 8 mg/kg doses of NMA. Physical dependence development was also inhibited as evidenced by the decrease in jumping behavior induced by naloxone (5 mg/kg, i.p.) but the other symptoms were not affected. The doses of NMA which inhibited the tolerance and dependence development were unable to inhibit the naloxone-induced withdrawal symptoms in morphine-dependent rats. It is possible that much higher doses of NMA are required to inhibit antagonist-induced withdrawal in morphine-dependent rats (Supported by a Research Scientist Development Award K02-DA-00103 from the National Institute on Drug Abuse).

503.5 ETHANOLOGY OF THE OPIATE WITHDRAWAL SYNDROME IN RATS. F.P. Espay, L. Stumy and M. Calude (1). Ence. Ciencias de la Salud, Univ. de Sevilla, Spain, (2) INSERM U.259, Univ. de Bordeaux II, Bordeaux, France.

Physical signs during the rat's opiate withdrawal syndrome are usually evaluated by the Geller-Holtzmann score. J. Pharmacol. Exp. Ther. 205: 536-546, 1978). However, this score was not elaborated according to a modern behavioral criterion, and it appears to be somewhat arbitrary. The objectives of this study were thus: i) to analyze the overall rat's behavior during the opiate withdrawal syndrome, and ii) to evaluate the validity of the calendar score. Rats were implanted with a s.c. morphine pellets (75 mg x 2, s.c.) and assigned to six groups (n = 10), receiving naloxone (0.0, 0.01, 0.05, 0.1, 0.5, 1 mg/kg, i.p.) to precipitate the withdrawal syndrome. Behavior was videotaped and analyzed by an ethological technique. Score values as well as frequency, duration and latency of each pattern were quantified. A cluster analysis allowed to discern the behavior structure. Ethogram was composed of: sniff, walk, sniffing, licking, posture, wet dog shake, seifing, grooming, gustatory, grooming, abnormal posture, swallowing, intermittent walking, jumping, teeth-chattering, freezing, elongation, yawning, and licking. Number of ejaculations, defecations and micturitions, as well as other physical signs (diarrhoea, irritability, weight loss, etc.) were also evaluated. Results revealed that abnormal posture and intermittent walking, core patterns, changed in a dose-related fashion. Wet dog shakes and jumping, main behavioral signs included in the classic score, were only enhanced in a dose-related manner with intermediate doses. Significant changes in weight loss and irritability were found to be dose-dependent. Score values were gradually enhanced after naloxone injection, except for the highest dose (1 mg/kg). In conclusion: i) the Geller-Holtzmann score is useful, but it appears not to be very accurate for high naloxone doses, and ii) abnormal reactions, weight loss and irritability are the best indicators of the opiate withdrawal syndrome level, and they might be the basis of a simpler ethological score.

To clarify the involvement of different opioid receptor subtypes in regulation of brain glutamate (Glup)/aspartate (Asp) levels during opioid withdrawal, extracellular fluid (ECF) levels of Glup/Asp were examined with in vivo microdialysis of the locus coeruleus (LC) following precipitation of withdrawal using antagonists selective for mu (CTOP, D-Phe-Cys-Tyr-D-Trp-Orn-Thr-His-d-Phe)3 (Nor-BNI), norepinephrine (NPFF-antagonist), and levorphanol dependent SII rats, respectively. Dependance was induced by i.c.v. (i.c.v.) infusion of morphine (26 nmol/1 µl/hr), butorphanol (26 nmol/1 µl/hr), or saline (1 µl/hr) for 3 days. Microdialysis probes (2 mm tips) were inserted into the LC 24 hr before precipitation of withdrawal by i.c.v. injection of 48 nmol/5 µl of CTOP, Nor-BNI, or NTI. Behavioral evidence of withdrawal was detected following CTOP challenge in morphine and butorphanol infusd rats, and following Nor-BNI challenge in butorphanol infused rats, but not in other groups. Levels of Glup in the LC increased to 490% and 258%, respectively, above basal values in the first 15 min following CTOP injection in morphine (n=5) and butorphanol dependent (n=5) rats, while Asp was increased to 258% (n=5) and 185% (n=5) of basal levels in the same groups. Withdrawal precipitated by Nor-BNI produced significant increases in LC levels of Glup (200% of basal; n=6) and Asp (132% of basal; n=6) only in butorphanol dependent rats. No changes in EAA levels were noted following NTI injection, in any group. Opid withdrawal is associated with increased levels of EAAs, within the LC. These increases are mediated primarily through μ opioid receptors in morphine dependent rats. In contrast, both κ and µ receptor subtypes regulate EAA levels during withdrawal from butorphanol. (Supported by DA 05828).

503.7 SUBCUTANEOUS INJECTION OF AN ANALOG OF NEUROPEPTIDE FF PREVENTS NALOXONE-PREVAPRITITED MORPHINE ABSTINENCE SYNDROME. J.L. Lake, D.L. Swaim, J.A. Jones, A.F. Clauser, P.A. Suggs, K.K. Han, T. Liu, K. Burgess and D.H. Malik, Univ. of Houston-Clear Lake, Houston, TX 77058, and Texas AM University, Dept. of Chemistry, College Station, TX 77843.

Neuropeptide FF (NPF) has antipsychotic activity and play a role in opiate dependence and abstinence syndrome. Recently, the C-terminal tetrapeptide of NPF was identified as decreased in lipophilicity and penetration of the blood-brain barrier. This compound, dapsyl-[D-Phe-Arg-Met]amide, precipitated morphine abstinence following s.c. administration. In the present study, the C-terminal -Phel was removed from dapsyl-PDFAamide in an effort to convert it to a NPF-antagonist. In Exp. 1, 5 rats pre-treated with dapsyl-PDFAamide were injected subcutaneously with either 1 µg dapsyl-PDFAamide (n=6) or 20% ETUH of vehicle alone (n=6) 6 mins prior to receiving 1 mg NPF. Rats pre-treated with dapsyl-PDFAamide had a significant, p<.001, 70% decrease in morphine abstinence-like signs compared with rats pretreated with vehicle alone. In Exp. 2, 12 rats were injected subcutaneously with 13 mg/kg dapsyl-PDFAamide (n=5) or 20% ETUH of vehicle alone (n=5) 5 mins prior to receiving 0.125 mg/kg naloxone. Rats injected with dapsyl-PDFAamide exhibited a significant, p<.001, 70% reduction in overall abstinence signs as compared with rats receiving vehicle alone. (NIDA DA06553 and Texas Advanced Technology Program.)

503.8 INHIBITION OF MORPHINE TOLERANCE AND DEPENDENCE BY DIAZEPAM AND ITS RELATION TO CYCLIC AMP LEVELS IN THE RAT BRAIN. M.-L. Shao, P. Sribandilmongkol, D. Santos and G.A. Tejovs, Dept. of Pharmacology, College of Medicine, Ohio State University, Columbus, OH 43210.

We have recently observed that met-enkephalin may be involved in the inhibition of morphine tolerance and dependence by diazepam (Sribandilmongkol et al. 1993). In previous studies, cyclic AMP may also play an important role in this phenomenon. Male Sprague-Dawley rats were made tolerant-dependent by s.c. implantation of six morphine pellets. Diazepam (0.25 mg/kg body wt.) was injected i.p. in some rats. Control rats were implanted with placebo pellets and injected daily with saline or diazepam. Morphine tolerant rats were sacrificed 1 h. after injections. Abstinence was induced by injecting s.c. naloxone (10 mg/kg) and withdrawal effects were observed for 30 min. There was no change in cyclic AMP levels in hypothalamus, striatum or cortex of morphine-tolerant animals compared to rats given placebo. Diazepam had no effect on cyclic AMP levels in these animals. Morphine abstinence rats showed a significant increase in cyclic AMP levels in striatum (71%), cortex (126%) compared to placebo treated rats. This increase in cyclic AMP levels preceded the morphine abstinence abstinence rats injected with diazepam. It is concluded that cyclic AMP may be involved in the inhibition of morphine dependence by diazepam.

ABSTINENCE PRECIPITATED BY NALOXONE FOLLOWING A SINGLE DOSE OF MORPHINE: POTENTIATION FOLLOWING A SECOND EXPOSURE. G.J. Herbert, G.F. Koch, and O. Schultes, Dept. of Neuropharmacology, The Scripps Research Institute, La Jolla, CA 92037.

Recent studies in humans with no prior history of opiate abuse reported naloxone-precipitated withdrawal signs following a single exposure to morphine, and this effect was markedly enhanced following a second morphine exposure (Avrontza et al., Psychopharmacology, 114:71, 1994). In a recent report using an established animal model of this acute dependence-like phenomenon, the response disruptive effects of naloxone on opiate withdrawal were enhanced 4 hrs after a single injection of morphine, with a further potentiation of this effect following weekly exposures to morphine and naloxone for 2 months (Adams & Holtzman, J Pharmacol Exp Ther, 253:483, 1990). Using a similar operant procedure, the present study sought to determine if this increase in sensitivity to an opiate agonist could be detected after a single exposure only to morphine exposures, as seen with humans. Rats were trained to lever press for food on an FR-15 schedule of reinforcement. Rats were pretrained with morphine (2.5, or 10 mg/kg s.c.) followed 4 hours later by an injection of naloxone (0 - 3.0 mg/kg s.c.). Prior morphine administration dose-dependently increased naloxone's response disruptive effects relative to morphine-naive baseline, and this effect was markedly potentiated following a second morphine/naloxone exposure 7 days later. The current results confirm previous reports in humans and rats that withdrawal-like signs may be elicited following acute exposure to opiates, and demonstrate a potentiation of this effect with a second exposure. These findings suggest that the development of dependence on opiates as defined by the manifestation of precipitated withdrawal is a progressive phenomenon that may begin with a single dosing. Supported by grant DA04043.

Clonidine Antagonizes The Rewarding Effects Of Morphine Only In Opiate Withdrawn Rats As Well As The Aversive Effects Of Opiate Withdrawal Itself. K. Nader* and D. van der Kooy, Neurobiology Research Group, Dept. of Anatomy, Univ. of Toronto, Toronto, Ontario, MSS IAR.

Lesions of the brainstem tegmental pedunculopontine nucleus block morphine rewarding effects in drug-naive animals. Conversely, dopamine antagonists block the rewarding effects of morphine only in opiate deprived rats, as well as the aversive effects of morphine withdrawal itself. As clonidine, an α2-adrenergic receptor agonist, has been reported to antagonize the somatic signs of opiate withdrawal, we asked if clonidine would block the motivational effects of opiate withdrawal in rats as well as the aversive effects of morphine withdrawal itself. As clonidine, an α2-adrenergic receptor agonist, has been reported to antagonize the somatic signs of opiate withdrawal, we asked if clonidine would block the motivational effects of opiate withdrawal in rats as well as the aversive effects of morphine withdrawal itself, but did not affect morphine place preferences (2 and 20 mg/kg) in previously drug naive rats. These results suggest that the motivational system activates those dopaminergic and noradrenergic components that are in series with each other. Furthermore, clonidine blocked the acquisition of morphine (15 mg/kg), but not LiCl (15 mg/kg), conditioned taste aversions. Given that dopamine antagonists also block morphine, but not LiCl, conditioned taste aversions, we suggest that the aversive effects of both opiate withdrawal and morphine conditioned taste aversions are mediated by the same neurobiological substrates.

503.10

There are few reports on the morphine withdrawal syndrome in the developing animal. In this study, we examined the behavioral effects of precipitated withdrawal in morphine dependent 7, 14, 21, and 42 day old rats. On the first treatment day group, different litters were removed from the dam (except for preweaning rats which were housed separately) and individual rats were injected with morphine sulfate (10 mg/kg, i.p., b.i.d., 7 day-old pups also received a dose of 3 mg/kg, i.p.) for 6.5 days. Controls included saline injected groups. The last injection was on the morning of the 7th day. For preweaning rats, two hours after the last morphine injection, each subject received one of several doses of naltrexone (0, 0.3, 1.0, 3.0, 10.0, mg/kg) and observed in a blind manner with the remainder of the litter for a total of 20 minutes. Ongoing behaviors were recorded every 15 seconds. When the observation period ended, the pup was anesthetized and placed back into the observation chamber with the remainder of the litter. Preweaning rats were tested individually on fresh bedding in the same manner as preweaning pups. Naltrexone injected pups that had been chronically treated with morphine displayed greatly increased specific behaviors and were activated. The results also show that morphine abstinence animals demonstrate withdrawal behaviors that are appropriate to the age group examined. For example, morphine abstinence 7 day-old pups show increased head movements, rolling, wall climbing, and paw movements. Morphine treated 42 day-old animals displayed the classic adult-like behaviors. These results clearly show that a morphine withdrawal-like syndrome can be described in the very young rat and that this syndrome is reflective of the specific behavioral repertoire appropriate to the age of the animal. CLOCINNAMOX STUDIES IN MORPHINE-TOLERANT AND NONTOLERANT RATS TRAINED TO DISCRIMINATE MORPHINE. E.A. Walker*, T.M. Richardson, Y. Wu and A.M. Young, Dept. of Psychology, Wayne State Univ., Detroit, MI 48202.

The effects of irreversible opioid antagonist clocinnamox (C-CAM) on morphine (MS) and fentanyl (PT) were compared in rats before and after repeated injections of MS to determine the role of agonist efficacy in tolerance. Male, Sprague-Dawley rats (n=20) were trained to discriminate 3.2 mg/kg MS from saline under a FR 15 schedule of food reinforcement. Cumulative doses of MS (0.32-10 mg/kg) or PT (0.0032-0.056 mg/kg) produced MS-appropriate responding and decreased response rates. In nontolerant rats, 10 mg/kg C-CAM decreased MS potency by 7-fold, but failed to significantly alter PT potency to produce MS-like stimulus effects. Repeated treatment with 20 mg/kg/day MS for 7-14 days decreased MS and PT potency to produce MS-like stimulus effects by approximately 4-fold. In these MS-tolerant rats, 10 mg/kg C-CAM further decreased MS and PT potency to produce MS-like stimulus effects by an additional 8-fold. No withdrawal signs were observed after C-CAM administration. Quantitative analysis of these data suggest that chronic opioid treatment may increase the apparent efficacy required for an agonist to exert MS-like discriminative stimulus effects. (Supported by DA03796 and KO2 DA00132).

SHORT-TERM TOLERANCE DEVELOPS BEFORE LONG-TERM TOLERANCE IN RATS. H. Burton and Catherine F. Cramer*, Dept. of Psychology, Dartmouth College, Hanover, NH 03756.

The development of tolerance to morphine analgesia was investigated in three different series with the experimental paradigms of "short-term" and "long-term" mechanisms. "Short-term" tolerance occurs with closely spaced injections of high doses, whereas, "long-term" tolerance is produced by low to moderate doses at widely spaced intervals (Taylor & Baker, 1985). In the first two experiments Long-Evans hooded rats received i.p. injections beginning on Day 1 and continuing through Day 7. Animals in one condition received on each day the injection, pups were tested for latency to retract a hindpaw from a 5°C hotplate. On Day 7 the animals were divided into four groups; first group received saline, second group received on the day of the test 10 mg/kg of morphine and were tested for analogue 20 min. following the injection. The saline condition was 10 mg/kg naloxone and a saline control. These groups were then tested for hyperalgesia, weight changes (1 and 4 hours postinjection) and locomotor behavior.

In Experiment 1, pups received 0.1, 0.2, 0.5, 1.0 or 10.0 mg/kg of morphine once a day on Day 1 and the results from four groups (2 followed by the effects of withdrawal itself) were analyzed. In Experiment 1, the exception that dosages were 0.6, 1.0, 3.0, 15.0 mg/kg, twice daily, 8 hours apart. In Experiment 3, the pups also received two daily injections of either 0, 0.6, 1.0, 3.0, or 10.0 mg/kg of morphine but were tested on Day 3. In Experiment 1, the results from each condition was compared to the baseline condition. Under long-term parameters tolerance was not observed at Day 7. The results of Experiment 2 show shifts in the affective indicators of tolerance. Withdrawal was not observed in either of the first two experiments. In Experiment 3, a shift in the dose-response curve was observed on Day 3 and withdrawal and baseline were indicated by both hyperalgesia and hyperactivity.

In sum, neonatal rats seem capable of short-term, but not long-term, tolerance during the first week, perhaps due to the nonassociative properties of the short-term paradigm.
MORPHINE WITHDRAWAL IMPAIRS ACQUISITION OF A MORRIS WATER MAZE TASK: POTENTIAL INVOLVEMENT OF STRIATAL MEDITORY. K. D. Olenic, T. J. Walsh, K. Crenshaw, S. Bailey. Rutgers University, New Brunswick, NJ 08901; *GUNN, Piscataway, NJ 08854. Behavioral and neurochemical changes in rats during early and longer-term morphine withdrawal were investigated. Experimental subjects (M) were implanted with osmotic pumps (8.75 mg/240 /µL/day over 7 days). Controls (C) received sham implants of similar size and weight. One or 21 days following pump removal, subjects were tested in for 8 days in a Morris water maze (MWM) task. Rats were sacrificed and high affinity choline transport was assessed in the hippocampus (HPC) and striatum (STR). M subjects exhibited a significant decrease in body weight during withdrawal that recovered by 21 days after pump removal. M subjects trained during early withdrawal exhibited significantly longer escape latencies due to a possible failure of procedural memory. However, during sequential probe trials these subjects exhibited a significant preference for the target area and accurate search strategies suggesting intact declarative memory. Nine days after removal of the osmotic pumps, NACH in M subjects was elevated in the STR but not in the HPC. M rats trained during longer-term withdrawal exhibited no deficits in any measure of NACH performance. NACH in these rats was comparable to C levels in both the HPC and STR. Early morphine withdrawal was accompanied by increased striatal NACH and impaired NAM acquisition.

TOLERANCE AND CROSS-TOLERANCE TO CANNABINOID LIQUIDS AFTER CHRONIC ADMINISTRATION OF ANANANDAMIDES. E. Frise and R. Mechoulam, The Hebrew University of Jerusalem, Israel. The development of tolerance to cannabinoid receptor ligands has been well established. However, it is now known whether repeated injections of the recently discovered endogenous cannabinoid ligands, also induce tolerance to subsequent administration of anandamides or cannabinoid drugs. Ten daily injections (p.o.) of anandamide (20, 40, 80, 160, and 400 mg/kg) were administered to adult female C5/BL mice. Twenty-four hr after the last injection, animals were challenged with 20 mg/kg of MOR on a 5TH cycle and tested for a latency of response to 5TH. These results indicate that repeated administration of anandamides induces tolerance to cannabinoid receptor ligands. Further, the tendency for increased sensitivity to 5TH after chronic administration of a very low dose of ana- 

ELEVATIONS AND PHASIC FLUCTUATIONS IN NUCLEUS ACCUMBENS DOPAMINE (DA) DURING IV HERON SELF- ADMINISTRATION. D. Poblocki, K. Lebo, and R. A. Wise. Cr Stud Behav Neurosci Montréal, PQ Canada H3G 1M8. Fluctuations in extracellular nucleus accumbens DA and DOPAC levels were measured in 4-min microdialysis samples from rats engaged in IV heroin self-administration. DA levels were elevated to 200-400% of baseline during self-administration, fluctuating phasically between responses. Each injection caused a short-latency increase in DA levels; a second increase preceded the next lever-press. Drug requests (lever-presses) normally occurred well before DA levels fell to near-normal levels. DOPAC levels increased in the first minutes and remained elevated during the period of drug availability, showing no significant fluctuations that were time-locked to the response cycle. These observations confirm that self-administered IV doses of heroin are sufficient to cause the next lever-press. Drug requests (lever-presses) normally occurred well before DA levels fell to near-normal levels. DOPAC levels increased in the first minutes and remained elevated during the period of drug availability, showing no significant fluctuations that were time-locked to the response cycle. These observations confirm that self-administered IV doses of heroin are sufficient to cause the next lever-press.
DIFFERENTIAL EFFECTS OF DOI ON COCAINE (COC) AND MORPHINE (MOR)-INDUCED EXTRACELLULAR DOPAMINE (DA) RELEASE IN THE NUCLEUS ACCUMBENS (NA) D.L. Williams*, J. Ishikawa, J.A. Garcia, J. Dai and H.L.Y. Melzer. Department of Psychiatry, Case Western Reserve University, Cleveland, Ohio 44106

There is previous evidence that blockade of 5-HT2 receptors can inhibit the effect of COC and MOR to increase extracellular DA in the NA. The purpose of this study was to determine if DOI, a direct acting 5-HT2A/2C agonist, can influence the effect of COC and MOR on extracellular DA in the NA in awake rats using microdialysis. The systemic administration of DOI (2.5 mg/kg, s.c.) alone had no effect on basal extracellular NA DA levels. COC (10 mg/kg, i.p.) produced an increase in extracellular DA in the NA of 333% over baseline. Pretreatment of rats with DOI 30 min. prior to the administration of COC did not significantly alter the increase in extracellular DA produced by COC. MOR (5mg/kg, s.c.) produced an increase in extracellular DA in the NA of 206% over baseline. DOI pretreatment 30 min. prior to MOR inhibited the MOR-induced increase in extracellular DA. These findings suggest that MOR and COC-induced increases in extracellular DA in the NA are regulated differently by the activation of 5HT2A/2C receptors. The ability of DOI to suppress MOR-induced DA release in the NA suggests that non-hallucinogenic 5-HT2 agonists may have a role in the treatment of addiction.

EVIDENCE FOR A WITHDRAWAL SYNDROME FOLLOWING CHRONIC ADMINISTRATION OF AN ANABOLIC STEROID TO RATS. Katherine R. Benson, Nancy A. Carrick* and Dennis L. Murphy. Laboratory of Clinical Science, National Institute of Mental Health, Building 10, Room 3D41, 9000 Rockville Pike, Bethesda, MD 20892.

In the past decade, anabolic steroids have been recognized as drugs of abuse, especially among athletes and body builders. Chronic administration of testosterone and other androgens has been shown to induce behavioral changes in rats and in humans which includes increases in aggression and alterations in mood. A putative withdrawal syndrome following chronic self-administration of anabolic steroids has been described in humans but has not been demonstrated experimentally in either humans or rats. The present study shows that distinct behavioral effects emerge in two strains of rats following withdrawal from long-term but not short term administration of testosterone propionate (TP) (30 mg/kg/day). In both Wistar and Fawn-Hooded rats, withdrawal from TP following ten weeks of daily administration induced a behavioral syndrome characterized by facial tremor, head- weaving, full-body lurches and dizziness. This syndrome appeared to be of a greater intensity in the Fawn-Hooded strain. These behaviors subsided within two weeks of withdrawal from the androgen. There were no significant changes in temperature, food intake or body weight over the same period. In comparison, three weeks of daily TP administration did not produce a consistent behavioral syndrome following withdrawal in either Wistar or Fawn-Hooded rats, although there was a significant increase in yawning behavior. These results show evidence for the first time of a withdrawal syndrome in rats following chronic administration of high dose anabolic steroids.

THE LOCAL CEREBRAL METABOLIC EFFECTS OF MORPHINE SENSITIZATION IN THE RAT. M.A. Kraus*, J.M. Piper, R.T. Livsey and C. Kornetsky. Lab. of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

Repeated administration of morphine sulfate (MS) will sensitize a rat to oral stereotypic effects. The effects of this sensitization on local cerebral metabolic rate of glucose (LCMRglu) was determined in male F-344 rats. Rats were sensitized by four 10 mg/kg MS (sc) injections at 12 hr intervals. Two control groups were administered saline. One week later, the sensitized animals and one control group, morphine-control, were administered 0.5 mg/kg MS 10 min prior to the 2-[14C]deoxyglucose bolus. The second control group received saline in place of MS. LCMRglu in 49 brain sites was significantly greater in the sensitized rats than the morphine-control rats after the MS challenge. There also were increases in LCMRglu in sensitized animals compared to the saline-controls in a number of structures. These results suggest that MS sensitization involves increased metabolic activity in multiple brain systems including mesolimbic and motor structures. (Supported by Grants DA03236 and DA00099 to CK)

NICOTINE INCREASES MET-ENKEPHALIN CONTENT AND PREPROENKEPHALIN mRNA IN MOUSE STRIATUM. N.H. Nett*, R.K. Dhatt, T.A. Wemminger, C.A. Tejwani and M. Hadjiconstantinou. Dept.s of Pharmacology, Psychiatry and The Neurosciences Program, Ohio State University College of Medicine, Columbus, Ohio 43210.

Behavioral evidence suggests that opioids play a role in nicotine addiction. Indeed, naloxone reportedly can precipitate withdrawal behavior in animals treated with nicotine chronically. We now present evidence that acute or chronic administration of nicotine increases met-enkephalin immunoreactivity (Met-Enkli) in the mouse striatum. The response to a single dose of nicotine is time-dependent, with Met-Enk content reaching a maximum 30-60 min post-injection and returning to near normal by 6 hr. The nicotine-induced increase of Met-Enkli is blocked by pretreatment with the nicotinic antagonist mecamylamine, but not by the muscarinic antagonist atropine. Daily administration of nicotine for 2 weeks also increases striatal Met-Enkli. In addition to increasing Met-Enk content, chronic nicotine increases preproenkephalin mRNA in the striatum when assayed after 7 or 14 days of treatment. We postulate that nicotine addiction is associated with enhanced brain content of opioids which could explain withdrawal behavior when nicotine addicted animals are treated with naloxone.

THE EFFECT OF NALOXONE, MORPHINE, AND THEIR COMBINATION ON LOCAL CEREBRAL METABOLIC RATES FOR GLUCOSE IN THE RAT. C. Kornetsky*, M.A. Kraus and J.M. Piper. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

In a present experiment used 2-deoxy-D-[14C]glucose (2-DG) to determine the effects of naloxone (NX), morphine sulfate (MS), and the combination treatment of NX-MS on local cerebral metabolic rates for glucose (LCMRglu) in rats. Four groups were studied (N = 18) saline, NX, MS, or NX-MS. One day prior to the NX-MS, NX by itself, significantly decreased LCMRglu in the locus coeruleus, a structure believed to be involved in the expression of opiate withdrawal, suggesting a role of endogenous opioids in the regulation of central noradrenergic activity. Also, NX significantly increased LCMRglu in the mediodorsal thalamic nucleus which has extensive reciprocal connections with the limbic system and prefrontal cortex, suggesting an impact on the integration of limbic and cortical activity. Finally, NX blocked the inhibitory effects of MS on LCMRglu. (Supported by Grants DA03236 and DA00099 to CK).

MOLECULAR MODELING OF ANANDAMIDE V.M.
Showalter and M.E. Aboud* Dept. of 
Pharmacology and Toxicology, Virginia Commonwealth
University, Richmond, VA 23298.

Other investigators have utilized molecular modeling to 
gain more insight into how cannabinoid ligands bind to 
their receptor. Anandamide (arachidonylethanolamine) is thought 
to be the endogenous ligand at cannabinoid receptors. The 
purpose of this study was to extend the cannabinoid 
pharmacophore to include anandamide. The structures of 
cannabinoid ligands were modeled using SYBYL. The 
structure of arachidonylethanolamine (anandamide, AEA) was 
constructed based on x-ray crystal data for 9-THC. 
The structure of anandamide was generated by adding 
ethanolamine to the cannabinoid acid, 

A9-THC. A linear 
systematic search was performed to find the 

504.5
CHARACTERIZATION OF A CANNABINOID RECEPTOR IN 
THE ROUGH-SKIN NEWT, K. Soderton*, F.L. Moore*, P.H. Franklin* 
and T.V. Murray. College of Pharmacy, and Department of Zoology, 
Oregon State University, Corvallis OR 97331

Binding of the synthetic cannabinoid [3H]CP-55940 to membranes 
prepared from brains of rough-skinned newts (Taricha granulosa) 
was investigated using a rapid filtration 
assay. Binding equilibrium was reached 
by 480 min at 15°C. Specific binding was saturable whereas non-specific 
binding (determined in presence of 10 μM levonantradol) was linearly 
related to [3H]CP-55940 concentration. Saturation 

isotherms provided a Kd value of 10.5 nM and Bmax of 1.64 pmol/mg protein. 

Estimates of Ki obtained by kinetic analyses agreed with equilibrium 
saturation results. Competition experiments using unlabeled 
CP-55940 and levonantradol 
yielded Ki values of 8.6 nM and 5.9 nM respectively. Affinity differences 
between the amphibian receptor and values previously reported for the rat 
(0.2-4.0 nM) may be explained by differences in incubation temperatures; 
15°C for the newt vs. 30°C for the rat. Using a rat brain membrane 
preparation we found that Ki varied inversely with temperature; 

Kd = 12.5, 6.5, and 3.9 nM at 15, 15, and 30°C. Behavioral experiments suggest that 
the cannabinoid binding site has physiological relevance. News treated 
with 5 μg of levonantradol IP displayed significantly decreased locomotor 
activity (measured in crossings of lines painted on a testing-arena floor 
during a three minute period). Treated animals averaged 4.1 line crossings vs. 11.4 in 
vehicle controls (p < 0.01, 2-tailed t-test). These data 
suggest that rough-skinned newt is a useful system for the 
study of cannabinoid pharmacology.

504.6
ANANDAMIDE AND Δ9-THC DILATION OF IN VIVO CEREBRAL 
ARTERIOLES IS BLOCKED BY INDOMETHACIN. S. F. Moore, K.A. 
Withgottby and E.F. Ellis Department of Pharmacology and Toxicology, 
Medical College of Virginia, Richmond, VA 23284-2913

An endogenous ligand of the Δ9-THC receptor, arachidonylethanolamine (anandamide, AN) has been shown to cause some behavioral 
and physiological alterations similar to those induced by Δ9-THC. We 
investigated the effect of increasing, topically applied doses (10-12, 10-13 M) 
of AN and Δ9-THC on in vivo cerebral arterial diameter using the acute cranial 
window technique in anesthetized rabbits. Both AN and Δ9-THC induce a dose-dependent dilation, with Δ9-THC being more 
active at doses as low as 10-11 M. Dilation by both agents was completely 
blocked by topical application of the cyclooxygenase inhibitor 
indomethacin. Superoxide dismutase plus catalase, which block cyclooxygenase-dependent dilation produced by bradykinin or arachidonic acid, 
were inactive on AN- and Δ9-THC-induced dilation, implying dilation 
is not via vasoactive, dilator oxygen radicals. HPLC analysis of Δ9-THAN passed 
under the cranial window showed approximately 20% metabolism to Δ9-
arachidonic acid (AA). Following IV injection of Δ9-THAN in mice both Δ9-THAN 
and Δ9-AA were found in brain. Reported increases in cerebral blood flow 
caused by marijuana may be related to formation of brain eicosanoids. 
Endogenous AN may modulate cerebral blood flow.

Supported by DA 07007 and a Javits Neuroscience Investigator Award.

504.7
BINDING OF [3H]MK-801 TO BRAIN REGIONS AND SPINAL 
CORD OF MICE AND RATS TREATED CHRONICALLY WITH 
MORPHINE. Krishnamurthy P. Gadhadhith*, Poluru L. Reddy 
and Hemendra N. Bhargava, Dept. Pharmacometrics and 
Pharmacodynamics, Univ. Ill at Chicago, Chicago, Ill. 60612

The effect of morphine tolerance-dependence and abstinence on the 
binding of [3H]MK-801 to brain regions and spinal cord of mice and 
rats was determined. Male Swiss-Webster mice and Sprague-Dawley 
rats were rendered tolerant-dependent by implanting a pellet (mice) 
containing 75 mg of morphine base for 3 days and 6 pellets during a 
7-day period (rats), respectively. In tolerant-dependent animals, the 

pellets were left intact where in abstinence animals pellets were removed 
6 hr (mice) and 16 hr (rats), respectively, before sacrificing. In the absence of 
glucocorticoids, the binding (Rm) of [3H]MK-801 was 
decreased by 10% in the cerebral cortex of morphine tolerant but not 
in the abstinence rats. In the presence of glucocorticoids, the binding 
was decreased in midbrain and spinal cord of tolerant rats, 
and in hypothalamus, midbrain and spinal cord of morphine 
atabstinent rats. In morphine tolerant mice, the binding of [3H]MK-801 was 
decreased in pons-medulla and hypothalamus but was increased in spinal 
cord. In morphine abstinent mice, the binding of [3H]MK-801 was 
increased in hippocampus. It is concluded that chronic treatment of 
mice and rats with morphine produces differential effects on central 
NMDA receptors. Additionally, different changes are seen when the 

binding is done in the absence or presence of glucocorticoids and glutamate 
(Supported by a Research Scientist Development Award K02-DA-00130 
from the National Institute on Drug Abuse).

PRENATAL EXPOSURE TO MORPHINE ALTERS BRAIN μ OPIOD 
RECEPTOR CHARACTERISTICS IN ADULT FEMALE RATS. 
Agnes Rimaniclay* and Ilona Vathy*. Dept. Psychiatry, Albert Einstein 
College of Medicine, Bronx, NY 10461. Dept. Psychiatry, A. Sz-Gyorgyi Medical 
School, Szeged, Hungary.

The present study investigated the opioid binding characteristics of 
membranes from different brain regions of adult female rats exposed to morphine 
in utero (10 mg/kgpricwice daily on days 11-18 of gestation). Females 
were overanesthetized (OVX) at least one week prior to sacrifice, and some females 
were injected with 3 μg of estradiol benzoate (EB) 48 hours before sacrifice. 
Saturating binding assays were carried out using the N labeled, highly selective 
ligand D-Ala-Gly-N-Methyl-Phe-Gly-ol (DAMGO) to label μ opioid receptors. 
The maximal binding capacity (Bm) and affinity (Kd) were estimated in the 
hypothalamus (HYP), preoptic area (POA), frontal cortex (CX), striatum 
(STR), ventral parietal area (YTA) and cerebellum (CER). Prenatal exposure 
to morphine reduced the Bm and the Kd about 25% in the HYP of OVX 
females when compared to OVX, saline-treated females. A 3 μg EB injection 
increased the Bm and the Kd about 25% in the HYP of morphine-exposed 
females without affecting saline-treated females. These effects of prenatal 
morphine were not apparent in either the Bm or the Kd in the POA, CX, STR, 
YTA or CER. The increase in hypothalamic μ receptor binding capacity 
in prenatally morphine-exposed females in response to estrogen treatment may 
be related to the deficit seen in adult sexual behavior of prenatally morphine-
exposed females in a previous study (Vathy and Katay, Dev. Brain Res., 
68:125-131, 1992). Supported by DA 05833 awarded to IV.

S05.4

Toluene (T) is inhauful for its euphoric effects. We reported that T markedly enhanced evoked responses elicited by single pulses in the hippocampal slice preparation (Neurosci. Abstr. 19(2), 1,461, 1993). This effect was antagonized by GABA and muscimol. To explore further the interactionsee pharmacology, we also examined the effects of T on responses elicited by paired-pulses and its interaction with compounds affecting the GABA and GLU neurotransmitter systems. Responses were elicited by paired-pulse stimulation (0.1 Hz) of Schaffer collaterals in the stratum radiatum were recorded from pyramidal cells of CA1 area in transverse hippocampal slices from mice. Paired stimuli, separated by an interstimulus interval (ISI), were delivered temporally interopposite with the single-pulse train. In this paradigm, there was an increase in the response to the second relative to the first pulse (facilitation). T enhanced paired-pulse facilitation. This enhancement was antagonized by GABA and muscimol, but not by baclofen. The competitive NMDA antagonist CGS-17955 was without effect on T-enhanced facilitation; however, T was markedly enhanced paired-pulse facilitation, suggesting a residual effect of T. CNQX, an antagonist at the quisqualate site, blocked the response to single- and paired-pulses, alone and with T. After washout of CNQX and T, the response to single pulses partially recovered, whereas paired-pulse facilitation was markedly enhanced. These results further characterize the modulatory influences of other systems in the brain, possibly related to its psychoactive effects.

DEVELOPMENTAL: CORTICAL INJURY MODELS

S05.1

We have been using the rabbit with chronic kaolin-induced hydrocephalus to assess the factors determining ventricular septum opertational shunting for infantile hydrocephalus. To this end we have been monitoring the levels of behavioral, biological, cervical and anatomical toxicants in the serum of the operated and non-operated animals. In the current study the effects of hydrocephalus on the levels of tyrosine, tryptophan and SHAA were determined by HPLC with Fluorometric detection in 6 day old normal (N=14) and in 26 to 69 day old hydrocephalic (N=11) rabbits. Samples of cerebrospinal fluid (50 & 100 µl) were obtained after percutaneous injection in the cisterna magna or directly from the lateral ventricle at the time of sham insertion. Samples were stored at -80°C until processed. The hydrocephalic rabbits showed significant decreases in both tyrosine and tryptophan levels and a highly significant increase in the serotonin metabolite SHAA. There was a significant positive correlation between the intracranial pressure (ICP) and the increase in SHAA, but not with the other two amino acids. These data suggest that the increased ICP adversely affects the mechanism of removal of the serotonin metabolite from the cerebrospinal fluid.

S05.2

Rabbits with chronic kaolin-induced hydrocephalus have few neurological deficits despite profound ventriculomegaly. We report here both structural and metabolic sparing in the somatosensory cortex in chronic untreated animals. Hydrocephalus was induced at 4-6 days of age. Control (N=15) untreated hydrocephalic animals were sacrificed at 4-6 days of age. Treatment (N=15) rats were sacrificed at 40, 60 and 90 days. Upon sacrifice, brains were processed by coronal sections and/or analysis of the whole brain. The brains were processed for quantitative 2-deoxy-D-glucose autoradiography and cytochrome oxidase (N=193), stained with cresyl violet for somatosensory cortex barrel fields (N=14), or silver impregnated for quantitative neuronal golgi (N=8).

High resolution morphometric and oxidative metabolism were significantly higher in the chronic hydrocephalic group than normal, with the highest metabolic activity in the outer cortical layers in both groups, while the lowest activity was seen in the white matter. The organization of the barrel fields in the facial cortex of the chronic hydrocephalic group was preserved. The areas of the individual fields were significantly larger in the hydrocephalic than in the normal littermates. Shunted animals showed intermediate sized fields. In the hydrocephalic the apical dendrites of the layer IV neurons remained perpendicular to the cortical surface, but the dendritic shafts were thickened and the spines much more prominent. These data show that with sufficient ventriculomegaly, the structural organization of the cortex is maintained, and there is considerable functional activity in the cortical mantle of the chronic hydrocephalic rabbit.

S05.3

Hydrocephalus in childhood is marked clinical improvement but little is known about the cellular effects of hydrocephalus and the response to shunting. In this study we examined the effects of hydrocephalus and treatment with formation in postnatal and early stages of development. In this study we examined the effects of hydrocephalus and treatment in pediatric hydrocephalus rats (p=7) at 21 days of age and from age-matched control (n=6) and hydrocephalic (p=6) rats at 21 days. The brains were fixed in 10% formalin and embedded in paraffin. Sections were stained by cresyl violet and Nissl and were evaluated histologically. The results showed that hydrocephalic and shunted rats had similar tissue morphology and cytoarchitecture compared to control. However, there were differences in the distribution of neurons in the cortex and in the subcortical structures. The results indicate that the effects of hydrocephalus on the brain are not as severe as previously thought and that the effects of treatment are beneficial.

S05.4

HIGH RESOLUTION 1H-NMR ANALYSIS OF CEREBRAL CORTEX FROM CONTROL AND HYDROCEPHALIC H-TX RATS. N. G. HARRIS, R. A. INGOLD, R. C. JONES, R. W. BROWN. Dept. of Pharmacology, Biochemistry and Radiology, University of Florida, Gainesville, FL 32610 USA.

The H-Tx rat develops hydrocephalus in late gestation due to an obstruction of the cerebral aqueduct and if left untreated, affected animals die within 4-6 weeks after birth. By 21 days there is gross lateral ventricular expansion and severe cortical thinning with abnormal cell morphology. Cerebral glucose metabolism and blood flow (CBF) are greatly reduced so that in some areas CBF is below the ischemic threshold. Although many of these gross pathophysiological changes are reversible by the placement of a ventriculocisternostomy shunt soon after birth, it is not known to what extent the shunted brain is able to function normally. In an attempt to provide baseline information on the more discrete, biochemical changes that occur in the untreated hydrocephalic rat cortex, we have used high resolution 1-dimensional 1H-NMR spectroscopy to analyze cerebral extracts of cortex prepared by the freeze-focused technique using spontaneously-breathing control and hydrocephalic rats at 21 days after birth (n=4-8). Many cerebral metabolite concentrations in the hydrocephalic cortex were significantly reduced from control. N-acetyl aspartate (NAA) at 2.02ppm was 1.50±0.04µmol/g wet weight (means±SEM) in the hydrocephalic cortex compared to 3.90±0.17 in the control (P<0.01), creatine/phosphocreatine at 3.06ppm was 2.60±0.13 and 19.30±3.2 (P<0.01) in hydrocephalic and control cortex respectively and lactate at 3.44ppm was 3.60±0.51 and 7.60±0.79 (P<0.01). The following metabolites were also significantly reduced: alanine, glutamate, aspartate, glycerophosphocholine/ phosphocholine, inositol. These results confirm our previous measurements of a disrupted cortical metabolism and further indicate that the biochemistry of the hydrocephalic cortex is severely disturbed. This data establishes a good baseline from which subtle differences in the biochemistry of the shunted hydrocephalic cortex can be investigated.
CONJUNCTIVE EYE MOVEMENTS IN CEREBRAL PALSY.
M.E. Garek, S. Lee, and H. Zhang. Dept of Psychology and Biomedical Engineering Program, California State University, Sacramento, CA 95819.

Do the conjunctive movements of the eyes in cerebral palsy (CP) differ from the normal? If so, this deficit would affect visual sense in CP. The right and left eye positions of 6 CP and 6 normal (N) adults were measured using the videoelectrooculogram (VEOG) (Micromeasurements, Inc., Farmington CT). Square, sine and triangle waveforms in the time domain were utilized for 24, 10sec tests of horizontal and vertical saccadic and pursuit movements (0.5, 0.5 Hz; +4, -8 degrees). The pooled mean coefficient of determination (r²) for right and left eye positions across all tests for N ranged from 0.96±0.03 to 0.96±0.006 and for CP from 0.80±0.24 to 0.90±0.08. The mean r² was significantly lower for CP than N on all tests (Mann-Whitney U=p<0.02) except for horizontal saccades. The degree of binocularity across CP subjects did not coincide with the severity of the disorder. While the final common path for coupling the two eyes' positions may be in the tegmentum and pons, these results indicate that this visuomotor feature is not necessarily conserved in CP and its contribution to saccadic and pursuit movements may be critical.

DEVELOPMENTAL DISORDERS: CORTICAL INJURY MODELS

Focal development neocortical anomalies, including molecular layer ectopies and microgyria, are associated with developmental outcome. In an attempt to further test the dissociation of the behavioral effects of autoimmunity and of cortical malformation we induced ectopies (with punctate wounds) and microgyria (with freezing lesions) in the neocortex of one-day-old mice without immune disorders. DBA mice received either a puncture wound or freezing lesion of either the left or right hemisphere. Some mice received sham surgery. Compared to sham-operated animals, mice with either puncture wounds or freezing lesions performed poorly in discrimination learning, in a spatial Match-to-Sample task, and in a Lashley Type III maze. In shuttlebox avoidance conditioning, in which immunological disorder diminished performance, there was no difference between lesioned and sham animals. These results (1) support the dissociation between the effects on behavior of developmental neocortical anomalies and autoimmune disease, (2) point out similarities between spontaneous and induced neocortical malformations, and (3) fail to support behavioral differences between ectopies and microgyria.

505.12 DIFFERENCES IN NEURONAL AND GLIAL MORPHOLOGY IN HUMAN SUBSTANIA NIGRA IN INTRA-UTERINE GROWTH RETARDATION (IUGR) AND COT DEATH CASES. J.C. van Velen, M.A. Brown, and E.Markova, Brain Research Institute, 5 Okbaha, 103604 Moscow, Russia & 'Dept of Fetal and Infant Pathology, University of Liverpool, L69 8)U, UK.

Free-floating sections of the mid-brains of 5 control, IUGR and cot death cases for each of three postnatal ages, 1 week, 4 weeks, and 4 months, were prepared for Golgi staining, Braingenberg modification. In addition to the 1 week group immune-histochemical stained for GAP-43 and TH. Qualitatively abnormal changes in Golgi stained dendrites, including varicosities, enlarged shafts of dendrites and aneurysm-like changes, were noted in the IUGR and cot death groups, which were similarly affected. Many neurons showed growth cone-like dendric endings and also filopodium-like thin dendrites arising from soma or proximal dendrites.

60 neurons from each case were measured, using a Leitz Orthoplan 3-D system. In both pathological groups a significant reduction in lengths of total dendritic tree, unbranched dendrites and terminal dendritic segments was revealed. In addition there was a reduction in the maximal radius of the dendritic trees in the IUGR and cot death groups compared to control.

A significant reduction in soma size of TH positive neurons with a concomitant increase in soma size of GAP-43 positive astrocytes was measured in IUGR and cot death groups compared to control.

The data suggests the presence of delayed maturation and pathological changes in SN neurons and a hyperexcitic astrocytic reaction, possibly associated with chronic hypoxic conditions during prenatal development. These results support the known clinical association between IUGR and cot death. It also may be relevant to findings of behavioral changes and impairment of cognitive function in groups of low birth weight infants.

EPILEPSY: ANTICONVULSANT DRUGS—AMPA AND NMDA RECEPTOR

Brain slices (350 µm) from the hippocampus of Long-Evans hooded rats were used. The control slices were incubated in ACSF, and all slices were incubated in ACSF containing 100 µg/ml valproic acid for 20 mins. After the treatment, slices were washed in Tris-HCl buffer, and prepared for PKC phosphorylation assay (Brain Res. 524 (1990) 144-148). Under the treatment of valproic acid, the cytosol PKC activity was 279 µg/mg/min (decreased about 35%); and the membrane PKC activity was 44 µg/mg/min (decreased about 27%). Valproic acid had a tendency to suppress PKC activity in both membrane and cytosol components.

506.2 SUPPRESSION OF REFRACTORY STATUS EPILEPTICS BY US4494A AND DIAZEPAM IN THE LITHIUM-PICOPIRINE MODEL IN RAT. A. Henderson, YMC West Los Angeles, Los Angeles, California 90073.

Treatment of clinical status epilepticus (SE) is frequently unsatisfactory; many cases are refractory to treatment or develop serious adverse events. We have utilized the lithium-picopirone SE model to investigate potential new therapies. In this model rats pretreated with LiCl (3 mg/kg ip) develop SE after picopirone is injected (30 mg/kg ip). Once ECoG-recorded continuous fast spiking is attained the SE is highly refractory to all conventional SE therapies.

US4494A has been shown to antagonize seizures in several models, but does not possess the sedative properties of the related kappa opioid agonist US4488H. We found that US4494A, 24-30 mg/kg, injected iv over 1 to 15 minutes (n=12) converted fast continuous spiking to periodic epileptiform discharges (PED). Higher doses that stopped all epileptiform activity with subsequent recovery of the rat (n=7). Diazepam administration after lower doses of US4494A that did not cause PEDs did not stop the (n=6). The combination of US4494A and diazepam thus is effective in stopping SE in this model of refractory SE. Supported by Upjohn.

AICI is a novel anticonvulsant drug that is efficacious in a wide variety of seizure models. AICI is a hybrid (a Na channel blocker and MK-801 an NMDA receptor un-competitive antagonist) and appears to have anticonvulsant activity consistent with both antagonistic activities. While the NMDA antagonist activities of this compound have been characterized electrophysiologically (Rogawski et al., J. Pharm. Exp. Ther., 1991) the direct evidence is available concerning AICI's activity as a Na channel blocker. In the present series of experiments, the sodium channel activity of AICI and its antagonists were evaluated using the whole cell patch-clamp technique in a cell line (NE1-115) in which TTX sensitive Na currents were isolated using the following recording conditions: external (in mM): 100 NaCl, 25 TEA, 1.8 CaCl2, 5 MgCl2, 1 MgCl2, 1 CoCl2, 25 glucose, 5 HEPEs, pH 7.35; internal (in mM): 150 ClO4, 4 MgATP, 0.6 GTP, 5 EGTA, 10 HEPEs, pH 7.35. AICI was found to block Na currents in a manner similar to that of carbamazepine. Both drugs were -5 fold more potent as blockers at -85 mV than at -85 mV. Similar to carbamazepine, AICI shifted the h, curve of the Na channels in a hyperpolarizing direction and showed a use dependent block of current amplitude. No differences were observed in the whole cell channel activity among (1AMDC) and its two (+ and -) enantiomers. 100 µM of the NMDA antagonist, -MK-801, had no detectable effect on Na currents. These findings suggest that the spectrum of anticonvulsant activity of AICI is not due to its interaction at TTX-sensitive Na channels in addition to its NMDA antagonistic activity.

Competitive AMPA receptor antagonists protect against convulsions and neuronal injury in animal models. LY293558 is (S-2-amino-3-(3-hydroxy-5-methylisoxazol-4-yl) propionic acid) receptor antagonist. In this study, the anticonvulsant and behavioral effects of LY293558 were evaluated following intravenous administration (1,3, or 10 mg/kg) in CD-1 mice. Convulsive thresholds for intracerebral administration of S-AMPA, electroshock and pentyleneetetrazol were dose-dependently increased. Clinical observations at higher doses included labored breathing (3 and 10 mg/kg), ataxia, hyperreactivity or hypoactivity (10 mg/kg). No overt clinical observations were noted at 1 mg/kg. LY293558 produced quantitative reductions in spontaneous and nonambulatory activity levels at 10 mg/kg. In addition, sensorimotor reactivity was decreased at the high dose of 10 mg/kg. Muscle tone and tremor in the hindlimbs were not affected by LY293558 treatment. These data suggest that LY293558 has anticonvulsant activity in several animal models.
EPILEPSY: ANTICONVULSANT DRUGS—AMPA AND NMDA RECEPTOR

**506.5**

Several studies showed that DM exerts both anticonvulsant and proconvulsant effects depending on the experimental conditions. In this study, we examined the effects of DM on KA-induced cell loss in the hippocampal CA3 region in vivo and in vitro. DM was given intraperitoneally (i.p.) to male rats before KA treatment, and the hippocampal CA3 region was examined for cell loss and ultrastructural changes induced by KA. DM antagonized the proconvulsant effects of KA, as evidenced by reduced behavioral abnormalities in the tail licking test. In vitro studies showed that DM protected neurons against KA-induced cell death, as demonstrated by reduced cell death and increased survival of cultured hippocampal neurons. These findings suggest that DM may have potential therapeutic applications in the treatment of seizures in rat models of epilepsy.

VALPROIC ACID, PHENOBARBITAL AND PHENYTOIN DO NOT DISPLACE \( [^3H] \)-MK-801 BINDING. J. M. Brown*, Dept. of Pharmacology, Northeastern Ohio University College of Medicine, Rootstown, Ohio 44272.

NMDA antagonists have anticonvulsant properties and are capable of enhancing the effects of other anticonvulsant agents (Urbanek et al., Eur. J. Pharmacol. 200; 1991; 277-282). Previous studies have demonstrated that the antiepileptic valproic acid, phenobarbital and phenytoin inhibit [\( ^3H \)] NMDA receptor binding in rat cortical homogenates in vitro. NMDA receptor antagonists are thought to interact with the NMDA receptor at a site common to all three receptor subtypes. However, the precise mechanism by which these drugs exert their anticonvulsant effects is not fully understood. The present study investigated the binding of [\( ^3H \)] NMDA receptor antagonists with and without these anticonvulsant agents in rat cortical homogenates. The results of these experiments demonstrate that valproic acid, phenobarbital and phenytoin do not affect [\( ^3H \)] NMDA receptor binding in rat cortical homogenates in vitro. These findings suggest that these drugs may act independently of the NMDA receptor to exert their anticonvulsant effects. Further studies are needed to determine the precise mechanism by which these agents exert their anticonvulsant effects.

**506.7**

MK-801 reduces the convulsant and anticonvulsant effects of kainic acid in mice. This study examined the effect of MK-801 on the regional expression of heat-shock protein-70 (HSP70), HSP70 mRNA and neuropsychological outcome following systemic kainic acid. HSP70 is a marker of cellular stress that does not invariably precede cell death. Suvorov and Lowenstein, 1992. Rats received either kainic acid (9 mg/kg), MK-801 (1 mg/kg) or MK-801 one hour prior to kainic acid. Kainic acid alone caused convulsions in 74% of treated rats. Convulsing rats expressed HSP70 mRNA and HSP70, predominantly in limbic regions. Nocice was also seen in select limbic areas. Pre-treatment with MK-801 reduced the percentage of convulsing rats to 4% and inhibited HSP70 mRNA and HSP70 expression mainly in thalamus and cortex. HSP70 mRNA and protein was maintained in CA3, subiculum and the amygdala. Rats pre-treated with MK-801 and not convulsing showed no histopathological changes. These data identify brain regions putatively involved in the manifestation of limbic convulsions and through which the anticonvulsant effect of MK-801 might be mediated.

**506.8**

Remacemide (2-amino-1H-1,2-diphenyl-1,3-acetamidol) is a novel anticonvulsant drug that is metabolized to an open channel blocker of the NMDA receptor. Remacemide is also a weak NMDA receptor antagonist, but it appears to act at least in part, by a mechanism distinct from that of the metabotrophin. We have used several biochemical approaches to characterize the effects of cultured rat hippocampal neurons and [\( ^3H \)]idine binding to rat forebrain membranes to investigate the mechanism of the remacemide block. Remacemide inhibited NMDA-induced currents and displaced [\( ^3H \)]idine binding to rat forebrain membranes at a concentration of ~50 mM. The block of NMDA-induced currents at ~60 mV was weakly voltage-dependent and was reduced by ~15% at 0 mV. To estimate the voltage-dependent component of block, subsequent experiments were carried out at ~60 mV. Concentration-response curves for remacemide were obtained in the presence of absence of the NMDA agonist. Remacemide (100 mM) shifted the remacemide isotherm to the right (IC50 increased from 95 to 198 mM), whereas the purpored polyanamylate site antagonist diethylamidol (1 mM) produced a comparatively smaller shift (IC50 increased to 139 mM) using the rate of dissociation of [\( ^3H \)]idine as a measure channel activity, spermine (0.3-100 mM) was observed to markedly increase the rate of binding, whereas remacemide (10-100 mM) slowed the reaction. The concentra-

THE ANTI-CONVULSANT AND ANTICONVULSANT EFFECTIVE OF 2-NITRO-6-METHYL-7-CHLORO-2,3-DIMETHYL-1,3-QUINOXALINEDIONE (NMQX) AND 5-NITRO-1,3-DIMETHYL-2,3-DIQUINOXALINEDIONE (NDMQX), TWO NOVEL NMDA RECEPTOR/GLYCINE SITE ANTAGONISTS IN THE MES AND FORMALIN TESTS. M. I. Reza*, M. J. Latta, J. A. Reza, L. J. Reza, L. E. Reza, and E. W. Reza*. Acme Pharmaceuticals, Inc., Escondido Health Sciences Road West, Irvine, CA 92715; 2Dept. of Pharmacology, UC Irvine, Irvine, CA 92717; 3Dept. of Chemistry, University of Oregon, Eugene, OR 97403.

Recent studies have suggested a modulatory role for the N-methyl-D-aspartate (NMDA) receptor in mammalian psychological states, e.g., LTP, memory, learning, and depression. In the present study, we investigated the anti-convulsant and anticonvulsant effects of NMQX and NDMQX in the maximal electroshock (MES) and formalin test models in the female Sprague-Dawley rat. In the MES test, mice were injected i.p. with NMQX (1.25-7.50 mg/kg; N=4 mice/group) or NDMQX (5.0-15.0 mg/kg; N=4 mice/group). Control mice were injected with saline (0.05 ml) or dextrane (0.1 ml). Each compound was administered 30 min before MES. In the formalin test, following a 1 hr accommodation period mice were i.p. injected with NMQX (0.03-10.0 mg/kg; N=5 mice/group) or NDMQX (0.3-20.0 mg/kg; N=5 mice/group). Control mice were injected with saline (0.05 ml) or dextrane (0.1 ml). Each compound was administered 30 min before formalin injection. The results of these experiments demonstrate that NMQX and NDMQX are effective in the MES and formalin tests, and may have potential therapeutic applications in the treatment of seizures and pain.

Felbamate, 2-phenyl-1,3-propanediol dicarboxilate, is a novel, orally active anticonvulsant that is reported to exhibit neuroprotective properties. Felbamate has recently been approved for the treatment of a variety of seizure disorders, including absence, myoclonic, and tonic-clonic seizures. The mechanism of action of felbamate is not fully understood. Felbamate appears to inhibit the spread of seizures and to elevate seizure threshold in animal models.

A proposed mechanism of action for felbamate is via the N-methyl-D-aspartate (NMDA) receptor complex. Neurotransmission mediated by the NMDA receptor complex has been shown to be associated with seizures, ischemic neuronal injury, and other neurological disorders. The neutral amino acid glycine, which acts as a co-agonist for the activation of the NMDA receptor channel, is postulated to be involved with seizure disorders and neuroprotection. Felbamate is demonstrated to have a limited ability of felbamate to inhibit binding at the glycine site on the NMDA receptor.

The present study examined the effects of felbamate on glycine-stimulated calcium ion influx with a minimal effective concentration of 100 nM. Dose response studies suggest a concentration-dependent relationship between felbamate and the reversal of calcium ion influx.

However, due to limited solubility, an extensive range of concentrations of felbamate could not be studied.

Felbamate (2-phenyl-1,3-propanedionedi carbamate) is a novel antiepileptic with a unique structure; however, its mechanism of action is unknown. Felbamate has been shown to bind to strychnine-insensitive glycine sites (McCabe et al., 1993) but thus far, this action has not been linked to its anticonvulsant effects. In the present study the effects of glycine on felbamate's ability to block convulsions was studied in two rodent models: N-methyl-D-aspartate (NMDA)- and electrostoch-induced convulsions. Briefly, NMDA (20 kmol/mouse) was injected i.c.v. and mice (CF-1) were observed for 30 min for clonic and myoclonic seizures. Electrostoch-induced seizures (50 mA, 60 Hz, 0.2 s through cerebel electrodes) produced tonic seizures in at least 95% of the mice. The ED50 for felbamate was shifted from 59 mg/kg to 705 mg/kg by pretreatment with glycine (800 mg/kg Ip.), with a potency ratio of 0.08 (p<0.05). An even greater shift was observed for blocking NMDD-induced convulsions. This interaction appears to be unique to felbamate since the ED50's for phenytoin, vigabartate, carbamazepine and phenobarbital were not increased by glycine. Plans to study newer anticonvulsants are underway. These findings suggest that felbamate blocks the actions of glycine and thus is the first anticonvulsant clinically available that acts by this novel mechanism.

507.1

Since several observations underscore the potential contribution of APP gene overexpression or dysregulated expression to Alzheimer's disease pathogenesis we judged important to elucidate molecular mechanisms of APP gene regulation at the transcriptional level and, as reported previously (Grilli et al. Society for Neuroscience, 1993, 421.8), we have identified a nucleotide sequence we refer to as APPKb in the APP gene regulatory region which specifically binds a protein complex belonging to the NFkB/Rel family of transcription factors. We now report that in transfection studies with constructs in which the APPKb sequence has been linked to a heterologous eukaryotic promoter (herpes simplex virus p promoter) governing expression of the bacterial CAT reporter gene, this nucleotide sequence behaves as a transcriptional repressor. The complex able to bind the APPKb sequence, unlike most of the NFkB/Rel family members, is constitutively present in nuclear extracts from various rat brain areas and cell lines we examined. It is feasible that this repressor protein may contribute to maintain low levels of APP gene expression and that at an alteration at any step in this regulatory pathway may result in deregulated expression of the APP gene. Future experiments will be directed to investigate alterations of this pathway in patients affected by Alzheimer's disease.

507.2
TWO NUCLEAR FACTOR BINDING DOMAINS ACTIVATE TRANSCRIPTION FROM THE HUMAN AMYLOID B-PROTEIN PRECURSOR (APP) PROMOTER. Wolfgang W. Quitteck* and James P. Matthews Department of Psychiatry and Behavioral Science, State University of New York at Stony Brook, Stony Brook, NY 11794-8101.

The promoter of the APP gene was analyzed for its ability to activate transcription in selected cell lines that showed variant levels of endogenous APP transcripts. Transient transfection studies showed that 94 base pairs 5' to the main transcriptional start site are sufficient for high levels of cell-type specific promoter activity.

Two nuclear factors that bind to this region in a sequence specific manner were identified by mobility shift electrophoresis, DNase footprinting, and methylation interference. One of the factors binds to the recognition sequence GGATACGTGAC, here designated as APB/PP. The other binding domain APBB contains the recognition sequence GCCGCTAGGGT.

The contributions of the binding domains APBPs and APBB to the activity of the APP promoter were assessed by introducing block mutations into the respective recognition sequences, which were analyzed by transient transfection. The results suggested that APBB contributes approximately 70-90% and APB8 10-30% to the transcriptional activity from the APP promoter in all cell lines analyzed.

507.3
AMYLOID PRECURSOR PROTEIN: LOCALIZATION OF mRNA AND PROTEIN ISOFORMS IN RAT OLFACTORY EPITHELIUM AND ALTERATIONS IN EXPRESSION DURING NEURONAL DEGENERATION AND REGENERATION. N. Zaidi and B. Talma*, Tufts Medical School, Boston, MA 02111.

The major component of the senile plaques in Alzheimer's disease (AD) is A4A or amyloid protein, which is derived from a larger integral membrane protein, Amyloid Precursor Protein (APP). A4A is toxic to neurons in culture and may contribute to neurodegeneration in AD. APP is widely distributed in neurons and other cell types, but the role of APP under normal physiological conditions and in AD is not understood. A single APP gene generates various transcripts by alternative splicing in both humans and rodents. APP 695 is the predominant form in rat central nervous system, while APP 751 and 770 forms (containing a Kunitz protease inhibitor (KPI) domain) are abundant in peripheral tissues. Recent studies suggest a role for APP 695 in neuronal differentiation; KPI-containing isoforms have been implicated in neuronal repair, regeneration and synaptogenesis. Olfactory neurons in nasal mucosa turn over throughout life at a slow rate, but accelerated turnover can be achieved by olfactory bulbectomy, thus providing an excellent model for examining the role of APP in neuronal differentiation and repair in adult animals in vivo. We have previously used RT-PCR and in situ hybridization with digoxigenin-labeled riboprobes to show that APP mRNA is localized primarily in the neuronal layer of the olfactory epithelium. Immunocytochemical studies using a C-terminally directed antibody that recognizes all full length isoforms show that APP is localized both in the neuronal layer of olfactory epithelium, and in nerve bundles. Experiments are in progress to localize APP isoforms by using isoform specific digoxigenin probes in control olfactory epithelium and during neuronal degeneration and recovery following bulbectomy.

CHANGES IN AMYLOID PRECURSOR PROTEIN AND RNA IN PRIMARY CULTURES OF EMBRYONIC CORTICAL NEURONS UNDERGOING GLUTAMATE-INDUCED NERVEDEGENERATION. D. Willoughby*, L. Rozovsky, and C. E. Finch. Andrus Gerontology Center and Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089.

Extracellular deposits of β-amyloid (Aβ) in disease-affected regions of the brain are a diagnostic feature of Alzheimer's disease (AD). Aβ is a 39-43 amino acid peptide derived from the amyloid precursor protein (APP). A Kunitz protease inhibitor (KPI) domain is encoded by an alternatively spliced exon of the APP gene. KPI-mRNA may be related to AD deposition or neuronal cell death in the AD brain.

To examine possible relationships between APP RNA alternative splicing and neuronal cell death, we measured alternatively spliced APP-mRNAs in primary cultures of rat embryonic cortical neurons treated with 250 μM glutamate. By LiDH release assay, glutamate-induced cell death was 2% after 4 hours of glutamate treatment, with variable cell death after 9 hours. Cell death was 45%, after 24 hours of glutamate treatment, KPI-mRNA was increased 2-3 fold after 6 hours of glutamate treatment, while APP-mRNA lacking KPI was unchanged. Aminocephamoleucinate, a NMDA receptor antagonist blocked glutamate-induced increases in KPI-mRNA. Thus, induction of KPI-mRNA was dependent on NMDA receptor activation.

Recently, it was shown by M. P. Mattson and co-workers that APP protected cultured rat hippocampal neurons from excitotoxic-induced cell death. We measured APP in cell lysates and conditioned media of neurons treated with 250 μM glutamate. APP was decreased in cell lysates of glutamate treated neurons within 1 hour of treatment. Cellular APP remained depleted for at least 20 hours following glutamate addition to the cultures. APP was also reduced in conditioned media 4 hours after glutamate addition. These results suggest that sustained glutamate receptor activation results in rapid degradation of APP. Induction of KPI-mRNA may be a compensatory response to glutamate-induced APP depletion in the neuronal cell, supported by AG0093 and AG7909.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
ACIDOSIS, NOT HYPOGLYCEMIA, STIMULATES PROCESSING OF BETA-AMYLOID IN CULTURED HIPPOCAMPAL NEURONS.

Reductions in cerebral glucose or increases in lactic acid in Alzheimer disease (AD) may signal pathophysiological mobilization of the amyloid precursor protein (APP). We tested these stresses of cellular metabolism on cultured rat embryonic hippocampal neurons over 4 days of growth in serum-free medium, either lactic acid was added to the medium or the medium was exchanged with a medium containing 20% fetal calf serum. After 24 hr, whole-cell and cell extracts were tested for immunoreactivity with antibodies specific for residues 1-42 of Aβ (426) or residues 425-594 near the C-terminus of APP69 (369kD). Hypoglycemia was found to have no effect on APP synthesis or processing. In contrast, lactic acid stimulated processing of APP. Less APP was secreted into the medium and more was found in the cytoplasm, processed to forms of apparent 21 and 25 kD. These forms were reactive with the antibodies directed against sequences for Aβ4 and the C-terminus of APP. Accumulation in the brains of the elderly may contribute to processing of APP that is potentially amyloidogenic. Supported by the Illinois Dept. Public Health.

MICROGLIAL PHAGOCYTOSIS OF PRE-AGGREGATED Aβ 1-42 AFTER INTRA-hippocampal INJECTION IN RATS. S.A. Johnson, R.L. Behel and C.E. Finch. Andrus Gerontology Center and Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191.

Mature plaques in Alzheimer's disease brain are intimately associated with ameboid microglia that express surface markers consistent with antigen presentation and phagocytosis. EM studies showed intracellular amyloid fibrils in plaque-associated microglia, yet it is unclear if such intracellular amyloid was phagocytosed or degraded. Microglia in culture contain detectable APP mRNA, but in situ hybridization of AD cortex or hippocampus did not detect APP mRNA in plaque-associated ameboid microglia.

Since cultured microglia and fibroblasts accumulate exogenous Aβ 1-42, we examined the fate of Aβ 1-42 after intra-hippocampal injection in rats. Synthetic Aβ 1-42 was aggregated in PBS (1 mg/ml, pH 7.0, 48 hr, 25°C) with N-terminal biotinylated Aβ 1-42 (60:1:1) gift of Dr. C. Glabe) prior to stereotactic injection (tu). In pilot experiments, rats were sacrificed at 1 and 5d post-injection. Inset amyloid was visualized by avidin-biotin complex (ABC-HRP/DAAB histochemistry without antibodies, or by double-label histochemistry using nickel/DAAB to detect cell-specific antibodies.

We detected amyloid only at 5d post-injection. Double-label histochemistry showed bio-Aβ in Glial fibrillary acidic protein(184) positive macrophage/microglia. Combination ICC with anti-GFAP showed no intracellular accumulation of Aβ in astrocytes, but showed direct contact of astrocyte endfoot on extracellular Aβ. Numerous bio-Aβ-containing microglia (macrophage) surrounded the injection site. Some bio-Aβ-microglia were distant from the main Aβ 1-42 depot, occasionally surrounding, or even within, blood vessels, suggesting a route for clearance from the brain. This demonstrates microglial phagocytosis of extracellular, aggregated Aβ 1-42 in rat brain and suggests that microglia also phagocytose extracellular amyloid in the AD brain. Supported by AG10675 (SAJ) and AG07909 (CEF).

AN IN VIVO STUDY ON FACTORS AFFECTING AMINO ACID AND APP RELEASE FROM CORTICOSTRIATE NEURONS, USING PUSHER-PULL AND MICRODIALYSIS TECHNOLOGY.

A maintained inhibition on cortical pyramidal neurons through the 5-HT1A receptor contribute to the cognitive symptoms of Alzheimer's disease. In this study in the rat it was investigated whether a selective 5-HT1A receptor antagonist would enhance the activity of cortical pyramidal neurons, and whether an increased neuronal activity would stimulate secretion of APP. Striatal microdialysis and HPLC was used to assess aspartate and glutamate release as a marker of activity. APP in striatal pull perfuse was measured with Western blotting, using the N-terminal antibody 22C11. The selective 5-HT1A antagonist (+) WAY 100135 (50 μM) on the surface of the frontal cortex increased significantly basal glutamate release in the striatum, and potassium induced aspartate and glutamate release. Depolarization of striatal neurons with a potassium challenge through the pull pull probe induced an increase in 22C11 immunoreactivity. These results indicate that a selective 5-HT1A antagonist may be useful in attenuating the cognitive symptoms of Alzheimer's disease. In addition, as an increased secretion of APP may result in less amyloidogenic fragments being produced, an increased neuronal activity may also slow down the progression of the disease. Supported by the Brain Research Trust.

The post-ischemic time course of the expression of amyloid protein precursor (APP), apolipoprotein E (APO-E), glial fibrillary acidic protein (GFAP), and β-amyloid (β-AP), as well as the activation of microglia were examined immunocytochemically in the selectively vulnerable area of the hippocampus of gerbils subjected to 10 min of bilateral carotid occlusion-induced forebrain ischemia. These markers were compared to the time course of CA1 neuronal necrosis. Loss of CA1 neurons was detected between 3 and 72 hrs after ischemia, after which no further neuronal necrosis was observed. At 24 hrs postischemia, there was a decrease in APP, β-AP, APO-E, and GFAP in the CA1 region of the APO-E knockout mice. At 507.5 hrs, by 2 days, activated microglia were observed throughout the hippocampus. This coincided with a dramatic increase in the expression of APP, APO-E and β-amyloid between days 2 and 7. GFAP expression paralleled this increase, which is indicative of an activation of astrocytic protein synthesis. Reactive microglia were also observed in the CA1 region from days 4 to 7. It has been shown that the E isoform of APO-E, when observed, avoids binds to β-AP and, thus, increases the likelihood of β-AP deposition. Therefore, it is postulated that the increased expression of amyloid proteins coincident with an increased production of APO-E in response to ischemic neuronal necrosis provides conditions for the post-ischemic formation of amyloid deposits. Production of oxygen radicals by activated microglia may enhance the binding of β-amyloid to APO-E.

MICROGLIAL REMOVAL OF AMYLOID B PEPTIDE (AB) IS PREVENTED BY PROTEOGLYCAN. L.M. Shaffer*, M.D. Donley, S.G. Younkin and K.R. Brandt. GliaTech, Inc., Cleveland, OH 44123, and Case Western Reserve Univ., Dept. of Pathology, Cleveland, OH 44106.

In the Alzheimer's Disease (AD) brain, activated microglia are found closely associated with the core of mature neuritic plaques. The composition of the plaque is Aβ 40-42 amino acid peptide which aggregates to form fibrillar extracellular deposits. We have previously demonstrated that primary cultures of rat microglia and a human microglial cell line, GM1, are capable of removing Aβ under conditions where the fibrillar peptide was in solution or immobilized on a substrate, mimicking a plaque-like structure. There is thus a question of why plaques in the AD brain persist in close proximity to activated microglia. This persistence could result from the association of Aβ with other plaque components, such as, inactivating it in vivo and removal mechanisms. Since proteoglycans are inviable feature of all amyloidosis and are known to bind Aβ, they may contribute to plaque formation and persistence by altering microglial proteolytic ability. We have determined whether proteoglycans could prevent removal of Aβ by rat microglia and the human monocyte line, THP-1. Using zymo-vass-T staining to detect immobolized Aβ before and after treatment, it was found that both cell types showed good adhesion to the peptide substrate and removed the Aβ in approximately one week. Because astrocytes are a likely source of brain proteoglycans, primary rat astrocytes were grown in culture dishes containing immobilized Aβ to allow secreted molecules to associated with the peptide. We found that removal of the astrocytes and subsequent seeding of microglia or THP-1 cells, the conditioned Aβ was found to be resistant to breakdown. Direct application of proteoglycan purified from astrocytes onto the Aβ substrate also resulted in inhibition of microglial processing of the peptide. These data suggest that astrocyte-derived proteoglycans may play a role in the persistence of Aβ.

It is established in the literature that cholinergic stimuli increases APP secretion in a variety of neural and non-neural cell lines transiently expressed to the M1 and M3 muscarinic receptors. Occupation of M1 and M3 receptors results in phosphorylation via a G-protein. These data have led to the theory that APP metabolism is controlled, at least in part by neurotransmitter receptors. Therefore, we provide evidence that for the muscarinic control of APP processing in NT2N cells, which may provide a unique model system for understanding the contributions of neurons to amyloidogenesis. Previous studies, we have provided evidence that the NT2N cells expresses the 695 amino acid APP isoform and secretes intracellularly produced APP peptides. We now demonstrate that NT2N cells express similar levels of endogenous M2 and M3 receptors as well as the GTP-binding protein, Gq. Carbachol, an M1 and M3 agonist, induces the activation of phospholipase C in NT2N cells. Pretreatment with the EIPA, or in the levels of the second messenger end-products diacylglycerol and inositol triphosphate (IP3) which peaked at two min. Subsequently, as would be expected from the increased diacylglycerol in the cells, the levels of IP3 and PIP2, were increased in the levels of the second messenger end-products diacylglycerol and inositol triphosphate (IP3) which peaked at two min. Subsequently, as would be expected from the increased diacylglycerol in the cells, the levels of IP3 and PIP2, were increased.
PKC STIMULATION BUT NOT CHOLINERGIC RECEPTOR STIMULATION INCREASES THE PRODUCTION OF THE AMYLOID PRECURSOR PROTEIN (APP) IN CULTURED RAT CORTICAL NEURONS. J.L. Mills and P.B. Reiner

Kensington Laboratory of Neurological Research, University of British Colombia, Vancouver, B.C., Canada V6T 2E6.

The progressive deposition of the amyloid b-peptide (Aβ) is an early and invasive feature of Alzheimer’s disease pathology. The Aβ sequence is contained within a much larger precursor, called the amyloid precursor protein (APP) which can be processed by multiple proteolytic pathways. Converging secretory processing of APP is thought to be nonamylodigenic, since cleavage occurs within the Aβ sequence, resulting in soluble secretion of APP. Alternative processing routes are potentially amyloidogenic yielding the Aβ sequence intact.

PKC signal transduction pathways have been implicated in the regulation of APP secretion. These data are derived from studies in continuous cell lines. It is not known whether or not this same mechanism of control occurs in central neurones. In the present investigation, we examined whether direct or indirect stimulation of PKC increases the secretion of APP in primary cultures of rat cortical neurones. Activation of PKC by the phorbol ester phorbol 12,13-dibutyrate (PDBu) or phorbol 12-myristate 13-acetate (PMA) significantly increased the release of APP. In contrast, activation of the PLC/PKC-coupled muscarinic m1 receptor by oxotremorine-M did not significantly increase basal release of APP. Similarly, chemically induced depolarization using 35 mM KCl did not alter APP secretion. Our data indicate that although PKC stimulation can alter APP processing in central neurones, neuronal activity and cholinergic neurotransmission does not.

PROCESSING OF THE AMYLOID PRECURSOR PROTEIN WITH THE THIOGLYCERALDEHYDE REACTION IN THE SECRETORY PATHWAY. R.G. Perez and E.H. Koop, Brigham and Women’s Hospital and Harvard Medical School, Boston, MA 02115.

A mutation at codon 670/671 of APP (KM → NL) from one form of familial Alzheimer’s disease results in significantly elevated Aβ release by an undefined mechanism. Because we have recently demonstrated that Aβ production and release involves the internalization and recycling of cell surface APP, we asked whether the codon 670/671 mutation alters APP processing in this pathway. As expected, Aβ release was significantly elevated in CHO-K1 cells transfected with KM → NL mutation (6NL), as compared to APP751 WT (WT) cells. However, the kinetics of Aβ release was different in 6NL as compared to WT cells such that Aβ release occurred earlier in 6NL cells. The enhanced release of Aβ in 6NL cells was due to an intracellular 12 kDa C-terminal APP fragment. In addition, a lower molecular weight APP species was present intracellularly and released into medium of 6NL cells. By epitope mapping, this shorter APPs from 6NL cells is consistent with a "b-secretase" cleaved product. The premature intracellular cleavage of APP by b-secretase resulted in a 50% reduction of full length APP sorted to the cell surface. Moreover, Aβ release was not significantly elevated in 6NL cells after cell surface labelling, demonstrating that although Aβ generation also occurred after internalization, in 6NL cells, processing of APP was not altered in this pathway. In sum, our studies demonstrated that the KM → NL mutation resulted in a selective alteration of APP processing by b-secretase. More importantly, our results suggest that the early cleavage of APP at the b-secretase site occurs in a different compartment within the secretory pathway in 6NL cells.

The growing interest in the identification, isolation and inhibition of secretases which generate the amyloid b-peptide from APP necessitates the production of purified recombinant substrates for secretases. These purified polypeptides will be useful tools for studying physiological and pathological functions of APP, and for the identification and characterization of secretases involved in Aβ peptide formation.

Secretory cleavage of the amyloid precursor protein (APP) of Alzheimer’s disease (AD) is stimulated by the muscarinic agonist carbachol in human embryonic kidney (HEK) cells expressing human amyloid b-amyloid precursor protein (BAPP) which can be processed by multiple proteolytic pathways. Converging secretory processing of BAPP is thought to be nonamyloidogenic, since cleavage occurs within the Aβ segment, resulting in soluble secretion of BAPP (APPs). Alternative processing routes are potentially amyloidogenic yielding the Aβ segment intact.

Pu

THE INCREASES IN BAPP, puriﬁed from conditioned medium of APP expressing human embryonic kidney (HEK)-293 and BAPP-expressing human embryonic kidney (HEK)-293 cells after 24 hrs treatment with a combination of cholinergic agonists (carbachol) and a PKC activator (PMA) was determined. This result was conﬁrmed by immunocytochemistry using a cholinergic receptor antibody. This process was mimicked by staurosporine, a PKC activator. However, a more selective PKC inhibitor, G10920X, completely blocked the response to phorbol esters, but not partially inhibited by (SO2) the increase in the release of soluble derivatives of APP (APPs) elicited by carbachol. Since staurosporine also inhibits proteins tyrosine kinases, we investigated the involvement of tyrosine phosphorylation in the regulation of APP release. Carbachol increased tyrosine phosphorylation of a number of proteins in HEK cells, and this effect, like APPs release and PKC activity, was preferentially coupled to m1 and m3 receptors. Moreover, an inhibitor of protein tyrosine phosphatase (vanadyl hydroxide) prevented APPs release. The result suggests that both PKC and protein tyrosine phosphatase contribute to the immunocytochemical APP processing by muscarinic receptor activation. (Grant #MH67835 of NIMH)

Cathepin S is a cysteine lysosomal protease resistant to neutral pH. Our studies in rat brain as well as peripheral tissues have shown that it is preferentially expressed in cells from the mononuclear phagocyte lineage. Of all cell lines tested so far cathepin S transcript could be detected only in monocytic leukemia cell lines. Studies on enzolial cortex lesions in rat brain have shown an upregulation of expression of cathepin S in activated versus resting microglia, suggestive of an important role for this protease in responses of neuronal degeneration and regeneration.

We have studied the changes in the level of cathepin S transcripts that occur upon differentiation of the HL 60 leukemia cell line. The possibility of cathepin S to be secreted in the media of normal leukemia cells, differentiated leukemia cells as well as macrophages challenged with inflammatory agents was also assessed.

Cysteine lysosomal proteases have been implicated to take part in the metabolism of the Amyloid Precursor Protein (APP). The fact that this cathepin S is expressed in microglia in brain, a cell type pertinent to the pathology of Alzheimer’s and other neurodegenerative diseases, its resistance to neutral pH and its substrate specificity (preference for small neutral amino acids N- terminal to the cleavage bond), makes cathepin S a strong candidate for a protease involved in the generation of the Aβ peptide from the APP. On the other hand, other research groups have shown that secreted media from microglia are able to cleave soluble and aggregated Aβ peptide.

Here we present the processing pattern obtained by in vitro proteolysis of the wild type and mutant variants (Swedish and Dutch) of the full APP by cathepsin S. The ability of cathepsin S to degrade soluble and/or aggregated Aβ peptide is also addressed. Supported by NS26580 (L. D.).

THE LOCALIZATION AND INTERNALIZATION OF CELL SURFACE BAPP IN CULTURED NEURONS. 2. Yamazaki, D.J. Silkeas and E.H. Koo*, Brigham and Women’s Hospital and Harvard Medical School, Boston, MA 02115.

At the cell surface, the b-amyloid precursor protein (BAPP) may be released after cleavage by n-secreterase or internalized without clearance. Recent evidence suggests that the latter pathway may be important in the constitutive production and release of amyloid b-peptide. Using monoclonal antibodies that recognize the extracellular domain of BAPP, we previously demonstrated that cell bound BAPP in CHO cells is internalized via coated pits and targeted to lysosomes. In this study, we demonstrate that in primary neurons, BAPP is internalized into a lysosomal compartment. The length BAPP is similarly located on the cell surface and subsequently endocytosed. BAPP was present on the cell surface of neurons cultured at low density shortly after plating (Bampkin 1). Immature neurons (Stage 3) showed a discrete compartment and BAPP immunostaining on the soma. On axons and minor neurites, BAPP staining was distributed in a distinctly segmental pattern. Immature neurons (Stage 5) showed remaining discontinuous and was located principally on axons. BAPP immunoreactivity was colocalized with a1, a5, and B integrins, but not with NCAM, synaptophysin, transferrin, or neurofilament. In mature neurons, the internalized BAPP was located in a compartment which contained fluid phase endocytic markers. This staining pattern was also seen in both the perikaryal and neuritic processes. In mature neurons, internalized BAPP was located principally in axons and soma. To demonstrate endocytosis of BAPP from axonal surface, dissociated sympathetic neurones were grown in compartment (Campyon) cultures. Using this system, BAPP was clearly internalized from the cell surface of distal axonal sites and retrogradely transported to the neuronal soma. In summary, these studies in primary neuronal cultures show that 1) in early stages, cell surface BAPP was not distributed in a polarized manner, 2) in mature cultures, surface BAPP was localized predominantly at the axonal site and 3) in mature neurons, BAPP was retrogradely transported from the surface of distal axonal sites to the cell body.

NEURONS DERIVED FROM A HUMAN TERATOMA CELL LINE GENERATE INTRACELLULAR Aβ PRIOR TO ITS SECRETION INTO CONDITIONED MEDIUM R.S. Turner* and Y.M.-Y. Lee, Dept. of Neurology and Pathology and Laboratory Medicine, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104-4280.

Alzheimer's disease (AD) brain is characterized pathologically by neuronal and synaptic loss, neurofibrillary tangles which consist primarily of the microtubule-associated protein tau, and amyloid plaques which consist primarily of a 42-kDa peptide (Aβ) derived from one or more of at least three alternatively spliced amyloid precursor proteins (APP). We examined the kinetics and intracellular localization of APP metabolism in cultured neurons derived from a human teratocarcinoma cell line (NT2). These neurons constitutively secrete a 95-kDa fragment of APP (APPs) and Aβ. Metabolic labeling of NT2 neurons with [3H]leucine followed by immunoprecipitation of APP, APPs and Aβ from cell lysates and conditioned medium revealed that APP was first recovered from cell lysates and, after an approximate 2 hour delay, from conditioned medium. In addition, cellular Aβ increased overnight while Aβ in conditioned medium continued to increase. This suggests that APP is first generated intracellularly soon after APP synthesis and then secreted into medium. In the presence of 10 μM limiting chelator, cellular APP accumulated with no evidence of its metabolism, thus precluding the secretion of APP fragments into medium.

507.19

Human amyloid protein precursor (APP770) and its carboxy terminal portion (CT180) including β/α-3 domain were highly expressed in an E. coli system. The in vivo recombinant APP peptides were purified with a combination of urchin solidification and ion-exchange chromatography and used for proteolytic processing by thrombin. Three thrombin cleavage sites were predicted by the decrease of isoelectric point and the appearance of K56, 27 and a K45 fragments containing β/α-4 domain on SDS-PAGE gel and on the immunoblot. The carboxy-terminal proteolysis of plateaued APP expressed to thrombin resulted in the stimulated production of 60 and 27 kDa carboxy-terminal peptides containing the intact β/α-4. This thrombin-mediated proteolysis was catalyzed by the specific thrombin inhibitor. These results suggest that thrombin may play a role in APP-cleaved peptide precursors amyloidogenic intermediates in vivo leading to amyloid deposition.

EXPERIMENTAL CHLOROACETATE MYOPATHY IN RATS—MODEL FOR APP PROCESSING.

1Dept of Microbiology, 2Dept of Neuropharmacology, Sapporo Medical University, 3Dept of Psychology, Hokkaido University, Sapporo, Japan.

Deposition of β/α protein is most characteristic pathological change in Alzheimer's disease. There have been no good models for studying β/α production. Chloroacetate, a pyridoxine antagonist, induces muscle pathology in experimental and human disorders. Chloroacetate is a compound with toxicological properties similar to human β/α protein to induce muscle pathology, in which β/α deposition is observed. In this study, we present morphological, immunopathological, and biochemical data in regard to APP processing in this experimental model.

Isolated and denervated soleus muscle from chloroacetate treated and untreated WKA rats were studied. Atrophy of muscle fibers, numerous dense granule bodies, and vacuoles were seen in denervated soleus muscle of chloroacetate treated rats. Progressive destruction of muscle, and proliferation of connective tissue were predominant in WKA rats. Denervated soleus muscle stained with anti-cathapsin D, and several anti APP antibodies. Western blot analysis showed that 49, 50 kDa bands and 20 kDa bands were detected in buffer soluble, and detergent soluble fractions with anti β, 25, and anti C terminal antibodies respectively in chloroacetate treated rats.

This experimental model seems to be useful for study of APP processing. And present data suggests lysosomal pathway is involved in β protein production.

APP EXPRESSION IN THE CELL LINE NT1A2. R.B. Watson, P.R. Harris, P.W. Andrews, and E.C. Pearson, Department of Biochemistry, The University of Sheffield, Western Bank, Sheffield S10 2NY, UK.

The cell line NT1A2 is a useful tool for studying the mechanisms of protein processing with relevance to human neurodegenerative disease (Andrews, 1984; Wurtkin et al, 1993) particularly the differential expression of the mRNA encoding for Amyloid Precursor Protein (APP) in neurotrophic factor (NTF) rich work (Adkerman et al, 1991) has shown using cDNA libraries that APP105 and APP73 are present in undifferentiated and differentiated cell lines. APP73 was observed in libraries from differentiated, neurite-like cells only.

The study used as a new hybridization histochemistry to examine the occurrence of APP mRNA transcript and Western blotting to examine the relative isoforms produced in the NG108-15 cells. Hybridization probe for APP105 was used to probe the mRNA sequences for APP105 and APP73, a 2800 bp cDNA clone. Probenes were used to correspond to regions encoding the β/α sequence (β/α-3), to a sequence specific to APP73 (APP105, APP670), to some APP105, APP750, APP730, APP530, and APP420. APP105 was observed in libraries from differentiated, neurite-like cells only.

DEGENERATIVE DISEASE: ALZHEIMER'S—BETA AMYLOID VII

508.1 CEREBRAL AMYLOID ANGIOPATHY IS ASSOCIATED WITH CORTICAL NEURONAL LOSS. C. Zampi, B.A. Limousin, H. Chui. Department of Neurology, University of Southern California, Rancho Los Amigos Medical Center, Downey, CA 90242. The deposition of B-amyloid in cerebral blood vessels (so-called cerebral amyloid angiopathy (CAA)) is a frequent finding in Alzheimer disease (AD). An association between CAA and cerebral hemorhage and infarction is well-recognized, but potential ongoing effects of CAA on neuronal survival are not known. We examined the relationship between the severity of CAA and numbers of neurons in five neocortical areas and entorhinal cortex in 103 neuropathologically-confirmed cases of AD. CAA was rated on a semi-quantitative scale (0-3) in a thionine stained leptomeningeal and cortical vessels. Neurons, neurofibroblastic tangles, and senile plaques were counted in complete cortical columns in semi-adjacent sections stained with cresyl violet or Bielschowsky silver method. Some degree of CAA was found in at least one region in 87% (84/103) of cases. Severe CAA (grade 3 in at least one region) was found in 29% (30/103) of cases. Severity ratings for leptomeningeal and cortical CAA were highly correlated. The correlation coefficient was 0.79. The relationship between the severity of CAA and neuronal number in area 22 (r = 0.22, p = 0.0005) and the severity of leptomeningeal CAA and neurons in area 9 (r = 0.21, p = 0.048). The relationship between the severity of cortical plaques, senile plaques, and age at onset and neuronal number was further examined using multiple regression analyses in each anatomical region. Again, cortical CAA in area 22 (p = 0.007) and leptomeningeal CAA in area 9 (p = 0.02) were significant predictors of neuronal loss. We hypothesize that CAA may compromise blood flow and the delivery of essential nutrients to neurons; alternatively, B-amyloid may exert a direct neurotoxic effect. (NIH 2P50AG01424 and AG07624)

508.2 IN VIVO EFFECTS OF THE AMYLOID B PROTEIN IN THE RAT BRAIN. P.J. Action and D. Ghetti. Indiana Univ. Sch. of Med., Terre Haute Center, Terre Haute, IN 47809 and Indiana Alzheimer Disease Center, Indianapolis, IN 46202. The specific aim of this study was to compare the long-term in vivo effects of senile plaque cores (SPC) or synthetic amyloid b peptide (Ab) in the rodent brain at 2 different ages. SPC-enriched pellets were isolated from the temporal cortex of Alzheimer brains. Synthetic Ab (1-40) was purchased from Bachem, Philadelphia, PA, dissolved in phosphate buffered saline at a concentration of 50 µM and incubated at 37°C for 48 hrs prior to use. Pressure injections were performed in the cortex of young (6 months) and old (20 months) male Fischer 344 rats and the animals were allowed to survive 1 or 3 months. At the end of the survival periods, the rats were euthanized and perfused. The brains were processed for histology and immunohistochemistry. Hypersia and hypertrophy of astrocytes surrounding the injection site were observed at up to 5 months in all cases. The injection sites were clearly seen at 1 and 3 months due to cavitation and deposition of the injected SPC or Ab. These deposits were strongly immunoreactive to Ab antisemur at 1 month but were less so at 3 months. ALZ50 immunoreactivity, which is indicative of abnormal cytoskeletal changes, was seen and around the injection site at 1 month and was substantially decreased at 3 months. No major difference was seen between the use of SPC or Ab, or between young or old animals. Thus, over a long survival period, acute in vivo injection of SPC or Ab in the rat brain results in clearance of the injected deposits and attenuation of abnormal cytoskeletal changes. Supported by grant #P01AG10133.

508.3 HISTOLOGICAL AND BEHAVIORAL EFFECTS OF INTRAHIPPOCAMPAL INJECTIONS OF B-AMYLOID PEPTIDE (B-AP) IN THE MALE RAT. A.W. Doman, A. W. Bordon, E.N. Korelits, A. R. V. McCampbell, A. R. Peterson, G. P. Tinker. Dept. of Psychology, Illinois Wesleyan Univ, Bloomington, IL 61701. Neuroscience Dept, Abbott Laboratories, Abbott Park, IL 60064; Veterans Res Educ Clin Ctr. Veterans Admin Med Ctr., Bedford MA 01730. Alzheimer’s disease is characterized by the extracellular deposition in the brain of insoluble aggregates of the amyloid b peptide (Ab). Evidence from several laboratories has demonstrated the neurotoxicity of Ab in vitro, and in vivo. Few studies, however, have examined the behavioral effects of Ab when injected into the rat brain. In a series of experiments, a comparative histological and behavioral assessment were conducted following injections of Ab(1-42) into the hippocampus and medial septal area of male rats. Experiment 1: animals received bilateral injections into the hippocampus of 3.5 nmol/SL of either Ab(1-42), CA(1-42) in a scrambled form, or DM50. In experiment 2, animals were injected bilaterally into the medial septal area with 3.5 nmol with Ab(1-42), the scrambled sequence or DM50. In experiment 1, animals were tested on a radial arm maze. In experiment 2, 2 animals were tested following injections of Ab(1-42) using the Morris Water Maze. Following the behavioral tests, animals were sacrificed and analyzed for CA1 activity in the hippocampus either 7 or 14 days following injections. In experiment 3, another group of animals were injected with 3.5 nmol Ab(1-42) into the medial septal area or hippocampus. Following a two week survival period, animals were sacrificed and their brains were processed for immunocytochemistry with Ab antibody. Our preliminary results indicate that bilateral injections of Ab(1-42) into the hippocampus or medial septal area had no significant effect on spatial learning in the male rat. Additionally, no significant differences were found in CA1 activity activity in the hippocampus following injections of Ab into the septum at 7d controls (15.877 ± 0.371 pmol/min/g ptt; Ab = 15.65 ± 0.78 pmol/min/g ptt) or at 14 d. The histological study in in progress, and the results of this study will also be presented at this conference.

508.4 COMPARISON OF THE EFFECTS OF INTRAHIPPOCAMPAL INJECTIONS OF A-(1-42) IN COMBINATION WITH GLUCOCORTICOIDS AND IBOTENIC ACID ON THE ACQUISITION AND RETENTION OF A SPATIAL TASK IN MALE RATS. W.A. Doman, A. J. Giovannetti, A.B.Y. McCampbell, H. K. Witegwer, J.S. Puccio, L.J. Chapman, S.M. Bond, A.R. Peterson, J.H. Hickman. Dept. of Psychology, Illinois Wesleyan Univ, Bloomington, IL 61701. Alzheimer’s disease is characterized by the extracellular deposition in the brain of insoluble aggregates of the amyloid b peptide (Ab), a 39-43 amino acid peptide. Although the cause of neuronal degeneration in AD remains unclear, one major focus is on the role of BA. Evidence from several laboratories have repeatedly demonstrated the neurotoxicity of BA in vitro, however, other investigators have reported little direct neurotoxicity, but rather an increase in the vulnerability of neurons to EAs. Furthermore, few studies have examined the behavioral effects of Ab when injected into the rat brain. In a series of experiments, we assessed the effects of bilateral injections of BA(1-42) 5nmol/SL into the hippocampus on both acquisition and retention of a spatial task in the male rat. In experiment 1, intact or adenorexaminized animals were injected with either BA(1-42) or a scrambled sequence of BA with either daily injections of Tmgl/mL corticosterone at a concentration previously reported to induce artificial stress levels as assessed (controls). In experiment 2, animals were injected with either ibotenic acid (Hemato/PL) and corticosterone and BA(1-42) in a scrambled sequence; or IBO in combination with BA(1-42). Animals in experiments 1 and 2 all animals were pre-trained on a radial arm maze task with 5 of 8 arms baited. In group 1, half of the animals were pre-trained, the other half were tested for acquisition. After surgery the animals were tested for two weeks with the configuration preserved. Animals were tested for 2 weeks with the new configuration. A variety of behavioral parameters were measured using the radial arm maze. Our preliminary results indicate that there is a clear disruption of learning performance in animals that received BA(1-42) in combination with corticosterone.
DEGENERATIVE DISEASE: ALZHEIMER'S—BETA AMYLOID VIII

It has been suggested that the complete neurotoxic activity of BAP 1-40 may be contained in the fragment BAP 25-35. In this study, LPS-induced, multiple intrahippocampal injections of BAP 25-35 impaired retention of one-trial reward learning 2 weeks later. The present study investigated whether similar injections would cause such severe, long-lasting degenerative changes that the task could not be retained, even if training began 4 weeks after injection. If LPS was employed to reveal aging and modulation of cholinergic mechanisms. The subjects were 39 male rats, 3-4 months old. They received 7 hippocampal injections of 6 nmol BAP 25-35 (n=21) or distilled water alone (n=18), bilaterally. After recovery and deprivation to 82% of initial weight, they received an initial training trial 28 days post-injection, and 3 subsequent daily retention trials. The apparatus was a sunburst maze with 4-level alleys and 1 bated ascending alley with a grid floor. Rats were scored for errors (entrances into unbaited alleys). Each rat's retention score was its decrease in errors relative to the baseline trial. The control rats steadily reduced their errors from day to day, whereas the BAP-treated rats showed little improvement. Tukey's HSD procedure revealed significant, p<.05, differences between treatment groups on the last 2 retention trials.

It has been suggested that the complete neurotoxic activity of BAP 1-40 may be contained in the fragment BAP 25-35 and that pre-incubation of BAP 25-35 might increase their aggregation and neurotoxicity. Therefore, multiple intrahippocampal injection of BAP 1-40 impaired retention of learning that occurred 2 weeks later. In this study, 3-4 month-old rats received 7 hippocampal injections per side of 6 nmol BAP 25-35 (n=14) inoculated for 24 h at 37°C or non-incubated BAP 25-35 (n=3) inoculated 48 h after inclosure (n=3). After deprivation to 82% of initial weight, they received an initial training trial 14 days post-injection, and 3 subsequent daily retention trials. The apparatus was a sunburst maze with 4 level alleys and 1 bated ascending alley with a grid floor. Each rat's retention score was its decrease in errors (entrances into unbaited alleys entered) from the baseline trial. Retention scores, averaged across 3 trials were 5.4±1.4 (SEM) for the control group. For the incubated BAP group and for the non-incubated BAP group. ANOVA indicated a significant, p<.05, drug effect and post-hoc analysis (Tukey's HSD) indicated that only the non-incubated BAP group was significantly different, p<.01, from controls. One-sample t-tests indicated significant retention in all groups except non-incubated BAP.

080.7 EVALUATION OF SPATIAL LEARNING IN Rats WITH INTRAHEMISPHERIC INFUSION OF BAP. TATE, D. Rocas, R. E. Malocha and C.A. Marotta. Dept. of Psychiatry and Human Behavior, Miriam Hospital and Dept. of Neuroscience, Brown University, Providence, RI 02906.

A chronic intraventricular β-amyloid infusion model was used to assess cognitive and memory deficits. During infusions of either β-amyloid peptide (1-40) or glucose vehicle vehicles, male rats were tested in a spatial memory task. Animals were required to locate a hidden platform to escape from a pool of water. After 2-4 days of testing, the amyloid-infused rats had significantly longer lattencies to escape than glucose infused rats, but eventually reached latencies equal to control animals. After four days of testing, the platform was removed and the amount of time spent in each quadrant of the pool was measured. Only the glucose-infused animals spent significantly more time in the quadrant that previously contained the platform. Therefore, amyloid-infused rats showed subtle memory deficits. When animals were sacrificed, immunostaining of the brains revealed β-amyloid-positive deposits and significant glosis in the brains of amyloid-infused rats.

080.8 INFLUENCE OF AMYLOID PRECURSOR PROTEIN ON TROPHIC RESPONSE OF PC12 CELLS TO NEUROTROPHIC FACTOR. R.B. Malocha, S. Agrawal, E. Humke, J. Yang and C.A. Marotta. Dept. of Psychiatry & Human Behavior - Neuroscience, Brown University and Miriam Hospital, Providence, RI, 02912; and, Hybriedon, Inc., Worchester, MA 01605.

While the relationship between NGF and the amyloid precursor protein (APP) is of interest with respect to the potential therapeutic potential of growth factors applied to Alzheimer's disease, changes in APP levels and distribution in PC12 cells treated with NGF have not been reported. To explore the relationship between APP and NGF, we applied antisense oligonucleotides (AO), containing a phosphorothioate backbone, complementary to the 5’ and 3’ end region of APP mRNA, to stimulated and unstimulated PC12 cells. APP AO significantly reduced the level of APP compared to the non-nucleotided AO. Maintaining APP AO in cultures (2µM, 48hr) both prior to and during NGF addition increased retention of cell size and neurite extension, as compared with controls. Since reduction of APP levels by AO reduced the response of PC12 cells to NGF, APP may be a modulating element of the trophic factor cascade.

The protein products of the Jun and fos immediate early gene (IEG) families are cooperative transcriptional regulatory factors which act as cellular 'third messengers' and have been implicated in regulating the expression of many genes, including the amyloid precursor (APP). We have previously demonstrated that immunoreactivity for Jun and fos-related proteins is induced in the hippocampal dentate gyrus and associated with neuronal pathology (Exp. Neurol. 125: 286-305), that these proteins are induced by Aβ in cultured hippocampal neurons, and that Jun proteins are induced in DA-102-7E rat neurons that are resistant to Aβ-induced cell death (submitted). Several of these genes have been implicated in the control of apoptosis. As a result, we have suggested that the expression of some IEGs (e.g. one or more of the Jun proteins) may be related to or participate in Aβ-induced apoptosis, and that the expression of Jun proteins is an early event in Aβ-induced neuronal death. We have speculated that a variety of Jun proteins indicates that Aβ induces a sustained increase in Jun proteins in culture, whereas other agents which induce IEGs such as phorbol esters produce a more transient and typical expression in Jun protein expression. Immunoblotting with a specific antibody to Jun B shows a similar pattern of Aβ-induced Jun immunoreactivity, but do not provide evidence for the induction of Jun B in response to Aβ. These data suggest some specificity in the cellular response to Aβ, which should be apparent in the regulation of these genes at the mRNA level.

080.10 EFFECTS OF α2-ANTICHYMOTRYPsin ON THE TOXICITY OF β-AMYLOID FRAGMENT 25-40 IN RAT PRIMARY CULTURED NEURONS. N. Nishiyama*, T. KOBAYASHI and H. SAITO. Dept. of Chem. Pharmacol., Fac. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo 113, JAPAN.

B-Amyloid is the main component of senile plaques. Neurotoxic effects of β-amyloid peptide has been suggested to be involved in the pathogenesis of Alzheimer's disease (AD). We used a novel synthetic peptide β25-35, corresponding to the presumed presumable toxic domain, to test its effect on neuronal cells. α2-Antichymotrypsin (ACT), a serine protease inhibitor, colocalizes with amyloid deposits. ACT might contribute to the development of amyloid deposits and pathogenesis of AD through its protease inhibitory activity. We investigated the combination effects of ACT with a novel β25-30 on rats' primary cultured neurons. Single cell suspensions of hippocampus and cerebral cortex were prepared from fetal rat brain, and plated at either high (1x10⁴ cells/cm²) or low (5x10³ cells/cm²) cell density. Desired concentrations of ACT were added to the medium. The cells were visualized by cresyl violet staining or MAP2 immunohistochemistry. In some cases, cell viability was evaluated by MTT assay. Although ACT (0.1-10 µg/ml) did not affect the neuronal survival in high density culture, it decreased the number of surviving neurons concentration dependently, β25-30 (0.3-30 µM) significantly reduced cell viability in both high and low density cultures. Combination of ACT (10 µg/ml) with β25-30 did not affect the toxicity of β25-30 in high and low density cultures (F-value = 2.22 and 0.61, respectively). These results suggested that both ACT and β25-30 were neurotoxic but that there was no synergistic interaction between them.

β-amyloid and heparan sulfate are found in neuritic senile plaques in Alzheimer's disease (AD). The co-localization of heparan sulfate and amyloidogenic proteins is a common feature of amyloidoses. β-amyloid 1-42 has been proposed to be toxic to neurons in vitro, and aggregation and toxic activities have been associated with amino acids 25-35. The role of heparan sulfate in the pathogenesis of amyloidoses however, is unknown. To investigate this interaction, we examined the effect of heparan sulfate on β-amyloid in a cell culture model, rat hippocampal neurons were exposed simultaneously to heparan sulfate and amyloidogen and either 75 μM β25-35 (a 25-35-mutant) or 25-35 (β25-35 induces degeneration and neuronal death in a dose-dependent manner with an optimal effective dose at 15μM. Concentrations as low as 3–5 μM were observed to have some protective influence. Heparan sulfate alone at these concentrations did not significantly increase cell survival. Heparan sulfate had no significant influence on β1-42 induced toxicity, even when observed at concentrations as high as 80 μg/mL. These data suggest that the neurotoxic effects of β25-35 may not be identical to those of the full-length peptide. It is further suggested that β1-42 retains its biological activity in its native state, however the activity of smaller fragments of β1-42 may be modified by heparan sulfate.

PATHOGENIC INTERACTIONS BETWEEN CIQ AND β-AMYLOID 8 PEPTIDE IN ALZHEIMER'S DISEASE. Scott Webster and Joseph Tsong. Sun Health Research Institute, Sun City, AZ 85373.

Soluble amyloid β-peptide (Aβ) is present in CSF of normal individuals. This (and others) has made it increasingly important to identify mechanisms by which Aβ becomes aggregated into biologically relevant, pathogenic fibrils. Aβ is present in the amyloidotic brain. We have previously shown that CIQ, the first component of the classical complement pathway, binds to synthetic Aβ peptides. Such binding activates the classical complement cascade and potentiates Aβ aggregation in vitro.

The present studies had two objectives. First, we modified a previously reported fluorometric assay so as to demonstrate dramatic enhancement of Aβ aggregation by CIQ at physiologically relevant, nanomolar concentrations. Second, we employed enzymatically generated CIQ fragments to characterize the CIQ binding site for Aβ. The latter appears to be within the globular head region (GHR) of CIQ, a finding that may clarify not only the mechanism by which CIQ augments Aβ aggregation and β structure, but also the mechanism by which CIQ activates CIQ. The GHR provides multiple binding sites for the Fc region of Ig. By analogy, it must also provide multiple binding sites for Aβ, an optimal quality for accelerating Aβ aggregation. Likewise, Aβ and Ig share a similar target for binding and activating CIQ, the GHR. Thus, complement activation in the AD brain is interactive with and may even be a consequence of Aβ aggregation into its pathogenic form.

Society for Neuroscience Abstracts, Volume 20, 1994

Neurodegenerative changes in Alzheimer's disease (AD) have been hypothesized to be mediated by β-amyloid protein (Aβ), an amphipathic peptide composed of a 42-residue fragment of the β-amyloid precursor protein. Previous studies have shown that the α-helical form of Aβ is toxic to cultured neurons, and that the Aβ25-35 fragment may be the active region mediating this toxicity. To determine if Aβ binds to neurons via a specific ligand-receptor interaction, we synthesized (D) and (L) stereoisomers of Aβ25-35. Purified peptides were shown to agitate on HPLC, Phase-contrast microscopy, electron microscopy and sedimentation analysis revealed that the two peptides exhibited nearly identical structural characteristics and aggregation levels. In addition, both isomers induce neurite loss in cultured hippocampal neurons. These data suggest that the neurotoxic actions of Aβ do not result from classic stereospecific ligand-receptor interactions. Rather, Aβ neurotoxicity may result from alterations in surface proteins, perturbation of cellular membranes, or other processes in which fibril features of the amyloidogenic peptide are important. This possibility is consistent with recent reports of similar neurotoxic actions by amylin and prion, amyloidogenic proteins which share structural similarities with Aβ but that have not been shown to mediate neurotoxicity. The mechanism of Aβ-induced toxicity will likely benefit attempts to understand the neurodegeneration that occurs in AD and perhaps other amyloid-related disorders.

Clusterin (apo J, SGP-2, ADHC-9, SP-40,40) was recently found bound to Aβ in cerebrospinal fluid and proposed to be a chaperone for Aβ [Ghisla et al. (1993) Biochem. J. 293:27]. Since the aggregation/conformational state of Aβ is important for its neurotoxicity, interactions with clusterin may affect Aβ toxicity. To test the hypothesis that clusterin may modulate Aβ neurotoxicity, we expressed human clusterin (apoJ, ADHC-9, 92717) in CHO-K1 cells and a C-terminal fragment of apoJ (Bt184, kbp) DNA into the expression vector pG-T and stably transfecting the hamster cell line AV-12. Clusterin was purified from conditioned media between 10-60% homogeneity by anion exchange and size exclusion chromatography. To study the putative relationship between clusterin and Aβ, we evaluated Aβ neurotoxicity in the presence and absence of clusterin using primary hippocampal cultures from fetal (E18) rats. Clusterin activity was assessed using 50 nM Aβ (Bachem lot ZK140), a well-characterized lot of Aβ that shows prominent neurotoxicity over a four-day timecourse. Co-treatment for four days with 50 μM Aβ and 31.25 nM to 500 μM clusterin, but not BSA or PBS controls, resulted in Aβ neuroprotection in a dose-dependent manner. These results suggest that clusterin may interfere with the adoption of a neurotoxic conformation/aggregation state of Aβ in vitro and may have a similar function in vivo.

AGGREGATED β-AMYLOID INDUCES REACTIVE ASTROCYTOYSIS BOTH IN VITRO AND IN ALZHEIMER'S BRAIN. C.I. Pike, R.L. Cummings, and C.W. Cotman. Irvine Research Unit in Brain Aging, University of California, Irvine, CA 92717 USA.

The senile plaques characteristic of Alzheimer's disease (AD) are often associated with astrocytes expressing a reactive phenotype. Since β-amyloid (Aβ) is the primary component of plaques, reactive astrocytosis in AD may result in part from direct effects of Aβ on astrocytes. To investigate this possibility, we first examined the effects of Aβ peptides on cultured astrocytes. Aβ did not induce significant cell loss in these cultures. However, upon exposure to aggregated but not soluble Aβ, astrocytes rapidly and stably adopted a stellate, process-bearing morphology consistent with the reactive phenotype. This altered morphology was accompanied by increased immunoreactivities for two markers of reactivity, basic fibroblast growth factor (BFGF) and glial fibroblast acidic protein (GFAP). In addition, similar to their interaction with senile plaques, astrocyte reactive processes in vitro were able to envelope Aβ aggregates. To investigate whether Aβ may induce similar effects on astrocytes in the AD brain, we triple-labeled sections of hippocampal formation from six AD subjects with thioflavine-S and antibodies raised against GFAP and either Aβ or BFGF. Upon scoring the intensity of each label within individual plaques, we found that reactive astrocytes were co-localized specifically with plaques expressing positive but not negative thioflavine staining, a marker of β-sheet structure characteristic of aggregated Aβ. Similar to the in vitro findings, we observed increased immunoreactivity for BFGF in reactive, plaque-associated astrocytes. These data suggest that Aβ, in an aggregation-dependent manner, can induce a reactive astrocyte phenotype. Thus, in addition to its hypothesized direct neurodegenerative effects, Aβ may indirectly affect the progression of AD via reactive astrocytosis.

The fibrilisation and cytotoxicity of various linear fragments of the amyloid β-peptide (25-35) fragment are being studied in order to determine the sequence and conformational requirements for these properties. Previous reports have demonstrated the necessity of the β-peptide (1-40) and the (25-35) fragment (Behl et al. 1992 BBRC 186, 544) a correlation between fibrilisation and cytotoxicity (Pike et al. 1993 J. Neurosci. 13, 1676) and also a cell surface binding requirement (JBD unpublished observation) but have not related them to sequence. The fibrilisation and cytotoxic properties of analogues of the amyloid β-peptide (25-35) fragment, containing single alanine or Glu substitutions were tested. Peptides which did not fibrillise were found to be non-toxic, confirming a requirement for peptide aggregation. Loss of activity might be attributed to either loss of non-specific peptide aggregation, (ii) loss of quaternary structure, (iii) an additional loss of sequence specificity, due to the substitution. Chemical aggregation of the peptide to BSA failed to rescue activity, suggesting that the tertiary structure of the aggregate is important for toxicity. Future substitutions will further define β-peptide's determinants for cell surface binding.

It has been suggested that the aggregation of amyloid B-protein enhances its neurotoxicity, and may play a key role in the Danielite of senile plaques. We revealed that aluminum, an epidemiologic risk factor for Alzheimer's disease, promoted the aggregation of synthetic amyloid B-protein (1-40) using immunoblotting and centrifugation (KAWAHARA et al., B.B.R.C., 198; 235:3-7 (1994)). Here, we report that significantly aggregated 1-40 has neurotoxic effects on cultured rat hippocampal neurons.

After incubation at 37°C for 24 h in 25 mM HEPES buffer (pH 7.0), 1-40 (obtained from BACHEM) was separated by SDS-PAGE and immunostained by antibody to amyloid B-protein (nl06); the in excess of 500 μM of n20, 1-40 formed aggregates from higher molecular weight up to the gel top. The aggregation was inhibited by the presence of detexoflene, a chelator of aluminum. Other metals including Zn2+, Co2+, Fe3+ caused only a small degree of aggregation compared to Al. Pre-treated solutions of 1-40 (aged), pre-treated solutions with Al (aged &Al), and 1-40 without pre-treatment (new-Al) were added to cultured hippocampal neurons obtained from 18-day embryo after 8-10 days in culture. After 7 days, cells were fixed and stained by MAB2 and SA3. Neurons treated with aged-Al showed a remarkable degeneration compared to aged or new-Al. The neurites of the neurons were also damaged. Widespread fibrillar deposits of 1-40 appeared on cells treated with aged-Al and aged-Al, but not with new-Al. More condensed and characteristic deposits were observed in aged-Al. These results suggested that the degeneration of neurons and the deposition of amyloid B-protein are enhanced by Al.

508.19

Aβ25-35 is known to induce neurodegeneration in cultures of rat brain cells and rat neural cell lines (Yamaguchi et al., 1990, Science, 250:279-282; Bohs et al., 1992, Biochem. Biophys. Res. Comm. 186: 944-950). The current data show that these peptides induce similar neurodegeneration in SH-SY5Y neuroblastoma cells, extending characterization of Aβ toxicity to a human nerve cell line. SH-SY5Y cells were aggregated with Aβ with changes in cell shape, membrane blebbing, antigenic modification, loss of attachment to the substrate, and cell death. Aβ25-35 induces aggregation for maximum toxic effects, as cellular degeneration is evoked by aggregated Aβ 1-42 and aggregated Aβ 41-41 (Ile to Cys) but not by monomeric Aβ 1-40. Aggregated (pre-aggregated) Aβ 1-42 also evoked neurodegeneration. 

Antigenic changes comprise upregulation of Alzheimer’s type tau epitopes, recognized by the PHF-1 and A30-50 monoclonals. These changes in tau support the connectivity between this in vitro model and mechanisms leading to neurodegeneration in Alzheimer’s disease. A significant feature of the SH-SY5Y response is that cells must be differentiated before they become sensitive to the degeneration evoked by Aβ. Signaling pathways leading to Aβ-evoked neurodegeneration thus are under experimental control, becoming complete only when proliferating cells withdraw from the cell cycle and develop a postmitotic phenotype.

Transforming growth factor β1 (TGF-β1) is found in plaques of patients with Alzheimer’s disease. The β2-amyloid peptide (BAP), the major component of these plaques, has been shown to be directly toxic to neurons and has thus been linked to the pathogenesis of Alzheimer’s disease. In the present study we determined whether TGF-β1 is able to modulate BAP neurotoxicity and the synthesis of its precursor proteins (APP).

Cultured rat hippocampal neurons were exposed to 0.1 - 10 μM of the BAP fragments 25-35 (BAPP25-35) for a period of 5-6 days. Exposure to 1-10 μM BAP led to a significant decrease in neuronal viability, which was maximal at 1 μM. Terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling demonstrated that neuronal injury was accompanied by extensive DNA fragmentation, an indication of “apoptotic” cell death. A single addition of TGF-β1 (10 ng/ml) inhibited both BAPP25-35 neurotoxicity and reduced the extent of DNA fragmentation. Repeated treatments with TGF-β1 (4 x 10 ng/ml) completely prevented the death of the hippocampal neurons. In contrast to BAP, its precursor protein (APP) is thought to actually have neuroprotective properties. We next determined the effects of TGF-β1 on APP expression both in cultured rat hippocampal neurons and in secondary cultures of astrocytes. Treatment with TGF-β1 (0.1 - 10 ng/ml) led to an increased neuronal and glial production of APP, as determined by Western blotting and immunocytochemistry with a monoclonal antibody specific for APP.

We conclude that, in addition to its effect on Ca2+ homeostasis and β-2 expression, an increase in APP expression could underlie the protective effects of TGF-β1 against BAP neurotoxicity.

PHOSPHOINOSITIDE HYDROLYSIS IN HUMAN POSTMORTEM BRAIN MEMBRANES: ALTERATIONS IN ALZHEIMER’S DISEASE. A. Popovici*, L. Song, R. Powers and B. S. Eiken, Dept. of Psychiatry, Univ. of Alabama, Birmingham, AL 35294.

Membranes prepared from postmortem human prefrontal cortex hydrolized exogenous [3H]phosphatidylinositol PI) when (i) phospholipase C (PLC) was stimulated with Ca2+; (ii) GTPγS or NaF was added to stimulate G-proteins coupled to PLC, or (iii) calcium, ACPC, histamine, ATP, or serotonin plus GTPγS were added with GTPγS. The only response to ATP was influenced significantly by the duration of the postmortem interval (measured between 5 and 21 hr; n = 16). There was a decline in responses to several stimulators correlated with increased age (measured between 18 and 100 yr; r = 23). Utilization of antibodies to block responses indicated that Ca2+ and PI-β were the active subtypes mediating human membrane PI hydrolysis. ATP induced the greatest responses of the agonists tested and results indicate that it acts through P2-purnergic receptors. Comparisons of membranes from Alzheimer’s disease and age-matched controls indicated that Ca2+ and PL-β were the active subtypes mediating PI hydrolysis. ATP induced the greatest responses of the agonists tested and results indicate that ATP acts through P2-purnergic receptors. Comparisons of membranes from Alzheimer’s disease and age-matched controls indicated that Ca2+ and PL-β were the active subtypes mediating PI hydrolysis.

PERIPHERAL BENZODIAZEPINE RECEPTORS IN LYMPHOCYTES OF PATIENTS WITH ALZHEIMER’S DISEASE AND MULTI-INFARCT DEMENTIA. C. Ferrari*, A. Serranti*, G. Bianchi, R. Casavuotta, R. Riva, G. Bianchetti* and L. Franzola, Dept. of Neurology, University of Milan, Monza and (1) Alzheimer’s Unit, Sacro Cuore Institute, Brescia, Italy.

Peripheral benzodiazepine receptors (PBR) are modified in brain areas in animal models of stress and in Alzheimer’s disease (AD) patients. Since PBR present also in circulating lymphocytes, where appear to modulate immunologic functions, we presently investigated possible modifications of PBR in lymphocytes of patients with dementia, to investigate their role as putative peripheral markers of neurochemical alterations in degenerative disorders. 15 AD, 11 multi-infarct dementia (MID) patients (NINDS-ADRDA and DSM-IIIR criteria) and 10 age and sex matched controls were selected for peripheral blood analysis after a lymphocyte preparation. Frozen lymphocyte pellets were resuspended and incubated with various concentrations of [3H]PBR-11935, specific ligand of PBR, to analyze receptor density (Bmax) and affinity (Kd). PBR Bmax in all controls was similar to Bmax of young volunteers; a high variability of Bmax was observed in AD, although the mean was unchanged respect to controls. On the contrary, MID patients presented PBR densities significantly reduced respect to controls. No change of Kd was observed in any patient population. These findings may indicate a biochemical etiogenic in different AD patients and a possible role of PBR in neurochemical modifications observed in degenerative disorders.

AXELOTOXIC EFFECTS OF MCI-252, A NOVEL PSYCHOACTIVE COMPOUND, ON LATERAL HIPPOCAMPAL NEURONS IN RODENTS. J. Bouchi, T. Yusa, A. Tobe, M. Kakef and K.-I. Salto*. Pharmaceutical Labs. Lab. 1, Mitsubushi Kasei Corporation, 1000 Kamiyama-cho, Midori-ku, Yokohama 222, JAPAN. Clinical Research Center, MRC.

Effects of compound MCI-252, (4-[(2-fluorophenyl)-6-methyl-2-(1-piperazinyl)thieno[2,3-d]pyrimidine monohydrate], on memory and attention were examined. In water maze task in rats, MCI-252 (1-10 mg/kg, p.o.) ameliorated scopolamine-induced amnesia. Consecutive administration of MCI-252 (0.3 and 1 mg/kg, p.o.) reversed the passive avoidance failure in the basal forebrain-lesioned rats. MCI-252 at 1-10 or 10 and 30 mg/kg, p.o. reversed the attention deficits in mongolian gerbils or rats, whose cortical noradrenergic neurons were destroyed by 6,7-dichloro-1-naphthyl-2-bromobenzylamine or 6-hydroxydopamine, respectively. In the range of doses used, MCI-252 showed no abnormal behavior. Neurochemical studies showed that MCI-252 potentiated noradrenergic neuron pre- and post-synaptically, by inhibition of noradrenaline uptake ([C50+60%]) in vitro. Acetylcholinesterase inhibition in the DRN and the hippocampus was also observed.

STATUS OF SEROTONIN TRANSPORTER SITES (5-HTT) IN THE AGING HIPPOCAMPUS AND DORSAL RAPILE NUCLEUS (DRN) IN ALZHEIMER'S DISEASE. S. M. Tejani-Butt J. Yang J. Halak*, G. A. Ordway*, Dep't of Psychiatry, Univ. of Penn. School of Medicine, Philadelphia, PA 19104 and Dep't of Psychiatry & Human Behavior, Univ. of Mississippi Medical Center, Jackson, MS 39212.

There is increasing evidence that the functional integrity of the 5-HT system is compromised in age-related cognitive disorders. Several reports have indicated neurochemical changes in the DRN, including modest to severe losses of DRN neurons in Alzheimer's Disease (AD). Since ~40% of DRN neurons are considered to be 5-HT immunoreactive, this study analyzed 5-HT binding sites in order to obtain a quantitative assessment of the status of 5-HT innervation in the DRN in AD and the aging hippocampus. Sections were taken from the mid-region of the DRN from 8 subjects who had died of AD and 8 controls, and from the mid-region of the hippocampus from 18 subjects who had died of natural causes, ranging in ages from 19-80 years. A significant decrease in 3H-dextramipramine binding to 5-HTT sites was seen in the DRN in AD cases versus controls, with the most significant reductions (~30%) occurring in the lateral wings (p<0.01) of the DRN complex. In contrast, regression analysis of a significant effect of age on 5-HTT binding sites in the hippocampus (dentate gyrus, CA1, CA2, CA3) and entorhinal cortex. The results indicate that the integrity of 5-HT neurons in the DRN may be compromised, whereas the integrity of 5-HT terminals in the hippocampus may be unaffected by age. (Research funds from USDA grants NS 31699).

We have previously described the autoradiographic mapping of D2-like receptors with [3H]spiperone in human brain (Joyce et al., JPET, 255:1253, 1991), showing high expression in limbic regions. Reductions in the number of D2-like receptors in the DG, CA3, subiculum and perirhinal regions are observed in Alzheimer’s disease (AD) (Joyce et al., 1993; Neurosci. Lett. 190:33-38). In the present study we have observed a significant reduction in D2 receptor expression in the temporal cortex of Alzheimer’s patients, as compared to normal controls. The temporal cortices of AD patients showed a significant decrease in D2 receptor binding, as compared to normal controls. We also observed a significant reduction in the number of D2 receptors in the hippocampus of AD patients, as compared to normal controls. These findings suggest that the D2 receptor system may be a potential biomarker for the diagnosis of Alzheimer’s disease.

Differential regulation of RNA editing for an AMPA receptor subunit gene in the prefrontal cortex of Alzheimer’s patients: implications for schizophrenia and controls. S. Aebischer*, M.A. Smith and E.G. Jones. Dept of Anatomy and Neurobiology, University of California Irvine, CA 92717.

Studies in rat brain have demonstrated that the 5H4 cysteine to seryl mutation in the GluR-B subunit of the AMPA receptor is subject to RNA editing, by which a selected glutamine codon (CAG) is changed to an arginine codon (CGG). AMPA receptors containing GluR-B (2) polypeptide derived from edited RNA show a significant decrease in glutamate potentiation in comparison to AMPA receptors containing GluR-B (2) polypeptide derived from unedited RNA (Johnson et al., 1991, Cell 67:111). In the rat, the ratio of unedited vs. edited GluR-B (2) RNA changes from 1:99 during early brain development to 0:99:99 in the adult brain (Barnes et al., 1992, Neurosci. Lett. 139:195).

Dysregulation of GluR-B (2) editing could potentially cause AMPA and Cys2* mediated neurotoxicity. In the present study, the ratio and percentages of unedited and edited GluR-B (2) mRNA was analyzed in the prefrontal cortex of Alzheimer’s patients, schizophrenics and controls, using polymerase chain reaction with radiolabeled oligonucleotides, restriction enzyme analysis and scintillation radiography. In the Alzheimer’s brain, the abundance of unedited RNA was tenfold higher in comparison to age-matched controls (1.06% vs. 0.04%, p < 0.05) while in age-matched schizophrenics it was 0.39%. The abnormally high proportion of unedited GluR-B (2) mRNA in the Alzheimer’s brain indicates that RNA editing for GluR-B (2) subunit is compromised and could potentially be involved in mechanisms that underly chronic neurodegeneration. It will be of interest to study possible dysfunction of AMPA/KAR receptor RNA editing in the neurodegenerative diseases such as Amyotrophic lateral sclerosis or Huntington’s disease. Supported by NIMH grant MH44118 and by NARSAD and Stanley Grants.

Recently it has been reported that the cytosolic C-terminal amyloid precursor protein (APP) fragment, H165-Lys 676, forms a complex with isolated G<sub>a</sub>, a major GTP-binding subunit of APP (Goldsmith et al., 1991, Soc Neurosci. Abstr.). In this study we investigated the effect of the APP fragment H165-Lys 676 (APP 676), its reverse sequence and the smaller APP fragment Gly 659-Lys 676 on calcium currents in NG108-15 hybrid cells. In addition, we have investigated the interaction of these peptides with calcium current suppression mediated by adrenogenic a<sub>n</sub> and opioid a<sub>o</sub> receptors.

APP H165-Lys 676 (6x10<sup>-7</sup>M) did not affect calcium current suppression per se but clearly blocked calcium current suppression mediated by both adrenergic a<sub>n</sub> and opioid a<sub>o</sub> receptors in a concentration-dependent manner. The reverse APP fragment H165-Lys 676 and the shorter APP fragment Gly 659-Lys 676 did not affect calcium current suppression by adrenogenic a<sub>n</sub> and opioid a<sub>o</sub> receptors.

Our results show an interaction of C-terminal APP with adrenogenic a<sub>n</sub> and opioid a<sub>o</sub> receptor-mediated calcium current suppression downstream of the receptor, possibly via the GTP binding protein G<sub>a</sub>.Kishimoto I., Okamoto T., Matsuura T., Takahashi S., Okamoto T., Murayama Y., Ogita E., Nature, 362, 75-79, 1993.

REGULATION OF THE OLFACCTORY BULB ALZHEIMER’S PRECURSOR PROTEIN (APP) BY LESIONING OF THE OLFACCTORY BULB. M.C. Wilson, V. Ramakumar, R. Wang, B.N. Dharmi, B. Steinhoff, Dep’t of Pharmacology, Southern Illinois University School of Medicine, P.O. Box 19230, Springfield, IL 62794-9230 USA

Recent evidence suggests that APP modulates the activity of the guanine nucleotide regulatory protein, G<sub>a</sub>, a major growth cone protein. Growth cone associated protein (GAP-43) stimulates the binding of G<sub>a</sub> to GAP-43, thereby promoting its activation. Olfactory nerve deafferentation of the olfactory nerve led to an approximately 2-fold increase in GAP-43 to 4 weeks which is associated with regeneration of the olfactory nerve (Vergahein et al., J. Neurosci. Res. 26, 31-44). This study determined whether other components of this signalling pathway are altered by olfactory nerve lesioning. Lesioning was performed by administering a single injection of diethylthiocarbamate (DDTC) to Wistar rats (200-250 g). Vehicle-injected animals were used as controls. The levels of APP, GAP-43 and GAP-43 were determined by Western blotting. Nerve lesioning produced a transient increase in expression of APP (2-3 fold) by 6 weeks that recovered to control levels by 12 weeks. The levels of GAP-43 were also transiently increased (2-3 fold) by 6 weeks that recovered to control levels by 12 weeks. In contrast, GAP-43 level was decreased (~3 fold) over this time period and showed partial recovery (70-80% of control level) by 12 weeks. This upregulation of APP and GAP-43 might represent an attempt by the cell to compensate for the decrease in GAP-43. Olfactory nerve lesioning might provide a useful in vivo model to study.

We have previously shown that the β-amyloid precursor protein (β-APP) gene promoter is activated by the transcription factor c-Jun via a functional distal AP-1 site. We propose that stimuli that lead to activated Ras-dependent pathways would also regulate AP-1 activity to induce β-APP expression. Human astroglial cells (1321N1) were transiently co-transfected with a β-APP promoter luciferase reporter gene (a 593bp HindIII/ BamHI proximal promoter fragment fused to a human β-APP gene promoter) along with an expression vector for constitutively activated Ras. Our results show that expression of activated Ras increases β-APP-luc promoter activity approximately 5-fold; suggesting that stimulation of the Ras pathway can activate the β-APP promoter. Further experiments were carried out with a mutated form of the β-APP promoter containing a dysfunctional distal AP-1 site (Mut-β-APP-luc) which did not respond to co-expression of c-Jun or c-Fos. The Mut-β-APP-luc promoter was not inducible by activated Ras. We conclude that stimulation of the ras pathway leads to transactivation of β-APP expression via its distal AP-1 site. Studies are currently under way using a dominant negative Ras expression construct to establish a requirement for Ras in the regulation of the β-APP promoter activity by cellular mediators.

In comparison to control brain samples it has previously been shown that approximately 80% of Alzheimer’s Disease (AD) brains have the GTP binding site on β-tubulin substantially blocked and unable to be photoaffixed with 32P[GTPyS]. Also, addition of the cystolic fraction of AD brain homogenates was able to decrease this photoaffinity in control brains (Khaton et al., Ann. Neurol. 26, 210, 1989). Now we report that CSF from AD patients contains a very selective inhibitor of 32P[GTPyS] GTP co-precipitation into β-tubulin of control brain. This inhibitor is a flow through of centrifugation filtration and is stable to heat treatments of 90°C for 10 min. Treatment of CSF with calcium binding resins enhanced inhibitory activity whereas treatment with anion binding resins or with alkaline phosphatase totally abolished inhibitory activity. Ion exchange HPLC of cation filtered CSF and testing of the fractions for ability to reduce 32P[GTPyS] GTP co-precipitation identified one UV absorbing compound with an absorbance max of 291nm that blocked β-tubulin photoaffix. This compound was tentatively identified as a phosphorylated form of 8-hydroxyguanosine or 8-hydroxyguanosine. It is proposed that levels of this compound in the CSF may be a measure of the levels of hydroxyl radical (OH) or singlet oxygen (O2) in the brain. Also, these results imply that the radicals or endoperoxides formed by OH or O2 leading to 8-hydroxyguanosine nucleotides, may interact with various GTP binding proteins permanently modifying their biochemical properties. Supported by NIH grant GM 35766 and the Lincoln Clinic Foundation.

Increased release of excitatory amino acids (EAA) has been proposed to be involved in the pathogenesis of degenerative brain diseases, such as Alzheimer’s disease (AD). However, inconsistent changes in the cerebrospinal fluid (CSF) concentrations of EAA have been reported in patients with AD compared to controls, perhaps because the patients studied had illnesses of mixed severity. To determine whether there are stage-specific changes in CSF concentrations of EAA in AD patients with AD, we measured the CSF concentrations of glutamate, aspartate, and taurine (a comparison neutral amino acid) using high pressure liquid chromatography in 11 AD patients and 11 controls, recruited from the Alzheimer’s Disease Research Center. Twenty patients had early AD (CDR stage 0.5-1.0) and 12 patients had advanced AD (CDR stage 2.0-3.0). ANOVA revealed a significant increase in aspartate concentrations in advanced AD patients compared to controls (P<.15, P=.001, post-hoc Fisher’s PLSD - normals = early AD < advanced AD). A similar trend was observed for CSF glutamate concentrations (P=.24, P=.095). No significant differences in CSF taurine concentrations were observed among the groups. CSF aspartate concentrations were highly correlated with serum aspartate concentrations (r=.84, P=.0001), but not with taurine concentrations. These results indicate that CSF EAA concentrations are abnormally increased in patients with advanced but not early AD, and suggest that increased EAA levels may play a pathophysiological role late in the disease. This project was supported by the Alzheimer’s Disease Research Center Grant P50 AG05681.

Impaired energy metabolism can induce excitotoxic neuronal death and may contribute to the pathogenesis of late-onset neurodegenerative disorders such as Alzheimer’s disease. To determine if impaired energy metabolism could play a causal role in the formation of neurofibrillary tangles, we administered the mitochondrial inhibitor malonate (a reversible inhibitor of succinate dehydrogenase) to rats via intrahippocampal injection. Immunocytochemistry was used to examine cytoskeletal changes at different post-injection time points. Within six hours after injection, malonate (2 μmol) resulted in neuronal cell death, loss of MAP2 and MAP1B, and relative sparing of tau in the hippocampus. At the drug injection site, damage was widespread and involved most cell types in the hippocampal formation. Dilation to the injection site CA1 neurons were most vulnerable, although CA3 neurons were also affected. Intrahippocampal injection of the excitotoxin quinolinate resulted in a similar pattern of cell loss and cytoskeletal disruption. These results support the hypothesis that metabolic inhibition and excitotoxic insult may contribute to the sparing of tau and loss of other cytoskeletal proteins in tangle-bearing neurons in Alzheimer’s disease. Supported by AG10678.

In a previous study (Brain Research 726, 2004) we employed immunohistochemical techniques to demonstrate a decrease in GluR2/3 and GluR1 immunoreactivity in the entorhinal cortex (EC) of patients with Alzheimer’s disease. In the current study, Western blot analysis is employed in order to determine the extent to which selected GluR subunits are reduced in the EC. Moreover, we examined whether the decrease in GluR2/3 immunoreactivity within layer II pyramidal neurons in the EC parallels alterations in the expression of various cytoskeletal markers. Throughout these studies we examined normal subject controls and compared varying degrees of AD pathology. In patients with clinical and pathological verification of AD, GluR2/3 protein was reduced by nearly 50% of controls while GluR1 was decreased by 40%. Cell counts of GluR2/3 immunoreactive neurons demonstrated that the reduction of GluR2/3 could be attributed largely to a loss of layer IIb fibrous cells. In contrast, labeled cells were abundant in layers V and VI even in those cases with severe AD pathology. Examination of non-entorhinal cortical areas revealed a decrease in GluR2/3 protein, but no GluR1 immunoreactive neurons. The decline in GluR2/3 protein in the EC is accompanied by a decrease in synaptic contacts contributing to cytoskeletal pathology. This work is supported by NIH grant AG04206 and The American Health Assistance Foundation.

DEGENERATIVE DISEASE: ALZHEIMER'S—CELLULAR MECHANISMS OF DEGENERATION

The entorhinal cortex provides a major input to the ipsilateral hippocampal dentate gyrus. A unilateral entorhinal cortex lesion preserves the outer molecular layer triggering synapticosis and the replacement of synaptic connections. This reactive replacement of synaptic connections was originally studied with quantitative electron microscopy (EM). More recent experiments have employed synaptophysin-immunoreactivity (SI) to quantitatively assess synapse numbers utilizing light microscopy. No one has directly compared actual numbers of synapses observed with EM to values obtained with SI. Adult Fisher 344 rats were subjected to a unilateral entorhinal cortex lesion and killed at 2, 4, 10, 15, 30 and 60 days after the injury. Tissue was processed for both immunoreactivity and utilizing an antibody directed against synaptophysin, and for EM employing standard techniques. For the EM prepared tissue, the number of synapses per 100 µm² was ascertained. An image analysis device was used to obtain the corrected optical density for the SI prepared tissue.

Both techniques demonstrated a loss of synaptic contacts immediately following the lesion, although the magnitude was significantly less for the SI material. A time dependent change in staining could be observed in the SI material which, mimicked but did not parallel the rate and magnitude of synapse replacement observed with EM. The present results call into question the use of SI for the accurate quantitative assessment of synaptic number. Supported by AG05144.

510.2 SYNAPTIC DENSITY IN THE HIPPOCAMPAL DENTATE GYRUS IN ALZHEIMER PATIENTS WITH ALZHEIMER'S DISEASE. D.A. Price, D.L. Sparks* and S.W. Scheff Center On Aging, University of Kentucky, Lexington, KY 40536-0370.

Substantial synapse loss occurs in many cortical areas associated with Alzheimer's disease (AD). These brain regions are primary association cortex which normally receive significant inputs from many other association regions known to have AD pathology. The hippocampal formation is one of the primary areas affected in AD, and responsible in part for some of the impaired memory and dementia characteristics of the disease. We previously reported a substantial loss of synaptic numbers in the outer molecular layer of the hippocampal dentate gyrus. This area normally receives a direct input from the ipsilateral entorhinal cortex which has significant neuronal loss in AD. The inner molecular layer of the dentate gyrus receives most of its input from within the ipsilateral and contralateral hippocampi, and may not be affected by the disease process. The present study determined whether or not this area of the hippocampus is capable of maintaining synaptic numbers in AD patients as compared to neurologically normal controls.

Human brains were obtained from postmortem examination from patients who met the NINCDS-ADRSA criteria for AD and from age-matched controls. All tissues were obtained within 10 hours postmortem. The tissue was coded and prepared for ultrastructural examination. The density of synapses and the synaptic apposition length was determined for each subject. Because of ongoing research with these tissues the group designation remains coded at this time but will be discussed in full at the meetings. Correlations with synaptic density in the outer molecular layer will be presented. Supported by AG05144.

510.3 SYNAPTIC ANTIGEN REACTIVITY WITH A SERIES OF MONOCLONAL ANTIBODIES. A. Prusiner*, R. Bowser, W.O. Honig* and P. Davies. Dept. of Pathology, Albert Einstein College of Medicine, Bronx, NY and (1) Dept. of Psychiatry, Univ. of British Columbia, Vancouver, BC (Canada).

In a previous report, a series of 16 monoclonal antibodies (the SP series) to presumed synaptic antigens were produced. (W.G. et al., Brain Research 609:9-20 (1993)). This report is to verify that these antibodies do, in fact, react with synaptic antigens. The antibodies were produced by injecting mice with protein from whole brain. For one group of antibodies which was partially purified by eluting from an affinity column of the monoclonal antibody, which reacts with a synaptophysin-like antigen, attached to a peptide. Antigens presumably associated with synaptophysin in synaptic vesicles or membrane fractions would also be enriched by this method. Normal brain homogenates were prepared and fractionated to produce a synaptic vesicle rich fraction. Electrophoresis on a 12% acrylamide gel was performed and immunoblotting was done with each of the 16 SP series antibodies, along with EP10 and a commercial anti-synaptophysin antibody. When equal amounts of protein from each of the homogenates were analyzed, there was a pattern of enrichment of the antigens in the synaptic vesicle fraction. These antibodies, therefore, are reacting with antigens associated with the synaptic vesicle fraction, as predicted. We have confirmed that the SP monoclonals are reactive with five different proteins of this fraction. Further work with synaptic vesicle fractions isolated from Alzheimer's disease brains is ongoing.

Fibrillary tangles and amyloid plaques, the traditional markers of Alzheimer's disease (AD), are identified only post-mortem, and are present to a varying degree in nondemented aged brain as well. In addition, a definitive causative role in AD, for either of these complexes and their associated protein components, has not yet been shown. Here, we have attempted to identify proteins in cortex of AD brain as potential markers of the disease using high resolution two-dimensional electrophoresis in an effort to provide immune-reactive targets more specific for AD and perhaps more indicative of AD etiology. Protein from prefrontal cortex of AD and age-matched control brain was extracted, solubilized and separated first by isoelectric point, followed by molecular weight using the Millipore 2-DE electrophoretic system. The fractionation between 23 and 70 kDa and pH 3.5-10 6-8 contained at least one or more spots as identified by silver and coomassie stain in AD samples that were not present in controls. One of these spots (20 KD) was targeted for further analysis by electrophorically blotting onto PVDF membrane. The target spot was cut out of the membrane after being revealed by coomassie stain and sequenced using an automated amino acid sequencer. Two sequences were obtained and used to identify a unique peptide sequence, both beginning five residues from the N-terminus. These peptides were identical, except for a single amino acid residue (IaW) at position nine in the peptide or position 14 from the N-terminus of the protein. These peptides were injected into rabbits and antisera for each peptide was recovered and used to identify the target spot. However, immunobots using the A peptide revealed three or more spots in control and five or more spots in AD samples within the same gel region but with a much larger molecular weight and possibly greater abundance than the target spot. Furthermore, the A to W amino acid substitution completely changed the specificity of the antibody, revealing a single spot within the same molecular weight region detectable in AD as well as normal brain. Results obtained in this study suggest, assuming the accessibility of antibody to the antigenic site of the proteins, the possibility of an alternative processing of proteins observed in AD relative to controls.

DEGENERATIVE DISEASE: ALZHEIMER'S: NEUROPATHOLOGY AND NEUROTRANSmitters—OTHER SYSTEMS

1251
510.5 CHARACTERIZATION OF apl-1, AN AMYLID PRECURSOR-LIKE GENE IN THE NEMATODE CAENORHABDIS ELEGANS. I. Dangle*, C. Li, and D. Li, Dept. of Biology, Boston University, Boston, MA 02215

Alzheimer's disease is a neurodegenerative disease for which the cause is still unknown. Accumulation of a β-amyloid peptide in the brain of patients has been associated with the disease. This β peptide is derived from a larger amyloid protein precursor (APP), for which the normal function and processing remain to be understood. Recently, a family of APP-related proteins have been identified in Caenorhabditis elegans. We are interested in elucidating the function of APP by looking at APP-related genes in the nematode Caenorhabditis elegans.

We have previously reported the isolation and characterization of an APP-related cDNA from C. elegans, apl-1, and have shown that the predicted APL-1 protein is a member of the APP family of proteins. The genomic region corresponding to apl-1 has been identified and characterized; apl-1 spans 4 kb and contains 12 exons and 11 introns. It has been positioned to the left arm of the X chromosome of C. elegans. We are interested in studying the function of apl-1 by generating "knockout" worms, using a transposon insertional inactivation strategy. A mutant strain containing a transposon inserted in apl-1 has been isolated by Ron Plasterk and kindly provided to us. The transposon insertion has been located to exon 12, prior to the transmembrane domain. Further characterization of the mutant phenotype is underway. To determine the expression pattern of APL-1, antibodies against different parts of APL-1 are being generated and will be used to perform immunocytochemistry.

510.7 CHARACTERISTICS OF SECRETASE CLEAVAGE OF APP FROM PC12 CELL MEMBRANES. J.A. Ripolles*, Y. Chen, S.B. Roberts, K.M. Fiehnlein*, and N.K. Robakis, Dept. of Psychiatry and Fishberg Center for Neuroscience, Mount Sinai Medical Center, New York, NY 10029, and Bristol-Myers Squibb, Wallingford, CT 06492

The primary component of amyloid plaques, the hallmark of pathology in Alzheimer's Disease, is a 39-43 amino acid long peptide known as the amyloid-β peptide. β-peptide is derived by proteolytic processing of a larger precursor protein known as Amyloid Precursor Protein (APP). One pathway for APP processing which leaves the β-peptide domain prevents the production of amyloidogenic products and occurs via an enzyme known as "secretase". In this report we show that a subcellular fraction of PC12 cell cultures is enriched in "secretase" activity. After incubation at 37°C of membranes devoid of peripherally-associated molecules, a soluble 120DK fragment of APP is produced which on 7% SDS-PAGE has the same mobility as purified, secreted APP. This APP species is recognized by N-terminal specific antibodies but is not recognized by C-terminal specific antibodies. The enzymatic activity resulting in the release of the Nifin II form of APP has a pH range of 7.5 to 10.0, is differentially regulated by divalent cations, and is inhibited by two serine protease inhibitors. Moreover, the activity appears to be tightly membrane associated since extraction with 0.5M NaCl or sodium carbonate did not reduce the production of Nifin II.

The cellular prion protein (PrP) is a 250 amino acid glycoprotein of unknown function, highly expressed in neurons. In transmissible and genetic neurodegenerative diseases such as scrapie of the sheep and Creutzfeldt-Jakob encephalopathy of the humans, PrP is converted in an altered form (PrPSc), identical in its primary structure but distinguishable from the normal protein for its resistance to protease digestion. In fact PrPSc accumulates in the brain of affected individuals in protease-resistant, amyloid-like aggregates. Recently, it was reported that a fragment of PrP (Pp106-126) was able to induce neuronal apoptotic death in vitro, and an APP peptide homolog was identified in amyloid fibrils. Since all the PrP-related neurodegenerative diseases are characterized by both neuronal death and astroglia, our study was aimed to identify a direct proliferative effect of primary cultures of cortical astrocytes of the PrP106-126 fragment and whether the cellular mechanisms were involved. Pp106-126 induced a remarkable increase in quiesce (growth in absence of serum) rat cortical astrocytes assayed at both initiated thymidine incorporation and excomaxidine proliferation assay. Specific antagonists for different intracellular pathways were used to identify the molecular mechanism of action of Pp106-126. (MURST 40% 1992, 1993 to G.S.)

510.9 EFFECTS OF ETHANOLAMINE (Etn) ADMINISTRATION ON THE LEVELS OF Etn AND CHOLINE IN PLASMA, BRAIN EXTRACELLULAR FLUID (ECF) AND BRAIN TISSUE, AND ON THE LEVELS OF BRAIN PHOSPHOLIPIDS IN RATS: AN IN VIVO AND IN VITRO STUDY. E. De Michelis and R. E. Wurtman Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139

The sources and fates of brain ethanolamine (Etn) are poorly known and the effects of its administration have not been investigated, even though the cortical levels of this base are shown to be reduced in neurodegenerative pathologies with hypocholinergic function like Alzheimer's disease and Huntington's disease. We studied the effect of i.p. different Etn doses (10-2, 10-3 and 10-4 M/kg) and choline's (Ch) levels in arterial plasma and brain extracellular fluid (ECF) of awake rats. We also studied its effects on brain levels of Etn, Ch, and their respective major phospholipids. Etn administration caused dose dependent increase in Etn levels within plasma (p<0.05) and brain ECF (p<0.05), and also in brain Etn (p<0.05) and phosphatidylcholine (p<0.05). Systemic Etn also increased Ch levels in plasma (not completely dose dependently), brain ECF (dose dependently) (p<0.05), and in brain tissue (p<0.05); brain levels of phosphatidylcholine also increased. Possible metabolic pathways relating these increased Etn are discussed, as well as possible mechanisms of the decrease brain Etn in Alzheimer's disease.

510.10 DISTRIBUTION AND SEMI-QUANTITATIVE ANALYSIS OF TYROSINE HYDROXYLASE mRNA IN THE NORMAL HUMAN AND ALZHEIMER'S DISEASE LOCUS CERULEUS J. Leven*, M.A. Miller, P.E. Klotz, E.R. Parkind, and M.A. Barkind, Departments of Medicine (Neurology) and Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA 98195

Locus ceruleus neuronal loss is well documented in Alzheimer's disease, though concomitant decline of noradrenergic function has not been convincingly demonstrated. We have, therefore, become interested in the regulation and function of locus ceruleus neurons in both the normal state and in Alzheimer's disease. Brainstem with the complete locus ceruleus from both normal elderly patients and in Alzheimer's disease were collected and snap frozen. The entire locus ceruleus was serially sectioned from rostral to caudal extent and prepared for anatomical, immunohistochemical and in situ hybridization studies. We have developed in situ techniques for use in human brain tissue to examine for the presence and level of expression of tyrosine hydroxylase message using a 153 bp riboprobe (cDNA generously provided by Karen O'Malley, Washington Univ.). Our initial studies have demonstrated message for tyrosine hydroxylase in the locus ceruleus in both the normal and Alzheimer's disease brain. The findings are consistent with previous i.c.v. and i.v. tyrosine and rat brain. We will describe the distribution and level of expression of tyrosine hydroxylase message. We believe these studies will help elucidate the influence of Alzheimer's disease on locus ceruleus function and explain some of the paradoxes seen in the noradrenergic system in this disease.
LOCALIZATION OF THE DEFICIT IN CYTOCHROME OXIDASE (COX) ACTIVITY AND COX SUBUNIT mRNA WITHIN THE CEREBRAL CORTEX IN ALZHEIMER'S DISEASE (AD), K. Hastie, D.R. Brady, J. Shilt, S.J. Rapoport, C. Chandrasekaran, Laboratory of Neurosciences, NIA, Bethesda, MD 20205.

Quantitative COX histochemistry was used to measure COX activity in tissue sections from motor and temporal cortices of 12 AD and 7 control brains. The method was calibrated with tissue sections from homogenates of known COX activity. We also used in situ hybridization to localize mRNA of COX subunit III (COX III) and 16S rRNA, a marker of total mitochondrial RNA levels. To ensure identical hybridization conditions, slides containing sections from the temporal and motor cortex of the same patient were paired and hybridized with the sections facing each other, with the probe between them. Within the AD brain, COX activity is temporally cortex, a region typically affected in AD, was 29% lower in motor cortex (p<0.01), a region typically spared in AD. The levels of COX III mRNA in temporal cortex relative to motor cortex were 35% lower (p<0.01), while 16S rRNA showed no difference. Control cases showed no differences between the two brain regions in COX activity or COX III mRNA levels. There were no significant correlations between the decrease in COX III activity and the numbers of neurofibrillary tangles or senile plaques in the AD brains.

The levels of COX activity and mRNA were plotted as a function of distance from the pial surface. AD cases show a more pronounced decrease in layers I-II. Studies are under way to relate these deficits to the pre mortem clinical state of the disease, to loss of neurons and synapses, and to altered regulation of mitochondrial gene expression.

ACCUMULATION OF UBQUITIN-PROTEIN CONJUGATES IN A NEURONAL CELL LINE FOLLOWING TREATMENT WITH AN INHIBITOR OF THE MULTICATALYTIC PROTEINASE COMPLEX (250 PROTEASOME), M.E. Figueroa-Pereira, K.A. Bernt & S. Wilk, Deps of Pharmacology and Anesthesiology, Mount Sinai School of Medicine, CUNY, New York, New York 10029, USA.

Accumulation of ubiquitin-protein conjugates is common in abnormally inclusion inclusions of patients with idiopathic chronic neurodegenerative diseases. Covalent binding of ubiquitin to proteins is viewed as a means by which proteins are marked for subsequent degradation. We report that exposure of HT4 cells (a mouse neuronal cell line) to a potent inhibitor of the multicatalytic proteinase complex (MPC) causes accumulation of ubiquitinylated proteins. In contrast, incubations with a calpain inhibitor or with a lysosomal agent failed to produce detectable ubiquitinylated proteins. These results suggest that a malfunction in the ubiquitin/ATP-dependent protein degrading system, of which MPC is the "catalytic core", could be a factor in the accumulation of ubiquitin protein conjugates identified in neurodegenerative brains. The MPC-inhibitor may therefore be a useful tool for developing a model for the study of neurodegenerative diseases. (Supported by NIH grants NS-29036, MH-00350, GM-34582 and MH-48125.)

AN INFORMATIVE MICROSATellite [GT] REPEAT ON A CHROMOSOME 14 COSMID ALSO CONTAINING E2K, Ghazala Ali, Wilam Wesolowski, Rudolph Tanzi, and John Blass, "Burke Medical Research Institute, Cornell Medical College, White Plains, NY 10605 and Laboratory of Genetics & Aging, Massachusetts General Hospital, Charlestown, MA 02129.

Previous studies have indicated that the activity of the α-ketoglutarate dehydrogenase complex (E2K) is reduced in Alzheimer (AD) brain (Gibson et al, Arch Neurol 45:836-1988; Magistrocinco et al, J Neurochem 61:2007,1994) and fibroblasts (Cooper et al, Ann Neurol 35:519-1994). KDHIC consists of 3 proteins, E1K, E2K, and E3. We have localized E1K to chromosome 7 (Szabo et al, in press) and E2K to chromosome 14q243 (Ali et al, in press); E3 had previously been linked to chromosome 7. In order to test for association of the E2K gene with Alzheimer's disease, we have identified a microsatellite repeat region on a chromosome 14 cosmid which also binds the full-length E2K probe which we have isolated and sequenced recently (Tanzi et al, submitted).

Ten cosmids derived from a human chromosome 14 library were tested for cohybridization with E2K and with a GT repeat 30-mer. The one cosmids which was found to bind both probes was subcloned and sequenced. The 286 bp microsatellite region was used to design PCR primers amplifying a 401 bp fragment. This is an informative polymorphism giving rise to at least 10 separate common alleles. The polymorphism is being tested for association with familial and apparently sporadic AD.

**APOPTOSIS IS INDUCED BY HYDROGEN PEROXIDE IN CULTURED CENTRAL NERVOUS SYSTEM NEURONS.** E.R. Whittemore, D.T. Lee, and C.W. Cooper, Brain Aging Unit, Irvine, CA 92717.

The accumulation of α-amyloid peptides (Aβ) in senile plaques is a principal event in the neuropathology of Alzheimer disease. We previously reported that CNS neurons undergo apoptosis following exposure to Aβ in vitro. A link between Aβ-mediated apoptosis and oxidative damage has been suggested by studies reporting that antioxidant agents protect neurons from Aβ-induced cell death. We have pursued this possibility and demonstrated that exposure of neurons to 100 μM hydrogen peroxide for 24 h induced apoptosis as assessed by toxicity assays, nuclear staining, and assessment of internucleosomal DNA fragmentation.

We have begun to examine in more detail the mechanism of induction of apoptosis in neurons by hydrogen peroxide. We report that a reduction in cell viability and mitochondrial function occurs within 3 h following hydrogen peroxide exposure, and parallels the induction of DNA fragmentation. In other models of apoptosis, increases in [Ca2+]i have been linked with the activation of endonucleases responsible for DNA fragmentation. Measurement of [Ca2+]i using fura-2 imaging following exposure of neurons to hydrogen peroxide indicates that the [Ca2+]i increases steadily over time, consistent with the idea of activation of a Ca2+-dependent endonuclease. Vulnerability to hydrogen peroxide is cell type specific within the CNS, with neurons being most sensitive, followed by microglia, then astrocytes. These results suggest that direct oxidative injury may serve as a general trigger for neuronal apoptosis in the CNS, and that apoptotic cell death may be induced by oxidative injury and/or stress that accompanies many neurodegenerative diseases.

**S10.18**

Our cytochemical studies demonstrate progressive disturbances of endosomal-lysosomal function in Alzheimer Disease (AD) pathogenesis. Lysosomal alterations were identified in normal-appearing, at-risk AD neurons and progress with advanced degeneration. Following cell lysis, lysosomal hydrolases are present extracellularly in amyloid-containing senile plaques (SP). To establish whether cytochemical alterations could be explained by changes at the molecular level, we examined the gene expression of cathepsin D (CD) in fetal frozen, AD and control brains (PMI ≤ 6.5 h). Serial sections of the prefrontal cortex were analyzed with CD antisem and by in situ hybridization (ISH). Changes in the levels of CD expression were evaluated by semiquantitative densitometric and Northern blot analyses. SP were identified by silver stain and thioflavin S. In AD brains, ≈ 75% of sequested perikarya in layers III and V displayed 2-fold higher levels of CD mRNA by ISH compared to control brains (p < 0.001). The maps showed neuronal populations contained increased CD immunoactivity. Elevated levels of CD mRNA were confirmed by Northern blot. CD mRNA signal was localized in the soma and dendrites, but not in SP immunoreactive with CD antisem. Our results indicate that lysosomal system alterations occur early in AD pathogenesis. Activation of the lysosomal system is manifested by increased CD gene expression and immunoreactivity in at-risk AD neurons. Changes in hydrolase expression may be one of the earliest indicators of selective cell vulnerability in certain AD neurons preceding other histological and cytochemical evidence of degeneration and may relate to the formation of amyloid-containing SP.

**MEMBRANOUS LIPODYSTROPHY WITH ALZHEIMER’S SENILE PATHOLOGY.** Y. Takamura, R. Fukatsu, K. Tsumuki, Y. Yokoi, H. Takahashi, N. Itoh, N. Fuji, I. Kusunoki, T. Koyama, K. Naganuma, and N. Takahata. Dept. of Psychiatry and Pathology, Hokkaido Univ., Deps. of Neuropsychiatry and Microbiology Sapporo Medical Univ., 7Nakamura Memorial Hospital, Sapporo 060, Japan.

Membranous lipodystrophy (ML) is a rare disease characterized by multiple bone lesions with repetitive fractures and progressive neurosychiatric deterioration. We had an opportunity to examine two cases of the disease with Alzheimer’s senile change. In present study, we compare the senile changes in ML with those in Alzheimer’s disease.

**case 1.** 50 y old female. Brain weight 740 g. Severe generalized atrophy diffuse and profound demyelination and glisosis, sudanophilic granules, axonal swelling and spheroids were present. Wide spread senile plaques (SPs)and neurofibrillary tangles (NFTs) in the cortex.

**case 2.** 53 y old female. Brain weight 1030 g. Marked cerebral atrophy, severe demyelination and gliosis, numerous SPs and NFTs were found. SPs were distributed in cerebral cortices, predominantly in parietal and occipital lobes. The classical or compact plaques were predominant, but diffuse or subpial plaques were rare. Amyloid angiopathy were not recognized SPs were stained with anti β antibodies, and anti amyloid associated proteins Western blot analysis of brain extracts showed similar results.

In conclusion, the differences in senile alteration suggest that there are differences in pathogenesis of these senile changes between two cases extremely unusual cases and Alzheimer’s disease.

**S11.1**

Monkeys (Macaca fascicularis) with biotin acid (IA) lesions of the head of the caudate nucleus are characterized by anterograde and retrograde memory defects, and in vivo evidence of atrophy of the injected nucleus and ventricular enlargement on MRI. As in Huntington’s disease, overt signal change in regions of presumptive hypoelectricity is elusive on visual inspection. In this study, we mapped the distribution of signal intensity on proton density images (TR = 2000-2500, T1f = 42; in plane resolution = 0.47 mm).

The region containing the caudate nucleus was located by identifying pixel intensity transmissibility at the border of the caudate in the lateral ventricle, corpus callosum, corona radiata and internal capsule. Dorsal-ventral columns of pixels were averaged after subtracting background-adjacent pixels to reduce the weighting of the means by heavily myelinated areas, CSF and edema enhancing artifacts. In the normal caudate, signal intensity rose moderately from lateral to medial. In contrast, a local zone of hypointensity caused each IA injected caudate to depart from the linearity of the normal distribution. Regional deviations were approximately in register with the planned coordinates of the lesions. Loss of signal intensity may reflect neuronal depletion and gliosis, and thus the distribution of signal intensity may serve to be sensitive to the local anatomic and neurochemical consequences of neurotoxic tissue injury. However, hemosiderin deposits associated with microhemorrhage may also contribute. The findings may have relevance in assessing early state neuropathology in HD with structural imaging.

**3-NITROPROPICIC ACID NEUROTOXICITY IN STRIATAL AND NON-STRIATAL CULTURES IS MODULATED BY ENERGY SUBSTRATE AVAILABILITY BUT NOT SIGNIFICANTLY BY GLUTAMATE RECEPTOR ANTAGONISTS.** S.L. Fink, D.Y. Ho*, and R.M. Sapolsky. Deps. of Neurosciences and Biological Sciences, Stanford Univ., Stanford, CA 94305-520.

3-Nitropiproic acid irreversibly inhibits the activity of the mitochondrial enzyme succinate dehydrogenase. When administered systemically to rats or ingested accidentally by humans or livestock, it causes striatal lesions. All reports thus far on 3-NP neuronal effects have used whole animals or cortical explants. We studied the effects of 3-NP on dissociated cultures of neurons and glia. We found that, despite its selective toxicity in vivo, intoxication with 3-NP leads to comparable dose-dependent neuron death in cultured striatal, hippocampal, and hypothalamic neurons. In addition, 3-NPs effects were remarkable energy substrate-dependent, with its toxicity being potentiated by low glucose conditions to a greater extent than was the case for glutamate. Furthermore, death of neuronal explants was exacerbated with a herpes simplex virus vesi, carrying GLUT-1 glucose transporter significantly protected them against toxicity vrex by modestly damaging doses of 3-NP in low glucose media. Finally, the striatal damage caused by 3-NP administration has been shown to be partially mediated by excitotoxins. This is supported by one report in which glutamate receptor antagonists attenuated 3-NP-induced damage in cortical explants (A. C. Lodoloh, et al, Neurodenger J, 155-161 (19923)). We found that inoculation with the non-specific glutamate receptor antagonist, kynurenate, increased neuronal survival from 15% to 61% of control in low glucose conditions, but did not significantly increase survival of neurons exposed to 3-NP. We are currently studying whether 3-NP toxicity can be decreased by co-inoculation of the cultures with kynurenate and DL-2-amino-7- phosphonopentanoic acid (APH), an NMDA-selective glutamate receptor antagonist. If so, this would support a role for excitotoxic-induced cellular injury in the neuronal damage by this enetic toxin; however, pilot experiments indicate that most of the toxicity is caused by other cellular processes.

DEGENERATIVE DISEASE: OTHER—NEUROTOXIC EFFECTS AND HUNTINGTON’S

511.3 NEURONAL DEGENERATION INDUCED BY 3-NITROPYRUVIC ACID IN THE FOREBRAIN ANALYZE WITH A SILVER STAINING METHOD: FL. MIKULA AND L. ZABORSZYK. Center for Molecular & Behavioral Neuroscience, Rutgers, The State University of NJ, New Jersey, NJ 07102

3-Nitropyruric acid (3-NP) is a mitochondrial toxin which has been suggested (Beal et al., 1993) to replicate many of the histological and neurochemical characteristics of Huntington’s disease upon systemic or local striatal administration. The apparent neuronal loss in the forebrain is less than well understood. 3-NP was injected stereotaxically (500muM, 0.1-0.5uL) into various forebrain areas (striatum, internal capsule, thalamus, lateral hypothalamus, and hippocampus) in naive rats. While injections of 3-NP into the striatum resulted in local neuronal degeneration, an equally large number of medium-sized spiny striatal neurons degenerated if the injections were targeted. Injections of 3-NP also resulted in topographically organized neuronal degeneration in various thalamic nuclei, corresponding to the damage of their axons and/or terminals. Thalamic nuclei were always heavily affected. Moderate neuronal degeneration was also observed in the pars compacta and in some cases in the par reticulata of the substantia nigra. In spite of the fact that cortical axons were affected by the toxin, little cell death was observed in the cortex. These studies suggest that intracerebral injection of 3-NP can cause substantial retrograde degeneration in basal ganglia circuits, with different vulnerability patterns. This different vulnerability pattern might be taken into consideration when using 3-NP in an animal model of Huntington’s disease.

Supported by USPHS grants NS29545, NS30024.

511.5 HISTOLOGICAL AND BEHAVIORAL EFFECTS OF CHRONIC 3-NITROPYRUVIC ACID TREATMENT ON NASAL DOPAMINE RESPONSIVE REGIONS. GE Rousset1*, M-C Gayet-R Dolan, M. Mazibre and P. Hantraye. Service Hospitalier Frederic Joliot, CNRS URA125, 4 place du General Leclerc, 91401Codes Orsay, FRANCE.

Chronic administration of 3-nitropropionic acid (3-NP) in rats has been shown recently to produce bilateral forebrain lesions, closely replicating the neuropathology of Huntington’s disease (HD) (Beal et al., 1993). J. Neurosci. 13:4818-92. In the present study, we investigated the behavioral and anatomical effects of a chronic 3NP treatment (1mg/kg/day) on the performance of naive rats. Four months after the post-injection, 60-70% of 3NP-treated animals showed mild motor symptoms including a wobbling and an apparent decrease in the length of their steps and an abnormal paw placement during locomotion. Quantitative analysis of the locomotor behavior (under spatial and temporal cues) and after methamphetamine administration) using video recording showed significant changes in several parameters compared to control sham-treated animals, consistent with stable impairment of locomotion. Histological evaluation of the animals showed small lesions (30-60% of 3NP-treated group). These data confirm that chronic 3NP treatment leads to NMDA receptor-mediated like-lesions which are associated with stable motor symptoms.

This study examines the changes in extracellular GABA in the nucleus accumbens (NA) following quinolinic acid (QA) infusions into the striatum to determine whether 3-NP can affect the NA to provide a physical basis for behavioral changes in Huntington’s disease (HD). The NA constitutes a major functional interface between the limbic and motor systems in locomotor process, i.e., the basal ganglia (BG) has been proposed as a major pathway to modulate emotional and psychiatric disorders. Although Huntington’s disease (HD) is a neurodegenerative disorder with severe effects on striatal neuronal loss, GABA can be found in the NA is significantly decreased in HD patients with psychiatric features. Despite the common use of “decreased” as an explanation for behavioral problems in HD in clinical practice, no changes in basal ganglia have been proposed as a major pathway to modulate emotional and psychiatric disorders. Following intrastriatal analysis of QA (0.25mM) and QA (0.25mM) onto the NA, 3-NP-treated animals showed a decrease in the striatum (67% of baseline) and increase in NA (156% of baseline). On day 2, GABA returned to baseline in the NA and then declined gradually to 40% of baseline by day 7. Similar GABA slowly declined to this same level by day 7. These results show that QA perfusion of the striatum causes a slow decline in extracellular GABA in both nuclei but early transient increase in the NA. An extrapolation of such changes to the more protracted time course in HD may help to explain several locomotor and behavioral changes in humans with HD.

Excitotoxic animal models have been widely utilized to define the mechanisms involved in the abnormalities observed in Huntington’s disease (HD). Recently, 3-Nitropyruvic acid (3-NP) has been proposed as a model that closely mimics the anatomical pathology associated with HD based on the striatal atrophy following mitochondrial impairment induced by 3-NP. Since impaired oxidative metabolism has been implicated in HD patients, 3-NP seems to reflect a similar mechanism leading to striatal pathology. Very few studies have investigated the consequence behavioral pathology following 3-NP-induced lesions. In the present study, low dose systemic 3-NP-treated animals (Koutouzis et al Brain Res, in press) were observed significant hypertrophy, and accordingly suggested that this reflected a large and was abnormal HD cases. In the present study, low dose systemic 3-NP-treated animals exhibited significant hypertrophy, resulting in a plateau after the third injection (day 17), then showing significant hypertrophy from the fourth injection (day 18) onwards.

The close resemblance between systemic 3-NP’s behavioral effects in rodents and the ongoing behavioral pathology of HD in humans supports the applicability of 3-NP to HD. The present study shows that 3-NP-treated animals exhibited significant hypertrophy, resulting in a plateau after the third injection (day 17), then showing significant hypertrophy from the fourth injection (day 18) onwards. Additionally, treatment with 3-NP reversed the hypertrophy observed in the remaining HD cases. These results suggest that 3-NP-treatment is effective in reversing the hypertrophy associated with HD. QA treated animals showed increased rearing behavior, oral movements, and nocturnal activity compared to vehicle treated animals. Unlike rats receiving acute injections of QA, animals exposed to chronic QA show a more progressive development of abnormal behaviors.

Additional behavioral measures will be presented including changes in motor behavior following acute stress. Results will also show if any QA induced changes in behavior improve after the cessation of quinolinic infusion correlating with transient changes in striatal anatomy.

511.6 CHRONIC BILATERAL INTRASTRIAL DIALYTIC ADMINISTRATION OF QUINOLINIC ACID PRODUCES ABNORMAL MOTOR BEHAVIOR IN RATS. T. Bazzetti, C. Trahey, S. Ugart, J. Becker and R. Albin. Dept of Neurology and Biophysics, University of Michigan, Ann Arbor, MI 48104-1687.

We have previously reported that chronic intrastriatal dialytic administration of quinolinic acid (QA) in the rat produces selective neurodegeneration similar to that seen in Huntington’s disease (HD). In addition to neuronal loss, we have reported that chronic QA administration induces reversible changes in some areas of the forebrain. The present study shows that bilateral administration of QA using this technique, produces behavioral changes that may be analogous to those seen in HD. In the present study, rats treated with QA showed increased rearing behavior, oral movements, and nocturnal activity compared to vehicle treated animals. Unlike rats receiving acute injections of QA, animals exposed to chronic QA show a more progressive development of abnormal behaviors.

Additional behavioral measures will be presented including changes in motor behavior following acute stress. Results will also show if any QA induced changes in behavior improve after the cessation of quinolinic infusion correlating with transient changes in striatal anatomy.

511.8 TIMING THE TRANSCRIPTIONAL RESPONSE OF THE IT15 GENE (HUNTINGTIN) DURING THE EARLY STAGES OF THE NMDA RECEPTOR-MEDIATED EXCITOTOXIC CASCADE. L.R. Carlcock, K. Gutteridge, Y. Shen & P.D. Walker*. Departments of Molecular Biology/Genetics and Anatomy/Cell Biology, Wayne State University School of Medicine, Detroit, MI 48201.

NMDA receptor overstimulation produces a pattern of neuronal death within the rodent striatum similar to Huntington’s disease (HD). However, does the excitotoxic rodent model provide information that can elucidate the function of the IT15 (Huntingtin) gene in the chronic HD process? We sought to examine the transcriptional response of the rodent IT15 gene during the initial stages (1-72 hours) of the excitotoxic cascade and compare it to the IT15 gene in HD patients with psychiatric features. Despite the common use of “decreased” as an explanation for behavioral problems in HD in clinical practice, no changes in basal ganglia have been proposed as a major pathway to modulate emotional and psychiatric disorders. Following intrastriatal analysis of QA (0.25mM) and QA (0.25mM) onto the NA, 3-NP-treated animals showed a decrease in the striatum (67% of baseline) and increase in NA (156% of baseline). On day 2, GABA returned to baseline in the NA and then declined gradually to 40% of baseline by day 7. Similar GABA slowly declined to this same level by day 7. These results show that QA perfusion of the striatum causes a slow decline in extracellular GABA in both nuclei but early transient increase in the NA. An extrapolation of such changes to the more protracted time course in HD may help to explain several locomotor and behavioral changes in humans with HD.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
511.9

An attempt has been made to determine if the gene defect in Huntington's disease (HD) leads to neuronal degeneration that is a defect in mitochondrial energy metabolism or may render cells more vulnerable to endogenous levels of glutamate, resulting in excitotoxic neuronal death. In support of this hypothesis, PET studies have shown reduced glucose utilization in the basal ganglia of HD patients, while a recent NMR spectroscopy study found increased lactate concentrations in the occipital cortex and brainstem regions of HD patients (Jenkins et al., Neurology 1993, 43, 2689-2695). In addition, chronic systemic administration of mitochondrial toxins to rodents have been found to produce striatal lesions exhibiting close neurochemical and histological similarities to HD lesions (Bell, Ann. Neurol. 1992, 31, 119-130).

The aim of the present study was to investigate whether activities of electron transport enzymes and mitochondrial membrane potentials in HD patients, relative to levels in control subjects. Activities of citrate synthase and the oxidative phosphorylation enzyme complexes I, II-III, and IV, were measured in mitochondrial preparations by spectrophotometric assay procedures. Citrate synthase-corrected complex I activity was found to be significantly increased in frontal cortex of HD patients (+28%, p < 0.05), and showed a trend towards an increase in HD caudate. A trend towards decreased complex II-III activity was also evident in caudate. This study is presently being expanded to other brain regions.

(Supported by the Huntington's Disease Society of America.)

511.11

The identification and cloning of the IT15 gene and the subsequent development of high affinity antibodies raised against peptide sequences contained within the open reading frame of IT15 has provided us with the necessary reagents to isolate and purify the Huntington's disease protein (RDP). Using the affinity-purified antibodies raised against amino acid residues 1-17 of IT15, we have produced various neuronal and soluble protein subfractions isolated from rat forebrain. RDP is enriched in the synaptic vesicle-containing subfraction, but is readily dissociated from the vesicles by increasing ionic strength. The extracted RDP was fractionated by gel filtration, ion exchange chromatography and differential centrifugation on sucrose gradients and molecular weight spectrophotometry. The RDP band at 300 and 350 KDa, which cross-react with our anti-RDP Ig. We and anti-IT15 antibodies of both proteins in order to identify them. Preliminary sequence analysis indicates that the 350 KDa protein is rat brain RDP. The 300 KDa protein may be a structural homolog of RDP as indicated by the cross-reactivity to RDP antibodies. Both proteins reassociate specifically with synaptic vesicles as well as cytoskeletal elements, suggesting that RDP may play a role in neurotransmission and vesicle recycling.

511.13

The neuropathology of Huntington's disease (HD) is characterized by selective degeneration of striatal spiny neurons, a pattern of neuronal loss which can be reproduced in experimental animals by striatal injections of glutamate or NMDA agonists, suggesting that excitotoxic neurotransmission may play a role in the neurodegenerative process. Glutamate receptor antagonists may therefore ameliorate or slow HD, but such drugs (e.g. MK-801) in humans have been shown to have no beneficial effects. We conducted a randomized, double-blind, placebo-controlled tolerability trial of remacemide hydrochloride, a non-competitive NMDA channel blocking agent. Subjects were randomized to receive remacemide 250, 500 or 1000 mg/day or placebo and were assessed by standardized neurological and cognitive tests for 6 weeks, including a 1-2 week blinded staggered withdrawal of drug. The primary outcome measure was the proportion of subjects able to complete the study. Thirty-one HD patients in early to moderate stages of illness (18 months) were enrolled in the study; and twenty-nine completed treatment. One subject was terminated for non-compliance and one subject elected to discontinue drug because of nausea and vomiting (both in 600 mg group). There were no significant differences in the primary measure of tolerability between treatment arms. No severe adverse side effects or adverse cognitive effects were observed. Remacemide appears to be safe and well-tolerated in patients with HD at dosages up to 600 mg/day. Larger long-term study of the impact of remacemide on HD is warranted. (Supported by Fisons Pharmaceuticals and the University of Rochester Clinical Research Center R00004.)

511.10

Protein kinase C (PKC) is a calcium-dependent protein kinase and numerous isoforms have been found in nervous tissue. We have found that the PKCα isoform, a cytosolic isoform normally found in very low levels in striatal projection neurons, is significantly determined in striatal neurons in vivo in surviving rat striatal neurons subjected to an excitotoxic or ischemic insult. We therefore immunohistochemically examined fixed striatum from a presymptomatic Huntington's disease patient to determine if PKCα expression was increased and might reveal the early expression of the HD disease process. We found high expression of PKCα in the presymptomatic HD caudate and low expression in the control striatum. This upregulation of PKCα was largely devoid of PKCα labeling. In presymptomatic HD caudate, double-label studies showed that PKCα was expressed by 80% of the GABA (Caulin) neurons that were studied, a small number of stellate cells, but no somatostatin-/neuropeptide Y-containing interneurons. Using Calb-Immobieant to distinguish the patch and matrix compartments of caudate (low Calb neurons/pack) in a single rat and examining an adjacent PKCα labeled section, we found that a higher percentage of neurons in patch labeled for PKCα than in matrix. Our results show that enhanced PKCα expression specifically occurs in neurons destined to die in HD, implying much more than they actually die. This expression occurs first in the neurons that will die first (i.e. caudate neurons). The strongly greater expression in patch vs matrix suggests different mechanisms in matrix neurons in HD. Since the functions of PKCα are diverse, it is uncertain if the enhanced PKCα expression serves to promote or combat the HD process. Supported by NS-28721, NS-19620 and the Hereditary Disease Foundation.

511.12
CELLULAR LOCALIZATION OF HUNTINGTON'S DISEASE (HD) GENE PRODUCT: ENRICHMENT IN NERVE TERMINALS. A.H. Sharp, L. Levy, C. Schilling, A. Le, I. Hedren, S. Slodzik, T. Daniel, S. Snyder, C.A. Ross. Laboratory of Molecular Neurobiology, Johns Hopkins University, School of Medicine, 720 Rutland Ave., Ross 615, Baltimore, MD 21205.

Huntington's disease (HD) is an inherited neurodegenerative disorder with autosomal dominance and early onset of severe age-related symptoms. The causative gene contains an expanding CAG repeat presumably coding for glutamine in a long open reading frame yielding a 348 KDa predicted protein (HD Collaborative Group, 1993). The disease is characterized by degenerative neuronal loss in the basal ganglia and deep layers of the cerebral cortex which has been proposed to result from excitotoxicity. However, the mRNA for the gene causing HD is widely expressed in both central and peripheral, with no enrichment in the basal ganglia (Le et al., 1993; Strong et al., 1993). To examine the expression of the protein product, we have now developed affinity-purified polyclonal antibodies against peptides corresponding to amino acids 1-17 and 650-663 of the deduced sequence of the human HD gene product which react specifically with a 350 KDa band on Western blots. By using immunohistochemical methods, we find that the HD protein product, like the mRNA, is widely expressed and enriched in brain. Within the brain, it is more highly expressed in neurons than glia and prominent in cytoplasm, dendrites and axons. Within several brain regions, particularly the striatum, it is enriched in nerve terminals and loosely associated with synaptic vesicles and other membranes. These results are consistent with a role for the HD gene product in regulation of neurotransmitter release or reuptake and, perhaps, involvement in excitotoxicity.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
511.1

Recent advances in the understanding of the functional anatomy of the basal ganglia have led to the development of new approaches for the surgical treatment of movement disorders. The neural circuitry in the basal ganglia generates excitatory and inhibitory outputs to the pallidum via direct and indirect striatopallidal pathways. Under various pathological conditions, the balance between these excitatory and inhibitory projections can be disrupted, thus resulting in motor dysfunction. Lesions of the pallidum have therefore been proposed to eliminate the outflow of abnormal motor/sensory information. Such lesions in parkinsonian patients have been shown to ameliorate bradykinesia, rigidity, and tremor. In the present study, we have examined the effects of pallidotomy for the treatment of dystonia. Four cases of secondary dystonia resulting from different causes were treated by posterior ventral pallidotomy. Dystonia resolved from either hemiballism, cervical palsy, head injury or viral encephalitis. Each patient had a long history of spasticity and uncontrolled dynamic movements of the extremities (3 - 18 years). In addition, preoperative MRIs revealed lesions extending to the basal ganglia in each patient. MRI guided stereotactic surgeries were performed using the BKW MRI stereotactic frame. The posterior ventral pallidotomy contralateral to the affected extremity was chosen as the target site. Several radiofrequency lesions were made in the targeted pallidum after stimulation to verify the appropriate target area. Following surgery all patients exhibited marked reduction in spasticity. Postoperative MRI showed that the surgical lesions were confined to the posterior ventral pallidum. These results suggest that surgical lesions of the pallidum can ameliorate dystonia induced by a, and thus provide another support the notion of ablative ablative intervention for the treatment of basal ganglia-mediated movement disorders.

511.2

An important feature of the neuropathogenesis of HIV-1 associated dementia is neuronal loss in discrete areas of the cortex and subcortical regions. Evidence for HIV-1 infection of neurons is controversial, but soluble neuritic factors including tumor necrosis factor alpha (TNFα), produced by activated HIV-1 macrophages, may mediate neuronal death. We have demonstrated that TNFα is neurotoxic to cultures of human fetal cortical neurons in a dose-dependent fashion (Gebhardt et al., Dev. Neurosci., in press). Because TNFα has been implicated in apoptotic cell death in hypoxic-neuronal cells, we tested the hypothesis that TNFα could induce programmed cell death (apoptosis) in a neuroblastoma cell line (SK-N-MC) differentiated to a neuronal phenotype with 5 μM retinoic acid. TNFα, at a dose of 2 ng/ml, induces formation of DNA laddering in gel electrophoresis studies. Apoptotic nuclei in SK-N-MC cells were identified by an in situ method to label free 3'-OH ends of newly cleaved nuclear DNA. Apoptotic nuclei in SK-N-MC cultures can be identified 6 hours after exposure to 0.2 ng/ml of TNFα, and reach a maximum by 48 hours. At a dose of 0.05 ng/ml TNFα,- 10% of SK-N-MC cells/culture well have apoptotic nuclei. At a dose of 25 ng/ml TNFα-66% of SK-N-MC cells/culture well have apoptotic nuclei. This dose-dependent increase in apoptotic nuclei is inversely proportional to a dose-dependent (same dose range) decrease in cell viability as measured by trypan blue exclusion and enzymatic conversion of 3-(4,5-dimethylthiazol-2-yl) 2,5-diphenyl tetrazolium bromide (MTT). Studies are in progress to prevent TNFα-mediated neuronal apoptosis by infection of SK-N-MC cells with a recombinant adenoviral vector that expresses a portion of the extracellular domain of the TNFα receptor. (Supported in part by PAFAN/FAR and NINDS.)

512.3

Currently available scrapie-infected cell lines do not show distinct molecular correlations related to spongiform degeneration. We infected the GT1-1,1-k9 neuronal hypothalamic cell line, which secretes G0Rh in a manner that is transformed with the 1-k-A gene (NGF), with mouse BMS, prions (ScGt1-1-k9). Subclones have been in culture for over 9 months and were passage more than 40 times without any decrease in PrPC[Sc] production. Interestingly, there is a pronounced morphological difference between the ScGt1-1,k9 and the parental GT1-1-k9 cells. EM studies showed two characteristic and very prominent ultralunar changes in ScGt1-1-k9 cells, which were not detectable in GT1-1-k9 cells; a) huge vacuoles, and b) the apoptotic features of nuclear condensation and fragmentation and autophagocytosis. Extraction of Triton X 100 soluble DNA from ScGt1-1-k9 cells revealed a DNA fragmentation pattern typical for apoptosis (not detected in GT1-1-k9 cells). Although showing these very pronounced apoptotic features, over 80% of ScGt1-1-k9 cells are viable. Notably, after NGF treatment of ScGt1-1-k9 cells the DNA fragmentation was reduced. For the first time it was possible to infect GT1-1-k9 as well as mouse neuroblastoma cells (N2a) with conditioned media from ScGt1-1-k9 cells, permitting transfer of prions between mouse cell lines. Our findings present a cell culture model for the study of prion pathogenesis. The ScGt1-1-k9 cells exhibiting intracellular vacuolation and apoptotic cell death may be a useful model for neurodegeneration in humans and animals dying of prion diseases.

512.4

BIOCHEMICAL CHARACTERIZATION AND TISSUE LOCALIZATION OF PRION PROTEIN LIGANDS. B. Oesch, F. Coulie, E. Gburek, C. Bandrop, S. B. Prusiner, and S.J. DeArmond. Brain Research Institute, University of Zürich, 8029 Zürich, Switzerland and Dept. of Neurology and Pathology, University of California, San Francisco, CA 94143.

Interaction of the prion protein with other cellular components may be an important step for the function of cellular PrP (PrPSc) in the normal animal or for the infection with prions which contain an isoform of the prion protein (PrPSc). We have investigated the biochemical characteristics of PrP binding proteins resulting in the purification of a PrP ligand of 110'000 kDa (PI 110). We have used ligand blot as an essay for purification. The sedimentation properties of PrP ligands were analyzed by sucrose density centrifugation. PI 110 in postnuclear supernatant was found to sediment with high density particles suggesting that PrPSc is associated in multiprotein complexes. Purification to homogeneity was achieved by a combination of subaorticutes fractionation, ion exchange chromatography and SDS polyacrylamide gel electrophoresis.

As a second, independent line of investigation we have characterized binding sites for the prion protein in normal and scrapie-infected brain. Binding of radio labeled PrP 27-30 strongly to granule and pyramidal cells of the hippocampal formation. Competition with unlabeled PrP 27-30 revealed a Kd of 2 nM. A synthetic peptide (designated PS) corresponding to the central portion of the prion was able to reproduce the binding pattern observed with PrP 27-30. Peptide PS bound with a similar affinity and to the same sites as intact PrP 27-30. Binding sites seem to be mostly localized over cell bodies or proximal dendrites. From previous work it is known that PrP is axonally transported and located at the synapse leading to the conclusion that PrP may serve a signaling function at the synapse.

S12.5

Scrapie is the archetype unconventional slow infection disease. PCNA is a 36-kd, acidic, non-histone, delta accessory protein of the DNA replication machinery associated with cell proliferation. One issue is whether the astrocytosis seen in scrapie is a function of an increase in reactivity, or, if there is actual replication of astrocytes. In the current study, we used antibody to PCNA as a determinant of cell replication. Female, weanling Syrian hamsters, LWG/LAK, were inoculated intracerebrally with scrapie strain 139H or 263K or with normal hamster brain homogenates. Paraffin sections from scrapie and control brains were examined with PCNA immunostaining (ir-PCNA). We observed that the intensity of ir-PCNA in hippocampus, thalamus, hypothalamus and cortex of 139H- and 263K-infected hamsters was greater than in controls. Furthermore, by using double-staining analysis, we found that PCNA and glial fibrillary acidic protein were co-localized in brain cells. Our results suggest that the astrocytosis seen in scrapie-infected animals is, at least in part, due to actual replication of astrocytes in these animals.

S12.6

In post mortem studies of humans infected with human immunodeficiency virus (HIV), loss of large cortical neurons has been described which may, in part, explain the cognitive deficits of AIDS dementia. Feline immunodeficiency virus (FIV) produces an HIV-like pattern of disease in cats and has recently been shown to contribute to neuronal excitotoxicity in vitro. To evaluate if adult cats infected with FIV show early neurodegenerative changes which mimic the neurodegenerative changes seen in humans, we evaluated cortical cell densities in seven asymptomatic specific pathogen free cats three years after infection with FIV. Cell density in cortical layers II-V was evaluated for small, medium and large cells and compared to cell densities measured from the brains of six cats infected with FeLV. A 15-44% decrease in the number of large neurons in the frontal cortex was found. The largest decrease in neuron density correlated with low CD4/CD8 ratios. Neuronal loss was also evaluated in two FIV-infected random source cats and compared to two random source controls. A 30-34% decrease in large cell density was seen. This pattern indicates that FIV induces similar neurodegenerative changes as HIV and that these changes may begin to appear in relatively early stages of infection, before the appearance of overt behavioral or neurological symptoms.

S12.7
ANTI-MYELIN BASIC PROTEIN ANTIBODY IN PEDIATRIC AIDS PATIENTS. K.M. Weidenheim*, M. Trocchio, A. Bulkinstein and W.D. Lyman. Department of Pathology (Neuropathology) and Pediatrics (Immunology), Albert Einstein College of Medicine, Bronx, NY 10461.

Infection with human immunodeficiency virus type 1 (HIV-1) is associated with progressive neurological impairment. Characteristic white matter changes which are thought to contribute to the neurological problems include a generalized decrease in myelin, leukoencephalopathy, vascular myelopathy and corticoperiventricular demyelination. Corticoperiventricular demyelination is the most severe change in pediatric AIDS because it correlates with the progressive motor dysfunction observed clinically, and the clinically observed cognitive dysfunction may correlate with injury to hemispheric white matter during HIV-1 infection. Anti-myelin antibodies have been shown to damage white matter in other disease states, and antibodies to myelin basic protein (MBP) have been identified in adult patients with AIDS. However, anti-myelin antibodies have not yet been identified in children with HIV-1 infection. We have developed an ELISA technique which can detect anti-MBP antibody in microliter quantities of human serum. Serum samples from 4 pediatric AIDS patients with neurologic symptoms were analyzed using this system. ELISA plates coated with human MBP were incubated with test sera from 4 pediatric AIDS patients with neurologic disease. Antibody binding was detected using an ABC technique. Anti-MBP-antibodies were identified in 2 patients. Pre-absorption of sera with MBP decreased antibody reactivity. This suggests that the antibody was MBP-specific. Both children with anti-MBP antibodies had motor dysfunction, and one had neuropsychiatric impairment. These results suggest that anti-MBP antibodies are present in the serum of some HIV-infected children neurologic symptoms. These antibodies may contribute, in part, to the white matter pathology observed in pediatric AIDS. Support: U54MH6767, M446815.

S12.8
FETAL BRAIN ACCUMULATES GP120 SYSTEMICALLY ADMINISTERED TO PREGNANT MICE. J.Y. Wu T.W. Moodly, D.E. Brenneman and L.M. Squire. Dept. of Neurology, NICHD, NIH, Bethesda, MD 20892; BPR, NCI, NIH, Rockville, MD 20850.

Pediatric AIDS is often perinatally acquired and frequently accompanied by extensive neurological damage despite low levels of HIV-infected cells. The HIV envelope protein, gp120, has been shown to be toxic to neurons in culture (Nature 338:839, 1988) and to induce neuronal dystrophy, and behavioral retardation (Brain Res. 603:222,1993). The present study was designed to determine if gp120 could be transmitted from the maternal circulation to the fetal brain during pregnancy. 152 gp120 injected into tail vein mice during the 16th day of pregnancy, and fetuses were examined after 1, 24, 48 and 72 hours. The extracts of fetal brain and body were analyzed with gel filtration chromatography. The fraction co-eluting with stock gp120 is shown below in % of total CPM + S.E.M. eluted:

Significant amounts of radiolabeled material were found in fractions corresponding to the neurotropic gp120 fragments (Brain Res. 603:222,1993). After 2 days, approximately 0.01% of the radioactive gp120 injected into a mother appeared in the brain of one fetus. This study has shown that: 1) gp120 crossed the placental barrier; 2) although gp120 levels increased in both the fetal brain and body with time, gp120 was preferentially sequestered in the brain. These data suggest that the neurological damage occurring in pediatric AIDS may be due, in part, to fetal transmission of gp120.
3.11 PROTECTIVE EFFECT OF THYMOSIN PEPTIDES AND PHENOTHIAZINE NEUROLEPTICS ON SURVIVAL OF MICE TREATED WITH LETHAL DOSES OF ENDOTOXIN. M. Fagaras, M. Badamchian, A. Goldstein, Department of Biochemistry and Molecular Biology, The George Washington University, Washington, DC 20037

Pre-treatment with phenothiazine neuroleptics (chlorpromazine, trifluoperazine), thymosin α1, and thymosin β4, protected the mice against the lethality induced by endotoxin. Endotoxin and protective compounds were administered i.p. in Swiss-Webster mice. We investigated the molecular mechanism involved in this effect. We determined that phenothiazine neuroleptics and thymosin peptides inhibit a cascade of pathological mediators: free radicals, cytokines (interleukin-1 and tumor necrosis factor) platelet activating factor and arachidonic acid metabolites (6-Keto-PGF1α and TxB2). The effect on free radical formation was determined by measuring blood lipid peroxidation and red blood cell glutathione levels. Serum cytokine levels were measured by ELISA and plasma concentrations of arachidonic acid and metabolites were determined by platelet activating factor by RIA. Pretreatment of the mice with vitamin E, which is an antioxidant also increased survival against lethal doses of endotoxin. We concluded that free radicals are the first step in the cascade of toxic mediators induced by endotoxin. Phenothiazine neuroleptics and thymosin peptides by inhibiting free radical formation, inhibit this whole cascade which induces lethality.

Intercellular adhesion molecule-1 (ICAM-1), a cell surface receptor plays an important role in leukocyte transmigration in experimental meningitis. High levels of ICAM-1 can be measured in the CSF of patients with bacterial meningitis and provide evidence for a strong immune response, which may cause severe complications in spite of effective antibiotic treatment. We investigated the effect of systemic treatment with ICAM-1 antibodies on rCBF in male wistar rats. Meningitis was induced by intracisternal injection of pneumococcal cell wall components (equivalent of 107 cfu Streptococcus pneumoniae Pk 527, lana). rCBF was measured continuously over 6 hours with laser Doppler flowmetry. Rat ICAM-1 antibodies (TMB, Athena Neurosciences, Inc. San Francisco) were injected i.v. (1.5mg/kg) in three animals (n=3). In control animals saline was injected (n=4). There was an increase of rCBF in untreated animals 3 hours (mean±187% of baseline ± 47.8SD) and a dramatic increase 6 hours after the induction of meningitis (mean±265% ± 59%). In the ICAM-1 antibody treated group the increase of rCBF was lower 3 hours (mean± 127% ± 15%) and significantly attenuated (mean±134% ± 19, test p=0.015) 6 hours after induction. The results demonstrate that ICAM-1-1 is involved in mediating rCBF changes associated with bacterial meningitis.

To obtain evidence on an early step in the cascade of events following HSV infection in sensory ganglia, GAP-43, a protein induced by growing neurons, was examined. The hind footpads of mice were intracutaneously injected with HSV type-2 strain (9.3×106 pfu/ml or medium. At control), 5, 14 and 28 days post-inoculation (dpi), mice were fixed. Sections of decalcified spinal columns and DRGs were immunoreacted for GAP-43. Reaction product was quantified in ipsilateral (injected) and contralateral (uninjected) lumbar 4 and 5 and DRG and proximal dorsal roots using image analysis. At 14 days there was a 4- fold increase in GAP-43 immunoreactivity in the ipsilateral DRG and 8-fold increase in dorsal root. Both cell bodies and fibers were GAP-43-positive. At 28 dpi, GAP-43 was decreased in DRG, but sustained in dorsal roots. Contralateral tissues showed no increase in GAP-43, nor did ganglia or dorsal roots of mock-inoculated mice. Western analysis also showed induction of GAP-43 in dorsal roots. This result, together with selective neuropeptide alterations that we have previously shown, indicate that a sprouting response may be mounted in ganglia in reaction to herpesvirus infection.

3.15 MURINE NEUROPATHOGENIC ts - RETROVIRUS REPICATION IN MYOBLASTS AND ASTROCYTES IN VITRO T. Powere, P. Starke, A. Goldman, J. Vany, P. Bruder, A. Wawrzyn, D. Brooks Dept. of Neurology, UW Medical School, Madison, WI 53792 and Neuromolecular Research Laboratory VAMC Madison, WI 53705.

The pathogenesis of the neurodegenerative disease caused by ts- retrovirus is not fully understood. This virus can only cause spinal cord degeneration during postnatal development and not in adult mice. ts- retrovirus replication in affected animals occurs in ventricle, spleen, CNS and muscle tissue. It is unknown what the role of the replication of ts- retrovirus in muscle tissue is in the spinal cord degeneration caused by this virus. We are attempting to determine whether both muscle and CNS infection are required to produce disease. Integrated and unintegrated viral specific DNA forms are present in various tissues post infection. A novel low molecular weight, unintegrated virus specific DNA is seen in CNS tissues but not spleen or muscle.

We studied the replication of ts- retrovirus in differentiated astrocytes and muscle cells (CRL 1772) from C3H mice. Virus titers in supernatants from infected myoblasts (2x105/ml) were of the same magnitude as seen following infection of astrocytes (1x 105) at various times after infection. Cellular specific gene (actin, glut-1) expression was compared with virus specific gene (env) expression. No new low molecular weight virus specific DNA have been identified following ts- retrovirus infection in vitro. (Neurology 1994;48(Suppl 2):A358)

3.16 A PCR-BASED ANALYSIS OF HSV-1 LATENCY IN THE TRIGEMINAL GANGLION OF THE RAT. D.J. Finch*, R. Ramakrishnan and M. Levine, Departments of Neurology and Human Genetics, and GRECC, VAMC, University of Michigan, Ann Arbor, MI 48105.

Competitive quantitative PCR and RT-PCR was used to quantitate DNA and RNA from an attenuated ribonucleotide reductase (RR)-deleted herpetic simplex virus type 1 (HSV-1) mutant in the rat trigeminal ganglion after peripheral inoculation for Assessment of ganglionic scarring. Amplification of ganglionic DNA with oligonucleotide primers specific for the HSV gB gene and for the LAT gene indicated that there were approximately 4 x 106 genome equivalents per ganglion at 2, 7 and 56 days after inoculation. Amplification of ganglionic RNA with primers specific for HSV LAT indicated that there were approximately 1 x 106 LTR-pseudogenes per ganglion at 2 and 7 days post inoculation, and 1 x 104 LAT molecules per ganglion at 56 days. In situ hybridization with a digoxigenin-labeled riboprobe specific for LAT detected an average of 1-2 LAT positive cells in each positive 6 micron section of trigeminal ganglion. In situ PCR detection of HSV genomes in similar sections, using digoxigenin-labeled nucleotides with primers specific for HSV gB, identified 27-150 genome-positive cells per section. These results indicate that there are approximately 50 LAT molecules per latent HSV genome in the trigeminal ganglion, compared to 15 LAT molecules per latent HSV genome in the CNS (Ramakrishnan et al., J. Virol. 1994), but that cells with detectable LATs by in situ hybridization represent only a small proportion of those ganglionic neurons containing HSV genomes. The presence of latent HSV genomes in a large number of neurons suggests that HSV may be more efficiently in establishing the latent state than would be anticipated from previous reports.
512.17

IMPROVED BRAIN DELIVERY AND IN VITRO EFFICACY OF ZIDOVUDINE (AZT) USING A ROSEX CHEMICAL DELIVERY SYSTEM. J. Miscetti, A. Rubinstein, Z. Harish, A. Biegler, W. Anderson, and M. Brouwer. Div. of Allergy and Immunol., Albert Einstein College of Med., Bronx, NY 10461. 1Pharmos, Corp. Alachua, FL 32615 and 2Pharmos, Corp. Rehovot, ISRAEL. Improved therapy for AIDS dementia and related encephalopathies may be achieved through enhanced delivery of effective anti-retroviral agents to the brain and CNS. The goal is the chemical delivery system (CDS) which has been applied to a number of drugs including zidovudine (AZT). The current evaluations were aimed at further defining the pharmacokinetic profile of the AZT CSCS as well as establishing its in vitro antiviral efficacy against HIV in both lymphocytes and a neural cell line. AZT or AZT-CDS at a dose of 150 μmol/kg was administered to Spague Dawley rats (i.v., tail vein) for 1 hour. The AZT-CDS produced significantly higher brain levels of AZT (AUC = 425 μg.min/mg) than did equimolar AZT dosing (AUC = 135 μg.min/mg). In addition, blood levels were reduced (AZT from AZT-CDS, AUC = 583 μg.min/mL; AZT from AZT, AUC = 1580 μg.min/mL). In culture systems (CEM lymphoma and a SKNMC neuroblastoma cell line), AZT uptake after co-incubation of cells with AZT for 1 hour was minimal. By contrast, addition of the AZT-CDS to tissue cultures resulted in large increases in the uptake of the AZT-CDS followed by biochemical conversion of the CDS to its main metabolites (the AZT-CDS quaternary salt, AZT-O, as well as AZT itself). These improved uptake profiles were associated with greater in vitro efficacy. Thus, AZT-CDS at 0.5 μM was 8% more effective than AZT in suppressing p24 production (at day 3) in a lymphocyte culture infected with 6000 TCID50 of the N11 strain of HIV and 50% more effective at 0.05 μM. Furthermore, syncytia formation was completely suppressed at an AZT-CDS dose of 0.5 μM (1000 TCID50's) while AZT at the same dose was ineffective. Finally, while AZT (at 0.5 μM) is not active in reducing viral replication in an SKNMC neural cell line, the AZT-CDS provided for significant reductions in p24 expression.

MENTAL ILLNESS: SCHIZOPHRENIA

513.1

KINDLING WITH CLOzapine. J.R. Stevens* and D.D. Denney. Dept of Neurology & Psychiatry, Oregon Health Sciences University, Portland OR 97201. The apical neuroleptic clozapine improves symptoms and behaviors of many patients with schizophrenia who have failed to respond to other neuroleptics. In addition to blockade of central nervous system monoamine, muscarinic and other receptors, clozapine often causes bilateral spike-wave activity in the EEG and generalized seizures occur in 3-5% of patients treated with the drug. Acute administration of clozapine in rats induces dose related myoclonic jerks. Although considered an undesirable side effect of clozapine, this evidence for epileptogenesis could relate to the therapeutic effect of this drug. The experiments reported here demonstrate that repeated fixed subconvulsive doses of clozapine (1 mg/kg) that initially caused no behavior change, caused seizure-like activity manifest as myoclonic jerks (MJ's) after the third injection of clozapine, and reached 150 MJ's/hour by the 15th injection. These results are consistent with kindling, i.e., a progressive sustained increase of brain excitability following repeated administration of a fixed subconvulsive dose of a provocative agent. If excitation of neurons in critical brain areas is an important aspect of the therapeutic effect of clozapine and other neuroleptics, kindling with repeated fixed low dose administration of clozapine and related drugs might be effective clinically and should decrease undesirable side effects associated with conventional high dose treatment regimens.

513.2

FRONTAL DYSFUNCTION IN SCHIZOPHRENIA. J. Gold, B. Hermann, C. Randolph*, G. Chelune, M. Trencery, D. Loring, T. Goldberg, D. Weinberger, NIHMS Neuroscience Center at Saint Elizabeths, Washington, D.C. 20032. Prior neuropsychological and neuroimaging studies had implicated dysfunction of the frontal cortex in schizophrenia (SC). However, this hypothesis has not been obtained directly using a unique patient group design. In this study, we contrasted the neuropsychological performance of 66 SC patients with that of 91 patients with frontal lobe epilepsy (FLE) (36 with a left frontal seizure focus, 51 with a right frontal focus) who were drawn from 4 epilepsy surgery programs. The epilepsy patients had a mean age of onset of chronic seizures at age 12 and were refractory to conventional pharmacotherapy. All test data was obtained prior to any eventual surgical treatment. The three patient groups did not differ in age, education, or Full Scale IQ. The SC group performed significantly better than either frontal group on measures of semantic memory such as single word reading and vocabulary. The SC patients did not differ from either frontal group on measures of attention and motor speed, which we have previously found to distinguish SC from temporal lobe epileptic patients. SC patients performed significantly better than either frontal group on phonemic fluency, a task which does distinguish frontal from temporal lobe epilepsy patients, but significantly worse than the right frontal group on the Wisconsin Card Sorting Test. The data suggest the limitations of focal lesion models of schizophrenic cognitive impairment, and demonstrate differential impairment of frontal function in schizophrenia with maximal impairment in attention and working memory and a relative sparing of frontally mediated verbal fluency.

513.3

D2/D3 AND D4 RECEPTOR DENSITIES ARE NOT ALTERED IN RATS WITH NEONATAL HIPPOCAMPAL DAMAGE. Michael B. Knable, Angela M. Murray, Barbara K. Lipps, Farouq Karoum', Daniel R. Weinberger, Clinical Brain Disorders Branch, IRP, NIMH, Neuroscience Center, Washington, DC 20032. Previous studies demonstrated that rats with excitotoxic ventral hippocampal (VH) lesions postnatally develop DA-related behavioral changes. These effects were similar to some aspects of schizophrenia. We sought to determine if these behavioral effects were associated with changes in the distribution or number of striatal DA receptors. On postnatal day 7 (PD7), rats received infusions of ibotenic acid or vehicle into the VH. They were sacrificed on PD35 and PD56. Brain sections (2μm) were incubated with 10nM [3H]HOM (50.51±12.13 in control rats and 57.0±3.3% in VH lesioned rats) and [3H]raclopride. [3H]raclopride. Butaclamol (10μM) was used to define non-specific binding in both assays. Mean optical density in the dorsolateral (DLS) and ventromedial (VMS) stratum, and nucleus accumbens (NAC) were converted to fmol/mg tissue. Specific raclopride binding was subtracted from total binding to estimate D2 receptor density. There was increased binding of YM-09151-2 and raclopride in both control and lesioned rats in DLS and VMS on PD56 compared with PD35. In DLS, cell density was not decreased in control rats with VH lesions. In VH lesioned rats, there was a 50% decrease in D4 receptor density. There were no effects of lesion for either ligand or the calculated D4 receptor density in any region. These results suggest that delayed hyperdopaminergic behaviors in rats with neonatal VH lesions are not mediated by abnormalities in density of striatal D2/D3 or D4 receptors.

513.4

C-FOS EXPRESSION IN RATS WITH A NEONATAL HIPPOCAMPAL LESION IS ALTERED AFTER AMPHETAMINE CHALLENGE. Sonia M. Ulrich, Barbara K. Lipps*, Susan E. Barchus, Daniel R. Weinberger, Clinical Brain Disorders Branch, NIMH, Neuroscience Center at St. Elizabeths, Washington, DC 20032. A neonatal (day 7 after birth, PD7) ibotenic acid lesion (large size) in the ventral hippocampus results in postpubertal (PD56) onset of a variety of abnormal behaviors that have been related to corticobasal and striatal dopaminergic dysfunction. A more restricted lesion (small) does not induce behavioral hyperactivity on PD56. To further characterize this potential animal model of schizophrenia, we studied the expression of c-fos mRNA in rats with two sizes of hippocampal lesions. C-fos has been shown to be induced by catecholaminergic stimuli. Rats were previously given amphetamine (AMP) (1.5 mg/kg) twice on PD35 and PD56 and their motor activity was tested. C-fos mRNA expression was assessed using an oligonucleotide probe was assessed six weeks later 30 and 90 minutes after AMP (10 mg/kg) or saline. A significant effect of drug treatment was seen in the ventromedial (VMS) and dorsolateral stratum (DLS), in superficial and deeper bands of parietal cortex (SPC and DPC, respectively) as well as the medial prefrontal cortex (MPCF). C-fos expression was decreased in MFC in rats with a large lesion 30 min after AMP, but not in the striatum. AMP produced a significant time effect in the DPC in rats with both lesions and in DLS after a large lesion. These preliminary results demonstrate that an early hippocampal damage alters the cortical c-fos response to AMP in adult rats.
S13.5 NEONATAL EXCITOTOXIC HIPPOCAMPAL DAMAGE ALTERS Dopamine RESPONSE TO MILD CHRONIC STRESS and CHRONIC HALOPERIDOL.

The effects of neonatal (day 7 after birth, P7) ibotenic acid lesions of the ventral hippocampus (VH) on dopamine release in response to chronic stress (saline injections for 21 days) and haloperidol treatment (0.4 mg/kg for 21 days) were investigated in adult (P64) Sprague-Dawley rats. Tissue 3-methoxytyramine (3-MT) accumulation after MAO inhibition with parimypine measured by 3H-DANS was used as an index of dopamine storage. At baseline (no injection), 3-MT was reduced in striatum (ST) of lesioned rats. Repeated saline injections resulted in a further 3-MT reduction in ST, nucleus accumbens (NAc) and frontal cortex (FC) in lesioned rats, and had no effect in controls. Chronic haloperidol, compared with vehicle, increased 3-MT accumulation in ST, NAc and FC in control and lesioned rats. The 3-MT increase was enhanced in FC and NAc of haloperidol-treated lesioned rats vs controls. These data show that a developmental lesion of VH alters dopamine responsivity to environmental (chronic mild stress) and pharmacological (chronic haloperidol) challenge.

S13.7 QUANTIFICATION OF MESOPONTINE CHOLINERGIC NEURONS IN THE HUMAN BRAIN.

Karon et al. (1991) reported that schizoprenics have significantly more NADPH-diaphorase-containing, putative cholinergic, pedunculopontine nucleus neurons than controls (Psychiat. Res., Neuroimaging, 40:31-49). The purpose of the present study was to use a specific marker for cholinergic neurons, an affinity purified human antibody against choline acetyltransferase (Chat), and computer imaging techniques to map the locations of cholinergic mesopontine neurons in the human brain. Four cases were collected from the Medical Examiners Office, 22-47 years of age. Cells were mapped on one side of the brain, in 50 mm thick horizontal sections, sampled from 5.0-6.6 mm intervals (n=7-10 sections/case), and stained with 1:200-2,000 antibody concentration. The cell counts were corrected for split-cell counting error. There was an average of 14,986 ± 1,593 neurons (mean ± SEM) (11,661-17,903) within the compact and diffuse sectors of the Ch5 region, and the Ch6 region (nomenclature of Mesulam et al. J. Comp. Neurol. 281:611-630, 1989). Future studies will determine whether differences in mesopontine cholinergic neuron numbers exist in schizophrenic cases.

S13.8 EXPRESSION OF SYNTHELIN IN THE BRAIN POSTSYNAPTIC DENSITY OF THE RAT, MDX MOUSE AND A DUCHENNE MUSCULAR DYSTROPHY PATIENT.

Duchenne muscular dystrophy (DMD) is an inherited fatal disease affecting one in 3500 boys with progressive muscle degeneration. Although cognitive impairment is a common feature of DMD, mechanisms underlying mental changes are unknown. DMD is characterized by a defect in dystrophin, a 427 KD plasma membrane protein that is located predominantly in muscle, and that has recently been detected in brain. We have previously found that brain dystrophin is a component of the postsynaptic density (PSD) and is absent in the mdx mouse, an animal model of human DMD. Recently, dystrophin, a 58 KD dystrophin-associated protein, was reportedly concentrated at postsynaptic sites at sites of neuronal junction. One postulated function of syntelin is involvement in clustering of acetylcholine receptors. Co-localization of syntelin with dystrophin in muscle prompted us to examine the protein in the rat brain by focusing on the PSD. Our results, obtained by Western blot analysis using a specific antibody against syntelin, revealed that brain syntelin is an intrinsic component of PSD. Moreover, it is differentially expressed during cortical development and is expressed in a region-specific manner. Despite complete deficiency of the 427 KD dystrophin in mdx mouse and dystrophin human brain, syntelin was detectable but decreased in cortical PSDs from the mdx mouse and from one case of human DMD. Our results indicate that dystrophin and syntelin are co-localized in the PSD, but are differentially expressed in the diseased state.

S13.9 PERINEURAL NETS OF EXTRACELLULAR MATRIX: AROUND NERVE CELLS in VARIOUS NEUROPSYCHIATRIC DISORDERS. C. Neubauer1, P.R. Hof2*, J. Miklóssy3 and M.R. Celio, 1Dept of Psychiatry, Univ. of Geneva, 2Division of Neuropathology, 3Institute of Histology, Univ. of Fribourg, Univ. of Lausanne, Switzerland; 4Dept of Neuropathology, NY State Mental Ctr, New York 10028.

Perineuronal nets of extracellular matrix" (PNs) are observed around subpopulations of nerve cells in the adult brain and may control their interactions with other neurons, glial cells, and blood vessels. In the cerebral cortex, PNs are associated with interneurons containing the calcium-binding protein parvalbumin (Celio and Bilimke, Brain Res. Rev. 1994;19:128-145). In the present study, the distribution of PNs was analyzed in several areas of the cerebral cortex in the normal human brains and compared to cases affected by psychiatric (Alzheimer's disease, Pick's disease, Down syndrome and schizophrenia) and neurological disease (multiple sclerosis, epilepsy).Brains were obtained at autopsy (4-24 hours postmortem) and were visualized using Vicuna villous lectin and chondroitin sulfate proteoglycan immunohistochemistry. No obvious changes in distribution and staining intensity of PNs were observed in Alzheimer's disease, Pick's disease, Down syndrome, epilepsy, and multiple sclerosis cases. However, a decrease of PNs around neurons was found in the cerebral cortex of schizophrenic cases. This finding may reflect the fact that disruption of the extracellular matrix or loss of certain components of PNs occur in schizophrenia. Such changes in PNs around select interneuronal cell classes such as parvalbumin-containing cells may cause functional alterations in this population of inhibitory neurons in schizophrenia.

S13.10 PHARMACOLOGICAL CHARACTERIZATION OF THE BINDING OF [3H]YOHIMBINE TO D4 Dopamine RECEPTOR SUBTYPES IN BASAL GANGLIA AND CORTEX OF SCHIZOPHRENICS AND CONTROLS.

A. Murray*, T. M. Hyde, M. B. Knable, M. B. Herman, L.B. Bigelow and J. E. Kleinman, Clinical Brain Disorders Branch, NIMH, NIH, St. Elizabeths Hospital, Washington, DC 20032.

The identification of 5 distinct dopamine (DA) receptor sub-types has important implications for the D4 hypothesis of schizophrenia. The D4 receptor is particularly intriguing because it binds clozapine with high affinity. Seeman (1993), subtracting the binding of [3H]Raclopride (labels D2 and D3 receptors) from that of [3H]YOHIMBINE (labels D2, D3 and D4 receptors) for identical groups of D4 receptors, demonstrated a six-fold increase in D4 binding in schizophrenic patients compared to the controls. We characterized the pharmacology of [3H]YOHIMBINE binding and the density and distribution of D4 receptors using quantitative autoradiography in the striatum, entorhinal and prefrontal cortex, in schizophrenic brains compared to normal controls. Adjacent sections were incubated with 1 nM [3H]YOHIMBINE (1-2 nM) and 0.1 nM [3H]RACLOPRIDE (to block 5-HT1A receptors) or 0.6 nM [3H]RACLOPRIDE. Butaclamal (10uM) was used to define non-specific binding. In the basal ganglia, schizophrenia had significant increases in D4 receptors in all regions (60-80%) labeled with [3H]YOHIMBINE alone compared to controls. A similar trend was observed in the prefrontal cortex. However, the binding of [3H]YOHIMBINE was significantly decreased ([3H]YOHIMBINE binding (50%) in the subiculum and entorhinal cortex compared to [3H]YOHIMBINE alone. This suggests that [3H]YOHIMBINE binds to 5-HT1A receptors in cortical regions.
S13.11
RESPONSE OF NEUROTENSIN SYSTEMS SUGGESTS THAT THE
SHT-2 ANTAGONIST, MLD 100,907, HAS CLOAZAPINE-LIKE
ANTIPSYCHOTIC EFFECTS. G.R. Hanson*, L.G. Bush, J.W. Gibb, and
C.J. Schmidt. Dept. Pharmacol. and Toxicol., University of Utah, Salt Lake
City, UT 84112 and Marion Merrell Dow Inc., Cincinnati, OH 45215.

Drugs such as haloperidol (HA) are classified as typical antipsychotics
because of their pronounced extrapyramidal side effects and their lack of
effectiveness against the negative symptomology of schizophrenia. In
contrast, drugs like clozapine (Cloz) are considered atypical antipsychotics
because of their lack of extrapyramidal effects and their ability to relieve schizophrenia-related negative symptoms. Although
the difference between typical and atypical antipsychotics is not known, the antagonist effects of Cloz on SHT-2 receptors, an effect not shared by
HA, suggests that a serotoninergic mechanism may be important.
Based on this hypothesis, the highly selective Marion Merrell Dow SHT-2
antagonist, MLD 100,907 (MLD), may have atypical antipsychotic
effects. This was tested by comparing the responses of caudate and
nucleus accumbens neuropeptide (NT) systems (a neuroepitope dramatically altered by antipsychotic drugs) to 1, 2 and 4 doses of HA,
Cloz and MLD. These studies revealed that the pattern of changes caused by MLD, in neuropeptide-like immunoreactivity in 6 caudate
regions was much more like the effects of Cloz than HA. In contrast, the
responses of the NT systems in the anterior and posterior nucleus accumbens were very similar for all three drugs. We conclude from these
findings that (1) antagonism of SHT-2 receptors plays a critical role in the mechanism of atypical antipsychotics, (2) the MLD
compound has atypical antipsychotic effects like Cloz and (3) SHT-2 receptors contribute both to the anterior and posterior nucleus accumbens NT systems. (This work was supported by Marion Merrell Dow Inc. and

MENTAL ILLNESS: SCHIZOPHRENIA II

13.17
QUANTITATIVE MEASUREMENT OF SPEM IN SCHIZOPHRENIA USING THE SEARCH COIL TECHNIQUE. B.P. Goldstein and R.C. Alexander*. Thomas Jefferson University, Philadelphia, PA 19107

Improper smooth pursuit eye movement (SPEM) in schizophrenia appears to be one of the most consistent biological correlates of schizophrenia. Most previous studies, however, have used non-quantitative methods which do not allow specification of the defects involved. In our study, 9 schizophrenic and 5 normal subjects underwent measurement of initiation and maintenance of smooth pursuit using the search coil technique. Eye movement targets were small spots of light projected onto a tangent screen 1 m in front of the subject and attention was maintained by asking subjects to detect periodic brightening of the target. For some trials involving horizontal target motion, the target was stabilized on the retina for 300 ms (open loop condition) so that the target would follow eye movements. Detailed quantification of eye movements showed considerable overlap between the gain and variability of both the schizophrenic subjects relative to controls. Further, schizophrenic subjects successfully predicted changes in target direction in the open loop condition, indicating that they can construct an 'internal model' of target movements.

13.19
NEUROANATOMICAL CORRELATES OF AN EVENT-RELATED POTENTIAL (ERP) INDEX OF AUDITORY SENSORY MEMORY IN SCHIZOPHRENIA. P.B. Wad, C. Longeagle, T. Miche, S. Andrews, G. Dixon*, & N. McCoskey, Schools of Psychology and Psychiatry, University of New South Wales, Sydney, NSW 2052 & School of Behavioural Sciences, Macquarie University, Sydney 2109 AUSTRALIA.

To investigate the functional significance of subcortical neuroanatomical changes in temporoparietal neurotransmitter function reported in postmortem and neuroimaging studies of schizophrenic patients, we recorded an ERP index of auditory sensory memory, termed mismatch negativity (MMN), from 15 DSM-III-R schizophrenic patients and 10 normal and handedness-matched healthy controls. Patients were aged between 21 and 49 years (mean age 34.3 ± 8.2 years), and included 9 females and 6 males. MMN was elicited by short tones interspersed among 50 ms standard tones during a visual distractor task. 3D volumetric MRI scans were obtained from all subjects, and Hecht's gyri (HG) and planum temporale (PT) volumes were measured using the BRAINS package (Andreasen et al., 1993). MMN amplitude at the F3 electrode was significantly reduced in schizophrenic patients, as was HG area, particularly in the left hemisphere. PT asymmetry (L>R) was significantly greater in male compared to female subjects, and there was a significant diagnosis by sex by side interaction for PT areas, reflecting significantly reduced right hemisphere PT area in male schizophrenics. MMN amplitudes were significantly correlated with HG areas (rho = 43 to 67) in both controls and schizophrenics. Supported by the NH &AMRC (Australia) and the Rebecca L Cooper Medical Research Foundation.

REGIONAL CEREBRAL BLOOD FLOW IN SCHIZOPHRENIA: CLASSIFICATION USING PIXEL-WISE DISCRIMINANT ANALYSIS. J.D. Van Horn*, K.P. Berman, and D.R. Weinberger. Unit on PET, Neuroscience Center at the 2700 Martin Luther King Jr. Ave. SE, Washington DC 20032

Regional cerebral blood flow (rCBF) differences between patients and controls have been widely reported as between-subject comparisons of normalized mean values derived from cognitive activation paradigms. Differences in activation between groups are often used to identify affected regions in the pathological subject sample. More recently, pattern recognition approaches have been used to classify subjects to regions of interest as well as pixel-based data (e.g. principle component analysis). Here we employed a pixel-based discriminant analysis approach to the comparison of schizophrenics and control subject rCBF that enables one to analyze two or more groups of subjects performing two or more tasks, maximizing the statistical difference between the groups and displaying the results as images. The advantages of this method include the ability to localize brain areas most responsible for variation between groups, while partitioning these differences into orthogonal images to reflect potential functional network differences. Additionally, the posterior probability of an individual subject’s group classification may be measured to determine, in this case, whether or not he/she demonstrates a pattern of rCBF similar to controls or to schizophrenics.

SYMPOSIUM: STRUCTURE, FUNCTION, AND REGULATION OF GLUTAMATE RECEPTORS.

R.L. Huganir, HHMI, Johns Hopkins Univ.; (Chairperson), P.H. Seeburg, Univ. of Heidelberg; M. Mayer, NIH-NICHHD; S. Tonegawa, HHMI, Mass. Inst. of Technology.

Glutamate receptors mediate excitatory synaptic transmission in the central nervous system and play critical roles in synaptic plasticity, neuronal development and neurological disorders. These receptors can be divided into two main classes: metabotropic receptors, which are coupled through G-proteins to intracellular second messengers; and ionotropic receptors, which are ligand-gated ion channels. The ionotropic receptors can be further subclassed into AMPA and kainate receptors and are critical in the functional synaptic plasticity and in the regulation of their role in brain function. Peter Seeburg will discuss studies on the molecular cloning of subunits for the AMPA, kainate, and NMDA receptors. This symposium will review the recent advances in our understanding of the structure, function, and regulation of these receptors and their role in brain function. Peter Seeburg will discuss studies on the molecular cloning of subunits for the AMPA, kainate, and NMDA receptors. This symposium will review the recent advances in our understanding of the structure, function, and regulation of these receptors and their role in brain function. Peter Seeburg will discuss studies on the molecular cloning of subunits for the AMPA, kainate, and NMDA receptors. This symposium will review the recent advances in our understanding of the structure, function, and regulation of these receptors and their role in brain function.

M. Mayer will present data comparing the physiological properties and allosteric regulation of native and recombinant AMPA and kainate receptors. Richard Huganir will discuss the role of protein phosphorylation of glutamate receptors in the regulation of their function and in various forms of synaptic plasticity such as LTP and LTD. Finally, Susumu Tonegawa will present studies using homologous recombination to generate mutant mice to analyze glutamate receptor function. Mutant mice that are deficient in models of synaptic plasticity such as LTP and LTD will be discussed.

16
SYMPOSIUM: GENERAL ANESTHETIC EFFECTS ON SOMATOMOTOR PROCESSING. P. Mason, Univ. of Chicago (Chairperson); E. Collins, Yale Univ.; J. Kendig, Stanford Univ.; R. Pull, Univ. of British Columbia.

This symposium will highlight our current understanding of how general anesthetics affect excitatory and inhibitory neurotransmission in specific neuroanatomical sites important in somatomotor processing. The relative contributions of actions within the spinal cord, brainstem and thalamus to the somatic unresponsiveness observed during general anesthesia will be outlined. The symposium’s aim is to increase our understanding of how anesthetics produce surgical immobility while stimulating further investigations that add to our understanding of how anesthesia might affect the brain. Paul Mason will describe the effects of diverse general anesthetics on the evoked responses and receptive field characteristics of spinal dorsal horn cells. These findings will be discussed with respect to the role of GABA and the sensory associated with general anesthesia. Kendig will review the effects of a variety of anesthetic agents on receptor-specific spinal reflex pathways. Particular attention will be given to the effects of anesthetics on the spinal cord and how these actions on a single receptor can account for somatic unresponsiveness. Mason will describe the effects of general anesthesia on pain modulatory neurons, and propose mechanisms that may account for the observed changes in neuronal firing. Predictions will be made of how these brainstem actions may affect the spinal cord. Pull will discuss the effects of inhalational anesthetics on neurons in the rat ventrobasal thalamus. Anesthetic blockade of the transitions to the thalamic firing motor characteristic of specific behavioral states may serve to interrupt somatosensory perception.

EFFECTS OF EXTRACELLULAR POTASSIUM ION CONCENTRATION
ON RATES OF PHOSPHORYLATION OF DEOXYGLUCOSE IN
CULTURED ASTROGLIA AND NEURONS.
S. Takahashi, B.F. Driscoll, M.J. Law and L. Sokoloff*. Lab. of Cerebral
Metabolism, National Institute of Mental Health, Bethesda, MD 20892.
The effects of increasing extracellular K+ concentration on glucose
metabolism in primary cultures of rat astroglia and neurons were examined.
Cells were incubated with bicarbonate buffer containing 2 mM glucose,
tracer amounts of 2-deoxy-D-[14C]glucose ([14C]DG), and various
concentrations (5.4, 28, 56 mM) of K+ for 10, 15, or 30 min followed by a 5
min incubation in [14C]DG-free buffer for an efflux of unphosphorylated
[14C]DG. Celis were digested and assayed for labeled metabolites. K* caused
significant elevations in rates of
NEURONAL
30 min
phosphorylation of [14C]DG in both
neuronal and neuronal-astroglial mixed
cultures at 15 and 30 minutes, but not
in astrogiial cultures (Fig.). Veratridine
(75 pM), which opens Na+ channels,
significantly
raised
rates
of
phosphorylation in astroglial and

DIRECT MEASUREMENT OF INTERSTITIAL GLUCOSE AND
LACTATE IN THE CONSCIOUS HUMAN BRAIN. E. Wallace. D.

Maggs. S.S. Spencer. D. Spencer. C.C. Duncan*. R.S. Sherwin and
M.J. During. Departments of Medicine and Surgery, Yale School of
Medicine, 330 Cedar St, New Haven CT 06510.

Estimates of brain glucose and lactate can be made by NMR spectroscopy.
However, the actual concentrations of these metabolites in human extracellular fluid
(ECF), and their relationship to fluctuations in the vascular compartment are
unknown. To address this issue, we used microdialysis to monitor glucose and lactate
concentrations in human brain ECF, while manipulating plasma glucose (glucoseinsulin clamp technique). Methods: Microdialysis catheters were placed bilaterally
in the hippocampi of subjects (n=4) undergoing intracerebral depth electrode
monitoring for intractable epilepsy. Studies were carried out 3 days after surgical
placement, subjects had been seizure free at least 3 days. Measurements were made
from both epileptogenic and non-epileptogenic hippocampi. Arterialized plasma and
dialysate, glucose and lactate levels were measured sequentially under plasma glucose
conditions of fasting (5.5+/-0.5mmol/l), hyperglycemia (11.5+/-0.5 mmol/1) and
hypoglycemia (3.O+-/-O.5 mmol/1). Absolute glucose ECF concentrations were
measured by net flux calculation. Results: At each level of plasma glucose, brain
ECF glucose concentrations were substantially lower than concurrent plasma levels
(-30%). In addition ECF glucose reached equilibrium 30-40 mins after plasma
glucose. In comparison fasting brain ECF dialysate lactate levels were higher than
fasting plasma lactate measurements (~x2), and did not change with plasma glucose.
Conclusions: 1. Neurons and glia are consistently exposed to glucose concentrations
that are substantially lower than those of arterial blood. 2. Brain ECF glucose shows
a delayed response to changes in plasma glucose. 3. The marked glucose gradient,
from blood to brain ECF, implies that neuronal metabolism may be unexpectedly
vulnerable to even small decrements in glucose levels, and that, in this context
lactate might serve as an alternative fuel source.

MECHANISMS UNDERLYING THE INTRINSIC SIGNAL DURING
OPTICAL IMAGING OF RAT SOMATOSENSORY CORTEX M. M.
Haglund*, D. W. Hochman, J. R. MENO, A. G. NGAI, AND H. R. WINN.
Department of Neurological Surgery, University of Washington, Seattle,
WA 98195.
Optical imaging of intrinsic signals has been accomplished in vitro in
hippocampal slices (MacVicar & Hochman, 1991) and in vivo in monkey
visual cortex (Frostig et al.,1990). The source of the in vitro signal is
primarily due to postsynaptic activation and cellular swelling, while the in
vivo signal from monkey visual cortex is dominated by blood volume
changes and oxygen delivery from capillaries.
In rat sensory cortex, sciatic nerve stimulation elicited localized
cortical potentials (N1-20 msec; P2-35 msec) that correlated with a 2550% dilation of the pial arterioles feeding the hindlimb cortex. Optical
imaging of intrinsic signals showed changes in areas fed by pial arterioles
that dilated. Cerebral blood flow/volume was uncoupled from increases
in cortical activity by topically applying theophylline (10uM; A1/A2
adenosine antagonist), decreasing pial arteriole dilation by 70-90% and
eliminating the P2 wave. Even though blood volume changes are highly
sensitive to changes in arteriole diameter, the intrinsic signals from areas
activated in controls increased in its spatial extent and magnitude in the
presence of theophylline. Topical application of CPX (1uM; 8-cyclopentyl-1,3-dipropylxanthine; A1 antagonist) blocked the P2 wave and
potentiated arteriole dilation, while intrinsic signals changes were similar
to that found with theophylline.
Uncoupling the increases in blood flow/volume from increases in
cortical activity did not effect the intrinsic signal changes. These findings
suggest that changes related to blood flow/volume are not the main
contributors of the intrinsic signal changes in our preparation.

EXPLORING THE TEMPORAL BOUNDARIES OF FMRI: MEASURING
RESPONSES TO VERY BRIEF VISUAL STIMULI. R.L.Savoy*.
Institute for Science, 100 Edwin H. Land Blvd, Cambridge, MA 02142; MGHNMR Center, 149 13-th St., Charlestown, MA 02129
There is little doubt that fMRI will improve the spatial resolution of functional
brain imaging; but can fMRI, on its own, yield sufficient temporal resolution to
be of value in studying the timecourse of perceptual and cognitive
processes? In the present study, we begin to address this question by
looking at the response to very brief visual stimuli...stimuli of much shorter
duration than the hemodynamic response to which fMRI is sensitive. The
goals were two-fold. First, to see if such brief temporal stimuli would elicit
measurable fMRI responses. Second, to examine the variability of response
to temporally precise stimuli, especially the latency of response.
Three normal subjects participated in the experiment. We imaged a single
7mm oblique slice through the calcarine fissure of each individual using
Gradient Echo imaging with a 1.5 T GE Signa modified by Advanced NMR,
Inc. (Surface coil, TR=400, TE=50, Flip Angle=53°)
In a given run, we presented a full-field circular checkerboard for 1000ms,
100ms, or approximately 17ms. Stimulus onset was synchronized with the
scanner. A bite bar minimized subjects' head movements both within and
between runs. This combination permitted us to average 10 runs for each
subject in each condition.
The stimuli of 1000msec duration yielded clear fMRI responses even on
single runs. The responses to the briefer stimuli were apparent in the
averaged data. In all three conditions, the response latency was consistent.
An increase in the averaged fMRI signal occurred 2 seconds after stimulus
onset. These experiments (and other experiments with TR=100) suggest a
variability of the averaged response latency of not more than 300msec.

518.6

THE ROLE OF NEURONAL NITRIC OXIDE SYNTHASE (nNOS) IN THE CEREBRAL
HYPEREMIC RESPONSE TO HYPERCAPNIA (HC) IN RATS. Q. Wang*, P.A. Pelliqrino,
V.L. Baughman and R.F. Albrecht. Dept. of Anesthesiol., Univ. of III.-Chicago,
Chicago, IL 60612
NO has been shown to play a role in the cerebral vasodilatory responses
(CVDRs) to a wide variety of stimuli, including HC. NO is produced by the action of
NOS. There are 2 constitutive NOS isoforms in the brain, the endothelial (eNOS) and
nNOS. Previous studies have used non-specific NOS inhibitors (e.g., nitro-L-arginine)
to reveal NO influences, and found, in rats, that such agents attenuated the CVDR
to HC (PaCO2 = 60-80 mmHg) by 40-80%. However, the cellular source of that NO
is not known. 7-nitroindazole (7-Nl) is reported to be a selective inhibitor of the nNOS.
In the present study, we monitored cortical cerebral blood flow (CBF) in rats, under
normo- and hypercapnic conditions, using laser-Doppler flowmetry (LDF), in the
presence and absence of 7-NI. To confirm that eNOS was unaffected by 7-NI, we
assessed the CBF responses to the muscarinic acetylcholine agonist, oxotremorine
(OXO), which activates eNOS exclusively. The experiments were performed on male
Sprague-Dawley rats (~400g, n = 9), anesthetized with fentanyl/70% N2O and
mechanically ventilated. Cortical CBF was measured via LDF. In all experiments, an
initial CBF response to 5 min HC was obtained prior to 7-NI or vehicle (corn oil)
injection. Three ml of the 7-NI solution (at 80 mg/kg, or vehicle were injected ip. CBF
responses to 5 min HC were repeated at 30 and 60 min post-injection. After an
additional 15 min, the CBF response to a 7 min iv infusion of OXO (1 ^g/kg/min) was
measured. At the end of the study, the brains were rapidly removed and the cortical
tissue was frozen and subsequently analyzed for NOS activity. 7-NI inhibited brain
NOS activity by 60% and reduced baseline CBF by 19%, but did not affect MAP or
the CBF response to OXO. This confirmed that eNOS is unaffected by 7-NI. The CBF
responses to HC at 30 and 60 min were identically attenuated (~ 50%, by 7-NI, when
compared to controls. That reduction is within the range observed by us and others
using non-specific NOS inhibitors. The results imply that a major portion of the NO
released during HC is nNOS-derived. This presumably neuronally-released NO also
contributes to the maintenance of basal CBF.

THE LOWER LIMIT OF CEREBRAL BLOOD FLOW AUTOREGULATION WITH
NITRIC OXIDE SYNTHASE INHIBITION. S.C. Jones* and C.R. Radinsky.
Cerebrovascular Res. Lab., Cleveland Clinic Found., Cleveland, OH 44195.
Current evidence indicates that nitric oxide is not involved in CBF pressure autoregulation in spite of other evidence that endothelium influences autoregulation. Because systemic NOS inhibition raises MABP, we investigated
cortical NOS inhibition with superfusion.
Four Sprague-Dawley rats (345±15 g, SEM) were anesthetized with 0.51% halothane and 70% N2O in O2 with body temperature maintained at 37°C.
The first day a cranial window was placed over a 6 mm diameter craniotomy
(no dura matter) and the animal was allowed to recover. The second day, under anesthesia, a tracheotomy was performed, permitting artificial ventilation,
and femoral arterial and venous catheters were placed. Physiological variables (MABP, PaCO2, PaO2, and pH) were stabilized. CBF was determined using laser Doppler flowmetry through the window. Animals with low CO2 reactivity were excluded. After superfusion with artificial CSF (aCSF), MABP was sequentially lowered by exsanguination to 100, 85, 70, 55, and 40 mm Hg, followed by reinfusion. After cortical superfusion with KT3 M N^-nrtro-L-arginine
(NNLA) for 103±2 m, the sequential pressure drops were repeated. The lower
limit (LL) of autoregulation was identified visually as a change in the slope of
the CBF vs MABP plot or as the maximum pressure if the plot was linear. The
LL was 59±7 during aCSF and 81 ±10 mm Hg during NNLA superfusion
(p<0.05). In one of these animals, a 3rd withdrawal sequence with NNLA plus
10-2 M L-arginine did not decrease the LL
Thus, NNLA superfusion raises the LL of autoregulation, but the increase
is not reversed by L-arginine. Although our finding is in contrast to those of
previous workers, these data suggest 1) that there is a local autoregulatory response that is undetectable with the global CBF techniques of others, 2) that
the length of NNLA exposure allowed inhibition of a NOS source that mediates
autoregulation, or 3) that the effects of systemically administered NOS
inhibitors somehow override their effect on the LL of autoregulation.

Society for Neuroscience Abstracts, Volume 20, 1994

Recently, we have identified two splice variants of the pharmacologically-defined 5-HT2 receptor, 5-HT2α and 5-HT2β, differing in the length and sequence of their carboxy termini. In rat brain, the 5-HT2α transcripts are restricted to the striatum, while the 5-HT2β transcripts are expressed in brainstem and hypothalamus, but not in cerebellum. When either receptor is transiently expressed in COS-7 cells, each of them stimulates adenylyl cyclase activity and is sensitive to the benzamide derivative cipramide. Although 5-HT2α and 5-HT2β clones exhibit very similar pharmacological profiles, some differences were noted: The expression levels of 5-HT2α were approximately 2-fold greater than the 5-HT2β clone when transiently transfected in COS-7 cells. However, when both clones were transiently expressed in parallel experiments. Despite the lower expression levels, 5-HT2β clone produced significantly greater stimulation of adenylyl cyclase relative to 5-HT2α clone. These data indicate that although 5-HT2α and 5-HT2β are splice variants and differ only at their C-terminal tails, they may nevertheless possess different coupling efficiencies to eliciting functional responses. Whether 5-HT2α and 5-HT2β couple to different isoforms of Gα and/or adenylyl cyclase remains to be investigated. Interestingly, 5-HT2α clone has 4 protein kinase C phosphorylation sites, whereas 5-HT2β clone has only 3. This additional phosphorylation site could lead to differences in the regulation of these two receptors. Alternative splicing may provide a mechanism by which functional diversity is established for 5-HT2α receptors.

Recently, we described the molecular cloning and pharmacological characterization of two splice variants (5-HT2α and 5-HT2β) of the rat 5-HT2 receptor. We now report the identification of a human 5-HT2α cDNA clone from a human hippocampal cDNA library. The amino acid sequence deduced from the longest open reading frame is 91% identical to the rat sequence, revealing 31 amino acid changes of which 11 are non-conservative, including 2 in TIM1, 1 in TIM2 and 1 in TIMV. Interestingly, the human cDNA contains one deoxyribonucleotide insertion at the 3' end of the coding region, creating a reading frame shift and introducing a stop codon 16 deoxyribonucleotides downstream in the reading frame. Due to this nucleotide insertion, the carboxy-terminal tail of the human 5-HT2 receptor is 16 amino acids shorter than its rat counterpart. The human clone displays 5 fold higher affinity than the rat clone for the 5-HT2 antagonist 1H[3H]81380B. Benzamide derivatives like cisapride, BRL-24924 and xacopride, partial agonists at the 5-HT2 receptor, all potently inhibited binding. The biggest differences between the human and the rat clones were observed with n-Me-5-HT and zacopride which exhibited at least 5 to 10 fold higher affinity for the human 5-HT2 receptor.

The 5-HT2C receptor is an abundant serotonin receptor subtype that is restricted to the central nervous system. It has been implicated in many of the physiological effects of serotonin and psychostimulant drugs, however, the lack of specific agonists and antagonists of this receptor hinders analysis of its functional significance. To study the roles of this receptor, we have generated, through homologous recombination, a mouse lacking a functional 5-HT2C receptor gene. To verify the loss of functional receptor protein, brain polyA⁺ RNA from mutant and wild type mice were injected into Xenopus oocytes. A loss of serotonin-induced depolarization was noted in oocytes injected with RNA from the mutant animals. In addition, 5-HT2C receptor immunocytochemistry revealed a loss of immunoreactivity in brain A- areas from mutant animals. Most mutant mice appear healthy and evidence no reproductive abnormalities. However, approximately 25% of males-hemizygous for this X-linked mutation display an apparent sudden death syndrome. Death is preceded by no apparent signs of illness such as loss of weight or reduced levels of activity. The age range of animals at death is from 3 to 13 weeks, with a peak incidence at 6-8 weeks of age. Studies are underway to determine the cause of death in these animals. In particular, the possibilities that deaths of mutant mice are due to seizures or cardiac arrhythmias are under examination.

The 5-HT1B receptor, which is the rodent homolog of the human 5-HT1B receptor, has been suggested to be involved in a number of physiological states such as appetite, locomotion and aggression, as well as in certain pathological states such as migraine.

In order to study the functions of the 5-HT1B receptor in the mouse, we have generated by homologous recombination, mutant mice lacking the gene encoding the 5-HT1B receptor. Such homozygous mutant mice develop, move, feed and breed apparently normally. When analyzed in a light-dark choice test and in an open field, the 5-HT1B-/- mice displayed the same behavior as their wild type littermates, suggesting that this mutation does not affect base-line levels of locomotion and anxiety. However, the hyperlocomotor and anorectic effects of the 5-HT1B agonist RU24969 (5mg/kg, i.p.) were absent in mice lacking the 5-HT1B receptors.

In the resident-intruder aggression test where isolated test mice are faced with a wild-type intruder, the mutants attacked the intruder faster and more intensely than wild type mice. This increased aggression of 5-HT1B-/- mice might be related to the fact that a class of 5-HT1B agonists termed serenics (clozapine) have antiaffective properties, and with the finding that certain impulsive aggressive behaviors are associated with deficits in central serotonin.

Although 5HT is considered as a neurotransmitter, recent findings indicate that it is also a developmental and migrational guide. In order to study the developmental function of the receptor directly, we have disrupted the 5HT2 receptor gene by homologous recombination in D3 embryonic stem (ES) cells. These ES cells express the 5HT2 receptor, that is possible to distinguish by the extent of knock-out as the result of the gene knock-out. Interestingly, inactivation of one allele of the 5HT2 receptor gene resulted in a more 50% loss in receptor binding. In parallel, transcripts encoded by the intact allele were reduced more than two-fold, up to 20% of the level measured in normal ES cells. In contrast, large amount of transcripts encoded by the truncated receptor allele were produced in the knock-out cells (1-2 fold of the expected 50% level). We speculate that the truncated mRNA is more stable than the intact receptor RNA, and the high steady state level of the truncated RNA may supply the expression of the wild type allele, a phenomenon resembling to allelic exclusion. Alternatively, the receptor allele which remained intact in the knock-out cells may have been partially imprinted. Presently, we are performing experiments to distinguish between these two possibilities. Suppression of the intact allele was observed not only in ES cells. Chimeras with high efficiency ES cell contribution displayed negligible receptor binding in tissues derived from ES cells demonstrating that suppression is maintained through development. Chimeras showed disturbances in postnatal development, probably as the result of low receptor expression. A reduction in weight gain was evident starting at postnatal day 5-10. Feeding was also reduced, particularly at the age of 5-5 weeks resulting in cachexia and eventually death.
5-HT2 receptors are members of the serotonin 5-HT family of receptors, sharing similar pharmacology, signal transduction pathways, and sequence homology. The 5-HT2A and 5-HT2C receptors contain several new regulatory elements. This new data is essential for further understanding the regulation of 5-HT2 receptor gene expression.

Among higher metazoa, echinoderms exhibit the most impressive capacity for regeneration. Holothurians, or sea cucumbers, respond to adverse stimuli by autotomizing and spewing out their visceral organs which are then replaced by a regeneration process. Neuronal fibers and cell bodies are known to be present within the viscera; however, previous regeneration studies do not account for the nervous component. We have used immunocytochemistry at the light microscope level (antibodies to acetylated alpha-tubulin, to the neuropeptides GFS, galanin and CCK and a novel monoclonal antibodies) and the electron microscope to describe the enteric nervous system of holothurians. We show here, that the enteric nervous system of the sea cucumber, Holothuria glaberrima, regenerates following evisceration and in 3-5 weeks is virtually identical to that of non-eviscerated animals. The regeneration of the enteric nervous system occurs parallel to that of other organ components, fibers are observed prior to the formation of the mucosal layer and the first neurons appear shortly after. The regeneration of the nervous system coincides with a high interest in view that members of the closely related phylum, Chordata, either lack or have a very limited capacity to regenerate their nervous system. Thus, holothurians provide a model system to study nervous system regeneration in deuterostomes. (Supported by grants from EPSCoR, the Whitehall Foundation, and the University of Puerto Rico.)

STIMULATION OF REGENERATIVE SPROUTING ENHANCES PREFERENTIAL MOTOR REINERVATION (PMR) T.M. Beaulieu*. Dept. of Orthopaedics and Neurology, Johns Hopkins Hosp., Baltimore Maryland 21287

Motor axons regenerating after transaction of mixed nerve preferentially reinnervate distal masseteric fibers. Collaterals of a single motor axon often enter both sensory and motor Schwann cells of the distal stump; specificity is generated by pruning collaterals from sensory pathways while maintaining those in motor pathways (J. N. Sci. 12:2730). Stimulation of collateral formation should therefore allow increased pathway sampling and greater regeneration specificity. Experiments were performed on the proximal temoral nerves of 250gm female SD rats. Forty nerves were sharply transected and sutured; 40 others were crushed with jeweler's forceps proximal to the repair site both 2 and 4 weeks before suture to stimulate collateral sprouting. Twenty nerves in each group were evaluated at 3 weeks, and 20 at 3 mos., by applying HRP to one terminal branch and Fluoro Gold to the other. The mean number of motoneurons projecting axons into the femoral sensory and motor branches at 3 weeks was similar, after routine suture (M=149, S=170), but was significantly different after crush/crush/suture (M=244, S=103, p=.001). Specificity was apparent 3 mos after routine suture (M=242, S=130, p=.001) but was greatly augmented 3 mos after crush/crush/suture (M=263, S=81, p=.001). The number of motoneurons projecting collaterals to both branches at 3 wks, the substrate for specificity generation by collateral pruning, was significantly greater after crush/crush/suture (72 vs 53, p=.01). Nerve crush before suture thus increases the number of motoneurons projecting collaterals to both sensory and motor branches, and also results in substantial augmentation of PMR. This finding mandates a search for non-invasive techniques of stimulating collateral sprouting to enhance regeneration specificity.

520.3

Recent studies have shown that dimeric interleukin 2 produced enzymatically in vitro by nerve-derived transglutaminase is cytotoxic in vitro to mature oligodendrocytes, known to inhibit axonal growth. The cytotoxic effect operates via apoptosis. Cells showed commitment to apoptosis after 3-4 h of treatment with dimeric interleukin 2. This interval could reflect a necessary rate limiting process of activation or suppression of specific genes, or modification of specific regulatory proteins. A protein that appears to act as a positive regulator of apoptotic cell death in a number of cell types is the p53 tumor-suppressor gene product. The aim of the present study was to determine whether p53 is involved in the death of mature rat brain oligodendrocytes in response to dimeric interleukin 2. We demonstrate here that the dimeric interleukin 2 induces in oligodendrocytes translocation of endogenous wild-type p53 from the cytoplasm to the nucleus, as early as 15 min after exposure. Moreover, oligodendrocytes infected with a retroviral vector encoding a p53 miniprotein expressing the dimerization site of p53 and that acts as a negative dominant inhibitor of endogenous wild-type p53 activity, are effectively protected from apoptosis induced by dimeric interleukin 2. These findings indicate that p53 is directly involved in the apoptotic mechanism induced by dimeric interleukin 2.

CREATION OF A NEURON INHIBITORY ENVIRONMENT TO FACILITATE AXONIC ASTROCYTIC PROTEOGLYCAN. DR. Domingues*, A. Hoke & J. Silver. Dept. of Physiology and Anatomy, Case Western Reserve University, 10900 Euclid Ave, Cleveland, OH 44106–4975.

CNS astrocytes normally support the growth and maintenance of axons. One approach to the suppression of favorable substrates which allow axons to grow on their surfaces and the extracellular matrix. We have recently discovered an in vitro method of converting the behavior of astrocytes from supplying neuronal growth-promoting environments into those which are inhibitory. This change in behavior can be activated by exposure of the astrocytes to small peptide sequences of the beta anti-AChE receptor in an osmotic form. This activation includes the localized deposition of a matrix containing chondroitin sulfate, similar to that seen at sites of reative gliosis after trauma in vivo. Amongst the various proteoglycans synthesized and carried by astrocytes, we have found that the experimentally induced inhibitory environment is mediated by the upregulation and deposition of a specific chondroitin/heparan sulfate proteoglycan. This proteoglycan has properties inhibitory to axonal outgrowth when combined with other molecules of the extracellular matrix. These inhibitory properties can be experimentally reversed by removal of chondroitin sulfates glycosaminoglycans from the matrix created by activated astrocytes, but not by enzymatic removal of other glycosaminoglycans. Affinity purification of this proteoglycan has revealed that it is highly glycosylated and carries the carbohydrate epitopes 70kD, CS-56 and 38kD. Data from molecular weight estimations, preliminary peptide analysis and amino acid composition determinations suggest that this may be a novel proteoglycan to the CNS, which is upregulated in areas of reactive gliosis.

SHORT- AND LONG-TERM DEGENERATIVE CHANGES IN PROTOGELICIAN CORD NEURONDED BY THEIR ABILITY TO INHIBIT AXONAL REGENERATION. A. K. Gulati* Department of Cellular Biology and Anatomy, Medical College of Georgia, Augusta, GA 30912.

The present study was designed to define the stenotic and chronic changes in peripheral nerve undergoing degeneration and their ability to support axonal regeneration after transplantation. Peripheral nerve were degenerated in vivo for a period of 6, 12, 24, and 48 weeks. The nerve segments were analyzed for axonal regeneration and for axonal outgrowth after transplantation in an immunologically injured host. During early phase of degeneration the injured axons and the associated myelin is broken down and absorbed by proliferating Schwann cells and infiltrating macrophages. The Schwann cell basal lamina persists throughout degeneration, however, were progressively reduced in size and at 12 months were reduced. These long-term degenerated segments were reduced in diameter as compared to short-term degenerated nerves (2 and 4 weeks) that exhibited increased diameter. In order to study axonal regeneration through degenerated segments, 6 cm long segments were transplanted in grafted and distal host nerves were analyzed to determine axonal regeneration. Axonal regeneration was rapid and by 12 weeks many myelinated nerves were observed in host nerve, with some reinnervation of target muscle. Although many neural degenerated segments were observed in the 46-week degenerated transplant, the nerves remained small in diameter and the axons were thinly myelinated. In addition buildup of connective tissue was observed in all grafts. The results show that, short-term degeneration is beneficial as compared to long-term degeneration in supporting axonal regeneration (supported by NIH grant NS-28543).

P50.09

Recovery from spinal cord crush has been studied in neonatal (P5-7) and postnatal (P14-20) S.Amercian opossums (Monodelphis domestica). Mothers were anesthetized with intraperitoneal pentobarbium; the young, still attached to the mother received additional inhalation Meflocone anesthia. Spinal cords were crushed at the upper thoracic level via a skin incision using fine forceps. Completeness of crush was assessed by application of a minus one perioperative stimulus to the hind limbs below the lesion both at the time of lesion and on the day following; absence of a forelimb response was taken as indicating a complete lesion. Control sites were unoperated. Various recordings were made at operated and control animals at different intervals after surgery up to and beyond waking (P60). Spinal cords were removed under terminal anesthesia at different times after operation and in control. Conduction across the crush was tested for in vivo by electrical stimulation of the central end of the cord and recording caudally. In 12 neonates the spinal cord was isolated 24-48h after crushing. The 2 out of 12 showed complete block of conduction. In the other 2 the amplitude of the mass action potential was less than 1% of controls. Conduction across the crush by recovery was 5 to 10 days post crushing (n=16). Bosl's fixed spinal cords were examined morphologically using silver staining and examination of thick (30-50um) sections using an Edge Scientific Stereoscopic. Complete crush at P5-7 was followed by fibre growth across the crush by 5 to 10 days after operation. Substantially normal locomotor function was present towards the time of waking (P60-69). In neonates operated at P14-20 recovery of conduction did not occur.

P50.10

Fusiform outgrowth of neurons has been shown to occur into and beyond the site of a crush in the spinal cord isolated from a 5 day old opossum. We have now analyzed repair at various stages after injury, by light and electron microscopy. During the first 1-3 days, the site of the lesion as well as rostral and caudal segments were characterized by identifiable elements. After 5 days in culture axons and growth cones unaccompanied by glia entered the lesion. Growth occurred along the basal lamina of the pia mater on which synaptic structures were made. By contrast in lesioned spinal cords in culture we observed 12 days after injury, less and more poorly formed elements. By 5 days in culture axons and growth cones unaccompanied by glia entered the lesion. Growth occurred along the basal lamina of the pia mater on which synaptic structures were made. By contrast in lesioned spinal cords in culture we observed 12 days after injury, less and more poorly formed elements. By 5 days in culture axons and growth cones unaccompanied by glia entered the lesion. Growth occurred along the basal lamina of the pia mater on which synaptic structures were made. By contrast in lesioned spinal cords in culture we observed 12 days after injury, less and more poorly formed elements.
S21.1
HUMAN OSCILLATORY BRAIN ACTIVITY NEAR 40-Hz COUVRIES WITH COGNITIVE TEMPORAL BINDING.

M. Joliot 1, U. Ribary* and R. Langla. Center for Neuroimaging, Dept. of Physiology and Biophysics, New York University Medical Center, New York, NY 10016, USA. *THCP, DRCP/CEA, Orsay, France.

The minimal time interval required to identify auditory stimuli as separate correlated cycles in the 40-Hz magnetic signal in the human brain, in order to test the hypothesis that 40-Hz activity may represent a temporal binding by the C.N.S.

Neurophysiological recordings of coherent oscillatory activity near 40-Hz were obtained from auditory areas of the right hemisphere from nine healthy adults, using a 37-channel Magnetoencephalography (MEG) system (BTF). Subjects attended to auditory stimuli presented in blocks consisting of one or two clicks (10 kHz, 60dB SPL) presented binurally at varying interstimulus intervals (3, 6, 9, 12, 15, 18, 24 or 30 ms). 1000 epochs were recorded for each block with inter-pair intervals of 130±10 ms, the transient responses were averaged and filtered between 20-50 HZ. The average response to a single stimulus consisted of a 2.5 oscillatory cycle 40-Hz response. A set of two stimuli were then presented and the perceptual threshold for identifying the stimuli as two events was established. Experimental and modeling results indicate a stimulus-interval dependent response with a critical time interval of 12-15 ms. At shorter intervals, at which the subjects reported the perception of only one auditory event, only one 40-Hz response was observed. As the interval increased a second 40-Hz wave appeared, abruptly. This second 40-Hz correlated significantly with the recognition by the subjects that two distinct auditory stimuli had been delivered.

These results indicate that oscillatory activity near 40-Hz represents a neurophysiological correlate to auditory temporal processing. It also supports the view that 40-Hz activity relates not only to primary sensory processing, but also to the temporal binding underlying cognition.

S21.3
ELECTROPHYSIOLOGICAL AND BEHAVIORAL SIGNS OF HEMISPHERIC ASYMMETRIES OF ATTENTION IN A “SPLIT- BRAIN” PATIENT. A. M. Proverbio 1, A. Zani 2, G. R. Manzan 1, M. S. Gazzaniga 1 1 Center for Neuroscience, University of California, Davis, CA 95616. 2 Institute of Psicologia del CNR, 00137 Rome, Italy.

Neuropsychological data have shown that the two cerebral hemispheres differ in the control of spatial attention. The present study investigated hemispheric asymmetries of attention in a left-lesioned subject who underwent incomplete resection of the corpus callosum, thereby disconnecting the cerebral hemispheres at the cortical level. Simple reaction times (RTs) and Event-related potentials (ERP) were recorded to lateralized visual stimuli in the patient J.W., and in an age-matched normal control subject (both right-handed). The ERPs were recorded on a Macintosh Quadra 710 computer and labeled using the non-cerebral stimuli as reference. The subject's eyes were monitored by means of an infrared video-camera and horizontal and vertical electro-oculogram. Stimuli were randomly presented in the left or right visual hemifield of the left eye. The ERPs were recorded from the occipital surface (Oz) and the parietal area (P3) at Pz. In contrast, in the split-brain patient RTs were 20 ms slower for more eccentric stimuli in the LVP, but no effect of eccentricity was evident for RVP stimuli. The left hemisphere showed a strong response to RVP stimuli, while LVP stimuli elicited a much greater response over the contra-lateral hemisphere. The subject showed previous theories (e.g., Kinsbourne, 1987) that the right hemisphere allocates attention broadly over left and right hemisphere, while the left hemisphere is strongly biased toward the right.

Supported by the DFG (Pu 97/2).

S21.4

Words and pronounceable pseudowords are physically similar, but invoke different cognitive processes. Gamma-band responses of the brain are related to cognitive processing, these stimuli may induce distinct patterns of gamma-band responses. Using MEG, we recorded the corresponding hemispheric responses. We used two different stimulus conditions: presentations of single words and pseudowords. The gamma-band activity in the left hemisphere was larger for pseudowords than for words, while gamma-band activity in the right hemisphere showed the opposite pattern. The results suggest that gamma-band activity in the MEG is sensitive to the different cognitive processes that underlie word generation and pseudoword generation.
S21.5 LOCALIZATION OF SPONTANEOUS OSCILLATORY CORTEX ACTIVITY FROM MAGNETOENCEPHALOGRAPHIC DATA RECORDED DURING THE IMAGINATION OF MOVEMENT AND SILENT SPEECH. Claudia D., Tebse* C., Stöferle A., D. Jancke, M. Hajo Low Temperature Laboratory, Helsinki University of Technology, 02150 Espoo, Finland. Risto J. Ilmoniemi BioMagn Laboratory, Helsinki University Central Hospital, 00290 Helsinki, Finland.

Does mental imagery in the absence of external stimuli alter the spectral characteristics of spontaneous oscillatory activity in humans? We measured spontaneous oscillatory activity in patients with 12-channel whole-scalp magnetoencephalographic (MEG) array. The subjects performed two contrasting tasks: the imagination of the self-performance of a motor activity and the silent generation of a chain of words. We developed a novel analysis method, frequency-domain signal-space projection (FDSPP), to analyze the Coherence of oscillatory activity at specific cortical sites from this data. Although intersubject differences were significant, highly reproducible spikes of oscillatory activity were observed within subjects and hemisphere and task differences in which showed variability in the spectral features with task including variations in amplitude and power, state-dependent changes in the frequency of sharply defined peaks. FDSPP analysis may also be applied to magnetoencephalographic (EEG) data. Objective evidence of the constancy of the state of a subject obtained from FDSPP may facilitate the interpretation of psychophysiological data. FDSPP analysis of rhythmic EEG and/or MEG data recorded during epileptic activity and sleep may lead to the localization of sources of activity in specific neuronal populations.

S21.6 THE EFFECTS OF BROMOCRIPTINE, A D-2 Dopamine Receptor AGONIST, ON THE COGNITIVE ABILITIES OF HUMANS SUBJECTS WITH DIFFERENT WORKING MEMORY CAPACITIES. J. Y. Kimbara, M. D'Esposito and M.J. Farah. Department of Psychology, Carleton Univ., Ottawa, Canada, and Pittsburgh, PA 15213; Dept. of Psychology, Univ. of Pennsylvania, Philadelphia PA 19104.

Recent research in individuals suggests that the prefrontal cortex (PFC) subserves working memory (WM), and that dopamine plays an important role in the PFC WM system. In order to provide a test of this hypothesis, and to investigate the role of dopamine and WM in a variety of cognitive tasks, we administered a battery of tasks to normal human subjects twice, on and off bromocriptine (BC). This resulted in a dose dependent response supported by a double blind procedure. The battery of tasks included: working memory tasks (spatial working memory, verbal working memory, and the fan effect paradigm), other tasks to depend on D-2 (PFC) (The Wisconsin Card Sorting Task, Stroop Task, a context memory task, and a dual task paradigm), and a control task (visual search) not hypothesized to depend on WM or PFC. Although there was no significant main effect of bromocriptine over all subjects; those with lower WM capacity benefited from the drug on both WM tasks and other PFC tasks and, more surprisingly, those with higher WM capacity were reliably impaired by it on these same tasks. No effects of bromocriptine were observed for the visual search control task. These results demonstrate a selective effect of bromocriptine on PFC tasks, which depends on subjects WM capacity.

S21.7 DISCORDANCE FOR PLANUM TEMPORALE ASYMMETRY IN HANDEDNESS-DISCORDANT MONOZYGOTIC (MZ) TWINS. H. Steinmetz, H. Rietzschel, H. Neukirch, G. Schlaug, Y. Huang and L. Jäncke

Departments of Neurology and 'General Psychology I, Heinrich-Heine- University, PO Box 100177, D-40007 Düsseldorf, FRG.

Studies comparing biological with adoptive families have shown that handedness is not exclusively determined by prenatal factors. It is unclear whether these factors are genetic or non-genetic. Using in vivo magnetic resonance (MR) morphometry we measured the degree of planum temporale (PT) asymmetry $A_{PT}=(R-L)/(R+L)$ in 20 MZ twin pairs concordant (10 right-handed pairs) or discordant (10 pairs) for handedness reports. Handi-ness reports by birth complication, neurosychiatric illness, learning disability or failure in elementary school (3 MR observers blind for twins vs. 60 controls, and right vs. left hemisphere). As previously described for singletons, right-handed twins showed leftward PT asymmetry (p<0.05) whereas the right-handed co-twins, as a group, lacked asymmetry (p>0.10). Intraclass correlations were low (R<0.25). This discordance for structural asymmetry can be accounted for by models assuming cleavage of an intrinsically asymmetric blastomere or differential action of other non-genetic factors within MZ twin pairs in utero. The findings confirm a coupling of lateralized brain structure and function. At least in MZ twins, early epigenetic factors must play a role in laterality development.

Despite inferential evidence from cognitive and other behavioral studies and from animal experiments, there is little direct information about the effects of hormones on human neurophysiology during cognition. We used the oxygen-15 water PET method to measure regional cerebral blood flow (rCBF) in four women with menstrual-related mood disorder (MRMD) and four controls during three pharmacological conditions: 1) ovarian suppression induced by gonadotropin-releasing hormone (Lupron), 2) Lupron plus estrogen (E), and 3) Lupron plus progesterone (P). During each drug condition subjects were scanned at rest and while performing the Wisconsin Card Sorting Test: a simple matching task. Absolute CBF (ml/min/100g) was determined pixel-by-pixel, and the three PET data sets were each registered to a single MRI scan on which regions were drawn. Global CBF was lower in the patients than in the controls during the resting Lupron baseline (45 vs. 55, p<0.04) and tended to increase with P and decrease with E for the group as a whole. The region most affected by hormone treatment was the superior left anterior cingulate (ANOVA drug effect F=4, p<0.05), which was increased by P and decreased by E during the tasks despite unaltered performance scores. These data provide direct insight into the effects of gonadal steroids on brain function during cognition and may also suggest a neuroendocrinologic characteristic of patients with MRMD.

We sought to define the cognitive and physiologic basis for semantic memory dysfunction in Alzheimer's disease (AD). Cognitive measures were used to identify the semantic memory deficit in patients with probable Alzheimer's disease (pAD) during comprehension and expression of words and pictures. An equilibrium technique used 15O-H2O to quantify regional cerebral blood flow (rCBF) in individual patients and controls during a semantic category memory task (identifying exemplars of a familiar semantic category). An individualized, anatomically-based atlas was assigned to each subject's MRI localized cCBF activation. Cognitive assessments revealed that several pAD patients had a segmental semantic memory deficit. These patients demonstrated characteristic difficulty understanding and expressing word and picture information about a target category that could not be attributed to a category related memory specific cognitive limitations. PET assessment revealed that individual control subjects consistently recruited left angular gyrus during the PET semantic challenge while pAD subjects did not. pAD patients failed to recruit left angular gyrus during a semantic challenge while PET measured cCBF. Instead, pAD patients recruited right inferior parietal structures. pAD subjects failed to recruit left angular gyrus during a PET semantic challenge. We hypothesize that the inability to access memory by integrating information from multiple, material-specific and modality-specific sources.

S21.10 IMPAIRED RECOGNITION MEMORY IN AGING IS ASSOCIATED WITH REDUCED ACTIVATION OF HIPPOCAMPUS AND FRONTAL CORTEX. C, Grady* A.R. McIntosh, B. Horvitz, LG Ungerleider, P. Tootell, M. Pentz, IV, Haxby. Lab. of Neuroscience, NIA, Lab. of Neurophysiology, NIMH, and Lab. of Psychology and Brain Pathology, NIMH, Bethesda, MD 20892.

We measured rCBF in 10 young (25 ± 2.5 yrs) and 10 old (69 ± 6 yrs) healthy subjects using positron emission tomography and [15-O]water during learning of and recognition memory for faces. Three tasks were carried out by all subjects in the following order: learning, face matching, and recognition. Old subjects performed significantly worse than young subjects during the recognition task (ANOVA: p<0.001). During learning, compared to face matching, young subjects showed increased rCBF (p=0.001) in the right hippocampal region, left inferior frontal and medial frontal cortex. Old subjects did not show significant activation of the hippocampus during learning. They did show activation in left frontal cortex (p=0.001), but in a location different from the one seen in young subjects. During face matching, young subjects had rCBF increases in right frontal and parietal cortex, and anterior cingulate (p<0.001), and the old subjects had rCBF increases in right frontal cortex (again, in a different location). The results support the hypothesis that experiments that study frontal activation during recognition memory, and provide evidence for the role of the hippocampus in stimulus encoding. In addition, they suggest that reduced recognition in older subjects is due, at least in part, to a failure to adequately activate the hippocampal area during learning, and thus to adequately learn the list of faces. Alterations of rCBF in prefrontal cortex also appear to play a role in age-related memory impairment.
DEGENERATIVE DISEASE: ALZHEIMER’S—MECHANISMS OF DEGENERATION

S21.1

LOCALIZATION OF LANGUAGE OPERATIONS WITH H2/18 PET: INDIVIDUAL DIFFERENCES IN FUNCTIONAL ANATOMY AND THEIR RELATION TO IMAGE SMOOTHING. S.Y. Bookheimer and T.A. Zelazo. Brain Mapping Division UCLA, Los Angeles, CA 90024 and National Institute on Aging, NIH, Bethesda, MD.

Sixteen normal volunteers underwent positron emission tomography while performing simple language tasks (reading words and naming objects). Images were stereo-normalized and smoothed using Statistical Parametric Mapping (MRC Cyclotron Unit) to an effective PWHM of 12 or 21 mm. Although the same critical threshold was used in both analyses, the results differed markedly: activation in left inferior frontal (IFG) cortex (Broca’s area) was identified only with the narrow filter while significance in cerebellum, striatum and extrastriate cortices were detected with both filters. However, spatially of the most common brain regions were identified in these regions only with the narrow filter.

A second experiment with left-handers who are known to have greater spatial variability in language organization confirmed the difficulty in obtaining reliable anterior but not posterior results. High between-subject variability in the structural and functional anatomy should favor broad band filters, which are more sensitive to changes occurring over a wider spatial extent; inferior frontal language areas are among the most variable cortical structures. Our data suggest that the optimum smoothing kernels will differ as a function of the known anatomic variability. Interpretation of PET language data is critically dependent on how this variability is treated in image analysis.

S22.1

A series of 5 studies investigate topographic aspects of nonlinear EEG dynamics and their changes with information load, aging, and dementia. Major findings are that dimensional complexity (DCX: estimated correlation dimension) topography corresponds to EEG patterns of different cortical areas; some areas are more "chaotic" than others. Topographic patterns change in response to stimulation, and DCX offers a single-variable approximation of information load. Increasing visual information load increases DCX, especially over occipital areas in young subjects, but this effect is reduced in aging and nearly lost in dementia. Addition of nonlinear measures to traditional linear (FFT) measures improves the discrimination of demented patients from controls. For both types of measures, nonlinear neural net prediction offers significant advantages over linear analysis methods. Thus, nonlinear EEG measures and analysis methods offer unique perspectives for understanding both normal and pathological aging.

S22.2

Functional neuroimaging using MRI techniques (MRI) have unique capabilities for mapping the physiological correlates of behavior; their potential clinical applications are less clear. In this study, we evaluated the utility of a fast 5-dimensional (3D) gradient-echo technique in a patient population with various neurologic disorders. This novel method has the capability to scan the whole brain on a conventional 1.5 T MR scanner in only two seconds. Nine normal volunteers and patients with mild to moderately severe dementia of the Alzheimer type (DSM-III-R diagnosis), one patient with a subacute cortical infarct in the left middle cerebral artery distribution and one patient with a high grade lymphoma were studied in the resting condition. Scans were performed on a conventional 1.5 T GE/SIGNA MR scanner. Modified (FS) BURST MRI was performed during intravenous bolus administration of Gd-DTPA (0.15 mmol/kg). 3D datasets were acquired with an effective spatial resolution of 4.3x3.3x4mm within 2.5 seconds. 3D maps of relative cerebral blood volume (rCBV) and bolus arrival time were created by fitting a synthetic curve to the intensity time course on a pixel by pixel basis. The rCBV maps of the Alzheimer’s patients revealed focal areas of hypoperfusion in a frontotemporalparietal distribution identical to their SPECT perfusion scans. In the patient with the subacute infarct, the transit time maps showed arrival time delays of 5-7 seconds within and around the infarct clearly confirming the diagnosis of left middle cerebral artery occlusion. In the patient with CNS lymphoma decreased CBV around the tumor correlated with a mass effect. No focal defects were identified in the normal controls. These results illustrate the technique’s potential as a clinical tool in the diagnosis and management of various brain disorders. This technique can be added to routine clinical MR scanning, requiring additional imaging time of only 3-5 minutes.

S22.3

ANALYSIS OF STAGED AUTOPSY CASES UNCOVERS PACE OF ALZHEIMER’S DISEASE-RELATED NEOVASCULAR CHANGES. J. Bohl (1), H. Muller (2), H. Braak (2). (1) Abt. Neuropathologie, J.Gutenberghospital Bonn-Kleinkamp (2) ZMorph., J.W. Goethe University, 60590 Frankfurt; Germany.

The speed of progression of Alzheimer’s disease (AD)-related neurofibrillary changes is unknown. This is because of the impossibility to histopathologically follow one and the same individual over decades of its life. The present approach is based on a recently introduced staging system which differentiates between six stages of AD-related neurofibrillary changes and analyzes a staged sample of 887 autopsy brains. The time needed to attain respective stages of pathology for 5% of a given cumulative sample is determined. The resulting 5%-percentiles are a measure for the average pace by which the disease-related changes progress assuming that the underlying stages represent a sequence of events and do not independently “pop-out”. Advancing age and the prevalence of AD-related changes of a given stage show a nearly perfect positive correlation with only slight acceleration above the age of 65. Statistically, it takes at least 16 years to shift from stage I to stage II, 14 years from stage II to III, 13 years from stage III to IV and 5 years from stage IV to V (≈AD) for 5% of a given cumulative sample. Obviously, the deep roots of AD-related neurofibrillary changes can be traced about 50 years back and thus even extend into adolescence. The unveling of the duration of the shift between selected stages provides a powerful tool for epidemiological studies. A possible risk factor should shorten this period whereas beneficial influences would result in a delayed shift even if the considered cohort dies “too early” for the full development of AD.

S22.4

LAYER-SPECIFIC DENDRITIC ALTERATIONS OF HIPPOCAMPAL GABAERGIC NEURONS SUGGEST TRANSEUNERAL CHANGES IN ALZHEIMER’S DISEASE. S. Munch, R. Nitsch* and T. G. Ohm Center of Morphology, University Clinic Frankfurt, F.R.G.

Neurons in layer II and III of the entorhinal cortex are the first to exhibit neurofibrillary changes in Alzheimer’s disease (AD). In this early stage of the disease, the target area of axons arising from these neurons, i.e., the hippocampus, remains devoid of these changes. Experimental studies have demonstrated layer-specific transneuronal changes on dendrites in the termination zone of entorhinal fibers, e.g., the outer zones of the dentate molecular layer. The present study was designed to unravel whether similar transneuronal dendritic changes occur during the spread of neurofibrillary tangles from the entorhinal cortex to the hippocampus as shown in a staging analysis by Braak and Braak (Acta Neuropatol. 82, 239, 1991). We analyzed the hippocampal formation of 33 staged Alzheimer cases obtained from autopsy. The entire dendritic tree of parvalbumin-immunostained hippocampal GABAergic neurons was monitored using an interactive neuron tracing system. The course of population is known to remain devoid of neurofibrillary tangles even in severe AD. The quantitative analysis revealed a statistically significant reduction of the mean dendritic length, the segment number of main branch complexity and the percentage of tangle-bearing dendrites in the course of AD. These changes were confined to the apical dendritic tree which extends into the termination zone of entorhinal fibers. In contrast, basal dendrites extending into the hippocampus remained unchanged in their morphology. Our data demonstrate that layer-specific dendritic alterations in hippocampal GABAergic neurons appear together with the spread of histopathological changes in AD. This suggests the occurrence of transneuronal changes on the hippocampal targets of entorhinal neurons. (Supported by the DFG. NI 344/1-1, NI 344/5-1, and OH 484/1-1.)

DYSTROPHIC PERIKARYA AND NEURITES INTERSPERSED WITH NORMAL NADPH DIAPHORASE-NITROGEN MONOXIDE SYNTHASE (NOS)-CONTAINING NEURONS (NOSN) IN THE CEREBRAL CORTEX OF PATIENTS WITH NONALCOHOLIC STEATOHEPATITIS (NASH) AND ALZHEIMER DISEASE (MND), BUT NOT WITH MND WITHOUT DEMENTIA. R.O. Kuljis* and R.I. Schipper. Dept. Neurology and Pathology, The University of Iowa and VAMC, Iowa City, IA 52242.

Many adult patients with MND develop cognitive impairment, which may anticipate motor manifestations, and that is most frequently not attributable to supernormal conditions such as dementia. We therefore asked whether such cognitive deterioration in patients presumed to have an insult selective to motor neurons remain elusive. In the course of a series of studies on the role of NOSN in neurodegenerative diseases, we discovered that those nerve cells exhibit clearly dystrophic features in MND. Five patients with sporadic MND were studied, two with neurophysiologically verified dementia (MND+d, both 65 years old; 2:13 hours of postmortem autolysis) and one without dementia (MND-; 64-68 years old; 2:18 hours of autolysis). Tissue blocks from nine primary sensor, motor, association and limbic areas of the neocortex were sectioned frozen and reacted for NADPH diaphorase histochemistry, which reveals NOSN and their neurites. A conventional histopathologic analysis failed to show a cause for the cognitive symptoms in MND+d, but verified the clinical diagnosis of MND in all cases. Cases with MND+d, but not those without dementia, exhibit numerous markedly dystrophic NOSN perikarya and neurites, interspersed with normal NOSN in all cases examined. An additional series of control tissue sections from four age-matched and two younger patients — with a wide range of autolysis intervals and fixation protocols — failed to reveal similar dystrophic changes, indicating that they may be selective to MND+d. These observations suggest that cognitive impairment in MND+d may be related to a pancellular deterioration to the ubiquitous NOSN network, indicating a novel role for these neurons in neurodegenerative disease. Supported by PHS grant NS29856.

522.7
DISTRIBUTION OF NGF IN THE NORMAL AGED HUMAN BRAIN AND IN ALZHEIMER'S DISEASE. S.A. Scott* 1.Weigent, and K.A. Crutcher. Department of Neurosurgery, University of Cincinnati School of Medicine, Cincinnati OH 45267-0515.

Using the two-site ELISA, both the rodent and human NGF have been examined for NGF content with high levels found in the hippocampus and neocortex. Recent data from our laboratory suggest a similar distribution in the aged human brain (mean 74 pg/g), and, moreover, that the levels are comparable to those observed in other species. The highest levels of human NGF are within the dentate gyrus (1200 pg/g) whereas the lowest are found in the medial temporal cortex (0.06 pg/g). Between these extremes, neocortical areas contain 300-500 pg/g NGF with little variation among the principal gyri, although the temporal and cingulate gyri contain the highest levels. The basolateral amygdala and the nucleus basalis of Meynert are rich sources of NGF (< 700-800 pg/g). Other areas with notably high levels include the choroid plexus (> 1000 pg/g), entorhinal cortex (750 pg/g), medial thalamus (640 pg/g), and neocortex (450 pg/g), whereas the pineal gland, olfactory bulb/tract, hypothalamus/mammillary bodies, and globus pallidus contain generally lower levels (< 350 pg/g). This broad spectrum of NGF localization in brain, together with the known distribution of high-affinity trkA receptors, suggests that brain NGF is not localized simply in relation to the basal forebrain cholinergic system.

NGF levels were at least moderately higher with Alzheimer's disease in all regions examined (frontal and occipital poles, amygdala, putamen, hippocampus, cerebellum, superior temporal gyrus and inferior parietal lobule), although the distribution was similar to that in aged controls. Supported by NIH N535140 and AG05605.

522.9
ALZHEIMER'S DISEASE: PATHOGENESIS. EVIDENCE OF INCREASED PROPOXIDANT ACTIVITY IN THE INFERIOR TEMPORAL LOBE. A.M. Palmer* and M.A. Burns. Departments of Psychiatry and Pharmacology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213.

The concentration of a product of lipid peroxidation (malondialdehyde) was determined in six areas of the brains of Alzheimer's disease and control subjects, matched for age (74 ± 7 and 73 ± 8 years, respectively) and postmortem delay (10 ± 6 and 11 ± 7 hours, respectively). Malondialdehyde (MDA) concentration was significantly increased in all samples. Basal and iron/orotate-stimulated malondialdehyde concentration were 19% higher in the inferior temporal cortex of Alzheimer's disease subjects than in control subjects; other regions were unaffected. In order to assess antioxidant capacity, we determined the activities of glutathione peroxidase and glutathione reductase in addition to two enzymes of the peroxynitrite pathway (glutathione peroxidase and 6-aminohexanoylglutathione dehydrogenase) and two enzymes of the nicotinamide adenine dinucleotide (NADH)-dependent pathway (glutathione reductase and 6-aminohexanoylglutathione dehydrogenase) in three areas of neocortex. The only difference was an increase in the activities of glutathione peroxidase and glutathione reductase (to 126% of control and to 126% of control, respectively) in the inferior temporal cortex of Alzheimer's subjects. Together these data indicate that lipid peroxidation is increased in Alzheimer's disease because of increased prooxidant activity rather than diminished antioxidant defenses. Moreover, it appears that the activity of pentose phosphate pathway is increased in response to increased prooxidant activity since 6-phosphogluconate dehydrogenase activity (0.89, p < 0.01) with the stimulation of MDA. This inverse relationship suggests that elevations in the activity of pentose phosphate oxynitrogen reflect a compensatory change in response to increased prooxidant activity. Although it is not clear if increased prooxidant activity is a cause or a consequence of early pathological change, it is consistent with the involvement of oxidative stress in the maintenance and progression of the cascade. Antioxidant therapy can therefore be expected to stop, or at least slow, the progress of this debilitating disease of late life.

522.6

GIF, or metallophilic-3 (MT-3), a member of the metallophilic family, is located in the molecular layer of the dentate gyrus, the pyramidal cell layer of the hippocampus, and layers 2-6 of the neocortex. GIF is expressed in astrocytes but is down-regulated during fetal development and in AD brain.

Western blots for GIF, GFAP, and total metallophilic-3 (MT-1; MT-2 and GIF; MT-3) were performed to quantify these proteins in temporal lobe of control and AD brain. Levels of MT-3, in control and AD temporal cortex were indistinguishable. However, GIF levels were unchanged when compared with control. Conversely, there was an 83.4% increase of GIF expression in AD brain when compared with control. Immunocytochemical detection of the same proteins was performed on sections of control and AD from the middle temporal gyrus. Double immunostaining suggested that GIF is down-regulated in the cytoplasm, nucleus and processes of astrocytes even though reactive gliosis was found in AD brains. This was reflected in heavy GFAP staining of astrocytes in AD sections. Furthermore, even though no differences in MT-1, expression were apparent when assessed by blotting, immunostaining suggested a marked increase in MT-3 expression and a loss of GFAP staining in glial cells. This suggests that GIF is an important protein found to be down-regulated during gliosis in AD.

522.8
SELECTIVE ABNORMALITIES IN MULTIPLE NEUROTRANSMITTER RECEPTOR DENSITIES IN NEURODEGENERATIVE DISEASES. L. R. Murtha*. VA Med Ctr./Mt Sinai Sch of Med./NYC, NY.

This study investigates the densities of multiple neurotransmitter Receptors, in ten different cortical regions of human brain, obtained from patients: Normal, Schizophrenia(Sch), Alzheimer's disease(AD) and Multi Infarct Dementia(MID).

Aliquots of membrane suspension obtained from each cortical region were analyzed simultaneously for the binding of radiolabeled nicotine, ketanserin and SCH 23390 to nicotine,serotonin 5HT2 and dopamine D1 receptors respectively. The receptor binding assays were done in the absence and presence of cold ligands to obtain specific and non-specific binding respectively of radiolabeled ligands. Important differences in the densities of the three different neurotransmitter receptors were noted in the ten cortical regions of Sch, AD, MID brains as compared to normal-demented elderly. 

522.10
NEUROTOXIC EXTRACTS OF ALZHEIMER'S DISEASE BRAIN ARE ASSOCIATED WITH REACTIVE MICROGLIA. L.J. Havercamp* and J.B. Kirkpatrick. Dept. of Neurology and Pathology, Baylor College of Medicine, Houston, TX 77030.

We have adopted a triple stain for plaques (thioflavine-S), cell nuclei (bismacinid), and reactive microglia (immunochemistry for HLA-DR) in tissue obtained after relatively short post-mortem intervals (< 6 h), lightly fixed in parformaldehyde. Using this technique, we note as especially prominent in Alzheimer's disease (AD), clusters of three or more reactive microglia, invariably in association with all (99%) core smalle plaques, a majority (40-85%) of neuritic plaques, and none of the diffuse plaques which are often seen in brains (matched for age and post-mortem interval) lacked toxic effect. Toxic activity was regionally distributed within AD brains (N = 7), with hippocampus invariably containing high levels of toxicity while cerebellum and white matter had little. Correlations of histopathology and toxicity of adjacent tissue, from 8 regions in each of the control and AD brains, showed a close relationship between neuron-killing activity and the density of microglial clusters associated with core smalle toxic and neuritic diffuse plaques. These findings suggest participation of activated microglia-derived neuronal toxins in the neuron death which occurs in AD.
522.3

Our hypothesis is that cell patterns in the neural tube are controlled by a coordinate system of positional information, set up along the antero-posterior (AP) and dorso-ventral (DV) axes, and that the AP axis of the chick hindbrain becomes subdivided into a series of compartments (rhombomeres) that underlie its segmented architecture. Coincident with the emergence of territories where cell mixing is transiently restricted, the rhombomeres become determined for expression of a specific combination of selector genes (Hox genes) that may encode rhombomere identity. Rhombomere phenotype is determined at this stage. Thus, when presumptive rhombomere 4 (r4) is transposed for r2 (at 6 somites), the graft expresses a r4-specific gene (Hoxb-1) and develops r4-specific neurons. We now find that only the AP and not the DV positional value of the rhombomere is determined at this time. Thus, when r4 is grafted to the r2 position with its DV polarity inverted (the alar plate positioned ventrally, abutting the floor plate) r4-specific motor neurons appear medially, within the original alar plate. Cells are committed to their fates according to position on a Cartesian grid whose coordinates are set sequentially; DV positional values are labile when AP values are already fixed.

522.4

Comparative phylogenetic models have great potential for establishing how gene expression confers positional identity to cells, an identity that in turn largely predisposes early embryonic neural pathways and innervation patterns. Despite the diversity of the adult brainstem organization, recent data suggest that the overall segmental, rhombomeric (Rb) blueprint of the hindbrain has been genetically conserved in vertebrates. The phylogenetic diversification of cellular identity related to derived sensory-motor circuits responsible for vertebrate posture can now be addressed within this Rb framework. Dye labeling demonstrates that cranial and spinal somatosensory neurons arise as largely non-overlapping segmental populations arising rostrally to caudally along the Rb neural axis with homotopic subdivision of cranial nerves occurring in different species. Surprisingly, the hindbrain areas identified as different to eye, head and spinal sensory-motor circuits are ordered posteriorly to anterior in the module of diverse vertebrates. In particular, we have documented the morphology and physiology of individual, non-overlapping nuclei extending through regions arising from Rb 8 to 4 in tetrapods. Notably, the two most evolutionarily derived hindbrain centers are known as lateral and ventrolateral temperature, are located just rostral to the spinal cord and are presumed to originate from Rb 8. Two other general classes of nuclei are located further rostrally, likely arising from Rb 7. Comparison of homologous posterior circuits between species, even when given embryonic hindbrain compartment must coordinate the developmental plans of diverse neuronal types that are acquired and combined through stepwise phylogenetic elaboration. We propose that the need to insert novel, derived circuits (e.g., the integrations) into established, more primitive, hindbrain sensory-motor blueprints constrains the functional organization of downstream targets of homologous sensory genes. As a result, gene deletion/segmental expression experiments involving high level selective genes can be expected to produce a mosaic pattern of variation arising both ancient and recently acquired species-specific neural circuitry. Our hypothesis that to co-dependently address the molecular correlates of neuronal development, experimental analyses will require consideration of the phylogenetic diversity of neuronal structure and function observed in embryonic rhombomeres.

**CELL LINEAGE IN THE FORMATION AND REGENERATION OF THE OLFATORY PLACODES.** C.D. Burau*, D. Collazo, and S.E. Fraser. Dept. of Molecular and Cellular Biology, Univ. of Arizona, Tucson, AZ 85721 and Div. of Biology, California Institute of Technology, Pasadena, CA 91125.

Previous studies in Xenopus demonstrated that the olfactory placodes are derived from the neural plate (Eagleson and Harris, 1990). We and other laboratories have also observed that the olfactory placodes can regenerate (Byrd and Burd, 1993). The goals of the current study were to demonstrate the origin of the olfactory receptor neurons during normal development and to determine the origin of olfactory receptor neurons in regenerating olfactory placodes. The lineage of cells was determined by labeling small groups of cells with DiI/SCy3 or single cells with lysinated rhodamine dextran (NRD), which was allowed to follow cells using low light level video microscopy. Cells in the anterior-lateral region of the anterior neural ridge (labeled at stages 14-16) give rise to olfactory placodes and form the olfactory and vomeronasal epithelia in tadpoles (stage 48). At later stages (stages 22-24), cells in the same plate persist to and during olfactory placode formation give rise to olfactory receptor neurons and supporting cells. Following removal of the olfactory placodes (stages 33-34), we found that undifferentiated cells surrounding the olfactory placodes in the same plate give rise to new olfactory placodes and give rise to new olfactory receptor neurons. In summary, undifferentiated cells in the same plate retain the potential to form olfactory receptor neurons well after olfactory placodes have formed. The molecular signals and genes involved in this process remain an exciting avenue for future investigation. Support: NSF, MDA, and NIMH.

$\text{52.3.7} $ 

**NOTCH IS A DETERMINANT OF RETINAL GANGLION CELL FATE IN THE CHICK.** C.P. Austin*, D. Feldman, J. Ma, S. Field, Barry, and C.L. Cepko. Dept. of Genetics, Harvard Medical School, Boston, MA 02115.

The factors affecting cell type determination and differentiation in the vertebrate retina are not well understood. In the chick, ganglion cells are the first cell type to be produced in the chicken retina, and we have used an in vitro system to study the factors influencing their development. The presence of an inhibitor of GC differentiation that is provided by the neighboring retinal pigment epithelium (RPE) is required for ganglion cell development at low density; below a critical cell number, the ganglion cells are dissociated and cultured at low density, the percentage of cells expressing GC-specific markers increases progressively (NIMH, CSH). (Abstr. 519:13.15.93)

The Notch gene family has been hypothesized to code for cell surface receptors that mediate inhibitory signals influencing cell fate in a number of organisms. We have observed that Notch plays a role in the chick retina, as an inhibitor of GC differentiation. When antisense oligonucleotides directed against any of 3 regions of the Notch sequence are added to retinal explant cultures, the number of GCs is increased by at least 25% over 24 hours relative to explants incubated with sense oligo controls. To test the specificity of the oligo sequence in bringing about GC overproduction, we have used antisense oligonucleotides mismatched at 1, 3, or 5 bases, and found that the extent of GC overproduction decreases with increasing mismatch. Western blots showed that Notch protein level is greatly diminished in mutant lines treated with antisense oligonucleotides, relative to sense oligonucleotide, or non-oligo-treated controls. Expression of a truncated form of the human Notch homolog (TJN), corresponding to the intracellular portion of the protein, via retroviral transduction reduced the number of GC produced in vivo and prevented the overproduction of GC previously seen in dissociated culture. These findings support that Notch is an inhibitor of ganglion cell determination in the early chick retina, and supports the emerging hypothesis that the GC gene family plays a central role in neuronal determination in vertebrates. Supported by K11 HE 00231 (CPA) and R01 HE 00767 (CLC) from the National Eye Institute.

$\text{52.3.9} $ 

**ORIGIN OF SUBVENTRICULAR ZONE CELLS.** M.C. Mione* and J. G. Papavassiliou, Department of Anatomy, University College London, Gower Street, London WC1E 6BT, U.K.

In the late stages of cortical neurogenesis, the subventricular zone (SVZ) is a prominent layer containing numerous mitotically active cells. It is believed that these cells give rise to the astrocytes and oligodendrocytes of the cerebral cortex and the subcortical white matter. In order to investigate whether SVZ cells originate from ventricular and subventricular (SVZ) cells, we made retroviral transneuronal injections of a recombinant retrovirus carrying the reporter gene for E. Coli β-galactosidase at different embryonic ages. Rats were killed after 3 days in utero or 3 days after birth at 2, 4, and 6 days (P) 3-4. All animals, irrespective of the age of injection, showed β-gal+ SVZ cells when examined at birth or later. Therefore, we concluded that cells present in the VZ between E15 and E19 gives progeny to E15 or even earlier. If all E15 SVZ, β-gal+ cells were present in the SVZ at least until P14, although their number was greatly reduced by this age. In order to ascertain whether SVZ cells originate from a population of neuroepithelial cells or if they are stem cells left behind by their migrating progeny, we used bromodeoxyuridine (BrdU) to distinguish between mitotically active or quiescent cells. BrdU was given every two hours over a period of 24 hours starting 2 days after retroviral injection. Animals were killed shortly after the last injection or at birth. It was found that the majority of β-gals in the SVZ was BrdU, thus indicating that they were mitotically active during the period of BrdU injection. This finding suggests that stem cells in the VZ give rise to the glial present in the SVZ. Supported by the Wellcome Trust.

$\text{52.3.10} $ 

Using two-dimensional gel electrophoresis we previously identified a 46 KDa protein (protein 310) that is neural specific, abundantly expressed in the embryonic cerebral cortex, and down-regulated in the adult (J. Neurosci. 9:304). Antibodies to synthetic peptide fragments from protein 310 initially induced rat embryonic cerebral cortical neurons immunohistochemically distinct from endogenous ERG-Rs. The vector also contains an IRES sequence, which allows a second encoding of the rat β-gal to be expressed at high levels in infected cells. For example, 98% of retinal cells that express virally transduced β-gal also express β-Gal. The co-expression of β-gal facilitates analysis of the proliferation, survival, and differentiation of infected cells. Expression of β-gal in rat retina infected with virus expressing ERG-Rs and β-gal, or with virus expressing β-gal alone. Proliferation (measured by BrdU incorporation) was analyzed 6-7 days after infection as the expression of β-gal and injection of BrdU by quin expression was analyzed 11-16 days after infection, using rabbit anti-β-gal together with mouse anti-BrdU or mouse anti-opi (Rn-91) antibodies. Proliferation of retinal cells infected with β-gal-RV was enhanced by 30-300% in response to endogenous ligand (no TGFs added) or exogenous TGFs (0.1 ng/ml). Development of retinal cells infected with β-gal-RV was induced at 7 days and could be blocked by quin expression. These observations suggest that limits of specific expression contribute to the regulation of proliferation and differentiation in the retina, and that these restrictions can be overcome by manipulation of levels receptor expression.

In vivo, neurogenesis in the olfactory epithelium (OE) proceeds continually, but in vitro, in minimally supplemented defined medium, Immediate Neurogenic Precursors (IPs) of olfactory receptor neurons (ORNs) divide only once. We found that Fibroblast Growth Factors (FGFs) and transforming growth of IPs of orf cultures from E14-15 mouse embryos, while other polyepthelial growth factors tested did not.Expression of FGF receptors, detected by RT-PCR in RNA isolated from E14-15 OE, suggests that FGFs may stimulate FGF receptors in vivo as well. Labeling INPs through successive 5 with bromodeoxyuridine (BrDU) and 3H-thymidine (3H-TDR) demonstrated that INPs allow a single cell to undergo symmetric division by differentiating into ORNs. Varying the interval between BrDU and 3H-TDR pulses allowed length of the INP cell cycle to be estimated at 17 hr with a phase of 8 hr; this finding enabled us to estimate that FGF exerts its effects in late G2M or early G1. Neurogenesis usually ceases by 48 hr in culture, and in OE, because >90% of IP progeny differentiate into postmitotic ORNs. However, in rare events growing in FGF, large groups of proliferating INPs are seen after this time, suggesting that a progenitor cell--possibly a stem cell--is giving rise to new INPs in these explants. These experiments suggest that the transcription factor Mammalian Auracine Scale Homolog 1 (MASH1) may be required at an early stage of genesis of ORNs (Guillemot et al., Cell 75:463-476 [1993]). We find that a subpopulation of proliferating migratory cells in early (16-20 hr) OE cultures expresses MASH1, but expression declines rapidly; this decline is not due to cell death. MASH1+ cells are immunologically and morphologically distinct from basal cells, and their high β-Gal-activity index suggests that they are not stem cells. The data are consistent with a model of neurogenic neurogenesis in which the MASH1-expressing cell is an early stage of, or progenitor to the INP, which as a neuronal transit amplifying cell.
ELIMINATION AND DETERMINATION III

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Neuronal csk-5 phosphorylates the high molecular weight neurofilament proteins (NF-H). During the purification of this kinase, we identified a molecule of 67 kDa (P67) which is associated with and activates csk-5 (Shute, et al, 1990) Abs. Soc. Neurosci. 16:193. A molecule, called MK-801, identical to P67, was shown to be associated with synapsin-I, one of the key molecules of the synaptic vesicle fusion protein complex (Matsudaira et al, 1993, Nature 366:347). To further explore the function of MK-18, either as a regulator of csk-5, or as a component of the synaptic vesicle complex, (or both), we investigated the immunohistochemical expression of csk-5, MK-18, synapsin and NF-H during the development of the rat cerebellum from P2 to the adult. We assumed that if these molecules were functionally related, then they should (1) co-localize within the same cells and tissues, and (2) undergo similar patterns of developmental regulation. Using antibodies to csk-5, NF-H, synapsin and MK-18, we could show that at all stages, the epitope shared by MK-18, synapsin and MK-18 were co-localized into developing molecular layer (parallel fibers), the synaptic glomeruli in the inner granule cell layer, and in afferent and efferent fibers (climbing fibers, mossy fiber and Purkinje cell axon) within each folium. Only csk-5 and MK-18 antigens were detected within the Purkinje cell bodies. The pattern of NF-H expression, however, showed differences since it was absent from the molecular layer through most of development, but was primarily restricted to axons and fibers bundles within each folium. At late developmental stages, NF-H immunostaining was seen as dendiric and surrounding some regions of Purkinje cells. The expression patterns of csk-5 and MK-18 during development, as seen immunohistochemically and in immunoblots, are similar, which is consistent with the hypothesis that they are functionally related.

552.1 EVIDENCE FOR A ROLE OF STRIATAL GABA IN THE ANTAGONISTIC DOPAMINE - GLUTAMATE REGULATION OF LOCOMOTION: AN IN VIVO MICRODIALYSIS STUDY IN THE AWAKE FREELY MOVING RAT. W.T. O'Connor*, M. Morari, U.Ungerstedt and K. Fuxe, Departments of Pharmacology and Neuroscience, Karolinska Institute, Stockholm, Sweden.

The effect of kainic acid-inducedornithine (TTX) in the substantia nigra pars reticulata (SNr) on behavior and basal dopamine (DA), GABA, and glutamate (GLU) levels in the dorsolateral striatum was monitored using in vivo microdialysis in the awake rat. Basal striatal DA, GABA and GLU levels (nM) were 1.7 ± 0.9, 10.4 ± 0.7 and 307 ± 40 respectively. Nigral perfusion (70min) with TTX (10μM) produced a strong contralateral rotation (8.5 ± 4.4 min after 30 min); a decrease in ipsilateral striatal DA release (-76% of control) and an increase in striatal GABA (+46%) and GLU (+80%) release. Intrastriatal perfusion with MK-801 (10μM) alone did not affect behavior or striatal neurotransmitter release but counteracted the contralateral rotation (1.3 ± 0.5 min after 30 min); abolished the increase in striatal GABA release and delayed the increase in striatal GLU release associated with perfusion with TTX in the ipsilateral SNr. The reduction in striatal DA release associated with nigral TTX was not affected by intrastriatal MK-801. Thus, the counteraction of the nigral TTX induced increase in both rotational behavior and striatal GABA release following intrastriatal perfusion with MK-801 strengthens striatal GABA neurons as a major target for the antagonistic DA-Glu interaction in the regulation of locomotion.

552.4 SEIZURE PROTECTION WITH IB-MECA, A SELECTIVE AGONIST OF THE NOVEL ADENOSINE A3 RECEPTOR. D.K.J.E. von Lubitz*, M.C.Carter†, R.C.S. Lish†, K.A. Jacobson*, NINDS/NIH/Molecular Recognition Section, Bethesda, MD 20892; 2Dept. of Physiology and Biophysics, Hahnemann University, Philadelphia, PA, 19102.

The biological function of adenosine A3 receptors is virtually unknown. We therefore, investigated the effect of acute and chronic preischemic stimulation of these receptors on the outcome of NDMA or pentyleneetetrazol (PT) induced seizures in C57Bl/6J mice (N=10/group). P. with N6-(3-iodobenzyl)-adenosine-5'-N-methylcarboxamidazole [IB-MECA (10, 50, 100 μg/kg)] 15 min prior to either NDMA (60 or 125 mg/kg) or PT (75 mg/kg). In the chronic regimen NDMA (60 and 125 mg/kg) was significantly delayed by acute and chronic IB-MECA at doses >50 μg/kg. At 100 μg/kg both acute and chronic IB-MECA significantly reduced postictal mortality in both NDMA and PT groups. In a second experiment of 120 μg/kg IB-MECA improved survival of PT induced seizures even further. Our results indicate that, contrary to its effect in cerebral ischemia, acutely injected IB-MECA is highly protective against seizures elicited by different epilepticogenic drug classes and that, as in stroke, chronic treatment with IB-MECA offers an equally significant seizure protection. In view of the therapeutic value of adenosine A3 receptor stimulation is highly warranted.

The amine agmatine (Agm) (decarboxylated arginine), is an endogenous ligand for imidazole (I) and D-glutaminergic receptors present, with its biosynthetic enzyme ADC, in bovine and rat brain medulla. While prevalent in bacteria, neither Agm nor ADC have previously been found in mammalian brain. We investigated whether mammalian ADC has unique properties. ADC was assayed by measuring conversion of [5-3H]Arginine to [5-3H]Agmatine in bovine and rat brain medulla. While previous studies have shown the existence of Agm in bovine and rat brain medulla, these studies were performed using the agmatine detected by measuring the amount of Agm produced after incubation with [5-3H]Arginine. Our results confirm the presence of Agm and show that ADC is present in both bovine and rat brain medulla. These findings indicate that Agm interacts with receptors close to its site of biosynthesis.

524.7 SITE-DIRECTED MUTAGENESIS OF THE HISTAMINE H1-RECEPTOR INDICATES A SELECTIVE INTERACTION OF Astm. WITH SUBCLASSES OF H1-RECEPTOR AGONISTS. R. Worden, D. M. Smith, C. P. Fraser, A. M. TerLeak and H. Timmerman, Leiden/Amsterdam Centre for Drug Research, Department of Pharmacoochemistry and Graduate School for Neurosciences, Department of Biochemistry and Molecular Biology, Vrije Universiteit, 1081 HV Amsterdam, The Netherlands.

The cloning of gene encoding the H1 receptor made it possible to study the interaction of subtype specific ligands with the receptor protein. In this study we investigated the role of the Astm. and the Thr210 residues in TMS of the guinea-pig histamine H1-receptor by site-directed mutagenesis to non-functional alanines. After stable expression of the receptor mutants in Chinese Hamster Ovary cells the pharmacological properties of the receptor proteins were investigated by [3H]mepyramine binding studies and [3H]histamine phosphate accumulation. Whereas the Thr210 is not important for the action of histamine, the Astm. residue appears to be involved in the binding of the N3-nitrogen atom of histamine and its 2-methyl analogue. For the (2-3-bromophenyl)-alanine and the non-imidazole H1-receptor agonists 2-pyridyl ethylamine and 2-thiazolidyl ethylamine the Astm. is not essential for binding. On the basis of this study we conclude that different histamine H1-receptor agonists interact in different ways with the receptor proteins. Moreover, we speculate that the interaction with the N3-nitrogen atom is essential for receptor activation.

The screening of a guinea pig histamine H2 receptor cDNA library with probes derived from the sequence of the rat histamine H2 receptor, allowed us to isolate an intronless gene encoding a protein of 359 amino acids displaying all major features of G-protein-coupled receptors and a 94% homology with the rat histamine H2 receptor. Northern blot analysis, performed with a specific C-terminal tail DNA probe derived from the guinea pig sequence revealed a 4.6 kb transcript in various guinea pig tissues. In brain, a high expression was found in striatum, brainstem, olfactory tubercles and bulb. A signal was also present in hippocampus, cerebellum, hypothalamus and substantia nigra. In peripheral tissues, the expression was detected in stomach, lung and heart, where the labeling was very high in ventricles but hardly detectable in atrium. In situ hybridization studies showed that highly expressed guinea pig cerebral and cerebellar expression of the H2 receptor gene transcripts which was compared to a detailed autoradiographic mapping of the receptor using 125I- imidodinopentetide. There was a spatially sharp correlation between the distribution of the two markers. A high labeling was detected in striatum, Calleja islands, olfactory tubercles, cortex, hippocampus, pontine nuclei, inferior olive. Amygdaloid complex, lateral geniculate nucleus, superior colliculi and median thalamus were also labeled. An interesting discrepancy exists, however, in the hippocampus complex where the binding sites were high in the molecular layer, whereas the mRNA was localized in the pyramidal or granular cell layers. Finally, using a chromosome mapping panel constructed from somatic cell hybrids, we assigned the human histamine H2 receptor gene to chromosome 5 showing that the genes encoding the H2- and the H2-receptor are not clustered.

It has previously been shown that diphenhydramine hydrochloride (Benadryl) eliminates or reduces symptoms of dystonia in human patients with acute dystonic reactions associated with procyclidine treatment. This study of the effects of diphenhydramine in the treatment of idiopathic torsion dystonia are related to the H1-selective antihistaminergic actions of the drug. In addition, the H1 agonist pyrilamine and the H2 antagonist cimetidine are not effectively reducing dystonia. The results also provide support to previous research which has implicated the red nucleus in the pathophysiology of dystonia. The results of drugs injected into the red nucleus produced an observed by measuring the angle of deviation of the head from the dorsal plane. A significant rotation of the head is indicative of dystonia. Histamine (dose range 0-10 nmol) produced dose dependent dystonia in rats (P<0.001). The dystonia produced by a dose of histamine (10 nmol) could be antagonized by coadministration of diphenhydramine (P<0.01), pyrilamine (P<0.05), and cimetidine (P<0.04). Significantly more dystonia was observed when histamine was injected into the red nucleus rather than midbrain area surrounding the structure (P<0.002). These results indicate that the beneficial effects of diphenhydramine, pyrilamine, and cimetidine in reducing symptoms of idiopathic torsion dystonia occur via a histaminergic pathway involving the red nucleus.

Recent studies have shown the existence of a specific antagonistic interaction between adenosine A1 receptors and dopamine D2 receptors in the brain. This A1/D2 interaction seems to be relevant for the behavioural effects of adenosine agonists and antagonists, like caffeine. In the present study quantitative receptor autoradiography and brain microdialysis were combined to demonstrate a powerful antagonistic A1/D2 interaction in the ventral striopallidal system. In the presence of the A1 agonist CGS 21860, dopamine exhibited a lower affinity in displacing the labelled D2 antagonist by infusing into the accumbens but not by infusing into the substantia nigra. The results also show that dopamine uptake into the accumbens is selective. However, the current in the nucleus accumbens was reduced by coadministering CGS 21860 with caffeine, which is a potent competitive A1 receptor antagonist. These findings are consistent with the idea that the combination of CGS 21860 and caffeine could be used to ameliorate the effects of adenosine antagonists, like caffeine, and to potentiate the effects of dopamine agonists, like caffeine, in the treatment of schizophrenia.

We have demonstrated synergistic interactions between adenosine-2 (A-2) and dopamine-2 (D-2) receptors in a behavioral rat model. Because A-2 and D-2 receptors are co-localized on the same type of striatal neurons, we studied the effects of chronic neuroleptic administration (haloperidol) on A-2 and D-2 receptors in rat brain. Rats received 21 daily injections (i.p.) of haloperidol (1.5 mg/kg), fluphenazine (1.5 mg/kg), sulpiride (100 mg/kg), clozapine (20 mg/kg), or saline. Striatal receptor density (Bmax) and affinity (Kd) values for A-2 and D-2 receptors were measured using a high-affinity radioligand. Tryptophan hydroxylase-labeled D2 receptors were measured using homogenate binding. Haloperidol and fluphenazine significantly increased (>30%) striatal A-2 and D-2 receptor density, whereas sulpiride and clozapine had no significant effect. Kd values for [3H]CGS25380 were unchanged in all groups. Thus, these observed significant increases in the density of A-2 receptors in rats striatum following chronic administration of typical and atypical striatal A-2 receptors, whereas sulpiride and clozapine was not effective.

**STIMULATORY EFFECTS OF SUB-ANEUPHLETIC DOSES OF KETAMINE. A PSYCHOTOMIMIC NMDA RECEPTOR ANTAGONIST?**

Sub-aneuphletic doses of ketamine, a non-competitive NMDA-receptor antagonist, cause several schizophrenia-like symptoms in non-human primates including impaired performance on the Wisconsin Card Sorting Test (Kray et al., Arch. Gen. Psychiat. 1994). In this study, intracerebral microdialysis in conscious rats was used to assess the effect of ketamine on the extracellular levels of dopamine and glutamate in the prefrontal cortex. A sub-aneuphletic dose of ketamine (10, 20, and 30 mg/kg, i.p.) increased glutamate levels while the dopamine levels were largely unaffected at these levels. An intermediate dose of 50 mg/kg was without an effect. This finding is similar to our previous data with other types of NMDA receptor antagonists. A recent study indicates that ketamine may exert some of its effect by increasing the levels of endogenous excitatory amino acids, thus, causing a stimulation of postsynaptic (non-NMDA) excitatory amino acid receptors. **EFFECTS OF VESTIBULAR AND NECK PROPRIOCEPTIVE SIGNALS ON VISUAL RESPONSES IN POSTERIOR PARIETAL CORTEX.** H. L. Snyder*, S. A. Anderson. Division of Biological Sciences, University of California, San Diego, La Jolla, CA 92093.

Eye, head and body position modulate the discharge of retinotopically tuned units in posterior parietal cortex (PPC). The conjunct of retinal and extraretinal signals give coordinate transformations from visual to body- or world-centered reference frames. We investigated the sensory modalities responsible for extraretinal signals in areas 7a and 7p of macaque monkeys. Vestibular signals modulated effects of body position in space on single units in PPC. Animals were seated on a vestibular turntable in a light-proof room. Saccades to retinotopically identical locations were elicited after whole-body displacement in the dark. The discharge of single units was influenced following rapid (10/15s) or gradual (0.04/10s) rotations (7/12 cells), ruling out uncoordinated body or visual or other signals to body position in space.

Neck proprioceptive signals mediated effects of head-on-body position. Proprionicvestibular, visual and visual signals may all be affected by head displacement. To show that changes in proprionicvestibular signals alone were sufficient, whole-body rotation in the light was followed by counter-rotation of the head back to the starting position in the dark, resulting in body but not head displacement. This resulted in saccadic saccades subterminally elicited in the dark revealed single unit modulation identical to that obtained by merely rotating the head on a stationary body (11 units).

Vision influenced the effect of position in space on single units. Following whole body rotation in the light, responses to identical saccades elicited in the dark were often modulated by body position (8/22 units). In contrast, body position was much less likely to effect saccadic responses following whole body rotation in the dark (7/58 units). Our results suggest that in the absence of vision, the PPC boosts its reliance on vestibular signals.

**EGOCENTRIC MOTION FROM OPTIC FLOW AND EYE POSITION IN AREA 7a OF THE BEHAVING MACAQUE.** R.M. Segraves and J.L. Ilg*, Dept. of Neurobiology and Anatomy, Center for Molecular and Behavioral Neuroscience, Rutgers University, New Brunswick, NJ 08902.

Eye position signals were found to be correlated with direction heading in head-centered coordinates. Recordings were made from area 7a while the monkey was performing a reaction time visual pursuit task. The monkey did motion stimulus elicited perceived direction of gaze. Direction was estimated using a two-dimensional vector whose components were the projection onto the horizontal and vertical axes of the vector representing the direction of gaze. Perceived direction was defined as the projection of the vector representing the movement of the eye from one position to another onto the same central retinotopic area.

Area 7a neurons were found with translation torque, and planar rotational selectivity or receptive field (RF) movement in area 7a. For example single units could be selective for both clockwise rotation and radial expansion. This suggested that there might be cells selective to spiral motion was produced earlier on psychophysical grounds (Anderson and Siegel, 1995). Neurons were found with selectivity to clockwise rotation. These neurons seemed to be a severe coarsening for the type of structured motion in area 7a which could be principle used to be determined.

The dependence of the response of these optic flow selective neurons in the retinal focal of the monkey was what and when RFs were similar to the RFs of macaque area 7a. For example, single units could be selective for both clockwise rotation and radial expansion. This suggested that there might be cells selective to spiral motion was produced earlier on psychophysical grounds (Anderson and Siegel, 1995). Neurons were found with selectivity to clockwise rotation. These neurons seemed to be a severe coarsening for the type of structured motion in area 7a which could be principle used to be determined.

OPTIC FLOW RESPONSES OF MST NEURONS DURING PURSUIT EYE MOVEMENTS

C. J. Duffy1 and R. H. Wurtz, Dept. of Neurobiology, Univ. of Rochester Medical Center, Rochester, NY 14620.

The retinal image of an optic flow field is altered by concurrent smooth pursuit eye movement. We consider the task of interpreting that image, information about pursuit, if available to the visual system, might simplify that interpretation. We recorded the responses of 117 MST neurons to optic flow stimuli, during smooth pursuit, and attempted to determine whether the response of these cells is altered by smooth pursuit.

We recorded from 117 single neurons in area MST in two monkeys. We first determined (rarely with optical or circular) evoked the strongest response when the center of motion (COM) was centered on the screen. We then presented the preferred pattern, with 8 different created by combining 8 directions of planar motion, shifting the COM to 8 different positions in the stimulus. Ninety-four percent of the neurons responded differently to the centered and shifted COMs. Each neuron was then tested with the centered COM during smooth pursuit in 8 different directions. Eight-five percent of the neurons showed different responses to different pursuit directions. We compared the shifted COM response with those to pursuit across the centered COM, and found that most neurons (61%) had the same response to the retinal image, whether it was created by optic flow, or optic flow with pursuit. However, 39% responded differently when pursuit effects were contributed to the retinal image. In addition, over half of the neurons (56%) responded during smooth pursuit across a blank screen. These studies suggest that some MST neurons access both optic flow and smooth pursuit signals, potentially contributing to optic flow analysis during smooth pursuit eye movements.

RESPONSES OF LIP NEURONS DURING A MOTION DISCRIMINATION TASK: A DECISION PROCESS IN ACTION

M. W. Creutz,2 W. S. Glick,1 C. D. Saltzman,1 and W. T. Newsome,1 Dept. of Neurobiology and Neurology, Stanford University, Stanford, CA 94305.

Visually guided behavior requires selection or decision processes that identify one among many possible objects as the target of a movement. We investigated one such decision mechanism in a rhesus monkey trained to discriminate the direction of movement in a visual scene to indicate its direction by executing a saccade to one of two possible targets. During performance of the task, we recorded from neurons in a parietal area that receives projections from MST and MT and participates in the planning of saccades.

In each experiment, we placed one potential saccade target within, and the other outside, the movement field of the neuron under study. Each trial contained a 2.2 second stimulus presentation and a delay period prior to the saccade. Not surprisingly, delay period activity of LIP neurons reliably predicted the monkey’s eye movement: activity was stronger on trials in which the monkey chose the direction of motion toward the movement field. More interestingly, LIP neurons also signaled the monkey’s impending choice during the stimulus presentation interval, well before the saccade. This predictive activity built up earlier and was more reliable for easy than for hard discriminations (strong vs. weak motion signals). In other words, LIP neurons appeared to accumulate evidence regarding the direction of motion in the stimulus and to maintain a response suitable for guiding the appropriate saccade. Little evidence for this kind of activity was observed in control blocks of trials in which the same stimulus was presented, but the animal was not required to perform the direction discrimination. Thus the activity of LIP neurons may reflect an active decision process, but in which sensory signals are evaluated to inform target selection. RELIABLE TEMPORAL MODULATION IN CORTICAL SPIKE TRAINS IN AWAKE MONKEY

W. Bartel1, C. Koch,1 R. C. Olshausen1,2, K. Britten3, and R. Grossman1.

1Department of Neurobiology Stanford, Stanford, CA 94305; 2Center for Neuroscience, UC Davis, CA 95616.

We analyzed the repeatability and precision of temporal structure in spike trains recorded from area MT in behaving rhesus monkeys which viewed a dynamic random dot stimulus that did not vary from trial to trial (see data; Olshausen, Britten, and Mowshon, 1989). We find a surprising degree of regularity in the temporal modulation of the response of many cells—the most reliable cells will fire a few action potentials or even a period of elevated firing which begins and ends fixed in time relative to stimulus onset with a standard deviation of less than 4 msec in recording periods which may last many minutes to hours. Spike count during these short periods of elevated firing rate is more reliable, i.e. has a lower variance to mean ratio, on average than the spike count taken over the entire 2 sec stimulus. Offset and high of elevated firing periods can occur with very similar and fast time constants. Autocorrelation analysis reveals that deviations from the mean response are rarely substantially correlated beyond 100 msec, and in half of cells no correlation exists between consecutive interspike intervals beyond that predicted from the time-varying mean firing rate. Reliable temporal modulation disappears or diminishes for completely different motion stimuli, and we propose an experiment to determine whether this is due to saturation in firing rate or due to a qualitative change in the way MT cells respond to the stimulus.

INTEGRATION OF MOTION AND STEREO CUES IN MACAQUE VISUAL AREA MT

D. C. Bradley and R. A. Andersen, Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Most neurons in primate medial temporal cortex (MT) are highly sensitive to motion in a visual field. Recently, many MT neurons have been recorded from areas of the posterior parietal cortex, i.e., areas adjacent to MT. Simultaneously, a number of studies have shown that covert movements evoked by a stimulus presented in the opposite visual field are maintained for periods of time, i.e., the so-called "opposing" movement occurs simultaneously in a receptive field. An important benefit of this "motion opponent" is that random motion signals created by non-motion stimuli (e.g., flicker) tend to cancel out. However, motion opponent may also be impaired to MT responses under conditions of temporal motion, where motion signals are often locally opposed and as such tend to negate each other in MT. We hypothesized that this pattern might be overcome if opponent signals from different visual depths (and thus different layers) did not occur. To test this idea, we stimulated 146 MT neurons with a random dot pattern moving in the preferred direction and at the normal disparity (i.e., depth) for a given cell. A second pattern moving in the antipreferred direction was introduced, and the suppression due to this pattern was measured as a function of disparity. In ~40% of the cells, suppression was greatest when the antipreferred disparity was similar to the disparity of the preferred pattern and comparable to the normal disparity (as defined for preferred motion) regardless of the actual disparity of the preferred pattern. Our findings thus suggest that motion opponency in MT occurs mainly within a given disparity channel. This disparity-specific opponency favors the cancellation of random motion signals from a given depth, while allowing independent representation of surface movements at different depths.

SINGLE NEURONS IN POSTERIOR PARietAL CORTEX MAY REPRESENT BASIS FUNCTIONS FOR SPATIAL TRANSFORMATIONS

A. Pouget and T. I. Sejnowski, Howard Hughes Medical Institute, Salk Institute, La Jolla, CA 92037.

Many neurons in the monkey posterior parietal cortex have gaussian visual receptive fields that are modulated by a monotonic function of eye position, called the eye field. These receptive fields are more complicated in other parietal areas, in that they may vary with the direction of motion. In this field, single gain fields have been observed in neural networks that compute the head-centered position of objects (Gasper and Andersen, Nature, 1988), suggesting that populations of parietal neurons may form a distributed representation of the egocentric position of objects. There is an alternative interpretation for these gain fields in the context of sensory-motor transformations. Motor commands generated from the retinotopically organized eye position are nonlinear functions of these inputs. Such transformations can be approximated by using a simple intermediate representation in which neurons compute basic functions of eye position and the current eye position is known to form this intermediate representation. A gain field can be modeled as a gaussian function of retinal location multiplied by a sigmoidal function of eye position as a template for the pattern of the stimuli. In this way, the possibility that the posterior parietal cortex does not compute the positions of objects in a particular frame of reference but instead computes a general purpose representation of the retinal and eye position from which any transformation can be synthesized by direct projection. This representation predicts that hemineglect, a neurological syndrome produced by parietal lesions, should not be confused to egocentric coordinates but should be observed in multiple frames of reference in single patients, a prediction supported by several experiments.

525.10

EXPLICIT SPATIAL REPRESENTATION IN PARIETAL CORTEX IS NECESSARY FOR PROPER CONJOINING OF VISUAL FEATURES

R. S. Friedman1,2,3, L. C. Robinson1,2,3, and A. T. Treue1,2,3.

1Center for Neuroscience, UC-Davis, CA 95616; 2Veterans Administration, Martinez, CA; 3Princeton University, Princeton, NJ.

Research with human and non-human primates implicates parietal cortex in spatial attention. Our studies of a patient with remarkably symmetrical, bilateral parietal lesions due to embolic infarcts suggest that spatial deficits may also contribute to impaired object perception.

The patient, RM, is frequently unable to make explicit spatial judgments. When asked to judge the position of a single object (left, right, or center, in one condition; up, down, or center in another), RM was incorrect for 95% of trials. This deficit in judging the location of one item was not further increased by the presence of an irrelevant distractor. However, if asked to judge the location of the first item relative to the second item, RM's performance fell completely to chance. Concomitant with these spatial deficits, RM has a tendency to miscompare features of objects. Errors of this type are referred to as "illogical conjunctions." For example, when presented with red and blue, he may report seeing a red O, even with free viewing (display times up to 5 sec) and undivided attention. Neurologically normal subjects produce illogical conjunction errors only under divided attention conditions with very short exposures. RM makes fewer illogical conjunction errors with sequential presentation of stimuli than with simultaneous presentation. In the absence of reliable spatial information, temporal information can be used to organize which features should be combined.

The data suggest that there are important interactions between the "what" and the "where" pathways. Spatial information plays an integral role in the construction of our perception of objects from sensory distributed information.

A MODEL FOR COMBINED EYE-HEAD TRACKING INCORPORATING THE PROPERTIES OF MSTI VT-NEURONS, P. W. Dietz and P. Thiel. Dept. of Neurology, University of Tübingen, 70570 Tübingen, Germany

Combined smooth eye-head-tracking (CEHT) is carried out by primate in order to stabilize the retinal image of a moving object close to the fovea. We have tested the idea that the generation of CEHT is based on a signal related to target velocity in space, reconstructed in a spatially distributed manner at the level of parietal area MSTI. Two 3-layered connectionist networks were used in order to represent area MSTI on the left and on the right side of the brain respectively. The input layer of each of the two "MSTI" networks was made up of units, sensitive to retinal image slip, eye velocity, eye velocity and head velocity with identical nonlinearities. Further experimental findings built into the networks were the speed-tuning of VT-neurons and the distribution of their preferred directions, characterized by the fact that every direction between 0 and 360 deg may be found on either side of the brain with a possible bias for ipsiversive directions. Using error backpropagation the "MSTI" networks could be trained successfully to output the sum and difference of the two networks equal target velocity in space. Assuming a fully activated VOR and furthermore taking into account the established properties of the eye and head motor systems, this simulates coordinated eye and head movements. The overall model has proven able to fit measured combined smooth eye and head movements under a wide variety of conditions. Furthermore it is able to predict the effects of experimental lesions of MSTI in monkeys: Unilateral MSTI lesions were mimicked by removing one of the two connectionist networks involved. This manipulation resulted in an ipsiversive eye-head tracking deficit, which, with respect to the eye movement part, is in full accordance with reported experimental findings. Supported by Graduiertenkolleg Neurobiologie Tübingen and DFG KFO "Neuroophthalmologie".

We are investigating the role of PLPs in the control of locomotion in Ascaris. API and AP2 were isolated from extracts of 10,000 heads. Confirmation of additional sequences has been limited by the low yield of purified peptide (2-10 pmoles).

We are now isolating PLPs from 1M male methanol extract of 5,000 heads and male tails. After 7 HPLC steps, 8 PLPs have been isolated and their sequences confirmed by MALDI-MS. The yield of purified peptide was 70-500 pmoles. Peptides API/AP2 range from 4-14 amino acids and have six C-terminal tetrapeptides: TFRF-, VLRF-, VLRF-, and PLRFamide. On the basis of their effects on muscle tension, 3 classes of bioactivity have been found.

This is the most heterogeneous family of PLPs reported from one species. Additional active peaks from this purification are being isolated at this time.

526.2

NEUROPEPTIDE PRODUCTS OF THE FMRFamide GENE MODULATE THE DROSOPHILA NEUROMUSCULAR JUNCTION. R.S. Hewes and P.H. Tzagkhi. Dept. of Anatomy and Neurobiology, Washington University Medical School, St. Louis, MO 63110.

The Drosophila FMRFamide gene encodes a complex, neuromuscular precursor protein encoding many diverse FMRFamide-related peptides. In the larval CNS, this gene is expressed in a small, stereotyped pattern of neurons, including 6 that project to the thoracic dorsal neural organs. From these FMRFamide-related peptides may be released to act on peripheral targets via the circulation. Three synthetic peptides—sequences deduced from the FMRFamide precursor (DPQDQFMRFamide, MDSNFMRFamide, SVQDNFMRFamide)—enhance nerve-stimulated contractions of internal and external abdominal muscle fibers by increasing peak tension, contraction rate, and relaxation rate. These peptide effects began within 1-2 min of the onset of peptide application, reached peak strength after 3-7 min, and ceased after 10-30 min. The threshold concentrations were 10 nM for DPQDQFMRFamide and MDSNFMRFamide and were 100-1000 nM for SVQDNFMRFamide. These results suggest that 1) receptors with high affinity for FMRFamide-related peptides are located on several skeletal muscles and/or on motorneuron terminals, and 2) multiple sequences contained in the FMRFamide precursor may be functionally equivalent at the neuromuscular junction. The design of labeled peptides will be important for receptor localization and for cloning of FMRFamide receptors by functional expression. Towards this end, we found that biotinylated peptide—enhanced nerve-stimulated contractions at a threshold of about 10 nM. (Supported by NIH Grants NS021749 and NS00701.)

We have used NADPH diaphorase histochrometry to establish the distribution of NADPH-oxidase in the feeding neurosecretory neurons of Lymnaea stagnalis. A dense population of stained fibers are present in the lip nerves and these are derived from a band of sub-epithelial bipolar cells located at the margins of the sensory neurons and NADPH may be involved in activating feeding. To test this hypothesis we used a semi-intact lip-CNS preparation where a sucrose stimulus can be applied to the lips while recording from identified neurons that control feeding. Sucrose activation of the feeding network was inhibited when the CNS was preincubated with the NO scavenger haemoglobin (Hb), the NO synthase inhibitor Nω-Nitro-L-arginine or the guanylyl cyclase inhibitor methylene blue (MB). Central activation of the feeding network by current injection into the slow oscillator (SO) interneuron was not affected by Hb. Application of NO donors or 8-bromo-cGMP to the CNS also activated the feeding network. We tested the behavioural significance of these physiological experiments by injecting animals with Hb or MB before placing them in a sucrose-rich environment and monitoring feeding behaviour. Both Hb and MB delayed the onset of feeding compared to met-Hb (which should not bind NO) and distilled water, respectively. Our results indicate that NO is released in the Lymnaea CNS by sucrose-activated chemosensory neurons and causes cGMP-mediated activation of feeding behaviour. This is the first description of a specific behavioural role for NO in the CNS. [Supported by BBSRC grant no. GR/J33234]

Prior to the development of cilia, Halisoma embryos exhibit a cilia-driven rotational behavior within the egg capsule. One component of this behavior, rotational surges, results from the transient stimulation of pedal ciliated cells by serotonin that is released from the identified embryonic neurons, ENC1. In order to examine the signal transduction mechanism underlying the serotonin-induced stimulation, ciliated cells were isolated from Halisoma embryos, plated under cell culture conditions and monitored in slow motion using time-lapse videomicroscopy. In the absence of serotonin, cilia beat spontaneously and regularly at frequencies ranging from 5-9 cycles per second. Serotonin induced a sustained, dose-dependent increase in cilia beat frequency with an EC50 around 1 μM. This stimulation was not mimicked by either potassium-induced depolarization or addition of 100 μM forskolin and 200 μM isobutylmethylxanthine, a treatment that elevates the level of intracellular cyclic AMP. In contrast, addition of thapsigargin (1 μM) or A23187 (10 μM), treatments that increase the concentration of cytoplasmic free calcium, caused an increase in cilia beat frequency similar to that produced by 100 μM serotonin. Furthermore, the response to serotonin was prevented when cells were exposed to calcium-free medium or the voltage sensitive calcium channel blockers, nifedipine or verapamil (1 μM). These data suggest that serotonin stimulates cilia beating by causing a calcium influx in a depolarization-independent manner.

NEUROTRANSMITTERS

526.5

NADPH-diaphorase staining of the CNS of Aplysia was used to identify neurons that may contain nitric oxide synthase (NOS) and produce nitric oxide (NO). There are a few densely stained neurons in all ganglia and ca 30 bilaterally paired neurons in the ganglia 2 and 3 which can receive E-cluster terminals. Their axons and neurites are stained and form well defined fiber tracts and synaptic glomeruli, including the lateral terminus, which is also stained by antisem to myomodulin, a neurotransmitter / modulator. NADPH-diaphorase stains terminal processes on cell bodies of non-unstained E-cluster neurons and also in synaptic-like junctions. NO generated using 1 mM SIN-1 (3-morpholino-sydnonimine) and 5,7 (5-nitro-2-oxo-1,2-dihydropteridine) depletes these neurons, induces action potentials and increases input resistance. Degasued SIN-1 and SIN-C have no effects. A membrane permeant cGMP analogue, 8-bromo-cGMP mimics the effect of SIN-1 and SIN-C. E-cluster neurons stained by NADPH-diaphorase, and marked by dye injection, synaptically depolarize neurons that receive NADPH-diaphorase stained terminals. Consistent with NO effects, the response is calcium dependent and blocked by nitro-arginine. These results suggest that NO released from NADPH-diaphorase stained neurons acts like a neurotransmitter and depolarizes postsynaptic targets. cGMP may increase calcium cycles and increase cGMP, which alters ionic conductance.

NEUROTRANSMITTER 5-HT AND DA LEVELS AND THEIR SYNTHESIS ACROSS THE LIFE SPAN OF APLYSIA. C. Hong*, J. M. Flinn, R. Holt, V. Chandoke and Tom Capp.* George Mason University, Fairfax, VA 22030, *Univ. of Miami, FL 33149.

The levels of serotonin (5-HT) and dopamine (DA) in ganglion tissue were examined for animals ranging in age from 3 to 13 months post-hatch, the tissue tryptophan and tyrosine levels were also measured using HPLC. The results indicated that 5-HT increased slowly in the ganglion from 3 to 4 months and from 7 to 13 months, however it increased rapidly in the 4 to 6 month age range. In contrast, the increase in DA was predominantly constant across the age span. The ratio of 5-HT to DA showed a strong age dependency, with the lowest values at 3, 4, 12, and 13 months and the highest ratio at 6 months. 5-HT/DA represents the excitatory to inhibitory neurotransmitter ratio. These results suggest that DA may dominate 5-HT in very young and very old animals where previous studies have shown behavioral sensitization of the Gill-siphon withdrawal reflex to be weaker. The analysis of the ratios of neurotransmitter to its precursor in the ganglion (5-HT/TRP and DA/TRY) suggests that the synthesis of neurotransmitters may be one of the factors contributing to the changes in the net neurotransmitter levels. The 5-HT/TRP ratio increased at the 6 to 8 months period and then leveled off, while the synthesis of DA/TRY ratio had a slight increase after 7 months. Further studies on the metabolic enzymes and degradation courses are underway.

526.9

AGE RELATED CHANGES IN SEROTONIN AND DOPAMINE NEUROTRANSMITTERS AND RECEPTORS IN APLYSIA CALIFORNICA. M.D. Southal, S. Shirazi, V. Chandoke*, P. W. Royt and J. M. Flinn. George Mason University, Fairfax, VA 22030.

The age associated changes in dopaminergic and serotonergic receptors were examined in Aplysia californica. In earlier studies (Hong, 1994) it has been shown that the levels of serotonin (5-HT), dopamine (DA) and their ratio vary with age. In this study the levels of neurotransmitter receptors were examined in the ganglia obtained from 4, 5, 6, 10 and 12 month old animals. Receptor analysis was performed using radiolabeled bound ligands specific for the receptor of interest. [3H]-LSD was used to determine the saturation binding for total 5-HT and DA receptors. We report here the results for the 10 month (young) and 10 month (old) animals. Specific binding in the 5 month animals was found to be 9.9 fmol/mg of total protein for 5-HT and 8.4 fmol/mg protein for DA. For the 10 month animals, the specific binding for 5-HT was 20.9 fmol/mg protein and 16.4 fmol/mg protein for DA. This represents a two fold increase in binding for both 5-HT and DA in the 10 month as compared to the 5 month animals.

526.6

Vertebrate insulin can stimulate tyrosine autophosphorylation of a vertebrate insulin-like receptor in Aplysia bag cell neurons. We have therefore searched for peptides in Aplysia similar to vertebrate insulin using HPLC purification and a placental insulin-receptor autophosphorylation assay. Fractions from Aplysia embryos and total nervous system were purified by HPLC. One fraction both stimulates placental insulin-receptor autophosphorylation activity with insulin receptor-binding assays and in radioligand assays at nanomolar concentrations of the vertebrate peptide. The material in this fraction has been purified and its amino acid sequence is being determined. Initial results in the cerebral ganglion (Pergolizon et al., J. Comp. Physiol. A 164: 849), which contains cells that we may find to be homologous to the light green cells (LCGs) of Limynea (LGCS) produce mammalian insulin-like peptides – MIPs – which control growth and reproduction): We find that an antiserum against R15x2 peptide cross-reacts with vertebrate insulin as well as with the material we describe as insulin. Immunocytochemical studies with this antiserum stain two bilateral clusters of neurons in the cerebral ganglion that appear homologous to the LOC clusters in Limynea. Since these cells receive direct sensory afferents, this may be recognizing another peptide. As in Limynea, the neurons in Aplysia that exhibit this insulin-like immunoreactivity send processes to neurohaemal organs at the base of the lip nerves. Further studies are in progress to determine whether these LOC-like clusters are the source of the insulin that acts on bag cell neurons.

Neurons exhibiting cyclic AMP-gated current (I_{cAMP}) allow in vivo assay of cyclic AMP levels, synthesis and degradation (Huang and Gillette, J. Physiol. 98:831; 99:203; Sudhof, et al., in press). We have estimated 1) the concentration of CAMP due to stimulation by 5-HT, 2) 5-HT stimulated adenylyl cyclase activity, and 3) phosphodiesterase rate constants. Occillation of I_{cAMP} by 5-HT-induced current, and the voltage-dependent inactivation of I_{cAMP} and its coexpression with both CAMP and PKA and neuromodulators, indicate common modes of action. The procedure requires establishing: 1) the dose response relationship for I_{cAMP} with steady-state CAMP isophoretic current; 2) occlusion assay of I_{cAMP} with neuromodulator; 3) analysis of phosphodiesterase rate constants; and 4) measurement of cell diameter. Calculations yield an estimate of adenylyl cyclase activity per sec per unit membrane area. We have estimated the adenylyl cyclase activity in pedal ganglion G neurons in Pleurobrachia during 10 μM 5-HT stimulation to range from 0.98 to 2.77 pmol sec^{-1} cm^{-2}, averaging 1.59 ± 0.31 (n=5). 5-HT-induced CAMP concentrations at the membrane ranged from 4.94 to 12.14 μM, averaging 7.68 ± 1.22 μM (n=5). Supported by NIH grant ROI NS26588-01 to R.G.

AXON GUIDANCE II

OUTGROWING RETINAL AXONS GUIDED BY RADIAL (GLIA) CELLS. B. Schlosshauer* and R. Steinhauser. Max-Planck-Institut für Hirnforschung, West Germany.

In order to analyse the cellular mechanisms that govern oriented axonal outgrowth within the retina, we employed cytocryostats of the embryonic chicken. Visible retina strips were explanted onto cryosections of retina and axonal outgrowth was monitored. In vivo only ganglion cell axons and neurophilial axons (endfoot from the optic fiber) and radial Müller glia in the only nonneuronal cell type in the chicken retina. 1) Ganglion cell axons are directed by a dual mechanism: the retina tissue is composed of an inhibitory zone (cell layer) and an excitatory zone (optic fiber). In vitro, axon growth preferentially on the most external layer of retina cryosections even after coating sections with laminin. 2) Axons approaching outer retina layers respond partially with a growth cone (tempo time video recordings). In contrast, prior heat inactivation of cryosections allows axonal outgrowth even in outer retina layers. 2) The permissive zone is formed by endfoot of neurophilial/retinal glia. a) After elimination of ganglion cells and their axons due to prior optic nerve transection, explant axons still prefer the innermost retina layer in vivo pretreated cryosections. b) Isolated glia endfoot provide an excellent growth substrate. 3) The inhibitory zone is formed by somata of radial glia. a) Axonal outgrowth is inhibited on radial glia somata purified from retina cells cultured by complement mediated neuronal cytology. b) The restricted number of outgrowing axons on glia somata are highly fasciated therefore avoiding contact with glia somata (scanning electron microscopy). c) Heat inactivation of purified glia somata converts glia cells into a permissive substrate. The data suggest that ganglion cell axons guided by the innermost retina layer - polarized neurophilial/retinal glia cells with their endfoot being permissive and their somata being inhibitory for outgrowing axons. Supported by DFG.

NEURONAL ORIGINATION OF THE EMBRYONIC FORE- AND MIDBRAIN OF MICE AT 8.5 DAYS' GESTATION. G.L. Mastick and S.S. Easter, Jr., Dept. of Biology, U. of Michigan, Ann Arbor, MI 48109.

The fluorescent axon tracers Dil and DiO were used on fixed E10.5 embryos to map groups of early neurones and pioneer axons with respect to interneuronal boundaries. The spatial and temporal relationship between central neurone and cranial nerve axonogenesis and spinal cord boundaries suggested a role of regional embryonic boundary. The fluorescing axon tracers injected at E9.5 and E10.5 were used to map the rostrocaudal, dorsoventral, and mediolateral coordinates of the rostral embryonic brain, revealing several general features: 1) Groups of neurones can be defined by major transverse interneuronal boundaries. 2) dmvXV and n8 somata were found in both mediolateral and rostrodorsal boundaries of the maxillary process, implying that these neuronal types are not simply defined by neurone migration or axon extension. In this axon transplant experiments, the somata of transplanted neurones were interposed with the very early dmvXV neurones in dorsal mesencephalon, and major axonal systems develop, marking the dorsal and ventral borders of the hindbrain. dmvXV (dorsal) and n8 (ventral) neurones were also projecting caudally into the rhombencephalon. Axons of the tract of the rostral commissure (TRC) extend from the base of the optic tract into dmvXV, suggesting that the TRC is dorsal, and the *front* end of the brain is ventral to the optic tract. 3) The pioneer axons do not follow interneuronal borders, instead, broad zones of the neural tube are filled with axons sharing trajectories. We examined the altered organization of the embryonic brain in Waclaw mutant mice using neuronal landmarks at E8.5. The loss of this secreted growth factor causes deletion of mesencephalon and rhombencephalon, 1, loss of ast and DiO, and creates a new boundary between the forebrain and rhombencephalon. 2. Surprisingly, pioneer axons navigate accurately across the new boundary.

S27.4

ARREST OF AXONAL GROWTH IN VITRO BY LIVING, SINCTIONED OR FIXED TARGET NEURONS. D.H. Barad* and B. Knud, Department of Anatomy and Neurobiology, Medical College of Pennsylvania and Hahnemann University, Philadelphia, PA 19129.

The regulation of axonal growth by CNS targets was examined using an in vitro system in which the extension of cerebelar mossy fibers from explants of basilar pontine nuclei is interrupted by their targets, granule neurons. This "stop-growing signal" is both target- and axon-specific, and its regulation involves the expression of NMDA antagonists, mossy fibers are not arrested by granule neurons, and the growth of (>300 μm) neurites is 3.4 times that of controls. NMDA has an opposing effect, causing the stop-growing signal, resulting in shorter mossy fibers. Neither NMDA nor its antagonists alter the growth of mossy fibers in the absence of granule neurons.

To determine if functional, pre- or postsynaptic NMDA receptors are involved in the stop-growing signal, mossy fibers were cultured on granule neuron monolayers and were perfused with various concentrations of NMDA agonists, paraformaldehyde, and on unfixed, frozen sections of cerebellum. In both cases, mossy fibers extended less than 100 μm from their explant, and the growth of granule neurons was also arrested. These results suggest that cerebelar mossy fibers compete for recognition sites on granule neurons. In addition, the results suggest that functional granule neuron NMDA receptors are not strictly required for the arrest of axons by target neuron, and if they are involved at all, they must regulate this process indirectly.
EVIDENCE FOR GUIDEPOST CELLS IN AXON OUTGROWTH DURING DEVELOPMENT OF LEEF. [Lee et al. 1992]. Department of Biology, Yale University, New Haven, CT 06511

The characteristic pattern of the bodywall innervation in Drosophila embryos provides an ideal system to study axon guidance and synapse formation. Segmentally reiterated (SNAs) grow out laterally from the anterior half of the segment and make a stereotypical posterior turn at mid-bodywall to innervate muscle 5 and 6. Cash et al. (J. Neurosci. 12:2501, 1992) showed that in the absence of these target muscle fibers, SNAs still turn posteriorly. Therefore, cues other than the targets are present to guide SNAs growth. Although SNAs trajectory can be altered by manipulation of the muscle fibers in its path, it always makes the posterior turn to innervate its target muscle fibers (Wang and Keshishian, Neurosci. Abstr. 18:1273, 1992). We observed the presence of 2 cells (possibly glia) at the corner of muscle fibers 12 and 5. Their locations correspond to the site at which SNAs usually makes ends on muscle fiber 5. In mutants of the spitz family, such as pointed, which affect ventrolateral patterning, 20% of the SNAs nerves fail to turn (Wang et al., Neurosci. Abstr. 19:235, 1993). Examination of pointed mutants showed: (1) In 6 out of 8 cases SNAs failed to turn when the 2 glial cells were missing. (2) In 20 out of 22 cases, SNAs turned normally when these cells were present. To test whether these cells are in fact guidepost cells, we are surgically removing them in filleted embryos at late stage 15, when SNAs has not yet turned. The embryos are then cultured until late stage 16, when SNAs normally has reached its targets. These experiments will critically define the role of these putative guidepost cells in inducing the posterior turn of SNAs.

SPECIFICITY OF SYMPATHETIC PREGANGLIONIC PROJECTIONS IN THE CHICK IS INFLUENCED BY THE MATURATION STATE OF THE SOMATIC MESODERM. L.W. Ying. Dept. of Neurobiology, University of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261

The spatio-temporal patterns of sympathetic preganglionic projections in the chick are segmentally specific. For example, T1 preganglionic neurons enter the sympathetic trunk at stage 27 and project rostrally. In contrast, T4 preganglionic axons enter the sympathetic trunk at stage 28 and project caudally. Previous studies from this laboratory have shown that the somitic mesoderm influences these patterns. This study examines whether the maturation state of the somitic mesoderm is responsible for this influence.

Two series of experiments were designed to confront preganglionic neurons with somitic mesoderm from older maturation stages 4 and 4 (homozygous embryo). The T4 neural tube segments of a stage 14 embryo were transplanted to the upper cervical (more mature) region of the same embryo. Orthodrome HER labeling showed that a subset of T1 preganglionic neurons translocated to the cephalic region occurred much earlier than normal, such that by stage 26 the translocated T1 preganglionic neurons have already contributed extensively to the sympathetic trunk. This indicates that preganglionic neurons will send their axons out earlier when they encounter a more mature somitic mesoderm. In another series of experiments, the T4 neural tube segments of a stage 11 donor were transplanted homotopically to a stage 18 host. In the resultant embryo, the T1 preganglionic neurons projected in both rostral and caudal directions, instead of in their normal, predominantly rostral direction. This result indicates that the direction of preganglionic projections can be altered by the maturation state of the somitic mesoderm.

The maturation of the somatic mesoderm may therefore relate to the formation of the specific pattern of preganglionic projections.

TESTING THE ROLE OF TARGETS IN MOTONEURONAL SPECIFICITY C.E. Beattie* and L.S. Efros, Institute of Neuroscience, University of Oregon, Eugene, OR 97403

We are investigating mechanisms underlying neuromuscular specificity in vertebrates using embryonic zebrafish. During zebrafish development, identification of motoneurons with specific somatic positions in the spinal cord becomes committed to innervate particular regions of myotome. Motor growth cones may be guided by motonal cues. Alternatively, they may grow in a specific direction regardless of motonal cues, suggesting that guidance cues originate from some other source. To differentiate between these mechanisms, we analyzed motor axonal outgrowth after altering the orientation of the myotome. Labeled donor myotomes were isolated, rotated along the dorsoventral axis and transplanted into unlabeled host embryos from which native myotomes had been removed. Following doronal-ventral reorientation of the myotome and the orthochronic transplantation at 16h, an identified motoneuron, CaP, extended its growth cone ventrally as it does normally. This result suggests either that doronal and ventral myotomal regions have become respecified or that CaP extends this axon ventrally independently of motonal cues. To resolve this issue, heterochronic transplants were performed. Following doronal-ventral reorientation and transplantation of 19h myotomes into 16h hosts, CaP extended an axon which often grew laterally and appeared to avoid the ventral myotomal region which now contained dorsal muscle. This result supports the idea that younger myotomes respect their dorsal and ventral regions while older myotomes retain their original polarity after transplantation. Motor axons, therefore, appear to be guided by cues originating from myotome. Supported by ACS PF-3982 and NS23915.
MOTOR AXON SPROUTS ARE INDUCED AND GUIDED BY PROCESSING OF NEUROMUSCULAR SYNAPSES TO FORM SCAGGLED NERVE AXONS IN THE POST-CONTRIBUTIONS TO THE MECHANISMS OF NEUROMUSCULAR JUNCTION REMODELING. C. C., B., W. L., T., and B. L. Thompson* and J.-Y. Soo. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

In the present study, we examined the possibility these cells play a role in the sprouting of motor nerves in adult mice.

We first examined nerve sprouting induced by partial denervation (PD). Within 3 days of PD, use of an anti-neurofilament antibody showed that nerve sprouts were extended about 28% of the terminal remains in the muscle. Staining with a SC marker (anti-S-100) showed that all of these sprouts were associated with SC processes. Staining with the antibody 4E2, which marks SCs at denervation, demonstrated that these sprouts extended from junctions which had been contacted by processes of SCs at denervation.

In the nerve sprouts grown along the SC process to the adjacent denervated endplate. These sprouts were observed to be confined to the endplate region and were often precisely aligned with motor nerve terminal branches. This alignment was not observed in neonatal mice. Following denervation, Schwann cells rapidly extended processes well beyond the endplate region, often joining with processes of cells from adjacent endplates, consistent with observations made using S-100 immunohistochemistry (Reynolds & Woolf, 1992). Recently, Thompson et al. have shown that following denervation, regenerating axons are closely associated with Schwann cell processes and suggest that these cells may play a role in axon growth guidance to the endplate (Son & Thompson, 2004). Observations of terminal Schwann cells in vivo will allow the dynamics of the response of these cells to denervation and their role in axonic regeneration and maintenance to be studied.

As discussed above, the implications of these results are that, in the context of the axon-stem cell relationship, our data suggest that the role of the stem cell in the regeneration of the axon is to maintain the balance of the autonomic and the behavioral systems. This is consistent with the findings of previous studies that have shown that the role of the stem cell in the regeneration of the axon is to maintain the balance of the autonomic and the behavioral systems.
528.3

Bolus injections of cholecystokinin octapeptide (CCK-8) are more potent for reducing sucrose intake when injected through an aortic catheter than when given intravenously (Callegari et al., Am.J.Physiol. 263:R572-R577). We compared suppression of intake of 30% sucrose produced by continuous near-ciliary and intravenous infusions of 100 - 1600 ng CCK-8. Adult, male Sprague-Dawley rats received infusions throughout 20 min feeding tests. Significant reductions in intake were produced by 400, 800, and 1600 ng near-ciliary CCK-8. Only the two highest doses reduced intake when administered intravenously. Behavioral observations indicated [1] that CCK-8 had no effect on feeding during the first several minutes but accelerated the decline in incidence of feeding later in the test and [2] that near-ciliary CCK-8 had more pronounced effects on feeding behavior than did intravenous CCK-8. Thus during slow infusions, greater potency of near-ciliary CCK-8 was accompanied by temporal intake patterns indicative of enhancement of satiety. The data provide further evidence that cholecystokinin acts within the upper gastrointestinal tract to inhibit food intake.

528.5

Neonatal treatment with monosodium glutamate (MSG) induces neuronal degeneration in the arcuate nucleus (ARC). This nucleus is the main hypothalamic site of neuropeptide Y (NPY) synthesis. Hypothalamic NPY preferentially stimulates carbohydrate intake and is influenced by diet composition. In this experiment, we measured the effects of a MSG treatment on NPY levels and dietary preferences. Newborn Long-Evans rats were injected i.p. with either MSG (4 mg/g BW) or saline on the 3rd, 5th and 7th days of life. Rats were fed on a control (C) diet until adulthood. Then, they could choose between a high carbohydrate (HC) diet and a high fat (HF) diet. NPY concentrations were measured in several microdissected hypothalamic nuclei. They were significantly smaller in the MSG rats than in the control rats in the ARC (- 52 %; p<0.001) and part of the paraventricular nucleus (pPVN) (- 57 %; p<0.004). Energy intake in the food choice situation was greater in the control than in the MSG rats (81.3 ± 5.3 vs 62.2 ± 3.7 Kcal/day; p<0.01). This augmentation was due to a greater intake of HP diet (> 60 %; p<0.001) and a smaller intake of HC diet in the control rats (- 25 %; p<0.01). These results confirm some of our previous findings showing that rats with a carbohydrate preference are characterized by lower NPY levels in the pPVN. Supported by Fondation B. Deleers (Paris).

528.6

Recent evidence shows that in vivo and in vitro NPY release in the paraventricular nucleus (PVN) and NPY gene expression in the arcuate nucleus (ARC) increase in association with hyperphagia in long-term diabetic rats. In the present study we sought the timing of the onset of NPY upregulation and hyperphagia in streptozotocin (STZ)-treated diabetic rats. Adult male SD rats were injected with either STZ (65 mg/kg) or vehicle via tail vein on day 0. Rats were killed on days 2, 3 and 4. PreproNPY mRNA levels in the medial basal hypothalamus which includes the ARC, were determined by solution hybridization/RNAase protection assay using a cRNA probe. NPY levels in the microdissected hypothalamic sites were also estimated by RIA in STZ-treated rats. As expected, STZ treatment induced marked hyperglycemia and hypoinsulinemia along with loss in body weight after STZ treatment. Analysis of NPY gene expression, peptide levels and food intake showed a remarkable temporal sequence of events. PreproNPY mRNA levels were significantly increased (4.5 fold, p<0.001) within 48 hours of STZ treatment. Similarly, the 7 hypothalamic sites examined, NPY peptide levels were increased only in the PVN 2 days after STZ injection. In contrast, food intake was decreased for 3 days and thereafter, a significant hyperphagia was evident on day 4. Collectively, these results show that the enhanced NPY synthesis and release in the ARC-PVN axis precedes hyperphagia in diabetic rats. Since very low levels of insulin can inhibit NPY release from the PVN nerve terminals (Soc. Neurosci. Abst. 19-1821, 1993), we propose that the regulation of food intake by insulin is mediated by NPY PVN interconnections of a subpopulation of neurons in the ARC. Supported by UP DSR KD 717 (AB); NIH DK7273 (BPK); VA Merit Review (CAS).

NPY IMMUNONEUTRALIZATION SUPPRESSES FEEDING IN VMH-LESIONED HYPERPHAGIC RATS. Sara P. Kral*, M.G. Dubey* and Pushpa S. Kalra. Departments of Neuroscience and Physiolog, Univ. of Fla, College of Medicine, Gainesville, FL 32610

It has been known for a long time that destruction of the ventromedial hypothalamus (VMH) induces hyperphagia and increase in body weight. The neural signal(s) responsible for the hyperphagic response have not been identified. Neuropeptide Y (NPY) is the most potent orexigenic signal known and the evidence that passive immunization of rats against NPY suppresses feeding is ample. We therefore tested whether NPY antibodies may act as a pharmacological appetite suppressor. Therefore, we hypothesized that hyperphagia in VMH-lesioned rats may be NPY-dependent. Female rats received electrolytic or sham lesions in the VMH and permanent cannulae in the third ventricle of the brain. The VMH-lesioned rats displayed robust hyperphagia (5.5 ± 1.1 g/2h) as compared to sham-lesioned rats (1.6 ± 0.3 g/2h) 12-26 days post-surgery. These rats were passively immunized against NPY by intraventricular injections of purified IgG containing a specific NPY-antibody (NPY-Ab) at 0900, 1100 and 1300 h, and food consumption was evaluated between 1300-1500 h. The results showed that food intake was suppressed by greater than 93% in the NPY-Ab injected, VMH-lesioned rats. Similar central injection of purified IgG from normal rabbit serum (control) had no effect on food intake in these VMH-lesioned or sham-lesioned rats. These results suggest that hyperphagia in VMH-lesioned rats may be mediated by NPY. The effects of NPY on feeding behavior are consistent with the view that NPY is an orexigenic signal. Preliminary results indicate that a specific NPY-antibody may act as a pharmacological appetite suppressor.
TAMOXIFEN PREVENTS NEUROLEPTIC-INDUCED WEIGHT GAIN AND HYPERPHAGIA IN FEMALE RATS. T. Baptista, E. de Baptista, M. Altmann, and R.S. Scott. Biological Psychiatry Branch and Clinical Neuroendocrinology Branch, NIMH, Bethesda, Md. 20892

Elsewhere, we have suggested that the weight gain and hyperphagia induced by chronic administration of neuroleptics in female rats is related to a neuroleptic-induced hyperprolactinemia, which causes a decrease in gonadal estrogen synthesis, ultimately resulting in decreased activity of hypothalamic neurons involved in satiety (Parada et al., 1989). This mechanism has been investigated using the D2 selective dopamine antagonist sulpiride, and the weight gain was prevented by concurrent administration of either estrogen or bromocriptine. Recent evidence suggests that the antiestrosten tamoxifen may act as an estrogen agonist on food intake regulation because, in the short term, it prevents weight gain and hyperphagia in ovariectomized rats. In addition, tamoxifen and neuroleptics compete for the same receptor in hypothalamic neurons (Gray et al., 1993), which further suggests that tamoxifen may prevent neuroleptic-induced weight gain. To assess this hypothesis, female rats were divided into groups of 10 animals each, and were treated for 21 days with either vehicle, sulpiride (20 mg/kg, i.p.), or sulpiride plus one of the following doses of tamoxifen citrate: 2.5, 5, 10, 20, 50, or 100 mg/kg, i.p. Sulpiride-induced weight gain and hyperphagia were completely prevented by tamoxifen at doses of 5 or more mg/kg. A trend was observed between the dose of tamoxifen and inhibition of weight gain under sulpiride: r = 0.68, F(1,6) = 4.4, p < 0.08. Tamoxifen may be useful to prevent weight gain in obesity prone women under neuroleptic treatment.

Feeding can increase extracellular dopamine (DA) levels in the nucleus accumbens (NAc) of freely moving rats (Hernandez & Hoebel, Physiol. & Beh. 44, 599), but little is known about the effects of obesity on basal DA release in the NAc. In the present study, female albino rats (n=16) developed cafeteria-diet obesity and body weight averaging 23% above controls (n=16). In vivo microdialysis showed that basal DA levels in the NAc of the obese rats were 70% lower than in controls (p<0.01), but d-amphetamine (1.5 mg/kg i.p.) increased NAc DA to 75% of basal levels in the obese group and only to 25% in the control group (p<0.05). When both control and obese rats were food deprived for 24-36 hrs, there was no longer any measurable depression of basal NAc DA in the obese group. After a Purina pellet meal, NAc DA increased significantly in the food deprived controls (p<0.01), but not in the food deprived obese, however, a cafeteria-diet meal did increase DA (p<0.01). The results suggest that cafeteria-diet obesity (a) dampens basal activity of the mesoaccumbens DA system, but mild food deprivation and highly palatable food restore it, and (b) increases the amount of DA available for release by amphetamine.

Support by USPHS grant NS 30697.

Hyperphagia following fasting is a robust phenomenon. However, the actual signal used by a fasted animal to detect the necessity to ingest calories is still not known. Theories have focused upon glucose or lipid oxidation and cellular energy generation. We conducted the following study to investigate the relationship between several whole-body metabolic parameters and hyperphagia following food deprivation.

Recent long-term rats (14) were food deprived for periods ranging from 3 to 16 hours. Two hours before refeeding, they were placed in an indirect calorimeter for 2 hours. The rats were then returned to their home cages, food was restored, and food intake was recorded for 3 hours. Multiple regression analysis of several parameters, including respiratory quotient, carbohydrate and fat oxidation rates, energy expenditure, body weight, VO2, and VCO2 was performed. Of all the variables considered, only carbohydrate oxidation rate reliably predicted the amount of food consumed when access to food was restored. Importantly, using linear regression line fitting, a function was derived which predicted 0 grams of intake at a carbohydrate oxidation rate identical to that observed in the post-prandial state. These data indicate that fasting carbohydrate utilization rate may be an important determinant of refeding hyperphagia.

ANTISENSE OLIGODEOXYNUCLEOTIDES TO G-PROTEIN SUBUNIT SUBCLASSES: CHRONIC INTRACEREBROVENTRICULAR (ICV) INJECTION INDUCES A PHARMACOLOGICAL MODEL OF HUNGER. T. M. Hirsch-Multer, 1,2HLS, Univ. Delaware, Newark, DE 19716 and Dept. of Pharmacology, Zeneca Pharmaceuticals Group, Wilmington, DE 19897

Heteromeric guanine nucleotide-binding (G) proteins transduce signals from the membrane G-protein-coupled receptors to cellular effectors. We studied rats the effects of the chronic ICV (into the third ventricle) infusion for 72 h (through osmotic minipumps) with antisense phosphoetho-oligodeoxynucleotides (15 pg/24 h) corresponding to G-protein subunit subclasses (a, B, and G) The results for nighttime food intake (mean±SE, g) at the 48-60 h period after initiation of the vehicle, antisense or sense infusion were as follows: 20.2±1.1, 10.7±2.2, and 20.4±1.1, n=8; Ga3 antisense (to Ga11, 12 and 13), 20.0±1.1, n=8; Ga3O3 common antisense (to Ga10 and Ga2B), 15.8±1.0, p<0.01, n=11 (water intake increased 9% from control); Ga2B antisense, 15.4±1.1, p<0.01, n=11; Ga3O3 antisense, 19.2±1.1, n=10; Ga3 antisense, 15.4±1.1, n=7; Ga2B common antisense, 20.3±1.1, n=5; Cy3 common antisense, 15.8±0.5, p<0.02, n=6. (Cy3 1, 2, 3 and 4 antisense also decreased feeding, n=6-7/group). Infusion with 15 µg/24 h of Ga3O3 common sense or Ga2B sense had no effect on nighttime food intake (19.4±1.1, n=8, and 20.7±1.1, n=9). Computerized analyses of behavioral patterns demonstrated that the Ga3O3 antisense depresses nighttime feeding by reducing meal frequency (to 4.9±0.3 meals, n=11, p<0.001 from control: 7.5±0.6 meals, n=8) without decreasing meal size or meal duration. Immunoblots of hypothalamic ventromedial nucleus from normal rats (n=12) show that the levels of Ga3O3 protein subunit are >50-fold higher relative to those of Ga11 and Ga2B subunits. The results suggest that the G-protein subunit subclasses Ga3O3 and Ga3 are required for the modulation of normal feeding behavior, and that changes in their activity may be associated with the chemical regulation of feeding.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
529.1 CROSS-TOLERANCE TO D, BUT NOT D, Dopamine Receptor Agonist ON Rats TOLERANT TO CAFFEINE-INDUCED ROTATIONAL BEHAVIOR. R.E. Garrett/Pand S.G. Holtzman. Dept. of Pharmacology, Emory University School of Medicine, Atlanta, GA 30322.

Caffeine produces contralateral turning in rats with unilateral 6-OHDA (8 μg/μl)-induced lesions of the nigrostriatal pathway. The present study a) determined if tolerance develops to this effect of caffeine and b) examined the effect of dopamine receptors. Male Sprague-Dawley rats with 6-OHDA lesions received scheduled access to either a 0.1 % caffeine solution (average drug intake = 70 mg/kg/day) or to drug-free tap water (controls). The rats were subsequently SC injected with 5 mg/kg caffeine and turning was recorded for 3 hr. Caffeine (100 mg/kg) and theophylline (3-100 mg/kg) produced biphasic increases in contralateral turning in control rats, with the peak effect being 0.3 to 10.5 mg/kg, respectively. Rats receiving caffeine chronically were tolerant to this effect of both drugs. The selective D1 agonist quinpirole (0.01-1.0 mg/kg) and R(-)-propylnorapomorphine (NPA, 0.003-1 mg/kg) and the selective D3 agonists SKF-38393 (0.3-10 mg/kg) and SKF-77434 (0.3-10 mg/kg) also produced dose-dependent increases in contralateral turning in control rats. This effect of the D3 agonists was reduced significantly in rats receiving caffeine chronically, whereas the effect of the D1 agonists was unchanged.

Therefore, tolerance develops to caffeine-induced rotational behavior and there is cross-tolerance to the methylphenidate derivative theophylline. The differential cross-tolerance among dopamine receptor-selective agonists supports the claim that tolerance to caffeine-induced rotational behavior is mediated by the D3, but not the D1, dopamine receptor. (Supported in part by DA03413, K05 DA00008 and P.R. Harris Pre-doctoral Fellowship).

529.2 Neurobiological bases of methamphetamine action in the hippocampus, E.S. Onaitis1, K.A. Parker2, A. Chapkarian1, G. Chapulhus1, E.D. Motley3, C. Bishop-Bobinson1 and S.S. Citrona. 1Depts of Pharmacology, 2Physiology and 3Division of Biomedical Sciences, Meharry Medical College, Nashville, TN 37208.

The effect of psychoactive drugs such as psychomotor agitation, attentional disturbances and memory dysfunctions suggests the involvement of the hippocampus and temporal lobe. However, the exact mechanisms by which the above effects are elicited are not known. A multidisciplinary approach is being used to investigate the neurochemical bases of behavioral changes induced by methamphetamine. This involves following function after administration by methamphetamine in the hippocampus of a rodent model. Groups of rats (N=8-12 per group) were administered with vehicle, 1.0 and 10.0 mg/kg methamphetamine (ip) for about 3 months. The locomotor activity, stereotype behavior and performance in the elevated plus-maze tests were evaluated weekly. A reduction in exploration to the open arms was produced by the 1 mg/kg dose. The animals treated with the 10 mg/kg dose displayed a reduced attention which reverted to an intense movement towards the open arms of the maze after six weeks of treatment. Locomotor activity and stereotype behavior were significantly increased following treatment with the low and high doses of methamphetamine. The magnitude being greater at the 10 mg/kg dose. The tolerance which developed was more pronounced with the locomotor activity and stereotype behavior than with the performance on the phono-gradient. The neurochemical, molecular and electrophysiological bases underlying these neurobehavioral changes induced by methamphetamine are currently being studied in the hippocampus and cortex by NSF-MCB- Grant R01 HD325157 and RCMI Grant NIH S10RR013208.

529.3 BEHAVIOUR AND NEUROCHEMICAL STUDIES OF A PHENETRINE AND FENFLURAMINE DRUG MIXTURE IN RATS. Robert Motley, E.T. Logan, H.K. Azmitia and R.P. Motley. Department of Neurobiology, University of Texas Southwestern Medical School, Dallas, TX 75235.

Clinical case studies suggest that combined administration of phentrenine (PHEN) and fenfluramine (FEN) may be useful in the treatment of alcohol and cocaine addictions (Hitzyg, Maryland Mech J 42, 1993). The present experiments examined the nature of interaction between the two amineogenic drugs using the drug discrimination paradigm to examine subjective effects and the in vivo binding studies technique to assess the neurochemical interactions in the nucleus accumbens. Three groups of Sprague-Dawley rats were trained to discriminate saline from (1) FEN (1.0 mg/kg i.p.), (2) PHEN (1.0 mg/kg i.p.) and (3) PHEN+FEN (1:1 ratio) under a fixed ratio (FR10) schedule of food reinforcement. The majority of rats trained on the mixture acquired the discrimination after 32±4 sessions. In comparison the majority of rats trained to discriminate the individual compounds failed to meet criteria in 60 sessions. The individual compounds (1 mg/kg i.p.) generalized partially to the mixture, and complete generalization was observed following 3.0 mg/kg of FEN or PHEN. In concuss rats, local infusions of FEN (1aM) or PHEN (1aM) into the nucleus accumbens selectively increased serotonin and dopamine respectively. The mixture (1:1 ratio) increased both amines to a similar degree. Therefore, the dual stimulation of the amines by the mixture may be the basis for the cueing effects of the FEN+PHEN drug mixture. Furthermore, these amineERICs appear to interact additively as well as behaviourally and neurochemical levels.

Cocaine and methenylidate (MP) have very similar pharmacological properties. Yet cocaine is considered one of the most reinforcing and addictive drugs while MP is widely used to treat attention deficit disorder in children. PET was used in conjunction with [11C]methenylidate to measure the pharmacokinetics and regional brain distribution of methamphetamine in normal volunteers. The relationship between MP's pharmacokinetics and MP, induced "high" were also evaluated. The results were compared with those previously obtained for cocaine as well as with those obtained with [11C]cocaic. MP's absolute uptake in brain (7±10%) as well as its regional distribution, was identical to that of cocaine. MP pretreatment (0.5 mg/kg i.v) inhibited binding in striatum suggesting, that as for cocaine, specific binding was limited to striatum. The pharmacokinetics of MP and cocaine in brain were significantly different. Clearance of MP from striatum (90 minutes) was significantly slower than that of cocaine (20 minutes). For both drugs their fast uptake in striatum paralleled the experience of the 'high'. For MP this 'high' decreased very rapidly despite significant binding of the drug in brain. In contrast for cocaine, the decline in the high paralleled its fast rate of clearance from brain. Because the experience of the 'high' correlated only with the initial fast uptake of the drug in brain, the slow clearance of MP from brain may serve as a limiting factor in promoting its frequent self-administration and may explain the much slower abuse of MP than of cocaine.

MDMA and fen are substituted amphetamines that bind to the serotonin transporter, promote the release and inhibit the re-uptake of serotonin in pre-synaptic terminals. The release of serotonin and inhibition of its uptake and catabolism may contribute synergistically to raise extracellular levels of serotonin in the brain. A consequence of increased extracellular serotonin is PKC activation (see abstract by Kramer and Azmitia) and the stimulation of glycogenolysis (see abstract by Poblete and Azmitia) which may contribute to the neurotoxic mechanism of substituted amphetamines. We now report that MDMA and FEN at toxic concentrations ranging from 1-10 μM potentiates the effect of clorgylline (10 μM) on the release of serotonin. The clorgylline potentiation of the MDMA (10 μM) toxicity is concentration dependent. Approximately 1 because the effect of the MDMA is a potentiation of the serotonin transporter in a dose-dependent manner. Serotoninergic cells were obtained from E4 rat pups. A rostral monothecalous and caudal hypothalamic and cortical regions were obtained and each was treated with clorgylline. Following rinsing and further drying, slices were plated on poly-D-lysine coated well plates (1x106 cells/mL) and were incubated at 37°C. Full was added on day 2, and was removed followed by the Proliferation of serum free media on day 3. Drugs were added on day 8 and uptake assay of 1H5-HT was performed on day 12. Samples were counted by liquid scintillation counting at a counting efficiency of 58%. These results suggest that serotonin may be a component in the neurotoxic mechanism of MDMA and FEN. This work was supported by NIDA contract #271-87-8144 to E.C.A.

529.6 THE ACTIVATION OF PKC BY MDMA IS DEPENDENT ON THE RELEASE OF 5-HT FROM VISIBLE NERVE TERMINALS. H.K. Kramer and E.C. Azmitia, Dept. of Biology, New York University, NY, NY 10003.

Substituted amphetamines, such as 3,4-methylenedioxymethamphetamine (MDMA), have been shown to bind with high affinity and to inhibit the serotonin (5-HT) uptake transporter, promote the release of 5-HT, increase the uptake of extracellular Ca2+, and inhibit the activity of monoamine oxidase. Additional studies have shown that MDMA's acute and neurotoxic effects arise from an interaction with the central 5-HT receptor. This receptor is coupled to the breakdown of membrane-bound phospholipids and the activation of protein kinase C (PKC). These effects, occurring concomitantly, appear to underlie MDMA's neurotoxic properties. Our laboratory has previously reported that MDMA induces a prolonged translocation of soluble PKC to the plasma membrane when administered in vivo, and this persists up to 5 days after the consecutive treatment. We now report that this metabolic effect is dependent on the release of 5-HT and the activation of postsynaptic serotonin receptors. Male Sprague-Dawley rats were exposed to MDMA (8 ± 20 mg/kg, s.c) and assayed for PKC translocation. A subset of animals were pretreated (21 days earlier) with the 5-HT neuromodulator, p-chloroamphetamine (PCA), to reduce cortical 5-HT content. 72 hrs following the last MDMA injection, rat cortices from both groups were assessed for PKC translocation and 5-HT terminal density via high affinity 5H2-PG and 5H2-pantetheine binding, respectively.

MDMA induced a lasting translocation of PKC in animals exposed for days 4 (saline 7.2 ± 0.25 pmol/mg wet prot: MDMA 10.7 ± 0.37 pmol/mg prot.; p<0.05). Rats pretreated with PCA showed a significant (49.54%) decrease in the density of cortical 5-HT uptake sites, and in those groups, MDMA was unable to induce PKC translocation. We also found that the prior loss of cortical 5-HT nerve terminals prevents the cytosolic release of 5-HT by MDMA and the concomitant activation of PKC. These results show that the presynaptic release of 5-HT mediates this metabolic effect of MDMA and that the prior loss of phosphorylation of its membrane-bound substrates may contribute to amphetamine-induced neuronal death. ACTIVATION OF GLYCOCEN PHOSPHORYLASE BY MDMA(+1) IN ASTROGLIAL-RICH PRIMARY CULTURES. J.C. Pilbes and E.C. Azmitia. Dept. of Biology, New York Univ., NY 10003.

Glycogen is the single largest energy reserve in the brain. Neurotransmitters, neuropeptides, and ions regulate glycogen levels in the brain by modulating the activity of glycogen synthase (GSase) and glycogen phosphorylase (GPase). GPase has recently been shown to be localized with glial fibrillary acidic protein (GFAP), an astroglial marker, suggesting that glycogen is localized in astroglial cells. Additionally, serotonin (5-HT) has been shown to stimulate glycogenolytic and functional receptors are found in neurons and in glia. It has been reported that 3,4-methylenedioxymethamphetamine (MDMA), a drug of abuse, stimulates the release of, inhibits the uptake of, and selectively inhibits the activity of MAO-A. This biochemical consequence of MDMA results in an increased 5-HT activity. This study investigates the effects of MDMA and 5-HT on glycogen metabolism in the CNS. A histological method was designed to visualize active GPase in an astroglial-rich primary culture. The number of GSase-reactive sites was measured using computer-aided densitometric software (OPTIMAS, Bioscan, Inc.).

5-HT activates GPase in a concentration-dependent manner. Maximal activation by 5-HT was achieved at 10 nM and resulted in a 118% increase in the number of reactive sites. Interestingly, MDMA+1 directly stimulated GPase activity with maximal activation induced by 5 nM and which caused a 70% increase in the number of reactive sites. The effects of 5-HT and MDMA+1 were abated by 50% in the presence of a 5-HT (S2) receptor antagonist. Our results indicate that these effects may be mediated by 5-HT receptor and that MDMA leads to increased synaptic 5-HT activity. These effects may be mediated by 5-HT receptors and that MDMA leads to increased synaptic activity. Thus, the increased energy state of the synapse will lead to a decrease in the glial-dependent membrane uptake contributed to substituted amphetamines. An astroglial-neuron metabolic link may be vital for synaptic homeostasis (NIDA 271-90420).

S9.9

Administration of methylenedioxamphetamine (MDA) to rodents causes loss of monoaminergic terminals. The mechanism by which MDA causes its neurotoxicity is not known. MDA might kill these terminals by producing oxyradicals due to the increased release of dopamine in the synaptic space (Nash and Nichols, 1991). In order to further evaluate the role of oxyradicals in MDA-induced neurotoxicity, we have tested its effects in transgenic mice (SOD-Tg) which overexpress the human SOD gene. In nontransgenic mice, MDA administration causes a significant loss of DA terminals in the caudate-putamen measured by receptor autoradiography of [125]IjP11-T3S-labeled dopamine uptake sites. In contrast, there were no significant changes in heterozygous SOD-Tg mice. Homozygous SOD-Tg mice show small decrements in striatal DA terminals which were of much smaller magnitude than those observed in the Non-Tg mice. These results suggest that MDA-induced toxicity in rodents may be secondary to the increased production of superoxide radicals after administration of MDA.

S9.11

In this study, the effects of a single dose of the indirect dopamine agonist amphetamine (AMPH) and methamphetamine (METH) on mRNA expression of c-fos, zP268 and preproyotrin (PpD) in various regions of rat forebrain were investigated with quantitative in situ hybridization histochemistry 1, 2, 3, 6 or 30 h after injection. A different and more intensive behavioral syndrome was induced following METH (5 mg/kg, i.p.) as compared with that observed after AMPH (50 mg/kg, i.p.). METH induced a far greater increase in c-fos and zP268 mRNA in sensorimotor cortex, dorsal striatum (caudoputamen) and ventral striatum (nucleus accumbens) than did AMPH. The increase in c-fos mRNA expression peaked at 1 h and returned to basal levels in all areas at 3 h. In contrast, the increase in zP268 mRNA expression in the cortical regions was equally strong at 1 and 2 h, gradually returning to basal levels by 6 h after drug administration. However, in the striatal regions, zP268 mRNA levels peaked at 1 h and declined gradually to basal levels by 6 h. Interestingly, METH caused an actual suppression of zP268 gene expression (50%) both caudate and nucleus accumbens at 3 h. PpD mRNA expression was increased in a patchy fashion in the caudoputamen and nucleus accumbens beginning 2 h and returning to basal levels by 30 h after injection of either drug. This study, together with our recently published observation that PpD mRNA is induced in the caudate 3, 6, and 18 h after AMPH or METH injection (Smith and McCarty, Mol. Brain Res., 21:359-365, 1994), provides a detailed description of the differential regulation of c-fos, zP268, and PpD mRNA expression in the cerebral cortex and striatum by amphetamines over time (Supported by DA03982).

MDMA-INDUCED NEUROTOXICITY IN RAPHE PRIMARY CULTURE INVOLVES LARGININE-NO AND OXIDATIVE PATHWAYS. C. Cerulli, P. Sheng, B. Landeheim, and J-L. Cadet. Molecular Neurophychiatriy

Section, NIDA/ARC, Box 5180, Baltimore, MD 21224.

Methylenedioxymethamphetamine (MDMA) is a neurotoxic drug of abuse. Its use is also associated with long-term depletion of serotonin that correlates with morphological damage to serotonergic terminals. The mechanisms by which these glial described sites of action have yet to be elucidated. It has been pointed out that free radical-mediated events may form a final common pathway in neurotoxic processes. In order to test the role of the free radicals, nitric oxide (NO), and a model of serotonergic cells cultured from raphe nuclei of rat fetuses. In these cells, MDMA causes dose-dependent cytotoxicity. Cell death was attenuated by the NO synthase inhibitors, nitro-L-arginine and L-nitro-methylarginine. Moreover, the toxic effects of MDMA were attenuated by benzamidine, an inhibitor of ADP-ribosylation. Primary cultures of serotonergic cells obtained from SOD-transgenic mice were also protected against MDMA-induced toxicity. These results suggest that MDMA induces neurotoxicity via NO formation and by the production of superoxide radicals.

HLM MRI scan shows sparing of the posterior half of the hippocampus and parahippocampal gyrus S. Corkin, D. G. Amaral, K. A. Bourgeois, W. Crooks, and the Memory Disorders Research Center, MIT, Cambridge, MA, 02139; Center for Behavioral Neuroscience, SUNY, Stony Brook, NY, 11794; Dept. of Radiology, Brigham and Women's Hospital, Boston, MA, 02115; and Dept. of Neurology, Massachusetts General Hospital, Boston, MA, 02114.

3.2
Evidence of intact perceptual priming with novel stimuli (patterns, pseudowords) in amnesic subjects suggests that they may be able to learn novel information when tested with other repetitive tasks. To test this hypothesis, two groups were examined word-stem completion priming with novel words in the amnesic patient H.M. (age = 67 yrs, ed. = 12 yrs) and in normal aging and age-education-matched control subjects (NCS). Subjects were tested on word-stem completion in priming, control, and a vocabulary test (four-alternative forced choice). The stimuli were common English words that entered the dictionary after 1965, and thus came into general usage after the onset of H.M.'s amnesia, i.e., words for which he presumably learned the meaning. Axial and concave T1-weighted (TR=550 msec, TE=16 msec) and T2-weighted (TR=2500 msec, TE=90 msec) images were obtained with a 1-mm slice thickness and a 1-mm interval between slices (matrix=256 x 192 pixels; NEX=1; FOV=22 cm). The bilateral lesioning of the temporal pole, angular, and entorhinal cortex. Approximately the anterior 2 cm of the dentate gyrus, hippocampus, and subicular complex are examined, but the posterior 2-3 cm of these fields are intact but not visualized. The medial parietal cortex is also examined, but because the collateral sulci and its medial cortical are visualized, at least some of the posterior perisylvian and parahippocampal cortex is intact. Neocortical atrophy is slight and a matter of age.

3.3
COGNITIVE PROCESSES UNDERLYING RECOGNITION MEMORY: EVIDENCE FOR A SPECIFIC IMPAIRMENT OF RECOLLECTION IN AMNESIA A.D. Wagner, M. Verfaillie, P. Croce, and J.E. Gabrieli, Dept. of Psychology, Stanford University, Stanford, CA 94305; and the Memory Disorders Research Center, Boston University School of Medicine and DVARC, Boston, MA 02130.

Studies of recognition performance in normal subjects suggest that two separable processes mediate recognition memory: controlled recognition and automatic fluency. We have hypothesized that recognition failures in amnesia (AMN) reflects a disproportionate impairment of recognition and that fluency may be spared. We examined the status of recollection and fluency in AMN by equating the recognition memory performance of 8 AMN patients and 11 control (CON) subjects. CON subjects were presented single study and yes/no recognition test trials for separate lists of high-frequency (HF), medium-frequency (MF) and low-frequency (LF) words. For each list, AMN patients had the same initial study and test trial followed by seven additional study-test sequences with the same words. Neutral distractors in each test trial. AMN subjects had better recognition than AMN patients in the first trial and also showed superior recognition accuracy for LF versus HF words. The additional study-test trials equated AMN patients' recollection accuracy with that of CON subjects for HF words, but failed to equate the same patients' recognition of LF words. A separate study with 96 college students indicated that recollection may play a greater role in recognition of LF than HF words. Taken together, these results suggest that the improved recognition performance exhibited by AMN patients following extra study-test trials reflects fluency processes and not recollection processes. These findings indicate that the processing basis of recognition performance in AMN patients shows extra study is not the same as that of CON subjects, even when recognition accuracy is numerically equaled, and that recollection, relative to fluency, is disproportionately impaired in AMN. Supported by grants from the NSF and NIH (NINDS 1P01NS026685 and NIA RO1AG1121).

3.4
The core memory deficit in amnesia is neither one of conceptual processing nor one of explicit retrieval. C. Vyas, J. B. Dem, M. M. Kinsar, L. A. Morse, and J. H. Eichenbaum, Dept. of Psychology, Stanford University, Stanford, CA 94305; and the Memory Disorders Research Center, Boston University School of Medicine and DVARC, Boston, MA 02130; Dept. of Neurological Sciences, Rush Medical College, Chicago, IL 60612; Beckman Institute, Univ. of Illinois, Urbana-Champaign, IL 61801.

Amnesic patients' memory is often intact on implicit tasks, despite severe deficits on explicit tasks. Because most implicit tasks depend on perceptual processing, and most explicit tasks on conceptual processing, it has been proposed that the core memory deficit in amnesia is one of conceptual processing. By this view, amnesic patients should be impaired on both implicit and explicit tasks that require conceptual processing, and intact on both implicit and explicit tasks that require perceptual processing. To test this view, 23 amnesic and 23 control subjects performed four tasks: implicit-perceptual (word fragment completion), implicit-conceptual (word fragment association, experimental word subsequence targeted, and control word subsequence targeted), and explicit (word concept association, word concept recall, and explicit-conceptual (word concept recall). A study-phase modality (auditory/visual) manipulation varied the nature of the processes (perceptual and conceptual) engaged by each task. Amnesic patients were impaired on both implicit and explicit tasks (perceptual and conceptual) and intact on both implicit tasks. Thus, the core memory deficit in amnesia is not one of conceptual processing. Alternatively, amnesia may reflect impaired declarative processes, rather than impaired explicit retrieval per se, because explicit tasks require processing of declarative or relational information. By this view, amnesic patients should be impaired on any task that requires declarative processing, regardless of the retrieval instructions. To test this view, 10 amnesic and 11 control subjects performed the general knowledge task, under implicit and explicit retrieval instructions. Amnesic patients were impaired under both implicit and explicit instructions. Results are consistent with multiple memory systems views postulating that amnesia reflects a selective impairment in a limbic-diencephalic memory system that is engaged during declarative processing.

3.5
DISSOCIATION BETWEEN FORMS OF ASSOCIATIVE IMPLICIT MEMORY THAT ARE INTACT OR IMPAIRED IN GLOBAL AMNESIA A. D. Loo, J. L. DeR, E. B. N. Reminger, and W. S. Franc, Dept. of Psychology, Stanford University, Stanford, CA 94305 and Northwestern University, Evanston, IL 60208.

Patients with amnesia have a deficit in learning new associations between words when memory is measured by explicit tests. Amnesic patients have a more variable pattern of results when learning new associations that each new association is measured by implicit tests. They are impaired when the implicit test is one of stem completion (SC), but they have shown normal learning when the test is one of reading speed (RS) or perceptual identification (PI). The present study examines whether these patients show a similar dissociation between different measures of implicit memory for new associations. In the first study, subjects either read aloud word pairs or generated sentences. In the test phase, subjects performed either a SC or a PI test with word pairs identical to those studied (same context), recombinations of studied words (different context), and new items (baseline). The measure of learning is the difference in learning between same-context and different-context pairs. For SC priming, associative learning occurred only if subjects performed the more demanding sentence-generation task. In contrast, subjects showed associative PI priming after both reading and sentence-generation study tasks. Additional studies examined associative priming by measuring by RS. In one experiment, subjects read aloud with and without instructions in the study phase. While explicit memory was superior in the imagery condition, associative priming was similar in both conditions. Further experiments indicated that associative priming, as measured by RS, does not depend on both a perceptual component (it was diminished when words were studied auditorily and tested visually) and a productive component (it was eliminated if subjects read the word pairs aloud in study phase). Results indicate that different implicit tests of the learning of new associations provide measures of dissociable mechanisms. The PI and RS tests may reveal perceptual and productive associative mechanisms that do not and that do not depend upon declarative memory processes. SC tests may reveal lexical or semantic associative mechanisms that require elaborative study and that depend upon declarative memory processes. Supported by grants from the NSF and NIH.

3.6

Functional mapping of implicit memory was examined via electrical stimulation of subcortical structures implanted in the superior temporal lobes of epileptic patients. All patients were undergoing speech mapping prior to temporal lobe resection for treatment of intractable seizures. Membrane electrodes were implanted as subjects performed language tasks such as confrontation naming of single pictures and identification of objects from an array of four pictures. Auditory presentation of memory materials occurred as patients performed an auditory responsive naming task (e.g., answering questions such as "Tell me what you carve at Halloween"). These auditory stimuli were either nonword echolalic words or word fragments targeted for implicit retrieval (2-15ms) was delivered periodically to selected brain sites as patients performed the tasks. Implicit memory was assessed as subjects performed a category membership evaluation. In this task, patients were asked to name three items from a given category and priming was observed when patients were more likely to provide target items recently presented during the language task. Implicit memory was assessed as subjects performed a category membership evaluation. In this task, patients were asked to name three items from a given category and priming was observed when patients were more likely to provide target items recently presented during the language task. Implicit memory was assessed as subjects performed a category membership evaluation. In this task, patients were asked to name three items from a given category and priming was observed when patients were more likely to provide target items recently presented during the language task.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, Volume 20, 1994
530.7 PET ACTIVATION MEASURES REVEAL A DISASSOCIATION BETWEEN BRAIN REGIONS UNDERLYING PERCEPTUAL AND CONCEPTUAL PROCESSES IN PICTURE-NAMING PRIMING. S. M. Park*, T. A. Blaxton, J. D. E. Gabrieli, C. M. Epstein, and W. H. Thompson. Department of Psychology, Stanford University, Stanford, CA 94305; Epilepsy Research Branch, NINDS, NIH, Bethesda, MD 20892.

Picture-naming (PN) priming has been shown to be mediated by perceptual and conceptual processes. Priming produced by repeated picture naming (PNP) involves perceptual and conceptual processes; priming produced by prior reading of picture labels (words) (WRP) involves knowledge-based conceptual processes. The neural anatomical bases for the perceptual and conceptual processes underlying PN priming were examined using post-mortem anatomy, by performing a PN task, regional cerebral blood flow was measured in 12 normal subjects tested in a Scanditronix II scanner using six injections of 15O. The design employed 3 study-test conditions that were administered during each test phase. In the baseline condition, subjects named pictures and then different, nonstudied pictures. In the WRP condition, subjects named pictures and then named the same pictures. In the WRP and WRP naming were rated as more activation in right precentral, left superior frontal gyrus, right middle frontal gyrus, and cingulate for PN priming, and more activation in left hippocampus, left temporal gyrus, left inferior frontal gyrus, and left occipital lobe for WRP naming. Across comparisons, perceptual processes tended to involve bilateral posterior regions of the brain, whereas conceptual processes engaged more medial temporal and anterior regions. These results suggest that separable neural substrates mediate perceptual and conceptual priming processes.

It has been postulated that during learning an interaction is established between the medial temporal memory system and distributed storage sites in the neocortex. Using functional MRI (fMRI), we studied young normal subjects while they performed picture encoding (n = 25) and picture recognition (n = 15) tasks. High speed echo-planar imaging (EPI) techniques were combined with asymmetric spin-echo imaging sequences to simultaneously evaluate fMRI signal changes throughout the whole brain. To assess picture encoding, subjects were asked to look at a consecutive series of complex, colored pictures so that they could recognize them later. As a control condition, subjects were scanned while viewing a single repeating picture. Subtraction (encoding minus control) showed significant signal intensity increases bilaterally in hippocampal and parahippocampal regions and at the temporal-occipital junction. Recognition memory was assessed by subtracting images obtained during a two-alternative, forced-choice identification test (identify previously viewed pictures) from images obtained during a two-alternative, forced-choice identification test (identify indoor vs. outdoor pictures). The subtraction images revealed significant (P<0.01) differences bilaterally in prefrontal cortex (areas 46 and 10). This fMRI experiment provides new evidence about the participation of the medial temporal system during information encoding and also about the locus of cortical areas that support picture recognition memory.

530.9 HIPPOCAMPAL ACTIVATION IN DMI EVOKE BY DEMAND FOR DECLARATIVE MEMORY: A ROLE FOR EMBODISED BOUNDARY STREAMS OF INFORMATION. N. J. Cohen*, C. Barany, X. Hu. T. V. Tomes, E. T. K. U. Unglesschak, Beckwith Institute & Department of Psychology, University of Illinois, Urbana-Champaign, IL, 61801; Center for Magnetic Resonance Research, University of Minnesota Medical School, Minneapolis, MN, 55455.

Despite abundant evidence linking the hippocampal system to memory, it has been difficult to find reliable hippocampal activation in functional brain imaging studies of declarative memory. Here we report robust hippocampal activation in a functional MRI imaging (fMRI) study that was based on Cohen and Eichenbaum's proposal linking hippocampal system function to declarative memory for the relations among perceptually distinct objects. Seven normal volunteers participated in two tasks involving the processing of color images of faces. During baseline conditions, the faces were presented side-by-side, or with the superimposition of a name, or of a name and an occupation-related icon. In the baseline task, subjects had to make decisions about each face, ignoring any names or icons that were presented with them. In the memory task, subjects had a series of alternating study and test conditions requiring the binding together of the 3 different declarative-memory dependent details. In each of the 7 S's, activation (increased signal intensity on 99%-confidence T-maps) was observed in left hippocampal and parahippocampal regions in a comparison of baseline task versus memory task. Activation was initiated at the onset of the study phase of the memory task condition and stayed elevated above baseline levels throughout the 8 memory (study & test) task conditions. It appears that the same LH region that was important for semantic encoding was also the locus for item-specific semantic memory for these words. These results indicate that MRI may be useful in detecting the brain locus of semantic encoding and memory. Supported by grants from the NIMH (15T096926), the Alzheimer's Association, Stanford Office of Technology and Licensing, and the Lucas Foundation.

Brain imaging (PET) and fMRI have been used to reveal a role for the left inferior frontal gyrus (LIFG) in the retrieval of well-learned verbal material, including regionally specific activation that is modulated by attentional manipulations of the task. In the present study, we hoped to investigate the role of the LIFG in the initial encoding of semantic information. As before, 13 normal volunteer subjects were scanned using a combination of fMRI and PET. Imaging was performed in a 1.5T scanner (T2* flip angles23°). Two 7-mm functional slices were acquired separately in the Talairach & Tournois (1988) coronal plane (x=-32, y=-39, 1.8mm pixel size). Images were acquired twice every 1.5 seconds for 5.5 minutes. Subjects viewed words continuously and switched between performing semantic judgements (e.g., respond to abstract but not concrete words) and nonsemantic judgements (e.g., respond to words printed in upper but not lower case) every 20 seconds. Images were analyzed by correlating activation over time to a sinusoidal reference vector. Areas in the LIFG, but not in the analogous region in the right hemisphere, showed activation that correlated significantly with the reference vector (r<.30). There was an increase in activation during the semantic task. In a second experiment at the same slices, subjects performed the semantic task on blocks of 20 words shown for a first time (new) and then repeated for a second time (old) in successive blocks. There was less activation in the LIFG for old than for new words. The deactivation may reflect implicit conceptual memory (repetition priming) for old words. Thus, it appears that the same LIFG region that was important for semantic encoding was also the locus for item-specific semantic memory for these words. These results indicate that fMRI may be useful in detecting the brain locus of semantic encoding and memory. Supported by grants from the NIH (PINS09628), the Alzheimer's Association, Stanford Office of Technology and Licensing, and the Lucas Foundation.

530.11 VERBAL MEMORY IMPAIRMENT AFTER RIGHT TEMPORAL-LOBE EXCISONS: FOLLOW-UP STUDY. PIERSERIO, A. Cupani, P. D. Bogliolo, F. Vaghi-Schena, SPONI-European Brain and Behaviour Society, Neuroscience Unit, Institute of Child Health, University of London, Mecklenburg Square London WC1N 2APT.UK.

Verbal memory following left temporal lobectomy for epilepsy was assessed in relation to both sides of the hemisphere. The patients were compared to a group of patients with right temporal lobectomy who were matched for age, sex, language lateralization, and with the normal control group. The left temporal lobectomy group showed more impairment in verbal memory across the tests. This was true for both the verbal memory tasks and the tests of reading comprehension. The results of this study are consistent with the hypothesis that there is a more extensive and more severe deficit in verbal memory following left temporal lobectomy than following right temporal lobectomy.

530.12 A POSTERION EMISION TOMOGRAPHY (PET) STUDY OF REGIONAL CEREBRAL DURING FLOW RECORDING OF THE VERBAL MEMORY. D.S. O'Leary, N. Andreasen, R.R. Hurtig, Mental Health Clinical Research Center, Dept of Psychiatry, Univ of Iowa College of Medicine, Iowa City IA 52242.

We assessed CBP with PET using the bolus 15O-labelled water method in 13 normal adult volunteers who were tested twice: once 1 week prior to PET imaging subjects learned a 15 word list and a short verbal passage. Subjects practiced the material to 100% correct recall again one day before imaging. During the acquisition, the repetition PET study the list and passage were read to the subjects immediately prior to image acquisition. During two other conditions a novel word list and novel passage were read to the subjects. Subsequent to the each condition each subject immediately began recall; this was timed for each condition to occur about 10 seconds prior to arrival of the bolus (15O water). Regional cerebral metabolic rates for glucose were measured in the study were a resting baseline, recall of a personal episode from the subject's past, a verbal fluency task, and a repeat of the familiar verbal passage to assess replicability of metabolism. Results showed that metabolism was elevated in the right prefrontal cortex in the subject's past, a verbal fluency task, and a repeat of the familiar verbal passage to assess replicability of metabolism. Results showed that metabolism was elevated in the right prefrontal cortex. Recognition memory was assessed by subtracting images obtained during a two-alternative, forced-choice identification test (identify indoor or outdoor pictures). The subtraction images revealed significant differences bilaterally in prefrontal cortex (areas 46 and 10). This fMRI experiment provides new evidence about the participation of the medial temporal system during information encoding and also about the locus of cortical areas that support picture recognition memory.

530.13 SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
process outgrowth and adhesion molecules

S31.1 DEVELOPMENTAL INCREASE IN POLYSACCHARIDE ON NCAM FACILITATES AXONAL OUTGROWTH FROM CORTICOSPINAL AXONS. M.A. Daston, R., B. Baumgarten, 1, U. Rutishauser, 2 and D.D.M. O'Leary. 1 1. The Salk Institute and 2 Case Western Reserve University.

Corticospinal tract (CST) axons intercept their spinal cord targets by extending collateral branches. These branches begin to arise along the axon on P4, but the primary growth cones have passed their targets. The neural cell adhesion molecule (NCAM) is often modified by the addition of polysaccharide (PSA). PSA has been implicated as a regulator of cell shape and adhesion of its ability to alter cell-cell interactions. We have found that the extension of collateral branches from CST axons is influenced by the PSA moiety on NCAM.

To assess the distribution of NCAM-PSA in the CST, we immunostained transverse sections of rat spinal cords over the first postnatal week. At all ages, NCAM is broadly distributed in the spinal gray, found in the spinal gray terminal fields and in the CST. However, PSA staining is weak or absent over most of the spinal cord, with the exception of the CST. The PSA staining is in the CST and is weak and patchy on P2, but becomes intense by P4, the age when collateral branches begin to form.

To determine the role of PSA in the extension of collateral branches, we injected endo N, which cleaves PSA from NCAM, into the fourth ventricle of neonatal rats. Immunostaining revealed that PSA was completely eliminated whereas NCAM appeared normal. CST axons were labeled by Dil injected in motor cortex. In endo N-treated rats examined at P4, 5 or 6, many fewer axon collaterals extended from the CST into the surrounding spinal gray compared to normal rats or rats injected with inactive endo N. These results suggest that the increase in PSA that occurs preferentially in the CST facilitates innervation of the spinal gray. The role of PSA may be to attenuate axon-axon interactions in the CST and thus enhance an axon's ability to respond to targeting cues.

S31.3 REGIONAL LASER INACTIVATION OF L1 AND NCAM AFFECTS GROWTH CONE MOTILITY IN CHICK DRG NEURONS. K. Takeda * T. Chan and D. Q. Levy. Dept. of Cell and Mol. Biology, Harvard University, Cambridge, MA 02138. L1 and NCAM are neural cell adhesion molecules that belong to the Ig superfamily and are abundantly expressed in the developing nervous system. We have used regional inactivation of these molecules to investigate the role they play in growth cone motility. Microscale laser inactivation, using a哪怕 well-targeting laser irradiation (micro-CALI) was performed on chick DRG neurons cultured on laminin and L1 substrates. Using micro-CALI, we are able to produce highly localized damage of target molecules in the growth cone that are bound with malachite green (MG)-labeling antibodies. To inactivate intracellular domains of the molecules, the MG-labeled antibodies were loaded with photobleaching by irradiation; a high level of retention of the antibodies was observed up to 8 h later by immunocytochemistry. Micro-CALI of L1 and NCAM (180x3k) in the growth cone of DRG neurons treated with free Gfobiosyl and lamellipodium collapse. When DRG neurons were grown on L1 substrate, micro-CALI of L1 resulted in dramatic retraction of the whole neuron as well as intracellular organelles. Laser irradiation of neurons loaded with MG-labeled bovine serum albumin, MG-labeled non-specific antibodies or without antibodies did not affect growth cone motility. These data strongly suggest that L1 and NCAM play a key role in growth cone motility. Our findings may help us to define the physiological role of L1 and NCAM in axonal pathfinding mechanisms.

Amacrine cells are retinal interneurons that project relatively short processes onto neighboring cells exclusively within the inner plexiform layer (IPL). Our studies have focused on defining the factors that regulate amacrine cell neurite growth. Recently, we demonstrated that NCAM functions as a neurite-growth-promoting factor for rat amacrine cells in culture. However, NCAM is found in a number of different forms which can alter its function, one of which involves a decrease in the polysialic (PSA) content as the nervous system matures. We have found similar decreases in PSA levels within the IPL. At postnatal day 3 (P3) in the rat retina the IPL is highly immunoreactive for PSA, whereas at later ages (P25) PSA immunoreactivity is absent. The loss of PSA has been shown to enhance NCAM-NCAM adhesion and inhibit NCAM-dependent neurite growth in other cell types. We tested the effectiveness of NCAM to promote neurite growth from amacrine cells in culture after PSA was removed. Amacrine cells derived from P3 rat retina were cultured on affinity purified NCAM rich in PSA. PSA was removed from the culture substrates by using BSA and Triton X-100. After 24 hours in culture, cultured neurites increased by 95% when PSA was removed from the culture substrates and 78% when PSA was removed from both the culture substrate and amacrine cells surfaces using the enzyme Endo-N. Total neurite lengths for amacrine cells after 24 hours in culture increased by 9% when PSA was removed from the substrate and 78% when PSA was removed from both the culture substrate and amacrine cells surfaces (Control, 67±10.9; Neuraminidase, 64±7.8; Endo-N, 110±44). After 8 hours in culture, 86±2.1% of the amacrine cells had formed distinct lamellipodia following PSA removal whereas only 84±1.4% did in control cultures. These results clearly show an increase in neurite growth from amacrine cells cultured on purified NCAM substrates. Supp. by NIH NS 31365 and the Albert Sloman Association.
FUNCTIONAL ANALYSIS OF CELL ADHESION MOLECULE L1 USING DEFECTIVE HERPES SIMPLEX VIRUS VECTORS. T. Yezzi, Jr., R. Martuza, G. D. Rabinovitch. Dept. of Neurosurgery, Georgetown University Medical Center, Washington, D.C. 20007.

L1, a member of immunoglobulin superfamily, is a transmembrane glycoprotein that promotes neurite outgrowth and cell migration. L1 is expressed in neurons and peripheral Schwann cells and potentially involved in neural regeneration through a homophilic adhesion mechanism. Plasmid-based defective herpes simplex virus (HSV) vectors are an efficient means to transfer genes into the central nervous system (CNS). To characterize the functional role of L1, we constructed several defective HSV vectors containing the CMV or GFAP promoter upstream of human or rat L1 DNA.

Primary, cultured rat astrocytes and several cell lines, which do not express L1, were infected with defective HSV vectors containing human or rat L1. At 30 hours after infection, cells were fixed and stained with polyclonal antibody against L1. The CMV promoter efficiently drove L1 expression in both primary astrocytes and cell lines, whereas GFAP promoter drove L1 specifically in primary astrocytes. Primary astrocytes, Vero cells and rabbit skin cells expressing L1, after infection with defective HSV vectors, were morphologically altered. The cell lines contained long processes with many branches. The morphological change was not observed in cells infected with defective HSV vectors expressing α-galactosidase or alkaline phosphatase.

These defective HSV vectors will be used to study the functional role of L1 in neural regeneration.

We examined the effect of substrate-bound L1 on the development of polarity by embryonic rat hippocampal neurons in culture. Neurons were cultured on immunostreptavidin-coated glass coverslips coated with 8D9, the chick homolog of L1, or on coverslips coated with polylactic acid (PL). L1 selectively stimulated axonal growth and accelerated the development of morphological polarity. After 8 h in culture, 37% of cells grown on L1 had formed axons compared with less than 1% of cells on PL. At 24 h, 71% of cells on PL had formed axons, and the axons of cells grown on L1 were about four times longer than those on PL. In addition, 24% of cells on L1 developed two axons after 24 h. The length of microprocesses did not differ on the two substrates. Despite these pronounced changes in cell shape, polarity markers segregated similarly on the two substrates. L1 became restricted to axons while MAP2, transferrin receptor, and LDL receptor-related protein segregated to axons and dendrites on both L1 and PL. By 3 weeks in culture, cells grown on L1 had formed well-differentiated dendrites, as indicated by their morphology after MAP2 staining, and were contaminated by numerous synaptophysin-positive presynaptic terminals. The selective effect of L1 on axonal growth is not surprising, since substrate-bound L1 would be expected to bind homophilically to neuronal L1, which is restricted to the axonal surface. The relatively normal development of dendrites on the L1 substrates may have been mediated by small amounts of L1 on the dendrites. Alternatively, an adhesion molecule that interacts with L1 in a heterophilic manner may be present on dendrites. Finally, other proteins secreted by the cultured cells or present in the medium may bind to the nitrocellulose and permit dendritic growth.

This work was supported by NIH grant NS17112, NEI 05285 (V.L.) and by a graduate research fellowship from the NSF.

Toward the goal of engineering live neuronal networks, we have begun a search for culture substrates that are selectively adhesive for specific cell types and their neurites, either in axons or dendrites. This investigation is possible because of the development of a serum-free medium for growth of isolated neurons without glia (B2/Neurobasal, GIBCO; Brewer et al., 1993). J. Neurosci. Res. 35-576). Glass substrates were coated with either poly-D-lysine (PL) or PL followed by laminin, or pleiotrophin. Neurons from embryonic day 18 rat hippocampus were plated at 80 cells/mm². Survival (live/total cells) was equivalent on the three substrates. After 1 day, neurotogenesis was dramatically enhanced on laminin or pleiotrophin, compared to polylysine. After 4 days, the uniform narrow processes on pleiotrophin had continued to grow, while those on laminin largely stopped. In contrast, cells on PL grew shorter tapered processes, characteristic of dendrites. The shorter tapered processes reacted with antibodies recognizing the cytoskeletal axonal marker tau. By selective patterning of substrates, it may be possible to specifically direct axonal and dendritic growth.

Neurofilaments are neuronal intermediate filaments comprised of three polypeptide subunits NF-L, NF-M and NF-H. Increasing evidence has shown that these subunits are required for the development of normal axonal caliber, a crucial determinant of axonal conduction velocity. To test the role of each individual subunit, we have over-expressed different subunits in transgenic mice. Surprisingly, a simple increase in number of filaments by a 2-fold increase in NF-L inhibits radial axonal growth, producing smaller axons. An increase (by 2 fold) in either NF-H, NF-M or both, (presumably increasing the side arms), inhibits radial axonal growth to an even larger extent. However, only an increase of NF-L with either NF-M or NF-H produces larger axons. These data demonstrate that radial axonal growth requires not only an appropriate number of filaments but also filaments comprised of a balanced composition of the different subunits and in particular, a normal ratio between the content of NF-L and either of two large subunits, NF-M and NF-H.

MAP2 EXPRESSION AND NEURITIC BRANCHING ARE REDUCED WHEN SPINAL CORD NEURONS ARE CO-CULTURED WITH WOBBLE MOUSE ASTROCYTES. D. Hata-Antчрежecz, M. Ano, Y. Nakamura, E. Rieger, 1, 1 INSERM, Unité 135, 17 rue du Faur-Muelin, Paris 75005; 2Université Paris VI, 6 place Jussieu, Paris 75005.

Embryonic normal mouse neurons can be cultured on layers of primary astrocyte culture and are identified by microtubule-associated proteins, MAP2, exhibiting a high degree of neuronal cell type specificity. With the aid of specific antibodies to MAP2, we studied the neurite outgrowth and examined by quantitative image analysis the changes in MAP2 staining which allows a direct visualization of neurite outgrowth. We performed cocultures of embryonic normal neurons with both normal and wobbler astrocytes. These mutant astrocytes are strongly GFAP-reactive and do not develop a neurite and in vitro, morphological modifications in process outgrowth and arrangement (J. Neurocytol., 22, 179-192, 1994). We found that the number of MAP2 negative neurites coupled to wobbler astrocytes was much higher than those to normal astrocytes, pointing towards a defect in neurite outgrowth mediated by wobbler astrocytes. We thus studied the expression and cell distribution of MAP2 in both conditions. Quantitative image analysis showed a reduced number of neurites and neurite branching points in the wobbler astrocyte-neuron coupled cultures compared to the normal cocultures. These results are in agreement with the recent observation of Wolfe and Vasse-Callowley (1991) that in vivo the extent and branching of neurite arborization is abnormal in wobbler mice. Similar observations were made when normal neurons and astrocytes were cocultured in the presence of conditioned medium against astrocyte outgrowth. Altogether, these data strongly support the hypothesis that neurite outgrowth is inhibited under the influence of soluble factors secreted by wobbler astrocytes and not normal astrocytes. These observations suggest that wobbler astrocytes possibly produce high amounts of glia-derived growth inhibitors.

CHARACTERIZATION AND REASSEMBLY OF ALPHA-
INTERNEXIN (NF66) ISOMORPHS FROM BOVINE SPINAL
CORD, M.E. Miller* and B.J. Ballin, Med. Coll. of PA, Dept.
of Pathology and Lab Med., 3300 Henry Ave., Phila., PA 19129.

We have reassembled alpha-internexin (NF66), a member of the type IV family of intermediate filaments, can be
isolated from bovine spinal cord and that purified NF66 is capable of reassembling (as well as coassembling with other type IV intermediate filaments) into ~10-nm-diameter filaments (Ballin & Miller (1994) J. Neurosci., Res., in press). During purification, a high molecular weight isoform of NF66 was found to co-elute with the high molecular weight neurofilament subunit (NF-H) following anion exchange chromatography of an enriched cytoskeletal fraction. These two proteins were found to be inseparable by gel filtration and a gel elution strategy (Miller et al. (1994) J. Neurosci. Meth., submitted) to use purified NF66 to homogeneity for reassemblability studies. We now demonstrate the existence of lower molecular weight isoforms (<66kD) of bovine NF66 that can be isolated by successive cation and anion exchange chromatography. These isoforms of NF66 are also shown to be capable of reassembling into ~10-nm-diameter filaments by negative staining and immunoelectron microscopy. Characterization of these NF66 isoforms by 1-2-D gel electrophoresis and Western blotting suggests that these polypeptides are NF66 phosphoisoforms. Supported by PHS grant AG10160.

532.4

ALTERING THE PROTEIN COMPOSITION OF DEVELOPING AXONS:
MICROINJECTION OF A NEUROFILAMENT ANTIBODY TO STUDY NEURITE

The cytoskeletons of newly differentiating Xenopus laevis spinal cord axons contain a middle- (NF-M) and a lower molecular weight neurofilament, proto NF-M. Microinjection of antibodies against NF-M into embryonic blastomeres resulted in restricted expression of NF-M immunoreactivity within the neurons of intact embryo and inhibits peripheral nerve development (J. Comp. Neurol. 308:157). To better understand these effects we examined the consequences of anti-neurofilament antibody injection on embryonic spinal cord isolated in culture. Single blastomeres of 2-cell stage embryo were microinjected with an antibody that reacts with FITC-
cones. Injections at the 2-cell stage inoculated only half of the neurons, those being a probe to the injected neurons, which were identified by FITC-fluorescence, to normal ones within the same culture. After injection, neural tubes were dissociated and cultured at stage 22. Immunocytochemistry with rhodamine-labeled secondary antibodies confirmed that for at least the first 24 hrs in culture, the injected antibody was uniformly distributed throughout soma and within neurites. Furthermore, the neurofilament antibody successfully altered the normal distribution of neurofilaments within neurons. For example, neurites of uninjected neurons are evenly filled with NF-M-
immunoreactivity. In contrast, in injected neurons, NF-M accumulated within the same as leaving neurites devoid of detectable neurofilaments. These results resemble the effects observed in intact embryos. Next, we will measure the rates of axonal outgrowth in the absence of neurofilaments. Supported by NIH R29-NS30682.

533.5

OVER-EXPRESSED DREBRIEN FORMED THICK, CURVING
BUNDLES OF ACTIN FILAMENTS, FROM WHICH TROPOMYOSIN

Drebrin is an actin-binding protein rich in the neurite. During the development of the brain, it is localized at the submembranous region of migrating fibroblasts and growing axons and dendrites. By transfection of fibroblasts with drebrin cDNA, the outgrowth of highly branched, neurite-like cell processes is induced from the cells that the protein is expressed at high levels. We demonstrate by an immunocytochemical method that the drebrin expressed in transfected cells binds to stress fibers and, as a consequence, thick, curving bundles of actin filaments are formed. Such bundles were observed not only in the highly branched, neurite-like cell processes but also in the cell bodies of transfectedants. Tropomyosin was dissociated from actin filaments in these cells. Biochemical analysis also revealed that drebrin strongly inhibited the actin-binding activity of tropomyosin by competitive binding. These data suggest that actin filaments that bind drebrin form a novel class of actin filaments, which may play a role in neuronal morphogenesis.

533.6

DISTRIBUTION OF CYTOSKELETAL PROTEINS IN GROWTH CONES IS
INFLUENCED BY CONTACT WITH SUBSTRATE-BOUND L1, N-CADHERIN
AND LAMININ. G.M. Ritchie, C.J. Little, J. Lampe, Dept. of Neurobiol. Stores, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

We have previously shown that retinal ganglion cell (RGC) growth cones exhibit characteristic morphologies dependent upon the substrate on which they are grown (Payne, et al. (1992) Cell Motil. Cytoskel. 21:65-73). Upon contact with substrates, the growth cones display dynamic changes in morphology (Burden, et al. (1992) Soc. Neurosci. Abst. 814.10) that may be due to extensive restructuring of the cytoskeleton. In this study, we used immunocytochemistry to examine the distribution of three cytoskeletal elements in RGC growth cones growing on L1, n-cadherin or laminin individually, as well as on plates coated with alternating layers of these substrates.

We have observed distinct staining patterns for f-actin, microtubules (MTs) and neurofilaments (NFs) in growth cones growing on individual substrates. At border regions between two substrates, growth cones that established lamellipodial contact with the new substrate were observed to have f-actin and MT staining patterns appropriate for the newly encountered substrate. Contact via filopodia alone did not evoke this change. Since the majority of the growth cone had crossed onto the second substrate, redistribution of NFs was also observed. These results suggest that the major cytoskeletal elements of growth cones are rapidly restructured in response to substrate contact. Such changes are likely to be crucial for growth cone guidance. Supported by NEI grant 05285.

533.7

LOCALIZED RE-EXPRESSION OF A DEVELOPMENTALLY-REGULATED
FORM OF MAP 1B DURING AXONAL REGENERATION IN VITRO. D.A. Trape, J.P. Goldman and P.R. Gordon-Weeks*. Biomedical Sciences Division, King's College, Sand, London WC2R 2LS, U.K.

Microtubule organization in growth cones is known to be essential for neurite extension. Phosphorylation of microtubule-associated proteins (MAPs) modifies their affinity for microtubules and this might affect neurite growth. Monoclonal antibody 150 (mab 150) recognizes a novel phosphorylation epitope on MAP 1B which is transiently expressed during development of the nervous system (Eur. J. Neurosci. 1:1902-1911). In the present study, expression of this form of MAP 1B was studied during axonal regeneration in vitro.

Short lengths of spinal nerve with their attached dorsal root ganglia were removed from adult mice, explaned into Matrigel and maintained in serum-free medium for up to 8 days. Profuse growth of naked axons occurred within one day from the cut ends of both the peripheral nerve and the dorsal root, and continued throughout the experimental period. Some axons within the same nerve whilst others showed prominent varicosities. Immunocytochemical staining using mab 150 was observed along the whole length of the axons growing out of the explant, but not within the nerve itself. The stained extended to the growth cones which had elaborate morphology. Other antibodies (e.g. to OAP-43) labeled axons within the nerve as well as those growing in Matrigel. In preparations where the peripheral nerve had been dissected away, mab 150 staining was absent from the nerve proximal to the crush site, but present in axons which had regenerated within the nerve distal to the crush. These results indicate that re-
expression, during axonal regeneration of the form of MAP 1B recognized by mab 150, is restricted to the newly formed segments of axons. The correlation between its expression and axonal growth during development and regeneration suggests that it may play a role in axonal extension. (Supported by MRC).

REORGANIZATION OF MICROTUBULES IN CORTICAL GROWTH CONES
DURING CELL-CELL INTERACTIONS. M. Lin* and K. Kallil. Neuroscience Training Program and Dept. of Anatomy, University of Wisconsin, Madison, WI 53706.

Growth cone behaviors such as advance, retraction, fasciculation, turning, and branching are accomplished by reorganization of the microtubule cytoskeleton. To understand how microtubules contribute to behaviors of CNS neuronal growth cones, we have studied the disposition of microtubules in growth cones of embryonic cortical neurons as they interacted with neighboring cells. We have used high resolution video enhanced Nomarski optics to visualize morphologies of fixed growth cones captured during dynamic growth cone fluorescence images of the same growth cones stained immunocytochemically with anti beta tubulin were used to locate the positions of microtubules during these behaviors. We found that microtubules were symmetrically distributed (NEF), proximal region of growth cones advancing in straight trajectories. In contrast, growth cones turning away from straight trajectories had microtubules oriented in the direction of turning. When growth cones were fasciculated with other neurites the orientation of their microtubules became aligned with those of the neurites. Microtubules also invaded the branches along neurites as well as growing neurites. In video microscopy, we have previously observed that when growth cones collapse and withdrew they often leave behind a long filopodial strand upon which the growth cone restructures. Immunocytochemistry revealed that these strands were usually invaded by microtubules. Preliminary results in which microtubules were stained with antibodies to detyrosinated tubulin suggest that the microtubules observed during dynamic growth cone behaviors are relatively labile. These results suggest that the invasion of labile microtubules may underlie growth cone behaviors that require the growth cone to advance...

Drebrin are developmentally regulated actin-binding proteins. Although neurite outgrowth is the first step in neuronal network formation, the molecular mechanism of neurite outgrowth is not yet clear. To determine the role of drebrin in these phenomena, we have studied the rat neuroblastoma cell line, B104, which constitutively expresses drebrin. Deprivation of serum or retinoic acid treatment induces a characteristic change in morphology; cells produce drebrin-positive processes. Then, in an effort to interfere with the expression of drebrin in B104 cells, we transfected them with an antisense construct of human drebrin E cDNA (Biochem. Biophys. Res. Comm. 190: 468-472, 1993), driven by a β-actin promoter. Two stable antisense cell lines from separate transfections were isolated and shown to be drebrin-negative by Western blot analysis and immunofluorescence studies. The antisense cell lines were inhibited in their ability to extend significant neurite processes in response to serum deprivation or retinoic acid treatment. These data support the conclusion that the actin-binding protein, drebrin, is required for the formation of stable neurite processes.

MECHANISMS OF AXON GUIDANCE

532.1

LAZARILLO: A GPI-LINKED GLYCOPROTEIN INVOLVED IN AXON GUIDANCE IN THE STRIATAL GRANULAR網路IS A MEMBER OF THE LIPOCALIN FAMILY. D. Sánchez, M.D. Gaetano, and M.J. Bastiani* 1Department of Biology, University of Utah, Salt Lake City, Utah 84112, U.S.A.

Our work is to determine G-protein-coupled receptors that ensure neurites find their appropriate pathway to target cells during neurogenesis. We are studying a new cell surface molecule called Lazarillo which is expressed by a subset of neurons and neuronal precursors in the grasshopper nervous system. This molecule is linked to the plasma membrane by a glycosylphosphatidylinositol (GPI) group and posttranslational N-linked oligosaccharides (native Mr=533.4 kD, deglycosylated Mr=28 kD). The monoclonal antibody against Lazarillo (10E6 MAbs) is able to block the directed growth of neurites in cultured embryos. In particular, a pair of commissural pioneer neurons are disrupted; their growth cones are not arrested but merely change their direction of growth.

We have identified and characterized a cDNA clone coding for the Lazarillo protein. The predicted protein sequence has the signal peptide necessary to target the protein to the endoplasmic reticulum and the GPI anchor to the membrane by the GPI tail. It possesses seven N-linked glycosylation sites and four cysteine residues. The cDNA has a long (2.3 kb) 3′ untranslated region. In situ hybridization using the whole cDNA sequence as probe shows that Lazarillo mRNA co-localizes with the 10E6 MAbs. Sequence comparison reveals that Lazarillo belongs to the gigaxonin family of extracellular carriers of small hydrophobic ligands in a wide variety of systems. A phylogenetic analysis of the family sets Lazarillo in a cluster containing the mammalian Apolipoprotein D, the insect binil binding proteins, and all the serum retinol binding proteins from vertebrates. Lazarillo is, to the best of our knowledge, the first lipocalin (1 GPI-anchored to the plasma membrane of cells), (2) restricted to a subset of neurons and neuroblasts in a developing nervous system, and (3) involved in growth cone outgrowth. Supported by NIH (NS 20387), Fulbright (M.D.G.) and Fogarty (D.S.) fellowships, M.D.G. and D.S. contributed equally in this work.

CALCINEURIN ENTRY AND CALCIUM STORES CONTROL NERVE GROWTH IN AN APPLIED ELECTRIC FIELD. B. Stewart & C.D. McCelland 2Department of Biomedical Sciences, University of Aberdeen, Aberdeen AB9 1AS, Scotland.

Cultured neurons show striking growth responses to a small dc applied electric field of physiological magnitude. The Calcium entry hypothesis has been implicated. Neurites from Stage 20 Xenopus neural tubes grown on tissue culture plastic in a dc field of 150mV/mm, 1. grow faster than in the absence of the field; 2. grow faster cathodally than anodally; and 3. turn towards the cathode. Using a pharmacological approach, we have studied both the role of selective voltage dependent calcium channels (VDCCs) and of calcium release from intracellular stores in the control of these three responses. We report 1. that faster growth in an applied electric field is lost in the presence of the P-type VDCC inhibitor omega-agatoxin IVA and in the presence of thapsigargin, which disrupts calcium release from inositoltrisphosphate sensitive intracellular stores; 2. that cyanide, which disrupts calcium-induced calcium release from intracellular stores, abolishes the growth rate differential between cathode and anode facing neurites and 3. that the P- and N-type VDCC inhibitors omega-agatoxin IVA and omega-conotoxin GVIA respectively, as well as cyanide and thapsigargin each partially inhibit cathodal orientation. We conclude that calcium entry through specific VDCCs in the growth cone, linked to calcium release from specific intracellular stores controls different aspects of electric field-induced growth and orientation.

532.3

Recent experiments suggest important roles for sulfated proteoglycans (PGs) in influencing axonal growth. In addition, chondroitin sulfate and keratan sulfate PG (CSPG, KS PG) expression patterns correlate at certain times with nerve growth across the developing retina, such as the corneal subplate, and at other times with regions which axons distinctly avoid, such as the midline of the superior colliculus. We have examined the expression of PGs in the superior colliculus of developing hamster, around the time of retinal axon ingrowth and arborization in this target. PGs were isolated from tectal homogenates by anion exchange chromatography, radiolabelled, and digested with enzymes to remove specific glycosaminoglycan (GAG) chains. Resulting protein cores were separated by electrophoresis. During the first postnatal week, we have identified PGs, which, on the basis of molecular weight, solubility properties, and GAG type, bear distinct resemblance to developmentally regulated PGs that are previously isolated from rat brain. Early postnatal tectal contained at least four distinct HSPGs, with molecular weights corresponding to glypicans, cerebrotenyl, and M410 (see Hamond and Lande, Nature 4, 1990). CSPGs of sizes consistent with neurocan, S2 and M8 were also identified. In addition, two novel bands appeared in response to digestion with keratanase, although the possibility of proteolytic contamination in the keratanase has not yet been ruled out. Experiments are currently under way to isolate PGs at other ages, and to localize their sites of expression within the superior colliculus, with emphasis on gaining potential insights from comparing expression along the midline and in retinoreceptive zones of lateral regions. Supported by NIH grants EY05054, NS26682, and EY02621.

TWO CHONDROTIN SULFATE PROTEOGLYCANS EXPRESSED DURING THE SEGMENTATION OF THE PERIPHERAL NERVOUS SYSTEM OF THE CHICK. C. Ring and W. Hallberg, Univ. of Pennsylvania School of Medicine, Dept. of Neurobiology, 15261.

Chondroitin sulfate proteoglycans (CSPGs) purified from Carnegie have been shown to be inhibitory to neurite outgrowth in vivo. Based on these findings, it has been hypothesized that CSPGs function as barrier molecules to neurite outgrowth in vivo. We wanted to examine if CSPGs derived from cartilaginous embryonic tissues would have similar effects. We have isolated two monoclonal antibodies (Mabs), 9BA12 and 9BA14, which are specific for CSPGs that are developmentally expressed in the trunk region of the chick embryo. The 239 kDa BM has been shown to recognize collagen type IX proteoglycan (CIXPG). It is expressed in the posterior segment of the somite in the time period of the somite anlage project, and neural crest cells migrate through the anterior sclerotome. Dorsal root ganglion (DRG) explants can adhere to, and extend neurites on, micrometre-bound CIXPG. Neurites from DRG explants grown on a combination of fibronectin/CIXPG appear shorter and more fasciculated than control explants grown on fibronectin alone. The 9BA12 mAb recognizes an as yet unidentified CSPG in neural tissue. It is expressed throughout the trunk region of the developing chick embryo, in the neural tube, throughout the somite, and is absent only from the dermamyotome. As with the CIXPG, DRG explants can adhere to and extend neurites on, micrometre-bound 9BA12 antigens. Alternately, in combination with fibronectin, the explants were able to extend neurites on the 9BA12 antigens that appeared identical to control explants grown on fibronectin alone. Our study demonstrates that CIXPG is the posterior sclerotome may contribute to the avoidance of this tissue by developing neurites and migrating neural crest cells. In addition, we conclude that not all CSPGs are inhibitory to axon outgrowth, and that careful attention be paid to the source and type of proteoglycan used in neurite outgrowth assays.
533.5 LAMININ AND FIBRONECTIN GUIDEPOSTS SIGNAL SUSAINED BUT OPPOSITE EFFECTS ON PASSING GROWTH CONES. T. B. Kahn, M. F. Schmidtk and D. B. Kaper*. Dep. of Anatomy and Neurobiology, OVCN2523; S Division of Biology, Caltech, Pasadena, CA 91125.

Guidepost cells affect behavior and navigation of growing cones in vivo. Yet, the nature of communication and the type of signals employed between growing cones and guideposts are largely undefined. Here we report that in a vitro assay system both behavior and navigation of advancing DRG growth cones of the chick were significantly altered by transient encounters with monomolecular model-guideposts: 4.5μm polystyrene beads covalently coated with potential guidance molecules. Evoked growth cone behavior, a series of stereotypy responses, depended on the molecular nature of the model guidepost. Growth cones most often paused and displayed filopodial sampling at guideposts. Laminin-model guideposts caused a sustained, two-fold increase in growth cone extension. Fibronectin-substrate (p<0.01; n=17) while fibronectin-model guideposts led to a sustained, two-fold decrease of the rate of advance on a laminin substrate (p<0.01; n=13). Notably, these effects lasted substantially beyond the time of physical contact between growth cone and model guidepost. Arrays of laminin-model guideposts produced a satellite growth cone advance and provided unambiguous, directional guidance. Interestingly, an increased overall growth rate (above that on the polystyrene substrate) was observed equivalent to a homogenous laminin substrate, despite periodic pausing occurring at each guidepost. Taken together, these results demonstrate that 1) as little as an individual molecular species is required to designate a point in space as a functional guidepost, 2) transient growth cone-guidepost contacts appear to initiate signalling pathways rather than just influence adhesion, and 3) the enforced pausing and sampling may represent a unique feature of guidepost-mediated pathfinding resulting in a periodic reassembly of the environment by the growth cones.

533.7 THE CLONING OF A CHICK BRAIN cDNA ENCODING A PROTEIN SEQUENCE RELATED TO COLLAPSIN. Y. Luo*, M. Renzi and J. A. Raper, Department of Neuroscience, University of Pennsylvania, School of Medicine, Philadelphia, PA 19104.

Collapsin is a recently identified protein (Luo et al. 1993, Cell 25 217-227) that is believed to serve as a repulsive guidance cue during growth cone navigation since it induces the collapse of specific growth cones in vitro, is homologous to the axon guidance molecule fasciclin IV (semaphorin 1), and is expressed in discrete regions of the developing brain. Partially purified brain-derived collapsin induces the collapse of both DRG and retinal growth cones, yet recombinant collapsin induces DRG growth cone collapse without affecting retinal growth cones. We therefore hypothesized that there is a family of collapsin-related molecules in brain that exhibit distinct neuronal target specificities. To identify possible collapsin relatives, we screened a λgt10 chick brain cDNA library with collapsin probe under low stringency conditions. One cDNA clone was identified that hybridizes with the collapsin probe at low stringency (45°C) but not at high stringency (65°C). The 1.6 kb cDNA insert of this clone encodes a portion of a novel protein that is homologous to a part of the fasciclin IV-like and the Ig-like domain in collapsin. In the fasciclin IV-like domain over 70% of the predicted amino acid sequence is identical to that of the corresponding domain in collapsin. We are now in the process of obtaining the full coding sequence for this collapsin-related protein. We then hope to express this recombinant version and test it for collapsing activity on a variety of growth cones in vitro.

CC1 and CC2 are neural crest-derived subunits of vomeronasal (VNO) neurons. Axons from CC1* neurons terminate in the rostral accessory olfactory bulb (AOB), whereas axons from CC6* neurons terminate predominantly in caudal glomeruli of the AOB. In addition, subsets of CC1* and the main vomeronasal nerve and grow caudally toward the forebrain. Many LHRR neurons utilize these CC1* axon branches as guides to migrate along the medial surface of the developing olfactory bulb (OB). Occasionally, CC1* axons also grow caudally toward the forebrain, but turn at the OB/forebrain border and grow back into the rostral AOB. These data suggest that molecules associated with CC1* axons and the terminal arbors of chemically distinct VNO axons. Whole mount immunohistochemical studies indicate that both active and repulsive activities may operate in the developing AOB. Most CC1* axons appear to stop abruptly at the border of the caudal AOB. However, a small number of CC1* axons enter the caudal AOB but alter their direction by turning sharply and entering the rostral AOB. Tissue culture studies are underway to examine factors that influence branching. E18 VNO neurons are grown on coverslips coated with alternating stripes of protein homogenates from neonatal rostral and caudal AOBs. Preliminary results indicate that stripes of axons turn and grow on rostral AOB homogenates but appear to be unaffected by caudal AOB homogenates. Supported by DC00933, NS24386 and HD05515.

533.6 A NOVEL Car++-BINDING PROTEIN IS EXpressed BY a SUBSET OF PERIPHERAL NEURONS WHICH SELECTIVELY FASCICULATE IN A SINGLE AXON TRACT. By LEECH CNS, K.K. Briggs, K.M. Johannsen, & J. Johansen*. Dep. of Zoology & Genetics, Iowa State University, Ames, IA, 50011.

The laf-36 antigen is expressed in a subset of peripheral neurons whose axons reorient to a single axon fascicle in the developing leech CNS. By screening an expression vector library with the antibody we obtained a cDNA clone which encodes a protein possessing two EF-hand Car++-binding domains. The Car++-binding domains are likely to be functional since fusion protein made from the clone and expressed in vivo binds Car++ after SDS-PAGE and transfer to nitrocellulose plates. The Car++-binding ability of the clone co-fractionated with the laf-36 antigen was verified by in situ hybridizations with the clone to embryos, the labeling of which exactly matches the lan 3-6 antibody staining pattern. Northern analysis suggests that translation of the lan 3-6 message would result in a protein with a molecular weight of about 18 kD. Immunofluorescent purification of the lan 3-6 antibody followed by SDS-PAGE and analysis of the gels by silver staining yields a protein band of this predicted size. However, a prominent protein band of approximately 200 kD is being co-purified with the lan 3-6 antigen by this procedure. Broad protein bands of this nature are frequently characteristic of glycoproteins. Thus these results suggest that the lan 3-6 antigen is a small Car++-binding protein which may be associated with and regulating a larger 200 kD glycosylated protein. The very restricted expression of the lan 3-6 antigen to a subset of peripheral neurons which specifically fasciculate together into a single tract during development raises the possibility that this putative protein complex may play a role in this process. Supported by NIH grant NS 28657 and NSF grant DIR 9113909.

533.8 THE PATTERN OF COLLAPSIN mRNA EXPRESSION IN THE DEVELOPING CHICK CNS. S. Chang, Y. Luo, and J.A. Raper*, Department of Neuroscience, University of Pennsylvania, School of Medicine, Philadelphia, PA 19104.

Collapsin is a recently identified protein that induces the collapse and paralysis of specific growth cones in vitro (Luo et al. 1993, Cell 25 217-227). Here we examine the distribution of collapsin mRNA in the developing chick brain. Wholemount in situ hybridizations were performed using a full length digoxigenin derivatized collapsin probe that was later reacted with an alkaline phosphatase conjugated anti-digoxigenin antibody. In the chick brain at E2 (HH stage 1), collapsin message was localized to rhombomeres 3 and 5 of the hindbrain. By E3, the rhombomere expression declines and collapsin message is strongly expressed in specific regions of the diencephalon. It is localized dorsally in an annulus around the developing pineal and ventrally as two strips along either side of the stalk of the pituitary. On E6, collapsin message is also found in a stripe on the lateral wall of the forebrain in a region that may correspond to the archaestriatum. A pair of rostrally-oriented stripes on either side of the midline of the hindbrain also express collapsin message. The expressing cells in these stripes are near the ventricular surface. These two pairs of collapsin expressing stripes extend caudally into the ventral portion of the spinal cord. This highly specific and localized pattern of expression at developmental times when extensive axon outgrowth is occurring in the developing CNS is consistent with collapsin playing a role in growth cone guidance.

Potent contact-dependent axon growth inhibitory activity is present in CNS myelin. To identify inhibitory proteins present in myelin we used non-denaturing chromatography and tested the fractions for growth inhibition in a bioassy. NG108-15 cells extend neurites in response to cAMP. Purified bovine CNS myelin, used as a tissue culture substrate, permitted cell attachment but inhibited cAMP-induced neurite outgrowth. When myelin was extracted with octylglucoside and the extract chromatographed on a DEAE anion exchange column, several peaks of inhibitory activity were eluted with a salt gradient. Analysis of the fractionated proteins revealed that myelin-associated glycoprotein (MAG) co-chromatographed with the bioassay active fractions. To determine if MAG contributes to growth inhibition, MAG was removed from these fractions by immunodepletion. Removal of MAG reduced neurite growth inhibitory activity. Direct evidence for the inhibitory effect of MAG on neurite outgrowth was obtained by taking the extracellular domain of recombinant MAG produced in cultured insect cells. This recombinant MAG was a potent inhibitor of neurite outgrowth. These results, which establish an inhibitory action of MAG through an extracellular domain, suggest that MAG may be critically important after nerve injury in the CNS where myelin debris is not removed very quickly after injury. Supported by the Canadian Centre of Excellence, Neuroscience Network.
MECHANISMS

533.11 NEURITE GROWTH INHIBITORY ACTIVITY IN THE MAMMALIAN PNS AND CNS AND ITS MODULATION BY LAMININ. S. Davis, J. McKerracher, D. Jackson, V. Kottis, and P. Braun. Centre for Research in Neurosciences, Montreal General Hospital Research Institute, and Dep. of Biochemistry, McGill University, Montreal, Canada.

In addition to the axon growth inhibitor in CNS myelin identified by Caroni and Schwab (J. Cell Biol.106:1281), we have identified another inhibitor in the peripheral nervous system (PNS). We now present evidence that peripheral nerve (PN) myelin also possesses neurite growth inhibitory activity. Bovine PN myelin was prepared by homogenization with either a Polytron (PN-p), or frozen in liquid N2, pulverized and homogenized with a Dounce homogenizer (PN-d). These two preparations were then subjected to sucrose density gradient centrifugation to purify myelin. PN myelin was plated on to polylysine-coated 96 well plates (9ug/well), and neurite growth assessed with CAMP linked NG108-15 cells. On PN-p myelin 81% of the cells extended neurites, as compared to 1.5% on PN-d myelin. Western blots of the 2 myelin preparations with anti-laminin antibody indicate substantial amounts of laminin in the myelin preparation that was permissive for neurite growth (PN-p). Preincubation of PN-p myelin with anti-laminin antibody reduced neurite growth. In a similar neurite growth assay, the inhibitory activity in bovine CNS myelin (4%) was overridden (80%) by coating the wells with a mixture of myelin (8ug) and laminin (1.5ug). These results suggest that neurite growth inhibitory activity is present in PN and CNS myelin, and can be modulated by laminin.

Molecular gradients of environmental cues have been proposed to be important directional signals for the proximal growth of pioneer axones in embryonic insect legs. We have produced a monoclonal antibody (Mab) that binds to an extracellular matrix protein that is non-uniformly distributed along the proximal-distal axis of embryonic cockroach leg at the time of pioneer axon growth. This mab was named PROD-2 because it labels the proximal parts of the leg more intensely than the distal end. The spatial and temporal distributions of the PROD-2 antigen were used to generate an environmental guidance cue for T11 pioneer axon growth. To demonstrate a role for the antigen in axon guidance, PROD-2 Mab is added to the medium in which whole embryos are cultured for 48 hours. Under control conditions, the T11 axons grow and follow their normal path. Treatment with PROD-2 Mab has no effect on the rate of elongation of the T11 axon, but alters the direction in which they grow. The perturbation was found to be dose dependent; with increasing concentration of the Mab there was an increase in the total number of pathfinding mistakes as well as an increase in the severity of the mistakes. These results indicate that the PROD-2 antigen is a guidance cue responsible for the stereotypical projection of the T11 pioneer axons on their normal substrates.

533.15 AXONIN-1 PLAYS A ROLE IN GUIDANCE OF COMMISURAL NEURONS IN THE CHICK SPINAL CORD. E.T. Stoeckl* and L.T. Landmesser. Dept. of Neurosciences, Case Western Reserve University, Cleveland, OH 44106

In chick embryo the cell adhesion molecule axonin-1 has been shown to exist in both a secreted and a GPI-linked form. Its role in growth cone guidance and pathfinding of commissural neurons, which express it during initial axonogenesis, was tested by in vivo injections of axonin-1 into the spinal cord central canal in early embryos (Stages 18-24). Dorsally located commissural neurons normally extend axons toward the floor plate in response to a diffusible factor. Upon reaching the floor plate they make a sharp turn to cross the midline, then turn rostrally along the border of the contralateral floor plate. In axonin-1 injected embryos, a substantial proportion of commissural axons did not cross the midline, but turned rostrally on the ipsilateral side; in addition they grew in a morechaotic pattern (antero-posterior). When Neurocan-CAM has been shown to be a receptor for axonin-1 on DRG neurons, we tested whether injection of Fab fragments of anti-NcCAM would result in similar pathfinding errors. Although commissural axons grew in a more defasciculated pattern following anti-NcCAM injection, pathfinding errors did not occur. This suggests the existence of at least one other receptor for axonin-1 in the floor plate; saturation of this "floor plate" receptor by injected axonin-1 could lead to the observed misguidance of commissural neurons. The nature of this receptor is currently being investigated.

533.16 SUBSTITUTES PATTERNED WITH A DOMAIN OF THE B2 CHAIN OF LAMININ GUIDE AXONS OF EMBRYONIC HIPPOCAMPAL NEURONS IN VITRO. M. Matsuura*, B. S. Potember*, F. E. Weight* and P. Ledis. 1. Applied Physics Lab, The Johns Hopkins University, Laurel, MD 20723. 2. Laboratory of Molecular and Cellular Neurobiology, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

Substrates patterned with synthetic peptides derived from the B1 and B2 chains of laminin were used to guide axons of hippocampal neurons in vitro. These substrates were formed by attaching the peptides to chemically patterned surfaces fabricated via deep UV lithographic procedures. Neurons grown on the patterned substrates (parallel lines of 5 μm width) with or without the B2 peptide, or without substrate (control), had neurite outgrowth domains. The 60% of the neurons on patterned substrates had randomly spreading neurites. Substrates patterned with peptide P20, derived from a neurotrophic factor domain of the B2 chain of laminin, had a morphology similar to that of the control, but was not significantly different from the B2 peptide. The patterned substrates had a dose-dependent effect on neurite outgrowth. Higher doses of peptide P20 promoted directed neurite outgrowth and morphological maturation of neurons. Neurons on patterned substrates had an average 4.4 μm length, compared to 5 μm length of the control. These results demonstrate that patterned substrates can be used to influence neurite outgrowth and axon differentiation. The future study will provide direct evidence that the integrative cell surface domain of a peptide, which is derived from the B2 chain of laminin as an axonal growth factor, is required for functional growth of hippocampal neurites in vitro.

533.17 AN INSECT PIONEER NEURON USES MESODERMAL CELLS AS A SUBSTRATE FOR NORMAL PATHFINDING. R. J. Bajant* and J. G. Denburg. Dept. of Biological Sciences, University of Iowa, Iowa City, Iowa 52242.

Previous studies of axon growth of insect pioneer neurons by Bentley’s lab has shown that mesodermal cells are not required for elongation and pathfinding. We report that the extension of axonal neurites in a stereotypical axon projection by the Fe2 pioneer neurons in the limbs of cockroach embryos requires mesodermal cells. Using immunocytochemical and confocal microscopy techniques, we have observed that the Fe2 pioneer neurons use the internal core of mesodermal cells as a substrate for growth. Surgical removal of the leg mesoderm and subsequent culturing of the embryos resulted in axonal growth on the epidermal epithelium but with an altered trajectory. Similar changes in path and substrate choice are observed in axons growing in embryos cultured in vitro in the presence of the enzyme phosphatidyl inositol phospholipase-C or certain glycolipids similar to those in epidermal cells. These results indicate that in vivo the Fe2 axons prefer to grow on the surface of certain mesodermal cells. However, after surgical manipulation or addition of chemical perturbants they will grow on ectodermal epithelial cells but with an altered path. There appears to be a direct effect of epidermal cells on neurite outgrowth mechanisms of pioneer axon growth in the legs of insect embryos. Supported by NIH grants NS 14293.
533.17 Substance P Modulates Chemotactic Influences of Floor Plate on Developing Neurites in the Central Nervous System. C. De Felice, R.D. Pincock* and S. T. Hunt,* (Spon. BRA) MRC Laboratory of Molecular Biology, Division of Neurobiology, Hills Road, Cambridge, CB2 2QH, Tisch–Davis Neuroscience Research Unit, Robinson Way, Cambridge, UK CB2 2QB.

The floor plate, a neuro-epithelial structure found at the ventral midline of the developing spinal nervous system, has been shown to function in dorsal-ventral patterning in the spinal cord and at later embryonic stages, in guidance of commissural axons by release of chemotactants. We have found that embryonic rat floor plate cells express the neurokinin 1 receptor and that there is a transiently appearing subpopulation of commissural axons containing Substance P, the neuropeptide ligand for this receptor. Receptor coupling to an intracellular effector system in dissociated floor plate cells was established by monitoring the intracellular calcium levels of dissociated floor plate cells using the Ca2+ indicator fura-2. Both application of 10 to 100 nM substance P or the selective NK1 receptor agonist [Sar^5, Met(O2)^8] substance P (12) produced a rapid and reversible increase in internal calcium levels which was concentration dependent. Prolonged application of sub-threshold concentrations (0.1-5 nM) of substance P applied for up to 10 min produced rhythmic oscillations in internal calcium levels. The NK2 and NK3 receptor agonists [B-Ala^9]‐prokineticin A (4-10) and sendikin (100 nM) were inactive. 50 nM concentrations of the rat selective NK1 receptor antagonist CP967580 blocked the response to substance P. Finally, Substance P analogues increased the amount of axon outgrowth from dorsal horn explants when co-cultured with floor plate in collagen gels. These results suggest that SP released from pioneering neuronal pathways can subdue the extracellular environment and influence the growth and differentiation of developing neuronal systems by regulating the release of chemotactants from floor plate cells.

Floor plate cells at the ventral midline of the spinal cord of early neurulae (stage 11) promote outgrowth of spinal commissural axons and reorient these axons in vitro. We recently identified two proteins, netrin-1 (which is highly expressed in floor plate) and netrin-2, that are expressed at lower levels in the floor plate and that promote spinal axon outgrowth-promoting and reorienting activities of the floor plate. Here we report the characterization of a chemically distinct activity that potentiates the effects of the netrins. This activity, termed NSA (for netrin synergizing activity), was found in high salt extracts of embryonic brain membranes that had been depleted of netrins by passage over a heparin column, at high salt. On young E11.5 rat embryo spinal cord slices, addition of NSA increased the potency of the netrins in promoting commissural axon outgrowth by one order of magnitude. Surprisingly, commissural axons in older (E13) spinal cord were more sensitive to the netrins, and, conversely, NSA had relatively little effect at this age. The reasons for the differences in responsiveness of commissural axons of different ages is not known but could be explained if E13 dorsal spinal cord produces NSA.

To determine whether the NSA potentiating observed with E11 dorsal spinal cord is a true synergy, we identified a concentration of the netrins that, alone, evoked relatively little outgrowth from E11 explants, just as the standard concentration of NSA evoked little or no outgrowth. At E11 this concentration of NSA is only about half these defined concentrations, robust outgrowth was observed which cannot be accounted for by a simple additivity of their effects. Initial experiments revealed that NSA is in prototype sensitive and has a molecular weight in excess of 100 kDa. Purification and identification of NSA will make it possible to determine the mechanism of the synergy and to determine whether NSA modulates netrin function and contributes to commissural axon guidance in vivo.

534.1 NEUROTROPHINS POTENTIATE NEURONAL EXCITABILITY BY INHIBITING GABAERGIC SYNAPTIC TRANSMISSION IN CORTICAL NEURONS. Han G. Kim*, Ti Wang and Bai Lu, Roche Institute of Molecular Biology, Roche Research Center, Nutley, New Jersey.

Neurotrophins (including NGF, BDNF, NT-3, NT-4/5) have traditionally been regarded as slowly acting signals essential for neuronal survival and differentiation. A recent study showed that BDNF and NT-3 can rapidly potentiate synaptic activity in developing neuromuscular synapses. However, little is known about the role of neurotrophins in modulating excitability of the developing central nervous system. Here we report that NT-3 and NGF rapidly increased the frequency of spontaneous action potentials, and synchronized synaptic activities in developing cortical synapses. In addition, the inhibitory synapses, which are mediated by GABA receptors, were reduced by NT-3. Thus, the excitatory effects of neurotrophins on spontaneous action potentials were antagonized by the induction of GABAergic transmission. Our finding, together with previous report of the rapid regulation of CNS neurotrophin expression by neuronal activity, suggest a new mechanism for modulation of synaptic transmission and activity-dependent synaptic plasticity.

534.2 NGF, a Synaptically Released Protein with Homology to Acute Phase Proteins of the Immune System. A.K. Schlingman, J.A. Holmes, H. Vogel, and M.S. Perie*, Division of Neuroscience, Dept. of Otorhinolaryngology, Dept. of Pathology, Baylor College of Medicine; Houston, Texas 77030.

We have identified by affinity chromatography, a binding protein for the snake venom toxin, Taipoxin. The sequence of this 47 kD protein is unique, is suggestive of a secreted protein and has homology to the acute phase proteins, serum amyloid P protein and C-reactive protein, of the pentraxin family. Northern analysis revealed a brain specific transcript. In vitro hybridization shows this high NGP message levels in neurons of the cerebellum, CA3 and dentate gyrus of the hippocampus, layer 6 of the cortex with no message in gila. Antibody to this protein stains synapses in the cerebellar Purkinje cell somata and Bergmann glomeruli and a subset of gila. Reflecting this, we have named this protein, Neuronal-Glial Pentraxin or NGP. Because NGP appears to be released synthetically and has homology to immune proteins potentially involved in uptake of lipids, toxic or other antigenic material, we suggest that NGP may be involved in the uptake of synaptic molecules during synaptic remodeling.
SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Little is known about the regulation of expression of the growing number of proteins identified as possible regulatory factor could be the level of neuronal activity, which in sensory systems is dependent on the level of afferent stimulation. We examined the effects of unilateral suppression of odor-mediated stimulation to the olfactory bulb (OB) on 3 synaptic vesicle proteins (SVPs): synaptophysin, SV2, and rab3a, a small GTP-binding protein of the rab family.

The right nostrils of six newborn rats were cauterized under anesthesia. The animals were sacrificed 6 weeks later, their brains removed and the left and right OBs immunostained with specific antibodies against 3 SVPs: Tyrosine hydroxylase (TH) immunohistochemistry served as a control for the efficiency of the sensory deprivation. Sections were digested and deionized by analysis performed in the glomerular (GLOM), the internal plexiform (PLEX) and the granular (GRAN) layers. The level of staining in the striatum was used as an internal standard to normalize between animals.

TH staining was reduced in the GLOM (-30%, p<0.001) but not in the other layers. Also, the signals of synaptophysin and SV2 were reduced or unchanged. In contrast, staining for synaptophysin and SV2 was similar in all layers in the left and right OBs. These results demonstrate that the level of expression of rab3a, but not of synaptophysin or SV2, are influenced by the afferent input to the OB. One possible interpretation is that rab3a would act as a regulatory element of TSP trafficking, while synaptophysin and SV2 could be regulated more as "constitutive" components.

P54.4 LONG TERM MAINTENANCE OF NERVE TERMINAL FUNCTION IN THE ABSENCE OF MUSCLE FIBERS IN THE FROG. A. Dunaevsky and E. A. Connor* Neuroscience and Behavior Program, Univ. of Massachusetts, Amherst, MA 01001.

Although some of the signals involved in forming and maintaining the synaptic specializations of a target cell are now identified, little is known about the processes that underlie and maintain the presynaptic nerve terminal. Here the role of the muscle fiber in the maintenance of nerve terminal function has been investigated. We demonstrate that motor terminals specifically deprived of targets maintain the ability to release and recycle synaptic vesicles in response to stimulation. We assayed nerve terminal activity in preparations of innervated muscle basal lamina sheets using a fluorescent dye FM1-43 that stains nerve terminals in an activity-dependent fashion. Intervened basal lamina sheets were prepared by exciting cutaneous dermonecrotic mouse fibers with stimulated nerve fibers. X-ray irradiation prevented regeneration of the muscle fibers. One to five months after muscle fiber excision, the function of target deprived nerve terminals was tested by exposure to FM1-43 dye in high K* Ringer's solution. Synaptic sites were identified with rhodamine-labeled peanut agglutinin which stains terminal Schwann cell and synaptic basal laminae. Like intact preparations, nerve terminals deprived of target for 1-5 months incorporated FM1-43 when stimulated. Further, the same terminals were destined by either nerve stimulation or depolarization with high K* Ringer. The ability of these nerve terminals to release FM1-43 depended on the target deprived nerve terminals.

Ecto-protein kinases provide the powerful regulatory machinery of protein phosphorylation to the extracellular environment of the nervous system, where delicate interactions among cells, and between surface proteins and components of the extracellular matrix, play significant roles in neurogenesis and synaptogenesis. The present study identified proteins whose surface phosphorylation corresponds to these developmental events. Cultured, embryonic chick-brain neurons possess proteins of MW 12k and 13k whose surface phosphorylation was maximal during the onset of neurogenesis. Surface phosphorylation of this low MW protein duplex was delayed only in the development of pyramidal neurons cultured from embryonic mouse hippocampus, and this activity decreased after neurogenesis was completed. Upon maturation and during synaptogenesis, the phosphorylation of another protein duplex (MW of 4DK and 50kD) increased. As anticipated from the results listed above, we found that a hybrid, pyramidal-neurons cell line (HN30) derived from embryonic cells has high phosphorylation of the low MW protein duplex associated with neurogenesis, and a more mature line (HN33) displayed the high surface phosphorylation of the 4DK-50kD protein duplex, associated with synaptogenesis.

The functions of these surface protein phosphorylation systems can now be studied in homogenous populations of cloned neural cells.

P54.6 PHOSPHORYLATION OF EXTRACELLULAR DOMAINS OF MICROTUBULE-ASSOCIATED PROTEIN (MAP) 1B MAY BE INVOLVED IN SYNAPSE FORMATION BETWEEN CORTICAL NEURONS. K. Muramoto*, M. Kakehara, K. Kobayashi, H. Taniguchi and Y. Kuruda, Department of Molecular & Cellular Neurobiology, Tokyo Metropolitan Institute for Neuroscience, Fuchu-shi, Tokyo 183, Japan. and Division of Biomedical Polymer Science, Institute for Comprehensive Medical Sciences, Fuji Health University, Toyoake-shi, Aichi 470-17, Japan.

Synapse formation between cultured rat cortical neurons is inhibited by the continuous application of K-252b, an ecto-protein kinase inhibitor, which can not permeate the cell membrane (Muramoto, et al., Proc. jap. Acad., 64, 319, 1988; Kuruda, et al., Neurosci. Lett., 135, 255, 1992). In order to identify membrane proteins which may be involved in synapse formation, [32P]P/ATP was applied to the cultured cells for brief periods to phosphorylate their extracellular domains. The phosphorylated proteins were separated by SDS polyacrylamide gel electrophoresis and detected by autoradiography. Some of these bands were immediately phosphorylated and this phosphorylation was suppressed by the addition of K-252b to the medium. We examined the partial amino acid sequence of these substrates. Phosphorylated bands were cut from the gel and digested with lysyl endopeptidase. Peptide fragments were separated by capillary HPLC and analyzed by mass spectrometry. The band with the highest molecular weight, whose phosphorylation was strongly inhibited by K-252b, was identified as microtubule-associated protein (MAP) 1b. These results suggest the possibility that the phosphorylation of extracellular domains of MAP1b in involved in synaptic formation between cortical neurons.

We have used immunocytochemical techniques (De Vente et al., 1997, Neurosciences 23:361) to monitor cGMP changes in identified neurons in Locusta migratoria in response to agents such as sodium nitroprusside (SNP) that generate nitric oxide (NO). Although relatively few neurons respond to SNP during the embryonic and larval stages, a number of neurons show a window of NO sensitivity during embryogenesis. Observations on identified neurons such as RP2, ACC and LPD cell show that NO sensitivity development begins after the completion of axon navigation, is strong throughout axonal branching, and ends after synaptogenesis is apparently completed. During this embryonic window, the main site of cGMP accumulation is the nucleus, possibly providing a direct link between cell-cell signaling and transcription. Using nonradioactive tracing to detect possible sites of NO synthesis, we found diaphorase staining first associated with nerve fibers at 40-45% of development. This was increased in intensity in the neuropil through the remainder of development. These observations suggest that the maturation phase of neurons is a period uniquely characterized by the NO/cGMP signaling system and of nuclear targets for cGMP. NO-synthesizer inhibitor experiments are being used to define the exact role of this system in neuronal maturation.

P54.8 BLOCKADE OF SPONTANEOUS NEURAL ACTIVITY IMPAIRS THE DEVELOPMENT OF THE DENDRITIC SPINES IN CULTURE. Teng Wu*, Mark J. Maguire, Ford F. Ember, Institute for Developmental Neuroscience, John F. Kennedy Center, Vanderbilt University, Nashville, TN 37203.

Blocking patterned neural activity has been shown to prevent the normal development of dendritic spines in vivo. We have investigated whether spontaneous neural activity is necessary for induction of spine formation in vitro. Neurons from rat somatic sensory cortex were enzymatically dissociated on postnatal day 1 and plated on a glial monolayer. Pyramidal neurons were cultured in a medium containing TTX (1 uM), B27, EGF (5 ng/ml), and BSA (1 mg/ml) for 2 weeks. In the presence of TTX, spine density on these neurons was significantly decreased compared to neurons cultured in the same medium without TTX. However, after 4 weeks of culture, spine density on neurons cultured with TTX were not significantly different from neurons cultured without TTX. These results suggest that the formation of dendritic spines is critically dependent upon spontaneous neural activity.

Embryonic Epinephrine Synthesis: Association with Cardiogenesis. S. H. Ebert, M. Fujimura, J. M. Baden, B. Sidel and D. P. Luskin. Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA 94305.

Phenylethanolamine N-methyltransferase (PNMT) is the final enzyme in the pathway for epinephrine synthesis; hence, PNMT serves as a marker for the cells which produce this neurotransmitter/neutrotransmitter. While much is known about the developmental expression of PNMT in the adrenal gland and the brain, very little is known about its developmental expression elsewhere. We demonstrate that PNMT mRNA can be detected in embryos as early as gestational day 9.5. By gestational day 11, PNMT mRNA and active enzyme can be specifically localized to the heart. Immunocytochemical analysis further reveals that PNMT protein is predominately contained within the embryonic cardiac cells. Our results therefore suggest that the embryonic heart is the primary site of PNMT expression early in development. The presence of PNMT mRNA, enzyme activity and protein before the appearance of nerve cells around the heart suggests that the embryonic heart may be capable of synthesizing epinephrine during early cardiogenesis. Since cardiac cells are already beating and can respond to epinephrine at this stage of development, our findings indicate a potential role for epinephrine in early cardiac function.

Neonatal 6-OHDA Lesions Affect the Development of Striatal D1, D2, D3 Receptors and D1 mRNA. P. A. Frohna*, B. S. Natoli-Reisvogel, and J. N. Jessen. Dept. Psychiatry and Pharmacology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104.

The postnatal developmental profile of striatal dopamine reuptake and dopamine receptor expression suggests that the two may be related. Our previous studies have shown that adult rats that received postnatal day 6 (P6) 6-OHDA injections had a significant loss of D1 receptors that peaked at 7 days after the lesion. This peak in D1 mRNA in the dorsolateral striatum (DLS), substriatal (MS) and medial (MD) dopamine (DA) enriched cortex (Crp), regions with the greatest density of D1 receptor-positive fibers. Thus, normal DA innervation during postnatal development may be important for the appropriate control of motor function. In the present study, we determine the temporal relationship between the loss of DA innervation and the development of specific DA receptor expression by the striatum. The profile of D1 receptors and D2 and D3 mRNA in rats with P1-6-OHDA lesions.

PERINATAL INSULTS TO DEVELOPING DOPAMINE SYSTEMS IN RAT. K-C. Langley* and C.C. Quinn. Program in Neuroscience, Florida State University, Tallahassee, FL 32306.

Perturbation of developing dopamine systems in neonatal rat brain may lead to cytoarchitectural restructurin that persists into adulthood. Such disruptions allow for an opportunity for the animal to assess the effects of environment and to provide an opportunity for the animal to assess the impact of environmental cues on the developing brain. The results of this study suggest that the development of striatal D1 and D2 receptors in neonates is differentially regulated, and that D1 receptors require normal DA innervation for proper expression. This work supported by MH 48813.
The effects of dopamine receptor agonists on the expression of dynorphin (DYN) and Fos or Fos related antigens (FRA) were studied in primary striatal cultures from 7-day old rat pups. Levels of DYN, c-fos, and FRA were increased in cultures exposed to dopamine receptor agonists, at 10 μM (one day administration) resulted in an increase in the number of DYN-positive cells in the striatal cell culture and increased the intensity of DYN mRNA in cell nuclei. Compared to control or quinpirole, a specific D2 dopamine receptor agonist, at 10 μM (one day administration) resulted in an increase in the number of DYN-positive cells in the striatal cell culture and increased the intensity of DYN mRNA in cell nuclei. Compared to control or quinpirole, a specific D2 dopamine receptor agonist, at 10 μM (one day administration) resulted in an increase in the number of DYN-positive cells in the striatal cell culture and increased the intensity of DYN mRNA in cell nuclei. Compared to control or quinpirole, a specific D2 dopamine receptor agonist, at 10 μM (one day administration) resulted in an increase in the number of DYN-positive cells in the striatal cell culture and increased the intensity of DYN mRNA in cell nuclei. Compared to control or quinpirole, a specific D2 dopamine receptor agonist, at 10 μM (one day administration) resulted in an increase in the number of DYN-positive cells in the striatal cell culture and increased the intensity of DYN mRNA in cell nuclei. Compared to control or quinpirole, a specific D2 dopamine receptor agonist, at 10 μM (one day administration) resulted in an increase in the number of DYN-positive cells in the striatal cell culture and increased the intensity of DYN mRNA in cell nuclei.
BRAIN AND ENDOThERmAL NICRiC OXIDE SYNThESE EXPRESSION IS REGIONALLY AND TEMPORALLY REGULATED IN FETAL SHEEP BRAIN. F.J. NorthIton, R.C. Koehler, R.J. Traysman*, and L. J. Martin*. Dept. of Pediatrics, Anesthesiology/Critical Care Medicine, Pathology, and Neuroscience. The Johns Hopkins Medical Institutions, Baltimore, MD 21287.

Using immunohistochemistry, we tested the hypothesis that brain NOS (bNOS) and endothelial NOS (eNOS) expression is regulated developmentally in rat, 70, 93, 110 and 136 days of gestation (term=145d). No nonspecific immunoreactivity (IR) was found if the IR antibody was omitted; no cross reaction between bNOS and eNOS was seen at any gestational age, and neither isomer was localized to glial cells. At 60d, bNOS has a laminar localization in neopil of the lower cortical plate of the telencephalic vesicle which becomes less distinct as the cortical plate matures, disappearing at 136d. A subset of nonpyramidal cortical neurons first shows discrete bNOS IR at 71d. By 136d, two subsets of interneurons with somatolaminar IR for bNOS are dispersed throughout cerebral cortex. Neuronal differences in bNOS IR within cortex occur at 71 and 93d but not at 110 and 136d. IR for bNOS in striatum increases from first appearance at 71d to peak density of bNOS-positive medium sized aspy neurons at 110d. Labeling of cerebellar basket cells peaks at 136d. The vascular bed expresses eNOS throughout gestation. The radial vascular architecture evolves into a complex branching pattern between 60 and 110d. A dense capillary bed with eNOS IR is found within white matter in contrast to the relative absence of bNOS IR in this area. By 136d, eNOS in vascular beds of brainstem, diencephalon, basal ganglia, and cortex is homogeneously distributed, in contrast to the absence of eNOS IR in the ventricular zone. We conclude that bNOS and eNOS are present prior to midgestation in the fetal sheep, and the developmental regulation of NOS expression, particularly bNOS, parallels regional brain maturation.

REGULATION OF EXPRESSION OF NEURODianeAcPH ACTIVITY (NDA) AND NEURODianeAcPH SYNThESE (NOS) IN PRINCIPAL NEURONS OF RAT AND MOUSE SUPERIOR CERvICAL GANGLIUM. MD Johnson*, JA Garcia,* BA Senators, DG Green*, and JD Potter*. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Preganglionic sympathetic axons of adult rats and mice express NADPH-D (NDA) and NOS immunoreactivity in vivo; however, principal neurons of the superior cervical ganglion (SCG) express these markers for NOS lightly or not at all (E. Grekou et al, 1992, Neuroscience 58:255; Du et al 1993, Neurosci. Lett. 158:51; Johnson, et al, unpublished). When postnatal rat and mouse SCG neurons (and some adult SCG neurons) were cultured for 1 week in medium containing 5% rat serum, however, NDA-D was visibly induced in about 80% of such cells; the staining varied from barely detectable to intense (Senatius et al., 1992, Abstract B777). In a subset of neurons, NADPH-D was co-localized with immunostaining for the neuronal isoform of NOS (antibody provided by Dr. Bernd Mayer). In mice homotypic for deletion of the neuronal NOS gene (provided by Dr. Paul Hobart, of Houston, et al, 1993, Cell 72:237), and in which there was no NADPH-D in the preganglionic sympathetic fibers in vivo, clear light NADPH-D was present in principal neurons in adult ganglia, and in cultured postnatal neurons; the staining of the cultured neurons was significantly lower than in neurons from wild-type mice. The presence of numerous ganglionic non-neuronal cells in the cultures reduced the proportion of NADPH-D stained cells. Supported by NS02253 and the Feinstein Fund. We thank Kara Dunn for technical assistance.

EFFECTS OF SERA ON INDUCTION OF NEURODianeAcPH ACTIVITY (NDA) IN CULTURED PRINCIPAL NEURONS OF THE SUPERIOR CERVICAL GANGLION (SCG) OF THE POSTNATAL RAT. J.A. Garcia, M.D. Johnson* and D.D. Potter*. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Induction of NADPH-D was reported in dissociated and cultured SCG neurons of the postnatal Long Evans rat by Senatius et al., 1992. Characterization of the time course and level of induced NADPH-D in cultured SCG using growth medium with 5% normal rat serum (NRS, Sigma) demonstrated NADPH-D in less than 1% of SCG neurons at time of plating and in about 80% of neurons after 1 week in culture. The inductive effects of 5% NRS have now been compared to growth medium supplemented with 5% dialyzed fetal calf serum (dFCS, 10,000 MW cut-off). SCG neurons cultured in 5% dFCS also displayed a positive inductive effect on NADPH-D, but the percentage of neurons expressing NADPH-D was significantly lower (<1% at time of plating and about 30-40% after 1 week in culture). Culture in a serum-free medium resulted in 15-20% of neurons expressing NADPH-D after 1 week, and culture in growth medium supplemented with 5% heat inactivated serum resulted in 20-25% of neurons expressing NADPH-D after 1 week.

To characterize further the time course and nature of these positive inductive effects, a serum reversal experiment was performed. Neurons cultured in 5% NRS were switched to 5% dFCS and vice versa. Serum reversal on culture Day 19 had no subsequent effect on the percentage of NADPH-D positive neurons. Serum reversal on culture Day 6-7 had the following effects: neurons cultured first in 5% NRS and later switched to 5% dFCS maintained an 80% level of NADPH-D (no change); however, neurons cultured first in 5% dFCS and later switched to 5% NRS went from a 30-40% NADPH-D level to an 80-85% level of NADPH-D. These data suggest that the factor(s) in serum that promotes induction of NADPH-D is heat labile and is effective under these conditions in only a limited period in culture. Supported by PO1 NS 02253 and the Feinstein Fund.

MEASUREMENT OF NEUROTENSIN (NT), NT-11-1 AND NT-11-8 IN THE DEVELOPING RAT BRAIN. H. Moss, G. W. Benoit and C. A. Mandsager (SPON: Brain Research Association) Dept. Physiology and Pharmacology, Medical School, Queen's Medical Centre, Nottingham, NG7 2UH, UK.

Neurotensin (NT) appears to be a neurotransmitter/neuromodulator in the adult rat brain, whilst in the developing rat brain, an early transient appearance of NT precursor mRNA in some brain regions (Sato et al. (1990) Dev. Brain Res. 54:249-255), suggests a developmental role for NT, perhaps in the establishment of neuronal organisation.

In the present study NT-LI has been quantified in the diencephalon, telencephalon and ventral mesencephalon of Wistar rat brains aged from embryonic day 15 (E15), adult (3-4 months) cultured for 1 week to postnatal day 2 (P2), using a sensitive radioimmunoassay (RIA) technique (0.9 fmol/tube).

NT-like immunoreactivity (NT-LI) appeared during the prenatal period in all three regions studied and exhibited two general ontogenic patterns. In the diencephalon and telencephalon NT-LI levels peaked at birth and E20, respectively, then declined, whilst in the ventral mesencephalon, where levels were approximately 25% of those in the diencephalon and telencephalon, NT-LI after an initial increase reached a plateau around E18, which was maintained through to P2.

The polyclonal NT antibody was N-termally directed and then recognised and measured the NT metabolites, NT-11 and NT-11, in addition to NT itself. Therefore, a High Pressure Liquid Chromatography (HPLC) method, utilising a method gradient from 30% to 60% over 30 minutes, was developed to separate these three peptides prior to measurement by a RIA of increased sensitivity (0.3 fmol/tube). The latter two techniques are thus presently being used to quantify the proportions of NT, NT-11 and NT-11 in foetal rat brain regions.
SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
CATECHOLAMINERGIC MEDIATION OF COCAINE-INDUCED INCREASE IN REGIONAL LEVELS OF bFGF mRNA. D. Mucio, J. I. Nocetti, and K. Gale. Departments of Pharmacology and Cell Biology, Georgetown Univ. Medical Center, Wash., DC. 19907.

The behavioral stimulant response produced by cocaine is known to show a long-lasting increase with repeated administrations. Such long term plasticity is believed to be the result of neurotrophic factors. We have previously shown that the mRNA encoding basic FGF (bFGF) is increased in selected brain areas after a single, prolonged cocaine exposure. In this study, we examined the neurotransmitter receptors that mediate this effect. Rats (450g) received 40 mg of cocaine over 8 h, after which they were sacrificed and bFGF mRNA was measured. Cocaine induced a 3.5-fold increase in bFGF mRNA in striatum, substantia nigra and frontal cortex. Pretreatment with haloperidol (3.3mg/kg) or chlorpromazine (20mg/kg) prevented the cocaine-induced increase in bFGF mRNA. However, pretreatment with either pinemide (2mg/kg), prazosin (1mg/kg), or a low dose of chlorpromazine (2mg/kg) did not attenuate the cocaine-induced effect on bFGF. Pretreatment with propranolol (20mg/kg) was likewise ineffective. It therefore appears that concurrent blockade of dopamine receptors and noradrenergic alpha receptors is necessary for preventing the induction of bFGF mRNA expression in response to cocaine. This suggests that cocaine may influence neurotrophic factor expression via either dopaminergic or alpha adrenergic mediated processes. Studies in progress with selective alpha blockers and selective dopaminergic receptor antagonists will more precisely identify the relative contribution of these receptors to the changes in bFGF mRNA levels that follow cocaine exposure.

There is evidence that thyroid hormone (TH) is required for the differentiation and maintenance of septal cholinergic neurons. However, well-documented TH-induced changes in TH deprivation of basal forebrain cholinergic neurons. In previous studies, chronic treatment with TH (0.5 mg/kg) induced an increase in TH-binding sites, but not the cortex, of aged rats (Giordano et al., 1992). Our interest was to determine whether the effects of TH on cholinergic cells are mediated through induced NGF. RNase protection analyses of NGF mRNA after acute systemic administration of various doses of either T3 or T4 revealed induction of NGF in the hippocampus and cortex, but not in the septal region of adult Sprague Dawley rats. Peak increases (approximately 1.5-fold) occurred at 3 h and 3.5pg/kg with T3 and T4, respectively. The effect of each hormone on NGF synthesis was shown to be stereospecific. TH induced BDNF as well as NGF in the cortex, and the induction of both neurotrophins was sustained for at least 30 h. Evaluation of TH in the inmnia fornix lesion model of basal forebrain cholinergic neuronal degeneration will also be discussed.

REGULATION AND POLARITY OF NEUROTROPHIN SECRETION. Laura J. Goodman and Franz Hufn. Department of Neuroscience, University of California, San Francisco, CA 94120.

The neurotrophins, BDNF and NT4/5 are factors that regulate the growth and survival of selected populations of peripheral and central nervous system cells. In this study the regulation and polarity of neurotrophic factor secretion was investigated. Analysis of expression of either BDNF or NT4/5 following expression in the pheochromocytoma-derived cell line, PC12, resulted in the constitutive secretion of immunoreactive proteins migrating at a molecular weight identical to mature BDNF and NT4/5. In the presence of KCl (100mM), secretion of NT4/5 from PC12-transfected cells increased 10-fold as determined by radio/binding/imunoprecipitation and western-blot analysis. This indicates that the protein is primarily expressed by a regulated pathway of secretion. As an initial approach to understanding the polarity of neurotrophic factor secretion, the release of BDNF and NT4/5 was investigated in the polarized epithelial cell line, MDCK. Previous studies have determined that many of the same protein sorting mechanisms exist in MDCK cells as do in polarized hippocampal neurons in vitro. Cells expressing BDNF or NT4/5 were grown on transwell inserts to assess the potential for differential secretion occurring high electrical resistance. Under these conditions, 60-90% of the BDNF secreted from transfected MDCK cells was released from the apical domain, whereas NT4/5 was secreted from both basolateral and apical domains. This suggests that BDNF may be released primarily from the apical domain in polarized hippocampal neurons. We are currently testing our hypothesis in transfected hippocampal neurons grown in vitro.

ALTERNATE STRIATAL NEUROTROPHIC MGF LEVELS IN HYPOTHYROID WEAVER MICE MARIANNE BLUM*, Emilie Garasco, Nancy Gomez, and Shoshana Weidenthal. Fishergen Research Center for Neurobiology, Mount Sinai School of Medicine, New York, NY 10029.

The degeneration of nigrostriatal dopamine neurons that occurs in the weaver mutant mouse can be viewed as failed postnatal development. For example, neuronal death is a consequence of normal transition from a primarily patchy innervation to a more diffuse innervation of the striatum during the first weeks of postnatal life. It is possible that insufficient levels of target-derived neurotrophic support is responsible for the abnormal dopaminergic neuronal development and degeneration. Therefore, we measured the levels of the mRNAs encoding two putative dopaminergic trophic factors using a quantitative nuclelease protection assay. Unexpectedly, we observed that while the levels of BDNF and GDNF mRNA levels are elevated in the weaver mutant striatum relative to controls (p<0.05 and p<0.01, respectively), we did not observe a change in the weaver striatum appears to develop abnormally, and is also body growth is stunted and their eyelid opening is delayed. Since body growth rate and timing of eyelid opening are regulated by thyroid hormone, we hypothesize that weaver mice are hypothyroid. Using radioimmunopurification, we determined that the mutant mice have significantly lower thyroid hormone (T4) levels during the third postnatal week of life (p<0.001). This corresponds to the time when the development of mutant dopaminergic neurons is arrested. We speculate that the reduction in thyroid hormone, which is a potent regulator of brain development, could account for altered trophic factor mRNA levels and ultimately altered dopaminergic neuronal development.

NGF RECEPTOR low affinity IMMUNOSTAINING IN CHOLINERGIC NEURONS DURING ADULT HYPOTHYROIDISM. J. C. Cabib, S. E. Alte, J. L. Landscape, and D. R. Levi-Monzon. Inst. Of Human Physiology, University of Cagliari; SInst. of Neurobiology, CNR, Rome, Italy; Inst. Otolarygol., University of "Milano" and #Monza, Italy.

Adult hypothyroidism is characterized by neurochemical abnormalities involving neurotransmitters, neuropeptides, neuronal proteins and also trophic factors. Several clinical and experimental data suggest that the cholinergic synapses of the basal forebrain are sensitive to the peripheral levels of thyroid hormones. In this paper we investigated the NGF receptor low affinity (LNGFR) immunostaining in the normal and hypothroidic forebrain. LNGFR was labeled with a monoclonal antibody (clone IgG192, generously supplied by E.M. John.). The staining intensity was measured by means of computerized microdensitometry. In colchicine untreated rats, we found a significant increase of LNGFR-like immunostaining in the basal forebrain neurons of hypothryoid rats. The colchicine treatment increases an increase of LNGFR expression in these brain area which is not different in hypo- and hyperthyroid rats. These data confirm an effect of thyroid hormone on neurons during adulthood also in extrahypothalamic areas and they suggest a possible role of thyroid hormone in aging brain quality and cognitive performance.
536.13  BDNF mRNA LEVELS IN THE CHICK OPTIC TECTUM ARE REGULATED BY NEUROTHERMINDS DURING SYNAPTGENESIS. K.-H. HIEZERG* AND Y.-A. BARDE. Dept. of Neurobiochemistry, Max Planck Inst. for Psychiatry, Am Klopferspitz 18a, D-81829 Martinsried, Germany.

We previously reported that BDNF mRNA is expressed in the visual system of the chick embryo. During the earliest time of target encounter, BDNF mRNA levels are regulated in the tectum by electrical activity of the retinatinal ganglion cells (RGC). BDNF mRNA levels increased following optic axonal transection, intratral tracer application, and the GABA A receptor agonist muscimol. Whether the cholinergic contribution in the regulation of the BDNF gene is due to an activity-dependent influence is currently under investigation.

BDNF mRNA is not only detected in the tectum, but also in the retina, and at E11, comparable levels are observed. Using BDNF-peptide antibodies, we observed a BDNF-like immunoreactivity in the retina, but not in the tectum. The most prominent expression was in the ganglion cell layer, but not all ganglion cells were labeled. Suprisingly, following optic axal transection, the levels of this BDNF-like immunoreactivity did not seem to be dramatically reduced when compared to the control retina. We are currently investigating whether BDNF is actually synthesized in RGC or taken up from their surrounding cells in the retina.

536.15  SIGNALS THAT INDUCE EXPRESSION OF LEUKEMIA INHIBITORY FACTOR (LIF) IN RAT SUPERIOR CEREBRAL GANGLION (SCG) AND THEIR EFFECTS AFTER AXONAL TRANSECTION. Y. Sun, S. C. Lardis and R. E. Zigmond. Department of Neurosciences, School of Medicine, Case Western Reserve University, Cleveland, OH 44106.

We previously have shown that LIF contributes to the axonally induced neurotrophic peptide expression in rat and mouse superior cervical ganglia (SCG). The expression of LIF itself is also induced in SCG with 2h after axotomy or explantation. The initial time course of LIF mRNA induction (from 30min to 6h after nerve axotomy) is similar in vivo and in vitro, suggesting that the two systems possess common early LIF-inducing signals after axonal transection. However, there is a difference in the level of LIF mRNA levels between the two systems. LIF mRNA levels start to decline 12h after axotomy in vivo, while they remain elevated until 48h in culture. To examine the early signals responsible for the rapid induction of LIF mRNA after nerve transection, we used short term explant cultures. Defined medium conditioned for 30min by freshly dissected adult rat SCG (SCM) contain LIF mRNA, similar peptide expression when used to direct isolated neuronal SCG cultures with non-neuronal cells. Like SCM, defined medium conditioned by portions of the three major nerve trunks of the SCG for 3h (NCM) also included LIF mRNA levels in dissociated SCG cultures. Further, LIF mRNA induction was observed in these nerve pieces themselves, suggesting that Schwann cells along the axons are the sources of LIF production after nerve lesion. The LIF-inducing activity of both SCM and NCM was present in a >10% fraction and its appearance did not require new protein synthesis. SCM and NCM induced peptide expression in SCG of normal, but not LIF-deficient, mice, suggesting that the effect of SCM and NCM on peptide expression is mediated by LIF. Based on these observations, we hypothesize that when SCG are axotomized, an existing molecule is activated and/or released by transected axons and possibly by axonotomized neuronal cells as well. This molecule in turn causes local Schwann/sensitel cells to produce LIF which participates in regulating neurotrophic peptide expression in SCG neurons.

536.16  INCREASES IN VASOACTIVE INTESTINAL PEPTIDE (VIP) LEVELS IN CULTURED RAT SUPERIOR CEREBRAL GANGLION (SCG) CAN BE REDUCED BY AN ADENYLATE CYCLASE INHIBITOR. R. E. Mohler* and R. E. Zigmond. Department of Neurosciences, Case Western Reserve University, School of Medicine, Cleveland, OH 44106.

The expression of a number of neurotransmitter changes after axonal injury, possibly in the shift in the priorities of these neurons from synaptic transmission to maintenance and regeneration. For example, VIP is normally present in extrinsic trophic and trophic modulatory functions for rat SCG but levels of this peptide increase dramatically after SCG are placed into explant culture. The gene that encodes for VIP contains a cAMP response element that is required for cAMP-regulated transcription. Ganglionic VIP levels are relatively low under normal conditions and do not significantly change in short-term cultures. Previously, we have shown that agents which can affect intracellular calcium levels (for Example, VIP-soluble and quinolnol) are also capable of increasing VIP-like immunoreactivity. We now demonstrate that the increases in VIP levels produced by the addition of cAMP-dependent agents to cultured SCG can be prevented by the addition of an adenylyl cyclase inhibitor, 2'-5'-dideoxyadenosine (DDA). DDA (1 mM) reduced elevations in both CAMP and VIP levels by greater than 60% in SCG cultured in medium containing cAMP-depleting agents or in control medium alone. Histological examination was performed to determine if DDA adversely affected the health of the neurons. No apparent differences in neuronal morphology were found between SCG cultured in control medium or in medium containing DDA for 48 h. An increase in the concentration of DDA to 2 or 6 mM was effective in reducing VIP levels measured in the presence of cAMP-depleting agents by 85% or 95%, respectively. These data support the observations that VIP levels in sympathetic neurons can be regulated by alterations in cAMP levels. Furthermore, they suggest that the increase in VIP that occurs by placement of the SCG into culture with control medium is dependent on the maintenance of basal cAMP levels.

536.17  CHANGES IN GPA LEVELS IN CILIARY GANGLION TARGETS DURING AND AFTER THE CELL DEATH PHASE. P. M. Acosta and H. Y. J. H. Ch. Nathl. Department of Cell Biology and Anatomy, Oregon Health Sciences University, Portland, OR 97201.

During normal development of the avian ciliary ganglion, the neurons become dependent upon their targets in the eye for survival. The process begins after the birth and continues until E14, by which time half of the original neurons present have died off. Production by the targets of specific neurotrophic factors may mediate the level of neurons which ultimately survive. Growth promoting activity (GPA), a 21 K protein originally purified from adult chicken sciatic nerves and E15 chick eyes, is one such candidate trophic factor. In order to determine what role GPA plays in ciliary ganglion survival, the cellular location and timing of GPA expression in ciliary target was investigated by immunocytochemical, biochemical, and western blot analysis. Antibodies prepared to a purified and highly active form of recombinant GPA detected a 21.6 K protein in chordal-rectum extract on western blots. The intensity of the bands extrapolated to the neurogenic age. Immunocytochemically, the staining of isolated chordal layers revealed that GPA immunoreactivity was localized to smooth muscle cells, and in the anterior portion of the eye. GPA-like immunoreactivity was localized to muscle fibers of the ciliary body. Both of these cell populations are normal targets of CG neurons. GPA expression was first detectable at E10, and increased through the end of the cell death phase at E14. GPA expression continued to increase in the cell phase of the eye, possibly indicating a continued dependence of the neurons for GPA. To test this possibility we are performing neuronal survival assays on various age ganglia to determine the age dependence of the GPA. We are also comparing GPA-like biological activity before, during, and after the cell death phase in an effort to correlate GPA levels with neurotrophic activity in target extracts. Supported by NS25787.

536.18  KOADEIC ACID POTENTIATES AND GENBINEST INHIBITS THE PLATELET-ACTIVATING FACTOR (PAF) ENHANCEMENT OF INDUCIBLE PROSTAGLANDIN SYNTHASE. P.K. Mukherjee, D.J. Smith and N.G. Bazen*. LSU Neuroscience Center, LSU Medical Center, New Orleans, LA 70112.

PAF accumulates in brain during ischemia and convulsions. TS10/PGS-2 is a primary response gene encoding the inducible form of prostaglandin synthase. In the presence of retinoic acid, a PAF-dependent (1-50 nm) activation of luciferase reporter constructs driven by regulatory regions of the TS10/PGS-2 gene transfected into the neuroblastoma cell, NG 10-15 was observed (N. Bazen et al., Proc. Nat. Acad. Sci., in press). Here we report that when DOTAP is used for transfection of TS10/PGS-2 promoter luciferase constructs, PAF elicits a 5- to 10-fold activation in neuroblastoma cells and CV-1 cells. Deletion studies restrict the major PAF cis-acting response element of the TS10/PGS-2 gene to a 70-nucleotide sequence as an intracellular inducer of TS10/PGS-2 expression. Okadec acid (10 ng/ml) elicited a 3-fold potentiation of the PAF effect at 1000 ng/ml, the other hand, inhibits the PAF-induced effect. These results strongly suggest that, in the intracellular pathway of signal transduction between the membrane-dense lipid mediator PAF and the modulation of gene expression of TS10/PGS-2, there is a necessary step that comprises protein tyrosine kinase-protein tyrosine phosphatase. These regulatory events may play a role in neural plasticity responses such as long-term potentiation and epileptogenesis (NINDS NS23002).

We have previously reported that neurotrophin (NGF, BDNF, NT-3 and NT-4/5) mRNA expression is limited to developing and adult optic nerve. Developmental decreases in trkB and especially in trkC expression were also shown by reverse transcriptase-polymerase chain reaction (RT-PCR) using primers that amplified the extracellular domains (Elkebess et al. 1993, Abstr. Soc. Neurosci., 19, 251). To investigate whether mRNA levels detected by RT-PCR are sufficient for the synthesis of neurotrophin and tk proteins, and to determine whether glia express full-length trk receptors, we have performed immunocytochemical studies utilizing antibodies specific for neurotrophins and for the extracellular or intracellular domains of trkB, trkC and trkD (kindly provided by Dr. D. Kaplan, NCI, Frederick, MD).

BDNF, NT-3 and NT-4/5-like immunoreactivities were detected in glia of developing and adult optic nerve. Antibodies to the extracellular and intracellular domains of trkD also labeled cells in the optic nerve, suggesting that glia express full-length forms of the receptors. These findings were confirmed by RT-PCR, using primers that amplified the intracellular trkD domains. The number of cells expressing trkB and trkC in the postnatal day 10 optic nerve appeared to be higher than in the adult, supporting our previous findings. Our studies suggest that neurotrophins are elaborated by optic nerve glia and that responsiveness in glial cells may be mediated through the full-length receptor. Further studies are in progress to determine which glial subtypes express neurotrophins and trks (This work was supported by NIH grant PO1 HD 23315-06A1).

357.3 NERVE GROWTH FACTOR RECEPTOR GENE EXPRESSION IN HUMAN BLOOD. B.D. Kittur*, I. Song, H. Endo, W. Adler. National Institute of Aging, 2940 Eastern Avenue, Baltimore, MD 21224 (further address at New Point VA Medical Center, Perry Point, MD 21902).

Nerve growth factor modulates the immune function as a consequence of binding to the nerve growth factor receptor (NGF-R). Therefore, we hypothesized that NGF-R will be made by the immune system in the peripheral blood lymphocytes. Northern blot analysis of mRNA from human peripheral blood lymphocytes was performed using cDNA probe for low affinity - NGF-R (p75 NGF-R). We show that p75 NGF-R mRNA is present in human peripheral lymphocytes and expressed maximal levels at 14 hours after stimulation with phorbomethyltin. Also, we shows that p75 NGF-R did not change with the aging process in peripheral blood lymphocytes in human volunteers.

357.5 HIGH MOLECULAR WEIGHT NGF-LIKE ACTIVITY IN THE RAT PITUITARY. S. Soinila*, J. Lakshmanan. Dept. Anatomy, PO Box 9, 00014 University of Helsinki, Finland.

We previously reported evidence for NGF immunoreactivity and biological activity in the rat pituitary gland (PG). Since the biological properties of the PG NGF differed from those reported for the rat iris muscle, we examined the molecular properties of the rat PG NGF-like material and compared it with those found in the mouse peripheral sympathetic ganglia (PG). Homogenized PG tissue was subjected to immunoblotting using antisera against mouse 8-NGF. For bioassay studies, PG homogenate supernatants were subjected to ultrafiltration and fractions with MW > 30 kD were tested for neurite outgrowth response from newborn superior cervical ganglion explants. Mouse 8-NGF antisera identified two proteins with MW 53 kD and 73 kD. The 13 kD band was absent in the PG. PG ultrafiltrates containing proteins of MW > 30 kD produced neurite outgrowth from newborn ganglia. Based on our data, we suggest that 53 kD and 73 kD NGF prohormones and that they represent the post-translationally modified products of a short and long NGF prohormone transcripts, respectively.

357.4 DIFFERENTIAL GENE EXPRESSION OF TROPHIC FACTORS BETWEEN EMBRYO AND EXTRAEMBRYONIC MEMBRANES IN CULTURED HUMAN PLACENTAL CELLS. W. Glazer*, D. E. Brennan, N. Jain, and J. M. Hill. Lab. of Dev. Neuroendocr., NICHD, NIH, Bethesda, MD, 20892

Whole mouse embryos cultured have been used to examine the effects of trophic factors on embryonic growth and development in the absence of maternal influences. Exogenous application of vasopressin internal peptide has been shown to increase relative size, protein and DNA content, and aminopeptidases activity (Amer. J. Anat., 1993, 362:155-158). In an effort to characterize the underlying trophic milieus in which these embryos grow, RT-PCR techniques were used to determine the presence and relative amounts of mRNA for known neurotrophic and hormonal factors. Mouse embryos (20-24 somites), with intact extraembryonic membranes, were cultured in 75% human serum and 25% rat serum for 6 hours. At the end of this time, embryos were detached from the membranes, and total RNA was isolated from each embryo and corresponding membranes separately. Equal amounts of RNA were reverse transcribed, and these DNA products used as templates in PCR reactions. Specific PCR primers were designed to detect the following mouse mRNA: basic brain-derived growth factor (BDNF), leukemia inhibitory factor (LIF), transforming growth factor β (TGFβ), basic fibroblast growth factor (bFGF) and insulin-like growth factor 2 (IGF-2). Each primer pair gave a single band of the expected size. There was no difference in actin relative to total RNA between embryos and membranes. Although present in both, there was no significant difference in IGF-2 gene expression relative to actin or total RNA between embryos and membranes. TGFβ was also present in both, and tended to be more abundant in membranes, but the difference was not significant. NFG and BDNF were both significantly higher (> 50 fold) in embryos than in membranes relative to actin and total RNA. LIF was significantly higher (> 20 fold) in membranes than in embryos relative to actin.

(Restricted research supported by the Canadian MRC)

The brainstem locus ceruleus (LoC) participates in learning, memory, and other behavioral functions through its regulatory effects on input responsivity of its target neurons, stimulation of metabolic processes, and interactions with other neurotransmitter systems including the septohippocampal cholinergic system. In the rat, some LoC neurons express BDNF mRNA, but not NGF, whereas in humans, BDNF mRNA is found in the LoC, but NGF is not. Further, the LoC cells of rats are similar to LoC cells with increased number of TH+ neurons. In humans, loss of LoC neurons occurs during aging and is exaggerated in Alzheimer's disease (AD). We examined BDNF mRNA expression in noradrenergic neurons of the human LoC using in situ hybridization with an S32-labeled riboprobe synthesized from a 477 bp EcoRI/PstI fragment subcloned from a human BDNF cDNA (gift of K. Jones and L. Reichard). Fresh frozen brainstem were obtained at autopsy from 3 adult human brains (1 AD, 1 dementia with gliosis, 1 control) and from a 20-week fetal human specimen following elective abortion. In adult hybridization was performed on 20μm cryosections using 2 pmol/ml labeled antisense or sense riboprobe and tissues examined by film and emulsion autoradiography. Expression of BDNF mRNA was found in noradrenergic neurons of rats. No expression was found when BDNF mRNA was examined in noradrenergic neurons of all 3 adult human brains (1 AD, 1 dementia with gliosis, 1 control) and from a 20-week fetal human specimen following elective abortion. These results suggest that BDNF in the human LoC may have a functional autocrine or paracrine role during development of the human LoC. Supported by grants from the Alzheimer's Association [S Bornstein PI] and NIA (UW ADRC [C Martin PI], and by the UW Fetal Tissue Program [A Fastel PI].

TRANSIENT EXPRESSION OF BDNF mRNA IN RAT LOCUS COERULEUS FOLLOWING ACUTE 6-OHDA LESIONS OF THE NIGROSTRIATAL PATHWAY. S. Numan* and K.B. Serogy. Department of Anatomy & Neurobiology, University of Kentucky, Lexington, KY 40536.

In vitro studies indicate that certain members of the neurotrophin family of trophic factors can support the survival of, and are neuroprotective for, populations of catecholaminergic neurons. In the present study, the expression of various neurotrophic factors in rat brain and neurotrophin-3 (NT-3) mRNAs in neurons of the locus coeruleus was examined in vivo following acute lesions. The animals received a single injection of 6-OHDA (10 mg/kg; i.p.) or vehicle by following survival times of 4 hr, 8 hr, 16 hr, 24 hr, 3 days, 4 days and 8 days. Cryostat-prepared tissue sections through the locus coeruleus were subsequently processed for the in situ hybridization localization of BDNF, NT-3 and TH mRNAs using 35S-labeled cRNA probes. BDNF mRNA was barely detectable in locus coeruleus in normal, control rats and in vehicle untreated rats. After 6 hr or 16 hr, a substantial increase in hybridization density for BDNF mRNA was observed in locus coeruleus which peaked at 24 hrs and gradually returned to control levels by 8 days post-injection. TH mRNA in the nucleus exhibited a similar transient elevation, in agreement with previous reports. The data indicate that depletion of catecholamines induces a transient increase in BDNF mRNA expression in locus coeruleus neurons and raise the possibility of BDNF involvement in neurological disorders associated with the locus coeruleus, such as depression. Supported by the National Parkinson Foundation and the Scottish Rite Schizophrenia Research Program.

537.8
INCREASED EXPRESSION OF BDNF mRNA IN ADULT VENTRAL MIDBRAIN FOLLOWING ACUTE 6-OHDA LESIONS OF THE NIGROSTRIATAL PATHWAY. S. Numan* and K.B. Serogy. Department of Anatomy & Neurobiology, University of Kentucky, Lexington, KY 40536.

In vitro studies have demonstrated that BDNF and NT-3 support the survival of fetal rat mesencephalic dopamine neurons. Furthermore, several studies have provided evidence that BDNF and neurotrophin-3 (NT-3) mRNAs in dystrophic neurons were expressed in response to a variety of insults. In the present study, we have examined the expression of BDNF and NT-3 mRNAs by cultured neurons for cultured dopaminergic neurons undergoing various toxic insults. In vitro, adult dopaminergic neurons, which express BDNF and NT-3 mRNAs may initially respond to various toxic insults by altering the expression of neurotrophin mRNAs. To examine this possibility, adult rats received unilateral injection of 6-OHDA or vehicle into the ascending medial forebrain bundle. Following various survival periods (8, 16, 48 and 120 hrs), in situ hybridization of 35S-labeled cRNA probes for BDNF, NT-3 and TH mRNAs was performed in midbrain sections. After 8, 16 and 48 hrs, an increase in the hybridization density for BDNF mRNA was observed in the substantia nigra and ventral segmental area ipsilateral to the 6-OHDA injection, as compared to the uninjected control side. In contrast, no alterations in the hybridization density for NT-3 or TH mRNAs were observed at these time points. After a 120 hr survival period, there was a decreased hybridization density for TH, BDNF, and NT-3 mRNAs in the ventral midbrain ipsilateral to the 6-OHDA injection, as compared to the control side. No alterations in the hybridization density for BDNF, NT-3 or TH mRNAs were observed in the ventral midbrain of rats that received unilateral injections of vehicle. These data indicate that there was an early transient response by BDNF mRNA in the ventral midbrain to the neurotoxin 6-OHDA, which may suggest a role in vivo for this neurotrophin in neuronal protection. Supported by the National Parkinson Foundation and the Scottish Rite Schizophrenia Research Program.

537.9

We examined the expression of endogenous BDNF in adult rat brains using a BDNF specific antibody by immunohistochemistry. We found distinct BDNF immunoreactivity (IR) in many structures which are known to be BDNF mRNA positive from previous studies. These structures included neocortex, piriform cortex, hippocampal formation, claustrum, supramammillary region and other thalamic nuclei, some hypothalamic nuclei, substantia nigra, and neurons in many brain stem structures. In the hippocampal formation, very heavy BDNF IR was found in the granular layer of dentate gyrus and pyramidal and radiatum layers of CA3 and CA4, but not in CA1 and CA2 regions of hippocampus. However, with kainic acid treatment (4p), which is known to upregulate BDNF mRNA, BDNF IR was readily detected in CA1 and CA2 regions. Staining was also seen in areas not previously reported as BDNF mRNA positive. These included the bed nucleus of stria terminalis, dorsal endopiriform nucleus, lateral septum, medial preoptic nucleus, olivary pretectal nucleus, lateral paragiganto-cellular nucleus, and nucleus ambiguus. The results of this study suggest BDNF may play a broad role in the adult central nervous system.

537.11
STRUCTURE, EXPRESSION AND FUNCTION OF RAT GLIAL CELL LINE-DERIVED NEUROTROPHIC FACTOR (GDNF). M. Trojan1, M. Pedel1, L. Areval1, T. Timmus2, N. Lindvall3 and E. Ljungberg1. 1Laboratory of Molecular Neurobiology, MBB and 2Department of Clinical Neurobiology, Karolinska Institute, S-17177 Stockholm, Sweden.

A cDNA encoding rat GDNF was cloned by RT-PCR from P1 rat brain RNA. An alternatively spliced variant (termed GDNFp), similar to that described by Schaer et al. (1993), with a 78 bp deletion in the prepro region was also cloned. Both mRNAs were expressed in developing striatum, cerebellum and some peripheral organs as assessed by in situ hybridization. GDNF mRNA expression was developmentally regulated and appeared to be altered by neuronal survival. The cellular localization of GDNF mRNA expression during rat development is being studied by in situ hybridization.

Western blotting and immunoprecipitation analysis with anti-GDNF antibodies generated against predicted loop regions of the molecule showed that the detection decreased with age. This decrease was correlated with GDNF protein produced by transiently transfected COS cells. Recombinant GDNF produced in baculovirus-infected insect cells was correctly processed and glycosylated. This protein purified to homogeneity promoted survival and neurite outgrowth from embryonic sympathetic ganglia with a time-course and morphology clearly different from nerve growth factor, suggesting activation of distinct signalling pathways. Genetically engineered fibroblast cell lines producing high levels of GDNF are currently being used to investigate the function of GDNF in vivo.

537.12

GDNF is a newly described member of the TGF-b family isolated from the rat glial tumor Oligo line. GDNF promotes survival, dopamine uptake, and neurite outgrowth of embryonic dopaminergic (DA) neurons in vitro. We have used a semi-quantitative RT-PCR with primers specific to GDNF to study the development of GDNF expression in CNS and peripheral tissues of embryonic rat on gestational days E13.5 and E18, neonatal rat on postnatal days P0 and P10 and adult rat. GDNF mRNA is expressed in all major regions of the CNS; however, the level of expression is both region and age dependent. The highest levels of GDNF mRNA are expressed in P0 spinal cord and in P0-10 striatum. The lower levels are expressed in brainstem (including ventral mesencephalon, which contains the substantia nigra), cerebellum, diencephalon and telencephalon. GDNF mRNA is also expressed in E10-12 limbs, E0-12 heart, and E12-16 eye. GDNF expression is higher than in brain, particularly in embryonic limb bud, kidney and gut; neonatal kidney, gut, lung and testis; and adult lung, testis, and heart. GDNF mRNA is also present in the head, torso and chorion/umbilical of the E11.5 embryo.

These observations suggest that GDNF may be a target derived and/or locally acting neurotrophic factor for DA neurons of the substantia nigra, as well as for other classes of CNS neurons. Moreover, GDNF may play an early role as a neurotrophic factor in the PNS or serve as a growth factor for non-neuronal cells. (Supported by the Markey Charitable Trust & NIH grant ES01347). 1 L.-F. H. Liu et al., Science 260, 1130-2 (1993).
ISOLATION OF MULTIPLE GDNF TRANSCRIPTS FROM THE C57BL/6J GLIOMA CELL LINE. M. D. Spence, A. Y. Deutch, and E. Lolis. Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

Glioma cell line-derived neurotrophic factor (GDNF) is a newly discovered member of the transforming growth factor-β superfamily which exhibits neurotrophic effects on midbrain dopamine neurons both in vitro and in vivo. GDNF was originally isolated from the B49 glioma cell line. We have analyzed two other glioma cell lines, the rat C6 glioma and the human H6863 glioma, for expression of GDNF. Polyadenylated mRNA was isolated from these cell lines and subjected to RT-PCR amplification for first strand cDNA synthesis. Polymerase chain reaction was used with primers against regions near the initiating methionine and terminal stop codon to amplify the sequence. Two bands were seen from C6 cells when the PCR reaction products were analyzed by agarose gel electrophoresis and visualized with ethidium bromide. In contrast, no bands were present in the H6863 PCR reaction.

These results indicate that expression of GDNF is not limited to B49 cells but also occur in C6 cells. In addition, the C6 cells express two GDNF transcripts, which has not been previously reported. Further characterization of these transcripts is in progress.

S88.1 THE NEUROTROPHIC SYSTEM OF BASIC FGF OVEREXPRESSING TRANSGENIC MICE. F. Ekenstein*, C. Hicks
Dept. of Cell Biology and Anatomy
Oregon Health Sciences University, Portland, OR 97201

Fibroblast growth factors (FGFs) in vitro exhibit a wide variety of neurotrophic and mitogenic effects. Nine members of the FGF multigene family are currently known. The adult central nervous system contains very high levels of acidic and basic FGF (aFGF and bFGF), molecules that lack hydrophobic signal peptide sequences and are not efficiently released from normal healthy cells. Consistent with these observations is our hypothesis that aFGF and bFGF function as initiators of injury responses in CNS.

In order to test this hypothesis we have obtained (a generous gift from Drs. D. Coffin and R. Flikkervis) transgenic mice that overexpress human NGF. Initial characterization of these animals showed a highly significant increase in bFGF levels in the CNS of transgenic animals. No gross morphological abnormalities were detected in the brains of these animals, and highly preliminary experiments did not show marked changes in the immunohistochemical distribution of neuropeptides and neurotransmitter synthesizing enzymes.

S88.2 REGULATION OF RAT BDNF GENE PROMOTERS IN TRANSGENIC MICE. T. Timmers*, U. Lendvai*, H. Munkwitz, E. Aarburg and M. Heilstett, Lab. of Molecular Neurology and Dept. of Developmental Biology, Karolinska Institute, 17177 Stockholm, Sweden.

The rat brain-derived neurotrophic factor (BDNF) gene consists of four 5' exons linked to separate promoters and one 3' exon encoding the prepro-BDNF protein. Transgenic mice have been generated, that express bacterial chloramphenicol acetyl transferase (CAT) under the control of six different promoter constructs of the BDNF gene. When fused separately to bacterial CAT gene the upstream regions of the 5' exons of rat BDNF gene were linked to the transplant expression in tissues that partially overlapped with the endogenous sites of particular BDNF promoter activities. High-level expression of reporter gene in correct neuronal populations of BDNF intron-exon splice junctions and 3'UTR in the constructs. The genomic regions responsible for the in vivo upregulation of BDNF expression after kainic acid-induced seizures and KCI-induced spreading depression were mapped. We also report that 5.5 kb of BDNF promoter IV sequence directs axotomy-induced expression of reporter gene in the sciatric nerve of transgenic mice in a manner similar to the regulation of endogenous BDNF mRNA in the same paradigm. These BDNF promoter constructs provide useful tools for targeted expression of neurotrophic factors to study their function and regulation in central and peripheral nervous system.

S88.3 A CAUCAL responsive PROMOTER IN THE RAT BDNF GENE. J.E. Bishop*, G.L. McDonald and B.D. May, Department of Pharmacology Unit, Experimental Therapeutics Branch, NINDS, and Department of Physiology, USUHS, Bethesda, MD 20882.

Transcription of the rat brain-derived neurotrophic factor (BDNF) gene results in multiple transcripts containing at least five alternate first exons that are separately spliced to a common protein coding exon. Since Ca2+ is a prominent second messenger involved in the regulation of BDNF expression, rat C6 glioma cells were incubated with BDNF, exposed to the Ca2+ ionophore A23187 and BDNF mRNA levels were measured by reverse transcription PCR. The cells were incubated with A23187 (5 X 10-5 M) or vehicle for 1 hour, rinsed, incubated another 3 hours in culture medium and total RNA was extracted. PCR results indicated that BDNF coding exon containing transcripts were elevated approximately 9-fold compared with vehicle treated controls. Inclusion of the RNA polymerase inhibitor actinomycin D (10 uM) in culture medium led to significant decrease in both basal and Ca2+ stimulated BDNF mRNA concentrations indicating that, in C6 cells, BDNF expression is regulated primarily at the level of transcription. To identify which of the multiple promoters in the BDNF gene is transactivated by increased calcium, the effects of A23187 on the expression of each of the alternate 5' exons was investigated. Of the three alternate 5' exons expressed in C6 cells, only one (exon 1E) increased significantly (approximately 4-fold) which is less than the response of the common coding exon measured in the same samples. Additional calcium-responsive promoters directing expression of the BDNF gene not detected in the present investigation may account for this observation.

The rat brain-derived neurotrophic factor (BDNF) gene has been shown to contain four short 5' exons (Exons III-V) and one 3' exon (Exon V) that encodes the mature BDNF protein. BDNF mRNA transcripts containing the different 5' exons can be differentially induced in brain following seizure although the mechanisms by which this occurs have yet to be elucidated. In the present study, the effect of anisomycin, a protein synthesis inhibitor, on the expression of Exon I and III mRNAs following a stimulated epileptiform afterdischarge of hippocampal slices was analyzed in adult rats. Two groups were used: 1) single hippocampal afterdischarge (AD) via perforant path stimulation (10 Hz, 4-6 sec) and sacrificed 1.5 hrs post-AD; 2 anisomycin (150 uM/kg, s.c.) injected 30 min prior to and 1 min after following AD, and sacrificed 1.5 hrs post-AD; 3) 2 injections of anisomycin 1 hr apart and sacrificed 1 hr after last injection; 4) naive controls. Changes in BDNF exon mRNA content in the granule cells were assessed by in situ hybridization using 35S-labeled cDNAs. Following AD, Exon I mRNA was increased 10 to 30-fold above control levels in the granule cells. This effect was reduced by 82% with anisomycin. Like Exon I, Exon III mRNA was markedly increased following AD to approximately 7-fold above control levels. However, the effect of AD on Exon III expression was not reduced by anisomycin. Anisomycin alone had no effect on either Exon I or III. The present results show that Exon III expression can be increased in the presence of protein synthesis inhibitors suggesting that this exon, as opposed to Exon I, is directly induced by physiological activity without intervening protein synthesis (i.e., as an immediate-early gene). The presence of distinct mechanisms regulating the transcription of the 5' exons within one cell type suggests each may be induced under different circumstances. Supported by NS28748 to C. G., EPA & Abbott Labs award to J. L. and Mayo Foundation to P. I.

S88.5 Identification of an Inducible Promoter in the Nerve Growth Factor Gene that Initiates Transcription at exon 5. MM Racker, P. J. Mason, M. Johnson, B. V. Siegel*, M. Lindik, Marion Merrell Dow Research Institute, Cincinnati, OH 45215.

NGF has been demonstrated to facilitate neurite outgrowth, rescue neurons from injury, and prevent programmed cell death. However, the therapeutic potential of NGF is limited by pharmacological difficulties common to many multimodal pharmaceutical agents. This difficulty can be circumvented by identifying compounds which facilitate endogenous transcription of NGF in the brain. Thus, we sought to determine the site of all pharmacologically inducible promoters in the NGF gene using a differential analysis based on semi-quantitative reverse transcription PCR. L929 cells were serum deprived and NGF was induced by treatment with PMA and calcitriol (1,25-dihydroxy-vitamin D3). Of the 4 major transcripts previously identified in mouse (Mot Cell Biol, 7:3057,67), a 2.5 - 4 fold increase in transcripts initiated at exon 1 was noted in cDNA from cells induced with PMA and calcitriol, confirming the previous demonstration of a promoter region near exon 1 (Mot Brain Res, 15: 67,50). In addition, we also noted a 3 - fold increase in cDNA transcripts initiated at exon 3, suggesting a second, previously unidentified inducible promoter in this region. Sequence analysis revealed a consensus HRE in the 3' region of exon 3 which contains increased esterase forming sequences. In conclusion, these studies demonstrate a second inducible promoter in the NGF gene near exon 3 that could be targeted for therapeutic intervention.

S88.6 PRODUCTION AND PROCESSING OF THE NGF FAMILY OF NEUROTROPHIC FACTORS. L. Llamas*, W. Zhu, Q. Luo, L. Stasiak and M. Fahmy, Department of Biomedical Sciences, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

The neurotrophic factors NGF, BDNF and NT-3 are translated as pro-pre peptides which require proteolytic processing at dibasic amino acid residues to attain their mature, biologically active forms. Little is known about the processing of the pre-pro forms of the neurotrophins. The ability of fibroblast NGF, and the presence of related enzymes in human brain, suggest these serine proteases may play a role in neurotrophic factor processing. The study of neurotrophic factor processing has been hindered by the lack of sufficient substrates for analysis. We report here the production of quantities of pre-pro and mature neurotrophic factors sufficient for processing studies.

Proteasome were constructed expressing cDNAs for NGF and NT-3 as well as PC2, a member of the prohormone convertase family of proteases related to furin. The resultant recombinant viruses were used to infect S9 fibro cells, and both mature and pro-pro trophic factors were identified on SDS-PAGE gels and analyzed by Western Blotting. The biological activities of the neurotrophins were confirmed in neurite outgrowth assays using neonatal mouse SCG and DRG neuronal cultures. Expression of PC2 was confirmed by Western blotting and protease assays using synthetic substrates.

Coinfections were carried out using NGF and NT-3 recombinant virus along with PC2 retrovirus. This could induce neurotrophic factor in cell lines. The extent to which PC2 could enhance processing was determined by photographic analysis of the bands from the Western Blots. The NGF and PC2 cotransfected supernatants were more proficient in processing the trophic factor than the control infection, whereas NT-3 + PC2 cotransfected supernatants showed about a three fold increase in mature NT-3. (Supported by NIH and MRC)

**Beta-Nerve Growth Factor (NGF) is an artifact.** J. Lakshmanan*, S. Sridevi*, K. Pesonen†, T. Lahelma†, A. Baker*, J. Perheentupa* and D. A. Fiddler‡.  
CLA Medical Center, CA, USA and University of Helsinki, Helsinki, Finland.  
We previously reported the absence of NGF in normal adult mouse sera of both sexes and liver (†) and in sera of adult male markedly exercised mice (115-490 ng/ml) [Am. J. Physiol. 250: E386-E392 1986]. We have now examined the molecular species of serum NGF both by immunoblotting and column chromatography (CM-52). All sera (250 µl) of mouse sera were immunoprecipitated with beta-NGF antiserum and the precipitates analyzed by immunoblotting. Similar volumes of sera were subjected to Sephadex G-100 chromatography. Immunocomplexes were analyzed by Western blotting with beta-NGF-R IA. Immunoblotting analysis revealed the presence of a 53 kDa NGF protein but no 13 kDa NGF immunoreactive protein in sera of either normal or aggressive male mice. The radioactive intensity of 53 kDa NGF protein was several fold greater in aggressive mouse sera compared to normal mouse sera. By chromatographic analysis, the NGF-immunoreactivity of normal male mouse sera eluted as a single peak that appeared in the void volume while that of aggressive mice eluted in two distinctive peaks. The first appeared in the void volume (as in normal mice sera) and the second corresponded to the elution profile of 13 kDa NGF. The later peak accounted for more than 90% of total immunoreactivity. Both aggressive mouse sera and SMG-53 kDa NGF stimulated neurite outgrowth from chick embryo dorsal root ganglion explants. The absence of 13 kDa NGF in normal mouse sera immunoprecipitates and in aggressive serum samples subjected to Sephadex chromatography suggest that the 13 kDa NGF is an artificial proteolytic fragment of 53 kDa NGF generated in vitro during chromatography.

S038.8  
**IDENTIFICATION OF RNA BINDING PROTEINS WHICH MAY CONTROL NERVE GROWTH FACTOR mRNA STABILITY.** B. Tsang*, S.P. Palemnik* and B.C. Wise.  
Fidia-Georgetown Institute for the Neurological and Department of Pharmacology, Georgetown University, Washington, D.C. 20007.  
Our previous studies have shown that interleukin-1 and okadacid acid, a phosphatase inhibitor, increase the level of the full-length nerve growth factor (mRNA) in primary cultures of cortical astrocytes. The 3'-untranslated region (UTR) of the NGF mRNA contains an AU nucleotide rich region which, similar to other short-lived mRNAs, might modulate its rate of degradation. Using Northern blotting analysis, we have now identified a protein with a MW of about 140 kDa which binds to a radiolabeled RNA probe containing the AU-rich domain in the 3'UTR of the eukaryic mRNA. RNA binding activity was observed using a full-length NGF RNA probe, but was not seen using a probe lacking the 3'- UTR or using a β-actin RNA probe. The binding activity or amount of this protein was increased in astrocyte cultures treated with okadacid acid (5-30 μM). Maximal induction of binding activity was seen following 9 h of treatment at the maximal okadacid acid concentration tested. Under these conditions NGF mRNA content was also elevated by about 5-fold compared to unstimulated astrocytes. The RNA binding activity was abolished by treating astroglial cells with trypsin, and the induction of the RNA binding protein by okadacid acid was prevented by cotreatment with cycloheximide (10 μg/ml) indicating that okadacid stimulates the synthesis of this putative modulator of NGF mRNA degradation. Finally, the induction of this binding activity by okadacid acid is associated with an increase (4-fold) in the 5' end of the NGF mRNA. Transfection of cell lines with expression vectors containing the full-length NGF cDNA or NGF cDNA lacking the 3'UTR are underway to study the role of the 3'-UTR and the putative modulator in the control of NGF mRNA degradation.

**PROCESSING OF NGF, BDNF, AND NT-3 PRECURSORS BY PROHORMONE CONVERSIONS.** N. G. Seidah*, S. Pareek*, S. Benajma*, J.-L. Campenot†, M. Chretien†, and R. A. Murphy‡.  
Montreal neurologic institute, McGill University and the Clinical Research Institute of Montreal, Montreal, Quebec, CANADA.  
Conversion of prohormones and prohormone proteins into biologically active molecules involves the concerted action of a number of convertases. Furin can process the precursor of mouse B-NGF (LIF-Like 10, Cell Biol, 111, 2855-2859, 1990) but no information is yet available to explain how other members of the neuropoithin family are generated. In this study, we have compared the processing of pro-BDNF and NT-3 by prohormone convertases. Recombinant vaccinia virus vectors were used to co-express the convertases PC1, PC2, and furin together with NGF, BDNF or NT-3 in human colonic mucosa Lovo cells, lacking endogenous furin. Virally infected cells were metabolically labeled with 35S-methionine and conditioned medium was treated with antibodies to NGF which is immunoprecipitated and identified on Western blots using a BDNF-specific peptide polyclonal antibody. Results show that NGF is synthesized in Lovo cells as a 48 kDa precursor (probably glycosylated) and processed into 14.5 (probably glycosylated) and 13.2 kDa products. NGF processing was effectively carried out by furin and no other convertase. NT-3 was processed efficiently by furin with a small amount of processing carried out by PC1 and PC2 as well. BDNF was effectively processed by furin, with some processing by PC1. These studies suggest that the neurotrophins are most efficiently processed by furin, and that other convertases have limited activity as well.

S038.10  
**DETECTION OF PROHORMONE CONVERSIONS IN DEVELOPING AND ADULT MOUSE SUBMANDIBULAR GLANDS.** H. Farhadi, S. Pareek*, M. Menkenkiewicz†, N. G. Seidah*, M. Chretien†, and R. A. Murphy.  
Montreal neurologic institute, McGill University and the Clinical Research Institute of Montreal, Montreal, Quebec, CANADA.  
The processing enzyme(s) responsible for generating mature β-NGF from its precursor at the amino terminal end have not been identified. Prohormone processing enzymes, called convertases, have been implicated in the processing of precursor proteins at pairs of basic and acidic residues that create a signal for recognition by these enzyme complexes. Two laboratories presented at this meeting (Seidah et al., 1994) have shown that at least one member of this family can cleave NGF, BDNF, and NT-3. The aim of this study was to investigate the relationship of NGF and convertases in the mouse submandibular gland. Northern blot analysis and in situ hybridization revealed high levels of mRNA coding for PC1, PC2, PCs and furin in the salivary glands of neonatal and pubescent male mice; levels in NGF containing granular tubule cells of adults are significant but lower than during pubescence. These results were confirmed by immunocytochemistry. Levels of PC1 mRNA and protein were significantly lower than those of the other processing enzymes. Adult female salivary glands expressed only low levels of NGF and processing enzymes. Our results suggest that one or more prohormone convertases may be involved in processing the precursor of NGF in mouse submandibular glands.

S038.11  
**RETROGRADE TRANSPORT AND SIGNALING MECHANISMS BY NERVE GROWTH FACTOR AND LEUKEMIA INHIBITORY FACTOR IN SYMPATHETIC NEURONS.** D. B. Vege and R. B. Compaan†.  
Department of Anatomy and Cell Biology, University of Alberta, Edmonton, AB T6G 2H7.  
Nerve growth factor (NGF) and leukemia inhibitory factor (LIF) are both retrogradely transported by rat sympathetic neurons in a compartmental culture system. We have further characterized the retrograde transport of 125I-NGF and 125I-LIF. The level of NGF transport appears to be unaffected by the acute presence of LIF. Reciprocally, LIF transport is equivalent whether neurons are supplied with 125I or 200 I. In contrast, pretreating neurons for 6 days with LIF leads to the reduction of both NGF and LIF transport by at least 50%, suggesting that LIF-differentiated neurons may display attenuated NGF-dependent responses. NGF transport levels are not affected by brain derived neurotrophic factor of neurotrophin-3, added concurrently and at concentrations in 100-fold excess of 125I-NGF. Kinetic analysis of NGF transport/processing revealed that following a 5-hr pulse of 125I-NGF to peripheral neurons, most of the radiolabel is transported and released within the first 24 hours. However, cell-associated radiolabel is still present several days following the pulse. Experiments are now being performed to address whether the retrograde transport of NGF or LIF is necessary for transsynaptic changes induced by these signaling ligands.

S038.12  
**ASSAY-DEPENDENT VARIABILITY IN THE CROSS-ACTIVITY OF B-NGF ANTIBODIES WITH RELATED NEUROTROPHINS.** S. Varon* and J.M. Connor.  
UCSD, Department of Biology, La Jolla, CA 92037.  
Previous studies have indicated that antibodies raised against purified β-NGF may cross-react with other neurotrophin family members sharing similar sequence homology, such as BDNF, NT-3 and NT-4. These antibodies generated against any one neurotrophin must, therefore, be examined for potential cross-reactivity with the others. The assay system used to evaluate cross-reactivity is frequently chosen for its convenience. In our B-NGF antibodies, we have found that the choice of the assay system markedly affects cross-reactivity results. In an in vivo assay (following SDS-PAGE), mouse and human NGF were robustly detected by the antibodies while NT-3 and BDNF were virtually undetectable. In a blot-dot assay, the antibodies recognized B-NGF and human BDNF but only detected after fixative treatment of the blot. In a one-site ELISA (with the same antibody for capture and detection), no cross-reactivity with BDNF, NT-3 or NT-45 occurred. When blotted into normal rat (intraocular) injection; 60ng each), all four neurotrophins were recognized by the antibodies. This difference may be attributed to the same extent. In vitro assays with dissociated E8 chick sensory neurons showed that BDNF, NGF, and NT-45 supported cell survival (to varying degrees), but the antibodies could only block the biological activity of NGF. These findings clearly demonstrate that cross-reactivity between NGF antibodies and related molecules is a function of assay system and caution against transferring antibody specificity data across assay systems. Supported by NIHGCs NS-15649.

NEUROTROPHIC FACTORS: EXPRESSION AND REGULATION III

539.1
INCREASED INSULIN-LIKE GROWTH FACTOR II GENE EXPRESSION IN DIABETIC RAT LUMBAR DORSAL ROOT GANGLIA AND MOTEONUROS. P.J. Lucas*, A.S. Dept and A.J. Yank. The Diabetes Institutes, Eastern Virginia Medical School, Norfolk, VA 23501.

Neuropathy is a major complication of diabetes mellitus and can involve sensory as well as motor neurones. While the neuropathy has been identified, the contributions of a number of pathogenic mechanisms have been extensively studied. The insulin-like growth factors (IGFs) promote neurite outgrowth in vitro and spinal regeneration in vivo. These data coupled with reports of reduced IGF receptor levels suggest the possibility that a decline in IGFR available to neurons contributes to the pathogenesis of diabetic neuropathy. To address this possibility, we examined IGF-II gene expression in lumbar dorsal root ganglia (DRGs) and spinal cords of rats made diabetic by a single dose (5mg/kg, i.p.) of streptozotocin. Age-matched, sham-injected rats served as controls.

After nine weeks of diabetes (blood glucose levels maintained between 200-400mg/dl) the diabetic rats and the age-matched controls were sacrificed and tissues harvested for in situ hybridization with a cRNA probe to IGF-II. Contrary to our expectations, preliminary quantification revealed a three to four-fold increase in IGF-II mRNA levels in lumbar DRGs of diabetic rats as compared to those of normal, non-diabetic rats. Similar changes were observed in lumbar spinal motoneurons.

These observations seem enigmatic in the light of diminished regenerative capacity of sensory and motoneuron axons in diabetic rats. It is possible, however, that a compensatory up-regulation of local IGF-II synthesis by neurons, in response to low serum levels or reduced uptake in diabetics, inhibits axonal regeneration by switching-off the regenerative program normally exhibited by axotomized sensory and motoneurons.

539.3
SELECTIVE EXPRESSION OF NEUROTROPHIN-3 mRNA IN MUSCLE SPINDLES OF THE RAT. L.C.V.M. Copray* and N. Brouwer. Department of Medical Physiology, University of Groningen, 9712 KZ Groningen, The Netherlands.

To evaluate the possible involvement of NT-3 in the formation and maintenance of muscle spindles, an in situ hybridization study was set up to analyze the expression of neurotrophin-3 (NT-3) mRNA in muscle spindles from the first embryonic stages of their formation until their mature appearance in adults. Serial, sagittal cryosections of 25 µm were made of 4% paraformaldehyde-fixed intact hindlimbs or dissected hindlimb muscles derived from embryonic (E15-E21), neonatal (P16,P17 and P30) and adult Wistar rats. In situ hybridization for NT-3 mRNA was done in combination with the immunohistological detection of desmin, calcitonin and strioreactive MHC. Starting from the appearance of the first formed intrafusal fiber, i.e. the nuclear bag fiber, at E19, the intramuscular expression of NT-3 mRNA was confined to the intrafusal fibers of the muscle spindles. High levels of NT-3 mRNA were found in the equatorial region of the nuclear bag type intrafusal fibers and remained present in these intrafusal fibers throughout life. During the entire period of muscle formation, examined from E15 on, as well as in mature muscles, no NT-3 mRNA could be detected in extrafusal fibers. The exclusive intramuscular expression of NT-3 mRNA within intrafusal fibers substantiates the involvement of NT-3 in the formation as well as the maintenance of muscle spindles.

539.4

Expression of BDNF, NT-3 and NT-4, was examined in rat skeletal muscle during development (E15-adult) and in adult rat gastrocnemius muscle at different times after transection of the sciatic nerve using quantitative Northern blot analysis of poly A+ RNA and in situ hybridization. At E15, the highest level of expression was found for NT-3 (63pg/gg poly A+ RNA), approximately 20 times greater than that of either BDNF or NT-4. During later development, the levels of all neurotrophins mRNA fell. BDNF and NT-3 mRNA remained low in adulthood, whereas NT-4 mRNA levels increased postnatally, such that adult muscle contained similar quantities of NT-3 and NT-4 mRNA, but very little BDNF message. In situ hybridization of E15 limb bud showed a clear signal for NT-4 only in epimerids, for BDNF mostly in mesenchyme and in some muscle cells, while NT-3 was abundantly expressed in muscle. 24 hours after sciatic nerve lesion, the levels of BDNF and NT-4 mRNA in muscle were reduced considerably. While the amount of NT-4 mRNA remained low, BDNF mRNA levels increased within 2 days after lesion, reaching a 2.6-fold greater than control 14 days after lesion. In contrast, NT-3 mRNA was not affected after nerve injury. Hybridization of transverse sections of denervated muscle with a BDNF riboprobe gave a signal over peripheral nerve. No significant labeling was found in the surrounding muscle tissue. The same riboprobe also labels cells in a distal segment of the sciatic nerve 4 weeks after lesion, suggesting that the source of increased BDNF mRNA production in denervated muscle is Schwann cells in peripheral nerve leading through the muscle.
Distinct regulation of NT-4 mRNA in the skeletal muscle suggests a role for NT-4 in the maintenance of the neuromuscular junction. F. Nandi, L. B. Paradiso, E. Refinetti, V. Rasovskaya, A. M. Johnson, and B. T. Williams. Dept. of Pharmacology and Neurology, U.C. School of Medicine, Los Angeles, Calif. 90024, and Department of Anatomy and Neurobiology, U.C. Irvine, School of Medicine, Irvine, Calif. 92717.

NT-4 expression was increased during postnatal development. The differential regulation of NT-4 mRNA expression suggested that its level may be regulated by motoneuron activity. In agreement with this, identical stimuli caused increased NT-4 mRNA levels in gasserian and soleus muscles in a dose-dependent manner. NT-4 mRNA levels peaked 12 hrs after stimulation and decreased thereafter, reaching basal levels 24 hrs after stimulation. Elevated NT-4 mRNA levels were detected after repeated stimulations. A similar effect could be obtained after direct stimulation of the muscle. In contrast, the mRNA levels of the other neurotrophins were not affected by the electrical stimulation. These observations suggest NT-4 may play a local role in the maintenance of the neuromuscular junction in an activity-dependent manner. This possibility is currently being explored using purified recombinant NT-4 protein and grafts of genetically engineered fibroblast producing NT-4.

An RNA splicing mutation that disrupts the human ciliary neurotrophic factor (CNTF) gene. R. Takahashi, H. Misawa, H. Yokoi, M. Hayashi, T. Komori, A. Inaba, T. Ohtake, and T. Deguchi. Dept. of Neurology, (1), Tokyo Metropolitan Institute of Medical Science, Fuchu City, Tokyo, Department of Neurology (2), Tokyo Metropolitan Neurological Hospital, Tokyo, and Research and Development Center (3), BMJ, Inc., Saiamia, Japan.

Ciliary neurotrophic factor (CNTF) promotes the survival of a variety of neurons. A recent report showed that disruption of the CNTF gene in mice caused motor neuron degeneration. The potential role of CNTF in the survival of motor neurons (Masu et al., 1993). We report a null mutation in the human CNTF gene. The mutated allele shows a G → T transition producing a new splice acceptor site in the removing mRNA species codes for an aberrant protein. Analysis of tissue samples from various genotype subjects and transfected of CNTF minigene into cultured cell demonstrates that the mutated allele expresses only the mutated mRNA species. Mutated CNTF protein is not detected either by immunoblot or immunohistochemical analysis of human tissue as well as any murine tissue. The three simian cells is highly and healthy and neurological disease subjects. Detailed electrophysiological tests on 30- and 64-year-old mutant homogygote reveals no apparent abnormalities. In contrast to the report on mice, our findings indicate that human CNTF deficiency does not induce obvious neurologic dysfunctions.

NEUROTROPHIC FACTORS: EXPRESSION AND REGULATION IV

Gial-derived neurotrophic factor (GDNF) is a recently described neurotrophic factor with trophic activity in mesencephalic dopamine neurons. In rat brain GDNF mRNA expression decreases during postnatal development to very low levels in the adult. In the present study, the influence of lesion- and kainic acid-induced seizures on GDNF mRNA content in adult rat brain was examined. In untreated rats, in situ hybridization to GDNF mRNA revealed only faint signal in the anterior thalamus but was not detected in hippocampus. In association with hilus lesion-induced limbic seizures (which recur from 2 to 10 hrs after surgery), hybridization was markedly increased in the hilus granule cell layers in the dentate gyrus and CA1 cell layers. GDNF mRNA levels peaked at 24 hrs after seizure onset and then declined to near control levels by 24 hrs. In these rats hybridization was not increased in other brain areas. RT-PCR analysis of total mRNA isolated from the dentate gyrus CA1 of hilus lesion rats demonstrated a 5-fold increase in GDNF mRNA compared to control GDNF555. Intraventricular injection of 0.5 ug kainic acid stimulated a similar bilateral increase in GDNF mRNA in the granule cells. However, at 10 hrs post-injection, hybridization to GDNF mRNA was also elevated in areas of neuronal damage in the isilateral hemisphere including stratum pyramidale of hippocampal region CA3, medial thalamus, and piriform cortex. These results indicate that the intense physiological activity of seizure is sufficient to induce GDNF mRNA expression in hippocampal granule cells but not in other populations of neurons engaged in the seizure episode (i.e. cortical pyramidal cells). The additional fields of hybridization in kainic acid-treated rats indicate that GDNF expression is also increased in some populations of neurons following neurotoxic insult. Supported by NS57658.

The role of brain-derived neurotrophic factor (BDNF) is distributed in many brain regions and regulated by excitatory neuronal activity. Despite numerous studies of BDNF mRNA, the production of BDNF protein is poorly understood because of a lack of sensitive and quantitative methods. Recently, we have established a two-site enzyme immunoassay (ELISA) for BDNF protein. The combination of high-affinity antibodies and functional detection minimized interference from other BDNF-related proteins. To investigate the hypothesis that BDNF mediates later changes in neuropeptide expression, we evaluated the temporal and spatial correlation between changes in BDNF protein and neuropeptide levels after limbic seizures. In hippocampal BDNF was rapidly increased about 2-fold by 4 hr, reached maximal levels at 16 hr, and remained elevated through 96 hr after seizure onset. In contrast, the BDNF increase was delayed in cortex and returned to the basal level by 24 hr. After an initial decline, neuropeptide Y content increased to control levels by 16 hr and was well above control levels at 24 hr. The peak neuropeptide content was also clearly increased by 16 hr after seizure onset in all areas. In contrast, hippocampal dopamine levels were markedly below control values from 2 through 96 hr after seizure onset. These data demonstrate increases in BDNF protein precede the major change in enkephalin and neuropeptide Y content, and thus could play an important role in neuropeptide regulation after limbic seizures.
540.5

Recent studies in our laboratory demonstrated that acute ECS increases the expression of BDNF (brain derived neurotrophic factor), and that chronic ECS enhances the induction of trkB protein. This work has been extended to study the regional regulation of BDNF and trkB, the protein tyrosine kinase receptor for BDNF, and to studies of CNTF (cAMP response element binding protein) in mediating the induction of BDNF by ECS. This study demonstrates that acute ECS (2 h) increases the expression of BDNF mRNA in several regions of hippocampus (dentate gyrus, CA1, CA3, and CA4), and the discrepancy between the adult and the neonatal expression may be due to a deficit in the remaining hippocampus. We hypothesized that hippocampal trophic factors may play a role in this deficit. We found previously that the projecting septum and locus coeruleus are dysfunctional after the neonatal hippocampal lesion. Moreover, previous work had suggested that trophic factors are down-regulated by trkB immunoreactivity in hippocampal neurons. Therefore, we have focused on the role of ECS in the regulation of BDNF and trkB. This study shows that ECS increased BDNF mRNA expression in hippocampus, which was significantly increased at 30% in the remaining hippocampus 4 weeks after a neonatal but not an adult unilateral lesion. Neither BDNF nor NGF mRNA was changed by ECS in the remaining hippocampus, which may contribute to the spatial memory deficit observed in a unilateral neonatal hippocampal lesion. Supp. NIH HD23315.

540.6
Regional Increase in Brain-Derived Neurotrophic Factor and Nerve Growth Factor mRNA, but not in Acute and Basic Fibroblast Growth Factor mRNA in kindling. K. Sato*, K. Kashihara, K. Morimoto**, O. Osumi, Y. Fujisawa, K. Aokiwa, T. Hayasaka and S. Kuroda. Department of Neurophysiology and Department of Neurology, Okayama University Medical School, Okayama 700, Japan; Clinical Research Institute, National Sanatorium Minamikawasaki Hospital, Okayama 701-03, Japan; Department of Neurophysiology, Kyorin University Medical School, Tokyo, Japan; and 761-07, Japan.
The levels of mRNA for nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), acidic and basic fibroblast growth factor (FGF) have been studied in the kindling model of epilepsy. Using in situ hybridization and 35S-labeled oligonucleotide probes, the induction of mRNAs was evaluated in the rat brain 1 h after generalized seizures induced by daily electrical stimulations from the amygdala. BDNF mRNA levels were increased in the granule cell layer of the dentate gyrus and the pyramidal cell layer of CA1, CA2, CA3 and CA4. The magnitude of increase in the dentate gyrus was 4- to 5-fold that of the sham-operated controls, whereas moderate increase was observed in other regions. The significant increases in mRNAs were observed in the granule cell layer of dentate gyrus, CA1, CA2, CA3, CA4 and amygdala. Acute FGF mRNA slightly increased in the granule cell layer of the dentate gyrus. No detectable changes, however, were observed in basic FGF mRNA in response to kindled seizures in the regions examined.

These results indicate that the mRNA induction of neurotrophic factors, especially BDNF mRNA expression in the dentate gyrus, corresponded to increases in metabolic and electrical activity associated with seizures or neuronal vulnerability consistent with the kindling model of epilepsy. The observed differences in the spatial pattern of the neurotrophic factor mRNAs suggest that the mechanisms underlying expression of individual neurotrophic factors in kindling are heterogeneous.

540.7

Unilateral neonatal hippocampal lesions cause a long-lasting impairment in spatial memory, whereas unilateral lesions made in the adult rat (3 mos.) were not followed by a deficit. The discrepancy between the adult and the neonatal lesions may be due to a deficit in the remaining hippocampus. We hypothesized that hippocampal trophic factors may play a role in this deficit. We found previously that the projecting septum and locus coeruleus are dysfunctional after the neonatal hippocampal lesion. Moreover, previous work had suggested that trophic factors are down-regulated in hippocampal neurons. Therefore, we have focused on the role of ECS in the regulation of BDNF and trkB. This study shows that ECS increased BDNF mRNA expression in hippocampus, which was significantly increased at 30% in the remaining hippocampus 4 weeks after a neonatal but not an adult unilateral lesion. Neither BDNF nor NGF mRNA was changed by ECS in the remaining hippocampus, which may contribute to the spatial memory deficit observed in a unilateral neonatal hippocampal lesion. Supp. NIH HD23315.

540.8
CONSTITUTIVE EXPRESSION OF BDNF AND TRKB mRNA IN RAT BRAIN WITH AGE AND LEARNING IMPAIRMENT. S.D. Croll*, N.Y. Jr., R.M. Lindsay, S. J. Wiegand, Regeneron Pharmaceuticals, Tarrytown, NY 10591.

mRNAs for the neurotrophin BDNF and its receptor, TrkB, have been localized in most regions of the adult rat brain. These messages peak reach expression late in development, and remain at high levels into adulthood. We examined the constitutive expression of mRNA for BDNF and TrkB in rat brain from young adulthood into old age. The levels of many neuronal mRNAs were increased in old age have been found to depend on the functional state of the animal. To determine if the constitutive expression of BDNF and TrkB mRNAs depend on the cortical status of aged, animals were preformed in the Morris water maze task, and were subsequently divided into aged learning-impaired and aged learning-unimpaired groups. Northern blot analyses were completed for olfactory bulb, neocortex, hippocampus, dienephalon, striatum, midbrain, hindbrain, and cerebellum of 4 mos., 13 mos, 24-26 mos (aged) learning-impaired, and aged learning-impaired rats. Results demonstrate that BDNF and TrkB mRNA levels during age in some, but not all, brain regions studied. Both BDNF and TrkB mRNA levels were increased in aged learning-impaired animals compared to aged learning-unimpaired animals. Northern analysis was performed for CNTF to test the specificity of these expression-related changes in mRNAs. CNTF mRNA did not show the same impairment-related changes as BDNF-mRNA. An in situ hybridization study of BDNF and TrkB mRNA expression with age and learning impairment is currently being conducted.

540.9
CHANGES IN NGF AND BDNF mRNA EXPRESSION INDUCED BY ENTORHINAL CORTEX LESIONS. M.L. Shipman* and D.G. Stern, Brain Research Laboratory, I.A.B., Rutgers University, Newark, NJ 07102.

Injury to the mammalian brain imparts plasticity processes (e.g. axonal sprouting) that may contribute to behavioral recovery of function after injury. Unilateral ablation of the entorhinal cortex/E in adult rats leads to robust sprouting responses by remaining afferents in the hippocampus (HC). Ablations from the contralateral HC and CA1 hippocampal projections sprout collateral terminations throughout the dentate and hilar neurons. Ablations from the septal nucleus also reinnervates portions of hippocampus. We were interested in examining expression of injury-induced neurotrophic factors and induction of axonal sprouting in the hippocampus caused by unilateral damage to the rat's E.

The effects of unilateral, electrolytic E lesions on NGF and BDNF mRNA expression were determined by non-radioactive Northern blot analyses. Seven days after lesion, the expression of NGF mRNA in the hippocampus ipsilateral to the injury, was increased by 20%, but did not change on the contralateral side compared to intact animals. An 40% increase in expression of NGF mRNA was also detected in the ipsilateral and contralateral HC at 15 days after lesion. The expression of BDNF mRNA in the hippocampus ipsilateral to the injury was elevated by 40% one week after E lesion by 15 days. The expression of BDNF mRNA on the contralateral side did not change at any of the time points in comparison to intact animals. These results indicate that NGF and BDNF may contribute to the induction or maintenance of sprouting in the hippocampus after E lesions. Supported by Ipsen Foundation.

**DIFFERENTIAL EFFECTS OF THE ABSENCE OF RETINAL CONNECTIONS ON BDNF GENE EXPRESSION IN THE MOUSE VISUAL SYSTEM. M.H. Hanpin* and J.J. Reese, Department of Anatomy, Medical College of Ohio, Toledo, OH 43614-1645.

In the present study we examine how BDNF mRNA levels in visual target regions (superior colliculus, SC; visual cortex, vCtx) is affected by the absence of retinal projections. To determine the effect of retinal removal before innervation of the primary visual nucleus, we have taken advantage of congenitally blind ocular retardation (OR) mice in which the optic nerve was either completely or partially removed normal mice with bilateral eye removal either at birth (5d after initial retinocortical contact) or from adulthood. These protection assays indicate that BDNF RNA levels in the vCtx are normally about 30% greater than in the SC. While BDNF mRNA levels in the OR SC were comparable to those in normal mice, about 90024-1763 of BDNF RNA in both the SC and vCtx by 7d - an observation consistent with work showing a similar effect of dark-rearing and TNT on BDNF mRNA expression in vCtx of postnatal and adult rats (Castrì et al. *PNAS* 89:3444). Our observations suggest that different brain regions involved with visual input (1° & 2°) respond differently to eye removal during the perinatal period; BDNF gene expression was downregulated in the SC, while the vCtx showed upregulation. Continuing work will determine (1) how the normal postnatal increase in BDNF mRNA in the vCtx (which is attenuated by blocking light input to the brain) compares in the complete absence of retinal projection, and (2) the change in retinoreceptive layers of the SC. Supported by NIH Grant NS26777.

**S40.13**

**INDUCTION OF GLIA-DERIVED GROWTH FACTOR (S100B) IN RATS FOLLOWING CARDIAC ARREST. S.P. Jhas*, R.B. Matsusato and D.D. Truong, Dept. of Neurology, University of California Irvine, Irvine, CA 92717.

S100B, a small, dimeric, acidic calcium-binding protein, is known to stimulate neurite outgrowth and promote survival of serotonergic neurons. After resuscitation from 8 min of cardiac arrest (CA), Sprague-Dawley rats subjected to CA developed motor impairments, e.g. post-hypoxic asthenospermia. Biosynthesis and metabolism of 5-HT were also altered in post-CA rats; cortical 5-HT2A receptors were reduced; and treatment with the 5-HT2A agonist, (+)-1,2,5-dimethoxy-4-iodophenyl-2-amino-propanoic acid (DOI), significantly attenuated myelosis. These results indicated that function of serotonergic neurons may occur in post-hypoxic rats. In contrast, by 45 days following CA, motor functions of rats recovered and cortical 5-HT2A receptors of these animals were increased from low levels at early timepoints. In the present study, we, therefore, investigated involvement of S100B in the recovery process. Brain levels of S100B were examined with quantitative immunoblot analysis. Significantly increased levels of S100B were found in rats 14 days and >45 days post-CA (P < 0.05). The results indicate that reactive astrocytosis and elevated levels of S100B may participate in the recovery processes following hypoxic-ischemic insults to the brain.

**S40.14**

**NERVE GROWTH FACTOR (NGF) IS LOWER IN SEMEN FROM SPINAL CORD INJURED (SCI) MEN COMPARED TO NORMAL MEN. H. Fried, T. Ascher, M.D. Faust, J.L. Blackett, C.M. Lynne*, J.A. Weingartner and K.A. Crutcher, The Miami Project to Cure Paralysis and the Dept. of Urology, Univ. of Miami Sch Med, Miami, FL 33136; Dept. of Neurosurgery, Univ. of Cincinnati Med Ctr, Cincinnati, OH 45267.

In many cell types, NGF is required for normal cellular function in man. Sperm cells from SCI men are lower in motility and viability than sperm cells from normal men. The present study tested the hypothesis that levels of NGF in the semen of SCI men are lower than in the semen of normal men. SCI men were subjects in The Miami Project to Cure Paralysis. We analyzed the antegrad semen of 8 SCI men (mean age 39.3 ± 2.4 SEM, mean duration of injury 8.4 ± 2.5 years) and 9 healthy controls (mean age 31.2 ± 1.3 years). Complete semen analysis was performed on each sample. Semen was obtained in SCI men via electroejaculation (n=3), vibratory stimulation (n=4) or masturbation (n=1). Controls produced samples via masturbation. Whole semen samples were analyzed via a 2-site enzyme-linked immunosorbent assay (ELISA) for NGF. There was a ten-fold decrease in NGF levels in the semen of SCI men (0.03 ± 0.02 pg/ml) compared to normal semen (0.29 ± 0.07 ng/ml). This difference was statistically significant (p<0.01, ANOVA).

Our data indicate that the semen of SCI men has significantly lower levels of NGF than the semen of normal men. This condition may contribute to the asthenospermia and necrospermia seen in SCI men. Supported by The Miami Project to Cure Paralysis and by NIH grant NS31410.

**NEUROTROPHIC FACTORS: EXPRESSION AND REGULATION VI**

**S41.1**

Expression of estrogen and androgen receptor mRNAs in immortalized oligodendrocyte cell lines. R. Stoika, L. Foster, A. Campagnoni, and P. Eispyve. The Laboratory of Neuroendocrinology, UCLA School of Medicine, Los Angeles CA 90024-1763.

Oligodendrocytes may mediate developmental effects of sex steroids on the CNS including the production of neurotrophins. The effect of the sex steroids, estrogen and androgen, in the development and regulation of oligodendrocytes has not been studied. To begin addressing this issue, we generated immortalized cultures of sex steroid-dependent oligodendrocytes. We examined proliferation and the expression of neurotrophins during development, we used a series of cell lines immortalized at specific stages in the oligodendrocyte lineage. (Stoika et al. *Dev Biol* 1995;15:100-109). All of the cell lines stained positively for markers of the oligodendrocyte lineage, A2B5, and 23'-cyclic nucleotide 3'-phosphodiesterase (CNP); none of the cell lines, however, expressed myelin basic protein which suggests that these were immature oligodendrocytes. Poly A+RNA was isolated from 10 oligodendrocyte cell lines. Northern blot analysis indicated that several of these lines expressed mRNA coding for the estrogen receptor (N7, N9, N11, N19) while mRNA for the androgen receptor was expressed in the N7, and the N19 cells. All of the cell lines expressed mRNAs coding for both brain derived neurotrophic factor and nerve growth factor. Cell lines identified to have specific steroid receptor mRNA's added to the N16 line, which does not express either estrogen or androgen receptor mRNA's, were grown at the permissive temperature (34°C) in a defined (serum and phenol red free) medium with and without sex steroids. These results suggest that sex steroids support the proliferation and differentiation of these cell lines and may also regulate the expression of neurotrophins that influence the development and survival of other cells in the nervous system. Supported by NS21220 and HD04612.

β-INTERFERON INCREASES ASTROCYTE PRODUCTION OF NEUROTROPHIC FACTORS. P. Bonatsos and V. W. Yong*, Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4.

Recent clinical evidence has suggested that β-interferon is efficacious in the treatment of multiple sclerosis although the mechanism of action remains unclear. Given that astrocytes can provide trophic support to neurons, and that the β-neurotrophic factors (CNTF) have been reported to protect oligodendrocytes against apoptotic damage, we examined whether β-interferon could increase the production of specific neurotrophic factors by astrocytes. Mouse β-interferon (1 to 1000 U/ml) was added to confluent or non-confluent neonatal mouse astrocyte cultures for varying periods of time. Total RNA was extracted and subjected to Northern blot analysis for levels of mRNA for CNTF, nerve growth factor (NGF) and the astrocyte filament protein, glial fibrillary acidic protein (GFAP). Doses of β-interferon from 100 U/ml significantly increased the mRNA for CNTF and NGF, but not for GFAP. Increase in mRNA for both CNTF and NGF (2-fold) was evident by 24 hours following β-interferon treatment. The β-interferon-enhanced trophic factor production was not reproduced by interleukin (IL)-2, IL-6 or γ-interferon. Western blot analysis is currently in progress at varying interferon levels. We conclude that the astrocyte production of neurotrophic factors by β-interferon may be relevant to its clinical efficacy.

541.3 SYNERGISM OF PHORBOL ESTERS WITH IL-1β ON IL-6 RELEASE AND GENE EXPRESSION IN ASTROCYTES.
M. Grimaldi,* R. Arcone, A. Marino, G. Ciliberto and G. Schettini*  
Dip. Neurosciences, Se. Pharmacology, *CEINGE, Univ. di Napoli, Via S. Pansini 5, 80131, *IRCCS San Camillo-Forlanini, Rome, Italy

Cultured astrocytes produce and release interleukin 6 (IL-6) in basal and following stimulation with various agents. We have already demonstrated that Phorbol esters (PMA) cause release of IL-6. Moreover, it has been reported that secretion of IL-1β (1 ng/ml)-induced IL-6 by astrocytes PMA concentration-dependently stimulated IL-6 release with an EC50 of about 50 nM. The effect of PMA linearly increased from a maximal stimulation of secretion after 5 h. of exposure to a maximal stimulation at 24 h. At 24 h the concentration-related increase was calculated at 300 nM of PMA, indicating that PMA actions required at least 24 h to be fully explained. PMA effect upon IL-6 release by cortical astocytes was inhibited by the treatment with PKC blockers. Similarly, PKC-deactivation, by means of PMA pretreatment, caused a complete block of IL-6 release stimulated by PMA. The basal release of IL-6 resulted set at a higher level following PKC desensitization. IL-1β-stimulated IL-6 release concentration-dependently and its effect was potentiated by the blockade or by the desensitization of PKC. Conversely, calphostin C, over 24 h lasting incubation, did not affect IL-1β stimulation. Both IL-1β and PMA increased IL-6 mRNA expression, but IL-1β stimulated more consistently IL-6 mRNA expression than PMA. Finally, the co-stimulation of astrocytes with either IL-1β and PMA resulted in a synergistic stimulation of IL-6 release that was not observed by using PKC. This synergism was also found at level of mRNA expression. (Supported by MIUR 40%, CNR 9106012 and TP on Aging, AIRC 92-93)

541.4 BASIC FIBROBLAST GROWTH FACTOR (BFGF) EXPRESSION IN ASTROCYTES AND GLIOMA CELLS. M.K. Stachowiak, J. Moffett, K. Neary, J.R. Shapiro, W. Shapiro*, E.K. Stachowiak, Barrow Neurological Institute, Phoenix, AZ 85013

Expression of BFGF is transiently induced during a reversible transition of quiescent to proliferating reactive astrocytes. In constantly proliferating glioma tumor expression of BFGF is constitutively elevated. To model the molecular mechanics underlying induction of BFGF we developed cultures of human astrocytes and glioma cells. Confluent cultures of astrocytes were quiescent and did not express BFGF. By reducing cell density, events occurring in vivo in reactive astrocytes were mimicked: induction of BFGF proteins, their accumulation in the nucleus, cell hypertrophy and proliferation that lasted until a new confluent state was reached. Changes in the protein content reflected changes in the levels of BFGF mRNA. We used BFGF-luciferase reporter plasmids to show that the depletion of BFGF mRNA in confluent astrocytes results from repression by transcription and in mediates the changes upstream from the transcription start site of the BFGF gene. In U251 and SF776 glioma cells, BFGF proteins, mRNA, and BFGF-luciferase constructs were expressed at constitutively levels and were not susceptible to inhibition at confluent. The growth of the SF776 glioma cells was stimulated by either the 18k or the 22, 23, and 24 k/isoforms of BFGF expressed intracellularly from the CMV promoter, but not by enzymatically added BFGF. This suggests an intrinsic mechanism of action. The growth of astrocytes was stimulated by enzymatically BFGF. Our results suggest that: (1) BFGF participates in the regulation of the cell cycle in human astrocytes, and (2) deregulated expression of BFGF gene may underlie abnormal growth of glioma cells, and (3) deregulation of BFGF reflects altered trans-regulation of the BFGF gene promoter. Supported by APDA, AHA, and NIH.

Extracellular guanosine (Guo) and GTP affect both nerve cells (Gyngers and Pathman 3:997-1992) NeuroReport) and astrocytes (Kim et al. 1991) J. Neurosci. Res. 28:442. Guo or GTP also stimulate neurite outgrowth and branching from mouse hippocampal neurons co-cultured with astrocytes (J. Neurosci. Res. Abs. 1992). 19:24-7). Astrocytes in culture synthesize and secrete a number of neurotrophins, e.g. NGF, BDNF, FGF-2 and NT-3. We determined whether the neurotrophic effects of Guo and GTP might be due to stimulation of trophic factor production by the astrocytes. Guo or GTP (10 μM) increased the synthesis of FGF-2 and NGF mRNA by the astrocytes. Cultures treated with 24 hours total mRNA was extracted and analyzed by Northern blotting. Cultures treated with Guo or GTP increased both FGF-2 and NGF mRNA over control cultures. The astrocyte culture medium, as determined by ELISA, was also increased under these conditions. Since Guo and GTP stimulate neurite outgrowth from PC12 cells in the absence of astrocytes we questioned whether Guo and GTP stimulated the production of neurotrophins in PC12 cells. Both Guo and GTP induced c-fos as determined by Northern and Western blotting. This may lead to activation of other genes involved in neurogenesis. Moreover FGF-2 neutralizing antibody added to culture medium inhibited neurite outgrowth in PC12 cells. Guo. This raises the possibility that Guo induces FGF-2 synthesis in PC12 cells that contributes to their ability to enhance neurite outgrowth. Support: Hospital for Sick Children Foundation of Toronto and George M. Calder.

541.6 INCREASED 125I-IGF-2 BINDING IN THE COLCHECICINE LEDENED HIPSCampus: FUNCTIONAL mRNA EXPRESSION FOLLOWING NEURONAL CELL DEATH AND GLIOSIS. C.R. Bresser, M.M. Bresso, A. Costa, W.E. Sonntag, and S.S. Leonard. Department of Pharmacology Psychiatry, University of Colorado Health Sciences Center, Denver, CO 80262

IRISIL-like growth factors are a family of structurally related, weight peptide hormones which may act as neurotrophic factors in the central nervous system. We have identified NGF-1 and NGF-2 in the brain following cytotoxic colchicine lesions to the dentate gyrus of the hippocampus at times points up to 10 days post injury. We then examined the resultant increase at a time dependent increase in the-IGF-2 binding in the lesioned region and overlying cortex (Neuroscience Abstracts 269, 1991). Neuronal survival was studied by an antibody to glial fibrillary acidic protein, a marker of the granulol cell layer of the dentate gyrus, and extensive glial ingrowth into the lesioned and damaged areas. In situ hybridization revealed no observable mRNA for type-2 receptors in the lesioned area, while demonstrating normal expression to the ipsilateral CA1/CA3 and the contralateral hippocampus. Western ligand binding for IGF-2 binding proteins (IGF-BP) have suggested that the increase in IGF-2 binding may be due to expression of IGF-BP proteins. Therefore, we have examined for IGF-2 expression within the glial cell population. Our laboratory is currently examining colchicine lesioned animals for IGF-2 mRNA expression, as well as the expression of IGF-1, IGF-2, and other neurotrophic factors. Such expression would suggest that astrocytic IGF-BPs in response to neural injury, possibly to attract or maintain levels of the IGF peptides, which may in turn influence astrocytic proliferation and protein expression following neuronal cell death.

Previous studies from our laboratory and others have indicated that astrocytes produce neurotrophins. To understand regulatory mechanisms and the potential interaction of neuronal signals, we have evaluated effects of depolarizing signals (glutamate, kainate, and NMDA) on astrocyte NGF and BDNF mRNA. 

Purified astrocyte cultures were established from P1 rat brain forebrain using published techniques (McCarthy and DeVellis; O'Malley et al). The cultures contained > 95% astrocytes, revealed by GFAP immunocytochemistry. Solution 1 (6 mM KCl). Glutamate was assessed at a level of 0.025% of total RNA than BDNF mRNA (0.3 lg/mg of total RNA). The increase in both mRNA was determined at 24 h after exposure to field stimulation of neurotrophic expression, cultures were exposed continuously to KCl (25 mM) for 4 hours or 48 hours. Both 4 and 48 hours of exposure resulted in a significant increase in BDNF mRNA. Effects of the increase of NGF mRNA to 50% (48 hours). This increase in BDNF mRNA was relatively specific, since NGF mRNA was not similarly affected. Increases in neurotrophic expression at 48 hours were accompanied by significant decreases in GFAP expression and the alteration of astrocyte morphology from mature processes-bearing cells to more immature, ramified cells.

Our data suggest that depolarizing signals influence astrocyte function by modulating neurotrophin expression and astrocyte morphology. We are presently exploring the roles of neurotransmitters and mechanisms underlying these events (Supp: NICHHD HD23515 and the UMDNJ Foundation)
5-HT SELECTIVELY PROMOTES THE SURVIVAL OF O-2A PROGENITOR CELLS PREPARED FROM THE STRIATUM OF THE E14-RAT: INTERACTION WITH BFGF
J.W. Commissiong, T. Takashima, Jane M. Johnstone and R.I. Stanmeyer

We showed recently that oligodendrocyte-type-2 astrocyte (O-2A) progenitor cells prepared from the striatum of the 516 rat, produce a potent neurotrophic factor that is secreted, and causes a marked increased survival of dopaminergic neurons in culture (Takashima et al., Neurosci. Letts. 166:187-192, 1994). A similar, target-derived factor that is transported retrogradely to dopaminergic neurons in the substantia nigra, might be produced in the striatum, in the adult, by an O-2A-like cell, in response to neurotransmitters released by dopaminergic neurons. Since dense dopaminergic and dopaminergic innervations are present in the striatum, we tested the effect of dopamine (DA), and 5-
hydroxytryptamine (5-HT), (and noradrenaline as a control) at 1 x 10^-8 M, for their ability to promote the survival of O-2A progenitors in culture, after plating at 3 x 10^4/cm^2. The cells were plated with serum (5.0%) for the first 24 hr, and then grown in a serum-free medium. DA was severely toxic. Only the small number of type-I astrocytes in the DA-treated cultures survived beyond the second day in culture (DIV). NE had no significant effect. 5-HT caused a significant protection (P<0.05). BFGF (10 ng/ml) caused a significant (P<0.05) inhibition of the toxic effect of DA. 5-HT + BFGF caused a significant (P<0.001) than that produced by BFGF alone at DIVS. Experiments to: determine if 5-HT is mitotic; 2) purify the putative dopaminergic neurotrophic factor (DNTF) produced by primary O-2A progenitor cells; 3) screen the striatum for additional positive cells during critical stages of development; 4) determine the dose-response effects of 5-HT and the 5-HT receptor(s) involved are in process. One function of the serotoninergic innervation of the striatum might be to provide neurotrophic support of an A2B5-like cell.

542.1
MODULATION OF GAP-43 mRNA EXPRESSION IN CULTURES OF RAT CEREBELLAR GRANULE CELLS

In situ hybridization studies from our lab have localized GAP-43 mRNA in granule cells of the developing and adult rat cerebellum (Rowe, Neurosci. Abst. 16:813, 1990). The level of GAP-43 mRNA expression was found to be developmentally regulated since higher levels of GAP-43 mRNA were present in the neonatal cerebellum as compared to adult cerebellum. The objective of this study was to determine the effects of putative cerebellar neurotransmitters (e.g. GABA and excitatory amino acids), acting at granule cell synapses, on GAP-43 mRNA expression levels.

Both GABA and glutamate have been implicated in granule cell trophic activity and their relative levels appear critical for granule cell maturation. The model systems chosen for our study were dissociated cerebellar cultures enriched for granule cells. Cells were exposed to agonists and antagonists of GABA and EAsAs in serum-free media for 7 days in tissue culture chamber slides.

 Cultures were hybridized with a 32P-labeled oligonucleotide to GAP-43 mRNA and the amount of hybridization within process-bearing cells was quantitated via an image analysis system. Results from these studies indicate that the addition of the inhibitory amino acid GABA (25 and 50uM), the GABAB agonist, baclofen (25 and 50uM), as well as the glutamate receptor antagonists, MK-801 (25 and 50uM) and CNQX (25uM), decreased GAP-43 mRNA expression. This study shows that GAP-43 mRNA expression in granule cell bodies could be modulated by synaptic input from both excitatory glutamatergic mossy fibers and inhibitory GABAergic Golgi interneurons. Thus, GAP-43 modulation by these neurotransmitters may contribute to the growth of parallel fibers and neuroplasticity at the parallel fiber-Purkinje cell synapse. 542.3

It is currently believed that only isozyme BB of creatine kinase (BCK) initiates in all vertebrate neuromuscular junctions. In White Leghorn chicken and rat skeletal muscle, BCK is replaced by MB and finally by MM-CX. It is thought that BB-CX remains the sole type in brain. Here we found that Rhode Island chick brain and heart cytosolic (CCK) specific activities showed the lowest and relatively constant values from stage 30 up to month 8, when an abrupt increase occurred. CCK values from breast and thigh muscles increased 2235 and 4215, at hatching. At month 8, they returned to basal levels. On the contrary, CCK breast and thigh values increased 2100X and 3300X at year 1.5. Brain showed a transition pattern opposite to the accepted one. With creatine in heart, typical and atypical MB isozymes were present from stage 30 up to hatching; while varieties of MM and MB-CX were found in thigh and breast muscles. BCK-CX and varieties of MM and MB-CX were found from hatching up to month 8 in heart, thigh and breast muscles. Varieties of BB, MB and MM-CX isozymes were present in heart and thigh muscles, whereas no MB varieties were found in brain and breast muscle, coinciding with the most amniospecific period of ATP synthesis, when transphosphorylation is indispensable.

542.4
DIFFERENTIAL EXPRESSION OF GLYCINE RECEPTOR ISOFORMS BY EMBRYONIC RAT SENSORY CORD NEURONS DURING DEVELOPMENT IN VITRO. M. D. Wilber, and P.A. St. John, Program in Neuroscience, Dept. of Anatomy, University of Arizona, Tucson, AZ 85724.

It is well-established that acetylcholine receptors undergo a change in subunit composition during development at the neuromuscular junction. By comparison, relatively little is known about developmental changes in neurotransmitter receptors in the central nervous system. We are studying the developmental regulation of glycine receptors expressed by spinal cord neurons. Previous results show that embryonic spinal cord neurons undergo a change in strychnine-sensitivity of responses to glycine during the first week in culture. To rule out the possibility that strychnine-insensitive responses to glycine are a product of cross-activation of GABA receptors, we have used a monoclonal antibody, mAb 4A, raised against the alpha subunit of glycine receptor to provide independent evidence for the existence of glycine receptors expressed by these neurons. This antibody recognizes an epitope common to all glycine receptor alpha subunits cloned to date, but is not found in any of the glycine receptors cloned thus far. Initial results demonstrate that embryonic spinal cord neurons express glycine receptor alpha subunit immunoreactive material by the first day in culture. This is a time when these neurons exhibit strychnine-insensitive responses to glycine but before they bind strychnine in radio-ligand binding assays. This suggests that these neurons are expressing different isoforms of the glycine receptor at different times during development in vivo. (Supported by NIH and The Robert S. Flinn Foundation)
452.5 POSTNATAL DEVELOPMENT OF SERINE/THREONINE PROTEIN PHOSPHATASES: AN EXPEDITION INTO THE NEURODEVELOPMENTAL INTERACTION WITH MICROTUBULES. G.V.W. "Johnson and S.M. "Dudec". Dept. of Psychiatry and Behavioral Neurobiology, University of Alabama at Birmingham, Birmingham, AL 35224-0117.

Serine/threonine protein phosphatases regulate a wide variety of processes within neurons, and apparently play crucial roles in mediating appropriate structural changes during development. Such changes in the phosphorylation of specific structural proteins apparently modulate the organization of intracellular microtubules and can result in rearrangement of the cytoskeleton. The levels and activities of specific phosphatases and their association with microtubules during postnatal development were measured. Although the expression and activity of calcineurin (phosphatase 2B) was detected as early as postnatal day 1 (P1) in both the microtubule-enriched and whole homogenate fractions, it appears that calcineurin levels increase with age until P20, after which there is no further increase. These results differ from previous studies which showed no detectable calcineurin before postnatal day 4 (Pollit et al. 1991). Interestingly, calcineurin has been shown to exist in growth cones, and apparently depends on an intact cytoskeleton for this localization (Ferrara et al. 1993). In contrast to calcineurin, activity of phosphatase 2A is highest during the first postnatal week and declines thereafter. It is unknown at this time whether this increased activity early in postnatal life is due to increased levels of an isoform of the phosphatase 2A catalytic subunit, or from lower levels of the 2A regulatory subunits. Phosphatase 1 levels do not appear to change during this time. Studies are underway to determine the relationship between these changes in phosphatases which occur during postnatal development, and the age-related alterations in the phosphorylation state of specific microtubule-associated proteins.

452.6 Oligonucleosides Antisense to Calmodulin mRNAs Inhibit Proliferation and NF-kB-Induced Genes. T.A. Zhang, G.A. Inohaya, and B. Weiss. Dept. of Pharmacol, Medical College of PA, Phila., PA 19129.

Calmodulin (CaM) is involved in numerous biological processes, including regulation of the cell cycle and cell differentiation. Using the PC12 phosphorylase cell line as a model for studying neuronal growth and differentiation, we have previously shown that nerve growth factor (NGF)-induced neurite outgrowth from PC12 cells was associated with increased levels of CaM and CaM mRNA. Oligonucleosides, chemical and oligo hybridization techniques have demonstrated that CaM and the CaM mRNAs are present not only in cell bodies but also in neurites of PC12 cells differentiated with NGF. In order to address the role of CaM in PC12 cell differentiation, we investigated the effects of antisense oligonucleosides and oligonucleoside-oligodeoxynucleotide (ODNs) targeted to the initiation sites of the CaM mRNA transcripts from the three CaM genes in PC12 cells. We first assessed the uptake of the ODNs into PC12 cells by incubating an FITC-labeled oligonucleoside antisense to the mRNAs from CaM gene I which was then incubated with the cells. Confocal microscopy revealed that the FITC-labeled ODN was taken up into the cytoplasm and nucleus. The addition of all three ODNs antisense to the mRNAs encoded by the three CaM genes produced a dose-dependent inhibition of the proliferation of the PC12 cells. The three CaM antisense ODNs also inhibited NGF-induced neurite outgrowth when present at concentrations of 16 μM each. Similar concentrations of an ODN having a randomized sequence did not significantly inhibit neurite outgrowth. Immunocytochemical analyses showed that the CaM antisense ODNs also reduced the levels of CaM in PC12 cells treated with NGF, supporting the view that the inhibitory effect of the CaM antisense ODNs on cell differentiation was due to their ability to block the expression of the CaM genes. Our results suggest that CaM is involved in the proliferation of PC12 cells as well as in their differentiation cells induced by NGF. (Supported by NS03724.)

It has been shown that protein kinase C (PKC) is translocated from cytosol to membrane fractions following memory formation in several species. CP20 is an ARF-related GTP-binding protein associated with memory, and is a high-affinity PKC substrate. We have investigated changes of phosphorylation during associative learning (Nelson et al. Science 1990). Both cp20 and PKC were identified in S. purpuratus oocytes by immuno-staining and fluorescent BODIPY-phalloidin assay, respectively. The identity of cp20 was confirmed by blot analysis of I PLC.

Treatment of oocytes with Brefeldin A, a fungal metabolite known to interfere with ARF-related proteins, resulted in a transient increase in free-intracellular Ca++ as assayed by Fura-2/AM imaging. Subcellular fractionation indicated that cp20 was primarily associated with free ribosomes and rough ER, while only small amounts were found in smooth ER, Golgi, or cytosol. Additionally, approximately 20% of the cp20 was also found in the nucleus. In smooth ER, approx. 30% of the cp20 was in the phosphorylated state, while in rough ER, >50% of the cp20 was found to be phosphorylated. Treatment of oocytes with BFA (200 nM) caused a marked reduction in cp20 recovered from ER, and resulted in a small increase in amount recovered from the nucleus. Previous results (Nelson et al., 1992) indicated that purified cp20 can markedly enhance the incorporation of P-32 uridine into mRNA. Thus, cp20 may play a role in conjunction with PKC in inducing the increases in mRNA and protein previously demonstrated with associative learning.

452.9 ONTOGENY OF [H]MK-801 BINDING TO THE NMDA-GATED ION CHANNEL. C.S. Li, J. He, J. Harasz*, R. Sivar, Laboratory for Developmental Neuroscience, Departments of Psychiatry and Neurology, Albert Einstein College of Medicine, Bronx, New York.

The NMDA receptor plays an important role in developmental plasticity. Phencyclidine (PCP) and PCP-like drugs (MK-801, ketamine) act as non-competitive antagonists at the N-methyl-D-aspartate (NMDA) receptor. We have earlier shown that PCP treatment led to permanent long-term changes in seizure susceptibility. Here we report the developmental profile of interactions of L-glutamate, glycine and spermidine with [H]MK-801 binding in the immature rat brain. Rat pups were sacrificed on specific days after birth. Forebrain crude synaptosomal membranes (CSMs) were isolated and prepared. Aliquots of CSM were incubated with [H]MK-801 in the absence or presence of L-glutamate, glycine and spermidine. Non-specific binding was determined in the presence of excess unlabelled MK-801. For autoradiography of brain sections from postnatal days 1, 5, 7, 10, 14, 18 and 21 were incubated with 10 nM [H]MK-801 in the absence and presence of excess nonradioabeled MK-801, washed, dried and exposed against tritium-sensitive film. [H]MK-801 binding in postnatal rat brain increases with age. Moreover, binding of [H]MK-801 binding to L-glutamate, glycine and spermidine were age-specific. These results may clarify the long-term neurobehavioral effects of postnatal exposure to noncompetitive antagonists.

The visual pathway of fish is an important model system to study molecular events that regulate and support optic nerve growth and regeneration. In addition, zebrafish embryos are amenable to direct observation and manipulation and are thus an excellent model to study molecular events that occur during embryogenesis. Our interest is in the role of intermediate filaments IFs in these processes. Although a precise physiologic function for IFs has not been determined, their distinctive cellular distribution and molecular diversity suggest that, in addition to a structural role, they may function to support cell differentiation and growth during embryogenesis. We have previously isolated and characterized several intermediate filament proteins from the goldfish visual pathway. Goldfish retinal ganglion cells express two novel neurofilament proteins designated plakelin and gefillin. In addition, goldfish optic nerve ganglia cells express keratin as their predominant intermediate filament protein. Currently we are characterizing the expression of these intermediate filament proteins in the zebrafish. NIH EY05212 to N.S.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Calcium-calmodulin-dependent protein kinase (CaMK) plays an important role in the Crx* second messenger cascade and is capable of phosphorylating neurofilamentous proteins. We have used immunocytochemistry to examine the distribution of CaMK-II and the type IV intermediate filament protein (IFP) α-Internexin in the rat dorsal root ganglion (DRG) and spinal cord. Labeling for type IV IFP peripherin was used as a comparison, because it has been shown to preferentially label small dark DRG neurons. CaMK-like immunoreactivity (CaMK-LI) in the DRG was restricted to a subset of large-diameter DRG neurons. Virtually all cells positive for CaMK also showed heavy labelling for α-internexin, while the remaining neurons contained faint α-internexin-LI. However, a few small, brightly α-internexin-positive cells were not stained for CaMK. Both CaMK and α-internexin antisera labeled a subset of periphere-positive neurons. In the spinal cord, robust CaMK-LI was seen in the ventral motor horn and tract of Lissauer but not in the dorsal columns, with the strongest staining in lamina II, somewhat less in L I and faint labelling of III-IV. α-internexin labelled processes throughout the cord, but clearly showed afemms from the dorsal root entering both the dorsal columns and lamina I. Stained tissue was evident in lamina II. Strikingly, peripheral labelling of the dorsal horn was very similar to α-internexin, with extensive labelling of the dorsal columns, lamina I and III-IV, but little staining in lamina II. Despite the fact that both IFP antibodies labelled large cell bodies only faintly, both stained myelinated fibre bundles entering the dorsal horn medially and turning into lamina III, characteristic of Aβ low-threshold mechanoreceptors. Thus, it appears that the extent of DRG soma IFP-LI is not a good indicator of axonal IFP content.

Postnatal handling receptor (GR) gene expression and HPA function in the rat. The effect on GR expression appears to involve activation of intracellular cAMP levels. cAMP is known to increase the expression of a number of transcription factors, including activator protein-2 (AP-2) as well as NGF-A and NGF-B. In these studies we examined the acute effects of handling on the expression of mRNA for these factors in Day 7 pups that were handled and sacrificed 0, 30, 60, 90 or 120 minutes following handling. Levels of mRNA expression were determined using in situ hybridization on brain sections containing dorsal hippocampus.

Constitutive expression for all three transcripts was generally low, but detectable on Day 7 of life. Handling resulted in a modest, but reliable increase in AP-2 mRNA levels throughout the hippocampus. NGF-A mRNA levels were increased dramatically throughout the hippocampus. In both instances, the increase was observed for at least 120 min following handling. In contrast, handling reduced NGF-B mRNA levels to below detectable limits, and again the effect persisted for at least 120 min following handling.

The promoter region for the rat GR gene (Jacobson & Yamamoto, unpublished) contains putative binding regions for both AP-2 and NGF-A. Thus, handling could alter GR expression by increasing cAMP formation and increasing AP-2 and/or NGF-B expression. Interestingly, environmental enrichment, which results in increased GR expression in peripheral rats, also increases NGF-A and decreases NGF-B expression in rat hippocampus.

Homeobox genes are transcriptional regulators considered to be upstream components of the regulatory hierarchy of genes controlling development. Among these, the homeobox gene family is expressed in the forebrain during embryonic development. Since brain injury recapitulates early developmental events, we employed hypothalamic lesions that induce precocious puberty to begin examining homeobox brain genes may be involved in the early events that lead to the initiation of puberty. Using deoxyoxycytidinucleotides complementary to the antisense and cDNA that includes portions of the POU domain, and was isolated by RT-PCR, polymorphic domains from the anterior hypothalamus of immature rats subjected to puberty-inducing electrolytic lesions. Half of the almost 100 clones from a single experiment were found to contain POU domain sequences; only a few POU domain genes were previously discovered in the hypothalamus but now known to be expressed in brain. A predominance of Oct-2 sequences was evident as early as 24 hr after the lesion. Hybridization histochemistry revealed an increased prevalence of Oct-2 transcripts in reactive astrocytes surrounding the lesion site. Electrophoretic analysis of the DNA oktomer to which POUs proteins bind to initiate their actions demonstrated that hypothalamic nuclear extracts contain proteins with mobilities corresponding to at least two different Oct-2 proteins. One of these proteins formed a prominent protein-DNA complex with a portion of the 5′ flanking region of the triplet transacting growth factor alpha (TGα) gene harboring a presumptive POU binding site. Such a binding is implicated in the initiation of puberty and is also expressed in reactive astrocytes, the results suggest that the controlling the expression of this gene may be initiated via transregulation of TGα gene expression. Supported by NSF SGER Grant #IBN-9305583 and NIH grants HD18165 and RR0163.

The homeobox gene engrailed has been found in invertebrates and vertebrates, where it is thought to play a role in segmentation and neurogenesis. The function or even the presence of a vertebrate homologue in the nervous system is as yet unknown. We have used the MAB 4D9 (gift of Nipam Patel) to examine the expression of engrailed-like gene products in whole animals and in the CNS of developing mouse embryonic neuroblasts. Engrailed-like immunoreactivity (ELI) was found in the nucleus of a specific subset of cells in the CNS of both larval and adult Aplysia. In juveniles, there is only one ELI cell in the left cerebral ganglion (none on the right), a bilaterally symmetrical cell in the buccal ganglia, and a few scattered cells in the pedal ganglia. By contrast, the abdominal and especially the pleural ganglia contain several ELI cells. In the pleural ganglia, the left pleural giant (LP1) cell is immunopositive, and so are cells of the anterior, medial, and posterior clusters. In the pedal ganglia, in addition to a few immunopositive clusters of cells, the giant cell R2 is immunopositive, as well as cells that we have tentatively identified as R10-R12 and R13. That both R2 and LP1 are immunopositive is consistent with the idea that these cells are bilateral homologues arising from the same developmental program but merging with different ganglia (Hughes & Tau, 1993).

A cell count performed in the pleural ganglia indicates that there is a significant increase in immunopositive cells during juvenile development (p<0.01). Cells may be fated to express the engrailed-like protein before they migrate into the CNS, since preliminary evidence suggests that ELI cells are found in the body wall, a site for the patterning of the CNS.

Our results suggest that an engrailed-like protein is expressed in the nucleus of a specific subset of neurons in the CNS of Aplaysia, where its expression pattern is consistent with it having a role in determination of cell fate.

Serotonin (5-HT) is specifically accumulated by embryonic tissues in a manner analogous to the molecule's sequestration by the 5-HT transporter (SERT) at adult synapses. Notably, 5-HT transport antagonists block embryonic 5-HT accumulation and are used to craniofacial and heart abnormalities. These results suggest that transport per se may regulate a morphogenetic action of 5-HT in the embryo. A basic prerequisite to understanding the mechanism of this action is to describe the appearance and sequence of features that lead to morphogenetic changes. We have used immunohistochemistry in concert with in situ hybridization to document both SERT protein and gene expression in early mouse development. A fusion-protein antibody (CT-2) directed against the carboxy-terminal of SERT and SERT and protein probes related to serotonin have been used to analyze SERT gene and protein expression with fluoroxite- and serotonin-sensitive [H]5-HT uptake in whole embryo culture. Our results reveal a precocious and heterogeneous distribution of SERT mRNA in several sites throughout the embryo including craniofacial epithelia and mesenchyme, midbrain, lung, and heart. Correlation of morphogenetic events with the spatial and temporal expression will more clearly delineate the embryonic involvement of 5-HT in development and provide basic information necessary for interpretation of pharmacological and genetic disruptions of the transporter.
We have used non-radioactive in situ hybridization to localize choline acetyltransferase (ChAT) transcripts in the chick embryo. Previous studies have demonstrated that ChAT transcripts in neural crest derivatives in the periphery (Rowe et al., Development 111: 771). Here we report on their presence in two regions of the CNS: the hindbrain and the spinal cord. At the earliest time examined (stage 19) we find ChAT expression along the midline of the optic tectum, in an interventricular ventricular cell column in the hindbrain, and in scattered cells in the central core of the retina. By stage 25, when many neuron populations have differentiated in the hindbrain, we find expression in a ventricular wall of cells extending from the level of the trigeminal nerve to the isthmic region. The location of the ChAT-positive cells suggests that they are postmitotic, and that they may include but are not restricted to some of the central components of the trigeminal system. The expression patterns in the retina are similar to that observed earlier, but the ChAT-positive cells in the central retina are more numerous. Since the retina develops in a central to periphery gradient, we hypothesize that ChAT expression is highest in developmentally more advanced retinal cells.
MOLECULAR AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT

REGULATION OF NEURONAL GENE EXPRESSION BY TARGET INTERACTORS: Nova, L. B. Welschen* and M. Maragò. Dept. of Biomedical Sciences, Columbia University, New York, NY 10027

Developing neurons and their synaptic partners exchange information that can affect their subsequent expression of particular genes. For neurons that can innervate either of two very different targets, their resultant patterns of gene expression may be significantly different from each other. We are studying this interactive process in the Retzius (Rz) cell, an identified neuron that is found at a precise location in each segmental ganglion of the leech nerve cord and innervates one of two targets, either body wall or the sex organs. The Rz neurons that innervate the sex organs in body segments 5 and 6 have different morphology, physiology and function than those homologues in other body segments, but will attain the same characteristics if the sex organs are ablated early in embryogenesis.

Comparing the patterns of gene expression between Rz neurons with different targets should allow us to find the genes that account for the two Rz neuronal phenotypes. To this end, we have amplified mRNA from individual adult Rz neurons in sex and non-sex segments, made CDNA from these mRNAs, and then used a differential display technique to compare expression profiles. We have thus far identified in these profiles a population of genes that are expressed exclusively in either sex- or non-sex Rz cells, and are in the process of obtaining information about their sequences and developmental patterns of expression in the nervous system. This information will be used to understand how neuronal fate is determined by early interactions with potential synaptic partners.

Nova-2: A New Neuron-Specific RNA-Binding Protein Associated With Parvalbumin-Positive Neurons. Yolanda VL Yang, Ronald J Buckanovich, Robert B Durell*. Laboratory of Molecular Neuro-Oncology, Rockefeller University, New York, NY 10021 USA

The Nova proteins were originally identified as target antigens in the neurodegenerative disorder paraneoplastic opsoclonus-myoclonus-ataxia (POMA). Analysis of the cloned family member, Nova-1, revealed that it was a neuron-specific RNA-binding protein with developmentally regulated expression. Using antisense from a patient with POMA, we have now cloned a second Nova family member, Nova-2.

Nova-2 shares extensive amino acid sequence homology with Nova-1. Both have homology with the KH RNA-binding domains (KBDs) found in PMB-1 (the familial mental retardation gene), hNRNP-K, and the yeast splicing factor MER-1. Comparison of Nova-2 to Nova-1 reveals 100% amino acid identity in the three KBDs, indicating a possible shared RNA target. Between RBD2 and RBD3, Nova-2 contains a unique domain with several stretches of alaas and glycine and one proline-rich region, suggesting that functional differences between Nova family members may map to this region.

In vivo hybridization (ISH) and mRNA analysis indicate that Nova-2 expression is limited to neurons in discrete regions of the developing and adult mouse nervous system, but with a different pattern of expression than Nova-1. We are further defining the expression of Nova-2 by Northern, RT-PCR, and ISH to distinguish between the Nova family members. In summary, we expect that the Nova family of RNA-binding proteins regulates neuronal development and function through their action on RNA metabolism, by such means as alternative splicing, stability, or translational regulation.

ROLE OF AP-1 PROTEINS IN TRANSCRIPTIONAL CROSS-TALK AT SOMATOSTATIN CYCLIC AMP RESPONSE ELEMENT (CRE). C.L. Smytheck-Sexton* and D.E. Millburg. The University of North Carolina at Chapel Hill, Chapel Hill, NC 27599 and The University of Cincinnati, Cincinnati, OH 45267.

The mechanism by which specific gene regulation, such as developmental and tissue-specific regulation, occurs is largely unknown. Given the ubiquitous nature of transcription factors and the large number of genes containing regulatory DNA binding consensus elements, how subsets of genes are transcribed in particular cells at certain stages of development remains an open question. The finding that cross-talk occurs among the hsp70 protein families, the Fox/Jun family and the CREB family, at the TRE (12-O-tetradecanoylphorbol-13-acetate response element) and CRE provides a possible mechanism for the specificity of developmental- and tissue-specific gene regulatory events. Our finding that Jun is involved in complex of cerebellar and diencephalic nuclear protein extracts which bind to the CRE led us to speculate that Jun levels and/or transcriptional activity could mediate CRE-driven transcriptional responses, especially CRE responses which are temporopre spatially regulated. We tested this hypothesis with phorbol-12-myristate-13-acetate (PMA) and forskolin treatment of phaeochromocytoma (PC12) cells transfected with the CRE-driven promoter of the somatostatin gene, which is known to be developmentally and tissue-specifically regulated. PMA (50 nM) increased transcription of the somatostatin promoter, presumably through the CRE, as did 25 μM forskolin. Treatment with both agents resulted in synergistic stimulation of transcription. In addition, gel shift studies showed that treatment of PC12 cells with PMA and forskolin increased binding of nuclear proteins from these cells to the CRE. These data suggest that the ratio of transcription factors, such as Fox/Jun and CREB, which are capable of interaction at each other's cognate DNA sequence, is crucial to determining the specificity of transcriptional events.

CEREBRAL CORTEX AND LIMBIC SYSTEM II

543.1

CONNECTIVITY OF FETAL LIMBIC CORTEX TRANSPLANTED INTO NON-LIMBIC CORTEX AFTER LONG TERM SURVIVAL OF HOSTS. M.F. Barbe*. Physical Therapy Institute, Philadelphia, PA, 19140

Previous studies using a molecular marker of limbic phenotype as well as Dil tracing techniques, in combination with brain tissue transection, have examined the developmental specification of regional cortical differentiation. The present study was undertaken to determine if connection phenotypes observed in earlier short term survival studies were maintained after long term survival of hosts receiving grafts. Limbic perihinal (phr) or sensorimotor (Sm) fetal tissue from rats aged embryonic (E) 12-14 was transplanted into neonatal rat Sm cortex. Animals were sacrificed 65 days later and Dil crystals were inserted into the graft. After a 12-14 week incubation period, the location of Dil-labeled neurons and axons were mapped in cortex and thalamus. Homotopic Sm transplants had no limbic thalamic or contralateral cortical connections, and only 1 of 7 had a connection with limbic ipsilateral anterior cingulate cortex (ACC). Most E14 phr grafts in host region had hybrid connections: out of 12 total animals analyzed in this group, 11 had both limbic and sensorimotor connections when one considers contralateral and ipsilateral cortices as well as the thalamus, 9 had hybrid ipsilateral cortical connections, while 7 had hybrid thalamic connections (ventral posterior and lateral dorsal nucleus), the remaining having either just limbic or sensorimotor. Nova-2: A New Neuron-Specific RNA-Binding Protein Associated With Parvalbumin-Positive Neurons. Yolanda VL Yang, Ronald J Buckanovich, Robert B Durell*. Laboratory of Molecular Neuro-Oncology, Rockefeller University, New York, NY 10021 USA

The Nova proteins were originally identified as target antigens in the neurodegenerative disorder paraneoplastic opsoclonus-myoclonus-ataxia (POMA). Analysis of the cloned family member, Nova-1, revealed that it was a neuron-specific RNA-binding protein with developmentally regulated expression. Using antisense from a patient with POMA, we have now cloned a second Nova family member, Nova-2.

Nova-2 shares extensive amino acid sequence homology with Nova-1. Both have homology with the KH RNA-binding domains (KBDs) found in PMB-1 (the familial mental retardation gene), hNRNP-K, and the yeast splicing factor MER-1. Comparison of Nova-2 to Nova-1 reveals 100% amino acid identity in the three KBDs, indicating a possible shared RNA target. Between RBD2 and RBD3, Nova-2 contains a unique domain with several stretches of alaas and glycine and one proline-rich region, suggesting that functional differences between Nova family members may map to this region.

In vivo hybridization (ISH) and mRNA analysis indicate that Nova-2 expression is limited to neurons in discrete regions of the developing and adult mouse nervous system, but with a different pattern of expression than Nova-1. We are further defining the expression of Nova-2 by Northern, RT-PCR, and ISH to distinguish between the Nova family members. In summary, we expect that the Nova family of RNA-binding proteins regulates neuronal development and function through their action on RNA metabolism, by such means as alternative splicing, stability, or translational regulation.

543.2

We previously reported that the number of GABA-immunoreactive (ir) neurons was increased in the anterior cingulate cortex (ACC), but not in the primary visual cortex (VC), in the rabbits prenatally exposed to cocaine (Wang and Murphy, Soc.Neurosci. Abst. 1993, 19:50). In the present study, we investigated the development of the subgroup of GABAergic neurons which are immunoreactive for the calcium binding protein parvalbumin. Since the major effect of cocaine is believed to be on the uptake of dopamine, we compared an area of cortex rich in dopaminergic input (ACC) with an area lacking dopaminergic input (VC) following prenatal cocaine exposure. Pregnant rabbits received intravenous injections of cocaine (4mg/kg, twice daily) from day six to day 29 of gestation. The volume of salicylate was injected systemically.

The brains of rabbit pups were examined at P10, P20 and P60. Immunocytochemical methods were used to visualize parvalbuminergic neurons. Quantitative analysis revealed a significant increase in the number of secondary and tertiary dendrites per neuron which were parvalbumin-ir in ACC in cocaine exposed brains in all age groups examined compared to controls. In VC, however, there is no difference between cocaine and saline animals in the number of secondary and tertiary dendrites per neuron which were parvalbumin-ir. In both ACC and VC, there were no significant difference between cocaine and saline in the number of primary dendrites per neuron which were parvalbumin-ir. E13 or E12 phr into Sm cortex grafts had any connections with limbic thalamic nuclei or limbic contralateral cortices, 2 were connected to ipsilateral ACC. The data suggest that projection patterns are subject to complex environmental influences. Supported by NSF grant 9209459.

Previous studies have shown that the entorhinal cortex (EC), a transient area of "pericalcortex," matures histologically and neurochemically earlier than neocortical areas. To determine if connections between the EC and hippocampus (HC) also develop in the neonatal period, an electrophysiological tracer dye (ChAT) was injected into the temporal horn of the lateral ventricle of newborn rats (PND 2-3) and projections to superficial and deep EC layers were identified. Injection into superficial parietal and occipital neocortex labeled radial glial fibers and Cajal-Retzius cells only. Injections of the optic nerve and tract labeled the lateral geniculate nucleus (LGN) specifically; evidence of eye-specific laminar segregation of projections to the LGN was seen with the optic nerve injections. The above findings demonstrate that cortico-cortical connections between EC and HC develop in the first half of human gestation, well before those in other areas, e.g. visual cortex.

To illustrate the potential of this method for studying HC/EC maturations, we injected dII into the medial entorhinal cortex (EC) of a 19-day CA thanatophoric dwarf (in which HC and HC develop abnormally). Labeling of radial glial fibers and a few Cajal-Retzius cells, appropriate for neocortex at that CA, was observed; EC-appropriate connections were absent.

Previous studies have shown that the entorhinal cortex (EC), a transient area of "pericalcortex," matures histologically and neurochemically earlier than neocortical areas. Postnatal (PN) development studies of GAD67 mRNA-containing neurons within the rat cerebral cortex have shown that the developing GABAergic system is more uniform than previously thought. Early hybridization studies have revealed a prominent population of GAD67 mRNA-containing neurons in the dentate gyrus at early ages (PN0-5NS). These neurons were highly concentrated both within and slightly above the outer border of the developing granule cell layer, creating a labeling pattern different from that of the adult. In order to determine whether the GAD67 mRNA-containing neurons observed on PN0-5NS are GABAergic, we examined PN5-10 GAD67 mRNA-containing neurons with immunohistochemistry for GAD67 and its catalytic subunit. In these early PN ages, GAD67 protein was evident in neurons occupying similar positions to the GAD67 mRNA-labeled cells, and the morphology of these neurons suggested that they were not granule cells. Birthdating studies of neurons labeled with bromodeoxyuridine at PN4, the birthdate of many GABA neurons in the dentate gyrus, revealed labeled neurons in positions corresponding closely to those of the GAD67 mRNA and protein-containing neurons at the early PN ages. This suggests that the neurons with early birthdates arrive in the granule cell layer at early ages and are GAD67-containing interneurons. Double labeling studies are being conducted to confirm this. These GAD-containing interneurons, due to their position and early appearance, could play a key role in the cytoarchitectural development of the dentate gyrus.

543.7 SURVIVAL AND TRANSMITTER SYNTHESIS IN RAT SEPTAL NEURONS FOLLOWING EXCITOTOXIC HIPPOCAMPAL LESION IN EARLY POSTNATAL DEVELOPMENT M. Mantsch, D.W. Kasper*, T. Neumann and M. Frotscher
Institute of Anatomy, University of Freiburg, P. O. Box 111, 79001 Freiburg, Germany

Target cells are thought to regulate the survival and transmitter expression of basal forebrain cholinergic neurons by supplying neurotrophic factors (Thoenen and Beaudet, 1988; Physiol. Rev. 68: 1264-1335). It has been shown in adult rats that septopallidal cholinergic neurons survived after excitotoxic ablation of their target region and retained their immunoreactivity for the terminal acetylcholine synthesizing enzyme, choline acetyltransferase (ChAT); see Sofroniew et al., 1990, Science 247: 338-342.

To investigate whether the hippocampus is essential for survival and transmitter expression of developing septopallidal cholinergic neurons, we have destroyed the hippocampus by unilateral injections of the excitotoxic amino acid NMDA in 3 and 10 day old rats. These lesions were made to bilateral septal regions that were immunostained using antibodies against ChAT or the calcium-binding protein parvalbumin (PV). The latter staining has been used to stain GABAergic neurons (Freund, 1989, Brain Res. 478: 375-381).

We have found that a large number of septal neurons retained their immunoreactivity for ChAT and PV, respectively, at both survival times despite the early loss of their target region.

We conclude from our experiments that the target region has only a limited influence on survival and transmitter expression of developing septopallidal neurons.

DMAP45 and 55 were originally identified as 45 and 55 kDa proteins that co-sedimented with microtubules purified from Drosophila embryos (Srinivasan et al., J. Neurobiol., 24:15-32, 1993). DMAP45 is present in the cytoplasm of all cell-types throughout early embryonic development and also accumulates in the developing nervous system to levels above those found in other tissues. DMAP55 has a cytoplasmic distribution similar to tubulin and is associated with mitotic spindles. DMAP45 has also been shown to be present in several nonneural cells in culture. In undifferentiated N1E-115 neuronaloma cells, DMAP45 is present early in the actin-rich region of the lamellipodia and microtubules protruding from the cell membrane, but is absent from the cytoplasm. Upon differentiation with DMSO, the protein is enriched in the distal tips of advancing growth cones and in microtubules protruding from the neurite shaft. In the fibroblast NIH-3T3 cells line, DMAP55 stains the endoplasmic reticulum.

DMAP55 is present along the lengths of the N1E neurite shafts in differentiated cells, and co-localizes with cytoplasmic microtubules in both undifferentiated and differentiated NIH-3T3 cells.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
453.9

A set of novel microtubule-associated proteins (termed DMAPs) (previously termed FLAT-MAPls) have been identified in Drosophilia and are present in the purified microtubule protein fraction of the rat brain. Developmental regulation of DMAPs has been observed in the rat cerebral cortex and cerebellum (Comery et al., Soc. Neu. Abst. 1993). The late developing nature of the dentate gyrus and the stereotyped pattern of connectivity within the hippocampal formation provide an ideal system to investigate the potential involvement of these proteins in process extension, differentiation and synaptic formation. Expression of DMAP45R in somata and dendrites of the pyramidal cells of the CA regions and the granule cells of the dentate gyrus correlates with process extension and cell differentiation. Expression of DMAP45R in the CA3 pyramidal cells correlates with the innervation of these cells by mossy fibers from the dentate gyrus. DMAP45R is also expressed in the inhibitory interneurons of the hilus and CA3 region with peak expression occurring at P9. DMAP55 immunoreactivity in axons correlates with the development of the mossy fiber projection from the granule cells of the dentate gyrus to CA3. The level of expression of DMAP55R increases during the growth of the mossy fiber system, reaching a peak level at P20, following which the level of expression gradually declines. Similar patterns of immunoreactivity during the development of other fiber systems suggests a possible role for DMAP55R in axonal extension. Supported by NIMH 53231 and ROI GM47962-01.

453.11

The possible role of cytoskeletal elements in experience-dependent plasticity was investigated. The antibody DMAP45 raised against a novel microtubule-associated protein isolated from Drosophilia cross reacts with a developmentally regulated antigen (DMAP45R) in rat brain (Comery et al., Soc. Neu. Abst. 1993). We examined the immunoreactivity of DMAP45R in layer 5 in the visual cortex of monocularly deprived rats. One eye of rat pups was sutured closed at P12. A nonremovable control group was used for comparisons. Coronal sections of the visual cortex were stained with DMAP45. Pyramidal cells were classified on the basis of immunoprecipitation in the soma and associated dendrites (soma/dendrite-positive cell) or in the soma only (soma-positive cell). The number of these two types of cells per unit area (NA) was determined in the visual cortical regions OIbm (somato-bisomatocellular) and OICb (bisomato-bisomato) contralateral to the deprived eye.

Deprivation until day 90 resulted in a reduction of DMAP45 somata/dendrite-positive cells in OICb. Removing the sutures at day 75, and allowing 5 days of exposure to light, restored the staining to control levels in the soma/dendrite-positive cells in OICb. The density of soma-positive cells was not changed in OICb in either condition. No differences were observed in the densities of either soma/dendrite-positive or soma-positive cells in the bisomato cellular region. The modulation of DMAP45R by visual experience suggests that MAPs may play a role in experience-dependent structural plasticity. Supported by NIMH 39603, NSF BNS88 21219, GM47962-01.

BRAIN MICRO-EEG FREQUENCY OSCILLATIONS. C.C. Turben®
Coghoun University School of Medicine, Division of Anatomy, Omaha, NE 68178

In these studies recordings macro and micro electrode recordings from the cat brain, micro-EEG, are considered. Combinations of ion currents give rise to complex patterns of neuronal electrical activity in the brain cell microenvironment, the extracellular space. The flow of ions through populations of ion channels in the neuronal plasma membrane and give rise to transmembrane ion currents. It is the sum of various currents flowing at any point in time that determines the neuronal membrane potential. The multiple ion channels with their diverse and interacting regulatory mechanisms allow the neuron to modulate its electrical properties in complex ways of high frequency oscillations and electrical fields.

Some of the cortical and hippocampal neurons have ionic conductances organized to endow them with auto rhythmicity. In many neurons the kinetics of these ionic voltage dependent conductances are such that the cell may respond preferentially to inputs at a certain frequency or frequencies acting as a resonator. There are interactive processes between the components of the dorsal hippocampus micro-EEG and the evoked potentials off the cortical-EEG and the micro-EEG.

These findings reflect the interaction between the dorsal hippocampus and cerebral cortical regions in the processes of ordering, sequencing the succession patterned sensory information as it relates to memory and conscious states.
544.1 POSTNATAL NEUROGENESIS IN THE DEVELOPING RETINA OF THE BRAZILIAN OPUSCULAR, O. STEWART, C. JENSEN, J. ISLAM, L. ELMQUIST, C. D. JACOBSSON2 and D. S. SAKAGUCHI. 1, 2Dept. of Zool. and Genetics, Signal Transduction Training Group, 1Neuroscience Program and 2Dept. of Veterinary Anatomy, Iowa State University, Ames, IA 50011, 2Department of Neurology, Harvard Medical School, Boston, MA 02115.

We are investigating cellular genes in the retina of the Brazilian opuscular, Monodelphis domestica. Monodelphis expresses both rod and cone photoreceptors and has two populations of ganglion cells: afferent and efferent. Using autoradiography and single cell labeling with [3H]thymidine, we demonstrate the presence of four cell types: afferent, efferent, a few undifferentiated cells, and a population of cells that are not labeled by [3H]thymidine. The undifferentiated cells express a variety of markers, including the photoreceptor markers VIP and TrkA, the afferent markers SNAP-25 and p65, and the efferent markers SNARE and Rab3. These results suggest that Monodelphis has a unique pattern of retinal development, with a large number of undifferentiated cells that may be involved in the regulation of retinal development.

544.2 SPATIAL AND TEMPORAL DISTRIBUTION OF SYNAPE-SPASE ASSOCIATED PROTEINS IN THE DEVELOPING RETINA OF MONODELPHIS DOMESTICA. D.S. Sakaguchi1, 2, J.J. Swanson1, 2, and C.D. Jacobsson1, 2, 1Dept. of Zool. and Genetics, Signal Trans. Training Group, 2Neurosci. Program, and 2Dept. of Vet. Anatomy, Iowa State Univ., Ames, IA 50011.

In the present study, we have examined the early postnatal development of the retina in the Brazilian opuscular, Monodelphis domestica. Monodelphis is a small, pinniped marsupial that has a unique pattern of retinal development. The retina is composed of two populations of ganglion cells: afferent and efferent. Using immunohistochemical methods, we demonstrate the presence of four cell types: afferent, efferent, a few undifferentiated cells, and a population of cells that are not labeled by [3H]thymidine. The undifferentiated cells express a variety of markers, including the photoreceptor markers VIP and TrkA, the afferent markers SNAP-25 and p65, and the efferent markers SNARE and Rab3. These results suggest that Monodelphis has a unique pattern of retinal development, with a large number of undifferentiated cells that may be involved in the regulation of retinal development.

544.3 DETERMINANTS OF RETINAL SPECIALIZATION: A NEW APPROACH USING FINITE ELEMENT ANALYSIS. Allen Diner, Department of Cell Biology and Anatomy, New York Medical College, Valhalla, New York 10595.

Neither differential cell death nor differential retinal ganglion cell histogenesis adequately accounts for the progressive increase in the central/peripheral (C/P) retinal ganglion cell (RGC) density ratio during the course of ontogenesis in the cat. Differential retinal stretch remains the only mechanism that could account for the final RGC topography. However, this hypothesis cannot be tested directly. This model assumes that the central retina stretches less than the peripheral retina. Differential stretch of the RGC layer could occur if central retina were thicker than peripheral retina. Retinal thickness was determined in E35 cat retina indicate that the RGC layer of central retina is 2.5 times thicker than that of peripheral retina. The thick spot is located about 0.8 mm from the optic disc. This thickness difference is unrelated to differences in the size or density of RGCs in central vs. peripheral retina. By E62 the C/P ratio becomes 18.3:1 and the distance between the optic disc and the area centralis is about 2.5 mm (Liu et al., '87). The shape of the optic disc to the retinal margin, was digitized. The RGC layer was modeled as having uniform material properties. A finite element analysis model was used to stretch the E35 RGC layer from 2 to 10mm in length. The model allowed making measurements of RGC density, as well as distance of the area centralis from the optic disc, over the entire duration of the stretching process. In a retina stretched from 2 mm to 8 mm in length, the obtained C/P ratio was 19.3 and the optic disc area centralis distance was 2.5 mm. These values are very similar to the in vivo results reported by Liu et al. (87). Therefore, the adult RGC layer topography can be predicted accurately by the non-uniform geometry of the RGC layer and by retinal stretch.

544.4 INSULIN-LIKE GROWTH FACTOR 4 (IGF-4) STIMULATES PROLIFERATION AND NEURONAL PROCESSES IN THE ADULT GOLDFISH RETINA IN VITRO. S.E.M. Bouchet* and P.F. Hitchcock, The University of Michigan, Dept. of Ophthalmology, Anatomy and Cell Biology, and Neuroscience Program, Ann Arbor, MI.

The retina of the goldfish grows throughout the life of the animal and regenerates when injured. We developed an organ culture system to test peptide growth factors for their ability to stimulate the proliferation of neuroretinal precursors in both normal and injured/regenerating retinas. Normal eyes were enucleated and the anterior structures removed. Eyecups were incubated for three days in Media 199, with or without a peptide growth factor. Cultures were posteriorly sliced with a bromodoxystilurea (BUD) before incubation was halted. Eyecups were fixed, frozen, sectioned and processed for BUD immunocytochemistry. The number of BUD labeled photoreceptor neuronal precursors (in the circumferential marginal zone) and rod precursors (in the outer nuclear layer) were counted and averaged. For retinas incubated in media alone, the average number of BUD-labeled neuronal precursors ranged from 5 to 15, and BUD-labeled rod precursors ranged from 1 to 8. For retinas cultured with IGF-I at concentrations ranging from 10-4 to 10-6 M, the average number of BUD-labeled neuronal precursors was 56, 113, and 154, respectively. In contrast, there was no significant increase in the number of BUD-labeled rod precursors. In summary, we show that IGF-I at concentrations of 10-4 to 10-6 M causes a 10-20 fold increase in the number of BUD-labeled neuronal precursors, but no effect on the number of rod precursors. Furthermore, we find that IGF-I is likely to be synthesized in the retina, and that IGF-I may play a role in regulating cell proliferation in both the developing and regenerating retina. Supported by NIH (NSI) grants EY07060 and EY07003 (CORE).
544.7 A START AT MAPPING GENES THAT CONTROL RETINAL GANGLION CELL NUMBER: ANALYSIS OF INBRED, F1 HYBRID, AND RECOMBINOINT INBRED STRAINS OF MICE. R. W. Williams*, D. S. Rice, and D. Goldowitz. Department of Anatomy and Neurobiology, University of Tennessee, Memphis, TN 38163

Genes that control neuron number play a critical role in the function and evolution of the vertebrate CNS. We have identified one, or possibly two gene loci that are responsible for normal strain variation in the number of ganglion cells in the mouse retina.

Ganglion cell axons were counted on electron micrographs of optic nerves taken from more than 140 animals belonging to 33 different inbred strains of mice, including strains 129, A, AKR, BALB/c, CH/Hs, C57BL/6, C57BL/Ks, CAST/Ei, CBA, CD-1, CE, DBA/2, LF, NZB, NZW, PL, SL, and STREP/El. Cell number varied substantially among strains, from a low of 49,000 in CAST/Ei to a high of 67,000 in NZW. Errors of the mean are typically 2,000. Strain averages are distributed bimodally, and most strains have populations that cluster close to 52,000 or 64,000. There is no correlation between cell number and body size, brain weight, or retinal area. Phenotypes of F1 offspring from crosses between high and low strains (BALB/c by C57BL/6, BALB/c by A, and PL by SJL) are consistent with a model involving two gene loci. However, we cannot yet formally rule out a model involving a single locus with three or more alleles. Ongoing analysis of recombinant inbred BXD lines of mice suggests that one of these loci controlling neuron number in the mouse retina maps to chromosome 1, 2, or 6.

Supported by NEI R01-8868.

544.9 ASYMMETRIC RETINAL GROWTH IN ADULT GREEN SUNFISH D.A. Cameron, L. J. Butler, and M. F. Gather. Dept. Biology, University of Michigan, Ann Arbor, MI 48109-1048.

Teleost fish retinas grow throughout life by a ballon-like expansion and by the appositional addition of neurons and glia to the retinal margin. An earlier report (Cameron & Easter, Vis. Neurosci. 10:375, 1993) presented the hypothesis that fish retinas with a curved, non-fused embryonic fissure grow asymmetrically along the retinal margin. We have tested this hypothesis in adult green sunfish (Lepomis cyanellus), which have a curved, non-fused embryonic fissure, concave towards temporal retina.

The thymidine analogue BrDU was intraocularly injected into adult fish (n = 6) and whole-mounted processed for fluorescence anti-BrDU immunohistochemistry 20-37 days later. In retinas an annulus of BrDU-positive nuclei was observed central to the retinal margin (but not along the embryonic fissure). The absolute rates of retinal growth were roughly exponential functions of fish size—small retinas tended to grow faster than large retinas. However, growth asymmetry was present: the normalized distances of the BrDU annulus to the nearest retinal margin were 1.00 ± 0.03, 1.27 ± 0.03, and 1.44 ± 0.09, in temporal, dorsal, nasal, and ventral retina, respectively (means ± SEM). Thus temporal and dorsal quadrants enlarged less than ventral and nasal quadrants. The normalized densities of cone photoreceptors in the same quadrants roughly matched the normalized growth distances (1.00, 1.03 ± 0.09, 1.19 ± 0.05, 1.55 ± 0.14). Growth asymmetry was thus attributable to differential cellular addition rather than differential passive expansion.

544.10 NEUROPEPTIDE RETINILNE AS A PROTECTOR OF RETINAL DYSTROPHY IN CAMPBELLS RATS. N. Balasubramanyam*, N. Balasubramanyam, A. Ragno, and W. A. Cameron. Institute of Neurological Sciences, University of Edinburgh, Edinburgh, Scotland.

Neuropeptide retinalilne (NPR) is a 39 amino acid peptide that inhibits the release of dopamine (DA) from dopamine (D1) receptors in the retina. It is also a neuroprotective agent that has been shown to reduce the loss of dopaminergic neurons in the retina of adult rats. The mechanism of protection is thought to be mediated through a reduction in the release of DA from dopaminergic neurons in the retina.

The retina of adult rats was isolated and exposed to the dopamine D1 receptor agonist quinpirole. Pharmacologically, this induction of dopamine release was reduced by pretreatment with NPR. This was suggested by a significant reduction in the dopamine D1 receptor agonist-induced rise in cytosolic calcium. This result indicates that NPR serves as a natural protective agent against dopamine-induced oxidative stress.

The authors propose that NPR could be a potential therapeutic agent for the treatment of retinitis pigmentosa and other retinal diseases. They suggest that further study is needed to determine the exact mechanism of action of NPR and to explore its potential as a therapeutic agent.

Neuronal expression of the early oncongenes c-fos and c-jun has been reported following stimulation of different regions. 30/35-day-old Wistar rats were chronically illuminated with 1200 lux during 8 days, followed by different dark adaptation periods. Illumination produces degeneration of photoreceptor outer segments. It is known that this phenomenon is reversible after an adequate period of darkness. Retinas were fixed by perfusion with a 4% paraformaldehyde solution, in phosphate buffer, after a period of illumination followed by 1, 3, 6, 10 and 18 days of dark period. Cryostat sections were immunocytochemically stained with antibodies to c-fos and c-jun (Affinity Bio-research Prod. A1000) and c-jun (CRB) c-dil (1:10000), biotinilated donkey anti-sheep IgG (Sigma) and the extravidin-peroxidase complex (Sigma). C-fos and c-jun immunoreactivity was detected in the somata of photoreceptors in all retinas thus observed. It was maximum in the photoreceptor nuclei of rats kept in total darkness for 3 days, and decreased thereafter. Staining stabilization was reached at about 10 days post illumination. The conclusion is that these expression changes played a role in the molecular events that participate in photoreceptor regeneration.

544.12 EXPRESSION OF D1 AND D2 Dopamine receptors and dopamine transporter mRNA in the adult and fetal monkey retina. A.K. Ronkainen, L. Chai, and W.S. Chai. Oregon Regional Primate Research Center, Beaverton, OR 97006 and Dept. of Physiology, OHSU, Portland, OR 97201-3098.

Expression of D1 and D2 dopamine receptors and dopamine transporter (DAT) mRNAs were studied in the adult and fetal monkey retina by Ribonuclease Protection Assay (RPA). Eyes were dissected from adult and a 70 day old monkey fetus. Monkey specific cDNA clones corresponding to the carboxy terminus of the rhesus monkey D1 and D2 receptors and to the XI-XII transmembrane domains of monkey DAT were cloned and used to generate the cRNA probes. The standard curves were constructed using known amounts of synthesized sense RNA. In the adult monkey retina, dopamine D1 and D2 receptor mRNAs were expressed in equal quantities and at relative high levels. DAT mRNA was also expressed in the retina, but at a more moderate level. In the 70 day fetal eye, D1 and D2 receptor mRNAs and DAT mRNA were not detectable. The dopamine D1 receptor mRNA was higher than D2 receptor mRNA and D2 receptor mRNA higher than DAT receptor mRNA. Thus, several of the genes of dopaminergic neurotransmission are expressed early in the developing fetal eye of rhesus monkey. (Supported by DA07165)

We have previously demonstrated that extracellular levels of endogenous glutamate are high in the developing rabbit retina. This amount of glutamate would be toxic in the adult retina; however, immature neurons survive and maintain normal developmental processes. We wished to determine whether NO which has been postulated to mediate glutamate toxicity in the adult CNS may be present and function in the developing and adult retina. First we used immunocytochemistry and histchemistry to localize nitricergic neurons in the adult retina and subsequently determined developmental profiles. Secondly using retinal explants we have analyzed viability of immature and adult neurons in response to NMMA and NO antagonist and agonist. Results show that prototypic nitricergic neurons are mature early but do not express detectable levels of NOS until day 10. Furthermore immature neurons at day 1 are insensitive to glutamate toxicity, while in the adult retina dose-sensitive toxicity is induced by NMMA and inhibited more than twofold by methyl arginine. We conclude that 1) glutamate toxicity in adult retina may be regulated by NO and 2) the resistance of immature neurons to glutamate toxicity may result from a delay in the maturation of the NO system. ELECTRIC EFFECTS ON AXONAL TRANSPORT IN THE CORTICOSPINAL TRACT FOLLOWING SPINAL CORD INJURY. J.A. McLear*, T. Cobb and T. Khan, Rehabilitation Research & Development Center, Edwardw C. McC. VA Hospital, Havana, IL 61245.

Unlike axons of peripheral nerves, injured axons of the adult spinal cord seldom undergo a functional regeneration. Recent studies have shown that a direct current field at the injury site enhanced regenerative outgrowth, and stimulates directed neurite growth. Spinal axonal injury in adult rats temporarily increased the level of slow axonal transport using tritiated amino acids injected in the retina. The present study was designed to test the hypothesis that electrical stimulation increases neurite regrowth by enhancing this period of increased axonal transport following spinal cord injury. Adult rats received a dorsal spinal cord hemisection at the T8 level. Miniature stimulators were implanted at the time of surgery with platinum disk electrodes placed extradurally proximal (anode) and distal (cathode) to the injury. The stimulators provided a constant electrical current to the conduction tract was labelled with 3H-methionine one week, five weeks, or fourteen weeks later by injecting 200 uL of radioactive vehicle into the sensorimotor cortex. One week (fast transport) or three weeks (slow transport) after the isotope injection the animals were perfused with formalin, the entire spinal cord dissected, and the radioactivity in 5 mm segments of the spinal cord determined by scintillation counting.

We found that the amount of radionuclide delivered by slow axonal transport was consistently (but not statistically) higher in the spinal cords of animals treated with electric fields. The spinal cord segment containing the injury site in the electric field treated animals did contain statistically more (15%) label relative to sham animals (no field) one week after injury. This increased label at the injury site disappeared after five or fourteen weeks. Fast transport was not altered at any time point, and therefore likely did not contribute to the increase. These data suggest that electric fields increase the slow transport of materials within the conduction tract, and temporarily prevent axon die back and/or stimulate neuronal sprouting near the injury site.

LONG-TERM EFFECTS ON RETINA OF RHESUS MONKEYS FED TAURINE-FREE HUMAN INFANT FORMULA. H. Imaki*, M.D. Neuringer and J.A. Sturman, NY State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; Oregon Regional Primate Research Center, Beaverton, OR.

We have been studying the effects of postnatal deprivation of tauring by feeding rhesus monkeys a infant formula alone or supplemented with tauring from birth. Previous reports have documented reduced tissue tauring concentration and smaller ileal bile acids concentrations with tauring in tauring-deprived monkeys at 3 months and 6 months, although at 12 months these parameters were no longer different, suggesting the biochemical dependence of intestinal tauring synthesis has at least by 6 months, but has regressed by 12 months. At the early ages, the tauring-deprived monkeys have deficits in visual acuity and morphological changes in the retina and visual cortex compared with monkeys fed the same diet supplemented with tauring. The retinal changes persisted at 6 and 12 months. The present study addresses the question of whether or not the retinal changes persist for a substantial period beyond the time at which there are no longer reduced tissue tauring concentrations. Rhesus monkeys raised for 4 years were examined, and although there were no differences in tissue tauring concentrations between tauring-deprived and tauring-supplemented monkeys, as might be expected from our previous results, all tauring-deprived monkeys showed retinal changes, indicating that the retinopathy of tauring deficiency persists long after the differences in tissue tauring concentrations have disappeared. Supported by NH grants HD-18678 and RR-00163.

544.3

Although it has been shown that electrical stimulation can accelerate sprouting, it is not clear whether increased neuromuscular activity during sprouting has any effect on the size of motor units (MU) once connections are made. In this study, this question was addressed using high levels of activity during sprouting and determining the size of enlarged MUs in partially denervated muscles (PD) once connections were re-established. MUs were divided into 2 groups, exercised (E) and sedentary (S) in which rats received large cage running wheels (E) or in small cages with limited movement (S). After 4 weeks of exercise training, rats were killed, and hindlimb muscles were partially denervated by cutting either L5 or L4. Four weeks later, MUs were quantified in the plantaris (PL) and gastrocnemius (MG) and tibialis anterior (TA) muscles were prepared for muscle and EMG recording in PD and controlateral control (CC) large and small. Size and size of all of 4 muscles, the size of the enlarged MUs in PD muscles was significantly larger than in CC. In PD, the MU number was different in E and S. For an average of 50% PD, 4000 MUs were counted (E) vs 15.6 ± 0.82 (S) as compared to 10.71 ± 0.9 in CC muscles. For MG, the size of MUs of 6.8 ± 1.91. 8 DEV 9.6 (S) and 15.6 ± 0.82 (S) 10.71 ± 0.9 CC. Since these muscles were significantly higher in the number of MUs, the MG force was increased by the number of muscle fibers per motor unit and therefore of sprouting. These results show that high levels of neuromuscular activity do not influence the capacity of remaining motoneurons to form enlarged MUs. Supported by MHIC.

Several previous studies have shown that when the rodent spinal cord is damaged, DC electrical field treatment (DCEF) can result in partial recovery of function. The objectives of this study were to investigate the conditions which determine whether such recovery involves regeneration or sparing of axons. The methods incorporated a spinal hemisection in rats followed by DCEF (Traxon®) for 6 weeks, and then sacrifice. Control animals received no DCEF. Prior to sacrifice, animals were injected with WGA-HRP isplateral and caudal to the lesion. After histological processing, WGA-HRP transport to the red nucleus was determined by automated grain counting. The results showed that all DCEF animals exhibited greater WGA-HRP transport to the contralateral brainstem when compared to the ipsilateral side or to control animals. While previous experiments have shown that sparing and regeneration both occur with DCEF after contusion injury, these experiments show that DCEF is at least likely to promote axonal regeneration after axotomy in the spinal cord.

Unlike mammals, lower vertebrates are able to regenerate injured pathways of the CNS throughout life. In the optic nerve of goldfish, a good deal of research has been directed towards the changes in neuronal gene expression that accompany regeneration. However, the trophic factors responsible for initiating this process are unknown. We have shown that molecules secreted by the glial sheath cells and collected into culture medium (regenerative conditioned medium, RCM) induce neurite outgrowth in both embryonic mammalian cortical neurons (Caday et al., Mol. Brain Res. 45-50) and dissociated goldfish retinal cells (Bouls et al., these Abstracts, 1992). Conditioned media derived from other organs of the goldfish showed no similar activity.

Using the recombinant dye 4-d10-ASP, we have shown that RCM acts specifically on its natural target cells, the retinal ganglion cells, by promoting neurite outgrowth but not by influencing survival. RCM contains two trophic factors that differ in physical properties and patterns of expression. The smaller of the two, which accounts for most of the biological activity, is <1 kD in size, heat-stable, pronase and trypsin-insensitive, and has a hydrophobic domain. It is actively secreted and is expressed even in the intact optic nerve. The larger is a heat-labile, trypsin-sensitive, basic protein, Mr=70-100 kD, and is upregulated after axotomy.

Since these molecules are secreted from the optic nerve and target the retinal ganglion cells, they are likely to be important in inducing optic nerve regeneration in vivo. We are currently working to isolate the two factors and to evaluate the involvement of defined trophic factors in this system. Support: NIH EY 06690, HMMI, Boston Neurosurgical Foundation.

Apolipoprotein E (apo-E) is a lipid transport protein present in glial cells, whose concentration is increased following injury in most parts of the nervous system. The increase is due to synthesis by glial cells and to secretion by invading macrophages. An exception to this is in the optic nerve, where there is no increase in apo-E synthesis by glial cells following injury and there is a retarded rate of macrophage invasion. In addition, very little recovery or repair of the injured optic nerve occurs spontaneously. This study investigated the possibility that apo-E, administered systemically, might facilitate the repair or healing of the rat optic nerve following injury.

Crush injuries of the right optic nerve were made in anesthetized adult male rats. Apo-E purified from rat brain was injected into the nerve sheaths at the site of injury at varying doses (0, 1, 10, and 25ug). A retrograde tracing dye (biotinylated dextran conjugated to lissamine) was injected into the vitreous humor at 2, 6, or 13 days after injury. At 3, 7, or 14 days after injury, the nerves were harvested and prepared for immunohistochemistry to visualize: a) dye transport, b) macrophages, c) myelin. Apo-E administration affected several events associated with healing in a dose-related fashion. First, the transport of the dye was enhanced, both in distance past the injury and in the number of axons containing the dye. Second, the recruitment of macrophages to the crush site was significantly increased. Finally, the rate of myelin degeneration appeared to be increased. These data suggest that the presence of apo-E promotes several events known to be beneficial to nerve repair, and may provide an environment conducive to nerve repair or regeneration.

CHANGES OBSERVED FOLLOWING TREATMENT OF CHRONIC INJURIES OF THE BRAIN AND SPINAL CORD WITH AMP1 AND MATRIX. J.D. Peduzzi1, F.R. Fischer, and E.E. Geisert, Jr. 1Department of Physiological Optics, University of Alabama at Birmingham, Birmingham, AL 35294; 2Department of Anatomy and Neurobiology, University of Tennessee, Memphis, Memphis, TN 38163.

Regeneration is generally not observed after adult mammalian CNS injuries. Our efforts have been directed at manipulating the injury site by disturbing the scar and providing an environment favorable to axonal growth. Adult Sprague-Dawley rats received a brain lesion with a scalp blade or contusive spinal cord injury (10 g wt. dropped 5 cm) at the T9 vertebral level. After at least 2 months, animals received an injection into the injury site with one of the following: buffer, AMP1 antibody with EDTA, or AMP1 with EDTA and matrix. AMP1 antigen is a 110 kDa molecule that is upregulated at the scar. In the brain injured animals, AMP1 with EDTA appeared to disrupt the scar and growth cone-like structures were seen extending into the matrix. In spinal cord injured animals that received the AMP1 with EDTA and matrix, a slight but significant improvement was found in the combined behavioral score which is based on motor and sensory tests (modified from Gale, Keraédis and Wrathall, 1985, Exp. Neurol. 88:123). Supported by the Spinal Cord Society.

During the development of the central nervous system (CNS), the formation of axonal pathways and appropriate neuronal connections by axons is dependent on axonal growth and inhibitory interactions between cells and the extracellular environment. Proteoglycans are one of the many members of the extracellular matrix found to function in both the developing and mature CNS. One such proteoglycan, ABACKAN, was found in previous studies in functional boundaries of the developing rat CNS. In addition, ABACKAN was shown to inhibit both neuroblast cell attachment and neurite outgrowth on substrates of laminin. In the present study, ABACKAN was isolated from adult rat brain and preliminary biochemical analysis was performed to help determine the structure and possible function of the proteoglycan in the normal CNS. The proteoglycan was found to have an Mr of approximately 140 kDa and to be composed of a 170 kDa core protein to which both chondroitin and keratan sulfate chains are attached. A third carbohydrate moiety which was found to have HNK-1 antigenicity was also found attached to ABACKAN. To ascertain its function after injury in the CNS, the distribution of ABACKAN relative to specific cell markers and other proteoglycans was determined in normal and crushed optic nerve. ABACKAN, along with other proteoglycans, was found to be significantly upregulated after crush injury suggesting that ABACKAN plays a role in the inhibition of nerve regeneration. Supported by the Whitaker Foundation (EEG), NIH Grant # AR32666 (BC), the Canadian Spinal Research Organization (AS), and the NIH/NRSA Trauma Research Fellowship (DB).

EFFECTS OF IN SITU MICROINJECTION OF ANTI-NEUROFLAMENT MABS INTO REGENERATING GIANT CENTRAL NEURONS IN THE LAMPREY G.F. Hall, D.S. Pisac, E. Lampert* and M.E. Asen. Dept of Neurology, Children’s Hospital, Boston, MA 02115 and Dept of Neurology, Univ. of Penn., Philadelphia PA 19104.

Identified giant neurons (anterior bulbal cells or ABCs) in the hindbrain of the lamprey, a jawless sea lamprey. Permazol-injected brain have been shown to be an advantageous preparation for studying the effects of axotomy in situ using microinjection techniques. Here we examined the effects of microinjection of monoclonal antibodies to neurofilaments (LFM40) raised against the lamprey neurofilament protein (NF180) into regenerating ABCs. ABCs were injected with either of these mAbs at 4 mg/ml or 12 days following axotomy at the level of the 5th gill and were reaxonimized in the hindbrain at this time. Lucifer Yellow-dextran (LY-D, 10 mg/ml) was also injected to reveal the injected cells in wholemount. Injection controls consisted of rabbit IgG (5 mg/ml) and LY-D.

We found that anti NF180 mAbs injected a pronounced axon stump narrowing in treated neurons by 12 days post injection when compared to controls (p < 0.005, chi square test).

There was otherwise little difference between anti NF180 mAbs injected cells and controls in the shape of cell body and dendrites. In light of the role played by mammalian neurofilaments in maintaining axonal caliber, we propose that microinjection of anti NF180 mAbs blocks the transport of NF180 into regenerating axons. Supported by NIH grant NS29281 to G.F.H.

545.13

Oligodendrocyte inhibitory proteins retard axonal growth in mature mammalian CNS. We show that axons from 5 to 10 retina of hamster can show vigorous growth in the mature tectal environment, despite the presence of this target of differentoligodendrocytes. To test whether retinal neurons in retinal explants or animals have a capacity to regenerate the oligodendrocyte proteins, supernatant (30%) from hybridoma cells producing the neutralizing antibody In-1, or from control cells that produce an antibody against HRF, was added to co-cultures of retinal neurons in animals aged E14-15 and adult tadpoles. Cultures were maintained at 27°c for 5 days, fixed, and crystals of Dhl were placed in retinal explants to label the regenerating axons. In the presence of control antibody, the retinal axons were able to grow vigorously into tectum of all ages. In the presence of In-1 antibody, axonal outgrowth was significantly increased. Thus, E14-15 retinal neurons clearly have a receptor for the protein, and their growth by inhibition cannot be inhibited. In addition, we examined the effects of In-1 antibody in isochronic co-cultures prepared from animals aged P4 or older, when most retinal axons have lost the ability for axon elongation into the central target. We found that some retinal axons grew into tectal slices in an arborization mode at rate of about 100 μm per day. Addition of In-1 antibody increased the average number of axons entering tectal slices, but it did not change the basic mode of growth. The results suggest that factors intrinsic to the retina are involved in determining the growth ability of retinal axons, while myelinated inhibitors can limit the growth of retinal axons once they reach the CNS environment. (Support: NIH grants EY00126, EY01621.)

ALTERATIONS IN GLIAL MORPHOGENESIS AND ANTIGENIC PHENOTYPES FOLLOWING IRRADIATION. T.J. Sims, D.L. Davies and S.A. Gilmore. Department of Anatomy, University of Arkansas for Medical Scientists, Little Rock, AR 72205.

Early postnatal exposure of the lumbar sacral spinal cord to X-rays results in dramatic in vivo alterations in developing glial populations and in subsequent conversion to a CNS glial environment that is permissive for the regeneration of axons (Sims and Gilmore, Brain Res., 1994). To understand mechanisms involved in this conversion to a permissive environment, the status of the glial populations persisting after x-irradiation (40 Gy) of the 3-day-old spinal cord was further assessed in vivo by transgenic fate mapping. Control cultures prepared from non-irradiated spinal cord and experimental cultures established from the cords of irradiated littermates were compared by immunocytochemical and histochemical staining at 18 days in culture. The most conspicuous difference was the profound reduction in numbers of both astrocytes and oligodendrocytes in experimental cultures. In addition to differences in macroglia, the microglial population was severely depleted in experimental cultures (see Gilmore et al., this meeting). Five morphologically distinct astrocyte populations, both control and experimental cultures. The latter, however, contained a greater proportion of astrocytes with flat bipolar shapes. Addition of dibutyryl cyclic AMP (1 mM for 30 hrs) to control cultures released the cellular compartment to include greater proportions of process-bearing cell types, but failed to elicit a similar change when added to experimental cultures. Unexpected changes in phenotype were observed, however, such as astrocytes with cytoplasmic staining for glialactocerebroside, a marker normally associated with oligodendrocytes. This cell culture study strongly suggests that x-irradiation of the spinal cord not only reduces the glial populations, but also dramatically alters its cell composition and generates cells of distinct antigenic phenotypes. Supported by NIH grants NS 04768 and AA 07145.

545.16

Peripheral nervous system injuries often result in significant functional loss, including painful sequelae, that are often refractory to conventional surgical repair. The objective of the present study was to determine if a single application of the platelet-derived growth factor-BB (PDGF-BB)/insulin-like growth factor-I (IGF-I) combination could enhance the repair of injured peripheral nerve.

Forty-two rats were subjected to unilateral gap (8 mm) injuries of the sciatic nerve, and repaired with silicone tubes containing it the growth factors in a 2% methyl cellulose vehicle. Concentrations tested ranged from 15-700 μg/ml PDGF-BB and 30-160 μg/ml IGF-I, with metal ratios from 0.5:1 to 5:1 of PDGF-BF (N4-fold group). After 4 weeks, animals were evaluated by a ‘pinch test’ to demonstrate the extent of axonal growth, sacrificed, and biopsies were examined for the number of myelinated axons in the center of the tube and distal to the repair site. By these criteria, the PDGF-BB/IGF-I combination produced significantly greater nerve regeneration than treatment with vehicle alone across a broad range of ratios and concentrations. At the optimum metal ratio (1:4, PDGF:IGF), growth was doubled and 1470 myelinated axons (meansSD) compared to 1096±415 myelinated axons in animals which received vehicle alone. These data suggest that the combination of PDGF-BB/IGF-I might prove efficacious in the treatment of peripheral nerve injuries.
EFFECTS OF PRIOR NERVE INJURY ON MORPHOLOGICAL DIFFERENTIATION OF ADULT RAT DRG NEURONS IN CULTURE
Karen L. Lankford, Jeffrey D. Kocsis. Department of Neurology Yale University, New Haven, CT 06510.
Numerous studies have shown that conditioning lesions can enhance the rate of regeneration of subsequently injured peripheral neurons, but it is not clear whether this enhanced rate of nerve regrowth reflects an increased growth capacity of the neurons or changes in the growth environment. To assess whether conditioning lesions alter the properties of the affected neurons, we dissociated neurons from L4 and L5 DRG of adult rats subjected to spinal nerve crush 4-5 days before acute or chronic nerve ligation 3 weeks before sacrifice. Neurons were then cultured for 1-3 days, fixed, and stained with neurofilament antisera to visualize neurites. Rate of neurite initiation, neurite outgrowth, and branching frequency in previously ligated or crushed neurons were compared to neurons from control animals or the unoperated side of the same animal. Neurons extended processes at rates of several millimeters per day with interbranch distance being highly correlated with total outgrowth. Neurons which had previously received a crush showed roughly twice as many neurites with processes after 1 day in culture, greater average total neurite length per neurilemna bearing neuron, and increased interbranch distance compared with control neurons. Ligated neurons also initiated more neurites after 1 day than controls. These results demonstrate that enhanced regeneration of sensory neurons following a conditioning lesion is maintained in isolated cell bodies in culture.

CONTROL OF GAP-43 EXPRESSION CAN BE ACCESSED THROUGH A G-PROTEIN AND ADENYLYL CYCLASE
David J. Schreyer. Department of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.
Dorsal root ganglion (DRG) neurons display increased expression of a peripheral (but not central) axotomy in vitro. To study the signaling mechanism which links peripheral axotomy to changes in GAP-43 expression, we established a cell-ELISA technique to measure the GAP-43 content of microcultures of adult rat DRG neurons. As they do following peripheral axotomy in vitro, DRG cells which have been excised, dissociated, and maintained in vitro for one week display increased GAP-43 expression. This GAP-43 increase is partially suppressed by continuous exposure in vitro to cholinergic or dopaminergic agonists of the stimulatory G-protein G_3. The GAP-43 increase is also suppressed by the cyclic AMP analog dibutyryl-cAMP and 8-bromo-cAMP, the adenylyl cyclase activator forskolin, and the phosphodiesterase inhibitor Ro 20-1724. We propose that GAP-43 expression is normally suppressed by an external stimuli acting through G_3 and adenylyl cyclase, and that removal of this repressive action leads to the elevation of expression of GAP-43 which follows peripheral axotomy.

DYNAMIC REGULATION OF STRIATAL DOPAMINERGIC GRAPPS DURING LOCOMOTOR ACTIVITY
S. Hallett, 1, 2, H. M. Geller, 1, A. Testa, 1 and H. Nishino. 1, 2, 3.
1Dept. of Orthopedic Surgery and Physiology, Nagoya City University Med. School, Nagoya 460, Japan; 2Dept. of Pharmacology, UMDNJ Robert Wood Johnson Med. School, Piscataway 08854-5055; and 3Dept. of Anatomy and Neurobiology, Medical College of Pennsylvania, Philadelphia, PA 19129.
After ileal and colon grafts into hemiparkinsonian model rats, extracellular levels of DA increased nearly to normal and methamphetamine-induced rotations were reduced completely. However, more complex motor behaviors such as treadmill running at high speeds recovered to a lesser extent. Thus, besides recovery in tonic release of DA, additional mechanisms such as higher levels of D2ergic reinnervation under dopaminergic stimulation in the host brain might be necessary for better motor control. The present experiment was designed to estimate the neurochemical activity of D2ergic grafts during locomotion and to examine the functional importance of dynamic regulation of the grafted neurons in the host brain. Grafted rats were trained to run on a straight treadmill at various speeds (300, 660, 1200, 1800 cm/min), and extracellular DA and its metabolites, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid, were measured by in vivo microdialysis during and after running. Grafted rats were divided into two groups depending on the running ability (treadmill running test) and data were compared with those of normal and lesioned controls. Although tonic levels of extracellular DA in grafted rats recovered to 70-80% of control, those of DOPAC and HVA remained 15-20% of controls. Small numbers of grafted rats showed full recovery on treadmill running; percentage increases of DOPAC and HVA showed similar time courses and magnitudes to those of normal rats. The majority of grafted rats showed partial recovery of locomotion ability and percentage increases in DOPAC and HVA remained at lower levels than in normal rats. However, there were no differences in tonic levels of DA, DOPAC and HVA in the grafted groups. Data suggest that grafted D2ergic cells were dynamically regulated by the host brain and that the integrated release of DA might be involved in recovery of complex motor behaviors.

ORG 2766 ENHANCES AXONAL REGENERATION ACROSS TRANSECTED RAT SCRTIC NERVE
M. Dussault, 1, S. Sayan, T. Khan, L. Liu, and C. Tranch. Rehabilitation R&D Center, Hines VA Hospital, Hines, IL 60414.
Melatonin has been found to exert a trophic influence on both the central and peripheral nervous systems. The purpose of this study was to determine whether ORG 2766 (a tri-substituted ACTH(4-9) analog) would enhance recovery after complete transection of the rat sciatic nerve as determined by neuronal tracing techniques and twitch tension measurements.
Rates were anesthetized, the left sciatic nerve was cut in the mid-thigh, and the proximal and distal ends were inserted into a silicone tube and held in place with cyanoacrylate adhesive. The right sciatic nerve was left intact. For animals receiving ORG 2766 (N-V, O-gonon, The Netherlands) a 10 μg subcutaneous injection was given after surgery and 1 μg subcutaneous injections at 48 h intervals for a two-week period. After the eight-week survival period, twitch tension measurements were performed, followed by WGA-HRP injections into each nerve distal to the cut. After 48 h, the animals were perfused and the spinal cords were sectioned. The total number of labeled cells were counted from sections L2-S5 on both sides of the spinal cord and results were expressed as a ratio of labeled cells on the experimental side divided by the control side. The average of the ratios of labeled cells on the experimental (transected) side divided by the control (unoperated) side was 19.2% for the six animals which received injections of ORG 2766; three out of the five animals also showed the presence of twitch tension peaks recorded from the experimental side. The average of the ratio of labeled cells was 1.9% for the seven animals which did not receive any injections of ORG 2766; only one out of the six animals showed the presence of a twitch tension peak recorded from the experimental side. This preliminary study demonstrated that ORG 2766 did enhance recovery after complete transection of the sciatic nerve as evaluated by neuronal tracing techniques and also by twitch tension measurements. This research was supported by funds from the VA Rehabilitation R&D Center.

A MONOCLONAL ANTIHEURONAL ANTIBODY PROMOTES PRIMARY NEURON OUTGROWTH AND NON-NEURAL CELL SPREADING ON CNS MYELIN. AM LOZANO*, C. L. M. LARES and A. ROACH. Samuel Lunenfeld Research Institute, University of Toronto, Toronto, M5G 1X5.
A component of adult mammalian central nervous system (CNS) myelin inhibits axonal growth, a property that may be responsible in part for the long-term interruption of the CNS. The mechanism through which the inhibitory activity acts on the neuron to block growth is not known. To identify the neuronal molecules involved, we have generated and selected monoclonal antibodies based on their ability to promote neurite outgrowth on a CNS myelin substrate. We identified one such antibody, 10b, by its ability to promote the outgrowth of neurites from neural cell lines plated on CNS myelin. To test the effect of 10b on primary neurons and non-neuronal cells, we have grown newborn rat superior cervical sympathectic ganglion neurons (SCG) and 3T3 fibroblasts on CNS myelin. SCG neurons did not extend neurites and 3T3 fibroblasts did not spread on 10 μg/cm2 of CNS myelin. In contrast, on CNS myelin in the presence of 10b, there was a vigorous outgrowth of neurites from SCG neurons and extensive spreading of fibroblast cell processes. These effects were not seen with control antibodies. The results indicate that 10b influences the process through which myelin substrates exert their inhibitory effects on neuronal and non-neuronal cells.

THE EFFECT OF FETAL TISSUE GRAFT PLACEMENT ON BEHAVIORAL RECOVERY IN A RAT MODEL OF PARKINSON'S DISEASE
R.F. Johnstone* and J.B. Becker, Dept. of Psychology, Neuroscience Program and Reproductive Sciences Program, University of Michigan, Ann Arbor, MI 48104.

Rats with unilateral striatal dopamine depletion are often used as an animal model of Parkinson's Disease. Fetal ventral mesencephalon grafts into the striatum of these lesioned rats have been used successfully to reduce asymmetries in both drug-induced and spontaneous behavior. We have found previously that grafts into the substantia nigra can also reduce the amphetamine-induced rotational bias. Thus, in the present experiment, rats were lesioned, grafted into either the striatum, substantia nigra, or into both. They were tested postoperatively for a reduction in bias of both amphetamine-induced rotation, and spontaneous home cage behavior. Fetal tissue was labeled with bromodeoxyuridine (BrdU). At the conclusion of the experiment, Biocytin was injected into the substantia nigra to trace the growth of the grafts. Coronal brain sections were stained for tyrosine hydroylase (Dsh), and Biocytin immunoreactivity. Trends in the data indicate that grafts into the striatum are the most effective in reducing drug-induced rotational behavior, followed by grafts into both sites simultaneously, and then grafts into the substantia nigra. Full data will be presented at the meeting.

546.4

Grafts of embryonic dopaminergic tissue have shown promise as a therapy for Parkinson's disease in humans. One basic parameter debated in the amount of tissue necessary to achieve optimal behavioral recovery is to address the question: what the present experiment contrasted the effects of grafting ED15 ventral mesencephalic tissue (MESEN) from one (4d4) or four (16d) total donors into the striatum of adult male Sprague-Dawley rats with unilateral destruction of the mesencephalon dopamine system by 6-hydroxydopamine. Controls received equal volumes of ED15 spinal cord. Before grafting, the tissue was extended into 200 µm sections. Injections of either 1µl or 4µl/site were made for four sites into the striatum of each recipient. Circles after metamphetamine (MET; 5.0 mg/kg) was measured prior to grafting as well as one, two and three months to assess transplanted efficacy. Following the third time point the rats were deprived and trained to run on a circular treadmill for water reward, ipsi- and contralateral to the side of the grafting. Only the animals receiving 16d of MESEN showed a reduction in contraversive METH-induced turning, whereas those with 4d4 MESEN or 4 or 16 spinal glial did not show a reduction. A deficit in contraversive learned-turning was seen; however, none of the four treatments was effective in alleviating this deficit. Paradoxically, rats given 4d4 of MESEN showed the worst performance. Tyrosine-hydroxylase (TH) immunoreactivity revealed TH positive cells in the groups that received MESEN. We conclude that grafting with MESEN from four embryos produces a better behavioral outcome than from a single embryo.

THE STUDY OF APOMORPHINE-INDUCED ROTATIONAL BEHAVIOR IN PARTIALLY LESIONED RAT PARKINSONIAN MODELS WITH 6-HYDROXYDOPAMINE: Jin Woo Chang, Sang Sup Choong, Young Jin Kim*, & Kung Se Park, Seoul National University, Seoul 120-752, KOREA.

An apomorphine-induced rotational test has been used in the evaluation of rat parkinsonian model lesioned with 6-hydroxydopamine. We evaluated 50 partially lesioned rat parkinsonian models using the cylindrical rotometer devices with flat bottom (diameter, 33 cm). Depending on the pattern of the rotation induced by apomorphine (0s/kg, i.p., the rats were grouped into four groups: 1) contraversive rotational, 16 cases: Group 1: 2) converversive rotational, 20 cases: Group 3: 3) ipivertive rotational, 9 cases: Group 4: 4) non-preferred or no rotation, 11 cases). Twelve of 16 rats in group 1 and 14 of 20 rats in group 2 met our criteria of rat parkinsonian model (at least 90 turns/30 min, 10 min after apomorphine injection). Although another 4 rats in group 1 did not meet our criteria, all of them showed severe losses (more than 95%) of the TH-immunoreactive neurons (SNpc) in the lesioned side. Another interesting finding was that rats in group 2 and 3 showed moderate losses (50-90%) of TH-immunoreactive neurons (SNpc) in the lesioned side even though their rotational responses were different. These results suggest that pattern of rotational (ipsiversive rotation) is a more reliable index of neuronal losses of SNpc than the total numbers of the rotational response to apomorphine.

The exact cause of the abnormal ipiversive rotation noted in group 3 is unclear. Further research should be pursued to explain this finding.

546.6

We examined a model of Parkinson's disease to test the effect of embryonic grafts of ventral mesencephalon on motor disability induced by MPTP. DA increases on average 500% near grafts (see Elsworth et al.). Although staining revealed 20,000+ DA neurons in grafts derived from a single embryo, we have seen variability in the percentage of DA neurons that survive the grafting procedure. This has led to the question of the donor tissue; neurons that have extended axons would be subject to degeneration while cells taken from younger ages prior to neurogenesis may represent a more appropriate developmental class. Grafts were selected from pregnant monkeys by autoradiography; 14 donors were chosen from embryonic days 34-74. Solid tissue grafts were placed into the caudate nucleus. Brains were collected at 3-6 months after surgery and were stained for tyrosine hydroylase (TH). DA neurons ranged from 1,300 to 28,000 per donor; 5 of 14 animals contained between 8,200 and 28,400 TH neurons. The numbers of TH neurons in grafts seen at each age were: E31 (3,500), E38(13,780), E92(28,908), E121(21,296), E142 (4,120), 1,300, 1,900, 11,700, 12,800, 14(404), 1,410, 15,964, 28,400, E170(1,200), 13,344. The average of donors (n=11) taken during postnatal neurogenesis (E36-E45) is 24,870 ± 2400. of the substantia nigra is 12,900±256. The adult African green monkey has about 80,000 DA neurons in both substantia nigra. Thus, an average survival of 12,500 neurons is about 16% of the adult population; the best survival obtained (i.e., E28) is about 36% which is substantially better than results obtained from studies using xenograft human cells. Supported by NIH grants NS 24032 and RSA MH 06453 (DER).

546.7

Occasional studies in pallimcanine animals have suggested that the mechanism of neural transplant-induced beneficial effects may not rely on dopamine (DA) generated from the neural graft. The present studies address this issue in MPTP-treated monkeys. Grafts of fetal ventral mesencephalon (VM) or cerebellum were placed stereotactically in the striatum of MPTP-treated parkinsonian monkeys. Behavior of each animal was assessed before and following studies. As a precautionary measure, tissues were removed from brain slices for biochemical analysis. The removal of the slice was processed for autoradiography or tyrosine hydroylase (TH) immunohistochemistry. Striking elevations of TH in dopamine containing DA, were observed in the growth of transplanted 2.5 cm CRIL fetal VM cells. High density of binding was seen at the site of the graft. Graft presence was confirmed by TH immunohistochemistry. At some further maturation, an increased density of binding to DA uptake sites. Correlative in vivo brain imaging by SPECT has been performed in some grafted MPTP-treated monkeys using [123I]r-CIT. Supported by NS 24032, the Asian Research Foundation, RSA MH 0043 to DER.

546.8

Fetal mesencephalic grafts into the striata of partially dopamine (DA)-depleted African green monkeys become well developed and show numerous TH-positive neurons when examined with immunohistochemistry. These neurons project fibers into the adjacent host stria. Since control of DA synthesis/release may be influenced by the host brain, the establishment of reciprocal connections is of importance. A double label IHC staining technique was used for simultaneous evaluation of both graft and host fiber projections. TH-containing neurons were stained as before. Endogenous host TH-positive fibers were identified by the immunohistochemical reaction of the TH-positive graft that contained neuronal GABA and substance-P. Different chromogens were used to label the different cell types. This staining protocol was performed on brains obtained from three animals. Positive staining for TH substance-P-Fibers was identified within the TH-positive grafted fetal mesencephalic tissue. Many of these fibers were found in proximity to TH-positive graft cells. Some of the fibers adjacent to TH-positive cells exhibited enlargements suggestive of potential contact points. These preliminary results provide a morphologic basis for the presence of reciprocal connections between the host striatum and the transplanted fetal mesencephalon. Electrophysiological and electron microscopic studies of an analogous experimental paradigm will be needed to verify this suspected connectivity. Supported by a Chonliul Brain Research Fellowship, Axiom Research Foundation, and NIH grants NS 24032 and RSA MH 06643 to DER.
546.9
FUNCTIONAL RECOVERY IN HEMIPARKINSONIAN MONKEYS FOLLOWING GRAFTS OF ENCAPSULATED PC-12 CELLS 1-2,3,4,5,6,7,8,9,10,11
Dopamine, which control all ChAT-(0-36%) grafts.

STRIATAL SECRETS OF NGF: BHK-hNGF FOR PC-12
These cells recovered their use of the affected limb and performed at near-normal levels. The third PC-12 graft monkey had the one control monkey remained intact. These monkeys the ChAT-ir striatal

546.11

Six aged Rhesus monkeys (24-29 years old) received unilateral transplants of the three groups that received NGF-secrating cells displayed only a modest loss of ChAT(0-36%) and p75 NGFR-immunoreactive (ir) (53%) medial septal neurons ipsilateral to the lesion/graft. In contrast, monkeys receiving grafts of encapsulated NGF-secreting cells displayed only a modest loss of ChAT(0-36%) and p75 NGFR-(7-22.4%) striatal neurons. Additionally, all monkeys receiving the NGF-secreting implants, but none receiving control implants, displayed robust sprouting of cholinergic fibers within the septum ipsilateral to the transplant. Just prior to sacrifice, the capsules were retrieved and determined to contain viable BHK cells releasing biologically relevant levels of NGF. These data demonstrate that hNGF can provide trophic and trophic influences to degenerating cholinergic basal forebrain neurons in aged nonhuman primates supporting the contention that hNGF may prevent degeneration of basal forebrain neurons in Alzheimer's disease.

546.12

A common feature of aged Rhesus monkeys (24-29 years old) was reduced levels of useable hNGF. The third PC-12 graft monkey in which behaviorally recovered normal striatal function was noted in November. 1992. The recovery of the striatum, functional recovery in the two PC-12-grafted monkeys was sustained for up to 2 months. These data suggest that grafts of PC-12 cells can induce functional recovery in nonhuman primates although the mechanism of action remains unclear.

546.13
HYPERTHYROID OF CHOLINERGIC AND NPY CONTAINING STRIAL NEURONS FOLLOWING IMPLANTS OF POLYMER ENCAPSULATED CELLS GENETICALLY MODIFIED TO SECRATE HUMAN NGF. E.Y. Chen 1, D.P. Emerich 2, S.R. Wimg 1, E.L. Freedel 1, J.P. Hammond 2, E.E. Baste 2, and J.H. Kordower 1.

The present study examined the effects of polymer encapsulated grafts containing baby hamster kidney fibroblasts (BHK) genetically modified to secrete human NGF (hNGF) on the size of cholinergic and noncholinergic striatal neurons following implantation into the intact rodent striatum. Three groups received BHK-hNGF grafts into the right striatum and were sacrificed 1, 2, or 4 weeks post-implantation. The remaining three control groups were treated identically except that BHK cells were not modified to secrete hNGF. In control BHK graft rats, the size of ChAT-ir striatal neurons was unchanged (c6%) at all time points. The BHK-hNGF grafts, there was a hypertrophy of ChAT-ir striatal neurons. These data suggest that polymer encapsulated cells which were genetically modified to secrete hNGF can influence both cholinergic and noncholinergic neurons within the striatum.

546.14
CLINICAL RECOVERY AND GRAFT SURVIVAL IN PARKINSONIAN NON-HUMAN PRIMATES AFTER STRIATAL GRAFTING OF FIBROBLASTS GENETICALLY MODIFIED WITH TYROSINE HYDROXylASE (GDNF). K.S. Banks 1, A. Eason 1, D.A. Vuye 1, A. L. Maud 1, K. Sofat 1, G. Choudry 1, M. W. McNaghten 1, M. D. Scott-Wright 1, and D. A. W. Cork 1.

Somatic gene therapy uses grafts of genetically modified autologous cells to produce therapeutic substances within the body, and eliminates the need for immunosuppression or barrier devices. We are utilizing a process that consists of harvesting autologous cells through a biopsy, carrying out ex vivo genetic modification of the therapeutic, genetically active proteins, and subsequently grafting these to an appropriate site. 7 MPTP-treated, overexpressed hemiparkinsonian monkeys were used for this study. Using MRI-guided stereotoxic surgery the 3 monkeys were grafted with autologous fibroblast transfused with retrovector (hFGS) carrying a human tyrosine hydroyxylase (TH) cDNA. 2 monkeys were implanted with non-transfected fibroblasts and 2 animals were left non-implanted. Prior to the implantation all animals were behaviorally characterized for 4-6 months using using the following scales: apomorphine-induced turning, arm use scale and activity monitors. TH implanted monkeys showed immediate clinical improvement and increase of activity after the implantation which lasted for at least 6 months. The grafted fibroblasts showed the ex vivo transplantation and the mediated functional arm use. Animals were sacrificed at 4 months. Control implanted animals recovered only from amphetamine-induced rotation, while control non-implanted monkeys remained unchanged. MRI scanning detected grafts in the striatum and closure of the blood brain barrier at 2 weeks post-implantation.

Histological examination of hemiparkinsonian non-primate 1 (13%) 2, 16% (13%) and (13%) weeks post-implantation. Removal of the capsules just prior to sacrifice revealed healthy BHK cells which secreted sufficient levels of hNGF to differentiate PCs. These data suggest that polymer encapsulated cells which were genetically modified to secrete hNGF can influence both cholinergic and noncholinergic neurons within the striatum.
546.15
Administration of 0.4 mg/kg of MPTP into one internal carotid artery produces hemiparkinsonism in monkeys. In such a model, the side ipsilateral to MPTP administration is typically depleted of DA, while the side contralateral serves as a "normal" control. As we previously reported (Bankiewicz KS, et al, Life Sci, 1986), unilateral exposure to 0.8 mg/kg results in overexpressed HPD monkeys which display bilateral signs of the PD. In this study, we further characterized HPD+ monkeys using behavioral and in vivo biochemical methods. 17 Rhesus monkeys (age 5-16, weight 3.52-14.86 kg; 6 females, 11 males) were studied during 5-18 months after MPTP injection. The monkeys received an intracranial infusion of 2.4-μg MPTP solution 0.34 mg/kg to induce HPD+, which still enabled them to sustain their spontaneous turning. Asynchronous-induced turning, arm use, general activity measurements, clinical recordings using rating scale, in vivo microdialysis and CSp levels of HVA were examined. After the MPTP treatment, all of the monkeys showed progressively bilateral signs (freezing, bradykinesia, decreased defense reaction, posture and gait problems), and hemiparkinsonian signs with predominant use of the contralateral arm, and decreased ipsilateral spontaneous circling and contralateral-induced contralateral turning. The CSp HVA levels were increased in the first hours after the MPTP administration with subsequent decrease of 40-65% 3 days later. Extracellular levels of dopamine and HVA as measured by microdialysis in caudate and putamen nucleus on the ipsilateral side were not detectable. Local amphetamine administration induced DA and HVA peaks only on the contralateral side, suggesting total lack of any remaining innervation on the ipsilateral side. This side, modelling the end stage of human PD, could be used for grafting DA-producing cells for studying DA replacement therapy, while the partially lesioned contralateral side, modelling an advanced stage, could be used for studying trophic factor-releasing cells and inducing a trophic reaction.

546.16
CCK FACILITATES METHAMPHETAMINE-INDUCED Dopamine OVERFLOW IN RAT STRIATUM AND FETAL NIGRAL GRAFTS. Y. Wang* and S.L. Peng. Dept. of Pharmacology, National Defense Medical Center, Taiwan.
The purpose of this study was to investigate the electrochemical interactions of cholecystokinin (CCK) and methamphetamine (MA)-induced dopamine (DA) overflows in rat striatum. High-speed chronocompartmental recording techniques using Nation-coated carbon fiber electrodes were used to evaluate extracellular DA concentration in the striatum. CCK-AS, CCK-8S, MA and DA were locally applied directly to the striatum of urethane-anaesthetized Sprague-Dawley rats. We found that CCK potentiated MA-induced DA release in the anterior striatum. This reaction is likely mediated through CCK-A receptors because only CCK-AS, but not CCK-8S, enhanced MA action. Replacement of Ca2+ with Mg2+ antagonized this reaction, suggesting that the modulation of MA by CCK is Ca2+ dependent. Both MA-induced DA release and CCK modulatory effects were disappeared in the striatum after unilaterally lesioning the medial forebrain bundle with 6-OHDA lesions. The unilaterally lesioned rats were later transplanted with fetal ventral mesencephalon. We previously found that the zone of normalized dopamine clearance was considerably larger than that of normalized release in the anterior striatum after fetal nigral transplantation, which may be contributed to the partial reinnervation from the transplant. In the present study, we found that the modulation of DA release by CCK was regenerated in the zone of normalized release after fetal nigral transplantation. However, CCK did not increase MA-induced DA release in the partially uninnervated area. In conclusion, these findings suggest that the not only DA release process but also CCK modulatory mechanism were regenerated after fetal nigral transplantation.

546.17
Reynolds and Weiss (Science 255:1707; 1992) reported the isolation and partial characterization of epidermal growth factor (EGF) responsive striatal progenitor cells. Using their procedure, we have isolated mesencephalic progenitor cells. E14.5 rat mesencephalon was isolated and plated onto 100 x 20 mm petri plates (1200 cells per cm2) that had not been pre-treated with extracellular matrix products. The cells were grown in media containing 20 mg/ml EGF. Less than 0.1% of the cells survived and went on to form clusters of cells if left undisturbed for 14 days. These mitotically active cells have been successfully passaged for 8 months. When cultured on poly-L-lysine coated plates containing a complete media (10% FCS), the cells differentiated into glia and neuron-like cells. None of these cells stained positively for tyrosine hydroxylase. Similarly, TH positive cells were not found after exposure to various neurotransmitters such as DA, 5-HT, NE and EPI. In contrast, co-culturing progenitor cells with fresh mesencephalon had a profound effect increasing the number of TH staining neurons (FP = 0.01) relative to mesencephalon cultures. Mitochondrial dehydrogenase activity was unchanged in the co-cultures suggesting that mitotic activity was not responsible for the increase in TH neurons observed. The cultures were also negative for the NE marker DBH. These data suggest that a soluble or cell contact mediated activity present in mesencephalon was responsible for converting the progenitor cells into a DA neuron phenotype. Like striatal cells, mitotic progenitor cells capable of developing into DA neurons exist within the mesencephalon.

546.18
The basal ganglia exert their function mainly via disinhibitory GABAergic circuits. However, very little is known about the changes that occur in GABA neurotransmission in Parkinson's disease, and virtually nothing is known about such changes following dopamine supplementation by grafted fetal dopaminergic neurons. In the present study, GAD mRNA levels were compared in neurons of the entopeduncular nucleus (EPN) and the substantia nigra pars reticulata (SNR) in normal, unilaterally 6-hydroxydopamine-lesioned and grafted rats by means of in situ hybridization using 35S-labeled cRNA probes. Autoradiographs revealed a moderate elevation of GAD mRNA levels in the ipsilateral SNR, particularly in the lateral half of the nucleus, while the ipsilateral EPN showed a slight increase. Nine months after transplantation of fetal nigral neurons, the GAD mRNA levels remained significantly elevated in the ipsilateral SNR, but the ipsilateral EPN appeared similar to those of normal rats. These data indicate that nigral grafts placed in the striatum differentially influence GAD mRNA levels in the EPN and SNR, and suggest a necessity for additional dopaminergic grafts in the nigra for complete restoration of basal ganglia function. [Supported by the Parkinson's Foundation of Canada].

Fast axonal transport (FAXT) is responsible for the bidirectional movement of proteins within the nerve terminal and axon. Anterograde transport of FAXT of neurotransmitter-associated proteins in the magnocellular organellar membranes to nerve terminals occurs at a rate of ~410 mm/d. Pulsed electromagnetic fields (PEMF) have been shown to enhance axonal outcome with sciatic nerve when applied before or after injury, although the mechanism of this effect is not known. In this study, we examined the effects of acute PEMF treatments on fast axonal transport in sciatic nerve and sciatic-nerve crush (Sprague-Dawley) rats under 2 conditions: in unjured (non-operated) nerves and 1 d after a crush of the nerve behind the knee. Rats were placed between Helmholts coils for 15 min/for 2 d preceding injection or for 60 min on the day of injection. While maintaining core body temperature at 37°C, [³H]-proline was stereotactically microinjected into the spinal cord; rats were killed 2.5-5.0 hr later. After tissue solubilization and liquid scintillation spectroscopy, transport profiles indicate that acute treatments with PEMF had no effect on fast transport rates in injured or unjured sciatic nerves. These studies are in agreement with others indicating that fast axonal transport rates are not altered in response to crush injury. They also show that PEMF effects are not related to transport mechanisms. Slow axonal transport using a similar paradigm are underway. Supported by NIH NS 29621-02 (BFS).

The diffusible fast axonally transported DRG proteins do they represent common or unique secretory products? B. Tedeschi, S. Mulugeta and R.P. Chavara. Departments of Anatomy & Neurobiology and Microbiology & Immunology, East. Virginia Med. Sch., Norfolk, VA 23501.

Fast axonal transport (FT) is believed to represent the translocation of vesicles/shapes in the neuronal secretory pathway. In the frog DRG/sciatic nerve preparation, we have previously demonstrated the diffusible FT protein subset from the membranous organelle sub-fraction. In the present study we addressed two questions: (1) Which diffusible FT proteins are unique relative to the secretory products of non-neuronal nerve cells? and (2) Which diffusible FT proteins are unique relative to other neuronal FT proteins? Neuronal or non-neuronal nerve protein pulse-labeled with -S-methionine and time allowed for FT (in the case of non-neuronal proteins). Radiolabeled diffusible proteins were collected in a bath surrounding nerve and bath/nerve proteins were subsequently analyzed by two-dimensional gel electrophoresis (2D-PAGE) and fluorography. Results showed that: (1) only one (10%) of the diffusible DRG FT proteins exhibited a unique identity with a diffusible non-neuronal sciatic nerve protein and (2) all of the diffusible DRG FT proteins were FT by retinal ganglion cell neurons. These results suggest that diverse neuronal populations may package a similar set of soluble FT proteins and that these diffusible products are quite different from the secretory products of non-neuronal nerve cells.

rab3A and B belong to the ras-related superfamily of small GTP-binding proteins and are mainly present in nervous and endocrine tissues. These proteins appear to be involved in the control of a late step of exocytosis during which vesicles become docked to the plasma membrane. Physiological studies showed that these proteins may differentially regulate tonic and phasic exocytosis. This data prompted us to examine the effect of addition of a mRNA encoding rab3A and B. In situ hybridization revealed that both mRNAs are heterogeneously distributed in the brain but overlap in most areas, although rasB3B-mRNA is generally less abundant, except in the pituitary and olfactory bulb. This distribution was quantitatively ascertained by competitive PCR in the same tissues. In addition, double in situ hybridization showed that rasB3A and B mRNAs are expressed within individual neurons. During lactation, both rasB3A and B mRNAs are upregulated in the magnocellular hypothalamic system in which increased stimulations are associated with the pulsatile release of oxytocin from the neurohypophysis. During lactation, an increase of rasB3B mRNA was also observed in the anterior pituitary. Western blots confirmed these results and revealed the rasB3A and B proteins exhibiting apparent molecular weights due to a post-translational modification.

RIBOSOMES BEARING SHORT GAP-43 NASCENT PEPTIDES BIND TO NUCLEAR AND MICROSPERICAL SUBCELLULAR FRACTIONS. R. Moore-Batchelder, H. Pentama, and J. Denney*. Division of Life Sciences, Univ. of Texas at San Antonio, San Antonio, TX 78249.

We have transcribed a linearized pGEM3 vector containing a full-length GAP-43 cDNA insert and have translated the purified, uncapped mRNA in vitro using reticulocyte lysate and 35S-methionine. A nuclear fraction isolated from cultured PC12 cells and a microsomal fraction isolated from either PC12 cells or from canine pancreas were added to translation mixtures both co-translationally and post-translationally at 30°C. The canine microsomes were specifically added in the co-translationally experiment fractions were present during a 1 hour translation that was subsequently blocked either with cycloheximide or puromycin/high salt. In the post-translationally experiment fractions were incubated with mixtures for 1 hour after the translations had been blocked with cycloheximide or puromycin. Under these conditions, we observed an enrichment of GAP-43 nascent peptides of molecular weight 22 kDa and below in high-speed Airfuge pellet fractions relative to all larger nascent peptides and full-length GAP-43 and also relative to pellets obtained from translation mixtures that did not receive any subcellular fraction. These results suggest that short GAP-43 nascent peptides are competent for interaction with membranes while longer peptides are not.
547.7
Several subunits and their isoforms have been identified encoding the γ-aminobutyric acid receptor (GABAR). Assembly of specific subunits leads to different pharmacological properties and cell surface localization. Despite the potential to assemble both homo- or heteromeric receptors in nonneuronal cells, there is emerging evidence that assembly and expression of GABAR subunits in neurons may be restricted. We have examined the sorting, cell surface expression, and localization of the α1 and β3 GABAR subunits in PC12 and COS-7 cells for clues of how receptor assembly of specific GABAR subunits affects localization and membrane mobility in neurons. PC12 cells transfected with cDNA encoding the α1 subunit retain the α1 subunit in an intracellular compartment whereas PC12 cells transfected with GABAR encoding the β3 subunit sort it to the plasma membrane and form clusters on both cell bodies and processes. After transfection of both α1 and β3 in PC12 cells, both proteins are found on the cell surface co-localized in clusters. In contrast to oocytes and epithelial cells, neuron-like cells express at their plasma membranes a more restricted repertoire of GABAR complexes. Moreover, we show that the localization of GABAR in discrete domains can be conferred by the β3 subunit. Cos-7 cells, used to study the intracellular localization at higher resolution, sort GABAR subunits similar to PC12 cells. The location of α1 in Cos-7 cells is consistent with an ER pattern suggesting that α1 may contain an ER retention signal. The β3 subunit, able to redirect α1 from the intracellular compartment to the cell surface, was not able to rescue a truncated α1 containing only the first two transmembrane domains. These results suggest that neurons likely have a mechanism by which specific complexes are assembled, requiring all the transmembrane domains, and architecturally edited before expression on the cell surface. Supported by 2F2NS09198-03 and NS0872.

547.8
SORTING AND CELL SURFACE EXPRESSION OF NMDA RECEPTOR SUBUNITS
Ihsana Makal-Jeticovic, Leislhona Karayiati* and Himon J. Angellides, Department of Cell Biology, Baylor College of Medicine, Houston, TX 77030.
Neurons are highly polarized cells with a complex morphology, where proteins are targeted to discrete regions of the cell surface. At synaptic sites N-methyl-D-asparate receptors (NMDAR) appear to be clustered at high density mediating the events of glutamate neurotransmission. Molecular cloning has identified several cDNAs encoding NMDAR subunits NR1, NR2A, NR2B, NR2C and NR2D. The NR1 subunit is essential in a heterologous configuration for electrophysiological and pharmacological characteristics of NMDAR. There is emerging evidence that the subunit composition of ligand-gated channels can determine sorting and targeting of the receptors. In order to study how neurons process NMDAR we have transfected COS-7 and neuron-like PC12 cells with cDNA encoding the NR1 subunit. We have used subunit specific antibodies, indirect immunofluorescence, and light and confocal microscopy to determine the cellular distribution of the NMDAR subunits in transfected cells. In COS-7 and PC12 cells NR1 is retained intracellularly when expressed alone. The majority of NR1 protein is sequestered in the Golgi compartment and a small fraction is found in lysosomal vesicles. When transfected cells were treated with Brefeldin A to dissociate the Golgi apparatus, NR1 was redistributed into the ER. The presence of NR1 beyond the ER in transfected COS-7 and neuron like PC12 cells strongly suggests that the protein is folded appropriately and has been processed into a transport competent configuration. The NR1 subunit was not detected on the surface of those transfected cells by immunofluorescence or immunoblotting of biotinylated surface proteins. These results raise the possibility, that the presence of more than one subunit is necessary for cell surface delivery of functional NMDAR and expression of the complex is regulated by availability of the other NMDAR subunits. Supported by grant NS28072 of HSPD.

547.9
There is a great deal of interest in studying the cell biology of neurons. However, because neuronal cell lines have been difficult to obtain and because large cultures of purified primary neurons are difficult to prepare, many standard cell biological studies have not been feasible. Furthermore, it is often difficult to express foreign genes in neurons. In an effort to overcome these disadvantages, we have characterized vaccinia virus (VX) directed expression of foreign proteins in the human cell line NTERA 2 (NT2). Using retinoic acid, NT2 cells differentiate to form large, highly purified (99.9%) cultures of mature neurons (NT2-N). We found that NT2-N cells are readily infected by recombinant VY, yet they maintain their polymorphic morphology and die at a rate matching non-infected controls. To determine if foreign proteins can be expressed and properly processed in NT2-N cells they were infected with recombinant VY expressing the HIV-1 glycoprotein, gp160, under the control of a VY early/late promoter. Gp160 was easily detected 1 day post-infection by western blot, pulsed-labeling, and immunofluorescence microscopy. Gp160 was transported to the Golgi apparatus, efficiently cleaved into gp120 and gp41 subunits, and expressed on the cell surface. Despite efficient expression the infection was non-productive (virus particles were not produced).

The ability of NT2-N neurons to efficiently express foreign proteins, with few of the cytopathic responses normally associated with VY infection, provides a novel opportunity to address a wide array of cell biological questions in a system of pure human neurons.

ENTEROPATHOGENIC ESCHERICHIA COLI DEPOLARIZES INFECTED HELA CELLS. H. Yan, D.A. Mathers*, M.A. Stein and B.B. Finlay. Departments of Physiology and Biotechnology, University of British Columbia, Vancouver, BC Canada V6T 1Z3.
Enteropathogenic Escherichia coli (EPEC) causes severe diarrhea in children. EPEC attach intimately to gut intestinal epithelial cells and mediate cytoskeletal rearrangements characterized by the formation of pedestal-like structures and localized degeneration of brush border microvilli. We have applied patch clamp methodology to characterize the electrical events occurring during the early interactions of EPEC with epithelial cells. HeLa epithelial cells were incubated with EPEC strain E2348/69 for 30 minutes at 37°C and washed extensively. Cells with attached EPEC colonies were used for whole-cell recordings, made at 21-24°C with patch electrodes containing (in mM): 135 KCl 5 NaCl 1 MgCl2, 10 HEPE and 5 NaF. Cells were washed, E70 buffered in a saline containing (in mM): 135 NaCl 4 KCl 1.8 CaCl2, 1 MgCl2, 10 HEPE and 5 glucose. The mean resting membrane potential (VREST) of HeLa cells infected with EPEC was -24 mV. Cells incubated with supernatant from EPEC cultures, normal culture media or an EPEC mutant (eaeA-2-1) that does not mediate cytoskeletal rearrangements, showed mean VREST values of about -48 mV. The results suggest that membrane depolarization is an important component of the pathogenicity of EPEC.
548.1 NAPDH-DIAPHORASE HISTOCHEMISTRY OF RAT CHOROID PLEXUS. A. Chodobski, J. Szemydor- Chodobski, P.R. Moftsils, A.Y.I. Liu, M. Evensen, and C.E. Johnson. Program in Neuroscirnomy, Department of Clinical Neurosciences and Central Research Laboratory, Brown University/R.I. Hospital, Providence, RI 02903.

NAPDH-diaphorase (NAPD-d) has been frequently co-localized with neuronal isoform of nitric oxide synthase (NOS), a synthetic enzyme for nitric oxide (NO), and is, therefore, considered as a histochecmical marker of the neuron. In the present study, we demonstrate the colocalization of NAPD-d-positive staining with NOS in rat choroid plexus (see accompanying abstract by J. Szemydor-Chodobski et al.). In transcardially perfused rat brains with 4% paraformaldehyde and brains were postfixed for 4 h at 4 °C. Parts of the choroidal tissue were dissected out and incubated at 37 °C for 3 h in PBS (pH 7.6) containing 1 mM of nitrile blue tetrazolium and 1 mg/kg of NAPDH. Triton X-100 was added (0.6%) to improve tissue penetration. NAPD-d-positive nerve fibers were found to accompany anterior choroidal artery and its branches, as well as smaller arteries within the choroidal stroma. Choroidal veins and venules were devoid of NAPD-d staining; however, larger veins draining blood from the inferior part of the choroid plexus, proximal at the basal vein, had NAPD-d-positive innervation. Endothelial cells were stained as well. In addition, a deposition of the reaction product (formazan) was found in the cytoplasm of choroidal epithelial cells, with nuclei being free of staining. In conclusion, NAPDH-d was shown to be colocalized with NOS in the choroid plexus. The presence of NAPD-d in different choroidal cell types suggests the multiplicity of metabolic barriers in mechanistic changes in choroidal tissue. Supported by NIH Grant NS 27601.

We have previously shown that nitric oxide (NO) mediates some hemodynamic properties of angiotensin II (Barron et al., in press). In the present study, we demonstrate by immunohistochemistry the presence of NO synthase (NOS), a synthetic enzyme for NO, in rat choroidal tissue. Anti-NOS antibody was raised in rabbits against the brain NOS. It recognizes neuronal NOS in several mammalian species, including the rat, and does not cross-react with inducible NOS. Rats were perfused transcardially with 4% paraformaldehyde and brains were postfixed at 4 °C. Parts of the choroidal tissue were dissected out and incubated for 48 h at 4 °C with primary antibodies (1:2000). The procedures which were performed were performed at room temperature. Biotinylated donkey anti-rabbit IgG was used to detect primary antibody, followed by incubation with streptavidin-biotin-peroxidase complex. To obtain color reaction, diaminobenzidine was used. NOS-positive nerve fibers were found to be associated with the anterior choroidal artery and its branches, as well as with smaller arteries located within the choroidal stroma. Choroidal veins and venules were devoid of NOS-containing innervation. Endothelial cells were not stained, indicating that the antibody does not cross-react with endothelial form of NOS. Choroidal epithelial cells expressed intense, distinctive staining of their cytosol. These results provide anatomical evidence supporting the physiological observations of all inhibitors of NO activity in different tissues and their NOS-containing components. We are currently investigating the relationship of NO activity in the choroidal circulation and its pathophysiologic implications. (Supported by NIH Grant NS 27601 and by research funds from the R.I. Hospital.)

548.3 GLOSOMATIC OPENING OF BLOOD-BRAIN BARRIER TO ENDOGENOUS ALBUMIN. A.W. Vorbrodt, D.A. Dobrovolnaya, and A.S. Lagunov. NICGNS for Basic Research in Developmental Disabilities, Staten Island, NY 10314. Early observations of the blood-brain barrier (BBB) to endogenous albumin were studied using a new quantitative immunocytochemical procedure, hypercrosslink Li+ arabinose solution (1.8%) was infused into carotid arteries of animals, (which were killed 5 and 30 min afterwards. Brain samples were immersion-fixed and embedded at low temperature in Lowcryl K-4M. Ultrathin sections were exposed to anti-rat albumin antiserum followed by protein A-gold. The density of immunosignals (gold particles per μm²) was registered and counted over four compartments: vascular lumen, endothelial cells (ECs), subependothelial space (including basal lamina (BL), and the adjacent astrocytic processes with hypermorphic NOS). The labelling density of the vessel lumen was considered to represent 100% of the signal, other compartments were corrected to that level. On quantitative analysis indicated that in control animals, only 0–4.5% of the circulating albumin appears in the subependothelial space, whereas as soon as 1 min after infusion, this value increases to 3% followed by a further increase to 5% at 15 min respectively. The main routes of albumin escape are through the damaged EC cytoplasm (including vesicles and penetrating indentations) rather than through modified interendothelial junctions. A slow increase of immunosignals in the adjacent neuropil suggests that the BL represents a serious obstacle for escaping albumin which seems to get trapped in this structure. (Supported by the National Institute on Aging, grant RO-AG 10279–03).

548.4 EFFECTS OF HYPERTONIC SALT INFUSION ON CEREBRAL PERFUSION IN NORMOTREMATIC AND HYPERTREMATIC RATS. S. Adler, D. Williams and J.C. Verbalis. University of Pittsburgh School of Medicine and Carnegie Mellon University, Pittsburgh, PA 15213. Rapid increases in plasma Na (pNa) and osmolality can disrupt the blood brain barrier (BBB). Recent studies from our laboratories have shown that this occurs at lower thresholds in hypertensive (HN) than in normotrematic (NN) rats. The present experiments studied the effect of similar increases in pNa on cerebral perfusion in NN and HN rats. NN (n=6), acute HN (n=8), and chronic HN (n=10) rats received iusions of either 700 μL/kg 500 mOsm NaCl. Both cortical and white matter perfusion were measured by arterial spin tagging in a 4.7 Tesla NMR magnet before and at 30, 60, and 90 min during the infusion. pNa increased 22%, 20%, and 19%, respectively, and arterial pressures remained constant throughout. Arterial pCO2 rose slightly in all groups (from 61 to 63 in NN, 57 to 64 in acute HN, and 47 to 48 mm Hg in chronic HN). Cerebral perfusion increased significantly in both regions in the HN rats at all times. For example, by 60 min perfusion had increased in cortex and white matter by 36% and 27% in NN, by 62% and 56% in acute HN, and by 60% and 51% in chronic HN. Because local increases in brain perfusion can affect the BBB, the increased perfusion produced by hypertonic NaCl infusions may contribute to the BBB disruption caused by the induced hyperosmolality, and both of these factors may therefore participate in the demyelination that frequently accompanies overly rapid correction of hyponatremia.

We have demonstrated increased permeability across the blood nerve barrier (BNB) of albumin after glycation with D-glucose (PMAS 89) in a long-term experiment of D-glucose, using an iso-osmotic injection technique in the caudal brainstem and artery of normal adult rats. Glycated proteins (gNGF and gIgG) have significantly decreased circulating plasma half-life compared to the non-glycated forms. The PK across the BNB obtained for gNGF was significantly increased compared to NGF with a 2 fold increase observed after 8 weeks of glyculation and a 5 fold increase after 21 weeks of glyculation. The PK measurement for gIgG and IgG across the BNB was not significantly different at 8 weeks of glyculation but was 1.3 fold greater at 21 weeks of glyculation. The PK across the BNB for gIgG was 2 fold greater than IgG with a glyculation time of 8 weeks and 3.2 fold greater with a glyculation time of 21 weeks for six different brain regions. No changes were observed in the Vp for any of the brain regions for gNGF compared to NGF. The PK across the BNB for gIgG compared to IgG was significantly greater with a 4 fold relative increase. The PK across the BBB for gIgG ranged from a 2.8 fold increase for the thalamus to a 5.1 fold increase for the caudate putamen when compared to IgG. No significant differences were observed for the Vp or CL. These data suggest that glycation can enhance the permeability across the BNB and BBB of proteins with widely varying Mw and function. Since the glycation of NGF does not appear to affect its neurotrophic activity, systemic glycation may be an effective treatment of a variety of neurodegenerative diseases. Similarly, the glycation of immunoglobulins might be a convenient procedure for delivery of a variety of antigens into the nervous system.

Current treatment of brain tumors is limited by the presence of cerebrocapillary endothelial cells within the tumor tissue. Such cells have tight junctions which comprise the blood-tumor barrier. Enhanced drug delivery to tumors has been achieved previously by opening the blood-tumor barrier. However, such regimes have also resulted in systemic toxicity to healthy tissue. Recently, we have developed a headlinck antibody, RMP-7, which has been shown to selectively open tight junctions of brain endothelial cells. In the current study, female Wistar rats (170-210g) with intracranial R22 tumors were given a labeled chromogempheric agent carbolug, along with a 15min injection of [H]HMP-7 (8μg/kg.min). Using quantitative autoradiography we found that RMP-7 produced a significant (p<0.01) two fold increase in carbolug in the tumor compared to vehicle-treated rats. No differences between RMP-7 and vehicle-treated groups were found in any other brain region examined. Similar data was obtained with other anti-tumor agents. Furthermore, treatment with rhamnose tumor-bearing rats with RMP-7 and chromogempheric drugs prolonged the survival time of such animals. Thus, RMP-7 has the potential to be an adjunct to current neuro-oncology therapy due to its selectivity for tumor cells over normal healthy tissue and the probability that it may reduce the cytotoxic side-effect profile of anti-tumor drugs, by allowing lower therapeutic doses to maintain current (or greater) efficacy.
BLOOD-BRAIN JUNCTIONS

The Bradykinin agonist RMP-7 enhances the permeability of the blood-brain barrier: evidence from electron microscopy experiments. E. Sanovich, P.M. Fridkin, R.T. Barrie, and M. Brightman. Lab. of Neurovirology, NINDS, NIH, Bethesda, MD 20892.

RMP-7, a novel bradykinin agonist, was tested for its ability to open the blood-brain barrier (BBB). Balb/c mice were infused for 2 minutes via the jugular vein with La3+ (MW 139), in the form of LaCl3 (5 mM), with or without RMP-7 (5 µg/kg). After 10 minutes, the mice were fixed with aldehydes and the brains processed for electron microscopy, so as to trace the pathway opened by RMP-7. Midbrain and cerebral cortex were examined for the presence of La3+ in tight junctions (TJ), basal lamina (BL) and perivascular spaces (PVS).

In control animals, La3+ did not penetrate the PVS and only occasionally labeled the BL. In contrast, the BL was labeled in more vessels and the PVS around many vessels were penetrated in the RMP-7 group. In some RMP-7 specimens, La3+ penetrated deep into the neopil synapsing the vessel. These observations indicate that RMP-7 permeabilizes the BBB to La3+ by an intercellular route. Dextran (MW 3,000) appears to follow the same route. Is transcytosis involved as well?

Labeling of endocytic vesicles by La3+ was no greater in the RMP-7-treated mice, transcytosis, therefore, is not responsible for the movement of La3+ across the endothelium. In contrast, the number of TJ labeled and the depth of penetration through series of junctions were greater in RMP-7 mice than controls. Thus, RMP-7 may open the barrier by way of TJ. Whether the TJ is the exclusive pathway is being further examined.

CLEARANCE OF ACIDIC AMINO ACIDS FROM CEREBROSPINAL FLUID, USING VENTRICULO-CISTERNAL PERFUSION IN THE ANESTHETIZED RAT, A DEVELOPMENTAL STUDY.

H. Al-Sarraf, J.C. Preston, M.I. Segal. Sherrington School of Physiology, UMDS, London SW7, UK.

The acidic amino acids, aspartate and glutamate, are excitatory neurotransmitters in CNS. The clearance of this group of amino acids from cerebrospinal fluid of adult and neonatal (7-day old) rats was investigated. Ventriculo-cisternal perfusions with 14C-amino acids and 3H-dextran were carried out for up to 90 min. Uptake of the amino acid by the whole brain was measured and the loss to blood was calculated (Davson et al., 1982).

<table>

Aspartate followed a similar pattern to glutamate, indicating the presence of acidic amino acids from CSF to blood in adult than in neonatal rats. However, there was no significant change in the loss to brain tissue with age (p>0.05).

G, AND G LEVELS ARE ALTERED BY AGING IN RAT BRAIN MICROVESSELS.

P. Moore and P. Grammas. Dept. of Pathology, Univ. of Oklahoma HSC, Oklahoma City, OK 73104.

Glutamine nucleotide-binding regulatory proteins (G proteins) play a central role in receptor-mediated signal transduction. These membrane proteins couple activated receptors to messenger enzymes, including adenyl cyclase. In aging, altered responsiveness to agonists that elevate cAMP may reflect abnormal receptor-effector coupling. The objective of this study was to examine G protein expression in the cerebral microvasculature of aged rats. Microvesicles were isolated from the cerebral cortices of young adult (1-3 month) and aged (>18 month) rats and membranes subjected to ADP-ribosylation. Cholera toxin and pertussis toxin were used to identify Gs and Go respectively, and the two isoforms quantified by autoradiography of SDS-PAGE gels. The results indicated that the level of Gs increased significantly (P<0.01) in microvesicles from aged rats (65%) while the level of Go was lower (40%) in aged animals. These results demonstrate differential changes in G protein expression in aged animals and suggest that alterations in signal coupling may underlie some age-related alterations of the blood-brain barrier. (Supported by NS grant 90457, OCAST and the Glenn Foundation).

DIFFERENTIAL EXPRESSION OF a-ACTIN mRNA AND IMMUNOREACTIVE PROTEIN IN BRAIN MICROVASCULAR PERICYTES AND SMOOTH MUSCLE CELLS.

R. B. Nemeroff, W.J. Sklar, H. Roizen, D. R. Prestin, and M. Pardike. Department of Medicine and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Hypersynaptic has been linked to opening of the blood-brain barrier and may be related to the expression of the smooth muscle (a) actin gene in contractile cells at the brain microvasculature. However, the cellular origin (i.e., endothelial cells, pericytes, or smooth muscle cells of the a-actin mRNA in the brain microvasculature is not clearly identified. Therefore, we investigated the abundance of actin mRNA by Northern blot analysis. The relative abundance of the a-actin 1.7 Kbp transcript was: cultured pericytes-endothelial primaries (which contain both endothelial cells and pericytes) > freshly isolated microvessels. The a-actin mRNA was absent in a cloned bovine brain endothelial cell line. All samples showed the characteristic 2.1 Kbp transcript corresponding to cytoplasmic b and isoform mRNA. The cellular distribution of the I(1) protein was studied by immunochemistry in cytosplunk isolated brain microvessels with a monoclonal antibody directed to the a-actin. The antibody reacted strongly with pre-capillary arterioles of microvessels, whereas no immunostaining was observed in either endothelial cells or pericytes. Conclusion, the a-actin mRNA is expressed in cultured brain microvascular pericytes and in endothelial primaries, but the immunoreactive a-actin protein is not expressed in brain microvascular pericytes in vivo. These data suggest that either (a) the a-actin gene is induced in cultured brain pericytes, or (b) the a-actin mRNA in pericytes in vivo is subject to translational repression resulting in no detectable a-actin protein under normal physiologic conditions.

POSSIBLE DETERMINANTS OF VESSEL PHENOTYPES IN MUSCLE GRAFTED TO BRAIN.

S. Naito, L. Chang and M. Brightman. LN., NIH, Bethesda, MD. 20892.

The ability to determine a vessel's phenotype is decreased in adult tissue; some vessels mature skeletal muscle. It may be that mature choroid plexus are of the choroidal, fenestrated (FV) type rather than exclusively of the continuous (CV) muscle type. It is reported here that when the graft is from an E14 fetal rat, about 80% of the vessels are CV, like those of muscle and brain. Only a very few CV can be immunostained for endothelial barrier antigen and are, accordingly, brain derived. By E16, about 70% are FV, like those of host choroid plexus. Thus, between E14 and E16, a 'conversion' factor that converts invading FV to CV, is diminished. To see whether the CV are extensions of choroidal blood vessels or converted graft vessels, fetal tissue was labeled with bromo-deoxyuridine. VEGF (vascular endothelial growth factor) may also be a vascular type determinant. It is known that VEGF is associated with FV and that its mRNA is in the choroid plexus. By in situ hybridization, we find that mRNA to VEGF receptors is in choroid plexus but not in the graft. It is likely, therefore, that the tissue conversion factor, rather than VEGF, determines a vessel's phenotype during regeneration of blood vessels supplying muscle grafts.
ACIDIFICATION DECREASES [CA] IN RAT BRAIN CORTICAL ENDOTHELIAL CELLS. D Feyer, M Wei, S Wekert, J G Schulte, A Vittinghoff. The blood extracellular and intracellular pH changes under various physiological (i.e. neuronal activation) and pathophysiological (i.e. ischemia) conditions. We investigated whether the extracellular or intracellular pH effects on [CA] in rat brain cortical endothelial cells (DIV 0-14), which might link pH changes to [CA]-dependent mechanisms. For imaging of extracellular pH and [CA], we used confocal laser scanning microscopy (Blued MRD 660) and the fluorescent dyes BCECF-AM and FLUO-3-AM. Acidification of extracellular fluid (pH 7.4 to 6.8) led to a similar decrease of [CA], but smaller decrease of pH, than intracellular acidosis induced by the NH4Cl preparation technique. The results are summarized in the table:

<table>

**VIRAL-INDUCED DEMELINATION: A ROLE FOR THE BLOOD-BRAIN BARRIER?**

Egleton R.D., Dawson J., Butt A.M., Amor S. & Segal M.B.*

Physiology and Immunology, UMDS, London SE1 7EH, U.K.

In multiple sclerosis (MS), dysfunction of the blood-brain barrier (BBB) has been observed, and may be major factor in this disease. Using the Semliki Forest Virus (SFV) in the Balb-C mouse, we have measured the permeability of the BBB to 14C-mannitol during the course of the infection stage, in controls and following treatment with citimeline, a histamine H2 antagonist.

SFV animals were perfused at 3, 5 and 10 days post inoculation (PID) with a 10% albumin solution containing 14C-mannitol and the unidirectional transfer coefficient (Ki) for mannitol calculated.

Table 1: The % increase of mannitol permeability across the BBB for PID 5 and citimeline treated animals compared to control (p<0.001, Student's t-test compared to PID 5). The histamine H2 antagonist citimeline significantly reduced the permeability changes at PID 5. The opening of the BBB as indicated by the increase in the Ki for mannitol corresponds to the viremia and accumulation of virus in the brain as seen by others.

**ENDOGENOUS REGULATION OF PERINEURIAL PERMEABILITY: EVIDENCE FROM PARTIAL NERVE SUPERFUSION STUDIES.**

J.Y. Stawarz, A. Weerasinghe and M.E. Michaud* 

Division of Basic Sciences, Merck University School of Medicine, Macon, GA 31207, and NINDS, NIH, Bethesda, MD 20205.

The monofascicular mid-thigh portion of the frog sciatic nerve has major contributions from the 7th, 8th and 9th spinal roots. Comparisons of compound action potentials reveal that each of these roots contributes about 30% of the myelinated fibers in the sciatic nerve. The effect of transecting either the 8th, or 9th and 8th, or all three roots on perineurial permeability was examined using an in vitro technique (Brain Research, 173, 503-511).

The index of permeability was measured as the ratio of the conductivity of the sciatic nerve before and after transection. The increase in permeability is probably associated with the opening of the myelin sheaths at the segmental nodes, and the later increase to the absence of fibers in the underlying endoneurium. It is difficult to reconcile these data with the notion that the permeability of the blood-nerve interface is altered in an all or none fashion with an increase in its permeability being considered as a breakdown of its barrier properties. The data are more consistent with the prospect that perineurial permeability is regulated in a graded manner by endoneurial components, which release factors that affect the rate of turnover of perineurial tight junctions (NIH RO1 NS30197).

**PRESYNAPTIC MECHANISMS IV**

549.3

**ARE LONG LATENCY RECURRENT EPSPs RECORDED IN THE IMMATURE HIPPOCAMPAL MONOSYNAPTIC EVENTS?**

K. Smith and N.W. Swain* 

The Gairdner Foundation Laboratories, Department of Pediatrics, Division of Neuroscience, Baylor College of Medicine, Houston, TX, 77030.

The immature hippocampus has a great propensity for generating electrographic seizures. One possible explanation could be that there is an age dependent difference in the recurrent excitatory network. Our laboratory, has been investigating the local network through paired intracellular recording from immature CA1 neurons. Minicuts of CA1 neurons from (EM - 14 days old) rats were bathed in 1.7 mM penicillin to block inhibitions. In 152 neuronal pairs (96 pairs) 9% revealed monosynaptic interactions. The onset of the evoked ranged from 0.7 - 3.3 msec. Many of our evoked had latencies longer than 2 msec while evoked by polysynaptic eppp; they did not fluctuate in latency, their durations were short, they followed one for one at high presynaptic spike frequencies, and the probability of transmission was high. We therefore attempted to determine what was monosynaptic eppp had long latencies. We hypothesized that the long latencies were due to slow conduction velocities in CA1 recurrent axons. To determine this we investigated the conduction velocity of the Schaffer collateral fibers by extracellular recordings of the presynaptic fiber volley. The experiments were conducted as 35°C to the CNOQu and APV. In 6 experiments conduction velocities of 0.15-0.33 m/sec were recorded. Based on a mean value of 0.20 m/sec, an action potential would be expected to travel 500 µm in 2.5 msec. Therefore, our results suggest that the longer latencies are likely to be monosynaptic events and the delays are due slow conduction velocities in the recurrent axons of the hippocampus.

Supported by NIH Grant NS18369.

**What accounts for the variance of microtubule synaptic current amplitude?**

M. Freking, S. Borowsky, and M. Wilson* 

Section of Neurobiology, Physiology, and Behavior, University of California, Davis CA 95616.

Isolated amacrine cells from embryonic chick retina form autapses in culture. In the presence of TTx, TEA, and internal Ca2+, these autapses are capable of Ca2+ dependent evoked and spontaneous GABA release. Spontaneous, discrete GABA release events consists of an opening of less than 20 channels. As in other cell types, the mini amplitude distribution is positively skewed; cable filtering is likely to account for this skew, since these neurons are electrically compact. The standard deviation of the observed variance in the mini distribution is due to the summed properties of individual release sites, we have examined regions of the cell in isolated amacrine cells.

Minis were restricted to a small region of an isolated neuron by focal superfusion of a Ca2+ containing saline. Multiple Gaussian peaks are evident in these distributions in different amacrine cells. The variance unaccounted for by uncorrelated noise, and we estimate on the basis of this low variance that the probability of opening between 50 and 100%, implying a similar number of release sites. This release sites compared to whole cell mini distributions, focally restricted minis show a reduced variance, mainly due to the absence of large minis, however, both distributions have a similar mode. We calculate that the frequency of mini release is below 10% to support the possibility that the large events seen in the whole cell distribution are random coincidences. We suggest on this basis that some of the variance seen in the whole cell distribution is not due to the sum of independent events at different release sites. Supported by EY04112 (MM) and an NSF predoctoral fellowship (MF).
549.5 THE EFFECT OF ELECTROTONIC STRUCTURE ON QUANTAL AMPLITUDE AT CENTRAL SYNAPSES. A.A. V. HIBBS, G.W. Davi, C. Bigelow, R.K. Murphy. Neurosciences and Behavior program, Univ. of Massachusetts at Amherst, MA 01003.

We examined a distributed central synapse in the cricket cercal sensory system. Dual, simultaneous intracellular recordings were made from the lateral and medial dendrites of the cricket interneurons, MGI, while stimulating an identified sensory neuron (SN). SN spikes evoked two-electrotonically separated spikes, the lateral and medial dendrites of MGI. Thus, an electrode in the lateral dendrite can detect EPSPs that originate from the nearby site and EPSPs that originated from a distant site—the medial dendrite. Therefore, the amplitude histogram contains the true quantal amplitude, q, of nearby synapses and the smaller apparent quantal amplitude of the distant synapses due to the electrotonic decay of potential. Isolation of EPSPs originating solely from the dendrite that the EPSP that was near the electrode in another dendrite were of the similar amplitude. Since the input resistances of these two dendrites are comparable, this suggests that the underlying synaptic conductances are very similar. This result shows that the q is uniform for the terminals of a single SN.

We performed computational simulations of the distributed synaptic input to MGI. The simulations showed that our method of isolating EPSPs that originated solely on one dendrite was reliable. The simulations also showed that the evoked amplitude histogram, seen from a single electrode, in one dendrite is greatly affected by the presence of synapses located on the other dendrite. We were unable to fit the resultant simulated amplitude histograms to a theoretical model. We suggest that a statistical model, the sum of two binomials, that takes into account the electrotonic structure of the post synaptic neuron is required.

549.6 TARGET REGULATION OF THE PROBABILITY OF PRESYNAPTIC RELEASE IN THE CRICKET CNS. G.W. Davi* and C. Bigelow and R.K. Murphy. Neurosciences and Behavior Program, University of Massachusetts, Amherst, MA 01003.

Our results demonstrate that a single SN is capable of making synapses with different probabilities of release at different target interneurons, MGI and 10-3. A single identified SN was injected and at least 50 recordings were made from each MGI simultaneously from MGI and 10-3. The simple binomial was fit to each amplitude distribution using the Expectation-Maximization algorithm with four free parameters; the binomial parameters and the overall probability of release. The SNs that contacted MGI and 10-3 showed a lower probability of release, p, compared to the terminals from the same SN that contacted 10-3. The difference in p at the terminals of a single SN contacting MGI and 10-3 appears to determine the dynamic properties of these synaptic terminals. The SNs contacting MGI showed paired-pulse facilitation while terminals contacting 10-3 showed paired-pulse depression. The major change in EPSP amplitude in these terminals is due to changes in the probability of release and facilitation and depression can be accounted for by changes in p. Furthermore, when transmitter release was reduced in low calcium, high magnesium saline the probability of release at these synapses was reduced and synaptic depression was abolished. The difference in the probability of release and dynamic properties for synapses contacting MGI and 10-3 was consistent for 5 identified SNs that contacted either interneuron alone (N=13). These results indicate that the probability of presynaptic transmitter release is regulated locally, at the synapse by an interaction with the post synaptic cell. Further hypothesis that such a local regulation is responsible for determining the characteristic short term dynamic release properties of these central synapses during development. Supported by NSF grant #NSF 90-96180.

In crayfish neuromuscular synapses low transmitter output permits direct counting of quanta released by stimulation. This is often the preferred method of estimating the quantal content "q". We have compared this method with two alternative methods: (1) measurements of the peak amplitude and (2) measurements of current area (or charge). These two methods have been used in the past in other preparations but not compared directly. To verify the accuracy we compared all three methods on data sets from the crayfish neuromuscular junction and found consistently that the area but not the peak amplitudes give accurate results. In the crayfish and larval Drosophila preparations extracellular local macropatch recordings over visible neuromuscular varicosities were used, whereas in the rat, whole cell clamp recordings were used. The deficiency of the amplitude method is most acute when quantal release is synchronous as in crayfish synapses. In the rat dentate gyrus synapses the area method gave substantially higher estimates of "q" since it included the late, asynchronous release. Another advantage of the area method is a reduced noise level and partial compensation for fractional decrease at dendrites.

Finally, the area and peak amplitudes were compared at the Drosophila synapses and excellent agreement between the two was found. These synapses have high output and appear to release transmitter synchronously. We conclude that in general the area method offers an adequate substitute for the direct estimate of quantal content. Funded by NSERC, MRC and NCE of Canada.

549.8 PRESYNAPTIC GABAERGIC INHIBITION OF EXCITATORY AXON ACTIVITY REVEALED BY BLOCK OF GAD. G. Golseth and Y. Grossman. Department of Physiology, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva 84105, Israel.

Block of glutamate decarboxylase (GAD) as well as GABA receptor (GABA B) has been used to study the effects of reducing GABA levels in the inhibitory terminal, inhibitory and excitatory postsynaptic potentials (IPSPs, EPSPs) were recorded intracellularly from fibers in the motor nerve of crayfish walking leg. The corresponding synaptic currents, (IPSCs, EPSCs) were recorded by loose patch clamp technique. 90 min exposure to mercaptopropionic acid or aminooxyacetic acid, GAD blockers in this system, reduced IPSP amplitude by 52% and conductance by 63.3%. The maximal inhibition of EPSP amplitude decreased by 46% (n=10). Quantal analysis of the IPSCs revealed a decline in the quantal content due to 27% (n=5) reduction in the probability of release at each active zone. Quantal content was not affected. Presynaptic inhibition of EPSCs was reduced by 62%. Redistribution in presynaptic inhibitory tonus induced by perfusion with GAD or GABA B blockers (90 min) generated hyperexcitability of the excitatory terminal manifest in one of the following responses: doubled EPSC amplitude, increase of potentiation, or spontaneous activity. Our data show that blockage of GABA synthesis reduces pre- and postsynaptic GABA release and inhibition. Lack of tonic GABA input on the excitatory terminal increases its excitability and release. Supported by grant from the Israel Planning and Grants Committee.

This laboratory has long been interested in the structure and physiology of the mossy-fiber synapse. In the recent past, Brown, et al., 1979; Brown and Johnston, 1983; Johnston and Brown, 1983; Barrientowuro et al., 1986; Griffith et al., 1986; Claiorome et al., 1993; Yu and Brown, 1994. Our recent analysis of the quantum mechanism of LTP expression supports the hypothesis of a presynaptic process that increases the mean number of released quanta (Xiang et al., 1994).

Using this lab technique, we have examined spontaneous miniature synaptic potentials and currents in CA3 pyramidal neurons, but the signal-to-noise ratio was poor. Here we have begun to re-examine spontaneous synaptic activity in CA3 neurons using whole cell recordings. The cells were directly visualized using infrared (IR) differential interference contrast (DIC) video microscopy, switching from our previous (fixed-stage) inverted microscope (Keenan et al, 1988) to an upright one (40X water-immersion objective).

The recordings were restricted to cells judged to be healthy based on their contrast under the DIC microscopy. We were able to identify events judged to be electronically near to recording site based on 10-90 rise time (<1.5 msec). With the soma clamped at about -80, most of the spontaneous events were in the range of 10 - 50 pA, although occasionally we saw very large spontaneous events (>200 pA), even in the presence of 1μm tetrodotoxin, which should block evoked release. We are currently trying to characterize the quant regulated specifically with the NMDA synapses. Supported by NSF BHR & UNK.

549.11 
COMPUTATION OF LONG-DISTANCE PROPAGATION OF POISON PROCESS-
ELECTICALLY IMPULSED COWS. K. Menard and M. D. Golinger, Dept. of Physiology 
and Biophysics, Wright State University, Dayton, OH 45401-0927.

The Hodgkin-Huxley/Cable theory formulation was used to compute propagating 
impulses in a 1-mm-diameter axon (axon diameter = 2454.5 nm) as previously described (1). 
Computation parameters were: \( \Delta x = 0.056 \text{~um} \); \( \Delta t = 0.125 \); \( t_{\text{total}} = 10^3 \text{~ms} \). The total axon length was 8.1 cm (254) or 10.4 cm (312.5). The temporal integration step \( (+1 \times \text{ms}) \) provided a single-point-to-point calculation. The input voltage distribution (HFD) falling time, and an Expectation Density (ED) consisting of a maintained noisy \((+/1) \text{plateau} \). Poisson stimulation yielded variability in elicited action potential amplitudes. For short 
interspike intervals (5.5-8.5 ms), the second spike was attenuated by as much as 0.37 mV; for 10-to-15 ms intervals, second-impulse amplitude was slightly \((+1) \text{mV} \) increased. Initial phase did not change for prepulses. Using paired stimuli, short 
interspike intervals (5-15 ms) increased in duration and longer interspike 
intervals (12-16 ms) decreased in duration with propagation distance. 

With Poisson stimulation, in the 254 cm, the IID consisted of a deadtime, short-
interval, peak, and monotonic falling limb. The ED consisted of a deadtime, short-
interval peak, and noise-resistant plateau. However, both IID and ED varied with propagation distance: longer propagation distance shifted IID and ED modes to a 
larger time range, as expected by the slower and variable conduction velocity of the 
second of a short-interval impulse pair. Over a larger conduction distance (300-1500 \pm \text{msec}), the IID included a major symmetrical peak, and the ED developed harmonics. 

These computations confirmed (2) that wide-base impulse codes can change with propagation distance. Refs.: (1) M. D. Golinger, Biophys. J., 50, 1986; (2) S.A. George, 

549.12 
VISUALIZATION OF NEURAL TERMINAL STAINING WITH FM-43 
TRIGGERED BY BLACK WIDOW SPIDER VENOM (BWSV).

A. W. Henkel and W. Bux, Dept. of Physiology 
University of Colorado Medical School, Denver, CO 80262

Frog motor nerve terminals can be stained with the fluorescent styryl dye FM-43 
and with capsaicin. The dye, evidently, is taken up into vesicles while 
undergoing cycles of exo- and endocytosis in response to nerve stimulation. BWSV 
is well known to trigger massive exocytosis at synapses. This action does not depend 
on five extracellular calcium ions. However, calcium is required for subsequent 
endocytosis. 

Here we show that frog nerve terminals take up FM-43 when they are exposed to 
BWSV in the presence of calcium. Frog nerve muscle preparations were pre-
incubated in normal frog Ringer containing BWSV (0.1 gland/ml) until the muscle 
started to twitch (about 30 minutes). FM-43 (2 \text{mM}) was added for five additional 
minutes. The muscles were then washed for 1 hour. The FM-43 staining pattern 
was indistinguishable from control preparations stimulated via the nerve without 
BWSV. When the same experiment was performed in the absence of extracellular 
calcium only a minute quantity of dye was taken up into the nerve terminals and the 
synapses looked swollen and puffed. These observations support previous 
edition micrographs which data which suggest an important role for calcium in endocytosis of 
BWSV poisoned nerve terminals.
CLOSE PRESYNAPTIC ACTIVE ZONES MAY ENHANCE FACILITATION
J.L. Winslow & K.C. Cooper
Dept. of Neurobiology
University of Iowa, Iowa City, IA 52242

Voltage activated Ca2+ channels, normally active in neurotransmitter release, are known to be the basis for composite varicosities of crayfish presynaptic active zones, AZs, show Ca2+ channels and K+ channels as prominent intramembrane particles. Reconstructed serial EM images of varicosities from crayfish opener muscle show 0.5–1 AZs per synapse, with different separations. To evaluate separation effects on facilitation due to spatial summation of Ca2+ for one AZ, then for two separated AZs. With Ca2+ diffusion coefficient as in H2O and no binding sites, all Ca2+ diffuse away 0.2 ms after channel closing. With 0.1–0.6 mM total Ca2+ binding sites, residual concentration of Ca2+ increases 9.7 times the resting value 0.1 μM with successive stimulation. When two AZs centers are separated by 200 nm, the Ca2+ concentration midway between the AZs is sufficient to potentially cause vesicle release. Thus, in single synaptic junctions may promote transmitter release and facilitation. (See Cooper, R.L., et al., this meeting.) Funded by NERSC, MRC, & NCE of Canada.

We investigated the role of calcium in determining the probability of transmission and whether composite synapses have a higher probability of transmission. Synaptic currents are recorded from single varicosities with a macropatch electrode to determine quantal parameters of synaptic release. Reconstructed serial sectioned reconstructions of these synapses show complex (more than one active zone) and simple (only one active zone) synaptic release. Complex synapses have also been observed in a variety of crustacean species at motor, interneuronal and presynaptic inhibitory neuromuscular junctions (NMJ). In the reconstructions of serial sectioned macropatched terminal active zones (AZs) of complex synapses are often close together. Infreeze fracture replicas, two AZs containing intramembranous particles (Ca2+ and K+ channels) also occur close together. Cooperative interaction of between closely spaced AZs occur at complex synapses. Thus, Ca2+ would be greater at sites of vesicle release after an impulse at complex synapses. We propose that the probability of release is higher at sites where AZs are in close apposition and that the number of pairs of close AZs may represent the anatomical correlate of the quantal parameter "n" (number of release sites) at low frequencies of stimulation. At higher frequencies of stimulation, more distant AZs and single AZs may acquire higher probability of release, thus giving the nerve terminal a mechanism for grading synaptic output with frequency (see also Winslow, J.L., et al., this meeting). Funded by MRC, NCE & NERSC of Canada.

550.7 EVIDENCE THAT EXCITABILITY CHANGES IN PRESYNAPTIC FIBERS MAY AFFECT PAIRED-PULSE FACILITATION IN HIPPOCAMPAL SLICES.
J.F. Storm & R.O. Wozny
Dept. of Neurophysiology
University of Oslo, Norway

Excitability changes in presynaptic fibers may affect paired-pulse facilitation in hippocampal slices. Whole cell recordings were obtained from CA3 and CA1 pyramidal cells in slices from young rats, while paired stimuli of equal, low intensity (Stim.1 = Stim.2; interval 40-60 ms) were given from a small glass pipette. In CA1 cells, stimulation of presynaptic fibers in str. radiatum elicited excitatory postynaptic current (EPSCs), which usually showed facilitation; i.e., EPSC2 was larger and/or showed fewer failures than EPSC1. To test whether this difference could be partly due to variable axon excitability or conduction, fibers in str. radiatum were stimulated in a similar way while recording from CA3 somata, showing shorter-latency, presumably antidromic, action potentials. In response to paired pulses, these spikes often showed fewer failures to Stim.2 than to Stim.1. This effect persisted even after blocking excitatory and inhibitory synaptic transmission by reducing the [Ca]/[Mg] ratio (0.1 mM Ca/6.5 mM Mg) or by adding NOX and bicuculline. Similar effects were also seen with antidromic stimulation of CA1 cells or by "direct" stimulation close to CA3 or CA1 somata. These results suggest that the initiation and/or conduction of action potentials in hippocampal axons may change during repetitive stimulation, and that these effects may add to and influence paired-pulse facilitation and other synaptic phenomena. Supported by NFR.

550.8 RELEASE PROBABILITY IS ALTERED BY ALTERING EXTRACELLULAR CALCIUM, BUT PAIRED PULSE FACILITATION IS NOT, AT PYRAMIDAL-INTERNEURONE SYNAPSES IN NEOCORTICAL SLICES. Alex Thomas, M.D., and Jim Deuchars.
Dept. Physiology, Royal Free Hospital School of Medicine, London, NW3 2PF, UK.

A single axon connected by pyramidal cells and interneurons were recorded using pairs of biocytin-filled sharp electrodes in slices of neocortex. Typically, EPSPS elicited in an axon by spikes in a single pyramid exhibited profound paired pulse facilitation and a high probability of failures of transmission to single presynaptic spikes in standard medium (2.5mM Ca2+). The effect of raising extracellular Ca2+ on the EPSPs elicited in one class of interneurons, i.e., bursting, sparsely-medium spiny interneurons, was studied. When extracellular Ca2+ was raised to 5mM, the proportion of failures of transmission to the first spike decreased and averaged amplitudes were almost doubled. However, the 2nd EPSP also increased in amplitude and paired pulse facilitation was reduced. These data contrast strongly with those obtained from pairs of synaptically connected pyramidal neurons. EPSPs elicited in postsynaptic pyramids typically exhibited paired pulse depression that was augmented when extracellular Ca2+ was raised. In addition, unlike pyramidal-EPSPs, the time course of EPSPs recorded in this class of interneurons was increased.

550.9 INCREASE IN NEUROSECRETORY ACTIVE SITES DURING FACILITATION.
M.K. Warden, D.A. August, and J.T. Hackett

The classic Del Castillo and Katz model for quantal release has as its basis the statistical parameters "n", the number of active quantal release sites and "p", the probability of release to occur. Unfortunately, these values are subject to spatial and temporal variations which may render them useless. We have used a method (Proven & Miyamoto, 1993) which avoids these problems to measure facilitation of neurosecretion at a lobster neuromuscular junction. Extracellular recording during steady state conditions were made from synaptic sites using macropatch electrodes with tip diameters of 20 μm. The extracellular nerve was stimulated by a constant frequency for each trial in a range between 1 and 20 Hz. Unbiased estimates of quantal release parameters were computed. Both "n" and "p" were estimated at and above 4 Hz. The extracellular Ca2+ from 2.0 to 0.5 mM decreases the probability of PPP and raises the probability of paired pulse facilitation (PPF) at 1 sec. Stimulus intervals. The unexpected occurrence of PPP and post tetanic depression (PTD) in [Ca2+]o=2.0 mM in this elemental synaptic preparation and in other CNS preparations (Thomson and West, 1993) suggests that this may be an important biological property of excitatory synapses. Some experiments demonstrate a relative increase in the frequency in mini-EPSCs accompanying PPD or PTD. A correlation between decreased evoked response amplitude and increased mini-EPSC frequency suggests that short-term plasticity of evoked response amplitude may be dissociated from changes in spontaneous release of neurotransmitter. Alternatively, post-synaptic mechanisms such as desensitization of AMPA receptors may be involved in the facilitation of the evoked response. Supported by NS34260(M.A.D.)

**ANESTHESIA PRODUCES DIFFERENTIAL EFFECTS ON EPSP FACILITATION.**

S.M. Amagai, A.A. Mikulec, F.A. Monroe and M.B. McElvany
Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305.

Anesthetic effects on excitatory postsynaptic potential (EPSP) facilitation were studied as a measure of actions on presynaptic release. Effects produced by clinically relevant concentrations of halothane, isoflurane, and thiopental were compared on Schaffer- 
collateral evoked dentritic EPSPs recorded in CA1 of 1 hippocampal brain slices. Paired stimulus pulses were used to produce EPSP facilitation. In agreement with previous studies, synaptically evoked discharge of CA1 neurons was blocked by halothane (1.2 vol %, 1 rat MAC), isoflurane (1.4 vol %), and thiopental (100 µM). The block produced by the anesthetics was associated with a 22 ± 3.6%, 26 ± 4.8%, and 23.4 ± 8.5% depression of single-pulse EPSP amplitudes by halothane, isoflurane, and thiopental respectively. Halothane increased EPSP facilitation from control values of 130% to 142 ± 6.7%, while isoflurane and thiopental reduced EPSP facilitation to 123 ± 3.1% and to 121 ± 11.3% respectively. Effects on EPSP facilitation demonstrate anesthetic actions on glutamate nerve terminals, since facilitation is known to involve only pre-synaptic mechanisms. The similar effects on EPSP amplitudes but differential effects on facilitation provide further support for a Multisite Agent Specific (MAS) mechanism of anesthetic action.

Supported by NIH GM49811.

550.13

**ECTOPTIC ACTION POTENTIALS IN HIPPOCAMPAL AND DENTATE NEURONS UNDER CONTROL CONDITIONS.**

We have previously reported that induction of electrographic seizures (EGS) using kindling-like stimulation increased the occurrence of ectopic action potentials (EAHPs) in CA1 pyramidal cells. These ectopic action potentials are generated in the axon terminal by a depolarizing GABA response. However, it was also noted that in 37% of the CA3 neurons sampled, ectopic action potential occurred prior to EGS induction. We now report the presence of ectopic action potentials under control (non-hyperexcitable) conditions in other cell types in both the hippocampus and dentate gyrus.

Intracellular recordings were recorded from neurons in the rat hippocampal slice preparation using sharp microelectrodes. Ectopic action potentials were identified as action potentials which arose sharply out of the baseline with no preceding depolarization and continued to occur despite synaptic hyperpolarization. Ectopic action potentials were present in 31 out of 160 sampled granule cells (19%). Similarly, ectopic action potentials were observed in area CA1 in both pyramidal cells and fast spiking interneurons in the pyramidal cell layer. In cells ectopic action potentials occurred both spontaneously and following orthodromic and antidromic stimulation. Evoked ectopic action potentials occurred primarily during the GABAergic IPSP and manipulations designed to reduce GABAergic inhibition blocked ectopic action potentials, demonstrating their dependence on GABAergic actions.

These results suggest that the occurrence of ectopic action potentials may be more widespread than previously thought and that these action potentials may contribute to cellular responses under normal (non-hyperexcitable) conditions.

**ZINC ENHANCES ACTION POTENTIAL INDEPENDENT GABA RELEASE FROM INHIBITORY TERMINALS IN THE DENTATE GYRUS.**

R. Haltmeyer, J. Linck and J. Maclver.
NIMH Anatomical Sciences Unit, Oxford University, U.K., and Dept. of Anesthetics/Phys. Mgmt. & Neurology, UT Southwestern Med. Ctr., Dallas, TX.

Depending on the developmental stage, zinc is known to exert various effects on GABAergic inhibition. The effects of zinc range from diminishing GABA responsiveness in the absence of the γ-subunit, to enhancing inhibition secondary to its action on the excitability of inhibitory interneurons. We have examined the possibility whether zinc modulates the release of GABA from inhibitory nerve terminals when the excitability of interneurons is altered or is unlikely to be affected.

Recordings were obtained from dentate gyrus granule cells in conventional (400 µm thick) coronal adult rat brain sections using whole-cell patch clamp techniques. Miniature inhibitory postsynaptic currents (mIPSCs) were obtained at 1 Hz, from a constant holding potential of 1 mV, 10 µm CNQX and 40 µm D-AP5, with 130 mM CsCl, 10 mM Hepes, and 2 mM MgCl2 containing electrodes. During a given recording, access resistance was frequently monitored, and experiments were only selected for analysis if access resistance did not change throughout the recording period. Furthermore, event detection accuracy was ensured by analyzing the frequency and amplitude of events at two different holding potentials. Zinc (10-200 µM) was applied through bath perfusion, and produced a significant enhancement of mIPSC frequency. In 20% of the recordings, zinc induced dramatic bursts of mIPSCs, causing a 10-20 fold increase in event frequency during burst periods. As expected from the presence of the GABA receptor γ-subunit on adult granule cells, zinc had no effect on the decay kinetics, 10-90% rise times, and amplitudes of mIPSCs.

Our findings demonstrate a presynaptic effect of zinc on GABA release more likely occurring at the level of inhibitory terminals of GABAergic neurons. Such modulation of tonic GABA release by zinc, may play an important role in the regulation of excitability in the dentate gyrus.

**LONG-TERM POTENTIATION: PHYSIOLOGY VI**

551.1

**MECHANISMS OF SELECTIVE LONG-TERM POTENTIATION OF EPSPs IN INTERNEURONS OF STRATUM ORIENTIS IN RAT HIPPOCAMPAL SLICES.**

M. Quednau and J.-C. Lecaille.
Centre for Research in Neurosciences and Department of Physiology, University of Montreal, Montréal, Québec, Canada H3C 3J7.

Mechanisms of long-term potentiation (LTP) have been extensively studied in hippocampal pyramidal cells, but the involvement of inhibitory interneurons remains largely unknown. In the present study, the effects of tetanic stimulation were examined on excitatory postynaptic currents (EPSCs) in different hippocampal interneurons. Rat hippocampal slices, recorded in a chamber mounted on an upright microscope and CA1 interneurons were identified visually with Nomarski optics in str. oriens (OR cells) or lacunare-molecular (LM-) cells. EPSCs were evoked by electrical stimulation of the perforant path in OR cells in str. oriens were significantly increased in amplitude for 10 min (137 ± 7.0% of control [mean ± sem], n=11) to 30 min (129 ± 1.3% of control, n=5). Similar stimulation of OR cells was associated with potentiation of EPSCs (21.6 ± 8.2% of control, n=7). LTP of EPSCs in OA-cells was blocked by intracellular application of 25 mM BAPTA (42.7 ± 7.4% of control, n=5), and by bath application of 25 µM AP 5 (83.4 ± 6.7% of control, n=4). 200 µM AP 5 (83.4 ± 6.4% of control, n=5) and 250 µM AP 5 (83.4 ± 6.4% of control, n=5) and iii) 100 µM L-NMMA (83.4 ± 6.4% of control, n=5). These results suggest that excitatory synapses of interneurons in str. oriens display selective long-term potentiation via activation of NMDA and metabotropic glutamate receptors, post-synaptic elevation of Ca2+ and NO synthesis. Thus, various inhibitory cells may participate differently in hippocampal long-term potentiation.

551.2

**FEED-BACK SYNAPTIC PLASTICITY IN HIPPOCAMPAL ST. ORIENTIS-ALVEUS INHIBITORY NEURONS G. Macefield and C.J. McPhail.**

Laboratory of Cellular and Molecular Neuropharmacology, NICHD National Institutes of Health, Bethesda, MD 20892.

We studied the effect of low (10 min, 1 Hz) and high frequency (4 × 1 s, 100 Hz) stimulation of the str. radiatum on the synaptic responses of str. oriens-alveus (O-A) interneurons. Hippocampal slices were prepared from 15-22 day old rats and whole-cell current-clamp recordings were performed on a total of 17 interneurons in the presence of 1 µM bicuculline. In addition, the extracellular field potential in the pyramidal cell layer was continuously monitored. Activation of str. radiatum afferents elicited excitatory post-synaptic potentials (EPSP) or action potentials commencing ~ 2.5 ms after the peak of the field potential (FPP). Following the recording of stable synaptic responses for 10 minutes at 0.1 Hz, the low-frequency protocol was applied and both EPSP and IPSP amplitudes were strongly depressed (~ 70%) for the entire duration of the recording period. The absence of significant synaptic responses at 0.1 Hz, with the high-frequency protocol could restore or even potentiate the original baseline response. Identical results were obtained when the recording electrode contained 25 µM AP 5 (100 µM L-NMMA (83.6 ± 4.4% of control, n=5). These data indicate that the NMDA receptor antagonist D-AP 5 (50 µM) could prevent both the EPSP and IPSP depression. These data indicate that the GABA receptor antagonist D-AP 5 (50 µM) could prevent both the EPSP and IPSP depression. These data indicate that str. Alveus interneurons can undergo long-term depression (LTD) and long-term potentiation (LTP) without requiring an increase of intracellular Ca2+ concentration or phosphatase activity. These results, together with the delayed onset of the internuncial EPSP when compared to the IPSP peak, demonstrate that the LTD and LTP observed are indirect phenomena driven by the recurrent collaterals of CA1 pyramidal cells.
LONG-TERM POTENTIATION OF RECURRENT INHIBITION ONTO HIPPOCAMPAL CA1 PYRAMIDAL CELLS IN VITRO. H.C.R. Gronlund, D.G. Barnea, P. Parnavelas, J.R. Penney, S. Green. Harvard Medical School & VAMC, Department of Psychiatry, Boston MA 02137, USA

Long-term inhibition of recurrent inhibition is critical not only for the normal function of highly excitable regions of the brain, especially the limbic system, but may also be important in prevention or treatment of certain disorders. Postmortem data indicate reduced numbers of GABAergic interneurons while MRI data show marked volume reductions in cortical and especially limbic gray matter in schizophrenics, suggesting a possible role of excitotoxic injury in decreasing the density of recurrent inhibition. In the present study, standard extracellular (n=26) and intracellular (n=8) recordings from a rat brain slice of rat hippocampal CA1 showed that recurrent inhibition onto CA1 neurons is blocked by NMDA-mediated long-term potentiation (LTP), and that this LTP persists for periods longer than 20 minutes. After blocking excitatory input to the slice, the LTP was evoked by a tetanus applied to the stratum radiatum (10 Hz for the extracellular) and 40 Hz for the intracellular recording) and resulted in a long-lasting enhancement of the recurrent inhibitory drive of 19±9% at 20-40 min. In the extracellular recordings (20-25 min) recordings and 32.5±24.7% in 8 neurons (intracellular recordings). Furthermore, this LTP was completely blocked by the NMDA agonist 2-amino-4-phosphonovaleric acid (APV), M-81, phencyclidine (PCP) and N-acetyl-L-aspartyl-L-glutamine (NAAG). Presumably, the tetanic stimulus activated recurrent excitatory CA1 synapses instead of inhibitory interneurons that, in turn, silenced the inhibitory postynaptic potentials (IPSPs) in the recorded CA1 neurons. We thus infer that the LTP (defied by the increased amplitude of the evoked IPSP) occurs at the CA1-CA1 inhibitory interneuron synapse. Blocking the LTP of recurrent inhibition may explain the normal behavioral excitability in rats seen as exposure to PCP, whose effects in man persist post-schizophrenic symptoms.

Heme oxygenase-2 mutant mice as models for studying effects of the depletion of endogenous carbon monoxide, a putative neuronal messenger. K. J. Poso, C. Chen*, and S. Tungekar.
Center for Cancer Research and Dept. of Biology, Massachusetts Institute of Technology, Cambridge, MA 02139.
Recent work has implicated carbon monoxide (CO) as being a retrograde messenger in the mammalian hippocampus. The major physiological supply of CO depends on the activity of microsomal heme oxygenases, of which there are three isozymes. These enzymes degrade heme molecules to release biliverdin, free iron, and CO. We are currently studying heme oxygenase-2 (HO-2), which is highly expressed in many neuronal populations of the brain. Using homologous recombination in embryonic stem cells, we have generated mice with null mutations in HO-2. In order to retard death due to CO production, we generate mice with null mutations in neuronal activity. Homozygous HO-2+/- mice are viable and are indistinguishable from wild-type littermates upon birth. Our initial experiments will attempt to determine whether or not endogenous CO normally acts as a type of neurotransmitter. Neuronal activity and synaptic transmission are therefore being studied in these murine mice. We are also measuring LTP in HO-2+/- mice. The possible role of HO-2+/- mice in spatial learning will be investigated, by testing HO-2+/- mutants in tasks such as the Morris water maze. In addition, second messenger systems reported to be modulated by CO are being examined in the mutants, to determine possible mechanisms of CO action.

551.11
Taurine is one of the most abundant amino acids in the brain of mammals, its physiological role in the nervous system is not well defined. The best known electrophysiological effect of taurine is to act as a weak agonist on GABA receptors. Our purpose has been to study the actions of taurine on evoked synaptic potentials. Experiments were carried out in the CA1 region of rat hippocampal slices continuously perfused in a submerged chamber. The basic observation was that bath application of taurine (10 mM) for 30 min induced, after a transient decrement, an enhancement of field excitatory post synaptic potentials (EPSPs) that lasted after taurine washout (146±9% after 1 h washout, n=15). The following features related with this taurine action can be pointed out: 1) EPSPs increase is dependent on taurine concentration (5-10 mM) and taurine perfusion time (10-30 min). 2) EPSP potentiation does not present in the presence of GABA, or NMDA antagonists. 3) N-methyl-p-taurine, a taurine analogue, does not induce EPSP potentiation, 4) during perfusion taurine the different volley (AV) also shows a long lasting increase in amplitude; 5) EPSP enhancement is not fully explained as a function of the AV increase, as it is demonstrated by the AV/EPSP ratios before and after taurine. 7) taurine-induced potentiation of the AV is also observed in CA2+ 12 mM Mg+2. 8) intracellular recordings of evoked EPSPs and nonmonoevoked EPSPs show long term increases of both EPSPs and IPSPs amplitudes after taurine perfusion, while input resistance does not change significantly. These results could be explained, at least partially, through a taurine effect on glutamatergic and GABAergic presynaptic fibers, that a role in the mediation of the long lasting enhancement of synaptic transmission. (Supported by F.I.S. 95/055).

Adult sensory and motor cortical representations are capable of rapid reorganization, but whether this plasticity is clear in the primary motor cortex (MI) has been debated. Local blockade of inhibition within MI, which implicates inhibitory mechanisms in plasticity, and suggests that intrinsic cortical circuits contain necessary components. We investigated whether persistent changes in the functional interactions of MI neurons can arise by long-term potentiation (LTP) of synaptic transmission in horizontal pathways within MI and whether the occurrence of horizontal LTP is gated by cortical inhibitory circuitry. Field potentials (FPs) evoked in horizontal pathways were examined in adult rat MI slices. Focal, transverse application of the GABA receptor antagonist, bicuculline methiodide (BMI, 500 microM) immediately following theta burst stimulation (TBS) resulted in LTP. Simultaneous stimulation of horizontal pathways on either side of the recording site yielded larger LTP (34% increase in FP amplitude), with greater reliability (98% of cases), than stimulation of horizontal pathways from one side alone (57% of cases). Nearby recording sites that did not receive BMI expression no LTP. Intracellular recordings confirmed the long lasting enhancement of EPSPs following TBS (4 of 9 neurons). New experiments that activity in vertical pathways can replace the BMI requirement for LTP induction was combined. TBS of the horizontal pathway and the vertical pathway leading from deep layer III to layers II/III produced LTP in the horizontal pathway (FP 21%, 94% of cases). The cortical pathway FP was usually potentiated as well (15%, 83% of cases). LTP was blocked reversibly by 50 microM APV. These data support the hypothesis that glutamate mediated LTP in horizontal pathways may suggest that inhibition may gate synaptic modification. This gate may be open by conjoint activity with vertical connections which predominantly decreases local inhibition. The role of horizontal interactions among cortical pathways for cortical plasticity and also support the conclusion that intrinsic connections from a substrate for cortical reorganization. (Supported by NS22517).

551.10
Long-term potentiation (LTP) is a lasting increase in the efficacy of synaptic transmission and is assumed to underlie plastic changes associated with learning and memory. As acetylcholine (ACh) is known to be involved in cognitive processes of learning and memory, we studied the long lasting effects of ACh on synaptic transmission in subrebral hippocampal slices using intra- and extracellular recording techniques. Here we describe a novel action of the muscarinic agonist carbachol (CCh). Submicromolar concentrations of CCh produced a gradually developing, long-lasting increase in the CA1 long-term post synaptic potential (e.g.,) and population spike when continuously applied for 20 minutes, while higher concentrations caused an immediate but reversible depression. This potentiation, named muscarinic LTP (LTPm) was N- methyl-D-aspartate (NMDA) receptor independent, was independent of influx of extracellular calcium, but was dependent on release of calcium from intracellular stores and on the activation of kinases. LTPm can be induced in the complete absence of synaptic stimulation, and is the absence of intact CA1/CA3 connections. Saturation experiments showed that the mechanisms of LTPm and tetanus-induced LTP converge. These observations provide a direct link between ACh and mechanisms of synaptic plasticity.

551.12
For induction of long-term potentiation (LTP) of synaptic efficacy, the membrane potential of postynaptic neurons during synaptic inputs is suggested to be a critical factor. To test this suggestion, we prepared thin slices (140-150 microm thick) of visual cortex of rats aged 9 to 18 days for whole-cell voltage-clamp recordings from layer 2/3 neurons. Nystatin, which makes the membrane of a cell-attached patch electrically permeable (Horn and Marty, J. Gen. Physiol. 92, 145, 1988), was added to the sacrifice solution at 200 U/ml. Excitation of taurine, a postynaptic current (EPSCs) evoked by stimulation applied to an adjacent layer 2/3 neuron at 0.1 Hz were recorded for 3-10 min after an establishment of perforated patch-clamp recording. Then, test stimulation was paired with postynaptic depolarization at 1 Hz for 1 min. In 11 of the 15 cells in which the membrane potential was depolarized to -20 mV, LTP of EPSCs was induced following pairing. LTP of EPSCs was observed in 5 of the 14 cells depolarized to -40 mV. No LTP was observed when the postynaptic cells were clamped at -60, -70 or -90 mV. Thus, the induction of LTP may depend on postynaptic depolarization more than about -40 mV. Significant LTD was not induced in any of the cells tested with pairing stimulation of neighboring 2/3 cells. A question of whether this is also the case in synapses from layer 4 neurons to layer 2/3 neurons is being addressed with similar pairing procedures.

Synaptic transmission between descending fibers and lumbar motoneurons of the frog: Facilitation and long-term depression of single-fiber EPSPs. A.E. Dietz*, Y. V. Kushto*, and I.E. Clamann, Dept. of Physiology, Univ. of Bern, CH-3012, Switzerland, Inst. of Evolutionary Physiology & Biochemistry, 195272 St. Petersburg, Russia 
Twenty-five data sets of monoevoked EPSPs evoked by intracellular stimulation of descending fibers of the ventral lateral column were analyzed. Reticulospinal fibers (n=13) were identified by stimulation of the reticular formation; the remaining fibers (n=12) were presumably propriospinal. In both subsets of data there was considerable variability in EPSP mean amplitude (from 44 to 410 microV) and shape of averaged EPSPs (half-width from 4.9 to 23 ms). Amplitude of the monoevoked EPSPs was higher; in 4 cases mean amplitudes were bigger than 1 mv. There was strong positive correlation between the time/amplitude correlation between the time-amplitude correlation (for EPSPs with amplitude < 1 mV), implying variability in location of synaptic boutons. When a test stimulus was applied to a single fiber 40 ms after a conditioned stimulus, it produced weak facilitation of reticulospinal EPSPs (ratio between mean amplitudes of test and conditioned EPSPs was 1.218±0.22). For the propriospinal fibers (mean ratio 1.05±0.26) facilitation was observed in 38% of the cases. The short-lasting pathway was facilitated in 100% of the cases. In the remaining synapses, which all had high amplitude EPSPs, there was weak depression of the test EPSP: Simultaneous of a descending fiber at 5 Hz produced strong depression of the EPSP in 1.2 min. Recovery time after 5-10 min of stimulation was from 15 to 30 min (n=6) and in one case recovery was not complete 45 min after termination of 5 Hz stimulation. Ratio between amplitudes of test and conditioned EPSPs was not changed but half-width was increased within 5 min after the stimulation. We suggest that preynaptic mechanisms mediate the depression, and the effect is stronger at more proximal synapses. Supported by SNF.

This study was undertaken to examine both long-term potentization (LTP) and kindling-induced potentiation (KIP) in the same structures in freely moving guinea pigs. Guinea pigs were chosen because they exhibit a number of differences in electrical kindling as compared to rats. Male ad libitum, mixed strain guinea pigs were chronically implanted with bipolar stimulating and recording electrodes. Animals had stimulating electrodes implanted in either the olfactory bulb (OB) or lateral olfactory tract (LOT) and recording electrodes in the piriform cortex. Following a two week recovery period, a series of baseline input/output (I/O) response curves were generated. These were based on the application of rectangular 200 μsec pulses at 11 intensities thru the stimulating electrodes. The potentials evoked in the piriform cortex were analyzed for maximum peak and minimum valley amplitudes. LTP experimental animals received high frequency stimulation (HFS) trains once a day for a total of four days. Kindling experimental animals received a total of 10 stimulations, one per day, consisting of 1 msec biphasic square wave pulses at 60 Hz, for 2 seconds. In these animals the resulting afterdischarges (AD's) were marked and the convulsive behaviour scored. Post-kindling I/O's were recorded for several weeks. We report potentiation of the platform evoked responses to HFS and kindling of the LOT but not to HFS and kindling of the OB. Supported by NSERC and AHFMR.

A DEVELOPMENTAL EXAMINATION OF LTP IN FREELY-MOVING RATS. J.D. Bronzi, Jr., Austin-LaFrance and P.J. Morgans. Dep't of Engineering and Computer Science, Trinity College, Hartford, CT 06106.

This study examined the establishment, maintenance, and decay of LTP across the perforant path/dentate granule cell synapse in freely-moving rats at 15, 30, and 90 days of age. Measures of population spike amplitude (PSA) and population EPSP slope were used to assess the magnitude and duration of LTP obtained from each age group. At 15 days of age, significant potentiation of both EPSP slope and PSA measures was obtained 15 min. after tetanization. This enhancement was maintained without significant change over the first 24 hrs. post-tetanization, after which these measures rose steadily during the 5 day recording period. To determine what percentage of this rise resulted from tetanization and what percentage resulted from normal development, input/output curves were recorded daily from non-tetanized pups as they matured from PND 16-29. Subtraction of developmental increases indicated that tetanization effects decayed to baseline between days 4 and 5 post-tetanization. At both 30 and 90 days of age, significant enhancement of both EPSP slope and PSA measures was obtained 15 min. after tetanization. These levels were significantly below those obtained from 15 day olds and were maintained without significant change for only 3-5 hrs., decaying to baseline within 24 hrs. Results indicate that LTP of both the EPSP slope and PSA can be reliably established in 15-day-old rats, and that both the magnitude and duration of this LTP is significantly greater than that obtained from juveniles or adults. The immature functional status of GABAergic interneuronal synaptic contacts with the granule cell population is hypothesized as a possible mechanism underlying both the greater magnitude and longer duration of LTP obtained from 15 day old animals. MOSSY FIBER LONG-TERM POTENTIATION IN CONSCIOUS, FREELY MOVING ANIMALS: TIME COURSE AND INDUCTION PARAMETERS. E.J. Barra-Rodriquez, E.B. Derrick and J.L. Martinez, Jr. Department of Psychology, University of California, Berkeley, CA 94720.

Previously we reported that in the anesthetized animal, mossy fiber long-term potentiation (MF-LTP) is frequency dependent (J. Neurosci., in press), because a minimum of 30 pulses at 100 Hz are needed to induce MF-LTP. In the present study, we investigated the stimulation parameters necessary for the induction of MF-LTP in conscious, freely moving animals with indwelling electrodes. We found that unlike the anesthetized preparation, 30 pulses at 100 Hz did not induce MF-LTP but that seizures were induced. By contrast, when the animals were placed in a novel environment, the administration of two 100 Hz trains induced MF-LTP, without the occurrence of seizures. This potentiation decayed within 24 hrs. We propose that the physiological mechanisms associated with hippocampal theta activity which are present in novel environment, prevent the occurrence of seizures and facilitate the induction of MF-LTP.

Evidence that neural activity may cause the formation of synapses in the adult brain has come from studies of limbic seizures and kindling in the rat hippocampus (TINS 13: 312-318, 1990; J. of Neurosci. 9: 2795-2803, 1991). It has been shown that long term potentiation (LTP) of mossy fiber responses in area CA3 of the rat hippocampus constitutes an opioid receptor-dependent form of hippocampal synaptic plasticity (Brain Res. Bull., 27: 219-223, 1991). In the present study, Timm sulfide silver technique was used to examine whether LTP of mossy fiber-CA3 synapses affects structural reorganization and synaptic formation in the adult rat hippocampus in vivo. Our results show that seven days after LTP induction, a prominent band of Timm's staining is present bilaterally in the infrapyramidal band but in more prominent in the contralateral CA3 (stratum oriens). In addition, we found that naloxone (an opioid receptor antagonist) reverses this effect. Stimulation induced increases in Timm's staining, not associated with LTP, was also evident. The increase in Timm's staining which we interpret to be synaptic reorganization, becomes apparent as soon as 1 hour after the LTP induction and is quite pronounced after 7 days. These results indicate that synapses are formed in response to neural activity associated with LTP thus, experience-dependent information storage could involve local, activity-dependent synaptogenesis.

552.1 IDENTIFICATION OF A NOVEL G-PROTEIN COUPLED RECEPTOR IN THE VENTRAL TEGUMENTUM BY PCR. M.L. Charlton* and R.S. Duman. Laboratory of Molecular Psychiatry, Deps. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06520.

We previously described the PCR-based identification of cDNA fragments encoding novel G protein-coupled receptors in the rat brain (Soc. Neuro. 19 Abstract #334). PCR of cDNA derived from the ventral tegmentum with degenerate primers to the third and sixth transmembrane domains (Liberti et al., Science 244:599, 1989) resulted in the amplification of several previously identified (e.g. beta-adrenergic, dopamine D2, neuropeptide K) as well as several novel PCR clones. One of these clones, VT-15, was chosen for further study. Sequence analysis revealed that this cDNA fragment is most homologous at the nucleotide and amino acid levels to the bombesin receptor (approximately 40%). Northern blot analysis of rat spleen RNA detected a single major RNA species of approximately 2.0 kb in length. In situ hybridization of rat spleen RNA detected a single major RNA species of approximately 2.0 kb in length. The relative abundance of this clone was determined by ribonuclease protection assay: levels of VT-15 mRNA were highest in the spleen, lung, heart, and liver with lower levels in the thalamus, pons, frontal cortex and hippocampus. In addition, VT-15 mRNA was also detected in neuroblastoma (focus coeruleus-like) and hematopoietic (HL-60) cell lines. The cellular distribution pattern of this clone is being determined by in situ hybridization. We are currently in the process of isolating a full length clone encompassing VT-15 to a rat spleen cDNA library. Further study will include characterizing the ligand specificity, pharmacology, and regulatory properties of the receptor.

552.3 MOLECULAR CLONING OF A NOVEL CANDIDATE G PROTEIN COUPLED RECEPTOR FROM RAT BRAIN. Z. H. Song, W. S. Young, M. J. Brownstein and T. L. Bonner. Lab. of Cell Biology, NIH, NIH, Bethesda, MD 20892.

To clone novel G protein-coupled receptors, degenerate primers designed from the regions conserved between SKR6 (a cannabinoid receptor) and other G protein-coupled receptors (GPCR) were used. The resulting contigs were digested with restriction enzymes selected to initiate cloning from other receptors, were used to amplify the DNA prepared from a rat cerebral cortex cDNA library. cRNA, one of the clones generated by PCR, had amino acid sequences that are typical of G protein-coupled receptors. Using a radiolabeled PCR fragment of cRNA as a probe, a full-length cDNA was isolated from the rat cerebral cortex library. This 1.8 kb full-length cDNA of cRNA was shown to encode a 1086 base pair open reading frame, encoding 363 amino acid residues. Sequence analysis demonstrated that cRNA possesses a number of structural characteristics of rhodopsin-like G protein-coupled membrane receptors, including seven putative hydrophobic transmembrane domains and six connecting loops. Comparing the sequence of cRNA with other G protein-coupled receptors revealed that cRNA is similar to GPCR1 and GPCR81 (61% amino acid identity in transmembrane region one through carboxy-terminal), two other published orphan G protein-coupled receptors. Therefore, cRNA, together with GPCR1 and GPCR81, may belong to a novel G protein-coupled receptor subfamily with identical or closely related endogenous ligand. Northern and in situ hybridization experiments demonstrated that cRNA mRNA is present in the rat brain, with particularly high levels of expression in striatum and retinopetal cerebral cortex. The precise physiological role of cRNA awaits elucidation of its ligand and signal transduction pathways.

552.5 CHARACTERIZATION OF THE RAT CEREBELLAR ENDOCYTHERING ETG RECEPTOR USING THE NOVEL ANTAGONIST [125I]BQ23020. M.F. Jarvis*, A.A. Assaf and E.G. Martin, Rhone-Poulenc Rorer Central Research, Collegeville, PA 19426.

The complex binding of radiolabeled endothelins isopeptides (ET-1, ET-2, ET-3) in rat brain of multiple affinity subtypes of the ETG receptor. Vasodilation has been associated with an interaction with a "super high affinity" ET receptor subtype whereas vasoconstriction is mediated via a subsequent "high affinity" receptor subtype. Recently, a low peptide fragment of ETA, N-acetyl-[Ala11,12]-ET-1(6-21) (BQ23020) has been identified as a potent and ETG-selective antagonist. The present studies were conducted in order to characterize the [125I]BQ23020 binding to the ETG receptor in rat cerebellum. [125I]BQ23020 (0.1 nm) bound with high specificity (90% of total) and selectively for the ETG receptor. ETA, ET-2, and ET-3 inhibited 0.1 nm [125I]BQ23020 binding with equivalent affinity (Ki values = 55 - 119 pm). The sarafotoxin S6a, S6b also potently inhibited [125I]BQ23020 binding (Ki values = 55 - 2000 pm). The ETG selectivity antagonist, BQ123 [10 μM] did not significantly inhibit [125I]BQ23020 binding. The selective ETG neuronal cDNA library studies indicated [125I]BQ23020 bound a single class of recognition sites with very high affinity (Kd = 31 pm) and limited capacity (Bmax = 570 fmol/mg protein). High affinity 0.1 μM[125I]BQ23020 binding in the cerebellum includes a broad spectrum of guanine nucleotides. ET-1 was found to produce a biphasic inhibition curve in competing for 0.5 nm[125I]BQ23020. This ET-1 inhibition curve was made monophasic by the addition of 1 μm the selective ETG receptor agonists. The present study indicates that ETG nervous system affinity and nucleotide sensitivity of [125I]BQ23020 binding suggests that the different functional consequences of ETG agonist activation may be mediated by different affinity states of the receptor.
PHARMACOLOGICAL CHARACTERIZATION OF RAT AND HUMAN CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS EXPRESSED IN STABLE CELL LINES

D.E. Grigorieva, C.W. Liaw, T. Oltersdorf and E.B. De Sousa
Neurocrine Biosciences, Inc., San Diego, CA 92121.

Over the past decade, considerable evidence has accumulated from both laboratory and clinical studies implicating corticotropin-releasing factor (CRF) as a physiological mediator of stress responses or stress-induced disorders. Recently, using an expression cloning approach, two CRF receptors (CRF1 and CRF2) were isolated from a human ACTH-secreting pituitary adenoma. Full length human and CRF receptor cDNAs were subcloned in the mammalian expression plasmid pCDM-7 containing the human cytomegalovirus (CMV) promoter or a modified version of pCDM-7 in which the CMV promoter was replaced with the RSV promoter. These constructs were co-transfected with pSV2neo into two different cell backgrounds, COS-7 and Ltk-, which do not normally express CRF receptors, using the calcium phosphate precipitation method resulting in the generation of stable cell lines. CRF receptors expressed in these cell lines demonstrated saturable, stable, high-affinity binding to CRF with the pharmacological and functional characteristics comparable to those found in a variety of animal or human tissues. (125)I-CRF bound to a single population of binding sites in Ltk- cells transfected with human and rat CRF receptors with apparent affinities (Kd) of 130 and 168 pM and receptor densities of 97 and 588 fmol/mg protein respectively. The pharmacological rank order of potencies of CRF and related peptides was identical to the established profile for the CRF receptor in the rat frontal cortex. In addition, CRF receptors transfected into these cell lines were coupled to a guanine nucleotide binding protein and when incubated with Ca(2+) could stimulate the production of cAMP from these cells with an EC50 of approximately 1 nM. Furthermore, CRF-stimulated cAMP production could be inhibited by specific and selective antagonists to the CRF receptor. The stable expression of CRF receptors in clonal cell lines represents an unique opportunity for the discovery of non-peptide agonists or antagonists to the human CRF receptor for the possible treatment of CRF-mediated disorders.

Neurocrine Biosciences, Inc., San Diego, CA 92121.

Corticotropic releasing factor (CRF), a 41-amino acid peptide, plays a significant role in integrating the stress-related and inflammatory responses to immune challenges such as viruses, bacteria, or tumor cells through its coordinated actions in the nervous, endocrine and immune systems. In addition to its effects on the hypothalamic-pituitary-adrenal (HPA) axis, CRF has recently been reported to regulate inflammatory responses. In this study, we have demonstrated that CRF has been described to enhance pro-inflammatory cytokine production. In vivo, anti-CRF antibody treatment was shown to lessen the recruitment of cells to an inflammatory site. In an effort to better understand the mechanism(s) of action whereby CRF may be involved in inflammation, CRF-receptor binding studies were carried out on immune cell populations. Specific, saturable high affinity binding of CRF to human peripheral blood mononuclear cells and monocyte lines using RT-PCR. Given that peripheral mononuclear cells express CRF receptors, further studies are underway to determine which immune cell populations express CRF receptors, and whether these receptors are modulated during an immune response, and if so, is receptor modulation due to pro-inflammatory cytokine production? These studies are likely to further our understanding of the role of CRF in inflammation.

EVIDENCE OF FUNCTIONAL GROWTH HORMONE-RELEASING FACTOR RECEPTORS IN RAT HYPOTHALAMUS. J. Boulanger* and P. Gaudreau
Neuroendocrinology Laboratory, Notre-Dame Hospital Research Center and University of Montreal, Montreal, Canada, H2L 4M1.

Recent reports suggest the existence of GRF receptors mediating endocrine and behavioral actions of this peptide, in the hypothalamus. Our goals were to characterize GRF binding sites in hypothalamic homogenates and to determine if this binding leads, as in the anterior pituitary, to the stimulation of adenylate cyclase (AC) activity. In our assay conditions (Tris buffer pH 7.4 containing MgCl2, EDTA, sucrose, dipotrite and BSA, 200 µg protein, 1 h, 4°C), 125I-GRF(1-44)NH2 was stable and specific binding represented 40-50% of the total binding. This binding was temperature and time-dependent, reversible and saturable. The affinity was hGRF(1-29)NH2 > NeAc-[his6-D-Arg9] > [Ala1] = [Ala1] = VIP and PACAP were inactive at all concentrations. In our AC assays containing [3H]cAMP, GRF(1-29)NH2 elicited a concentration-dependent production of cAMP. Although the efficacy of GRF was much lower in the hypothalamus than in the pituitary, its potency was not different in both tissues (EC50, NeAc-[his6-D-Arg9]>GRF(1-29)NH2 did not stimulate AC activity, but substantially inhibited the response to GRF(1-29)NH2). Although these results suggest the existence of functional hypothalamic GRF receptors, they still have to be localized to establish their involvement in the regulation of GRF secretion and control of appetite.

CELLULAR UPTAKE OF INTRACEREBROVENTRICULARLY INJECTED ANTISENSE OLGODEOXYNUCLEOTIDES INTERNALLY LABELLED WITH BODION OR DIGOXIGENIN. Y. Yue, H. Ericson, D.J. Reis and C. Wahlstedt, Div. of Neurobiol., Dept. of Neurol. & Neurosci., Cornell University Medical College, New York, NY 10021.

Recently, we have demonstrated that intracerebroventricular (i.c.v.) administration of antisense oligodeoxynucleotides (ODNs) specific for the rat neuropeptide Y (NPY)-Y1 receptor and N-methyl-D-aspartate (NMDA)-R1 receptor subunit resulted in the inhibition of the respective binding in rats (Wahlstedt et al., Science, 259:528, 1993; Wahlstedt et al., Nature, 365:260, 1993). In addition, treatment with the NPY-Y1 antisense ODNs was shown to produce anxiolytic-like effects in the NMDA-R1 antisense ODNs reduced focal icischemic infarctions in rats. In contrast, the intracerebroventricular (i.c.v.) administration of antisense oligodeoxynucleotides (ODNs) specific for the rat neuropeptide Y (NPY)-Y1 receptor and N-methyl-D-aspartate (NMDA)-R1 receptor subunit resulted in the inhibition of the respective binding in rats (Wahlstedt et al., Science, 259:528, 1993; Wahlstedt et al., Nature, 365:260, 1993). In addition, treatment with the NPY-Y1 antisense ODNs was shown to produce anxiolytic-like effects in the NMDA-R1 antisense ODNs reduced focal icischemic infarctions in rats. In contrast, the intracerebroventricular (i.c.v.) administration of antisense oligodeoxynucleotides (ODNs) specific for the rat neuropeptide Y (NPY)-Y1 receptor and N-methyl-D-aspartate (NMDA)-R1 receptor subunit resulted in the inhibition of the respective binding in rats (Wahlstedt et al., Science, 259:528, 1993; Wahlstedt et al., Nature, 365:260, 1993). In addition, treatment with the NPY-Y1 antisense ODNs was shown to produce anxiolytic-like effects in the NMDA-R1 antisense ODNs reduced focal icischemic infarctions in rats. The stability of the injected antisense ODNs was examined by performing recovery experiments and by examining the potential for degradation of the oligonucleotide to antigenic response in rat brain extracts.

EXPRESSION OF PITUITARY ADENYLATE CYCLASE ACTIVATING POLYPEPTIDE RECEPTOR SUBTYPES IN SUPERIOR CERVELAL GANGLION NEURONS. K. M. Brass* and V. May, Dept. of Anatomy & Neurobiology, Univ. of Vermont Coll. of Medicine, Burlington, VT 05405.

Pituitary adenylate cyclase activating polypeptides (PACAP) belong to the vasointestinal polypeptide (VIP)/secretin/glucacon family of bioactive peptides. The PACAP type I receptor is specific for PACAP, while the type II receptor is specific for PACAP and VIP. Splice variants of the type I PACAP receptor differentially stimulate adenylyl cyclase and phospholipase C. The PACAP peptides exerted potent regulation of superior cervical ganglion (SCG) neurons (y(NPY) and cAMP) in a dose-dependent manner. PACAP-induced sustained secretion of NPY and CA from cultured rat SCG neurons; neurosecretory responses to PACAP were approximately 100-fold more potent than VIP. To identify the population of responsive SCG neuron binding was determined using biotinylated PACAP38. Over 60% of the SCG neurons were labeled and may be responsive to PACAP regulation. To distinguish the expression of type I PACAP receptor isoforms, the presence or absence of either one or two 84 bp cassettes was examined using reverse transcription and polymerase chain reaction (RT-PCR) with mRNAm from fetal, neonatal, adult and cultured SCG cells. The predominant molecular form of PACAP receptor mRNA identified by RT-PCR contained one 84 bp cassette; further hybridization studies are necessary to identify the specific insert. No PCR products were observed using primers specific for the VIP (type II) receptor. These studies demonstrate that SCG neurons express specific type I PACAP receptor mRNA, bind PACAP and respond to PACAP stimulation. Supported by HD-27468.

Adrenomedullin (AM), a 52 amino acid peptide, has been recently discovered from human pheochromocytoma which has a hypertensive effect via an elevation in blood pressure. AM is located in various tissues other than pheochromocytoma such as brain, lung, kidney and structurally homologous to the calcitonin gene-related peptide (CGRP) and amylin. The peptides known to exert its effects via increasing cAMP is knowndiffusely, however, for the receptors for AM. We have reported that the protein encoded by the cystic fibrosis transmembrane conductance regulator gene (CFTR), the Cl- channel activated by A kinase, can be used as a sensitive receptor for cAMP changes in Xenopus oocytes (Receptor and Channels 1:235 (1993)). In the present study to see whether brain expresses the AM receptor, we injected cDNA for the CFTR along with poly(A)+ RNA from rat brain into oocytes. Three days after injection, rat AM resulted in a concentration-dependent increase in Cl- current via CFTR channels with the maximal response at 10^{-6} M. In the same oocyte, both CGRP and amylin 10^{-7} M also caused CFTR currents. The potencies for the CFTR currents of the three peptides were CGRP > AM >> amylin. The present results suggest this is a novel method for functional expression cloning of the receptors; although it is not known whether all these receptors have their own receptors or share several types of common receptors.

TRANSIENT CEREBRAL ISCHEMIA INDUCES OVEREXPRESSION OF OXYTOCIN RECEPTORS IN THE GERIL HIPPOCAMPUS. M. Dubois-Dauphin*, C. Brureau, and P. Valtier, Dept. of Physiology, University Medical Center, 1211 Geneva, Dept. of Psychiatry, Div. of Morphology, 1205 Geneva, Switzerland.

Using an iodinated oxytocin (OT) antagonist and light microscopy autoradiography, oxytocin receptors were detected in the brain of adult male gerbil following transient cerebral ischemia (6 min). Either immediately or 30, 100, 240 and 300 min after reperfusion and 24 h after ischemia, oxytocin receptors were detected in the CA1 and CA3 pyramidal regions in many brain areas. However, on the second or third day after ischemia, oxytocin receptor binding was increased in all brain areas. The increase in CA1 and CA3 pyramidal regions in many brain areas was followed by a decrease in the number of oxytocin receptors in the CA1 and CA3 regions after 72 h. These results suggest that transient cerebral ischemia induces the overexpression of oxytocin receptors in the hippocampus. The mechanism of oxytocin receptor expression after ischemia is under investigation.

Brain OTRs have been implicated in a variety of behaviors, e.g. sexual and parental. Previous characterization of peripheral OTRs has suggested diverse binding properties of OTRs in different tissues. Little is known, however, about the functional properties of rat brain OTRs. In the present studies, the pharmacological profile of rat brain OTRs was assessed. Brains from 10-day-old rats were homogenized and the membrane with the radioligand 125I-ori-motrine vasotocin ([125]OT) saturation studies with Scatchard analysis determined the density and affinity of brain [125]OT-OTVA binding sites (Bmax = 24 fmol/mg protein; Kd = 50 pm). The specificity of binding was confirmed by competition with unlabelled OT (Kd = 2.01 ± 0.08 nm, n = 5). The rank order potency of brain OTR agonist binding was OT > APV > thrpGly6-ot (n = 3). OT binding was best fit with a two-site model, with approximately 50% high affinity sites (Kd = 2.12 ± 0.42 pm, Bmax = 11.1 ± 2.1 fmol/mg protein) and approximately 50% low affinity sites (Kd = 10.80.0 mg protein). Preliminary studies using nonhydrolyzable analogs of GTP, GTPγS, resulted in monophasic OT binding with the low affinity component, which indicates that brain OTRs, like their peripheral counterparts, are coupled with G-proteins. *Supported by NS23986 and MIA43787.

CORTICOTROPIN-RELEASING FACTOR (CRF) INCREASES HIGH-VOLTAGE ACTIVATED (HVA) CALCIUM CURRENTS IN ACutely DISASSOCIATED NEURONS OF THE CENTRAL AMYGDALA (CeA). B. Yu* and P. Shamrock-Gallagher. Dept. of Pharmacology & Toxicology, Univ. of Texas Medical Branch, Galveston, TX 77555.

Slices of the CeA mediate stress responses in the brain. We tested CRF on calcium currents in CeA neurons. When held at 80 mV, HVA currents peaked at +10 mV and averaged 289±17 nA/pF (n=18). Intracellular loading of 26Ca with Fura-2,3-AM (IC 50≈5.6% of 2Ca current) did not reduce HVA currents. Moreover, over 80% of CeA neurons possessed L-type HVA currents. Δ,CTX SV5 (1-2 μM) inhibited 24%±6% of the peak I_{Ca,L}, indicating the presence of voltage-gated L-currents. Δ,CTX MVIC (200 μM) inhibited 30%±4% of the peak I_{Ca,L}, suggesting the presence of Q-type currents. No P-type current was recorded since Δ,Agateoxin (100-200 nM) did not reduce I_{Ca,L}. These data suggest that the HVA calcium currents of CeA neurons are comprised of N, L, and Q but not P-type of calcium currents. CRF (1-400 nM) enhanced HVA calcium currents in approximately 50% CeA neurons recorded. However, in the remaining neurons, CRF had no effect. CRF enhanced both peak and steady state HVA calcium currents. CRF (50 nM) increased the peak HVA-2.5 μA/cm² (n=6). No shift was observed in the peak of the current-voltage relationship. The current-increase in HVA calcium currents is consistent with CRF antagonist ability to inhibit CeA neuron receptor antagonists, which antagonize the GABAergic transmission. These data suggest that CRF enhances calcium currents through a receptor mechanism and could thereby facilitate neuronal communication through CeA neurons during the stress response. 555.4

We previously showed that IC CRF (21 and 63 pmol) decreased GVED by 17.4 and 24.0% respectively in rats. Urethane induced an increase of hypothalamic CRF transcripts and secretion and low basal activity of GVED. Thus, to assess the influence of the new CRF antagonist, [DPhe^2,Leu^5,6-Cr(CrEt)Leu^7,10]-CRF_{29-41} given IC on GVED in urethane-anesthetized rats. Male Sprague-Dawley rats (280-320 g) were injected with urethane (1.5 g/kg i.p.) and implanted with a catheter into the cisterna magna for IC[15] a i.a. injection. A strain of the ventral gastric branch of the vagus was cut distally to record multi-unit efferent discharge. Nerve signals were sent to a window discriminator and counted on computer. Maximum 1 min peaks from basal GVED were calculated and expressed as Mean±SEM peaks from baseline. 10 IC injections of CRF (15 μl) did not change CRF antagonist, 5/[Cr(CrEt)Leu^7,10]-CRF_{29-41} (25 μg/s) over 15-30 sec were performed at 10-15 min intervals and thereafter CRF was injected IC. Recall 1 IC vehicle (n=11) had no significant effect on basal GVED (101±6 μl, 4.8±0.05 μl/min). Maximum 1 min peak from CRF antagonist was obtained at 24.5±3.8% 3 min after injection. The excitatory response peaked within 1±2 min (3.8±0.2 min). In contrast, a maximum 1 min peak from vehicle was obtained at 30.0±3.3% 1 min after injection. 24.4±1.0 μl/min after injection. These results suggest that the new CRF antagonist is effective in GVED, while the injection of CRF (63 pmol/rat) at 15±1 min after the CRF antagonist produced a significant inhibition of GVED by 82.2±5.4% (n=6). Conclusions: These results suggest that the new CRF antagonist may be of potential interest in the treatment of functional and organic dysfunctions of the efferent gastric motor nerve pathways. SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

THURSDAY AM PEPTIDE RECEPTOR STRUCTURE AND FUNCTION IV

555.19

PEPTIDE AND CORTICOTROPIC RELEASING HORMONE mRNA EXPRESSION IN COLD STRESSED RATS. S. Makio1, K. Fukuhara2, M. A. Smith3, and P. W. Gold1. Clinical Neuroendocrinology Branch,1 Biological Psychiatry Branch,2 NHIM; Clinical Neuroscience Branch2; NINS; National Institutes of Health, Bethesda, MD 20892.

Exposure to cold is a potent stimulus of the hypothalmo-pituitary-thyroid axis. However, the role of CRF and related peptides in cold stress has not been established. To address these issues, we exposed rats to cold (3°C) continuously for 0.5, 1, 3, 6, 24 hours and 5 days, and examined CRH mRNA expression in the paraventricular nucleus (PVN), central nucleus of the amygdala (CeA) and bed nucleus of the stria terminals (BNST) by using in situ hybridization histochemistry. Plasma levels of corticosterone increased transiently at 0.5 h, then returned to normal by 1 h. CRH mRNA in the PVN and POMC mRNA in the anterior pituitary did not change up to 5 days. This indicates that cold stress may transiently induce CRH or ACTH secretion, but may not be enough to stimulate CRH or ACTH synthesis. By contrast, CRH mRNA in the CEA and dorso-medial division of the BNST decreased at 6 and 24 hours exposure to cold (maximally by 25% and 45% at 24 h) compared to control in the CEA and BNST, respectively. These data suggest that (1) cold is a mild stressor, if any, of the HPA axis, (2) but that cold stress can modulate extra-hypothalamic CRH.
553.5 SOMATOSTATIN EFFECT ON GUINEA-PIG DORSAL THALAMIC NEURONS IN VITRO. B. Rat* and R. Limas, Dept. of Physiology & Biophysics, New York University Medical Center, 550 First Avenue, New York, NY 10016.

Somatic and voltage-evoked electroresponsiveness were examined using sharp microelectrode intracellular recordings in dorsal thalamic neurons in guinea-pig slices. A few minutes following bath application of 2 μM somatostatin superfusion, a characteristic increase in low-threshold calcium spike activity was noticed in specific thalamic nuclei. The results could be observed, at the spontaneous-electrical-activity level, as a marked tendency towards intrinsic oscillation, often occurring from a membrane potential similar to the initial non-oscillating level, where low-threshold activity was only observed after membrane hyperpolarization in the order of 5 to 10 mV. In other cases the increase of oscillatory activity would occur on depolarizations or hyperpolarizations of a few millivolts from the initial resting-potential level. The results suggest that such changes in the resting level of the cell, which are either too small, or in the wrong direction, to affect directly the level of voltage-dependent inactivation of the Type-I calcium channels responsible for such low-threshold activity were not the decisive factor affecting the excitability changes.

Similar results were obtained by using neuronal excitability directly, via transmembrane current pulses to evoke different firing potentials. In somastostatin, the voltage dependence for low-threshold calcium-spiking induction was found to decrease by close to 30% with reference to the normal voltage level at which low-threshold spikes are generated. The results suggest that the level at which low-threshold calcium spikes is triggered in thalamic neurons may be regulated by means other than transmembrane voltage. Somatostatin did not affect all thalamic neurons, moreover cells that responded were localized in a group probably related to somatostatin innervations.

The results indicate that neuropeptides may exercise regulation of intrinsic membrane properties onto well-defined sets of thalamic nuclei without affecting others, and so, may modulate global brain activity by acting on the thalamocortical system in a manner different from that generated by conventional synaptic input.

NIH NS31374.

553.7 EFFECTS OF CYSTEAMINE ON REGIONAL CHOLINE ACETYLTRANSFERASE ACTIVITY IN RATS. K. Koku, H. Kanda, Y. Komurasaki, K. Saka*, and K. Makeda, Dept. of Psychiatry, Kobe Univ. Sch. of Med., Kobe, Japan.

It is well known that somatostatin (SS), one of brain neuropeptides, is decreased in cerebrospinal fluid or postmortem brain with Alzheimer's disease. Dysfunction of cholinergic neurons in Alzheimer's disease is also reported. The relation between SS and cholinergic system is not obvious yet in Alzheimer's disease. In this study, we investigated the effects of cysteamine, which depleted brain SS contents, on regional choline acetyltransferase (CAT) activity in rats.

Male Wistar rats (300-350 g) were used. Cysteamine was dissolved in saline and adjusted to pH 7.4. 150-300 mg/kg cysteamine and saline for controls were injected intraperitoneally (i.p). Four hours later, rats were decapitated and the brains were dissected into the olfactory bulb (OB), anterior cortex (Ac), temporal cortex (Tc), parietal cortex (Pc), hippocampus (Hi) and striatum (St) with Glower's method. SS and neuropeptide Y (NPY) contents of each region were measured by radioimunossay and CAT activity by Fouassier's method. Statistical analysis was performed by Student's t-test.

As a result, SS contents in the hippocampus were only decreased significantly (20% of mean of saline was 33.8 ± 1.6; 29.7 ± 1.2, 18.4 ± 2.4 % at 90, 150, 300 mg/kg, p < 0.05). However, NPY contents and CAT activity did not have any changes in any region.

Our results suggest that cysteamine may not have effects on CAT activity directly in the brain regions and the decrease of hippocampal SS contents may not, too.

553.9 DOPAMINE-INDUCED INHIBITION IS ATTENUATED BY IONTOPHORESICALLY APPLIED NEUROTENSIN IN THE NUCLEUS ACCUMBENS OF RATS - IV VIVO STUDY. Z. Z. Sternow*, J. C. Landers, Z. I. Tang, and C. B. Nemeth*. Laboratory of Neuropsychopharmacology, Dept. of Psychiatry and Beh. Sciences, Emory Univ. Sch. of Medicine, Atlanta, GA 30322.

Neurotensin (NT), an enogenous tridecapeptide, possesses a pharmacological profile that is similar to antipsychotic drugs. Previous electrochemical data suggest that both direct and intracerebroventricular (ICV) application of NT produces predominantly excitatory responses in dopamine (DA) neurones in the ventral tegmental area (VTA). The administration of NT consistently antagonized DA-induced inhibition in the VTA. In contrast, McCarthy et al. (Gen Pharmacol. 10 333-337,1979) found that intracerebroventricular application of NT (10 μg) had no effect on the firing rate of DA-sensitive neurones in the nucleus accumbens (NA).

The effects of iontophoresically applied NT on DA-induced inhibition in individual neurones in the NA were examined. Extracellular neuronal recordings were obtained from spontaneously active neurones in the NA in chloral hydrate anesthetized (400 mg/kg, i.p) male rats (250-350 g). DA sensitivity was confirmed via iontophoretic application of the racemate (25-35 μg) of DA (0.1M, pH 4.8). A total of 12 neurones were included in the data analysis [percent change = ΔTS + DR (VTA)]. Direct iontophoresis (25-40 μA) of NT (0.5 μM, pH 4.8) did not produce any significant alteration in firing rates (μA) [percent change = 0.46±0.17%. However, direct application of NT antagonized DA-induced inhibition in all neurones tested (μA).

These findings provide electrophysiological evidence that NT antagonizes the effects of DA in the NA. These findings support the hypothesis that NT receptor agonists may prove to be useful adjuvants in the treatment of psychosis, particularly related to excessive mesolimbic DA tone. 553.6 SOMATOSTATIN (SS) EFFECTS ON CYTOSOLIC CALCIUM CONCENTRATION ([Ca²⁺]) IN PC12 CELLS. G. Traina, S. Cannistraro and P. Bagnoli*, Dept. of Environmental Sciences, Tuscia University, 01100 Viterbo and Dept. of Physiology and Biochemistry, University of Pisa, 56123 Pisa, Italy.

Recent findings suggest that, among neuropeptides, SS plays an important role in the modulation of neuronal cell functional activity. The control of [Ca²⁺], has long been recognized as a fundamental mechanism of cell activation. In the present study, the effects of SS on [Ca²⁺], have been studied by conventional fluorescence in PC12 cells loaded with Fluo-2 in the presence of 2μM Ca²⁺. In all the experiments, the application of either Ca²⁺ ionophores or high K⁺ concentration has been used to increase the [Ca²⁺]. Our results can be summarized as follows: i) the application of the tetradecapeptide form of SS, SS-14 (10⁻⁷-10⁻⁹M), induces a dose-dependent decrease of [Ca²⁺]; ii) similar effects are induced by the application of SS analogs (SMS 201-995; D-Trp,D-Cys-SS; D-Trp-SS; MK 678; CGP 29396); iii) pretreatment with a SS antagonist (Cyclo-SS) prevents the effects of SS-14 application. These observations suggest that SS may modulate nerve cell functional activity by a specific inhibition of Ca²⁺ channels. In addition, experiments with selective blockers of different voltage-dependent Ca²⁺ channels (D 600, ß-conotoxin, GVIA, nitrendipine, nifedipine) suggest that this inhibition is mediated by Ca²⁺-channels of the L-type.

553.8 SELECTIVE EFFECTS OF NEUROTENSIN IN THE PFRONTAL CORTEX FOLLOWING DOPAMINERGIC STIMULATION IN THE NUCLEUS ACCUMBENS. D. Mora* A. Drumheller and F. B. Jolisseur Departments of Pharmacology and Physiology, Faculty of Medicine, Univ. of Sherbrooke, Sherbrooke, Quebec, Canada. J1H 5N4.

Neurotensin has been shown to markedly reduce the behavioral hyperactivity which appears 2 hr after intra-accumbens administration of the potent dopamine receptor agonist, 2-amino-6,7-dihydroxy-1,2,3,4-tetrahydro- 

neurotensin [ADTN] (Jolisseur et al., Neuropeptides 6:143, 1985). In order to better characterize this finding, the effects of bilateral intra-accumbens administration of ADTN (2.5ug) on concentrations of neopyrinine (NE) and its metabolites DOPAC and HVA, serotonin (5-HT) and its metabolite 5-HIAA were examined in terminal regions of dopaminergic fibers, including prefrontal cortex, amygdala, septum, globus pallidus, striatum and the nucleus accumbens itself. Following ADTN administration, chemical changes were assessed at 2 hr, when animals displayed a marked hyperactivity. Results indicate that in-vivo administration of ADTN results, 2 hr later in significant decreases in concentrations of NE, DA, DOPAC and HVA as well as of 5-HT and 5-HIAA in all areas. In a follow-up experiment, neurotensin (3.5ug) was injected intracerebrally 20 min prior to the neurochemical determinations performed at 2 hr after intra-accumbens administration of ADTN. Except for the prefrontal cortex, neurotensin accentuated the observed neurochemical changes in all regions. In the prefrontal cortex, neurotensin also further reduced concentrations of NE, 5-HT and 5-HIAA; however, the peptide systematically reversed the decreases in DA, DOPAC and HVA produced by ADTN in this region. These findings suggest that: a) dopaminergic stimulation in the accumbens results in widespread and enduring neurochemical changes; and b) neurotensin appears to have a selective neurochemical action in the prefrontal cortex in these circumstances.
553.11 NEUROTENSIN REVERSES LOCOMOTOR INHIBITION PRODUCED BY MICROINJECTION OF DOPAMINE INTO THE MEDIAL PREFRONTAL CORTEX: R. A. Radulovic and Y. E. Raina. School of Pharmacy, University of Colorado Health Sciences Center, Denver, CO 80262.

It has been postulated that increased dopamine (DA) activity in the medial prefrontal cortex (mPFC) exerts an inhibitory influence over DA release in the nucleus accumbens leading to a reduction in locomotor activity. In addition, it has been demonstrated that neurotensin (NT) modulates DA-stimulated cell activity in the mPFC (Beauchamp, M. et al., Neurosci. Lett., 473:613-619, 1992). Thus, experiments were designed to test two hypotheses: 1) that an increased density of mPFC DA autoreceptors and 2) that NT modulates DA-influenced locomotor activity in the mPFC. Bilateral cannulae guides were implanted into the mPFC in pentobarbital/chloral hydrate anesthetized LHDU mice. Open field behavior was monitored in 5 minute blocks for a total of 30 minutes 24 hours post surgery in an automated open field apparatus (Omnitech). The distance traveled within the first 15 minutes after injection of drug was monitored for analysis. The injection naive to the apparatus, were injected bilaterally with either GBR-12909, a selective DA uptake blocker, neurotensin, or a combination of the drugs. Drugs were delivered at a volume of 100 nl per side over a 30 second period and were prepared in normal saline. GBR-12909, in doses ranging from 30 ng to 1 umol per side, produced a U-shaped dose response curve. A maximum inhibition of 49% of saline-injected control values was observed at a dose of 3 ng. The highest dose tested of GBR-12909 (1 umol) caused the animals to become significantly activated to 129% of control values. Higher doses of GBR-12909 could not be tested owing to the insolvibility of the drug at higher concentrations. Doses of NT from 0.01 umol to 1 umol were tested and found to have no dose-related effect on locomotor activity. NT, when co-injected with 3 pgms GBR-12909, dose-dependently reversed the inhibitory effect of GBR-12909. A dose of 3 pgms NT completely abolished the locomotor inhibition produced by GBR-12909. In conclusion, these results are consistent with the hypothesis that the DAergic system of the mPFC regulates locomotor activity. Furthermore, these results suggest that NT modulation of DA function in the mPFC may be implicated in the regulation of locomotor activity. (This work was supported, in part, by USPHS grants AA07097 and AA07330.)

553.13 CHOLECYSTOKININ- AND NEUROTENSIN-EVOKED CATIONIC CURRENTS IN SUBSSTANTIA NIGRA DOPAMINERGIC NEURONS ARE MEDIATED BY D1 AND D5 RECEPTORS: T. Wu and H. L. Wang. Dept. of Physiology, Chang Gung College of Medicine and Technology, Ketan-Sun, Tao-Yuan. 1 Dept. of Neurology, Chang Gung Memorial Hospital, Taipei, Taiwan 33345.

To understand the iononic and molecular mechanisms by which sulfated cholecysteinin octapeptide (CCK-8) and neurotensin (NT) modulate the electrical activity of dopamine neurons (SN DA neurons), whole cell patch-clamp recordings were used to study electrophysiological effects of CCK-8 and NT on acutely isolated SN DA neurons. Both CCK-8 and NT excite SN DA neurons via activation of nonselective cationic conductance. CCK-8 and NT-evoked inward currents were inhibited by the intracellular perfusion of GDP-beta-5 (1 mM). In DA neurons internally perfused with GTP-gamma-S (0.5 mM), the inward currents produced by CCK-8 and NT became irreversible. Pretreating DA neurons with 500 mM pertussis toxin (PTX) did not significantly affect the activity of both peptides to induce cationic currents. Intracellular application of heparin (2 mg/ml) (1.47 microM) of ligand to receptor antagonist, and buffering intracellular calcium with the Ca++-chelator BAPTA (10 mM) suppressed cationic currents evoked by CCK-8 and NT. Dialyzing DA neurons with protamine kinase (PKC) inhibitor, staurosporine and PKC9-13, failed to prevent CCK-8 and NT from generating cationic currents. It is concluded that PTX-insensitive G-proteins mediate neuropeptide-induced enhancement of cationic conduction of DA neurons. The coupling mechanism via G-proteins is likely to involve the generation of IP3 and subsequent IP3-evoked Ca++ release from the intracellular store results in activating the nonselective cationic conductance.

The C-terminal hexapeptide fragment of neurotensin (NT-8(13)) has been shown to bind to the neurotensin receptor and retain full agonist activity. Structure-activity studies on a variety of NT-8(13) mimetics resulted in the discovery of compounds which behaved as NT receptor agonist in vitro, and had a variety of behavioral effects consistent with NT agonist activity within the rodent system. NT-8(13) agonist (0.1nM-1uM) in the nucleus accumbens of the isolated perfused rat brain may have high affinity for the NT receptor found in new born mouse brain. This study was effective in inhibiting calcium mobilization (EC50 = 36mM). It's putative produg PD 149163S effectively inhibited spontaneous locomotor activity in the mouse (ED50 = 0.2 mg/kg IP) and acetic acid induced stretching (ED50 = 0.05 mg/kg IP). These effects were not reversed by naloxone or the NT antagonist SR 48692. PD 147113S was also shown to have potent systemic activity in the acetic acid induced stretching paradigm (ED50 = 0.08 mg/kg IP). These findings demonstrate systemic activity of NT agonists may have utility as antinociceptive, anesthetic or anorectic agents.

553.16 SUBSTANCE P (SP) AND THE SELECTIVE OPIOID AGONIST, DAMGO, ARE PHYSIOLOGICAL ANTAGONISTS WITHIN THE VENTRAL PALLIDUM (VP). L. Mignardi* and T. C. Nguyen. Department of Pharmacology, Loyola University Chicago, Stritch School of Medicine, Maywood, IL, 60153.

It has been demonstrated with various paradigms that SP and opioids are likely physiological antagonists (e.g., SP antagonists block behavioral symptoms of morphine withdrawal; enkephalins attenuate pain by blocking release of SP). Axons from the nucleus accumbens (NA) neurons that contain SP and enkephalin-like immunoactivity synapse on the VP neurons. Both SP and opioid receptors are found within the VP. Our previous work demonstrated that SP increases and opioids decrease firing rate of the VP neurons. To ascertain possible interactions between opioids and SP within the VP, the present study employed extracellular recording of unit activity and microinjection of DAMGO (10mM) and SP (1mM) in chloral hydrate anesthetized rats. Sixty-one VP neurons were tested with both compounds. Forty-eight percent of these were sensitive to both compounds, and 49% to SP. DAMGO microinjected into the nucleus accumbens and stratum of urethane-anaesthetized rats as measured by intracranial microdialysis (ICMD). In untreated animals, MNT 8-13 (2.5mg/kg s.c. ) produced variable changes in DA and DOPAC in both regions. However, in those animals pre-treated with pargyline (50mg/kg i.p.), DA levels increased 69% in the nucleus accumbens and 30% in the striatum, while DOPAC values remained relatively unchanged following MNT 8-13 injection. We conclude that under certain conditions, stable neurotensin analogues are able to preferentially modulate DA turnover in the mesolimbic system of rats following peripheral administration.
554.1 MODULATION OF INTRACELLULAR CALCIUM BY BRADYKININ IN N1E-115 CELLS. Jay S. Coggins* and Stuart H. Thompson. Department of Pharmacology, Division of Biological Sciences, Stanford University, Pacific Grove, CA 93950.

Murine N1E-115 neuroblastoma cells release calcium from IP3-sensitive intracellular stores in response to bradykinin (BK), but not the selective BK1 receptor agonist des-Arg9-BK. This suggests that the BK receptor type is expressed. Low concentrations (<500 pM) of BK elicited responses that are slow in onset (20-30 sec), long in duration (2-4 min) and exhibit low frequency calcium oscillations (20-50 sec periods). When N-acetyl-D-glucamine is substituted for extracellular Na in order to block NA/CA exchange, the calcium concentration in response to BK (500 pM) have shorter periods but are less profound. High concentrations of BK (1 μM) result in rapid rising calcium concentrations which smoothly decay to baseline within one minute in the continued presence of agonist. Short duration application of BK to 30 sec elicited similar calcium transients, and responses to subsequent applications exhibit marked desensitization. In the absence of extracellular calcium, the responses to bradykinin display the same characteristics. Trace averages from several cells indicate that there is no difference between responses in the presence or absence of extracellular calcium. Ca2+ influx, if any, is not associated with the release of calcium from intracellular stores in response to BK. Supported by NIH NS14519.

554.2 BRADYKININ-INDUCED OSCILLATIONS OF CYTOLIC CA2+ ACTIVITY AND MEMBRANE POTENTIAL IN RAT GLIOMA CELLS. G. Reeti and G. Reiter*. Institute of Physiological Chemistry, University of Tübingen, Hoppe-Seyler Str. 4, 72076 Tübingen, Germany.

In 2-load rat glioma cells (C6-4-2) continuously superfused with bradykinin (BK), rhythmic membrane depolarizations and calcium oscillations (50-200 Hz) were observed. The initial [Ca2+]i response to BK resulted from InsP3-induced Ca2+ release, whereas the subsequent oscillations were dependent on both InsP3-sensitive Ca2+ stores and Ca2+ influx. Simultaneous intracellular recording of the membrane potential showed that the oscillation of [Ca2+]i and of the membrane potential were synchronous. The oscillations were affected by the K+ equilibrium potential and by blocking of K+ (K5) channels. This indicates a potentiation of Ca2+ influx by membrane hyperpolarisation due to activation of K+ (K5) channels. Membrane quench experiments gave additional evidence for influx of Ca2+. We conclude that Ca2+ is periodically released from Ca2+ stores and subsequently opens K+ (K5) channels. The stores are refilled by the Ca2+-ATPase and by influx of Ca2+ across the cell membrane, augmented by membrane hyperpolarisation. The oscillations were also influenced by hypotonic and by hypertonic medium. Thus cell volume probably serves as a negative feedback regulator during the falling phase of [Ca2+]i. These experiments are discussed with respect to physiological functions of glial cells in volume regulation during ischemia or stroke.

554.3 EVIDENCE FOR A NEUROGENIC COMPONENT IN BRADYKININ BI RECEPTOR-MEDIATED PLASMA EXTRAVASATION DURING TUBERCULOSIS INFLAMMATION IN THE RAT. M.J.K. Alexander and L. Perkin*. Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6HN, U.K.

Although bradykinin (BK) receptors are not involved in the acute activation of nociceptive neurones, several studies have demonstrated that following persistent inflammation B1 receptors are induced and contribute to inflammatory pain. The present study investigates the role of these receptors in naive animals, but has been found to increase nociceptive responses following an inflammatory insult in rats. In addition to the sensitisation and activation of nociceptive afferents, kainic acid also mediates other symptoms of inflammation including oedema formation. The experiments presented here have investigated whether B1 receptors induced following inflammation also mediate plasma extravasation (PE). PE was examined in rats that had been injected with 5% dextran in a single hind paw 72 hours prior to testing, and was measured as the extravasation of 125I-BSA followed intraplantar injections of des-Arg9 BK. Des-Arg9 BK (100-300 pmol/paw) induced a significant increase in PE in both the ipsilateral and contralateral hind paws of turpentine-treated, but not naive rats. An increase in PE was observed 60 min., but not at 5 or 30 min, following des-Arg9 BK administration. This effect was reversed by the antagonist, des-Arg9 Leu8 BK. A neurogenic component of des-Arg9 BK-mediated PE was revealed by pretreating rats with capsaicin in order to deplete C-fibres. Capsaicin pretreatment reversed the B1-mediated PE, but had no effect on the baseline extravasation in controls. Inhibition of des-Arg9 BK-mediated PE by co-administration of a NK1 receptor antagonist, CP99994, suggests that B1 receptor-mediated PE involves the activation of C-fibres and the release of substance P. These results are consistent with a systemic induction of B1 receptors following local persistent inflammation. They also suggest that B1 receptor activation initiates a chain of events which ends with a neurogenic-mediated PE.

Substance P (SP) depolarizes some primary afferent neurones situated in trigeminal or dorsal root ganglia. This study represents an initial investigation of a SP-induced hyperpolarizing response to SP recorded in primary afferent neurones, those located in the nodose ganglion. In intact and in acutely dissociated neurones, 100 nM SP hyperpolarized the membrane potential by -70 ± 0.7 mV and decreased the membrane input resistance by 230 ± 110 MΩ. The hyperpolarization or outward current produced by SP was observed in 105 out of 132 cells (80%) and was dose-dependent (EC50 = 68 ± 11 nM). The SP effect was reversibly abolished by 10 nM CP96,345, an NK-1 antagonist, and was mimicked by 100 nM ADMSP, an NK-2 agonist. The response was not affected by 100 nM SR48969, an NK-2 antagonist. The SP effect was reversibly abolished by lowering extracellular Ca2+ (400 ± 76 mV/10-fold [K+]0). Our results show that SP activates an NK-1 receptor coupled to a Ca2+-dependent outward K+ current. We have observed SP-like immunoreactivity associated with ferret nodose neurones and therefore propose that SP receptors on these neurones may function as inhibitory autoreceptors.

Several studies suggest the existence of the tachykinin NK1 receptor subtype in the rat spinal cord. To clarify this issue and to study the possible involvement of NK1 receptors in synaptic transmission, the specific NK1 receptor antagonist SR48969 was used during intracellular recording from functionally-identified lumbar motoneurones (rest potential 74±2 mV, means±SEM) of the neonatal rat (P5-12) spinal cord continuously superfused in drugs were bath-applied. In all cells SR48969 (0.5 μM) had no effect on resting membrane potential or resistance but it did reduce the depolarization (50±10%, n=5), the increase in input resistance (80±7%, n=5) and the baseline excitatory activity induced by the specific NK1 receptor agonist [Asp9]NOE [200 nM]. SR48969 did not affect analogous changes produced by substance P-methylster (200 nM) and Met-enkephalin-β-endorphin (200 nM), specific for NK2 and NK3 receptors, respectively. For synaptic transmission studies two different types of dorsal root stimulation was used to recruit either AS fibers alone or C fibers as well as C fibers. AS fibers were employed to elicit slowly increasing depolarizations with slow recovery (windups). In the presence of SR48969 no change in response amplitude for all three types of stimuli except for modest reduction (10%) in the duration of the depolarization tail following windup was noted. Our study confirms the existence of SR48969 sensitive NK1 receptors in rat spinal cord and supports their role in neurotransmission from dorsal root afferents to motoneurones. Supported by CNR and INFM.

554.6 IS THE GALANIN-INDUCED INCREASE IN POTASSIUM CONDUCTANCE AND DECREASE IN BARBITURATE RESISTANCE OCCURRING IN MUDPUPPY PARASYMPATHETIC NEURONS MEDIATED BY TWO DIFFERENT RECEPTORS? L.A. Merriam*, J.M. Malvancy and R.L. Parsons. Dept. of Anatomy and Neurobiology, Univ. of Vermont, Burlington, VT 05405.

Galanin increases inwardly rectifying potassium conductance (gK) and decreases voltage-dependent barium currents (IBa) in mudpuppy parasympathetic neurones. In the present study it was determined that the concentration dependence of galanin and sensitivity to pertussis toxin and the chimeric ligand galantide to determine whether galanin's actions are mediated by the activation of a single receptor or different receptors. All experiments were done on dissociated neurones from the medulla of the mudpuppy Necturus maculosus using the perforated patch mode of the whole cell voltage clamp technique. We found that the EC50 for the activation of gK was -44 ± 4 nM and the maximum conductance was 75 ± 10% (n = 4) of the maximum conductance. The EC50 for the inhibition of IBa was -0.4 ± 0.1 nM. Pretreatment with PTX (-10 μM) for 24-36 hrs inhibited both actions of galanin. Galantide (10^-10M) antagonized the increase in potassium conductance by 10^-8M galanin without any measurable agonist action. In contrast, galantide (10^-10M) antagonized a concentration-dependent decrease in IBa. IBa could be further decreased by 10^-6M galanin in the presence of galantide. These results suggest that although activation of a G protein is involved in both actions of galanin, two different galanin receptors may mediate the increase in potassium conductance and decrease in IBa in mudpuppy neurones. Supported by NS23978.
BARRECTOR FLEX MODULATION BY THE GALANIN FRAGMENT (1-15) [D. A. Jennewijen*+], P. L. Heidtmann, J. L. A. Agster, N. Yamaoka, S. Gonzalez-Spín and K. Fujita. Dept. of Physiology, Faculty of Medicine, University of Salamanca, Spain. Lab. of Bio-Organoic Chemistry, School of Pharmaceutical Sci., University of Shizuoka, Japan and Dept. of Neuroscience, Karolinska Institutet, Stockholm, Sweden.

Recent studies have reported that the galanin (1-15) [GAL (1-15)] administered centrally elicits dose-related vasopressor responses and counteracts the vasodilator activity induced by galanin (1-29) [GAL (1-29)]. For a better understanding of the role of the galanin peptide family on central cardiovascular control we have studied the modulation of the baroreflex responses (BBR) by both galanin molecules. Groups of unanesthetized rats occupational in the lateral ventricle (i.v.:) of 0.1 nmol of GAL (1-15), 0.3 nmol of GAL (1-29), 3 nmol of GAL (1-29) and 20 pmol of the cholinergic agonist, methylcholine (MCh) were tested by an automatic injection pump (30 μL/min). BBR was elicited before and after i.v. injections by intravenous bolus injections of few different doses of L-phenylephrine (LPE) (33 to 625 μg/kg i.v.) and normetanephrine (NME) (10 μM) at heart rate (HR) changes were recorded from a catheter in the femoral artery. BRR sensitivity was evaluated from the slope of the regression lines related to the maternal reflex bradycardia due to the transient hypotension induced by LPE. GAL (1-29) did not induce any statistical changes in the slopes compared with the controls at any dose tested. However, i.v. injection of 0.1 nmol of GAL (1-15) produces a decrease of BRR sensitivity (p<0.02) when compared with the control of the GAL (1-29) groups (p<0.05). The blocking effect of BBR by GAL (1-15) might explain in part its vasopressor action and may indicate a major role for this galanin fragment in central cardiovascular regulation could be suggested possibly acting on specific receptor subtypes for N-terminals fragments of galanin.

We used an in-vitro approach to investigate the influence of opiates and melanotropin on the activity of noradrenergic neurons in the caudal medulla of the rat. [N-Me-D-Phe]-MSH (NDF-MSH) had no effect on the synaptic activity of noradrenergic neurons in the A2 as gauged by in-vitro L-DOPA accumulation and dopamine release (DDM) in explants. NDF-MSH reduced the noradrenaline (NE) content of explants treated with N5D-1015 but had no effect on basal or

PRESYNAPTIC DELIVERY OF CGRP BY TRANSFECTED PC12 CELL CO-CULTURES. F. S. Schweitzer*, C.-J. Jing, and Susan J. H. Teo-Cheng*. Dept. of Anatomy & Cell Biology, UCLA Medical School, Los Angeles, CA 90024 and **Laboratory of Neurobiology, NINDS, NIH, Bethesda, MD 20892.

In order to examine the role of CGRP in synapse formation and maintenance, we have engineered PC12 cells to synthesize and secrete CGRP from regulated (presynaptic) secretory vesicles. We have previously shown that the transient expression of a full-length CGRP with norepinephrine-containing vesicles on density gradient fractionation, and is secreted upon depolarization of the PC12 cells in the presence of calcium. We have shown by immunoelectron microscopy that the CGRP is contained exclusively in dense-core vesicles in both undifferentiated and NGF-treated PC12 cells. CGRP is absent from the synaptophysin- and SV-2r rich small clear vesicles. The CGRP in the dense-core vesicles is therefore presumably the source of the CGRP secreted from the cells upon stimulation.

We have now co-cultured wild-type and CGRP-expressing PC12 cells with C2 myotubes, to examine the effect of the CGRP on the induction of ACh receptors and the formation of ACh receptor clusters. Preliminary evidence indicates that the location of the ACh receptor clusters on the surface of the myotubes is correlated with the presence of CGRP. We are now examining these co-cultures for evidence of a specific effect of CGRP on the rate or extent of ACh receptor clustering.

Pancreastatin Stimulates Cobalt Uptake by Hippocampal Neurons. C. S. Toonum* W. R. Millington. Division of Molecular Biology and Biochemistry, Univ. of Missouri-Kansas City, Kansas City, MO 64108.

Pancreastatin, a 49 amino acid peptide derived from chromogranin A, is widely distributed in neural and endocrine tissues. Pancreastatin modulates the secretion and synthesis of various peptides; however, the evidence of its function in brain exists to date. We tested whether pancreastatin activates hippocampal neurons by using a biochemical assay which measures cobalt uptake through a calcium permeable channel in tissue slices (Nakan et al. Neurosci 7590, 1991). Our initial experiments confirmed that kainate, an agonist receptor antagonist, produced a dose-dependent accumulation (1-100 μM) of cobalt in hippocampal neurons of the dentate gyrus and Ammon's horn (CA). Coincubation with the glutamate agonist, kynurenic (5mM) blocked the response completely. Pancreastatin also produced a concentration related activation of cobalt uptake, albeit at considerably lower concentrations (0.5, 1 or 10 μM) than kainate. The regional distributions of pancreastatin and kainate responsive neurons were similar. Pancreastatin (500μM) stimulated cobalt uptake in areas CA1 and CA2, whereas higher concentrations (1-100mM) also promote cobalt uptake into CA3 and pyramidal and hilar cells of the dentate gyrus. At a 2 μM concentration, cobalt uptake was visible only in small portions of the dentrites, whereas, at higher concentrations, the cell bodies were also labelled. Interestingly, pancreastatin stimulated cobalt uptake was also blocked by kynurenic (100μM) suggesting that a glutamate receptor may be involved in the response. These data demonstrate that pancreastatin activates hippocampal neurons, suggesting that it may function as a neurotransmitter. ENDOTHELIN-1 ACTIVATES CHEMOSENSORY TYPE I CELLS AND POTENTIATES THE HYPOXIC RESPONSE IN RABBIT CAROTID BODY. J. Chen, I. He, B. Dinger and S.J. Dignam*. Dept. of Physiol. Univ. of Utah Sch. of Med., Salt Lake City, UT 84108

Endothelin (ET) and ET mRNA have been localized to diverse structures in the central and peripheral nervous systems, and ET has been demonstrated to evoke release of catecholamines (CA) from adrenal chromaffin cells and corpus striata. In many tissues, the effects of ET are mediated by G-protein coupled receptors which initiate the hydrolysis of phosphatidylinositol. In the present study, we have examined the effects of ET-1 on insulin-phosphate (IP3) formation, CA release and carotid sinuses nerve activity elicited from in vitro superfused rabbit carotid bodies where vascular effects are eliminated. Submicromolar and micromolar concentrations (0,01, 0,1, 0,5 and 1 μM) of ET-1 elevated the accumulated IP3 (p<0,01), respectively. Similar concentrations (0,1 and 1 μM) of ET-1 potentiated the hypoxic-evoked release of CA by 1,36- and 2,16-fold (p<0,05), respectively. Finally, CSN activity evoked by hypoxic superfusion solutions (equilibrated with 20% O2) was elevated by 21,32% ± 5,84% (X ± SEM, p<0,001) in the presence of 1 μM ET. In preliminary experiments, ET-3 appeared to be less potent with respect to IP3 formation, CA release and CSN discharge. The data suggest that ET actions are mediated by elevated intracellular Ca2+ concentrations and protein kinase C in chemosensory type I cells. Endothelin may act as physiological antagonists to atrial natriuretic peptide, which are endogenous to the carotid body and exert powerful inhibitory influences on the carotid chemoreceptor. SDFNPLFlamamide (PF2), originally isolated from the free-living nematode P. redivivus, induces profound flecainide paralysis in neumuscular segments of the parasitic nematode, Ascaris suum, at 1-10 μM. We conducted binding studies to characterize the receptor for this peptide using [3H]PF1 (134 Ci/mmol) and membrane preparations from P. redivivus (whole nerve) and Ascaris (muscle, hypodermis, ovaries). Among the Ascaris tissues, preparations, a low level of specific binding was detectable only in the hypodermal membranes. Backwash analysis of the [3H]PF2 binding to P. redivivus membranes indicated both a high and low affinity binding site for the peptide. The high affinity site is characterized by a Kd of 3.7 nM and Bmax of 8.5 fmol/mg protein. Kd and Bmax values of 23.5 nM and 58.3 fmol/mg protein, respectively, were obtained for the low affinity site. Specific binding in these studies accounted for 49.1% of the total bound, and total binding was 1% of the label added. Competition binding studies revealed that, in the P. redivivus membrane preparation, the affinity of PF2 for SDFNPLFlamamide (PF2), another neuropeptide isolated from P. redivivus that has inhibitory effects on A. suum muscle.
554.20 STRUCTURE-ACTIVITY RELATIONSHIPS OF NEMATODE FMRFamide-like Neuropeptides in ASCARIS SUUM
D.P. Thompson*, A.R. Friedman, J.W. Bowman, T.G. Geary
M.P. Kellam, M.J. Wars, F. Bullock and A. Ichihara
Upjohn Laboratories, Kalamazoo, MI 49001.
We examined the structure-activity relationships of two FMRFamide-like neuropeptides found in nematode, AF1 (KNEFIRFamide) and PF1 (SDPNFLRamide). We substituted alanine for each amino acid to generate a series of analogs that could pinpoint residues important for biological activity. We also tested a series of PF1 analogs in which each amino acid was replaced with its d-isomer. Truncated AF1 and PF1 analogs were similarly analyzed. Activity was measured in an Ascaris suum muscle strip preparation. For both AF1 and PF1, elimination of the C-terminal amide abolished activity. In the AF1 series, N-terminal deletions or extensions had unfavorable effects on potency. 

555.4 EFFECTS OF QUINOLINIC ACID LESIONS ON THE DISTRIBUTION OF D3 RECEPTORS IN RAT BRAIN
Dept. of Pharmacology and Radiology, University of Pennsylvania, Philadelphia, PA 19184.
Quinolinic acid lesions of the cell bodies in the nucleus accumbens (NAC) were used to examine the cellular localization of D3 receptors in the rat brain. A unilateral injection of quinolinic acid (150 nmol/0.5 μl) was administered into the NAC (ML+1.5; AP+1.5; DV-6.8 from the dura) at a rate of 0.1 μl/min. The contralateral NAC received a vehicle injection. Eight days later, the animals were sacrificed and coronal sections were processed for histology and quantitative autoradiography. D3 and D2 receptors were labelled with [125I]-Trans-OH-PIPAT and [125I]-NCQ-298, respectively. A marked loss of neuronal perikarya was observed in the shell and core of the NAC surrounding the site of injection. The density of D3 receptors was reduced in both the shell (dorsal - 60%; ventral - 43±4%) and the core (dorsal - 54±10%; ventral - 42±6%) of the NAC. Quinolinic acid has been shown to eliminate GABAergic effenter neurons at this dose, suggesting that D3 receptors are on the cell bodies or dendrites of these cells. The density of D2 receptors in the NAC was not altered by the lesion, indicating that D2 and D3 receptors are not co-localized on these cells. The density of D3 receptors was also reduced in the (ipsilateral substantia nigra pars compacta (45±11%) and the ventral tegmental area. This result suggests that D3 receptors are also located on the terminals of striatogenous fibers originating in the NAC. The D1 receptor has a similar cell body and terminal localization, suggesting that D1 and D3 terminal receptors may be co-expressed by some cells in the NAC. CATECHOLAMINE RECEPTORS VI

555.3 EFFECTS OF PRENATAL IV COCAINE AND GENDER ON D2 AND D3 RECEPTORS IN THE NUCLEUS ACCUMBENS, D.W. Wallace*, C.P. MacIntosh and R.M. Booth, Dept. of Pharmacology, College of Medicine and College of Pharmacy, University of Kentucky, Lexington, KY 40506.
The effect of prenatal cocaine treatment on the density of D2 and D3 receptors was examined in the striatum and nucleus accumbens of male and female offspring. Intravenous cocaine injections were given on gestational days 6-14 (3 mg/kg X 1 daily) and on postnatal days 15-20 (3 mg/kg X 2 daily). MacIntosh et al., (1994). Pups (Sprague-Dawley) were sacrificed on postnatal day 35 and striatum/nucleus accumbens tissue removed and frozen (tissue homogenates) or whole brains were blocked and frozen (neurochemistry). Binding analysis of D2 and D3 receptor density was performed with [3H]-(-)-6-OH-DA (5 nM) and D2 receptor density was determined by [3H]-(+)-6-OH-DA (5 nM). All analyses were carried out at room temperature (21±1°C) for 90 minutes and terminated either by rapid filtration (homogenates) or by two successive 2 minute washes in ice-cold buffer (autoradiography). Densities of both D2 and D3 receptors, as determined by quantitative densitometry, were based on appropriate standards which were co-exposed with tissue sections. 

We examined the effects of alcohol consumption on the density of dopamine D1 receptors in the rostral and caudal striatum, nucleus accumbens, caudal ventral, frontal cortex, ventral pallidum and globus pallidus of Fischer 344 rats. In Fischer 344 rats, 23% of 28390 was used to radiolabel dopamine D1 receptors on the rostral striatum brain section. An improved binding technique was obtained from the 5, 14 and 24 month Fischer 344 rats that were per-fed a control or ethanol-containing liquid diet on a chronic basis prior to sacrifice. Additional rats received the control diet or ethanol diet for 28 days. FMRFamide-like neuropeptides were used to label dopamine D2 receptors on twenty micron brain sections. Binding was determined using the NIH Image program.

The results of these experiments demonstrated an age-related decrease in dopamine D1 receptors in both the rostral and caudal striatum and in the frontal cortex. This age-related decline was typically found in both control and ethanol-fed rats. In control rats, binding was significantly decreased in the ventral pallidum of ethanol-fed rats. No significant differences were found in the Kd for [3H]-SCH 23390 binding.

555.5 REPEATED CATECHOLAMINE ADMINISTRATION INCREASES DOPAMINE RECEPTOR-REGULATED ADENYL CYCLASE ACTIVITY IN RAT CAUDATE PUTAMEN. E.M. Unterwald*, J. Fillmore, and M.J. Kreek. The Rockefeller University, New York, NY 10021.

Cocaine binds to the dopamine transporter and prevents the release of dopamine into presynaptic dopaminergic terminals. Repeated daily cocaine administration to rats for 14 days has been shown to upregulate dopamine D2 receptors (Unsworth et al., 1994). Adenylyl cyclase activity was measured in homogenates of regions containing dopaminergic innervation using a method that measures cyclic AMP (cAMP) formed from ATP when the preparation is stimulated with dopamine receptor agonists. Male Fischer rats were injected three times daily at one-hour intervals with saline or cocaine HCl (15 mg/kg, ip) for 1, 7, or 14 days. The ability of dopamine and quinpirole to stimulate adenylyl cyclase in the rostral portion of the caudate putamen was examined using a CAMP radioisotope binding assay in crude membrane preparations. D2 agonists (-10^4 to -10^3 M) produced a dose-dependent increase in CAMP formation with a maximum stimulation of 207 ± 2.7% over basal levels in saline-injected rats. Administration of cocaine did not significantly affect dopamine-stimulated cyclase activity. SKF-82958, 10^4 to 10^3 M, produced a dose-dependent increase in CAMP formation with a maximum stimulation of 192 ± 5.9% over basal levels. Administration of cocaine for 1 or 7 days did not significantly alter SKF-82958-stimulated cyclase activity. However, 14 days of cocaine administration significantly increased the stimulation of cyclase activity by SKF-82958. These findings suggest that chronic, repeated cocaine administration results in an enhancement of D2 receptor-mediated effector function in the rostral caudate putamen. (Supported by grants from NIDA (EMU) and the Arrow Diamond Foundation (MKK)).

555.6 DOPAMINE-INDUCED DEPOLARIZATION OF MEDIAL Prefrontal CORtical NeURONS. W.-X. Shi* and B.S. Bunney, Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

Dopamine (D) innervation in the prefrontal cortex (PFC) is particularly sensitive to stress and has a powerful influence on subcortical DA systems. Malfunction of this system has been suggested to play a critical role in the pathogenesis of schizophrenia. To this end, we may ask the question: what is the PFC? The PFC, as defined as a whole cell recordings from rat medial PFC neurons in an in vitro slice preparation. Confirming the result of a previous intracellular study (Pertson-Sonta et al., Brain Research, 1987), we find that DA is depolarized (1-200 µM) in mPFC neurons located in layers V and VI (5043, ranging from 2.5 to 15 mV). This effect of DA persisted in the medium containing TTX (1 µg/ml, x 30 mV and 3 mm Mg, 20 mm Mg), suggesting a direct effect of DA on the recorded cell. Using electrodes containing Lucite Yellow (0.1%), nine DA-responding neurons were intracellularly labeled, six of them were identified as pyramidal neurons and three as non-pyramidal neurons, suggesting that DA affects both projection and interneurons in the PFC. Surprisingly, however, the depolarizing effect of DA was not mimicked by either the D2 agonist SKF38393 [(1-10 µM)] or the D2 agonist quinpirole (1-10 µM) or by the mixture of the two (5:1). The mixed D2/D2 agonist apomorphine (5 µM) also produced no effect on PFC neurons (n=5). Furthermore, the D2 antagonist SCH23393 (10-30 µM, n=7) nor the D2 antagonist eticlopride (10 µM) blocked the effect of DA. None of these preliminary results suggest that the depolarizing effect of DA seen in PFC neurons is not mediated by the known DA receptors that should be sensitive to the DA active agents used above. Whether DA produces this effect by acting on a new type of receptor or non-specifically on other transmitter systems is not yet known. This work was supported by HHS award MH82849, the NPF, the NARSAD, and the State of Connecticut.

555.7 EXPRESSION OF D, RECEPTOR-MEDIATED INHIBITION OF MIDBRAIN DA NEURONS REQUIRES CO-ACTIVATION OF POSTSYNAPTIC D2 RECEPTORS. D.L. Smith, W.X. Shi, B.S. Bunney, Department of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

We previously reported that low doses of the D2 antagonist SCH23393 partially but significantly reversed dopamine-induced inhibition of substantia nigra dopamine (DA) neurons in paralyzed rats (low cervical level preparation) and suggested that D2 receptors are involved in the feedback control of DA neurons. However, when we determined that the D2 agonist SKF38393 alone had no consistent effect on DA cells. Since dopamine by releasing DA activates both D2 and D3 receptors and SKF38393 acts on only D2 receptors, we hypothesized that the expression of the mediated effect on DA neurons requires co-activation of D2 receptors. To test this hypothesis, we examined the effect of SKF38393 in animals pretreated with the D2 agonist quinpirole. Quinpirole potently inhibited DA neurons. To avoid the possibility that low doses of quinpirole (400 µg/kg, i.v.) were first used to produce a partial inhibition. In most of these cells (89%), however, SKF38393 (20 mg/kg, i.p.) produced no effect on the remaining activity of the cell. Considering the fact that D2 receptors in the substantia nigra are much more sensitive to a D2 agonist than to postsynaptic DA receptors, we further postulated that a D2-mediated effect depends on activation of postsynaptic D2 receptors and that the doses of quinpirole used were not high enough to achieve these receptors. To examine this possibility, we injected quinpirole slowly to desensitize DA autoreceptors. By doing this, we were able to inject 40 µg/kg or more of quinpirole while keeping the cell active. In most of these cells (89%), SKF38393 clearly produced a further inhibition of firing, which could be completely reversed by SCH23393 (20-40 µg/kg, i.v.). These results suggest that activation of D2 receptors has an inhibitory effect on DA neurons and the expression of this effect requires co-activation of D3 receptors most likely located on non-DA neurons. Supported by MH82849, the NPF, the NARSAD, and the State of Connecticut.

555.8 THE D2 RECEPTOR AGONIST QUINPIROLE EXCITES NEURONS OF THE GLOBUS PALLIDUS IN FREELY-MOVING RATS. K.C. Hooper, D.A. Banks, and G.V. Rebec. Program in Neural Science and Dept. of Psychology, Indiana University, Bloomington, IN 47405.

We have previously shown that selective stimulation of D2 receptors by systemic administration of the D2 agonist quinpirole (LY-171555) inhibits the activity of neurons in the striatum of awake, behaving rats (Hooper et al., Soci Neurosci. Abstr. 1992; 18:995).

To assess how this change in striatal activity affects neuronal activity in the globus pallidus, an output nucleus of the basal ganglia that receives an inhibitory projection from the striatum, we monitored single-unit activity in the globus pallidus of freely-moving male rats in response to the systemic administration of quinpirole at a dose known to inhibit striatal activity (1.0 mg/kg). Our results indicate that quinpirole excites neurones in the globus pallidus of awake rats. This effect probably occurs through a disinhibitory mechanism since GABAergic striatal cells, which project to the globus pallidus, are inhibited by quinpirole. Consistent with this view, preliminary data indicate that the quinpirole-induced excitation of pallidal neurones is reversed by eticlopride, a D2 receptor antagonist. Supported by USPHS Grant DA 02451.

SELECTIVE DOPAMINE D3 RECEPTOR ACTIVATION BY 7-OH-DPAT INDUCES HYPOTHYROIDISM AND DECREASES STRIATAL DOPAMINE RELEASE BUT NOT METABOLISM IN ANKLE RATS. R.G. Gross, P.J. Gershon, J. Dostrovsky, J. Gershon, and M.E. Liebman.

We have previously found a rather good correlation (r=0.75, p<0.02) between the abilities of acute typical and atypical antipsychotics to preferentially dopamine (DA) metabolism or release in the rat dorsal striatum in vivo and their relative potencies at D2 and D3 receptor. Present microdialysis study in awake Wistar rats with se.

le mide of DA agonists 7-OH-DPAT (0.57 - 0.8 mg/kg, ICV) and (-)-7-OH-DPAT (0.0005 - 0.04) were used to estimate the interstitial free concentration (ITC) of 7-OH-DPAT in the dorsal striatum. 7-OH-DPAT as well as DA, DOPAC and HVA were detected by HPLC in 20 minutes after i.p. administration of 7-OH-DPAT in doses ranging from 1 to 10 mg/kg. The results were as follows:

The maximum concentration of 7-OH-DPAT was reached at 18-29 min (n=4). The marked decrease of DA release (to 20 - 30% of basal) and metabolism (to 50%) was also observed. Due to approximately a linear relation between the dose - dopamine concentration observed it was inferred that at 7-OH-DPAT dose of 0.55 mg/kg ITC which would not exceed 16 nM. Importantly, 7-OH-DPAT in this dose produced significant decrease of DA release (to about 80%), but failed to affect metabolites level in the rat striatum, whereas in dose 0.25 mg/kg (calculated ITC 80 nm) both DA release and metabolism were approximately of 30 and 70%, respectively. The threshold dose for the significant decrease of DA release was ~0.005 mg/kg (calculated ITC 8 nm), while even in a dose 0.01 mg/kg (calculated ITC 3.2 nm) the drug induced hypothyroidism. In conclusion, 7-OH-DPAT at the dose range well below the affinity to D2 receptor induces hypothyroidism and decreases DA release but not its metabolism in the dorsal striatum of awake rats.

555.12

Dopaminergic autoreceptors control ascending dopaminergic pathways Here, we employed the novel, selective D3 antagonist, S 14297, to evaluate the potential contribution of D3 receptors to this action. As a measure of synthesis, the ratio of the levels of the dopaminergic metabolite, DOPAC in the caudate versus 2.8-fold lower than in 7-OH-DPAT (0.016) at DA release, and therefore, failed to modify levels of DA. S 14297 (20.0) was inactive. In conclusion, D3 autoreceptors inhibit synthesis and release of DA in ascending dopaminergic projections and S 14297 acts as an antagonist at these sites. These data suggest a role of D3 receptors in the modulation of mood and in the pathogenesis of psychiatric and motor disorders.

CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001, and University of Goeteborg, Goeteborg, Sweden.

Behavioral experiments in rats show that the D3 preferring-agonists, SKF 38393 and SCH 23390 were more efficacious in reducing exploratory activity as compared to D2 agonists. In the same animals, the accumulation of DOPA or the release of dopamine in various brain regions was not affected by the ED50 dose causing reducing exploratory activity. In contrast, for the more D2 preferring-agonists, such as apomorphine, (+)-3PPP and quinpirole, there was a closer correlation between doses that reduce locomotor activity and doses that reduce DOPA accumulation and dopamine release. A similar trend was also observed for the D2 selective compound U-91356. The data suggest that the D2 selective agonists, in contrast to the more D2 selective agonists, are able to reduce locomotor activity at doses that do not affect dopamine release and/or synthesis. Furthermore, these data are in line with the hypothesis that the D2 receptor is postsynaptic with an inhibitory influence on rat locomotor activity. Our present work focuses on the interaction between D2 preferring-agonists and antagonists on behavioral and neurochemical parameters in order to shed further light on the possible functional role of the D2 receptor.

555.15

CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

In studies with cloned subtypes of the D2 receptor subfamily, Pramipexole (PPX) has higher affinity for the D3 as compared to the D2 and D3 subtypes, and none for D2 receptors (Neurovisc Abs 1980, 93). Using Sosoloff's quantitative 2-deoxyglucose (2DG) autoradiography method (J Neurochem 28:897, 1980). Using this method in several basal ganglia regions (substantia nigra, subthalamic nucleus), but increased it even more in sensory and motor cortex. No significant effects were observed in microdialysis DA areas (n. accumbens, olfactory tubercles, lateral septum and CA1 of the hippocampus), but the data was not conclusive in these areas. In the caudate nucleus, a D2 postsynaptic area high in D2 receptors, but in which D3 pharmacological effects also occur (Neurovisc Abs 1980, 93). 18.4 PPX binding sites were found in the lateral amygdala, an area dominated by D2 receptors (PAN 89:1855, 1992). Using D2 agonists i.c.v. in the n. accumbens, olfactory tubercle, as well as in the caudate nucleus, a D2 postsynaptic area high in D2 receptors, but in which D3 pharmacological effects also occur (Neurovisc Abs 1980, 93). 1.4 PPX binding sites were found in the VTA, an area rich in DA cell bodies, and in sensory and motor cortex. Thus, increases in energy metabolism occurred in areas low in D3 binding sites, but not in areas high in D3 binding sites, i.e., substantia nigra, subthalamic nucleus. Therefore, the ability of D2 DG autoradiography to measure downstream functional effects of pharmacological agents.

1 Dept. of Pharmacology, Medicinaregatan 7, 413 90 Göteborg, Sweden and 2 CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001, USA.

The dopamine D3 selective agonist R- (+)-7-OH-DPAT produced a significant increase in reward thresholds over a wide dose range (0.094 - 96.0 nmol/kg, s.c.) similar to the well described effects of the classical D2 antagonist haloperidol (0.005 - 0.16 mg/kg, i.p.) when tested in rats trained to self-stimulate in a rate-intensity brain stimulation reward paradigm. At higher doses, 7-OH-DPAT produced a significant facilitation of reward thresholds.

Society for Neuroscience Abstracts, Volume 20, 1994
CHARACTERIZATION OF A SELECTIVE DOPAMINE 3 RECEPTOR AGONIST LIGAND, (H)[^3H]PD 128907. H. C. Akam and T.C. Tsai. Jr. Department of Pharmacology, University of Rochester Medical Center, Rochester, NY.

To determine the characterization of a novel dopamine (D3) receptor agonist, we measured the binding of (^3H)PD 128907 to brain regions from naive rats. The binding was saturable and specific. The KD was 2.1 nM, and the Bmax was 430 fmol/mg protein. The D3 receptor binding was highest in the striatum and lowest in the cerebral cortex. The results suggest that (^3H)PD 128907 can be used as a tool to study the D3 receptor in vivo.

PD 128907 has been shown to be a dopamine (D3) receptor agonist-like compound. The authors used autoradiography to study the effects of PD 128907 on DA3 receptors in the rat brain. They found that PD 128907 increased DA3 receptor binding in the striatum, hippocampus, and hypothalamus. The authors suggest that these results may have implications for the treatment of Parkinson's disease.

REGIONAL DISTRIBUTION OF DOPAMINE receptors in the brain. H.C. Akam and T.C. Tsai. Jr. Department of Pharmacology, University of Rochester Medical Center, Rochester, NY.

The authors measured the distribution of D1 and D2 receptors in the rat brain using in vivo autoradiography. They found that D1 receptors were highest in the striatum and lowest in the thalamus, while D2 receptors were highest in the caudate-putamen and lowest in the hippocampus. These results suggest that D1 and D2 receptors may have different functions in the brain.

CHARACTERIZATION OF A NEW HIGHPERSEPTIC DOPAMINE 3 RECEPTOR AGONIST: (H)[^3H]PD 128907. H.C. Akam and T.C. Tsai. Jr. Department of Pharmacology, University of Rochester Medical Center, Rochester, NY.

The authors characterized a new dopamine (D3) receptor agonist, (^3H)PD 128907. They found that the KD was 2.1 nM, and the Bmax was 430 fmol/mg protein. The D3 receptor binding was highest in the striatum and lowest in the cerebral cortex. These results suggest that (^3H)PD 128907 can be used as a tool to study the D3 receptor in vivo.
556.1 INCREASED NITRIC OXIDE SYNTHASE ACTIVITY BY SIN-1 AND SODIUM NITROPRUSSIDE IN INTACT NEURAL CELLS. J. H. and P. E. El-Fakahany, Division of Neuroscience Research in Psychiatry, University of Minnesota Medical School, Minneapolis, MN 55455.

It has been shown that nitric oxide (NO) regulates NO synthase activity through negative feedback in cytosolic enzyme preparations in a variety of cell types. We tested the effects of the NO-generating compounds 5'-diamino-N-acetylornithine (SNAP), 5'-diaminopentane (SNP) and sodium nitroprusside (SNP) on NO synthase activity in intact neuramiblastoma NIE-115 cells. SIN-1 and SNP at concentrations which elicited almost complete inhibition of NO synthase activity in cytosolic enzyme preparations of these cells only inhibited about 30% of the enzyme activity in intact cells, as measured by the conversion of [3H]-arginine to [3H]-citrulline during incubation for 45 min. Surprisingly, SIN-1 and SNP stimulated [3H]-citrulline formation when cells were incubated with the compounds for > 1.5 hours. Neither inhibitor nor stimulatory effects of SNAP on NO synthase were observed in the intact NIE-115 cells. This is in contrast to the inhibitory effects of SNAP in cytosolic preparations of the enzyme. Measurement of the activity of lactate dehydrogenase indicated that there was no parallel increase in cell permeability in response to SIN-1 or SNP. The stimulation by SIN-1 and SNP of NO synthase activity was completely blocked by 3 mM EGTA, suggesting that an influx of Ca2+ is activated by the compounds in intact NIE-115 cells. Moreover, hemoglobin, superoxide dismutase, defereroxamine attenuated the effects of SIN-1, but not of SNP, on [3H]-citrulline formation. Our results demonstrate that NO-generating compounds might somehow enhance Ca2+ influx, resulting in an up-regulation of NO synthase activity. These effects might be dependent on the chemical nature of the NO species released by the compounds.

556.3 SIMPLE GUANIDINE ANTAGONISTS OF NITRIC OXIDE SYNTHASE. J. F. Macdonald, D. W. Reif, A. Wallace, Fisons Pharmaceuticals Divisional Research and Development, PO Box 1710, Rochester NY 14603.

The role of nitric oxide synthase (NOS) in the function of the nervous system under normal and ischemia/reperfusion conditions is a topic of great interest. The current known antagonists of NOS are limited in that they lack selectivity between the brain, endothelium and macrophage NOS isoforms. Thus, selective antagonists would be useful tools to elucidate the role of the three NOS isoforms. Using the H3-arginine to H3-citrulline conversion assay (PNAS 87, 682-685, (1990)), compounds were assayed for inhibition of rat cerebellar , mouse macrophage, and human endothelial NOS. In our initial search for novel antagonists of NOS, we speculated that simple guanidines would be a reasonable starting point. The screening results for a series of substituted guanidines will be presented. Briefly, we have discovered small simple guanidines which inhibit the NOSs in the micromolar range (similar to methylarginine and nitroarginine), but are not selective versus a particular isoform. We will present results which will demonstrate that all of the NOS isoforms are inhibited by small cyclic guanidines and that inhibition is very dependent upon the size of the molecule.

556.5 PHOTONEURAL REGULATION OF RAT PINEAL NITRIC OXIDE SYNTHASE. N.C. Schub*, Jiri Vasicek and P.E. Schulz Div of Clinical Psychopharmacology, Dept of Psychiatry of the University of Geneva, 1225 Cbde-Bourg, Switzerland.

Nitric oxide (NO) appears to play a role in the regulation of cGMP synthesis in the rat pineal gland. Pineal nitric oxide synthase (NOS) is dependent on calcium for its activity, and all its biochemical characteristics are similar to the constitutive form of the enzyme present in the cerebrovasculature. The factors regulating the expression of the constitutive form of NOS in the central nervous system remain largely unknown. We report here a photoneural regulation of NOS activity in the rat pineal gland. In the absence of the adrenergic stimulation following light exposure (LL) or denervation (bilaterial superior cervical gangliectomy), pineal NOS activity is markedly reduced. A maximal drop is measured after 8 days in LL (< 80% versus control). When rats are housed back in normal light-dark conditions (LD 12-12), pineal NOS activity returns to normal after 4 days. A partial decrease in pineal NOS activity is also observed when rats are placed for 8 days in LD 18:6 or shorter dark phases indicating that pineal NOS activity reflects the length of the dark phase. Because it is known that norepinephrine (NE) is released at night from the nerve endings in the pineal gland and this release is blocked by exposure to light, our data suggest that NOS is controlled by adrenergic mechanisms. Our observation may also explain the lack of cyclic GMP response to NE released in animals housed in constant light.

556.6 TRANSMITTER MODULATION OF NMDA-ACTIVATED NITRIC OXIDE SYNTHASE (NOS) ACTIVITY IN RAT FRONTAL CORTEX. S. Aleksargy* and K. M. Johnson. The Department of Pharmacology and Toxicology, The University of Texas Medical Branch, Galveston, TX 77555-1031.

We have previously reported that activation of classical N-methyl-D-aspartate (NMDA) receptors can stimulate NOS activity in the frontal cortex. In this study we focused on other transmitter that may activate NOS or modulate the NMDA-activation of NOS. We found that of the transmitters examined, glutamate and acetylcholine (ACh) receptor agonists were the only ones to affect NOS activity. Glutamate stimulated NOS activity and this response is blocked by NMDA antagonists, but was unaffected by non-NMDA antagonists. These data are substantiated by the fact that AMPA, kainic acid (KA) and quisqualic acid (QX) did not increase NOS activity, even in the presence of dizoxide which prevents desensitization of the glutamate receptors, suggesting that the glutamate response was due to activation of the NMDA receptor in this preparation.

Norepinephrine, dopamine and y-aminobutyric acid (GABA) had no effect on either the basal or NMDA-activated NOS. However, while the basal NOS activity was unaffected by ACh agonists, 1 mM carbamylcholine chloride, a mixed ACh agonist, inhibited the NMDA response completely. This inhibition was not reversed by atropine, nor was it mimicked by muscaricine. Nicotine (30 μM) inhibited the NMDA response, but this inhibition was not complete, perhaps due to receptor desensitization. The inhibitory effect of nicotine was insensitive to hemicholinum and duspiperazine. Complete pharmacological characterization of this apparent novel nicotinic mechanism is currently under investigation. Supported by DA-02073.

The presence of NADPH-dihydrogenase-positive nerves in the rat uterus, and the role of nitric oxide (NO) in the pregnant animal, suggests that neuropeptides containing NO may be important in regulating myometrial activity, uterine blood flow and other reproductive functions. NOS was isolated from the uterus of adult female rats by diethylaminoethyl (DEAE) column and further purified by HPLC agarose. The chromatographic properties revealed two bands, myosin and NOS. The molecular weights of both isoforms were approximately 155 Kd by SDS PAGE which was similar to NO, and NO, from rat brain. The enzymes required NADPH, Ca2+ and calmodulin as cofactors. However, in the absence of calmodulin or other calcium NOP, was reduced by 96%, while NOS was reduced by 70%. This maximal enzyme activity was similar for brain. These results demonstrate that the rat uterus contains NOS and the fundamental kinetic constants, Km and Vmax, are similar to brain NOS. The uterine NOS is NADPH-dependent and different enzyme isoforms are suggested by the calmodulin-dependence and trifluoroperazine-dependence of both uterine and brain NOS.

556.8 INDUCIBLE NITRIC OXIDE SYNTHASE IN CA1 NEURONS. L. Divac* and J. Beisner, Department of Medical Physiology, University of Copenhagen, Denmark, and Department of Morphology, University of Las Palmas de Gran Canaria, Spain.

Our results, obtained in collaboration with several colleagues, have shown that NAPDH-diaphorase activity can be induced in the pyramidal CA1 neurons of the hippocampus by different agents. The effective agents are: electrical stimulation, mild stress, and direct injury of the hippocampus, either in vitro by slicing or in vivo by surgical injections. After the induction, we found in hippocampal tissue an increased formation of cyclic GMP, indicating that the induced molecule has NOS enzymatic function. The induction of NAPDH-diaphorase activity in CA1 neurons following intrahippocampal injections of saline can be abolished by pretreatment with anti-inflammatory drugs, dexamethasone or indomethacin, but not by a NOS inhibitor, L-NAME. Surprisingly, an antibody raised against the constitutive neuronal NOS did not stain the CA1 neurons which are demonstrably stained for NAPDH-diaphorase. We conclude tentatively that a molecule, different from the constitutive NOS with both NAPDH-diaphorase and NOS activities, can be induced in some neurons.
556.7 DISTRIBUTION OF NITRIC OXIDE SYNTHASE (NOS) IN RAT CENTRAL NERVOUS SYSTEM (CNS): A COMPARATIVE STUDY OF QUANTITATIVE AUTORADIOGRAPHY AND ENZYME ACTIVITY

Departments of Anesthesiology (S.M., P.F.) Neurology and Anatomy/Cell Biology (O.R.H.), Mount Sinai Medical Center, New York, NY 10029.

NOS is a ubiquitous enzyme in the mammalian CNS. However, a meaningful assessment of its distribution is lacking. We have developed a novel method for quantitative autoradiography of 7H(-)nitric-oxide binding. Data obtained with this method have been compared to the distribution of enzyme activity across rat CNS measured by the cyclic assay. The (100 µM) nitroarginine-sensitive NOS activity was assayed (30°C, 10 min, 0.25-40 µM (H)-[14C]arginine) in three preparations: a crude homogenate and cytoplastic andparticles fractions derived from it. Quantitative autoradiography and nitroarginine binding were done under the same condition with 50 µM (H)-nitric-oxide, 20 µM cronal cytoplasmic sections of rat brain.

The values were compared to the enzyme across the rat CNS (1-3 µM) while the Vmax (fmol/mg of tissue) varied: the highest was observed in the cerebellum (000) and the lowest was found in the spinal cord (10). 20-40% of NOS activity was found in the particulate fraction, indicating an uneven distribution of the enzyme within cell compartments. Areas of highest binding included the olfactory tubercle, amygdala, fornix, subterritia nigra, periadendal gray, and the cerebellar cortex. Intermediate binding levels were obtained in the hypothalamus, hippocampus, septal nuclei, globus pallidus, and the superior colliculus. Low binding was observed in the frontal and parietal cortex, and the caudo-putamen. Arginine-sensitive (H)-nitric-oxide binding varied between 65% of total binding (olfactory tissue) to none (caudo-putamen).

This combination of two quantitative methods for assessing NOS is proposed as a powerful tool to study the enzyme in mammalian CNS.

556.8 LOCALIZATION AND BIOCHEMISTRY OF NADPH-DIPHORASE ACTIVITY IN THE DEVELOPING CHICK RETINA

R. E. Sigman and R. F. Smith

Department of Neurobiology, VPI & SU Institutes for Science & Technology, Blacksburg, VA 24061.

NADPH-Diphorase (ND) activity, reported to be identical to NOS in the chick retina, has been found in specific groups of neurons in the CNS. We studied the expression of the enzyme in the developing chick retina. Enzyme activity was measured by spectrophotometric assays, using retinal homogenates with NADPH and nitrous blue tetrazolium. The immunohistochemistry, performed using incubating 4% paraformaldehyde-fixed cryostat sections, with a specific antibody raised in sheep, revealed the presence of stained nerve fibers and retinal pericytes (ER). An adult pattern was observed at E10, when photoreceptors and cones were present, and sensitive. ND was detected biochemically in homogenates of retina at E14 and E16 retinas when we observed a 50% stimulation by Ca2+ and 70% inhibition by L-NMMA. The stimulation by Ca2+ decreased at E17 and was insignificant in post-hatched retinas. Inhibition curves obtained with increasing concentrations of NADPH and L-NAME (1M) gramine (NOS) in the presence and absence of Ca2+ suggested the presence of NOS in the retina. In conclusion, the biochemical data and different isoforms of NOS in the retina. The results showed that the NO biochemical assay can be used as a sensitive method for studying NO activity and that different isoforms of NOS are expressed in populations of chick retinal cells during development. (Supported by CMG and RO1-NS-099).

556.9 NITRIC OXIDE SYNTASE ACTIVITY INCREASED IN BRAIN IN EXPERIMENTAL HEPATIC ENCEPHALOPATHY

V.L. Raghavendra Rao, R. Audet and R.F. Butterworth

Neuroscience Res. Unit, Hosp. St-Luc (Univ. Montreal), 1086 St-Denis St., Montreal, Que.

Glutamatergic synaptic dysfunction has been proposed as a causal factor in hepatic encephalopathy. Increased glutamate release (Butterworth et al., J. Neurochem. 66, 1481, 1991) and decreased glutamate uptake into NMDA receptors (Peterson et al., J. Neurochem. 55, 386, 1990) were previously reported in the brains of rats following portacaval anastomosis. Our results demonstrate that the activities of this enzyme were significantly increased in cerebral cortex (65%, p<0.05), cerebellum (54%, p<0.001), hippocampus (88%, p<0.001) and striatum (64%, p<0.001) of shunted rats compared to sham-operated controls. As the transport system is a prerequisite for nitric oxide production, we also studied [H]arginine transport into the cerebellar and cortical synaptosomes prepared from the brains of portacaval shunted and sham operated rats. [H]arginine uptake was significantly increased (45-55%, p<0.001) in both cortex and cerebellum. Alterations of the NOS system and the resultant increased production of nitric oxide and cGMP in brain could be of pathophysiologic significance in hepatic encephalopathy. (Supported by MRC Canada).

556.10 NITRIC OXIDE AND CYCLIC GMP ACTIVATE LOCUS COERULEUS NEURONS IN RAT BRAIN SLICES: ROLE OF CYCLIC GMP-DEPENDENT PROTEIN KINASE

J.H. Kopant., J. Procha and G.K. Aghajanian

Nitric oxide (NO) has recently been shown to be a diffusible second messenger capable of stimulating soluble guanylate cyclase. Since the noradrenergic locus coeruleus (LC) is rich in the α, β, and γ-subsunits of soluble guanylate cyclase (Funayama et al., Mol. Brain Res. 20, 1993) we investigated the role of NO/cyclic GMP pathway in the LC. Extracellular electrophysiological recordings demonstrated that bath-applied 8-bromo-cyclic GMP (8BrgcGMP, 1mM) caused a gradual excitation of LC neurons; a more rapid response occurred when cyclic GMP (100mM) was introduced via patch pipettes. Similarly, during extracellular injection of NO donors sodium nitroprusside (SNP, 1mM) and N-nitro-S-acetylpenicilliamine (SNAP, 1mM) excited LC neurons. The SNP excitation could be blocked by prior application of 8BrgcGMP indicating that SNP was acting through the NO/cyclic GMP pathway. Furthermore, H-8 (100mM), a protein kinase inhibitor with a relatively high affinity for cyclic GMP-dependent protein kinase (PKG), antagonized both the SNP and the 8BrgcGMP activation of LC neurons consistent with an action through PKG. These results suggest that there may be a physiological role for the NO/cyclic GMP pathway in the LC.

556.11 NITRIC OXIDE (NO) GAS ENHANCES TRITIATED NOREPINEPHRINE ([3H]NNE) RELEASE FROM RAT HIPPOCAMPAL SLICES

A.K. Spout* and J. L. Woolverton

Department of Pharmacology and Toxicology, Medical College of Virginia, Virginia Commonwealth University, Richmond VA 23289.

Previous studies in our lab have shown that NO gas enhances N-methyl-D-aspartate (NMDA)-stimulated release of preloaded [3H]NNE from rat brain slices in a dose-dependent, oxygen-sensitive, and cyclic GMP-independent manner. In this study we have attempted to determine the mechanism for the enhancement of neurotransmitter release from NO gas. Aminoguanidine-enhanced transmitter release was not due to buffer acidification or generation of NO degradation products, since reducing buffer pH below 7.3 inhibited NMDA-stimulated [3H]NNE release and nitrate or nitrite ions (3-10mM) had no significant effect on release. Carbon monoxide (10-30mM), another diatomic gas with properties similar to NO including enhanced binding to guanylate cyclase, did not significantly affect release. NO was reported to be modulated by mono-A, ADP-ribosylation of cellular proteins, but ADP-ribosylation inhibitors nicotinamide (10mM-10mM) and luminol (1mM-1mM) did not diminish the enhancement of transmission seen with NO. The NE reuptake inhibitor desmethylimipramine inhibited nor blocked the effect of NO, suggesting that NO was not acting via inhibition or reversal of the NE transport. The metabolic inhibitors sodium cyanide, potassium cyanide (0.1mM), and 2,4-dinitrophenol (1mM) all dose-dependently enhanced NMDA-stimulated [3H]NNE release similar to NO. These results suggest that NO may enhance transmitter release by a direct effect on the calcium homeostasis. Supported by NIAAA A10898 and NIDA Training Grant DA 07027.

556.12 CHARACTERIZATION OF NITRIC OXIDE-INDUCED [3H]NOREPINEPHRINE RELEASE FROM HIPPOCAMPAL SLICES

We have previously reported that a long exposure to hydroxyamine, a nitric oxide (NO) generator, induced a tetradotoxin-insensitive, Ca2+-dependent release of [3H]norepinephrine ([3H]NNE) from rat hippocampal slices (Lourt et al., Eur. J. Pharmacol., 1992). These data suggested that NO induced the release of [3H]NNE directly from the noradrenergic terminals via exocytosis. However, we recently made observations which suggest the involvement of both NO-induced glutamate (Glu) release and non-classical [3H]NNE release via reverse NE transport. When we applied only a 10 min pulse of 100 µM hydroxyamine, which evoked a 10-fold increase in the [3H]NNE release, was reduced by 80% by 5µM tetradotoxin and 1mM kynurenic, a Na+-channel blocker and a non-selective nortopicglutamate receptor antagonist, respectively. Ten µM CNQX and 100 µM GYKI 52466, competitive and non-competitive AMPA/kainate receptor agonists, respectively, reduced the hydroxyamine response by about 50%. The NMDA receptor antagonists AP-5 and MK-801 reduced the hydroxyamine response only at concentrations which also inhibited high potassium and reverse NE transport. However, GY 19755, another NMDA receptor antagonist which had no effect on the [3H]NNE transport, did not influence the hydroxyamine-induced [3H]NNE efflux. Ten µM dextroamphetamine 10 µM d-amphetamine, potent inhibitors of noradrenergic uptake, reduced the hydroxyamine-evoked release from hippocampal slices by about 70%. 5-nitro-1-cyanoethyl, another NO generator (300 to 3,000 µM), stimulated the efflux of both [3H]NNE and [3H]Glu from hippocampal synaptosomes. These data suggest that moderate NO stimuli can evoke [3H]NNE efflux both directly from the noradrenergic terminals and indirectly via releasing glutamine. Supported by DA-02073 (K.M.J.) and the P. and A. Forman Research Foundation (G.L.).
LIPOLYSACCHARIDE INHIBITS THE PRODUCTION OF NITRIC OXIDE IN RAT PHEOCHROMOCYTA Cells. G. Cao*, R.L. Prior*, J.G. Strain and J.A. Joseph* *USDA- ARS, INRC at Tufts Univ. Boston, MA O2111 and *Dept. of Nutr. Sci., Univ. of Conn. Storrs, CT 06296 Nitric oxide (NO) is a recently recognized messenger molecule mediating diverse functions including vasodilation, neurotransmission, and antimicrobial and antitumor activities. NO is produced from l-arginine by NO synthase which has two isozymes, i.e. the constitutive NO synthase (cNOS) and inducible NO synthase (iNOS). The iNOS can be induced by bacterial lipopolysaccharide (LPS), phenol esters, and some cytokines like TNF-a, IFN-g and L-1B. However, the mechanism involved in the negative regulation of the NO production is not clear. Here, we report an inhibition of 43% and 58% in nitrite production in L10 cells, a variant of IC-12 rat pheochromocytoma cells, by adding 1 or 10 ug/ml LPS, respectively in the culture media for 3 days. Nitrite production was also inhibited by 43% in control cells not exposed to LPS but incubated with 0.5 mM N-methyl-l-arginine acetate, a compound that specifically and competitively inhibits NOS. The results suggested that these L10 cells were from cNOS and could be negatively regulated by LPS.

DOES CARBON MONOXIDE REGULATE CYCLIC GMP LEVELS IN THE RAT BRAIN IN VIVO? J.V. Laitinen* and K.E.M. Laitinen, Rovaniemi, Finland. RIA was used to study in vivo regulation of brain cGMP levels by the putative gaseous messengers nitric oxide (NO) and carbon monoxide (CO). Anesthetized rats were implanted with the microdialysis probes in the frontal cortex (FC) or the cerebellum. FC location was similar in both regions, but we observed marked differences in responses to the NO donor sodium nitroprusside (SNP) or to CO. Most notably, SNP was 3-fold in the FC and 90-fold in the CB. The perfusion with CO-saturated aCSF stimulated cortical cGMP levels transiently and reversibly but elicited an irreversible and delayed response in the CB. Perfusion with NO donor L-NMMA (2 mM) suppressed cerebellar cGMP by 75% but exhibited no potency in the FC. Quite opposite, local perfusion with the heme oxygenase (HO) inhibitor sin protoporphyrin IX (100 uM) suppressed basal cortical cGMP by 50% but was without effect in the FC, suggesting that CO, generated by HO activity, might regulate cortical cGMP production in vivo. As NOP may have actions independent of HO inhibition, we have begun to address these questions by using more specific tools including a microarray for HO activity in discrete brain regions, as well as antisense oligonucleotide targeting of NO gene in vivo. These tools are hoped to reveal whether endogenously produced CO participates in the maintenance of cortical cGMP levels in vivo.

REGULATION OF THE CAMP RESPONSE ELEMENT BINDING PROTEIN (CREB) IN THE LOCS COERULEUS (LC) AND NUCLEUS ACCUMBENS (NAc) BY DRUGS OF ABUSE. K.J. Whitney, D.S. Russell, D.W. Selt, M.D. Misriandranoo, G. Konrad*, S.E. Hyman* and E.F. Nestler. Laboratory of Molecular Psychiatry, Dept. of Psychiatry and Pharmacology, Yale School of Medicine, New Haven, CT 06510; *Massachusetts General Hospital, Charlestown, MA 02129. We have shown previously that chronic administration of morphine or cocaine alters the expression of the CREB-dependent gene and components of the CREB-interacting messenger system. These changes occur in specific brain regions known from behavioral and pharmacological studies to mediate aspects of drug action (see Neuron, 11:995, 1995). We are currently investigating the molecular mechanisms involved in these adaptations by focusing on regulation of CREB transcription factor (FCREB) in the NAc. Morphine administration regulates CREB phosphorylation in the LC, as would be expected given morphine regulation of the cAMP pathway (J. Neurochem, 51:1168, 1988). CREB protein was thought to be constitutively expressed in the brain, but we have found that chronic morphine increases levels of CREB immunoactivity in the LC. Interestingly, in the NAc, chronic morphine decreases CREB immunoreactivity. Preliminary evidence suggests that chronic cocaine also influences CREB levels in this brain region. In order to test whether CREB is directly involved in the observed changes in signal transduction proteins, we are investigating antisense PS oligonucleotides to CREB into the NAc. Chronic (5 day) antisense injections of CREB significantly decreased CREB in all regions examined, while CREB decrease in NAc appears to be associated with regulation of protein kinase A and G, as well as Fos-like proteins as would be expected. These studies should further elucidate the role of CREB in morphine and cocaine regulation of intracellular target proteins implicated in drug addiction.

Heme oxygenase (HO) catalyzes the oxidation of heme to biliverdin and carbon monoxide. Since HO is involved in the synthesis of prostaglandins, we have developed a new radioimmunoassay (RIA) for HO which uses 55Fe-labelled heme as substrate. As HO cleaves the heme ring to release Fe2+, this assay directly measures released 55Fe2+ bound to transferrin attached to Sepharose beads. As little as one pmol of 55Fe2+ can be readily detected, providing a sensitivity 50 to 100 times greater than conventional assays based on the absorbance of bilirubin formed from biliverdin by biliverdin reductase. The assay is specific, as no known brain enzyme other that HO releases Fe2+ from heme. The assay is simple to perform. Assays are conducted in the presence of the Sepharose-transferrin beads which are counted directly after incubation, centrifugation and washing. Thus, 100 to 200 assays can be performed in an hour. This assay permits detection of HO activity in very small brain samples and microwell samples of cell culture.

556.15 MORPHINE ATTENUATES FORSOKIN-INDUCED PREPROENKEPHALIN mRNA IN RAT STRIATUM: A QUANTITATIVE IN SITU HYBRIDIZATION STUDY. J.N. Simpson* and J.F. McGinty. Department of Anatomy and Cell Biology, East Carolina University, Greenville, NC 27858-4344. Activation of the adenylate cyclase-CAMP second messenger system leads to an increase in preproenkephalin (PPE) and preprodynorphin (PD) gene expression. Because opioid receptors are most likely involved in opioid drug actions, preopiod gene expression may be negatively influenced by opioid receptor agonists. We previously demonstrated an increase in striatal PPE and PD mRNA levels as well as an increase in striatal phospho-CREB and FOS immunoreactivity following intracerebroventricular (ICV) administration of forskolin (Simpson and McGinty, Neuroreport, June, 1994). In a preliminary experiment, medial striatal PPE and PD mRNA levels were measured in rats which received either unilateral ICV injection of soluble forskolin (FSK, 10 mM/10 ml dH2O) 1 h following systemic injection of morphine (MOR, 25 mg/kg, n = 4) or unilateral ICV FSK only (n = 4). In the MOR-FSK group, a booster injection of MOR (10 mg/kg) was given 2 h after ICV FSK. The mRNA hybridization signal in the striatum ipsilateral to ICV FSK was compared with hybridization signal in the contralateral striatum. FSK induction of PPE, but not PD, mRNA was significantly attenuated by MOR. In a separate experiment, levels of striatal pro- and zilb268 mRNA were examined 4 h following ICV FSK (10 mM/10 ml saline, n = 5) or ICV saline (10 ml, n = 5). FSK significantly induced PPE, PD, and zilb268 mRNA in the medial striatum. The finding that striatal zilb268 mRNA is induced by FSK supports previous reports that the promoter region of the zilb268 gene contains a CRE-like element. Results of a current study confirming morphine effects on forskolin-induced pro-opioid mRNA in the rat striatum as well as morphine effects on forskolin-induced zilb268 mRNA will be presented. Supported by DA05740 (JNS) and DA03892 (JFM).

556.16 MOLECULAR BASIS OF DOPAMINE/GLUTAMATE INTERACTIONS IN THE RAT STRIATUM. C. Konrad*, X.-M. Li*, R.L. Cole* and S.E. Hyman*, Laboratory of Molecular and Developmental Neurosciences, Massachusetts General Hospital, Harvard Medical School, Charlestown, MA 02129 and Department of Psychiatry, University of Saskatchewan, Saskatoon, SK, Canada.

Abnormalities in dopamine-glutamate transmission have been implicated in the pathogenesis of neuropsychiatric disorders including Parkinson's disease and schizophrenia. The goal of our studies is to elucidate the role of glutamate in drug-mediated gene regulation in striatum. Knowledge of dopamine-glutamate interactions may provide novel targets of drug therapy. We have previously demonstrated regulation of AP-1 binding proteins in rat striatum by dopamine agonists and antagonists. In addition, we and others have observed that D1 and D2 dopamine receptor-mediated c-fos expression is inhibited by pretreatment with the NKMDA receptor antagonist MK-801. Conversely, in primary striatal cultures, low levels of glutamate that are insufficient to induce c-fos expression significantly enhance dopamine mediated c-fos expression and AP-1 binding activity. This effect appears to be mediated by Ca2+ binding proteins, while glutamate has no effect on cAMP levels. In addition, the Ca2+ ionophore A23187 was able to mimic the effects of glutamate. These data suggest that interactions between Ca2+ and the cAMP pathway may be critical in the regulation of striatal gene expression in response to dopaminergic drugs.
557.1

BEHAVIORAL AND BIOCHEMICAL PROPERTIES OF GABA AND BENZODIAZEPINE RECEPTORS IN CBA AND C57 MICE.

C57B1/6 male mice show "normal" habituation in a locomotor activity test situation, whereas CBA/Ca background animals, CBA mice also display increased latency in a passive avoidance situation and an increased sensitivity to the convulsive actions of the GABAergic antagonist picrotoxin. Receptor binding studies revealed no differences in benzodiazepine (BDZ) binding properties or in the ability of various BDZ receptor ligands to inhibit BDZ binding.

Neither was there any differences in GABA- or pentobarbital-produced enhancement of BDZ binding. However, the binding of 3HBDP (2 nM) was about 30% higher in forebrain microsas of CBA mice as compared to C57, which was not strain difference, however in midbrain or DMCM-produced modulation of 3HBDP binding. Further experiments revealed no differences in GABA-stimulated 3Hcholine in CBA mice. However, midbrain-admained enhanced of 3Hcholine influx was significantly higher in forebrain microsas of C57 mice as compared to CBA mice. In contrast, the DMCM-produced a more marked reduction of GABA stimulated 3Hcholine in forebrain microsas of CBA as compared to C57. Our current data indicate that genetic differences in the GABAergic receptor system may explain at least some of the previously observed behavioral differences in the behavioral actions of BDZ receptor ligands in CBA and C57 animals.

FELBAMATE, A NOVEL ANTIPELLEPTIC AGENT, DOES NOT AFFECT COGNITION IN RODENTS (ID Smith*, ME Ozeki and VL Coffin). Scheinberg-Plough Research Institute, Kenilworth NJ 07033.

Felbamate (5-phenyl-1,3-propanedione dicarboxamide; Felbatol, Talacon) is a novel antiepileptic agent recently approved by the FDA for treatment of epilepsy in the U.S. While the mechanism of action of felbamate is not yet fully elucidated, recent evidence has accumulated that felbamate may act at the strychnine-sensitive glycine-binding site on the NMDA receptor complex. Since the NMDA receptor has been implicated in cognitive processes (i.e., LTP), the current study was designed to investigate the potential effects of felbamate on cognitive function.

Doses of felbamate up to 1000mg/kg did not produce deleterious effects in either mice or rats in passive avoidance tasks at the responding (PAR). In contrast, the noncompetitive NMDA antagonist MK-801 (dizocilpine) produced performance deficits at doses from 0.1 to 1.0mg/kg in both rats and mice. Both drugs prevented NMDA-induced convulsions (ED50=20.3 and 0.62, respectively). The therapeutic index (ratio of effective to anticonvulsant doses in ED50) for dizocilpine was less than one-fold, while felbamate had a greater than 50-fold separation. Taken together, these results indicate that felbamate does not produce cognitive deficits at doses more than 50 times the dose needed to block seizure activity in rodents.

Animal | Therapeutic Ratio
---|---
rat (24h) | 0.119 | >50
mouse (24h) | 0.078 | >50
mouse (1h) | 0.354 | >50

*Dose producing PAR deficit/Dose to block NMDA-induced seizure

INHERITABLE INDIVIDUAL-SPECIFIC BEHAVIORAL FEATURES OF RATS AND EFFECTS OF PROPOFOL.
R. Drinker 1, B. Elfenbrock 2 and A.R. Cools 3.

Institute for Anthropology, 1 and Dept. Psychoneuroepidemiology 2. University of Nijmegen, Nijmegen 6500HB, the Netherlands.

Inheritable differences in the physiological state of the brain that direct the display of behavior include those in the GABA transmission. This transmission is essential to the effects of many anesthetic, including propofol. The present study uses the 14th generation pharmacologically selected APO-UNSUS and APO-SUS rats to evaluate whether the neurobiological profile of individual-specific features affects the response to propofol. We assessed the duration of abolishment of propofol-induced movements (APM) and the incidence of propofol-evoked behavior after three different doses i.v., each injected at a one week interval. One week later, the rats were anesthetized with isoflurane and the effects of propofol on withdrawal reflexes, heart rate and blood pressures were measured. The induction of APM and magnitude of reflex inhibition representing the anesthetic equivalent of effect were not different for the two types of rats. APO-UNSUS rats showed a greater heart rate variability and their systolic blood pressures were lower than APO-SUS rats. Propofol reduced heart rate variables stronger in APO-UNSUS rats, whereas blood pressure variables were reduced to a greater extent in APO-SUS rats. Cardiovascular responses serve to indicate the sensitivity of an individual to an anesthetic in clinical conditions. Intravenous injection of propofol produced differences occurred at the same magnitude of anesthetic responses. Drug induced differences were observed in the two types of rats. APO-SUS rats showed a higher incidence of involuntary muscular contractions after i.v. injection of propofol, whereas the incidence of grooming behavior was lower. The difference in these adverse reactions may relate to the mirror image in functionality of GABA transmission after the nico-oligos pathways for the two types of rats. Translated to the human condition, personality may affect the severity of side-effects of propofol.
MODULATION BY INOSITOL OF CHOLINERGIC AND SEROTONERGIC-INDUCED SEIZURES IN LITHIUM TREATED RATS. M.B. Williams* and R.S. Jope. Dept. of Psychiatry and Behavioral Neurology, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

Lithium's inhibitory effect on inositol monophosphatase of the PI pathway was suggested to be involved in the mechanism of action of lithium treatment for bipolar affective disorder (Berridge et al., 1982). Inositol depletion occurs following toxic but not therapeutic doses of lithium. However, supplemental inositol attenuated seizures induced by acute lithium plus pilocarpine (PILO) (Tricklebank et al., 1991; Koffman et al., 1993). We used EEG measurements of seizures produced by PILO given to lithium-pretreated rats (acute or chronic) and determined the effect of myo- and epi-inositol on seizure latency. Myo-inositol (0.55 mmole, i.c.v) dose-dependently increased latency to seizures induced by acute lithium (3 mmole/kg, i.p) plus PILO (30 mg/kg, i.p). Epi-inositol, which is not utilized for PI synthesis, blocked seizures in 50% of tested rats. In chronic lithium treated rats, inositol did not block seizures produced by PILO. Similarly to its effect on muscarinic agonists, lithium increased the response to R(-)-DOI, a selective 5HT2 (PI-linked) agonist (Williams and Jope, 1994). While DOI (5 mg/kg, i.p.) alone was not convulsant, lithium plus DOI evoked seizures. Myo-inositol (i.c.v) blocked seizures in some rats treated with lithium and DOI.

The ability of many antidepressant treatments to increase synaptic concentrations of serotonin is believed to be the mechanism by which they exert their clinically beneficial effects. It is uncertain, however, via which receptors the increased concentrations of serotonin subsequently act. Several studies have shown that agonists at 5-HT1B receptors such as RU 24969 demonstrate antidepressant-like actions in the mouse tail suspension test. We set out to determine whether such treatments reduce immobility in the mouse tail suspension test and to compare the effects of two recently described compounds; WAY 100135 and GR 127935, selective agonists at 5-HT1A and 5-HT1B receptors respectively, on the effects of this and other antidepressant treatments. All drugs were administered s.c. RU 24969 significantly decreased immobility at doses of 1 or 3 mg/kg. Neither WAY 100135 (10 mg/kg) had any effect in this test up to doses of 10 mg/kg. WAY 100135 (10 mg/kg) had no effect on the decrease in immobility induced by paroxetine (1 mg/kg) or RU 24969 (3 mg/kg), thus we conclude that the effect of RU 24969 on the 5-HT1B effects of the 5-HT1B agonist but also blocked the effects of paroxetine (1 mg/kg) and imipramine (10 mg/kg) in the TST. In conclusion, these results indicate that the 5-HT1B/D receptor may be involved in the mediation of the behavioural action of antidepressant agents.
557.11
EFFECTS OF CORTICOSTERONE AND DEXAMETHASONE ON SCHEDULE-INDUCED POLYPсидIA IN ADRENAL CohEIZED RATS. F. Crippa1, H. van Oers1, E. R. De Kloet1 and S. Levine1.

Removal of circulating glucocorticoids by adrenalectomy prevents the normal acquisition of schedule-induced polydipsia (SIP), while corticosterone (CORT) administration reinstates this behavior in adrenalectomized (ADX) rats. These studies investigated which glucocorticoid (GC) receptor is responsible for mediating CORT effects on SIP. In Experiment I the effects of dexamethasone (DEX) and CORT on the acquisition of SIP were studied. DEX and CORT pellets (respectively, 15 mg and 200 mg) were implanted subcutaneously in ADX rats. CORT but not DEX replacement was able to reinstate SIP in ADX rats. Because DEX binds almost exclusively to glucocorticoid receptors (GRs), while CORT binds to both GRs and mineralocorticoid receptors (MRs), results from Experiment I indicate that GRs alone are not sufficient for SIP acquisition. In Experiment II CORT pellets of different concentrations (1, 10, 30, 200 mg) were implanted in ADX rats in order to distinguish whether MRs alone, or a combination of GRs and MRs is required for SIP reinstatement. Results from Experiment II showed that the 1 and 10 mg CORT pellets were not able to reinstate SIP in adrenalectomized rats, while animals implanted with 50 or 200 mg pellets did show the behavior. These results indicate that occupancy of both MRs and GRs is required for SIP acquisition.

557.12
3α-ANDROSTANE30 DIOL INHIBITION OF SEXUAL RECEPTIVITY AND NOCICEPTION: EVIDENCE FOR A GABAERGIC MECHANISM. C.A. Frye1, 2, K. V. Kueken and M. S. Erkens1.
1 Department of Biology, Boston University; 2 Cumming School of Medicine, Boston, MA 02215

Many steroids can act via intracellular receptors and at the GABA receptor complex (GBR). Progesterone (P) or its metabolites may initiate sexual receptivity and 3α-reduced androgens, particularly 3α-Androstan-30 one at the GBR, may produce female-like effects in some species. To investigate this hypothesis, ovariectomized rats (N=50) received 3α-Diol (0.6, 3.0, 6.0 and 7.5 mg/kg) via vehicle (10% (v/v) ethanol/proplylene glycol) at 1000h (hrs), and 2.5 SC injections of estradiol (E2; 1 μg/g; pil in 1% ethanol) at 1300h (hrs) and 1500h (hrs) daily for 2 days. P (0.5, 1.0, 2.0 and 4.0 mg/kg) or saline was given at 1400h after 2 days of 3α-Diol and E2. Behavioral testing was carried out at 1830h, 48-49 hours after the first injection of E2 at 4 hour after injection of P. 3α-Diol (3.0 and 6.0 mg/kg) significantly attenuated P (2.0 and 4.0 mg/kg) facilitation of sexual behavior (Lordosis Quotient, Lordosis Rating, Proceptivity). 3α-Diol and E2 both produced analgesia assessed via the radiant heat tail-flick method. 3α-Diol at 3.0 mg/kg inhibited P-induced, uniformly produced maximum analgesia, and dramatically increased GABA-stimulated chloride flow into cortical synaptosomes. As 3α-Diol binds poorly to its intracellular receptors, these data suggest that 3α-Diol may act via the GBR to inhibit sexual receptivity and promote analgesia.

THE CCK RECEPTOR ANTAGONIST CV-67736 INHIBITS ETHANOL INDUCTION OF IMMUNOCALL OF THE GLOUCOCORTICOID RELATED MECHANISM IN THE PARA-SOMNOCENTIC IN RATS. M. Hulset1, S. Bernardo1, J. M. Puntervold1, Dept. of Pharmacology, Sch. of Pharmacy, Univ. Copenhagen, Copenhagen, Denmark.

Rescue of ethanol (EtOH) withdrawal dependence by the CCK antagonist CV-67736, was assessed in the Sprague-Dawley rat model of withdrawal syndrome. EtOH withdrawal was induced by maintaining the rats on a liquid diet containing EtOH (8% v/v) for 21 days, followed by withdrawal for 5 days. Ethanol withdrawal produced a dose-dependent increase of the c-fos mRNA level in the hypothalamus, striatum, hippocampus and amygdala, but not in the cerebellum or cortex. Treatment with CV-67736 (1 mg/kg) attenuated the increase in c-fos mRNA levels in all regions except the amygdala. These results suggest that EtOH withdrawal produces a CCK-dependent increase in c-fos mRNA levels in several brain regions.

1 Neuroscience Program, University of Western Ontario, London, Canada.

The sulfated neurosteroid Pregnenolone Sulfate (PS) has been shown to have a variety of behavioral effects. Recently evidence has been presented that PS affects cognitive processes. The present study examined the effects of PS on spatial learning and memory in adult male rats. PS (0.5 and 1.0 mg/kg) and vehicle treated rats were tested in a Morris water maze task, where they had to learn the position of a hidden platform. PS treated rats were found to learn the task significantly faster than the saline vehicle controls, although the vehicle group had significantly better retention. The effects of PS on locomotor activity and swimming behavior were also examined. In a multivariate analysis of locomotor behavior, PS was found to cause a dose-dependent increase in activity. There were, however, no significant effects on swimming behavior. These results suggest that PS may affect spatial learning and locomotor activity. Supported by an NSERC to KPO and MK.

1 Department of Psychology, State University of New York at Buffalo, Buffalo, NY 14260.

The nitric oxide synthase inhibitor N-(G)-monomethyl-L-arginine (NMMA; 25, 50, and 100 μg) was microinjected into the medial preoptic area (MPOA) of male rats. In a test of ex copula sexual reflexion, restrained saline treated rats exhibited a dose-dependent increase in seminal emissions which was significant at the 400 μg dose. This effect was not mimicked by the inactive isomer N-(G)-monomethyl-D-arginine. In a subsequent copulation test, animals in the NMMA (400 μg) condition were significantly less likely to successfully initiate copulation than were animals in the vehicle condition. The results suggest that nitric oxide in the MPOA contributes to the regulation of male sexual behavior.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
558.1 ASSESSMENT OF DRUG-INDUCED REBOUND USING A THREE-LEVER DRUG-DISCRIMINATION TASK. W. E. Cast, R. J. Barrett, E. M. Huffman, and J. R. Stadler. Department of Psychology and V. A. Medical Center, Vanderbilt University, Nashville, TN 37240. Our previous research, using a two-lever drug-drug discrimination task, has shown that time-dependent, bidirectional changes in choice responding occur following administration of drug, EEDQ, and psychomotor stimulants. Because one limitation of the two-lever procedure is that it is not possible to identify cue states that differ from those associated with the training drugs, in the present study animals were trained on a three-lever task to discriminate among two drugs and vehicle.
Rats were trained over a 10-month period using a VI schedule of food reinforcement to discriminate between 0.5 mg/kg amphetamine, distilled water, and 0.03 mg/kg haloperidol. The dose-response functions for responding on each lever indicate that animals were responding on the basis of a continuum of dopaminergic activity. Subsequent to a large (10 mg/kg) dose of amphetamine, predominant responding shifted from the amphetamine lever at 9 hr, and then to the haloperidol lever at 20 and 24 hrs.

The behavioral effects of caffeine were studied alone and in combination with methamphetamine (MA) in squirrel monkeys trained to discriminate 0.30 mg/kg MA from saline using conventional drug discrimination procedures. In initial experiments, caffeine (3.56 mg/kg) substituted for MA to varying extents in four of seven monkeys, resulting in 67-100% MA-lever responding. However, the MA-like discriminative stimulus effects of caffeine diminished over successive determinations and could not be reinstated regardless of dose. Pretreatment with caffeine (10 and 4 mg/kg) did not systematically alter the discriminative stimulus effects of MA; on the other hand, pretreatment with a normally ineffective dose of MA did partially restore caffeine's MA-like effects (50-90% MA-lever responding). These findings suggest that, although caffeine and MA generally have dissimilar discriminative stimulus effects, their behavioral actions may overlap to a limited extent. Supported by DA 03774, RR00168, DA 00499 and MH 07658.

558.5 EFFECT OF FOURPHET, AN IRREVERSIBLE INHIBITOR OF STIMULANT BINDING, ON OCAMINE-INDUCED BEHAVIORS. N. Scholl* R. B. Gupta, and E. Asch, Div. Basic Med. Sciences, Medicine, UC-SF, Sch. Med., San Francisco, CA 94143. We have previously shown that 20 mg/kg (I.v.) Fourphet HCl (4-isoethyl-4-(1-methylcyclohexyl)pyridinidide; FPH), an irreversible inhibitor of [benhyl]methylphenidate binding to the stimulant recognition site on the dopamine transporter, decreases the total, ambulatory, and non-ambulatory movements caused by a single dose (15 mg/kg, s. p.) of cocaine/HCl (COC) 24 hrs after treatment with FPH. The present work examined the effect of the same dose of FPH on the behavioral responses to a high dose of COC (40 mg/kg, s. p.) of cocaine/HCl (COC) 24 hrs after treatment with FPH. The present work examined the effect of the same dose of FPH on the behavioral responses to a high dose of COC (40 mg/kg, s. p.) of cocaine/HCl (COC) 24 hrs after treatment with FPH. After overnight acclimatization in individual activity monitor cages, male Sprague-Dawley rats were injected with FPH or vehicle (VEN; 20% EtOH/saline), then challenged 24 hrs later with 40 mg/kg (s. p.) COC. Activity counts recorded after COC injection were analysed by 2-way (time x treatment) ANOVA with repeated measures on the first factor. Significant time x treatment interactions were obtained for the total (p<0.05) and ambulatory (p<0.05) activity counts recorded at these consecutive 25 min intervals, starting at 10 min after COC administration. Analysis by two-way ANOVA showed that FPH-treated rats were significantly less active than VEN controls during the first measurement interval. Although FPH had no effect on nonambulatory activity (often used as a measure of stereotypy), differences in particular stereotypic behaviors were found: FPH-treated rats exhibited more thigmotaxis (p<0.03) and less rearing (p<0.04) after COC than controls. The data show that FPH has a significant effect on behaviors caused by a high dose of COC. (Supported by NIDA #DA00305 and NINDS #NS28258).

558.6 MODULATION OF DOPAMINE RECEPTOR AGONIST INDUCED ROTATIONAL BEHAVIOUR BY PLG AND ITS NOVEL ANALOGUE PAPOA. D. When, R.K. Mishra* and R.L. Johnson. McMaster Univ., Hamilton, Ont. & Dept. of Medicinal Chemistry, Univ. of Minnesota, Minneapolis, Mn.
The interaction of L-prolyl-L-leucylglycinamide (PLG) and its novel synthetic analogue 3-(R)-[N-(L-prolyl)aminocarbonyl]-2-oxo-1-phenylalanine (PAPOA) with central dopaminergic receptors was investigated in 6-hydroxydopamine lesioned rats. PLG maximally potentiated amphetamine-induced rotations at a dose of 1.0 mg/kg (intraperitoneal injection, ip) and 100.0 ng (intrastriatal injection, i.s.). PAPOA was 100% more potent than PLG, inducing maximal potentiation at dosages of 10.0, 5.0, and 1.0 ng (i.s.) Co-administered intrastriatal injections of PLG and PAPOA (100.0 ng and 1.0 ng respectively) enhanced the agonist-induced rotational responses by 25% and 50%, respectively. These injections of PLG and PAPOA (1.0 mg/kg and 1.0 mg/kg respectively) similarly increased the rotational response by 50%. PAPOA also potentiated both SKF 38390 and quinpirole induced rotational responses by 50% and 100%, respectively. PAPOA maximally mediated its effects via D1 dopamine receptors as PAPOA produced an 85% increase in quinpirole (D1 agonist) induced rotations. In contrast, PAPOA yielded a modest 14% increase in SKF 38390 (D2 agonist) induced rotations. Haloperidol blocked these peptide potentiated dopamine actions and those induced by quinpirole regardless of the route of administration (i.p. or i.s.). D1 25330 blocked both D1 and D2 actions potentiated by PAPOA. Thus PAPOA, with greater potency than PLG to modulate the effects of dopamine agonists, is of therapeutic importance in the treatment of Parkinson's disease and the dyskinesic syndromes. (Supported by NIH Grant NS 20563).
558.7 DIZOCYLINE (MK-801)-INDUCED BEHAVIOR IN RATS IS INHIBITED BY NEUROLEPTIC DRUGS AND POTENTIATED BY ACVINIC. P. Andiné*, R. Axelson and M. Sandberg. Departments of Clinical Neuroscience, Section of Psychiatry, Sahlgrenska University Hospital, and Anxiety and Cell Biology, Institute of Neurobiology, University of Göteborg, S-413 90 Göteborg, Sweden.

N-Methyl-D-aspartate (NMDA) receptor antagonists are psychotomimetics offering the most schizophrenia-like drug-induced syndrome in humans. The NMDA antagonist dizocilpine (MK-801) causes a typical behavior in rats which is used as an experimental model for psychosis. We used adult Sprague-Dawley rats and observed them from 15-75 min after intraperitoneal administration of MK-801 (0.05-1.0 mg/kg). They were scored for locomotion, stereotyped sniffing and ataxia every 5 min throughout the experiment. MK-801 caused altered locomotion and stereotyped sniffing in lower doses and also ataxia in higher doses. Female rats were much more susceptible to MK-801 than males. Neuroleptic drugs, administered in a single-dose 30 min before MK-801, offered a potent reduction of MK-801 behavior, with a total inhibition at doses (haloperidol 1.0 mg/kg, perphenazine 2.0 mg/kg, chlorpromazine 10 mg/kg, remoxipride 20 micromoles/kg) that corresponded to their anti-psychotic potency in patients. An enhancement of MK-801 behavior was found in male rats pretreated with acvinic (100 mg/kg), an inhibitor of the putative amino acid reuptake enzyme gamma-glutamyl transferase. In vitro, acvinic did not influence extracellular (ec) glutamate, however, it increased ec glutathione. Glutathione may cause NMDA receptor blockade via redox reactions and thereby an enhancement of MK-801 behavior. In conclusion, MK-801-induced behavior in rats is aggravated by gamma-glutamyl transferase inhibition and abolished by neuroleptics.

558.8 THE EFFECTS OF DOPAMINERGIC AGONISTS ON DELAYED MATCHING-TO-SAMPLE (DMS) PERFORMANCE UNDER THERMAL NEUTRAL AND COLD STRESS CONDITIONS. D. Shurtleff*, J. R. Thomas, S. T. Albers, and J. Schott Naval Medical Research Institute, Bethesda, MD 20889-5607.

Dopaminergic drugs have been shown to be important in the modulation of working memory. This study examined the role of the D1/D2 agonist quinpirole (0.025-0.1 mg/kg) and the D2 agonist quinpirole (0.05 mg/kg) on working memory in rats using a DMS procedure. Each DMS trial required rats to respond to one of two cued levers, which initiated a variable delay of 1-16 sec. Following the delay, rats were reinforced for correctly responding to the lever. Under thermal neutral conditions (22°C) following saline, rats' matching accuracy showed a characteristic decline as the delay interval increased. Consistent with previous research and relative to 22°C, matching at 2°C (cold) was reduced. Both drugs increased matching accuracy at higher doses. Quinpirole did not prevent the cold-induced decline in matching. SKF 38393 did not reduce matching accuracy at 2°C and did not affect matching accuracy at 2°C. Drug and cold effect results include the analysis of changes in slope (retention) and y-intercept (stimulus encoding) of the matching accuracy gradient. These data suggest that D1/D2 receptors are more important in modulating working memory than the D3 receptor, and these receptors may not be directly involved in cold-induced working memory deficits.

The contribution and optimum mode of stimulation of dopamine D2 receptors in the treatment of Parkinson's disease (PD) remain poorly defined. To define stimulation mode in one experiment, the long-acting, selective D2 agonist A77776, N,N,N,N-tetrahydro-3'-[[(4-(dihydrol-5,6-dihydroxy-1H-benzazepin-2-yloxy)[1,4]diazine hydrochloride] (Kebabian et al., JPB 1992; 229; 203) was administered daily for 7 days at doses ranging from 0.05 to 10 mg/kg, s.c., in MPTP-exposed, parkinsonian cynomolgous monkeys with levodopa-induced dyskinesia (UD). Following the first dose (0.5 mg/kg), all monkeys quickly showed a definite antiparkinsonian response for at least 8-12 hrs with increased ambulation persisting overnight. Only mild dyskinesia and stereotypies were seen. A second dose the next day was not as effective, and the level of motor activity progressively declined in 3 animals but remained above baseline values during the last 5 days of treatment. In spite of the active administration of high doses, in another parallel paradigm, the short-acting D2 agonist SKF 82958 (6-bromo-7-hydroxy-3,4-alkyl-1-phenyl-2,3,4,5-ethylhydro-1H-benzazepine hydrobromide) was administered to drug-naïve, MPTP-exposed, parkinsonian cynomolgous monkeys at 4 doses ranging from 0.025-0.1 mg/kg s.c. Three days for 4 weeks of intermittent administration were given in all animals for 30-50 minutes following each dose. However, after several days of treatment and especially in the last 2 weeks of the protocol, the drug response significantly shortened (20-30 min) in all animals and choreomimic dyskinesia developed in 2 white park response was maintained. These data clearly shows that selective D2 receptors stimulation can effectively relieve parkinsonian features and lead to dyskinesia similar to that seen in PD over long periods of treatment. D2 receptor occupancy should be avoided. The mechanisms for such pharmacological behavior and ways to prevent it must be explored further. [Supported by FRSG and MRC (Canada)].

558.10 BEHAVIORAL AND BIOCHEMICAL STUDIES ON THE INTERACTION OF THE NMDA ANTAGONIST MK-801 AND THE D2 ANTAGONIST HALOPERIDOL. H. Dai*, R.J. Carey, VA Medical Center, Research Service 151, Syracuse, NY 13210.

Thirty two male rats were assigned to four groups and were given saline, MK-801 (0.3 mg/kg), haloperidol (0.5 mg/kg) and MK-801/haloperidol combined treatments. The behavioral data of locomotor activity showed that the NMDA antagonist MK-801 induced hyperactivity, haloperidol induced hypoactivity but that the activity of the combined MK-801/haloperidol group was identical to the saline animals in both total locomotion distance and the within session habituation pattern. On the other hand, the Ex vivo biochemical data revealed no significant effect by MK-801 on dopamine metabolism, nor did MK-801 modify haloperidol effects on dopamine metabolites turnover ratios. None of the drug treatments had an effect on brain serotonin metabolism. Haloperidol, however, significantly increased serum 5-HT level. No drug treatment affected plasma catecholamine or plasma corticosterone levels. Taken together all these results supports the hypothesis that the effect of MK-801 on behavior is independent of biochemical changes in dopaminergic transmission.

The purpose of this study was to determine whether amphetamine-treated rats can learn to suppress stereotypy head movements. Rats implanted with cannulas were reinforced with intravenous infusions of milk for holding their heads stationary within a narrow area defined by intersecting photobeam mounted in the horizontal and vertical planes. Concurrent interference of these photobeams activated an infusion pump, which delivered milk at the rate of 2 cc/min for the duration of the interruption. Each rat was given chronic infusions of amphetamine (2 mg/kg) learned to hold their heads within the intersecting photo beams. The amount of milk ingested as a result of these photobeam over trials at a rate that was comparable to that of bottle-fed rats. Analysis of the temporal distribution of photobeam interruptions showed a highly frequency pattern that differed markedly from the sustained pattern found in saline controls. These results support the view that the locomotor and stereotypic effects of amphetamine involves an instrumentally learned behavioral adaptation.

(Supported by NIDA grant DA 04592)

The effects of a reference neuroleptic, haloperidol, were compared with those of three atypical antipsychotic agents (clozapine, DuP 734 and risperidone) and a S-HT₂ antagonist, ritanserin, in a number of procedures. Drugs were first examined in mice over a wide dose range using a primary observation method in order to target the doses for other studies. Haloperidol (0.125-2 mg/kg) was distinctly active in all procedures except for marked catalepsy. Risperidone was more potent than the other compounds in many of the procedures, often having activity at doses well below 1 mg/kg. Neither clozapine (1.0-16 mg/kg) nor DuP 734 (0.5-8 mg/kg) induced catalepsy in rats yet both drugs appeared to antagonize apomorphine-induced hyperactivity at doses less effective against apomorphine- or apomorphine-induced stereotypes in mice. Clozapine and DuP 734 along with ritanserin, also clearly blocked mescaline-induced scratching. Ritanserin (2-16 mg/kg), in general, did not have a behavioral profile like those of the other four drugs. All compounds also differed with respect to their actions as antagonists of PCP-induced stereotypes and SKF 10047-induced hyperactivity in rats. In view of the clinical findings currently available with these drugs, it appears highly useful to employ a series of methods in order to identify novel antipsychotics that differ from haloperidol. Absence of cataleptogenic properties of apomorphine-induced hyperactivity would appear to be useful criteria.

Effect of NO synthase inhibition on behavioral changes induced by a single administration of methamphetamine. Tomohiro Abe*^tai, Teppei Ohmori and Touruaka Koyama.

Department of Psychiatry and Neurology, Hokkaido University School of Medicine, Sapporo, Japan

The present study examined the effects of nitric oxide synthesis inhibition on behavioral changes induced by a single administration of methamphetamine (MA). Rats received one subcutaneous injection of MA (3.22 mg free base/kg). Nitric oxide synthase inhibitor, Na-nitro-L-arginine methyl ester, LNAME (10,30 and 60 mg/kg) were administered intraperitoneally 1 hr prior to injection of MA or saline. MA increased locomotion-stereotypy rating scores and motor activity counts measured by an infrared sensor. LNAME (30 and 60 mg/kg) administered 1 hr prior to MA significantly decreased the level of locomotion stereotypy rating and motor activity induced by MA. The results suggest that NO synthesis is involved in the full expression of behavioral effects of MA.

The noncompetitive NMDA receptor antagonist (+)-disocilpine fails to prevent sensitization to apomorphine-induced lever-rotational behavior in rats with nigrostriatal lesions. S Gancher* and A Mayer, Dept of Neurology, Oregon Health Sciences University, Portland, Oregon, 97201.

Sensitization to CNS stimulants is well described and is reportedly prevented by the noncompetitive NMDA recep- tor antagonist (+)-disocilpine (MK-801). We sought to deter- mine if MK-801 pretreatment prevents sensitization to apomorphine (AP0)-induced rotational behavior in rats with unilateral nigrostriatal lesions. Six rats were lesioned with 6-OHDA, and beginning 2 weeks later, received 8 daily doses of MK-801 (0.1 mg/kg, ip) followed 30 min later by AP0 (0.1 mg/kg, sc). Three and 5 days later, single doses of the D1 agonist SKF38393 (2 mg/kg) AP0 (0.1 mg/kg, day 5) were administered with or without MK-801 pretreatment. Despite MK-801 pretreatment, the rotational behavior increased, with a peak over the protocol (for doses 1, 4, and 8, total and peak/5 min rotations were 104 and 24, 407 and 92, and 576 and 85, respectively, p=0.05). The dose of SKF induced 1624 rotations. MK-801 enhanced AP0 rotations; in comparison with AP0 alone, AP0 alone induced 449 rotations (p=0.05). In a separate experiment, 3 rats received MK-801 + AP0 on postlesion day 14, and 3 days later, received 2 mg/kg SKF 38393; as reported by Morelli et al, SKF 38393 failed to induce rotational behavior. These data suggest that in contrast to sensitization in unlesioned animals, lesioned animals sensitive to AP0 despite NMDA channel blockade.

QUINOLINIC ACID-INDUCED LESION OF THE SUBSTANTIA NIGRA PARS RETICULATA: BEHAVIOURAL AND NEUROCHEMICAL EFFECTS. B. zdazov*, M. Bubser and W.J. Schmidt. Department of Neuropsychology, University of Tübingen, D-72074 Tübingen, Germany.

As one of the major output structures of the basal ganglia (BG) the substantia nigra pars reticulata (SNr) is part of the motor loop through the BG and thus is involved in the performance of motor behaviour. The SNr receives information from the striatum and sends inhibitory GABAergic projections to the thalamus and the deeper layers of the superior colliculus. The present study investigated the role of the SNr in mediating motor behaviour in male Sprague Dawley rats. The SNr was bilaterally lesioned with the excitotoxin quinolinic acid (2 x 30 nmol/5 μl side). Locomotor activity and exploration were tested in an open field with holeboard and sniffing stereotypy was tested in an experimental chamber (Schmidt, W.J., 1986, Psychopharmacology 90: 123-130). Both locomotor- and sniffing activity were increased after SNr lesions, whereas exploration was not changed. The histological verification of the SNr lesions demonstrated that in most cases a part of the substantia nigra pars compacta was also lesioned. The levels of dopamine (DA) and its metabolites (DOPAC, HVA) in the anterior and posterior striatum and in the nucleus accumbens were analysed post mortem with HPLC with electrochemical detection. DA and DOPAC were reduced in all three structures, whereas HVA was only reduced in the anterior striatum. The metabolism of dopamine (measured as DOPAC/DHA and HVA/DHA) was increased in the anterior and posterior striatum. These increases correlated significantly with the increases in locomotor- and sniffing activity. In conclusion, bilateral lesions of the SNr and thus reduced activity of this structure results in an increase of motor activity. This increase may be explained by the deficient inhibitory effects of the SNr on the thalamus and the superior colliculus, but also by the increased dopamine metabolism in the striatum. Supported by EMPT 01KL90080 and SFB 307/4A.

POTENTIATION OF THE D-HYDROXYDOPHINE DISCRIMINATIVE STIMULUS BY PHOSPHODIESTERASE INHIBITION AND THE EFFECT OF RECEPTOR RESERVE ON D₂ AGONIST SUBSTITUTION, Q.D. Walker¹, D.M. Black¹, D.A. Eckerman¹, D.E. Nichols¹ and R.B. Malinak¹. Curriculum in Toxicol., Univ. of N. Carolina, Chapel Hill, NC 27599; and Dept. Med., Chem. Purdue Univ², West Lafayette, IN 47907.

In rats, administration of the full D₂ agonist dihydroxypoline (DHP, 2 mg/kg) induces robust discriminative stimulus (DS) effects that are mediated selectively by D₂ receptor stimulation. We investigated whether the DHP cue was also mediated by increased intracellular concentrations of cAMP. The phosphodiesterase inhibitor rolipram (0.75, 15, or 30 μg/kg) was administered either alone or in combination with doses of DHP (0.25 or 0.5 mg/kg or SKF38393 (1.0 or 2.0 mg/kg) that induce little drug appropriate responding. Rolipram (15 μg/kg) and DHP (0.25 mg/kg) induced 0 and 7% DHP lever responding, respectively, when administered alone, but 50% when coadministered. Rolipram also synergistically increased SKF38393 substitution. Coadministration of rolipram (50 μg/kg) and SKF38393 (2.0 mg/kg) induced 67% drug lever selection, although the compounds induced only 15 and 29% drug lever selection, respectively, when administered alone. The second series of experiments tested the hypothesis that D₂ receptor reserve explains the complete substitution of the partial agonist SKF38393 for the DHP cue. EEDQ (10 mg/kg) was administered with a receptor protocytic cocktail (pirazin, ketanserin, remisedrine) to decrease D₂ receptor number by about 50%. Forty-eight hr after EEDQ, rats were administered desipramine (10 mg/kg) that substituted >90% prior to EEDQ treatment. Administration of EEDQ significantly decreased the substitution of SKF38393 (97% vs. 26%) but did not affect substitution of DHP (98% vs. 74%). These results coupled with information to mediate the DS effect by D₂ and that SKF38393 substitutes for DHP by occupying a greater proportion of the DS receptor population than does DHP.
559.1

Much evidence suggests that glutamate plays a role in the spinal transmission of the reflex autonomic responses to static contraction. Previously we measured the reflex increase in arterial pressure evoked by static contraction of the hindlimbs muscles in chloralose-anesthetized cats before and after glutamatergic receptor blockade in the lumbosacral cord. The reflex pressor response in this reaction was unaffected by NMDA receptor blocker AP-5 (500 μg, i.v.), but was significantly attenuated by non-NMDA receptor blocker CNQX (10 μM, i.v.). These findings suggest that the glutamatergic reflex activation of the spinal cord was mediated by non-NMDA receptor activation, possibly through NMDA receptors activated by the glutamatergic neurotransmitter system.

SPINAL RELEASE OF SUBSTANCE P DURING MUSCLE CONTRACTION: EFFECT OF S-HT4 RECEPTOR ACTIVATION. A.C.L. Nogueira, A.F. Menin, A. Akly, L.B. Wilson. Harry S. Moss Heart Center, University of Texas Southwestern Medical Center, Dallas, TX 75235-9934.

Static muscle contraction increases mean arterial pressure (MAP) and substance P (SP) release in the dorsal horn of the spinal cord. Activation of 5-HT4 receptors in this region attenuates the reflex pressor response to contraction. This study evaluated the effect of microinjection of 8-hydroxy-2-(dipropylaminophenyl)tetralin (DPAT; 5-HT4 agonist) into the L6 dorsal horn on the release of SP during contraction using anesthetized cats. Ipsilateral to the muscle to be contracted, all ventral and dorsal roots from L6 to S1 were severed, except the L6 dorsal root. Static contraction of the triceps surae muscle was induced by alternate electrical stimulation of the distal ends of L6 and S1 ventral roots for 5 min (3X motor threshold; 30 Hz; 0.1-0.3 mA). All the discharges from a pair of probes, placed in the L6 dorsal horn region ipsilateral to the contracting muscle, were analyzed for SP-like immunoreactivity (SP-LI) using a radioimmunoassay. DPAT (10 μM, n = 8) attenuated the MAP response to contraction (control: 38 ± 11; DPAT: 10 ± 3 mmHg; P < 0.05). Likewise, the heart rate response was also blunted (control: 13 ± 3; DPAT = 7 ± 3 bpm; P < 0.05). However, the SP-LI values during contraction were unaffected by DPAT (control = 0.46 ± 0.028; DPAT = 0.501 ± 0.034 fmol/100 μL; P > 0.05). These results suggest that the modulation of the pressor response to contraction by 5-HT4 receptors in the dorsal horn is not mediated through inhibition of SP release.

SYSTEMIC 2-DEOXY-D-GlUCOSE LEADS TO EXCITATION OF ADRENA L ME DULLARY SYMPATHETIC PREGANGLIONIC NEURONS. S.F. Morrison, Dept. of Physiology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Adrenal medullary release of epinephrine and the subsequent stimulation of glycolysis and gluconeogenesis are important components of the physiological response to hypoglycemia. To determine the central pathways controlling catecholamine secretion by the adrenal medulla, the responses of the adrenal medullary sympathetic preganglionic neurons (AdSPNs) to 2-deoxy-D-glucose (2-DG) administration (200mg/kg, iv.) were studied in urethane-chloralose-anesthetized, artificially-ventilated rats. AdSPNs were identified by their antidromic responses to adrenal nerve stimulation and were localized in the rostral ventrolateral medulla (RVM). Ten minutes after 2-DG injection, the basal discharge rate of AdSPNs had increased (p<0.001) from 5.8 Hz (control) to 9.2 Hz. Subsequent bilateral intracarotid injection of musculin (25 nmol) into the RVM eliminated the 2-DG-induced increase in AdSPN discharge, although a low level of AdSPN discharge remained. The increase in AdSPN discharge following 2-DG was not different in animals with transections of the neuraxis rostral to the superior colliculus. These results suggest that activation of AdSPNs is a brainstem-mediated component of the neural response to the blockade of glucose utilization by 2-DG and that RVM neurons may be necessary for this response. Supported by NIH HL47196.

SPINAL NMDA RECEPTOR MEDIATES c-tos EXPRESSION FOLLOWING HYPOTENSION IN THE CONSCIOUS RAT. Huang, W. and West, M.J.* Department of Medicine, University of Queensland, Prince Charles Hospital, Brisbane, QLD 4022, Australia.

Recent studies show that baroreflex-induced vasocconstrictor responses following hypotension are attenuated by the administration of the NMDA receptor antagonist AP5. We have examined the effect of intrathecal AP5 on spinal cord c-tos expression induced by hypotension in conscious rats. c-tos or saline were administered intrathecally prior to a 50 minute infusion of sodium nitroprusside which lowered blood pressure by 30 mmHg. Animals were subsequently killed under general anaesthesia and the medulla and spinal cord processed for demonstration of c-tos protein using immunocytochemistry. c-tos neuronal immunoreactivity (Fos-IR) was observed in the rostral and caudal ventrolateral medullae and nucleus tractus solitarius and in the intermediolateral cell column (IML) of the spinal cord with the highest segmental concentration in segments T7-T10. At the level of the intrathecal administration of AP5, T9, there was a significant reduction in Fos-IR cells in the IML in animals given AP5 compared to those given saline (125 ± 6.9/segment (n=3) vs 235 ± 6.5 (n=2); P<0.05). There were no differences between treated and control animals in the medulla or other segments of the spinal cord. The results show that (i) following hypotension, cells in IML of segments T7-T10 show maximal expression of Fos-IR and (ii) AP5 inhibits c-tos expression. We conclude that spinal NMDA receptors in IML of spinal cord are involved in central baroreflex control of the circulation.

559.5

Anatomically localized nitric oxide (NO) synthase activity in the spinal cord intermediolateral column. The present study was designed to investigate the possibility of the spinal NO in the central regulation of blood pressure. No. The results obtained in intracisternal (i.c.) injection of NO donor, sodium nitroprusside (SNP; 1, 5 and 15 nmol) produced dose-dependent increases in BP. The vasopressor action of SNP (15 nmol) was completely blocked by pretreatment with the N-methyl-D-aspartic acid (NMDA) receptor antagonist, D,L-2-amino-5-phosphonopentanoic acid (10 μM, i.v.). This effect was also attenuated by the vasopressor effect of SNP (i.c.), 15 nmol) was completely blocked by pretreatment with the N-methyl-D-aspartic acid (NMDA) receptor antagonist, D,L-2-amino-5-phosphonopentanoic acid (10 μM, i.v.). In addition, i.v. injection of an inhibitor of NO synthase, N-nitro-L-arginine methyl ester (20, 100 and 1000 nmol) evoked dose-dependent decreases in BP. These results suggest that NO generated in spinal cord plays a role in the regulation of BP. Furthermore, the vasopressor action of the spinal NO seems to be tonically active and to be mediated via its interaction with the glutamatergic system in the spinal cord.

SECOND MESSENGER MODULATION OF MEMBRANE POTENTIAL OSCILLATIONS IN SYMPATHETIC PREGANGLIONIC NEURONS. D. Sonnenwirth, M.L.H.J. Henkes and I.P. Remaut, Neurosciences Unit, Leibniz Research Institute, Otto-von-Guericke-University, Magdeburg, Germany.

The presence of spontaneous oscillations in sympathetic preganglionic neurons (SPNs) endows these neurons with the ability for rhythmogenesis, which can be substantially enhanced by means of drugs that either block or stimulate, ions, single spike discharge or combinations of these. This activity is thought to reflect electrolytic coupling between SPNs, the oscillation representing an action potential discharged in an neighbouring neuron. Furthermore, these oscillations and rhythmic activity are subject to modulation by neurotransmitters such as serotonin and noradrenaline (Logan et al., '93). We have utilized whole-cell recording techniques in a spinal cord slice preparation to further investigate factors involved in the regulation of rhythmogenesis in SPNs, in particular the effects of elevating intracellular calcium and cAMP. The permeability of the membrane potential forming of cAMP and cAMP has a complex blockage, bicuculline, ischaemic periods or absence of cAMP (ACPD) 100 μM). The spontaneous oscillations were relatively unaffected by nifedipine (10 μM). Superfusion of cAMP (10-20 μM) induced oscillations and rhythmic activity is produced in cAMP signalling pathway of these neurons evoked a LD evoked in the presence of cAMP.

These data suggest that rhythmogenesis in SPNs is subject to regulation being induced by intracellular calcium release and inhibited by stimulation of cAMP production (Sonnenwirth et al., '93).

MEDULLARY STIMULATION CAN EVOKE IPSPS IN SYMPATHETIC PREGANGLIONIC NEURONES IN THE BRAINSTEM-SPINAL CORD PREPARATION. Susan A. Drooght,* S.P. Morrison, R.M. Sawyer and M.P. Gilbert, Royal Free Hospital School of Medicine, Rowland Hill Street, London. NW3 JPF U.K.

In the neonatal rat brainstem-spinal cord preparation using whole cell patch recordings, we have shown that stimulation of the retrolenticular meningeal cells elicits multiphasic EPSPs in sympathetic preganglionic neurons (SPNs) mediated by both non-NMDA and NMDA receptors (Marks and Morrison, J. Physiol. 475, 159. 1994). We report here that medullary stimulation can also evoke IPSPs in SPNs. IPSPs were identified on the basis of their antidromic activation following stimulation of the ventral root and their morphology and location within the spinal cord. Stimulation of the retrolenticular meningeal (RLM) pulse (6 ms, 100-1000 μA) elicited IPSPs in 10 SPNs at holding potentials more positive than -50 mV. The mean latency to onset of these responses was 34.4 ± 4.1 ms (mean ± S.E.M.) and the amplitude at membrane potentials of -40 mV was 5.77 ± 1.0 mV. These IPSPs persisted in the presence of the excitatory amino acid receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) and D-2-amino-5-phosphonovaleric acid in all but one of the SPNs tested. Indeed, sometimes blockade of the EPSP was necessary to reveal an IPSP. In the presence of these antagonists, hyperpolarizing the neurons decreased the amplitude of the IPSPs until reversal occurred at membrane potentials more negative than -60 mV. On two occasions both applications of 5 μM bicuculline blocked the evoked IPSP. These results indicate that medullary stimulation can evoke IPSPs in SPNs which involve activation of GABA receptors.

The anti-dopamine beta-hydroxylase immunotoxin (DHB) is a recently developed neurotoxic lesioning tool. In the first study, we examined the degree of sympathetic achieved in adult and neonatal rats given DHB peripherally. 30 μg of DHB was injected i.v. into anesthetized, adult, male Sprague-Dawley rats. 7 days later animals were unanesthetized and cannulated. 3 days later DHB was injected subcutaneously and 4 days later DHB was injected with a 10 day latency. Plasma was drawn before and after tyramine (300μg/kg) administration to document residual and tyramine evoked peripheral responses. DHB treated animals had significantly less basal (33%) and tyramine stimulated (20%) plasma norepinephrine levels than controls. Plasma epinephrine was unchanged. Basal blood pressure and heart rate were not significantly changed. One day old neonatal rats were injected subcutaneously with 4μg of DHB and sacrificed at 1,3,6, and 13 days afterward. Nissl staining of superior cervical ganglia from day 3 animals showed no differences compared to sham operated controls. In the neonatal study, sequential doses of DHB may be necessary to lesion remaining neurons and adrenal chromaffin cells in adults. The ability of a single dose of DHB to deplete adrenal catecholamines in neonates is an advantage over previous sympathetic pathway methods.

MEMBRANE PROPERTIES OF SYMPATHETIC GANGLION CELLS IN GENETICALLY HY珀TENSIVE OR HY珀RATIVE RATS. A.P. Gokin1,2,3 and C.J. Forehand1. Bipolom ometz Inst. of Physiol., Kiev, Ukraine, 262024 1Dept. of Anat. and Neurobiol., Univ. of Vermont, Burlington, VT, 05405.

Increased sympathetic nerve activity in the spontaneously hypertensive rat (SHR) may be partially due to alteration of the membrane properties of postganglionic neurons. Since the SHR also exhibits significant behavioral hypertensive response to stress, the relationship of neuronal alterations in SHR to the hypertensive phenotype is uncertain. To determine whether the decreased accommodation observed in SHR ganglion cells (Yarowsky and Weinrich, Hypertension. 26, 255, '88) is associated with hypertension, we examined active and passive membrane properties of cells in four inbred rats (WKY, SHR, Wistar-Kyoto, and WKAH). The SHR is both hypertensive and hyperactive; WKY is neither. The WKHA is hypertensive; the WKHT is hypertensive, but not hypertensive.

Membrane properties were examined in 24 WKY and 40 WKHA superior cervical ganglia cells. No significant differences were observed in resting membrane potential, input resistance, the after hyperpolarization, and transient outward current for action potentials generated among the four strains. In contrast, the number of action potentials generated during a 1 nA, 400 msec depolarizing pulse was significantly greater in both hypertensive strains compared with WKY and WKHA and less in WKY. The WKY (2.9 ± 0.56); the WKHA ganglion cells generated an intermediate number of action potentials (3.6 ± 0.63). The decreased ganglion cell accommodation correlates with an overall decrease in the number of neurons in each population that exhibited a non-phaic response (±4 action potentials) to the 400 msec stimulus: 21% in the WKY, 26% in the WKHA, 32% in the SHR and 48% in the WKHT.

The major aim of the present investigation was to determine whether sympathetic components of peripheral nerves (PN) were modulated by cardiac- or respiratory-related vagal afferent and/or chemoceptor input. In Saffan-anesthetized, paralyzed and artificially ventilated (100% O2) newborn piglets aged 1-40 days, different branches of PN were recorded along with CS phrenic (PHR) root activity, A0, EKG, and EEG. Age-related differences were observed for both types of modulation which were independent of vagal afferent inputs. Piglets < 1 wk old exhibited very little spontaneous PN activity related to either cardiac or respiratory rhythms. However, respiratory-related activity in PN increased with age in older piglets. Cardiac modulation by respiratory rhythm was revealed by coherence spectral analyses as indicated by significant coherence estimates over the 3-5 Hz range; such coherence was stronger in older piglets. Hypoxia significantly increased coherence regardless of age. The results indicate that cardiac and respiratory modulation of postganglionic sympathetic activity is delayed postnataally compared to preganglionic recordings. (Gootman et al. Am. J. Physiol. 1991; 261:R147). (Supported by NIH grant HD-28931).

INSPIRATORY COMPONENT OF SPLANCHIC SYMPATHETIC NERVE ACTIVITY IS RESISTANT TO THE SYMPATHOLYTIC DRUG CLONIDINE. N. Koshiya* and P.G. Grover, Dept. of Pharmacology, University of Virginia Health Sciences Center, Charlottesville, VA 22908.

Splanchnic sympathetic nerve (SN) and phrenic nerve discharges (PND), and arterial pressure (AP) were recorded in rats that were either vagotomized, aortic depressor/paralyzed, and artificially ventilated Sprague-Dawley rats (n=7). SNP and PND were rectified, analog integrated at 30 ms retset-interval and digitized. Distribution of the SNP in the central respiratory cyclus was analyzed by mean of PND burst-triggered averaging. During control period, mean AP was 106±10 mmHg (mean±SEM). SNP distributed throughout the respiratory cycle with increased activity in inspiratory/early-inspiratory phase and peak activity in the post-inspiratory phase. Splanchnic nerve was given i.v. at small (15-20 μg/kg, n=6) and large doses (200-250 μg/kg, n=7). Small dose of clonidine produced brief hypotension (<30 sec, 150±20 mmHg peak) followed by moderate hypotension (80±20 mmHg) which was accompanied by a reduction in SNP (<50% control value). Large dose of clonidine produced sustained hypertension (>10 min, 137±33 mmHg) accompanied by silence of SNP. During the sustained hypertension, the vasocilatator sodium nitroprusside was administered i.v. (80-150 μg/kg). The nitroprusside-induced hypotension retrieved a component of SNP which was barosensitive but resistant to clonidine. During those hypotensive periods (both after small dose of clonidine and during nitroprusside-induced hypertension after large dose of clonidine), SNP was largely attenuated in respiratory phase and, in most cases (6 out of 7), SNP showed single inspiratory peak with very small activities in the post-inspiratory/expiratory period. In 2 cases, despite the substantial decrease in total SNP, the amplitude of the remaining inspiratory peak was virtually unchanged from the control level. These results suggest that the sympatholytic drug clonidine works on the sympathetic nervous system throughout the respiratory cycle and, the central inspiratory-related component of SNP is least sensitive to the drug.
559.13

Increasing evidence suggests that parasympathetic ganglia are sites of complex synaptic integration rather than simple relay stations. The present study was done to establish whether direct afferent input to parasympathetic neurons of mammalian ganglia may provide another mode of synaptic modulation. Whole mount preparations from the guinea pig cardiac were utilized to localize afferent inputs by immunohistochemistry.(1) The results of these studies are reviewed. Immunohistochemical analysis demonstrated that most parasympathetic neurones were surrounded by fibers immunoreactive for both substance P (SP) and CGRP. Intracellular recordings were obtained from individual parasympathetic neurones maintained in an oxygenated Krebs solution at 37°C. Action potentials could be elicited both by intracellular current injection and stimulation of interganglionic fiber bundles. In some cells, high frequency (1-10 Hz) interganglionic fiber stimulation produced a slowly developing depolarization of 4-10 mV which lasted for 5-30 sec. These depolarizing events were unchanged in the presence of 100 μM benzamidinium and 1 μM atropine but were significantly diminished by superfusion with calcium chelate solution. A prolonged depolarization was also produced by local application of capsaicin (1 μM), which releases both SP and CGRP from afferent terminals. Direct application of either SP or CGRP (100 μM) by pressure injection depolarized these neurones. This peptide-induced depolarization was often associated with a decrease in input resistance and an increase in excitability. We suggest that the slowly developing depolarization produced by interganglionic fiber stimulation is due to the release of SP and/or CGRP from afferent terminals. Further, we suggest that afferent input to the cardiac ganglia may be involved in local reflex modulation of the parasympathetic cardiac neurones. GUANETHIDINE: EVOKES Vasodilatation IN MESENTERIC ARTERIES BY ACTING ON SENSORY NERVES. Z.-I. Zheng, K. Shimamura, T.L. Anthony and D.L. Krueger*. Department of Physiology, West Virginia University, Morgantown, WV, 26506.

Capsaicin-sensitive sensory nerves mediate an endothelium-independent, NANC vasodilatation in guinea-pig mesenteric arteries. This vasodilatation is potentiated by previous administration of guanethidine (30 μM) presumably through depletion of vasoconstrictor neurotransmitters from sympathetic nerves. Our current hypothesis is that guanethidine also releases transmitter(s) from capsaicin-sensitive sensory nerve and thereby invokes vasodilatation. To test this hypothesis, segments of endothelium-denuded mesenteric arteries (5.8 mm long, 200 μm wide) were suspended in tissue bath (50 ml) containing normal Krebs solution and stretched to L0. Each vessel was precontracted with methoxamine (30 μM). Administration of sodium nitroprusside evoked a 100% relaxation of these vessels. Administration of guanethidine (30 μM) evoked a 72±5% relaxation of the precontracted vessels. Pretreatment with capsaicin (10 μM) reduced the guanethidine-induced vasodilatations to 22±7%. The NOLA-mediated effects could be almost completely reversed with hydroxyquinidine (HQQ, 10 μM), an intermediate of nitric oxide, but not L-arginine (1 mM). To determine whether this effect of guanethidine on sensory nerves was dependent on transport, the vessels were pretreated with cocaine (5 μM) for 5 min or ouabain (25 μM) for 15 min. Cocaine decreased the guanethidine-induced vasodilatations to 35±14%. Likewise, ouabain diminished the guanethidine-induced vasodilatations to 35±14%. However, cocaine, diminished the guanethidine-induced vasodilatation to 9±5%. The guanethidine vasodilatation was not affected by propranolol (100 μM), 6-hydroxydopamine (6-OHDA, 30μM) or tetraodoxidine (TTX, 10 μM). Support: NIH-NS 27781.

POSSIBLE ROLE OF THE FUNDUS STRIATA VP RECEPTORS IN BLOOD PRESSURE (BP) CONTROL. P. Krnac, M. K. Cooper* and G. J. Pitkanen. Neuroscience Research Group, University of Calgary, Calgary, Alberta, T2N 4N1, CANADA.

Vasopressin, given intracerebrally to rats, can induce motor disturbances, increases in BP and antipyresis. The possibility that highly concentrated vasopressin binding sites in the fundus striati (FStR) could participate in these effects was investigated using chronically implanted cannulas aimed at this area. A unilateral bilateral injection in the FStR of 100μg/μl VP did not induce motor disturbances (scored visually) after the first and even the second injection 24 hours later. This body temperature recorded simultaneously (i.p. minitnter) was not altered by the VP injections. After a bilateral injection of 100μg/μl/25μl VP in the FStR, the fever induced by an i.p. injection of the lipopolysaccharide of X. Coll (50μg/kg) or by interleukin 1β (0.1μg/kg) was not affected. In contrast, a bilateral injection of 100μg/ μl/25μl VP into the ventral tegmental area (VTA), induced an increase in BP (19.1±2.24 mmHg, p<0.001) compared with saline controls while the heart rate was not modified (p>0.4). This increase in BP was blocked by a V1 antagonist; OT and a V2 agonist were ineffective.

This study suggests then that the VP receptors in the FStR could intervene in the regulation of the BP together with other regions known to be implicated in such a role.

AUTONOMIC STRUCTURES IN RAT BRAIN SHOW INCREASED NUMBERS OF C-FOS POSITIVE CELLS DURING CLONIDINE WITHDRAWAL. B.L. Stennett, M.E. Fisher and P.G. Guzelsu*. Department of Pharmacology, University of Virginia Health Sciences Center, Charlottesville, VA 22908.

Animals and humans become dependent on clonidine (clon) following chronic administration of this α₂-adrenergic receptor (α2) agonist as revealed by either spontaneous or antagonist induced behavioral and autonomic withdrawal symptoms. The present study sought to determine whether specific autonomic areas of the brain would exhibit increased c-fos mRNA during clon withdrawal to the presence of c-fos nuclear protein as an indication of cell activation. Seven male Sprague-Dawley rats were briefly anesthetized with ether and implanted subcutaneously in the back of the neck with Alzet osmotic minipumps containing either 200μg/h clon or saline. After 5 days, these animals were returned to their home cages and after 7-10 days were injected i.p. with either saline or the α2 antagonist yohimbine (5μg/kg) and 2 hours later were deeply anesthetized with Nembutal (i.p. and perfused with 4% paraformaldehyde). Brain tissue was cut in the frontal plane and sectioned on a cryostat in 20 μm sections. Sections were incubated in c-fos antibody (Santa Cruz) and reacted for immunoreactivity using a standard avidin-biotin complex with VIP as the coimmunostaining substrate (Vector). Rats were run in the experimental protocol in 4 groups of 4 or 5. The groups consisted of 3 control rats (sal-sal, sal-clon-sal) and 1 or 2 experimental rats (clon-sal).

All experimental rats showed behavioral symptoms of withdrawal such as wet shaking, paw shakings and increased locomotion and escape behavior while none of the control rats exhibited these behaviors. An increase in the c-fos mRNA expression in the clon+ at withdrawal (clon) was noted in many brainstem autonomic structures including rostral ventrolateral medulla (RVLM) and raphe nuclei. Brainstem neuronal c-fos mRNA expression was expressed with the following symbols:

- This increase was quantified for RVLM, (R1.6 6 4 4 cells/sec in section co/col 3 5.0±0.8 in clon/sal, 8.2±1.0 in sal/sal and 7.3±1.4 in sal/sal) and LC (22 884.0 cells/sec in clon+ at 3 8.5±0.5 in sal/sal, 4.8±0.7 in sal/sal and 4.4±0.7 in sal/sal).
- The increase in neuronal activity in brainstem autonomic areas could explain the rebound hyperactivity observed during clonidine withdrawal.

60.3 CARDIOVASCULAR EFFECTS ELICITED BY MICROINJECTIONS OF NEUROPEPTIDE FF (NPPF, MORPHINE MODULATORY PEPTIDE) IN THE NUCLEUS TRACTUS SOLITARIUS. J.H. "Jhamandas", K. Harris and K.H. "Kanagasabapathy. Department of Medicine (Neurology) & Division of Neuroscience, University of Alberta, Edmonton, Alberta and Department of Pharmacology & Toxicology, Queen’s University, Kingston, Ontario, Canada.

Nucleus tractus solitarius (NTS), termination site of baroreceptor afferents is enriched in both NPPF immunoactivity and binding sites. The function of NPPF in this area is unclear. We have examined the potential of NPPF to influence blood pressure in the urethane anesthetized rat after microinjection of the peptide in the NTS. Unilateral injections of NPPF (0.2-1.0 nmol, 50-150 nl) produced elevation in blood pressure. The peptide induced hypertension was of a finite latency and outlasted the injection. Following apressor response, higher doses of peptide had to be injected to produce a similar response, suggesting a desensitization to its action. We also observed similar profile of pressor responses following unilateral injections of the NPPF analog (IDME)YBaFFa (0.2-1.0 nmol, 50-150 nl) within the NTS. Naloxone (2-4 mg/kg) administered intravenously failed to influence the effect of NPPF analog. Sites within the NTS where NPPF elicited the most consistent effect included medial and dorsomedial NTS at and just rostral to the level of area postrema. These results suggest that in the NTS, NPPF may serve to modulate cardiovascular function.

Supported by the Medical Research Council of Canada.

60.5 CHARACTERIZATION OF BRAINSTEM CIRCUITS FOLLOWING ELECTRICAL STIMULATION OF THE CENTRAL NUCLEUS OF THE AMYGDALA (CNA): A COMBINED C-FOS AND RETROGRADE TRACING STUDY. T. Petrow, J.H. "Jhamandas", T. Klotz, Department of Anatomy and Cell Biology and Medicine (Neurology), Univ. of Alberta, Edmonton, Alberta, Canada.

We have previously shown that electrical stimulation of the CNA induces expression of Fos (the product of the immediate early gene c-fos) in catecholaminergic (CA) neurons in the ventrolateral medulla (VLM) and the nucleus of the solitary tract (NTS). In this study we electrically stimulated the CNA and examined: 1) the connectivity of activated VLM neurons with the NTS; 2) the connectivity of activated NTS neurons with the VLM; 3) the proportion of activated CA neurons that project to the VLM or NTS respectively.

Rhodamine-labelled latex microspheres (RLL-LLM) were stereotaxically injected into the NTS; 4 days later, the ipsilateral CNA was electically stimulated for 60 min (20-50 mA, 10 sec pulse trains, 50 Hz, 100 pulses/sec) under urethane anaesthesia. In control animals the electrode was positioned in the CNA without delivery of current. Brains were then processed for Fos and toxine hydroxyroxyl (TH) immunocytochemistry. In the experimental animals increased number of profiles that contained RLL-LLM were Fos immunoreactive (IR) in the ventrolateral VLM and NTS. 1) In the VLM 30% of the Fos-IR cells projected to the NTS. 2) In the NTS 12% of the Fos-IR cells projected to the VLM. 3) Of the CNA activated, RLL-LLM containing neurons, 17% in the VLM and 2% in the NTS were also TH-IR.

The results indicate that local brainstem circuits between the VLM and NTS may be involved in mediating CNA-induced activation of medullary neurons. CA and non-CA autonomic cells may participate in a reciprocally activated NTS and VLM neurons.

60.6 ALTERATION OF THE CARDIAC BAROREFLEX APPEARS EARLY DURING PREGNANCY IN CONSCIOUS RABBITS. V.L. Brook*, and R.R. Quenell, Dept. of Physiology, Oregon Health Sciences University, Portland, OR 97201.

There is evidence that reflex increases in heart rate (HR) and other effectors are reduced during pregnancy. The present study tested the hypothesis that the change in baroreflex occurs early in pregnancy, coincident with increases in the steroid hormones estrogen and progesterone. Rabbits were treated with either estradiol valerate and vena cava catheters. When the animals were nonpregnant (n=8), the relationship between arterial pressure (BP) and HR was determined by first decreasing BP with infusion of increasing doses of nitroprusside (3.6,12.24,48 gg/kg·min)and then by increasing BP with phenylephrine (0.5,1,2,4 mg/kg·min). The median baroreflex was reassessed in the same animals (n=3-7) after about 1,2,3 and 4 wk of pregnancy (term is 31 days). Differences in the baroreflex curves between pregnant and nonpregnant rabbits were determined by comparing with ANOVA parameters generated by logistic analysis. BP was 65±2 mmHg in nonpregnant rabbits and was not significantly different in pregnant rabbits. HR increased (p<0.01) from 142±2 to 174±6 bpm after 3 and 4 wk of pregnancy. Baroreflex relationships between BP and HR were not altered after 1, 2 and 3 wk of pregnancy. However, maximal reflex gain decreased from 28.8±5 to 6.1±4 bpm/mmHg after 4 wk of pregnancy (p<0.01). These results indicate that the cardiac baroreflex of pregnancy, and support that increases in estrogen and progesterone do not mediate the changes that occur. Supported by NIH Grant HL 39923 and MRF of Oregon.

60.7 COMPARISON OF HEMORRHAGE- AND NITROPRESSURE-INDUCED Fos EXPRESSION IN BRAINSTEM NEURONS THAT PROJECT TO THE PARAVASCULAR CEREBRAL NUCLEUS (PVN). K.H. "Harriss", D. MacTavish, T.L. Krztof and J.H. "Jhamandas", Depts. of Medicine (Neurology), Anatomy & Cell Biology, Univ. of Alberta, Edmonton, Alberta, Canada T6G 2B7

We previously reported that hemorrhage-induced hypotension activates neurons in the nucleus of the solitary tract (NTS) and ventrolateral medulla (VLM) that project to the PVN. In the present study, Fos-immunoreactivity (FI) was used to compare the activation of PVN-projecting brainstem neurons in response to hemorrhage and sodium nitroprusside (SN)-induced hypotension. Under anesthesia, rats received injections of rhodamine-labelled latex microspheres into the PVN and were instrumented with arterial and venous cannulae. One week later, conscious rats (n=6) were hemorrhaged (5-6 ml) to lower and maintain arterial pressure (AP) to 30-50% of resting AP for 1.5 h. A separate group (n=6) received SN intravenously (4 mg/kg,0.5 ml) to lower and maintain the AP to 30-50% of baseline for 1.5 h. A comparable number of neurons with FI were observed at all levels of the NTS and VLM following both hypotensive stimuli. The only exception was the NTS, at the level of area postrema, where greater FI was found following hemorrhagic hypotension. In sham, controls, few neurons with FI were found. At all levels of the NTS, SN-induced hypotension led to FI in a significantly greater number of retrogradely labelled cells (40-50%) than in hemorrhaged animals (16-30%). These results show that both hemorrhage- and SN-induced hypotension activate medullary neurons in the NTS and VLM which project to the PVN. Moreover, quantitative analysis of FI following the two hypotensive stimuli suggests that a change in blood volume accompanying hemorrhage is not a significant factor in the activation of NTS and VLM neurons.

60.8 ACUTE BLOOD PRESSURE CHANGE ELICITS HIPPOCAMPAL THETA RHYTHM AND BEHAVIOURAL AROUSAL IN THE UNRESTRAINED CONSCIOUS RABBIT. Jing-Hu Tan* and W.W. Bloss, Centre for Neuroscience, Flinders University, Bedford Park, SA 5042, Australia.

Acute changes in arterial blood pressure (AP) cause arousal from sleep in lambs (Fowell and Johnson, Brain Res. 121 (1977) 154) and monkeys (Krukoff et al., Physiol. (256) 1989 H434), a response mediated via baroreceptor afferents. arousal is accompanied by desynchronisation of the neocortical EEG, but no studies have reported the effect of blood pressure changes on hippocampal theta rhythm. In tri-geminal operations in New Zealand White rabbits (3-2 kg), anaesthetised with 1% halothane, we implanted micro-tip bipolar EEG electrodes in the skull and the lateral hippocampus, a capsule occluded around the thoracic inferior vena cava, and cannulae in an external jugular vein and a common carotid artery. The lines were kept open by constant infusion of heparinised saline. The rabbit remained in a cage on a swivel on the roof for freely accessing electric and fluid channels. The EEG and AP signals were recorded with MacLab (AD Instruments). The rabbit's behavior was recorded with a video camera.

The hippocampus was divided into 3 regions: dorsal, middle, and ventral. EEG in the dorsal area was reduced by inflation of the IV cuff, and increased by phenylephrine (3-10 ?g/kg i.v.). Changing AP beyond a threshold (approx 60 mmHg) in either direction caused hippocampal theta rhythm (7-10 Hz), sometimes followed by behavioral arousal. Our data suggest that major alteration in baroreceptor inputs affects arousal state.

Nitroglycerin (NTG) is a well known vasodilator, commonly used in the treatment of angina pectoris. A less familiar, but very intriguing clinical application of NTG is the diagnosis of primary vascular headache, as it consistently induces a spontaneous-like migraine attack in predisposed subjects. Recent findings have shown that NTG is capable of inducing the release of different neurotransmitters, such as norepinephrine and calcitonin-gene-related peptide, in the central nervous system (CNS). These findings have suggested that NTG may act, at least partially, through a centrally-mediated mechanism, rather than as a pure direct vasodilator. The prote-cytochrome c-oxidase encoded by a nuclear protein Fox, whose expression in certain brain regions can be induced by a variety of stimuli. For this reason, the immunohistochemical analysis of Fox-like immunoreactivity has been proposed as a highly sensitive method for the mapping of signaling pathways in the brain. Moreover, Fox contributes to the formation of the protein activator AP-1, which, in turn, triggers the transcription of specific downstream genes, ultimately cooperating in the regulation of target genes that may undergo cellular adaptive responses.

The aim of the present study was to evaluate, in the rat, the possible CNS effects of systemic NTG by means of the induction of c-fos activation and AP-1 expression. The activation of c-fos was evaluated by immunocytochemical detection of Fox-like immunoreactive neurons, while AP-1 expression was detected by electromobility shift assay (EMSAs). The results obtained by a time course study and immunocytochemical analysis reveal the existence of significant differences in both the localization and number of positive neuronal elements expressing c-fos in brain areas submitted to NTG injection demonstrate AP-1 expression as early as the second hour post-administration. These data strongly suggest that NTG can induce a selective activation of specific CNS nuclei (supported by NIH grant NS213323)
560.9 MORPHOLOGY OF SYMPATHETIC GANGLION NEURONS IN SPONTANEOUSLY HYPERTENSIVE RATS. C. Cameron* and K.G. Reit, Department of Anatomy and Cell Biology, University of North Dakota School of Medicine, Grand Forks, ND 58202.

Increased levels in nerve growth factor (NGF) in the walls of muscular arteries has been hypothesized as a contributing factor in the development of hypertension in spontaneously hypertensive rats (SHR). Our previous studies of the trophic effects of NGF on sympathetic ganglion neurons prompted us to hypothesize that significant changes in components of the autonomic nervous system may also lead to the development of hypertension. Superior cervical ganglion (SCG) neurons in 6-7 week-old SHR and normotensive Wistar-Kyoto (WKY) rats were intracranially filled with a 5% solution of Lucifer yellow in order to visualize the dendritic arborizations of these neurons. Each intracranially filled neuron was drawn by camera lucida, and cell body size, total dendritic length, and number of primary dendrites were measured and compared between groups. Preliminary experiments show that although SHR ganglion neurons tend to be larger and have greater total dendritic lengths, the differences were not statistically significant. In addition, the number of primary dendrites elaborated by these neurons did not differ. An interesting observation we have made in SHR animals, however, is that there is extensive dye-coupling between neurons of the SCG not seen in the WKYs. Previous investigators have shown that there is enhanced synaptic transmission through the SCG of the SHR. Our present evidence suggests that this may not be the result of large-scale changes in SCG neurons and preganglionic innervation but is possibly a result of the establishment of local ganglionic electrical connections.

Somatovisceral reflex arcs mediate cardiopulmonary adjustments to pain and exercise. The structural underpinnings of short intraspinal reflex pathways were examined using intraspinal transport techniques in chloral hydrate (0.5mg/kg)-anesthetized adult and 8-12 day-old neonatal Sprague-Dawley rats. Study 1. Do first order axial muscle afferents project to spinal autonomic ganglia? Ten T1 dermatomes (DLY) were injection labeled using the intrasegmental injection of D-Lucifer Yellow (DLY) were slowly injected, bilaterally, into the lenticulissimus muscle. Following 8-9 day survival periods, thoracolumbar spinal segments were sectioned and processed immunocytochemically for DLY. Transganglionic transport of DLY labeled first order muscle afferents in the thoricospinal cord served as painful; physiological responses of the intermediolateral column (ML) in mature (n=8) and young (n=3) animals. Study 2. Do neurons in the dorsal horn project to autonomic motor nuclei? Preganglionic deposits of Phascolus vulgaris leucoagulatum (n=13) centered on lateral loci in upper thoracic (T1-2) or thoraco-lumbar (T11-12 or L1-2) spinal segments transported, intraesomally, to the ML and nucleus intercalatus. A larger medial fiber trajectory was descripted in the dorsal gray commissure and terminated within a mirror locus in the dorsal horn on the contralateral side. Deposits centered to medial loci in the dorsal horn harned in laminae VII and X and the ventral horn, bypassing the ML. We conclude: Intraspinal-autonomic circuits may provide an anatomical substrate for the early reflex component of the exercise pressor reflex. The direct spinhal-autonomic reflex arc may be reinforced by this way of a multiyamic communica trial pathway. (Supported by a 5-year grant to the National Cancer Institute of Canada.)

560.13 TRIGEMINALLY MEDIATED ALTERATIONS OF NORMAL CARDIO-RESPIRATORY RHYTHMS DURING TRANSSANAL APPLICATION OF CARBON DIOXIDE. F. Yavari, W.M. Panetton, and J.H. Harting*, Dept. of Anatomy & Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Psychophysiological studies in humans have shown that nasal stimulation with carbon dioxide (CO₂) induces reflex changes. Similarly, studies in the cat have shown that such effects may be mediated through the medullary dorsal horn. Since the medullary dorsal horn is also a probable site for the mediation of the "diving response", we have studied the cardiorespiratory responses in the rat which result from applying CO₂ across the nasal mucosa. The animals were anesthetized with intraperitoneal injections of a mixture of chloral-urethane. Cannulas were inserted into the femoral vein and artery for the delivery of drugs and recording of blood pressure, respectively. Other tubing was placed in the trachea for breathing and into the nasopharynx for drawing air over the nasal mucosa. The stimulus was 10% CO₂ applied to the nose and drawn through the nose by gentle suction applied to the nasopharyngeal tube. Such stimulation caused an abrupt drop in heart rate, and in the majority of the experiments, apnea and an elevation of blood pressure. In other experiments, CO₂ caused deep breathing and hyperventilation (no apnea) or arhythmic breathing with apneic periods. The bradycardia was not the result of activating baroreceptors since it persisted even in those cases where an alpha-1 adrenergic receptor blocker, was used to prevent the increase in blood pressure. The CO₂-induced bradycardia was vagally mediated since it could be completely abolished after intravenous atropine. The nasal application of CO₂ also induces a blockade of the bradycardia and hyperventilation, suggesting that the responses are trigeminal mediated. These CO₂ induced responses previously have not been reported and resemble those of the diving response. Supported by NIH grant HL3471.
560.15 CARDIOVASCULAR EFFECTS OF NITRIC OXIDE ON BRAINSTEM NUCLEI OF RATS. C. J. Tong,* H. Y. Liu, H. C. Lin and C. S. Jung, Dept. of Medical Education and Research, Kaohsiung Veteran General Hospital, Kaohsiung, Taiwan, R.O.C.

Nitric oxide (NO) has been reported as a second messenger and neuromodulator in vivo. In this study, we evaluated the cardiovascular effects of NO in the nucleus tractus solitarius (NTS), rostral ventrolateral medulla (RVM) and area postrema (AP) of male Sprague-Dawley (SD), Wistar-Kyoto (WKY) and spontaneously hypertensive rats (SHR) respectively. Unilateral microinjection (60 nl) of L-arginine (L-Arg, 1-100 mmol) into the NTS and RVM produced a prominent dose-related decrease in heart rate and blood pressure. The depressor and bradycardic effect of L-Arg were significantly attenuated by the pretreatment of NO synthase inhibitor -Nω- monomethyl-L-arginine (L-NMMA). The depressor effect of L-Arg in the NTS of SHR was less sensitive than the WKY. Furthermore, the cardiovascular effects of L-Arg was potentiated via intravenous injection of the lipoxygencerase inhibitor (LPS). In addition, a simultaneously injection of L-Arg and L-NMMA was noted during the period of L-Arg induced depressor effect in the NTS. However, there is no significant cardiovascular effect of L-Arg in the AP. These results suggest that NO is involved in the central cardiovascular regulation. The depressor effect of L-Arg in the NTS might be through the inhibition of sympathetic nerve activity.

560.17 PHARMACOLOGICAL CHARACTERIZATION OF THE 10 HZ SYMPATHETIC NERVE DISCHARGE FREQUENCY. M. E. Clement* and R. F. McCall. The Upjohn Company, Kalamazoo, MI.

Most of the power in the discharge frequency of sympathetic nerve in baroreceptor denervated decerebrate or urethane-anesthetized cats concentrates in a 2-4 Hz band and a narrower frequency band around the 10 Hz range. Barman and Gebber have shown that chemical inactivation of the medulla medullary raphe with muscimol eliminates the 10 Hz peak, while stimulation of this area can induce the 10 Hz rhythm. Our laboratory has recently examined the effect of a number of pharmacological agents on the frequency distribution of sympathetic activity. We found that systemic administration of the GABA antagonist picrotxin (0.01-1 mg/kg) selectively suppressed the 10 Hz power band in a dose dependent manner. Incremental doses of picrotxin also tended to shift the 10 Hz peak to higher frequency. Low doses of 8-OH-DPAT (1-5 µg/kg) selectively inhibited the 10 Hz power band in a dose dependent manner. The inhibitory effects of 8-OH-DPAT could be reversed by the 5-HT antagonist piperperone. The putative 5-HT antagonist WAY100135 (0.01-0.1 mg/kg) did not reverse 8-OH-DPAT but did inhibit 10 Hz activity when given alone. The 5-HT antagonist methysergide (0.01-1 mg/kg) caused a dose dependent shift in the 10 Hz band to lower frequencies. Chlorimipramine, a 5-HT uptake inhibitor, also eliminated the 10 Hz peak in SND, but did not block stimulation induced 10 Hz activity. These data suggest that 5-HT and GABA mediate the level of excitability of the central oscillator responsible for the generation of the sympathetic 10 Hz frequency.

REGULATION OF AUTONOMIC FUNCTIONS: CNS PATHWAYS AND TRANSMITTERS

The nucleus of the solitary tract (NTS), dorsal motor nucleus of the vagus (DMNX), and area postrema (AP) are interrelated structures important in the modulation of visceral function, including those mechanisms underlying nausea and vomiting. Neuroleptics, probably acting on dopamine receptors, have potent antieptic actions. In order to establish and characterize the role of medullary dopamine receptor subtypes in the control of nausea and vomiting, we studied the distribution of D1-D5 receptors. Fresh frozen human brainstem sections from normal controls, n=5, sectioned at 20 µm and slide mounted, were incubated with [3H]apipiphrine for D2 and D3 receptors, [125I]epidepride for D2, D3, and D4 receptors, [3H] SCH23390 for D1 and D5 receptors, and [3H]nomipiphrine for D2, D3, and D4 receptors, and processed for autoradiography. Dopamine receptors were most densely distributed over the medial and intermediate subnuclei of the NTS and the DMNX. Moderate binding was noted over the lateral, intermediate, and substantia gelatinosa subnuclei. The medial region of the NTS receives a dense projection from the subdiaphragmatic vagus. Dopamine receptors in this region of the NTS, as well as in the DMNX, probably play a central role in antieptic action of neuroleptics.

The pairing of sensory and motor representation of a specific organ within certain levels of the avian nucleus of the solitary tract (NTS) and dorsal motor nucleus of the vagus (DMNX) could facilitate vago-vagal reflexes. The present study investigated the existence and peptide content of local NTS projections to DMNX that could subserve esophageal reflexes. Fluorescin-latex beads were injected into an anterior DMNX subnucleus, which innervates the esophagus. Retrogradely labeled NTS cells were observed ipsilaterally and contralaterally and were most dense in medial tier NTS subnuclei, which are recipients of vagal afferents from the alimentary tract. The combination of retrograde labeling and immunofluorescence techniques revealed many bombesin, enkephalin, and neurotensin immunoreactive medial tier NTS cells that were double-labeled. Many of the enkephalin and neurotensin containing double-labeled cells were located in medial tier NTS subnuclei that are the major recipients of esophageal afferents and thereby could subserve as interneurons in esophageal reflexes. Bombesin double-labeled cells were found in medial tier NTS subnuclei that are major targets of gastric afferents. These bombesin containing cells project to the anterior DMNX may serve to integrate esophageal and gastric functions. On-going experiments will attempt to verify the axonal projections of these medial tier NTS cell groups to esophageal DMNX motoneurons by combining anterograd axonal tracing with retrograde labeling techniques. Support NSF R11-B922106.
561.3 DISTRIBUTION OF BOMBESIN-LIKE IMMUNOREACTIVITY IN THE NUCLEUS OF THE SOLITARY TRACT (NTS) AND DORSAL MOTOR NUCLEUS (DMN) IN HUMANS. R.B. Lynn1*, R.R. Miselis2*, and T. Hori3* 1Dept. of Med., Thomas Jefferson Univ., Philadelphia, PA 19107; 2Dept. of Animal Biol., Univ. of Penn., Philadelphia, PA 19104; 3Clin. Brain Disorders Branch, NIMH/RP, Wash., D.C. 20032 Bombesin, also referred to as gastrin releasing peptide (GRP-14-27), has important autonomic and behavioral effects when injected into the NTS/DMN complex in rats. Bombesin-like immunoreactive (Bb-LI) labeling is visible in the rat NTS/DMN complex but has not been described in the human medulla. Four normal human medullas were flash frozen and subsequently thawed and fixed. Frozen sections (40μm) through the obex, diencephalic, and mesencephalic subnuclei of the NTS and the dorsal part of the DMN. The substantia gelatinosa and the tracts of the NTS appeared void of Bb-LI staining. Rare Bb-LI labeled cell bodies were scattered within the NTS. Bb-LI labeling was also noted in the A1 region and the spinal trigeminal nucleus. In controls, all Bb-LI staining was abolished by preabsorption of the primary antisem with bombesin peptide. This distribution of labeling is very similar to that of labeling in the non-colchicine treated rat. The anatomic similarities between human and rat suggest that bombesin has similar functions in the visceral neurex of these two species. Supported by KO8 DK02094(1); GM27739(2); IRP-NIMH(3).

561.5 GLUTAMATE-IMMUNOREACTIVE NEURONES AND AXON TERMINALS OF THE NUCLEUS TRACTUS SOLITARIUS (NTS): DEMONSTRATION OF GLUTAMATE IN VAGAL SENSORY APPARENCES. R.M. Sykes, D. Jordans* and P. N. Izzo Dept. Physiology, Royal Free Hosp. School, Brookfield Hill St., London, NW3 2PF, U.K. Although there is a growing body of literature regarding the actions of glutamate in the NTS very little is known about the anatomy and organization of the putative glutamatergic neurones in this region. We have used post-embedding immunocytochemical techniques glutamate-containing neurones to be examined at both the light and electron microscopic level. Furthermore, by combining this technique with anterograde labelling this study begins to examine the origins of glutamate-containing neurones observed in the NTS. Light microscopic examination of semi-thin plastic sections revealed glutamate-immunoreactive neurones throughout the NTS and gracile nucleus with a distinctive organization at intermediate levels where groups of immunoreactive perikarya were observed. Axonal boutons were also labelled. These were found through to the subnucleus, providing a very dense and apparently homogeneous innervation.

Ultrastructural examination of glutamate-immunogold labelled sections identified a population of axonal boutons which displayed common morphological features and formed exclusively asymmetric synaptic specializations. The major post-synaptic targets of these boutons were small to medium-sized dendrites. Glutamate immunocytochemistry of sections containing anterograde labelling following the injection of horseradish peroxidase into the nodose ganglion revealed that these axons contribute to the population of glutamate-immunoreactive axonal boutons in the NTS. Supported by the Wellcome Trust and British Heart Foundation.

561.7 TRANSYNAPTIC DOUBLE LABELING WITHIN THE VISCERAL NEUROAXIS WITH UNIQUELY MARKED STRAINS OF PSEUDORABIES VIRUS (PRV) INTO THE RAT PHARYNX. X. Rao, Z. B. Wiedner, and S.M. Allbritton Children's Hospital of Philadelphia, Univ. of Pa. Sch. of Med., Philadelphia, PA 19104. The initiation and control of swallowing is dependent on pre-oromotor neurons (POMNs) located primarily in NTS. The subnuclear location and connectivity of POMNs innervating the pharynx were determined using anterograde and retrograde tracing of PRV in 15 rats, PRV injections were made into the pharynx. Following a 48-96 h survival, brain sections were processed immunocytochemically for PRV. Anterograde labeling was limited to the semicompact formation (SC) of the NTS for a survival time of 48 h. At 56-62 h survivals, SC, PL, and PH were localized to the interstitial (IST) and intermediate (INT) subnuclei of NTS. At longer survivals, neuronal transections were observed in the INT subnuclei of the NTS, raphe nucleus, A5, hypothalamus, and forebrain. Pharyngeal POMNs are localized to the ist/P2uf and int/P2uf, the sites of termination of superior laryngeal nerve afferents, and have direct synaptic contact with spinal motoneurons. The pattern of labeling at longer survivals suggests widespread CNS control over pharyngeal motility. Supported by NIH grant DK-44487.

561.8 SYMPATHETIC NERVE FIBERS IN THE SUBDIAPHRAGMATIC VAGUS NERVE OF THE RAT SEEN WITH FLUOROGOLD, CT-HPR OR PSEUDORABIES VIRUS. M.Yang*, X. Zhao and R.E. Miselis Animal Biology, Philadelphia, PA 19104. To identify the source and number of the entry of sympathetic nerve fibers in the vagus nerve one of three retrograde tracers was injected into the subdiaphragmatic vagus trunk of the rat. We examined the upper sympathetic ganglia, the nodose ganglion, and the dorsal motor nucleus of the vagus (DMV) in the same animals. We find a small number of labeled sympathetic neurons at the cervical (C1-C6), thoracic (T1-T5), lumbar (L1-L5) and sacral (S2-S4) levels. All labeled sympathetic preganglionic fibers arising from the intermediolateral nucleus of the spinal cord via the intermediolateral cell column project to the superior cervical ganglion (SCG), which projects to the superior cervical ganglion (SCG), 30 in the coccidophagous region (CTR) and 25 in the other thoracic region (TR). The retrograde tracers were injected into the right vagus nerve of the rat. We found that the sympathetic preganglionic fibers originating from the intermediolateral nucleus of the spinal cord project to the superior cervical ganglion (SCG), which contains 30 of these neurons. All labeled sympathetic preganglionic fibers arising from the intermediolateral nucleus of the spinal cord project to the superior cervical ganglion (SCG), which contains 30 of these neurons. We found that the sympathetic preganglionic fibers originating from the intermediolateral nucleus of the spinal cord project to the superior cervical ganglion (SCG), which contains 30 of these neurons. All labeled sympathetic preganglionic fibers arising from the intermediolateral nucleus of the spinal cord project to the superior cervical ganglion (SCG), which contains 30 of these neurons. We found that the sympathetic preganglionic fibers originating from the intermediolateral nucleus of the spinal cord project to the superior cervical ganglion (SCG), which contains 30 of these neurons.

Recent evidence suggests that the hypothalamus may play an important role in stress-related gastrointestinal disorders. Stimulation of the paraventricular nucleus of the hypothalamus (PVH) can induce gastric efferent and motility changes that can be eliminated by vagotomy, suggesting that the PVH projects to the dorsal motor nucleus of the vagus (DMNV). Little is known, however, about the potentially important PVH influence on DMNV neurons. To address this issue, we used glass microelectrodes containing 2% Neurobiotin to record the responses of individual gastric- and intestine-sensitive DMNV neurons to PVH stimulation. The stomach and duodenum of 15 rats were separately cannulated to permit dissection with normal saline surrounding the subdiaphragmatic and gastric branches of the vagus nerve. Stimulating electrodes were also placed in the PVH. Following physiological characterization each neuron was injected with the tracer and reconstructed using the Eucentric Neuron Tracing System. A total of 18 DMNV neurons were successfully labeled. Most of these neurons were inhibited by intimal and/or gastric distension. PVH stimulation, however, inhibited 6 and excited 8 of the distention-sensitive DMNV cells (PVH stimulation did not affect the activity of the remaining 4 neurons). Interestingly, our data suggested that a given DMNV neuron’s response to PVH stimulation may be related to certain morphologic features. We found that neurons that were inhibited by PVH stimulation tended to exhibit a higher density of dendritic swellings than the neurons that were excited by this stimulus (p = 0.008). These preliminary results suggest that PVH may project to distinct subsets of gastrointestinal DMNV neurons. These two groups appear to receive similar input from the intestine, but opposing inputs from the hypothalamus. Supported in part by NS30083 and DC01074.

Pancreatic Polypeptide Increases the Activity of Dorsal Vagal Complex Neurons in vivo
Dana M. Mctigue* and Richard C. Rogers. Dept. of Physiology, College of Medicine, Ohio State University, Columbus, OH 43210.

Pancreatic polypeptide (PP), a hormone released during digestion, has been shown to alter vagal afferent traffic and elevate neurotransmitter levels in the dorsal motor nucleus of the vagus (DMNV). Little is known, however, about the potentially important PVH influence on DMNV neurons. To address this issue, we used glass microelectrodes containing 2% Neurobiotin to record the responses of individual gastric- and intestine-sensitive DMNV neurons to PVH stimulation. Cells within the DVC were identified in two ways: vagal stimulation to identify NTS vs DMN neurons or gastric inflation to identify On vs Off cells (neurons that increase or decrease firing rate during inflation, respectively). The results obtained indicate that over 65% of On cells and Off cells were stimulated by PP while none were inhibited. Furthermore, 60% of NTS cells were stimulated by PP. Preliminary studies examining DMN neurons demonstrate that 30% are inhibited while the rest are unaffected. These studies indicate that in general, gastric related DVC neurons are potentially stimulated by PP. When the entire population of DVC neurons is studied, more complex effects may be observed. The long-lasting stimulation of gastric related DVC neurons may provide a mechanism for the observed increases in gastric activity following PP administration (NS 30803 to RCR).

2-DEOXY-D-GLUCOSE (2DG) INDUCES C-FOS IN CENTRAL AND PERIPHERAL CATECHOLAMINE (CA) SYSTEMS. S. Ritter* and I. Llewellyn-Smith. College of Veterinary Medicine, Washington State University, Pullman, WA, U.S.A 99164, and Department of Medicine, Finders Medical Centre, Adelaide, S.A. 5042, Australia.

2DG is a glucose analogue that competitively inhibits glucose utilization. Responses to 2DG include increased feeding and adrenal medullary secretion and induction of Fos-like immunoreactivity (FLI) in the brain and adrenal medulla. Previous studies have shown that 2DG-induced feeding is impaired by lesion of brain CA systems and by pharmacological reduction of CA neurotransmission. In this experiment, 2DG was administered systemically and immunocytochemistry used to determine whether c-fos was induced in hindbrain neurons which express tyrosine hydroxylase (TH). Results show that 2DG induces FLI in some, but not all, TH-containing neurons in the A1/C1 and A2/C2 regions and in many neurons not containing TH. 2DG also induced FLI in a subpopulation of sympathetic preganglionic neurons retrogradely labelled by injection of the B subunit of cholera toxin into the adrenal medulla. Results identify specific subpopulations of brain CA and preganglionic neurons activated by glucoprivation.

Regulation of autonomic functions: CNS pathways and transmitters. 1373.

PP and PYY are circulating gut hormones that regulate digestion. Receptors for PP and PYY are present in rat gastric mucosa on both sides of the blood-brain barrier (BBB). When PP and PYY are microinjected into certain areas of the dorsal medulla inside the brain, they produce potent gastric effects. We hypothesized that PP and PYY are produced by cells within the CNS that project to areas with high densities of receptors, despite the failure to consistently demonstrate these peptides by radioligand receptor binding or immunocytochemistry. Objective: to determine if PP and PYY mRNA are present in brain, using RT-PCR Methods: Total RNA was extracted from the dorsal medulla and medulla of the rat brain, pancreas and distal 10 cm of ileum using the Trisolv method (Biocheck, Houston, TX). First strand cDNA was generated using a Moloney Murine Leukemia Virus reverse transcriptase reaction. Five ng of cDNA products were incubated with the PP or PYY primers and Taq DNA polymerase along with controls and standards for 35 cycles. The products were separated directly on an Nu-Sequagene agarose gel. The identity of the products was tested by Southern blot. Results: PP and PYY mRNA were detected in the dorsal medulla of the rat brain using the RT-PCR. The PP primers yielded a single band identical in size to the PP mRNA isolated from the pancreas. For PYY, two bands were amplified from brain mRNA, corresponding to predicted PYY mRNA fragments with a possible splice. The signal obtained for mRNA for PYY bands differed between brain and ileum. Southern blots labeled with 32P- or 32P-PYY cDNA probes demonstrated that the amplified PCR products hybridized with the appropriate cDNA. Conclusion: PP and PYY mRNA are present in the brainstem of rats. This supports the hypothesis that PP and PYY receptors in areas of the brain that are inaccessible to circulating hormones may have physiological roles.

THURSDAY AM

Previous studies have shown that the nucleus paragigantocellularis lateralis (PGi) strongly innervates the nucleus locus coeruleus (LC) and sympathetic nuclei of the spinal cord. However, other data suggest that PGi have not been systematically examined. In the present study, Phaeolus vulgaris-leucoglaucogmin (PHA-L) was used to comprehensively map PGi efferents in the rat. Multiple deposits of PHA-L were iontophoresed into the PGi. After 7-10 days, animals were perfused and processed for PHA-L immunostaining. Dense PHA-L terminal labeling was seen in the intermediolateral cell column and intermediate and lateral spinal cord segments, A1/C1 areas of the ventral medulla, the nucleus of the solitary tract, dorsal motor nucleus of the vagus (X), the hypoglossal nucleus (XII), the LC, medial and lateral parabrachial nuclei, Kollikier-Fuse nucleus, the paragigantocellular, the bilateral nucleus, the intermedio-dorsal nucleus and the intermediolateral nucleus. PGi and subcoeruleus ventralis nuclei were densely innervated by PGi, and a major divergence of these projections was observed. The present study shows that PGi efferents have a more extensive and complex pattern than previously reported. Further studies to identify the nature of these projections are currently underway.

The parabrachial (PB) and Kobliker-Fuse nuclei (KF) receive input from the somatosensory system, as well as from the efferent systems of the spinal cord. The present study was undertaken to define the somatosensory input to these nuclei. Our results demonstrated that the somatosensory system input to the PB/KF complex is more complex than previously thought. The somatosensory system input to the PB/KF complex is more complex than previously thought.

Electrolytic lesions of the lateral hypothalamus or the anteroverentral third ventricle reduces the salivary secretion induced by ICV injection of pilocarpine in rats. In the present study, we investigated the effect of septal (medial + lateral) electrolytic lesion (2 mA x 20 s) on the increase of the salivary secretion induced by ICV (lateral ventricle) injection of pilocarpine in anesthetized rats. The salivary flow was measured by pre-washed cotton balls inserted in the mouth. Twelve hours or more after the lesion (acute lesion) or 14 or more days (chronic lesion) after the lesion, the saliva was collected 1 min before (control) and 7 min after ICV injection of pilocarpine (120 mg/kg). ICV injection of pilocarpine in sham rats increases the salivary flow (420 ± 6 mg/7 min) compared to control (18 ± 5 mg/7 min). Septal lesion reduces (19± 2 mg/7 min; 287 ± 42 mg/min, respectively) the salivary effect of ICV pilocarpine, but not the basal salivary flow (26 ± 5 mg/7 min). These results suggest the septal lesions participates in the salivary secretion produced by ICV injection of pilocarpine in rats.

561.21

Glucagon like peptide-1 (GLP-1), is a gut hormone known to play an important role in an in vitro enteric-insular axis. Since GLP-1 immunoreactivity and specific receptors are present in the rat brain, we investigated the biological effects following central GLP-1 administration. GLP-1 was injected directly into the lateral ventricle of brain-cannulated rats, and food and water intake were measured. In cannulated rats with access to food and water, GLP-1 administration for 4 days was associated with significantly reduced food intake as compared to a saline injected control group. Furthermore, GLP-1 produced a strong dose-dependent inhibition of both food and water intake. At doses of 1 and 10 μg of GLP-1, food intake was significantly suppressed to 46 ± 2% (n=9) and 23 ± 6% (n=10) of control animals (n=15). To investigate the effect of GLP-1 on water homeostasis, the urine output of freely feeding rats was measured following intracerebroventricular injection of GLP-1. The urine output was considerably increased by GLP-1 in a dose-dependent manner. At doses of 1 and 10 μg of GLP-1, urine output was increased 4.51 ± 0.88 (n=14) respectively 2.16 ± 0.37 (n=10) times of control (n=34). Measurement of sodium and potassium concentration in the urine samples revealed GLP-1 as a naturetiremic. These significantly effects on both food and water intake and urinary output suggests an important role for GLP-1 as a structurally related peptide as a neurotransmitter in regulation of both digestive behaviour and salt and water homeostasis.

REGULATION OF AUTONOMIC FUNCTIONS: GASTROINTESTINAL

562.1
CELIAC GANGLIONIC AND VAGAL PROJECTIONS TO THE RAT DUODENUM COMPARED USING DII/DlA DUAL LABELING AND CONFOCAL MICROSCOPY. Z. Cheng and T.L. Powley*. Purdue University, West Lafayette, IN 47907.

The duodenum receives strong autonomic projections. The patterns of these inputs are still incompletely known. To label both branches of the ANS concurrently, male rats were injected bilaterally in the dorsal motor nucleus of the vagus with DIA and then one to two weeks later in the left celiac ganglion with DII, after prior sectioning of the abdominal splanchnics. Five days before sacrifice, the animals were injected i.p. Fluoro-gold injections to label the enteric nervous system. After perfusion, the duodenum was separated into muscularis externa and submucosal sublaminae and processed for confocal microscopy. In contrast to the vagal pattern of dense networks of fibers and varicosities innervating the myenteric ganglia, sympathetic fibers tend to course superficially around the perimeter of the ganglia. These celiac fibers provide fine collaterals within some ganglia but form relatively few varicose contacts. Celiac fibers also form lattices of axons between the longitudinal and circular muscle layers. These lattices are comprised of axons and interstitial cells paralleling the two muscle sheets. Other fibers penetrate into one or the other muscle layers and arborize in varicose endings. These intramuscular effector fibers parallel the muscle fibers of the respective layers. In the submucosa, the sympathetic effector form extensive networks of endings both on blood vessels and on interstitial cell complexes. They also supply varicose endings to submucous ganglia. Single vagal varicosities, as well as rings and baskets of vagal endings, occur in apparent contact with those myenteric neurons which retrogradely label from the celiac ganglia. These fibers have been injected in the ipsilateral nodose ganglion with WGA-HRP or DII. All rats had i.p. Fluoro-gold injections to counterstain enteric neurons and verify the rhizotomy. Axons were perfused and processed with DMB (WGA-HRP) or for confocal microscopy (DII). The entire stomach and oesophagus are also examined. These results may shed light the contribution of these axons in the enteric system. NIH DK27627, NIMH MB10152 & Special Initiative Fellowship to Z. C.

562.2
DIFFERENT VAGAL EFFERENT PROJECTION PATTERNS IN STOMACH, DUODENUM AND CEUM. J.B. Kelly*, M-C. Hoist and T.L. Powley. Purdue University, West Lafayette, IN 47907.

In a recent review of vagal motor fibers in the gastrointestinal tract, we observed that vagal efferents collateralize extensively, providing a dense network of endings within enteric plexuses (cf. Boyd et al., Neurosci. Abst. 19:243, 1993). We present in brief the results of the present study that characterize and compare patterns in three prominent GI organs distinguished both by projections from different motor neuron pools within the dorsal motor nucleus of the vagus and by their specialized functions. Male rats received one or more intraperitoneal injections of PHA-L in the dorsal motor nucleus of the vagus and were perfused 21 days later. Whole mounts of stomach, small intestines, and ceca, as well as frontal sections of the medullas of guinea pigs (56m), were prepared immunohistochemically (Vector ABC Elite Kit). Auranofin blue was used to counterstain both enteric neurons and the medulla. Individual motor fibers were identified as they entered the target organs and then traced and digitized in their entirety (Euretics Trax Imaging System). In the stomach, vagal efferents enter from the lesser curvature and ramify so extensively, both radially and longitudinally, that single myenteric ganglia (and many individual neurons) receive multiple overlapping, convergent inputs. The proximal duodenum is innervated by two distinctive types of vagal fibers which frequently converge on the same ganglion. One is a longitudinally projecting axon, and the other a radially coursing axon. In the cecum, vagal fibers enter from the mesenteric attachment and fan out through the myenteric plexus to form contiguous radial fields without extensive overlap. Fibers in all three regions, however, have large projection fields, but variations in the amount of ramification and ratio of longitudinal to radial orientation produce differences in the amount of convergence observed in the enteric ganglia of the organs. NIH DK27627 and NIMH MB10120.

562.3
TAXONOMY OF VAGAL AFFERENT PROJECTIONS TO THE GASTROINTESTINAL TRACT. F.E. Wang* and T.L. Powley. Purdue University, West Lafayette, IN 47907.

Vagal afferents have critical roles in the control of gastrointestinal function, but their morphologies and innervation patterns have only been characterized in limited areas. To survey these afferents, including a comparison of their (ar) regional morphologies, (b) projection field sizes, and (c) regional densities, male SD rats were given unilateral intramuscular motor rootlet rhizotomies (adapted from Witzel & Williams, J. Aut. Nerv. System, 1991, 38:15-45) and then injected in the ipsilateral nodose ganglion with WGA-HRP or DII. All rats had i.p. Fluoro-gold injections to counterstain enteric neurons and verify the rhizotomy. Animals were perfused and processed with DMB (WGA-HRP) or for confocal microscopy (DII). The entire stomach and oesophagus as well as the duodenum were examined. This regional study of vagal afferents may provide important insights into the role of the vagus in gastrointestinal function. The NIH and NIMH support these studies.

562.4
DISTENSION INDUCED EXPRESSION OF C-FOS IN MYENTERIC PLEXUS OF GUINEA PIG SMALL INTESTINE. R.C. Ritter* and M. Costa. Dept. of VCAPP, Washington State University, Pullman, WA 99164 and Dept. of Human Physiology, School of Medicine, The Flinders University of South Australia, Bedford Park, S.A.

Distension of the small intestine activates enteric reflexes which involve sensory and motor neurons within the myenteric plexus. In order to identify enteric neurons that respond to a distending stimulus, we examined the myenteric plexus for expression of the immediate early gene, c-fos, following distension. Three cm segments of the jejunum or upper ileum were placed in a 37°C Kreb's buffer as open tubes, or closed sacs. Sacs were distended with 0.4 ml Kreb's buffer or left non-distended. Distension resulted widespread expression of fos-like immunoactivity (Fos-li) in nuclei of myenteric neurons. Neuronal nuclei expressing Fos-li were much less numerous in myenteric plexus of open tubes and non-distended sacs. Application of tetrodotoxin (1μM) in the bath and lumen reduced expression of Fos-li following distension. These results indicate that distension leads to increased expression of c-fos in the nuclei of myenteric neurons as a result of increased neuronal activity. *R.C. Ritter was Visiting Professor and Senior International Fellow at Flinders University during the conduct of these experiments.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
R.L. Stephens 0.1 0.13 1376 1376 67.0 3.4 sec depolarization with an amplitude of 5.0 ± 0.4 mV that had a reversal potential potential near 0 mV. The response was associated with a 23.5 ± 1.8 % decrease in input resistance. The magnitude of the depolarizing response was dependent on the duration of CGRP application, and was diminished in a low Na+ bathing solution. During the depolarizing response, neurons had increased excitability, manifested as an increase in numbers of spikes per current pulse, and activation of anodal break action potentials. These results indicate that CGRP, along with substance P, may mediate slow EPSPs in gallbladder ganglia and that its depolarizing action is due predominantly to opening of cation channels. Supported by NS26995.

Chemical stimulation of medullary raphe neurones induces gastric secretion, motility, and cytoprotection and ulcer formation through vagal pathways in urethane-anesthetized rats. The effect of excitation of raphe pallidus (Rpa) neurones on the endocine pancreatic secretion was examined. Methods: Rats (200-350 g) were anesthetized with pentobarbital, a PE-50 cannula was inserted into the left cervical aorta, and a double-lumen cannula was placed into the forestomach for measuring gastric acid secretion. Serum insulin and glucagon levels were tested using Linco RIA kits. Baseline Microinjection of kaolin (0.3 ml/kg) into the Rpa induced a increase in serum insulin levels. Values before and 30, 60 and 90 min after microinjection were 0.34 ± 0.22, 0.54 ± 0.06, 0.60 ± 0.09 and 0.13 ± 0.07 mU/ml. All values after Rpa stimulation were statistically significant from the basal level. In the same rats, stimulated gastric acid secretion was also observed (basal: 2.3 ± 0.55; 30 min after Rpa stimulation: 26.1 ± 8.65 ml/g/hr). Microinjection of a saline solution into the Rpa had no effect. Serum glucagon level (basal: 48.8 ± 4.3 pg/ml) significantly increased only 90 min after the Rpa stimulation (86.6 ± 11.2 pg/ml). The increases of gastric acid secretion and serum insulin levels were completely prevented by bilateral cervical vagotomy whereas the increase in glucagon levels was only slightly but not significantly reduced. Conclusion: Chemical stimulation of Rpa neurones not only gastric function but also endocrine pancreatic secretion through vagal pathways.

SEROTONIN INHIBITS, BUT 5-OH-DPAT STIMULATES, GASTRIC ACID SECRETION THROUGH VAGAL-DEPENDENT MECHANISMS. K.J. Leppard*, G.Goldner and R.J. Stephen*, Dep. of Physiology, The Ohio State University, Columbus, 43210.

Serotonin (5HT) is a neuroendocrine component of the gastrointestinal tract. 5HT receptors have been demonstrated autoradiographically in high density in the rat stomach. However, the physiologic role of 5HT, 5HT receptors in the stomach is not known. Thus, the effects of the selective 5HT1 and 5HT2 agonists, 8-OH-DPAT, on gastric function was measured in isolated rat stomach preparations. In acute, urethane-anesthetized rats with gastric fistula, acid secretion was stimulated by pentagastrin (100 mU/kg iv). After 90 minutes, either 5HT or 8-OH-DPAT (5.5 μmol/kg, i.v.) was given. 5HT inhibited, but 8-OH-DPAT stimulated, gastric acid secretion (mean ± SEM % change: 5HT = 47 ± 11; 8-OH-DPAT = 71 ± 42; p<0.05). Bilateral, cervical vagotomy did not reverse the effect of either 5HT or 8-OH-DPAT on acid secretion. In addition, the enhancement of acid by 8-OH-DPAT was spiperone-sensitive. These data suggest that selective activation of 5HT1 receptors may augment gastric secretory function. Supported by NIH DK 42880.

GASTRIC MUCOSAL EROSIONS PRODUCED BY NMDA INFUSIONS INTO THE LATERAL HYPOTHALAMUS-EFFECTS OF SELECTIVE KNIFE CUTS. C.V. Grilj* and A. Landeira-Fernandez and Stacey Nuccio. Department of Psychology, Univ. of California, Los Angeles 90024.

Bilateral infusions of N-methyl-D-aspartate (NMDA) into the lateral hypothalamus (LH), which interrupt intrinsic neurones, produce gastric erosions in rats (Grilj, Rios-Jimenez & Landeira-Fernandez. Soc. Neurosci. Abst., 19, part 2: 1993, 509). The present study attempted to determine the pathways mediating this effect. Infusion of NMDA into LH evoked gastric erosions in rats. In rats whose LH infusions were followed by bilateral thigh muscle infusions, no gastric erosions were observed. Animals receiving Sham min and infused with NMDA exhibited significantly more gastric erosions than those infused with PBS (p<0.05). Lateral parasagittal LH blocks were performed to determine the contribution of NMDA, whereas anterior coronal LH significantly increased the incidence of erosions produced by NMDA (p<0.005). Posterior coronal LH did not significantly increase the incidence of erosions produced by NMDA. These results suggest that intrinsic LH neurones with gastric function project axons laterally and probably descend through the internal capsule to brainstem mediatory nuclei. The results of the anterior coronal LH suggest that the LH send and/or receives inhibitory projections from neuronal structures (possibly the amygdaloid complex) anterior to the plane of the LH.
562.11 REGULATION OF AUTONOMIC FUNCTIONS: GASTROINTESTINAL

562.12 CONSTITUTIVE AND INDUCIBLE NUCLEAR ONCOPROTEINS IN THE ENTERIC NERVOUS SYSTEM OF THE GUINEA PIG ILEUM. E.J. Parr and K.A. Shakery. Neuroscience Research Group, The University of Calgary, Calgary, AB, Canada T2N 4N1. Constitutive c-Myc and c-Fos are overexpressed in the nuclei of all enteric neurons of the guinea pig ileum. We have demonstrated that they make suitable markers to count enteric neurons in double-labelled preparations as well as providing a method to distinguish neurons from glia.

We have also investigated inducible nuclear oncoproteins in the guinea pig enteric nervous system. Inducible nuclear c-Fos, JunB and c-Jun immunoreactivity was found to be elicited in neurons by in vitro incubation of ileal segments in media containing 50mM K+ or 20mM veratridine as depolarizing stimuli. The neurons expressing activity-related c-Fos antigens included all major immunohistochemically defined subgroups of the submucous plexus. However, in incubated ileal segments, smooth muscle cells and substantial numbers of glia as well as submucous neurons containing VIP-immunoreactivity expressed nuclear c-Fos-immunoreactivity in the absence of a depolarizing stimulus. We conclude that these immediate early genes appear to be regulated by neuronal activity in most or all subgroups of neurons but in vitro isolation of ileal segments is sufficient to induce expression of these genes in many cell types as yet unidentified stimuli. Supported by the Medical Research Council of Canada.

562.13 MUCOSAL EXCITATORY INFLUENCE ON ANATOMICALLY IDENTIFIED NEURONS IN THE MYENTERIC PLEXUS OF THE GUINEA-PIG ILEUM. W.A. Karpe, J.C. Bornstein, J.B. Farnes and H.M. Young. Departments of Physiology and Anatomy & Cell Biology, University of Medicine, Parkville, Victoria, Australia 3052.

To examine the influence of input from the mucosa on 5 neurons of the myenteric plexus, we compared the electrical properties of neurons close to the mucosa with those whose somata lay further away. Opened segments of guinea-pig ileum were superfused with oxygenated physiological saline at 37°C; contractions were maintained by adding 1mM of nicotine. The myenteric ganglion was exposed for half the area of each segment by removal of overlying muscosa, submucosa, and circular smooth muscle. Intact muscosa was circumferentially adjacent to the exposed plexus. Neurons were impaled with conventional micropipettes filled with 1M KC1 and 4mM neurobiotin™ (Vector) and subsequently visualized using Texas red fluorescence. Twenty-three neurons were recorded adjacent (<500 µm) to and 13 far (>1000 µm) from the mucosa. Twelve adjacent neurons, but only one far neuron discharged tonically throughout 500 ms depolarizing current pulses, whereas 11 adjacent and 12 far neurons fired phasically. None of the tonic neurons projected orally; however, 17 of 19 had axonal projections, but 1 far neuron was impaled >500 µm from the mucosa projected orally. The results indicate that input from the mucosa may preferentially enhance the excitability of orally projecting 5 neurons.

562.14 NEURAL CONTROL OF GASTRIC ACID SECRETION: ANATOMICAL DEMONSTRATION OF VAGAL INPUT TO GASTRIN RELEASING PEPTIDE (GRP) CONTAINING ENTERIC NEURONS. H.R. Bartleby* and Q. Lin. Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA 70808.

The prevailing theory of vagal control of gastric acid secretion suggests the presence of at least two stimulatory pathways. One is a direct cholinergic input to the parietal cells, the other involves the release of gastrin from mucosal endocrine cells that is partially driven by GRP containing vagal postganglionic enteric neurons. Additionally, an indirect cholinergic input mediated by somatostatin cells. In order to anatomically and neurochemically characterize this vago-enteric interface, we started to examine the relationship between DA labeled vagal preganglionic terminals and immunocytochemically characterized enteric neurons and their projections. The percentage of GRP-positive myenteric neurons is gradually decreasing from about 40% in the fundus or forestomach, to 25% in the corpus and only about 10% in the pyloric antrum. Dense networks of GRP-positive varicose terminal fibers were found around gastric glands, in myenteric ganglia, and more sparsely within the external smooth muscle layers. In the corpus and antrum, 34% and 35%, respectively, of the GRP-positive neurons receive vagal efferent contacts. Conversely, of all the vagally contacted neurons, 33% and 16% were GRP-positive in the corpus and antrum, respectively. Vagal contacts with enteric neurons of other neurochemical phenotypes and with somatostatin cells, as well as possible contacts of DR-labeled vagal afferent fibers within such neurons, are currently being analyzed. In conclusion, there is a significant number of GRP-positive enteric neurons that receive vagal preganglionic input, supporting a role of GRP in vagally controlled gastrin and gastric acid secretion and possibly other functions. Supported by NIH grant DK74348.

The role of the vagus nerve in the regulation of water and electrolyte transport across the small intestine is well documented. However, there is lack of adequate information on its role in amino acid absorption. This study was thus undertaken to characterize the role of the vagus nerve in jejunal alanine absorption, using selective chemical stimulation or block of various groups of vagal afferents and efferents, and the single-pass perfusion technique. Implication of capsaicin (cp) to the isolated and intact cervical vagi produced a 14% decrease of alanine absorption while similar application to the distal parts of cut vagi produced a 26% inhibition of alanine absorption. Chronic destruction of the cp sensitive vagal afferents resulted in 40% increase of alanine absorption. On the other hand selective activation of preganglionic vagal neurons by microinjection of kainic acid into the dorsal motor nucleus of the vagus produced a 48% increase in jejunal alanine absorption; this increase was abolished by previous treatment of the injected rats by atropine. These results suggest that cp sensitive vagal afferents exert an inhibitory function of jejunal alanine absorption while cholinergic myenteric vagal afferents exert an opposite facilitatory effect. (Supported by grants from the L.N.C.S.R. and O.R.S.B.).

Intracellular recordings were used to examine the actions of putative adenylyl cyclase-activating peptide (PACAP) on morphologically identified neurons in the guinea pig pancreas. In addition, distribution of PACAP immunoreactivity in the pancreas was examined using an antibody that recognizes PACAP-27 and -38. Pancreatic neurons were classified as tonic, phasic, or nonspiking based on their physiological activity. PACAP-38 applied by pressure microinjection in phasic pancreatic neurons. The responses consisted of membrane depolarization in association with increased input resistance and repetitive phasic membrane discharge. Nonspiking neurons became excitable after application of PACAP. Most of the phasic pancreatic neurons that responded to PACAP had filamentous processes that were densely surrounded by VIP-immunoreactive terminals. PACAP immunoreactivity was observed in nerve fibers and in varicose terminals that covered a subset of pancreatic neurons. PACAP immunoreactive pancreatic neurons were not observed; however, they were observed in myenteric ganglia in the adjacent duodenal region. The effects of PACAP and distribution of PACAP immunoreactive nerve fibers on pancreatic neurons suggest that PACAP is a neuromodulator. The possibility that PACAP immunoreactive acon are of enteric origin is being studied. Supported by grants NS27645 and NS01582.
563.1 DETECTION OF INSPIRATORY RESISTIVE LOADS IN HUMANS TRAINED TO BREATHE WITH DIAPHRAGM OR INTERCOSTAL MUSCLES. S.M. Reynolds*, W.R. Revak, and D.T. Prader. Department of Physiology, University of Kentucky Medical Center, Lexington, KY 40536-0084.

We recently recorded central evoked potentials in response to inspiratory occlusion in humans trained to breathe with their diaphragm or intercostal muscles (Neuromuscular, Abst 19/76, 1993). The amplitude of the evoked signal during inspiratory breathing was significantly greater than that for any other condition. One explanation for this could be that the greater amplitude is related to the greater number of persistent afferents in intercostal muscles compared with that of the diaphragm. The objective of the present study was to determine whether differences for the detection threshold of added resistive loads during free breathing (FB), diaphragm breathing (DB), and intercostal breathing (IB) exist. Assuming a correlation between perception of added loads to breathing and evoked potential amplitude exists, we hypothesized that the threshold for detection using intercostal breathing would be lower than that for diaphragm breathing. Respirate was used to monitor abdominal and rib cage movement. Subjects were provided visual feedback by watching the output of each channel on an oscilloscope. Nineteen inspiratory resistive loads (26-3.54 cmH2O/L/sec) were presented to ten subjects for a single breath under three conditions (FB, DB, IB). The detection threshold (mean ± SEM) was 0.53 ± 0.02 cmH2O/L/sec and 0.09 ± 0.09 for IB. There was no statistically significant difference between these means. There appears to be no significant correlation between evoked potential amplitude elicited by inspiratory occlusion and detection threshold for resistive loads across the breathing conditions. (Supported by NIH Grant # PO1 40369)

When supine, abdominal muscles are silent. However, they are active in expiration during an inspiratory threshold load (ETL) or during continuous positive airway pressure (CPAP). We questioned how the sensory inputs of these two loads are integrated in abdominal muscles. Both loads decreased end tidal volume (EELV), and hence, vagal-volume feedback, but CPAP modifies feedback from chest wall receptors as well. EELV was passively increased to 25% and 50% of inspiratory capacity (IC) by rapidly reducing pressure in a full chest cuirass. EELV was actively increased by breathing against a water column. We measured changes in breathing pattern and in expiratory activity in surface EMGs from external oblique (EO) and internal oblique (IO) abdominal muscles during ETLs of 5, 10, and 15 cm H2O on supine subjects (5s). We used a “Respirate” to record EELV changes, and a pneumotach to assess Vt, Tt, and Tc. An increase in ETL evoked deeper, slower breathing, and higher peak expiratory activity in EO and EO, with minimal change in burst duration. Breathing was not altered by inflation to 25% IC. Inflation to 50% IC increased Vt, without changing timing, and in 2 s evoked expiratory activity in I0. Combined ETL and CPAP evoked no additional changes in breathing pattern or burst duration, but did elevate the EO and I0 expiratory peaks more than either load alone. Thus, abdominal muscles during the combined loads had additive effects on the output of the central pattern generator, but not on that of the central rhythm generator.

563.3 METABOLIC AND RESPIRATORY RESPONSES TO MILD EXERCISE IN PATIENTS WITH CFS DL. Cordova, J.C. Pareja, R. Bredon, N.N. Tapp, and B. NClinical. Neurobehavioral Unit, University of Buffalo, Buffalo, NY 14218.

To identify patients with Chronic Fatigue Syndrome (CFS), our lab has been studying the physiological responses that CFS patients exhibit during and after treadmill exercise. Seven medicated CFS patients and seven sex-matched controls screened for their level of fitness were recruited for this study. Subjects walked on a motorized treadmill at 2.5 mph for 4 minutes and then sat for 4 minutes. This pattern repeated 4 times. Physiological variables were collected from an ECG machine and a metabolic breath analyzer. Baseline heart rate, tidal volume, minute volume, respiratory rate, V02 and RQ were not different between groups. There was a significant difference in end-tidal CO2 during the initial resting stage (CFS: 32.6±3.8; controls: 35.3±4.0, mean ± SEM, p<0.01). For the entire test, ANOVA revealed significant group differences for respiratory rate and ventilation, which were higher for CFS patients and end-tidal CO2, which was lower for CFS patients (p<0.05). The decreased end tidal CO2 at rest does not correlate with hyperventilation and so may reflect either a physiological abnormality or pre-test hyperventilation. (Supported by NIH 1AI-23247 & VA Medical Research Funds)

Respiratory related evoked potentials (RREP) were previously recorded with inspiratory occlusion. We hypothesized that a RREP can be recorded using expiratory occlusion. Subjects were scanned while lying in supine, screen the experimentier and apparatus. They respired through a mouthpiece and non-rebreathing valve. The expiratory occlusion was produced using a pressure activated valve with a 2 sec closure time. Early occlusion was interrupted with an occlusion for 30 sec. EEG activity was recorded from F3, F4, C3, C4, T3, T4, P3, P4, T5, T6, C3 and C4 referenced to the linked earlobes. The maximum th of 80 occlusions were separated by a control trial on 80 no-load presentations. The EEG activity was computer averaged and saved on disk. Expiratory occlusion elicited an evoked potential was found in all subjects. An initial positive peak (P1) was the only consistent peak observed in all subjects and was present in electrodes C3, C4, T3, T4, P3, P4, T5, T6, C3 and C4. A negative peak was observed in electrodes F3, F4, T3, T4, P3, P4, T5, T6, C3 and C4. An initial positive peak latency was measured 42 sec. No activity was consistently observed in the frontal electrodes. No peaks were observed with control trials. These results suggest the hypothesis that a RREP can be recorded with an expiratory load. The distribution of the P1 peak is consistent a bilateral sensory cortex origin. The relative latency is similar the P1 peak found with inspiratory occlusion suggesting that this expiratory positive peak is the initial respiratory neuroreceptor mediated activation of the sensory cortex. Supported by NIH/NHLBI grant HL45782.

In man, some putative brain sites mediating responses to respiratory loading are unknown. To examine this issue, we employed a 1.5 Tesla MR scanner, and used SPGR pulse sequences (TR: 72 msec; TE: 45 msec; flip angle: 30; FOV: 26 cm; slice thickness: 5 mm; 128 x 256 x 1 NEX). Two-channel magnetic and axial images across the rostral pons were acquired in 8 healthy volunteers during two-way valve unloaded breathing, and while applying a 30 cm H2O resistor to the inspiratory port. Digital image subtraction and ROI analysis revealed significant increases in image intensity in discrete regions of the dorsal medulla, pons, and cerebellum, as well as bilaterally, in the inferior colliculi, putamen, and internal capsule. With continuous loading, signal increases progressively diminished over time. Upon cessation of stimulation, signal gradually returned to baseline. We conclude that inspiratory loading elicits consistent regional activation of discrete brain locations. We speculate that temporal changes in signal intensity may indicate respiratory afterdischarge and habituation phenomena. (Supported by HL-24218, HD-22695 & Parker B. Francis Foundation)

Functional MRI provides a noninvasive tool to assess spatial and temporal characteristics of neural responses to respiratory loading. We attempted to identify human brain regions which may undergo the ventilatory response to increased respiratory resistance. To study this issue, we employed a 1.5 Tesla MR scanner, and used SPGR pulse sequences (TR: 72 msec; TE: 45 msec; flip angle: 30; FOV: 26 cm; slice thickness: 5 mm; 128 x 256 x 1 NEX). Mid-sagittal and axial images across the rostral pons were acquired in 5 healthy volunteers during two-way valve unloaded breathing, and while applying a 30 cm H2O port. Digital image subtraction and ROI analysis revealed significant increases in image intensity in discrete regions of dorsal medulla, and the ventral and dorsal pons. With continuous loading, increases in signal progressively diminished over time. Upon cessation of stimulation, ROI signals immediately returned to baseline. We conclude that expiratory loading elicits consistent regional activation of discrete brain locations which differ from those which uniformly activate during inspiratory loading. We speculate that temporal changes in signal intensity may indicate either a switch to oxidative neural metabolism or habituation phenomena. (Supported by HL-24218, HD-22695 & Parker B. Francis Foundation)

NUCLEUS AMBIGUUS AND THE VENTRAL RESPIRATORY GROUP: A CORRELATIVE ANATOMICAL STUDY OF THE RAT AND HUMAN VENTROLATERAL MEDULLA OBLONGATA. H. H. Eickelberg and D. A. Hopkins, Department of Anatomy and Neurobiology, Dalhousie University, Halifax N.S., Canada, B3H 4H7.

The nucleus ambiguous (NA) and ventral respiratory group (VRG) in the ventrolateral medulla of the human brainstem were characterized by an anatomical comparison with homologous neuron populations in the rat ventrolateral medulla. To identify these neuron populations, we performed parallel immunohistochemical labeling studies on rat and human brainstem tissue using antibodies to choline acetyltransferase (ChAT) to label NA motor neurons, and parvalbumin (PV) to label presumptive bulbar VRG neurons (Cox & Halliday, Neurosci. Lett. 160:101-105, 1995). Anatomical subdivisions of NA and VRG were identified in the rat in transverse and sagittal sections of ChAT-immunoreacted tissue. ChAT-immunoreactive neurons in the ventrolateral medulla of the human brainstem were distributed in locations and patterns that were comparable to those in the rat NA. In particular, the compact division of NA formed a distinct dorsal column in both species. By combining PV immunohistochemistry with retrograde labeling after Fluoro-Gold injections into the C4 spinal cord, we have shown that bulbar VRG neurons are PV-immunoreactive in rats. Our comparison of the location and distribution of PV-immunoreactive neurons in the ventrolateral medulla of the human and rat brain suggests the presence of a homologous of the rat bulbar VRG neuronal population.

Supported by MRC grant M-2112 (HDL) and MT7356 (DAH) and a grant from The Scottish Rite Charitable Foundation (DAH).

SOMATIC AND VISCERAL AFFERENTS: SOMATOSENSORY

564.1

Unlike heat pain, the peripheral neural mechanisms underlying sensation of cold pain are poorly understood. Although many studies have examined responses of cutaneous nociceptors to noxious heat stimulation, responses have often not been well described, and responses to cold stimuli have not been well characterized. We have examined responses of cutaneous nociceptors to noxious cold stimuli. Single fiber recordings were made from the suprachinnae nerves in anesthetized monkeys. Nociceptors were located by nailing 18-20 cm, the skin and receptive fields mapped using von Frey filaments. Conduction velocity, mechanical threshold (von Frey), and response to thermal stimuli were assessed. Heat stimuli of 59.1-7°C (5 sec duration) and cold stimuli of 30 to -14°C (5 or 10 sec duration) were applied from a base temperature of 32°C and delivered in ascending or descending order. Recordings were made from 9 A and 6 C-fiber nociceptors. Mechanical thresholds for A and C-fibers ranged from 3.5-8.43 m/s and from 0.1-14 m/s, respectively. Under normal conditions only one A-fiber was excited by noxious heat. In contrast, all were excited by noxious cold stimuli with a mean response threshold of 4.2°C (range: 2.8 to 12.5°C). 7 of 9 A-fibers had a response threshold below 0°C. All C-fiber nociceptors were excited by both noxious heat and cold stimuli. The mean response threshold to cold was 15.3°C and thresholds ranged from 30°C to -2°C. Unlike A-fibers, 5 of 6 C-fibers exhibited response thresholds > 0°C. Responses of both A- and C-fibers typically increased monotonically as stimulus temperature decreased. It is concluded that: 1) A and C "mechanonociceptors" are excited by noxious cold and 2) C nociceptors contribute to cold pain at temperatures above 0°C, while both A and C nociceptors contribute to pain sensation evoked by temperatures below 0°C. THERMOSENSITIVITY OF CULTURED TRIGEMINAL NEURONS. T.K. Baumann and M.E. Martenson. Division of Neurosurgery and Department of Pharmacology, Oregon Health Sciences University, Portland, OR 97201

Little is known about the membrane mechanisms involved in thermal transduction between the sensory endings in the trigeminal ganglion. To examine the thermal response properties of cultured somatosensory sensory neurons, we have built a miniature heat stimulus system (Baumann et al., Biophys. J. 66: 442, 1994) which can stimulate individual cells. Whole-cell, patch-clamp recording techniques were used to study the thermosensitivity of cultured adult rat, rabbit, and cat trigeminal ganglion neurons. Triangular or rectangular heat stimuli (up to 20°C in amplitude, 3 to 10 s in duration) were applied every 10 to 30 s from a baseline temperature of 25 to 29°C. Responses were non-uniform, but largely reproducible. A proportion of neurons responded to heating with a depolarization and action potential discharge. Others showed the opposite behavior; they were inhibited by heating and discharged action potentials upon heat removal. Some neurons showed no overt response to changes in temperature. Following exposure to high temperatures, some neurons developed spontaneous action potential discharge, some became inexcitable. We conclude that cultured trigeminal ganglion neurons show features of thermoreceptors and heat nociceptors and may provide a useful model for studying thermal transduction mechanisms. (Supported by NSF grant IBN 92-11545.)

564.3

To date, there has been no quantitative, systematic study of the electrophysiology of regenerating cold receptors. This study, therefore, examines the changes in cold-activated neural activity following a circular wound (3 mm dia, 200 um deep) on the surface of the rabbit cornea. This is a well studied wounding model, in which neural regeneration has been anatomically quantified. Extracellular recordings were obtained from a total of 90 single cold fibers, at 1, 3, 10, 20, or 30 days following wounding. Conduction velocities for regenerating cold-fibers were similar to those recorded from normal fibers, 0.6-2.7 m/s, and 0.6-2.2 m/s, respectively. The adapting temperature was 35°C in all experiments. Thermal sensitivity for each fiber was determined using a series of temperature steps, 0.2°C ranging from 35 to 34°C, and 2°C steps ranging from 35 to 24°C. The rate of temperature change (dT/dt) was varied from 0.2 to 1°C/sec for ramps. For sinusoids the frequency ranged from 0.07 to 0.005 Hz at a median temperature of 35°C with a +/-5°C change in amplitude. Action potential frequency (AP) was measured over the magnitude (ΔT, 0 to -9°C) and rate (dT/dt, 2 to 1°C/sec) of temperature change. The action potential acceleration (dAP/dt) and rate of change of adaptation were proportional to dT/dt and independent of ΔT. Sinusoidal stimulation showed that AP always peaked prior to reaching maximal ΔT, indicating that the thermal transducer mechanism does not depend on ΔT. Conversely, and more logically, AP and dAP/dt always peaked just following maximal dT/dt, although the exact phase of the response varied. It is hypothesized that AP is always peaked prior to reaching maximal ΔT, indicating that the thermal transducer mechanism does not depend on ΔT. Convectively, and more logically, AP and dAP/dt always peaked just following maximal dT/dt, indicating that the thermal transducer mechanism does not depend on ΔT.
SOMATIC AND VISCERAL AFFERENTS: THERMORECEPTION

For these experiments, two thermal stimulating probes, 0.5 mm diameter, were employed. Each probe was calibrated so that a temperature change of one degree would correspond to a haptic sensation of the test subject. The probes were then used to determine the haptic localization of thermal stimuli in the dermatomes of the arm and hand. The results of these experiments indicate that the haptic localization of thermal stimuli is not determined by the size of the dermatome, but rather by the size of the region of the body that is supplied by the nerve fibers that are activated by the thermal stimuli. These findings suggest that the haptic localization of thermal stimuli is determined by the size of the region of the body that is supplied by the nerve fibers that are activated by the thermal stimuli.

564.6 TONGUE ADAPTATION TEMPERATURE INFLUENCES THE DYNAMIC AND STATIC RESPONSES OF LINGUAL NERVE FIBERS TO THERMAL STIMULATION. Robert F. Lundy Jr. and Robert J. Conners. The Florida State University, Tallahassee, FL.

The tongue is a highly sensitive organ that is capable of detecting a wide range of temperatures. The aim of this study was to investigate the effects of temperature adaptation on the dynamic and static responses of lingual nerve fibers. The results of this study suggest that temperature adaptation has a significant influence on the dynamic and static responses of lingual nerve fibers. These findings suggest that temperature adaptation is an important factor in the detection of thermal stimuli by the tongue.

ANATOMY AND PHYSIOLOGY OF MECHANORECEPTION

In this study, we used a combination of retrograde HRP and intracellular biotinimide to investigate the synaptic contacts between jaw-muscle spindle afferents and trigeminal motoral thalamic afferents. The results of this study suggest that the jaw-muscle spindle afferents make synaptic contacts with the trigeminal motoral thalamic afferents. These findings suggest that the jaw-muscle spindle afferents play an important role in the control of jaw-muscle movements.

In this study, we developed a circuit model for whisker receptive fields in the nucleus principalis. The results of this study suggest that the circuit model for whisker receptive fields in the nucleus principalis is a complex network of neuronal connections that is responsible for the generation of whisker receptive fields.

In this study, we used quantitative analyses to investigate the distribution of whisker and non-whisker primary afferents in the rat. The results of this study suggest that the distribution of whisker and non-whisker primary afferents is highly organized and is responsible for the generation of whisker receptive fields.

In this study, we investigated the possible inputs of GABA-immunoreactive neurons in the cuneate nucleus of the rat. The results of this study suggest that GABA-immunoreactive neurons in the cuneate nucleus receive inputs from a variety of brain regions, including the thalamus, cortex, and brainstem. These findings suggest that GABA-immunoreactive neurons in the cuneate nucleus play an important role in the regulation of pain and other sensory functions.
565.5 MECHANISTIC MODELS FOR TACTILE NEURAL CODING OF SHAPE. *K.A. Zvonarik* and K. Dandekar. Dept of Mechanical Engineering and Research Lab of Electrics, MIT, Cambridge, MA 02139.

The relationship between the biomechanics of primate fingertip and the responses of slowly adapting mechanoreceptors (SA-I) in the tactile sensation of object shape was studied. Finite element analysis was performed on a progressively realistic series of mechanistic models of the primate fingertip under a variety of shape stimuli. The shape of the models was related to a circular cylinder of about the same diameter as a typical primate fingertip to realistic 3-dimensional stimuli. The latter were generated from video images of accurate epoxy copies of monkey and human fingertips at various known orientations, obtained by using a videomicroscopy system. The internal geometry consisted of rigid bone enclosed by a homogenous or anisotropic material. The stresses, strains and deformations calculated from the models correlated with data from both biomechanical experiments on finger deformations and psychophysical experiments on the responses of SA-I.

In all models, the strain energy density and the maximum compressive strain were the leading contenders to be the relevant stimulus for SA-I. Because the models took into account the curvature and the stiffness of the primate finger, the predictions of SA-I population responses to rectangular gratings indented into the fingertip were more realistic than the predictions from previously proposed flat, semi-infinite models (Phillips and Johnson, J. Neurophysiol. 46(4), 1981). Although these population responses were radically different from the previous predictions, the spatial response profiles matched the neural data as well as before. In addition, the new models predicted that the spatial response profile of a receptor was strongly dependent on its location with respect to the center of contact region on the fingertip. Analysis of the nonlinear mechanics of contact between the models and cylindrical indents of various radii demonstrated good correlation between strain measurements and the relative types and corresponding neural response. (Supported by NIH Grant DC00625 and ONR URI Grant N00014-92-2-1814)

565.7 A VARIABLE THRESHOLD MECHANORECEPTOR MODEL. *P.J. Lock* and K.O. Johnson. 1Dept. of Elect. and Comp. Eng., Worcester Polytechnic Institute, Worcester, MA 01609 and 2Kriger Mind/Brain Inst. and Dept of Neurosciences, Johns Hopkins University, Baltimore, MD 21205.

The responses of primary mechanoreceptive (SA, RA and PC) afferents in macaque monkeys were studied using a sinusoidal vibratory stimulus and a two-pulse condition-test paradigm (CT). The CT experiments consisted of presenting either a mechanical or electrical conditioning pulse followed by a mechanical test pulse. For sub-threshold CT and CT delays 2msec and greater the mechanical test pulse amplitude required to elicit an action potential was essentially invariant - a result that would occur if there was no residual membrane depolarization. Above-threshold conditioning pulse required a significantly increased test pulse amplitude to generate an action potential. Supra-threshold CT experiments showed that threshold recovery following an action potential is slowly fit by a two-exponential decay function with time constants of 4ms and 15-40ms. These results suggest that the previous mechanoreceptive model [J. Physiol. 292:43-64, 1982] was flawed since these authors had proposed that fibers were not immediately fully repolarized following an action potential and that there is a substantial residual membrane depolarization following sub-threshold stimuli. A revised mechanoreceptive model in which threshold recovery was modeled by an exponential decay resulted in significant improvements in fits to the responses of mechanoreceptive afferents to sinusoidal frequency stimuli. In addition to effectively modeling the statistical regularity of the impulse trains, the variable threshold model also properly predicts the initial increase followed by a subsequent decrease in impulse rate with increasing stimulus frequency. Finally, the model predicts that the neural responses are only slightly affected by noise bandwidth or absolute refractory period and are moderately sensitive to the shape of the generator potential.

Impulse activity in axons generates after-effects on membrane excitability that can alter the conduction velocity of subsequently conducted impulses. We used compound stimulus patterns to assess two activity-dependent changes in conduction latency of functionally identified rat cutaneous afferents from the posterior tibial branch of the sciatic nerve. We measured two different parameters of activity dependence: supralinear and sublinear, a decrease or increase in conduction latency following conditioning with a single preceding impulse; depression, an increase in conduction latency during tetani; and recovery, the time course of the baseline conduction latency as measured before and after stimulation. We will present data on the effects of tetanic stimulation on the conduction latency of rat cutaneous afferents. We will discuss how various factors influence this variable and how this study relates to the function of these peripheral afferents. We will also discuss how various factors influence this variable and how this study relates to the function of these peripheral afferents.

Anoxia of Pacinian corpuscles (PC) [10:3] and rapid adapting mechanoreceptors (RA; n=6) of the glabrous skin were examined for activity-dependent changes in conduction latency using a two-pulse stimulus protocol. Following 5 msec isolation RA exhibited sublinearity, i.e., the second of two impulses initiated within 5 msec of another conducted less rapidly than the first. By contrast, only one PC exhibited sublinearity. PC and RA latency changes were directly related to the intensity of the stimulus. The results were consistent with the concept that the axon size of the sensory neuron is a major determinant of the mean normalized difference between the first and second impulse latency: in all three PCs the latency of the second impulse of the burst was normal, while in six of seven RA the latency was subnormal (p<0.05). Our data suggest that the function of mechanoreceptors in the glabrous skin may extend into their axon's conduction properties.

(NIH UHPS GM 35647)

565.6 RESPONSES OF CUTANEOUS MECHANORECEPTOR AFFERENTS TO STEP AND SINUSOIDAL SKIN DISPLACEMENTS. *J.C. Brown* and J. Truog. 1Instute for Sensory Research and 2Department of Bioengineering and Neuroscience, Syracuse University, Syracuse, NY 13244-5290

Neural activity was recorded from 100 mechanoreceptors innervating the glabrous skin of the cat hind-paw. Action potentials from individual nerve fibers of the medial plantar nerve were monitored in response to sinusoidal displacement at a frequency from 1 to 500 Hz and in amplitude from threshold to 250 μm. The same fibers were also characterized in response to step indentations (2 m/sec rise time) to intensities of 100 mm Hz. The responses showed periodicity of firing for the majority of fibers studied. Interval histograms demonstrated that the periodicty ranged from 3 to 35 ms depending upon the fiber type. The PC and RA fibers tended to have shorter interspike intervals in response to the SA fibers. Supported by NINCDS RO1-DC00380.

565.8 ADAPTATION OF MECHANORECEPTIVE AFFERENTS TO CONTINUOUS SINUSOIDAL VIBRATION. *Y.L. Leissa, S.S. Blain* and K.O. Johnson. 3Kriger Mind/Brain Inst. and 4Dept of Neurosciences, Johns Hopkins University, Baltimore, MD 21205.

The effects of stimulus duration, amplitude, and frequency on the adapting sinusoidal stimulus on thresholds of rapidly adapting (RA), slowly adapting (SA) and Pacinian (PC) mechanoreceptive afferents were studied. Recordings were made from medial and ulnar nerves of 3 anesthetized monkeys while vibration was delivered via a 1 mm diameter probe glued to the skin. The sinusoidal stimulus consisted of an adaptation period containing the adapting vibratory stimulus and a recovery period in which no adaptive stimulus was applied. During both periods, a sinusoidal test stimulus was presented once every 4 sec to track changes in absolute and entrainment thresholds. This testing rate was determined to have minimal effects on thresholds. The amplitude of the test stimulus was systematically varied between tests to make sure that the maximum stimulus was always applied. Adapting and test stimulus frequencies of 10, 30, and 60 Hz were used for SAs; 30, 60, and 100 Hz for RAs; and 60, 100, and 300 Hz for a total of 9 combinations of test and adapting frequencies for each afferent type. Amplitudes of the adapting stimulus ranged from 2 to 30 times absolute threshold and were applied for durations of 1, 2, 4 or 8 min. All afferents (6 SAs, 8 RAs, and 5 PC's) exhibit increases in thresholds with increases in either the adapting stimulus amplitude or frequency: there is about a 1 to 10 elevation in threshold over the range of frequencies and amplitudes studied. SA and RA thresholds increase and recover rapidly (t=15-30 sec) during both the adapting and recovery periods with stimulus durations greater than 1 min having no effect on the time constants nor on the level of adaptation. PC afferents adapt slowly (~5x) with the thresholds of some PCs still increasing after 8 min of stimulation. The PC's exhibit variable recovery time constants (30 sec to 6 min) and often have a small residual elevation in thresholds 50 min after the adapting stimulus was discontinued.

565.10 TACTILE SIGNALS GENERATED BY A TOOL USED TO DISCRIMINATE THE SOFTNESS OF OBJECTS. *J.E. LeMotee*, J. Zhang and J. Van. Department of Anesthesiology, Yale University School of Medicine, 335 Cedar Street, New Haven, CT 06510.

Subjects were 90-100% correct in ranking the softness of 9 rubber disks that differed in compliance (1.8 to 100 mm elevation) by indenting each specimen with the fingerpad, or by tapping each with a stylus held between two fingers. In order to study the role of tactile signals, the back of a finger was rigidly mounted to a lever and one rigidly mounted to another. The subject was able to discriminate a soft specimen from a hard one (p<0.05). For soft (≥7.7) specimens and a "medium soft" standard of 4.0 mm/g-wt when the velocity of tapping was held approximately constant. The perception of softness felt "natural" as a tap without percussion. This work is a previously recorded force trace from a specimen was "played back" to the operator. The subjects were unable to discern whether a "live" or a "played- back" trace was delivered. It was found that perceived softness depended primarily on the slope of the initial segment of the rising phase of the force trace which, for hard specimens, changed little with moderate variations in tapping force and velocity in comparison with that for softer specimens. The perceived softness of softer specimens decreased with increasing tap velocity suggesting that, for these specimens, passive touch without independent information about velocity and force was not sufficient for perceptual judgments of softness. It is hypothesized that the greater the initial force rate, the more likely that rapidly-adapting as opposed to slowly-adapting mechanoreceptors will be engaged and thus contribute to the perceived softness of objects. (Supported by ONR URI Grant 00019-92-J-1814)
565.11
INTERLAMELLAR FLUID DYNAMICS OF THE PACINIAN CORPUSCLE (PC). B. Pietrak* and S. J. Balogunski, Institute for Sensory Research and Biomechanics and Neurosience, Syracuse University, Syracuse, NY 13244.

Receptor potentials recorded from isolated PCs in response to sinusoidal vibrations have been shown to have non-linear asymmetrical input-output functions and U-shaped frequency characteristics. The PC's accessory capsule was studied both experimentially and theoretically to determine its mechanical contribution to the observed non-linear receptor potential. During compression of the accessory capsule, a shear stress is created and inter-lamellar fluid flows with velocity components orthogonal to the direction of displacement. The viscosity of the fluid imparts a resistance to the shear stress which arises as a force parallel to the compression. Inter-lamellar fluid is considered to be incompressible and, at the velocities considered herein, to have a resistive force proportional to its velocity. Measurements of reactive force in response to sinusoidal displacements have shown that the reactive force is linearly proportional with increasing frequency and amplitude. Furthermore, the reactive force can be described by a first-order linear differential equation of the form \( \frac{dx(t)}{dt} = k + c \cdot dx(t) \). A series of first-order linear differential equations was used to compute the inter-lamellar fluid velocities and lamellar displacements for a range of frequencies, stimulus amplitudes, and probe sizes. Computational simulations of the inter-lamellar fluid flow in response to sinusoidal displacement of the surface of the capsule shows that the multi-layered structure linearizes the inter-lamellar fluid velocity, thus linearizing the inter-lamellar compressive force. Video analysis of PCs subjected to a static stress shows that the stress load is carried by the outermost lamellae. Indeed, it is only during a highly time-dependent displacement of the surface (frequencies above 40 Hz) that a strain is observed below the outermost lamellae. Video analysis and computational simulations also show that the multi-layered capsule acts as a mechanical high-pass filter. Furthermore, the compressive strain and reactive forces increase with stimulus frequency. Thus, the non-linear asymmetric input-output function and the U-shaped frequency response cannot be mechanical in origin and must arise from intrinsic neural properties of the neurite. Work supported by NSF, BNS-911564.

565.13
A SECOND SYSTEM FOR INNOCUOUS MECHANORECEPTION IN THE HUMAN SKIN. H. Olejnik, N. Rekulu, J. Wessberg and Å. B. Vallbo, (SPON: European Neuroscience Association), Department of Physiology, Göteborg University, Medicinaregatan 11, S-413 90 Göteborg, Sweden.

In various mammals many unmyelinated (C) afferents respond to light touch. In man on the other hand, C-fibers with sensory functions have been identified almost exclusively with the senses of pain and temperature. For that reason it has been suggested that an older and slowly conducting system for innocuous mechanoreception has faded away during the evolution. Using the microneurography technique we have now found low threshold mechanoreceptors with conduction velocities within the unmyelinated region to be frequent in the hairy skin of the human forearm. The impulse rate associated with clearly innocuous mechanical stimulation amounted to 100 imp/s, leaving no doubt that light touch was the adequate stimulus. The thresholds to v Frey hairs ranged between 0.01 and 8 g with a median value of 0.25 g. The conduction velocity assessed using electrical or mechanical stimulation ranged between 0.7 and 1.0 m/s. For some units the receptive fields were explored in detail using a scanning method. The fields were found to be fairly large (10 mm x 5 mm) and composed of multiple areas of different sensitivity. Our study showed that low threshold mechanoreceptors are common in the hairy skin of the human forearm. It suggests that the human body is provided with a widespread system for innocuous mechanoreception subserved by C-fibers.

A NOVEL METHOD FOR SELECTIVE ELECTRICAL STIMULATION OF SMALL DIAMETER NERVE FIBERS. J.C. Petruska* and R.D. Johnson, Departments of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610.

There is a good deal of evidence that the small diameter nerve fibers in peripheral nerves, the thinly myelinated A-delta fibers and unmyelinated C fibers, display a high degree of central and peripheral plasticity in response to injury to the nervous system. The electrophysiological investigation of specific spinal cord input from these fibers is difficult because standard electrical stimuli recruit large myelinated fibers before small fibers. We have designed the following method for selectively stimulating small fibers.

In urethane-anesthetized rats, the caudal cutaneous sural and sciatic nerves were surgically isolated. A lumbar laminectomy was performed to isolate dorsal root filaments for recording. A bipolar Ag/AgCl electrode was placed around the sural nerve for stimulation of various fiber groups. Specially fabricated Ag/AgCl ring electrodes producing differential current densities were placed around the sciatic nerve. Using an arbitrary-waveform constant-current stimulus isolator and a modified triangular stimulus waveform, an anodal polarization block of sural-activated large A fibers was achieved at the sciatic site, allowing only the smallest A-delta and/or C fibers to conduct through to the dorsal root filaments.

This method could be used to study the input from small fibers into the spinal cord and/or the peripheral target without tissue damage by large myelinated fibers. Supported by NS 27511.

INHERENT FIRING PATTERNS OF MUSCLE AFFERENT AXON TERMINALS ARE GRADUALLY LOST IN CHRONIC NEUROMAS. J.B. Munro* and R.D. Johnson, Dept. of Physiological Sciences and Neuroscience, University of Florida, Gainesville, FL 32610.

We have previously shown that following transection and cross-regeneration of cat medial gastrocnemius (MG) muscle nerve into the sural nerve skin territory, large diameter muscle afferent fibers retained their stretch-sensitive and slowly-adapting firing patterns despite the presence of a foreign target devoid of muscle receptors. We have also shown that in short-term 6-day neuromas, even the sprouts of axonotomized muscle afferents retained these native firing patterns. Since these characteristics were evident for at least 2 years in skin, we designed the present study to determine if these firing patterns could be obtained from muscle afferent sprouts in long-term neuromas. In adult cats, the MG nerve was transected at the mid-thigh level and sutured into a blind-ending Gore-Tex sleeve. Following a recovery period of 3-16 months, the mechanosensitivity of sprouted afferents was tested by recording from both root and filament while mechanically stimulating the neuroma. Compared to afferents from 6-day neuromas, those from long-term neuromas were significantly more difficult to mechanically activate and showed a progressive decrease in conduction velocity, stretch-sensitivity, and slow-adaptation properties. We suggest that these of the physiological properties may be dependent on trophic factors present in peripheral targets such as muscle and skin absent in chronic neuromas. Supported by NS 15913 and NS 27511.
SOMATOSENSORY and THALAMOCORTICAL RELATIONSHIPS III

III.1

SHORT-TERM CHANGES IN EFFICACY OF CORTICOSEPTAL EPSPs FROM RACCOON PRIMARY SOMATOSENSORY CORTEX. P. Zorzin and P. Ijzenga. MRC Group in Sensory-Motor Physiology, Dept. of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Neurons in the cortical representation of glabrous skin of raccoon digits receive inputs from "off-focus" digits by direct thalamocortical connections. Weaker and less common inputs from "off-focus" digits are probably relayed by a corticopetal pathway from the heterogeneous zone a few mm rostral to the glabrous zone. "Off-focus" inputs quickly become more effective during short-term cortical plasticity, a change that could contribute to the formation of corticocortical synapses.

Our purpose was to test for short-term plasticity in the corticopetal pathway from the heterogeneous zone to the glabrous zone. Neurons were recorded intracellularly in the glabrous sheet of glabrous skin in the raccoon primary somatosensory cortex of raccoons anesthetized with nembutal. Short latency corticocortical EPSPs were masked following electrical stimulation (5 Hz) of the heterogeneous zone. Cortico-cortical synaptic responses were paired with simultaneous depolarizing current steps (up to 3 nA, 100 ms duration) injected intracellularly. Pairs of EPSPs with depolarizing current steps (50 pairings at 5 Hz) caused enhancement of corticocortical EPSPs lasting beyond the period of pairing. Enhanced EPSPs that could be relayed "off-focus" somatosensory inputs can be enhanced by over by depolarization of the target neuron by another input. Remaining questions are whether somatosensory EPSPs are also enhanced after cortico-cortical EPSPs are paired with current steps, and whether any such effects on somatosensory responses are restricted to "off-focus" inputs.

III.6.2

Clustered intrinsic connections in the cat somatosensory cortex (SSC) develop from an initially diffuse network. Although the shift from reverse homology to intermittent clusters can be observed visually, the transition is not easily defined. As a result, we found it important to quantify the developmental sequential identity of the changes that occur in intrinsic cortical development. To do this, confocal images were obtained from cat somatosensory cortex (SSC) of light green and gli-labeled kitten SSC at various postnatal ages. Several statistical tests were conducted in order to analyze the clustering of retrogradely labeled neurons and the distribution of tangential fibers emanating from the injection site. For some tests, individual sections were drawn to indicate labeled neurons. We analyzed neuronal neuronal clustering using spatial point process analysis. The null hypothesis, that the structure of labeled neurons at each age, did not differ from CSR (complete spatial randomness). Quad contours showed a change from a random distribution on PND3 (p<.001) to a clustered one on PND6 (p<.001). A refined nearest neighbor analysis confirmed conversion from a random distribution on PND3 (p<.43) to a clustered distribution on PND6 (p<.01). Other tests (disposition indices, density recovery profiles, etc.) verified the transformation of a diffuse organization of neurons to a clustered one. Coronal sections on PND 15 confirmed a pathway distribution of intrinsic connections resembling the adult distribution. The numbers of labeled neurons were significantly higher in clusters than in the intercluster zones (p<.001) on PND6. Profile analysis of the barrel hollo revealed a significant periodicity (center-to-center ~ 750um) on PND6. We demonstrate that the study of local circuit development of the cortical cortex is amenable to formal statistical analyses. Support: PHS NS24014.

III.6.3

SEQUENCE OF EVENTS IN THE DEVELOPMENT OF LAMINATION, INTRINSIC AND EXTRINSIC CONNECTIONS IN FERRET SOMATOSENSORY CORTEX. S.L. Julian*, R.V. Sonty, S. Palmer, P. Asimowicz, Depts. of Anatomy & Neuroscience, USUHS, Bethesda, MD.

Despite the relative immaturity of ferret neural system at birth, we previously demonstrated that axons of thalamic neurons reach the somatosensory cortex by PND 1, and are organized into distinct clusters by PND 5. Horizontal connections, in contrast, do not display a clustered organization until PND 28. To more precisely define the development of intrinsic and extrinsic connections in relation to the maturation of the cerebellum, we used slices of ferret pups aged PND 1-6. After injection of fluorescein-labeled dextran the slices were maintained in an oxygenated chamber to allow for transport of the tracer. On PND 1-3, injections into the deep cerebellar nuclei or, in subcortical white matter (WM), led to a slender radial column of labeled cells that extended from the upper portion of the cortical plate to the base of the ventricular zone. The labeled radial column contained both radial glia and neurons and their processes were evident within the soma. The cells within the column did not extend axons into the cortex, although horizontally-running fibers were seen beneath layer 6. In contrast, injections in the superficial cortical plate led to labeled neurons that extended their processes tangentially. Comparison with the locations of cells labeled with BRDU and born from 4E2-E38, indicate that neurons destined to occupy all cortical layers are present in the cortex by PND 3. At PND 1, injections into the white matter labeled thalamicocortical axons that terminated in crude clusters within the soma. With increasing age, the deeper injections lost their radial character and by PND 14 many axons extend into all cortical layers. After injections into more superficial cortical sites, a continuous band of labeled cells can be seen in layers 2-3. By PND 28, injections into the upper layers result in discrete clusters of labeled cells in layers 2-3. Supported by NS24014.

FACTORS THAT INFLUENCE NEURONAL RESPONSE VARIABILITY IN SOMATOSENSORY CORTEX: THE ROLE OF NMDA RECEPITORS. D. Prince, B. Whitham, M. Tommerdahl, O. Fayou, Departments of Biomedical Engineering and Physiology, University of North Carolina, Chapel Hill, NC 27599.

Potentials evoked in rat somatosensory cortical slices by single-stimulation of the white matter were examined (i) to determine the effects of stimulus frequency and intensity on intracellular response variability (hereafter referred to as response variability in SI neurons, and (ii) to evaluate the prediction that response variability is an indicator of the degree of cortical NMDA receptor activation (Lee and Whitham, 1995). Evoked potentials (EP's) were recorded for 50 to 100 consecutive stimulus presentations at a given stimulus frequency and intensity (frequencies between 0.2 - 5 Hz and intensities between 1.0 - 3.5 times the minimum intensity for evoking a response). NMDA EP's were recorded for each trial was determined by integrating the EP over the duration of the post-synaptic component; response variability was calculated as the coefficient of variation of the EP magnitude from the EPs recorded for each trial. To ascertain the contribution of the NMDA receptor population to response variability, some experiments were performed following application of ketamine, a selective NMDA receptor antagonist, and penicillin, which was found between response variability and stimulus intensity. As intensity was increased, variability decreased linearly, and the slope increased over the range 0.2 to 5 Hz. The relationship between stimulus intensity and variability of effects of stimulus frequency on this relationship was observed more clearly at more than superficial sites in SI cortex (those containing the highest density of NMDA receptors). (Here, variability decreased the dependency of response variability on stimulus intensity in a dose-dependent fashion. This work was supported in part by NIH RO1 MH48464 and the Whitaker Foundation.

NMDA RECEPTOR EXPRESSION IN THE RAT TRIGEMINAL PATHWAY TO BARRELL FIELD CORTEX DURING DEVELOPMENT. V. Remley and P. F. Brown. Institute for Developmental Neuroscience, Kennedy Center, Vanderbilt University, Nashville, TN 37203.

Polycyclic antibodies against the C-terminal and N-terminal domains of the NMDAR1 subunit were produced to examine changes in NMDA receptor expression during normal postnatal development of the trigeminal pathway to rat barrel field cortex. At P10 there is already substantial expression of NMDAR1 subunit in the trigeminal nucleus (V1) containing intra- and interlaminal thalamic nuclei, and in barrel field cortex. From birth to P180 there is relatively high level of NMDAR1 expression in the V1 complex, with a slight variation in the intensity of staining detectable as a peak at P30 and a gradual slight reduction from P30 to P180. Around P40 a single row of intensely immunoreactive cells is seen along the line between the 2 main cell clusters. The V1 nucleus is uniquely outlined by its intense staining from P3 to P40 when it blends with the moderate subunit density seen throughout the mature thalamus. POm has a more gradual onset to peak densities at P21 that is always less intense than VPM. Intra-laminar nucleus, especially CL, peak even later at P35, retaining scattered cells that express high levels of NMDAR1 for up to 12 months. Overall staining intensity in the barrel cortex increases from P3 to P- 21, when staining appears more diffuse but to a transient expression of NMDAR1 by astrocytes, which appear to be the fibers as such the corpus callosum and fornix. At P30, NMDAR1 is only marginally lower than P21, but at P35 & P40 neurons in layers IV & VI show markedly decreased expression. Analysis of the most intensely labeled barrel cortex shows very intense staining at P3 & P7 which reduces through P14, P- 11 & P-30. The expression in these cells again goes up at P35 where they remain for as long as 12 months. These differences are currently being quantified by Western & Northern blots in a z hybridization. (supported by NS-13031)
SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS

NMDARI subunits were localized with immunocytochemical methods in sections cut tangential to the cortical surface. In layer IV barrels, a strong reaction of NMDARI immunoactivity was created by the presence of a small number of densely labeled, large somata in the periphery of the barrel whose dendrites point toward the center of the barrel, and whose apical dendritic processes, roughly 1 μm in diameter, on their soma and dendrites, plus diffuse cytoplasmic labeling. Since NMDARI can form functional NMDA channels, the aggregates on cell membranes suggest that glutamate receptors are associated with glutamate receptor sites. These cell exhibit multiple dendritic morphology and few spines suggesting that they are aspiny, GABAergic, stellate cells. The distribution of these cells and their high content of NMDARI further suggest that they may be extraordinarily sensitive to changes in sensory activity levels arising from the whiskers and from other cells. These cells are surrounded by many other cells containing far lower levels of reaction product that is seen almost exclusively in their cell body. In addition to layer IV cells, each barrel contained a few clusters of densely labeled, small, circular profiles that we interpreted as cross-sections through some of the apical dendrite bundles of layer V cells. (supported by NS-25907)

Neurons in rat SI barrel cortex have been reported to develop biased receptive fields (RF) after days to weeks of experience with all but 2 whiskers trimmed on one side of the face ("whisker-pairing"). This type of adult plasticity or "bias" occurred in the superficial and deep layer neurons after only 24 hours of whisker pairing, a time prior to any change in layer IV neuronal RPs. These results challenge the question of whether early-born neurons in the superficial layers are required for the later layer IV plasticity. Epiphenal application of NMADA (150 μM for 15 min) under single whisker stimulation does not produce an increase in the field cortex. Fourteen days after the lesion, neurons of layers IV, V, VI still exhibit center (D2 whisker) and surround (D1, D3, C2 and E2 whiskers) RFs and evoked responses in nonanesthetized, trimmed whisker pairing 7 days after the cortical lesion, when all but 2 whiskers were cut on one side (leaving either D2 + D1 or D2 + D3). The trimming was repeated every other day for 5 days. On day 7 layer IV neurons in the D2 barrel failed to show the paired (ie., intact) whisker. In contrast, deep layer neurons in the same radial penetrations developed the bias. These results indicate that the superficial layers of SI cortex must be intact for normal plasticity in layer IV. We are studying now whether this apparent delay in layer IV plasticity is dependent on long periods of whisker pairing. (Supported by NS-25907)

CHARACTERIZATION OF A FUNCTIONAL WHISKER REPRESENTATION IN RAT BARREL CORTEX: OPTICAL IMAGING OF INTRINSIC SIGNALS VS. SINGLE-UNIT RECORDING. R.D. Frostig*, S.A. Markin, M.C. Koon, Dept. of Psychology, University of California, Irvine, CA 92717.

The whisker-to-barrel system provides the opportunity to stimulate an independent sensory unit in the periphery and measure the extent of its output in the cortex. To achieve this goal, we compared the functional representation of a whisker obtained with optical imaging of intrinsic signals to that obtained with single-unit recording. Specifically, we compared the area which exhibits stimulus and intrinsic signal responses to the area which exhibits stimulus-related neuronal responses.

We first determined the functional representation of the whisker in barrel cortex by imaging through a thinned skull during stimulation of an individual whisker for one second at 5 Hz. After imaging we removed the skull and performed depth spaced single-unit recordings guided by the imaged representation of the whisker while delivering identical whisker stimulation.

Although the largest change in the intrinsic signals are found within a localized area which we defined as the functional representation of the whisker (Masino et al., PNAS, 90: 9996-10002, 1993), it is a widespread area beyond the functional representation which exhibits a stimulus-related change in intrinsic signals. When we compared the area of the stimulus-related neuronal responses to the area of the stimulus-related intrinsic signal responses we found that the two were similar. Both response areas spread over a radial distance of approx. 2 mm from the center of the imaged representation. However, the spread of single-unit activity was not uniform: there was a significant decrease in single-unit responses starting at and extending beyond the border of the localized functional representation determined with imaging. These results demonstrate an extensive response area activated by stimulation of a single whisker as assessed by both techniques, and highlight the correspondence between intrinsic signals and underlying responses. Supported by the Beckman Foundation and NIH grant MH-50362.

EFFECTS OF WHISKER TRIMMING ON GABAa RECEPTOR BINDING IN DEVELOPING RAT WHISKER BARREL CORTEX: E. Salazar, S.C. Carpenter, R.L. Miller, T.A. Austing and J.J. Fuchs, Dept. Biological Sciences, University of North Texas, Denton TX 76203.

Sensory deprivation affects GABAergic systems in adult neocortex (e.g., Hendry et al. '90; Akhtar & Land '91), but little is known about the role of this permissive inhibitory system in shaping the developing neocortex. The present study investigates developmental effects of sensory deprivation on GABAa receptors in rat barrel cortex. Either the middle row or the outer rows of vibrissae were cut at P0. The middle row (P0) was relative to nondeprived barrel (P0.3). GABAa binding was low in immature (P0) and high in adult (P00-1) rats. When we compared GABAa binding between P0/P0(3) and P00-1, we observed a significant increase in GABAa binding in adult. We also examined GABAa binding in response to bicuculline and KA, and found that the GABAa binding was significantly lower in the adult rat than in the neonatal rat. These results suggest that GABAergic activity may play a role in sensory deprivation and that GABAergic activity may be important in shaping the developing neocortex. We are studying now whether this apparent delay in layer IV plasticity is dependent on long periods of whisker pairing. (Supported by NS-25907)

NONSPECIFIC SHORT-TERM ELECTRICAL STIMULATION OF A SINGLE FOREPAW DIGIT INCREASES THE PHYSIOLOGICAL REPRESENTATION OF THAT DIGIT IN LAYER IV OF RAT BARREL FIELD CORTEX: AN EXTRACELLULAR RECORDING STUDY. C.Y. Lee, R.S. Waters, C.A. McCandliss, E.J. Johnson. Dept. of Anatomy and Neurobiology, UT, Memphis, Col. of Medicine, Memphis, TN 38163

Limited differential sensory experience can alter the physiological organization of the glabrous representation of the forepaw in the forepaw barrel subfield (FBS) cortex in rat layer IV (see companion abstract, Waters et al.). To determine whether nonspecific short-term electrical stimulation can alter the physiological representation of the forepaw, we examined barrel cortex prior to and immediately after a short period of electrical stimulation.

Adult rats were anesthetized with Nembutal, head was stabilized, skull was opened over SI, dura was removed, and cortex was covered with warmed silicon fluid. Carbon fiber electrodes were used to map the representation of digit two (D2), D3, D4 prior to and immediately after electrical stimulation. Pulses of direct current (amplitude: 80-120μA, duration: 100 mssec, interval: 1 Hz) were applied to the tip of D3 for 2 hr. Following the period of electrical stimulation, the cortex was immediately remapped. The following results were obtained:

1. Following electrical stimulation, the area of cortex served by D3 increased by approximately 106.

2. These results suggest that brief periods of electrical stimulation are sufficient to immediately alter the physiological representation of the stimulated digits. These results bear directly on the role of plasticity in neocortex.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
566.13 DIFERENTIAL SENSORY EXPERIENCE ALTERS THE REPRESENTATION OF THE FOREPAW IN FOREPAW BARREL SUBFIELD (FBs) CORTEX IN RAT. B.L. Water1, C.A. Le., R.C. Fowler2, C.A. McCaig, Dept. of Anatomy and Neurobiology, University of Tennessee, Memphis, TN 38163; 1Dept. of Psychology, Unis. of Mississippi, Oxford, MS 38677.

The relationship between the forepaw and the barrel-like structures in the forepaw barrel subfield ( FBs) in rat SI cortex offers an excellent model system to study the differential effects of sensory experience on cortical structure and function. We have investigated the physiological mapping and morphological analysis of FBs in rats trained on a sensory-motor task.

Adult rats, water deprived, were trained to depress a 9mm disk to receive sticklebarn food in a period of 18-30 days. Following training, animals were anesthetized with Nembutal, the head was stabilized, the skull was opened over SI, dura was removed, and the cortex was covered with warmed silicon fluid. Carbon fiber electrodes were used to map the forepaw representation in SI cortex in both hemispheres. Lesions were made to identify specific recording sites and to relate the electrophysiological map with the morphological map in FBs. Following physiological mapping, the cortex was removed, hemispheres were flattened and cut tangentially. Tissue was stained with cytochrome oxidase (CO) to obtain the results. The results were as follows: 1. Sensory-motor training resulted in an average increase of 24% in the area of cortex represented by glabrous digits tips in trained as compared to untrained hemispheres. 2. No morphological differences within the FBs were observed between trained and untrained hemispheres. 3. Limited sensory-motor experience is sufficient to alter the physiological map of FBs without a noticeable change in the morphological map in FBs.

Earlier anatomical, biochemical and behavioral studies have shown that subject-environment interactions have significant effects on brain structure and learning capabilities. Moreover, it is well established that the cutaneous representations of the primary somatosensory (SI) cortex display a remarkable plasticity in response to environmental enrichment or deprivation through an experience-dependent process involving spatio-temporal cues. We have designed experiments to evaluate the influence of early differential tactile experience on the organization of the cutaneous "maps" of the SI cortex in the rat. Long-Evans female rats were housed under different tactile environments (standard, impoverished, enriched) for 1 month from the time of weaning. Their forepaw representation within SI was then reconstructed by using microelectrode mapping. The "standard" rats were housed in groups of 3, in a conventional environment. The " impoverished" rats were also exposed to a conventional environment, but each animal was housed in a separate cage. The "enriched" animals were housed in larger cages, in groups of 12 and were provided with objects of different shapes, sizes and textures. Preliminary results suggest that: 1) the skin territories more likely to be stimulated (prolephant skin surfaces) are best represented within the SI cortex; 2) early tactile enrichment through object manipulation and contact with mates improves the spatial resolution (smaller cortical receptive fields, RPs) of the cutaneous forepaw representation; 3) tactile impoverishment results in a degradation of the forepaw representation that is characterized by larger RPs, many double RPs, and by the emergence of non-cutaneous small "islands" within the cutaneous map. These results indicate that early tactile experience plays a critical role in the development and maintenance of the cutaneous cortical representations.

566.15 ACUTE CHANGES IN THE RECEPTIVE FIELDS AND NEURAL ACTIVITIES OF THE VPM-THALAMIC NEURONS DURING THE DEAFFERENTATION OF SINGLE DIGITS OF ANESTHETIZED RATS. A. V. Saganov1, P. DiSilvio1, A. H. Kiang2, A. B. Sininger1. 1Dept. Psychol, 2Vanderbilt Univ, Nashville, TN 37235 USA.

To investigate whether either temporary (TD) or permanent (PD) deafferentation processes recruitment of sensory maps in the forepaw area of the ventral posterior thalamus, we made single or multiple unit recordings from neurons VPM the thalamus of urethane anesthetized rats. Neuronal responses to subcutaneous electrical stimulation to the forepaw area, forepaw digit stimulation were quantitated by analyzing post-stimulus time histograms. After determining the minimal receptive fields or control period, either TD or PD of a RF (single digit) was carried out by ipsilateral injection 12% or amputation, respectively. Ten of 12 VPM units showed a reversible block of original RF (ORF) after TD and exhibited TD-like RFs. Nineteen units that belonged to neighboring neurons DPs were initially observed at 22.8 % of RF after TD and they disappeared at 57.3 % of RF after PD. The PD showed much weaker responses to the peripheral activation than ORF (determined by maximum 43.1-12.8% of the ORF RF). The final response latencies from the NRP (0.0-0.7-15.4-0.8 ms) were slightly longer than those from the ORP (7.1-0.8-15.4-0.8 ms). Seven VPM units were subject to PD study and they exhibited NRP sizes located anterior to the ORP. NRP sizes located anterior to the ORP (max. 96.8% of the ORP RF) were slightly larger than those from the ORP (96.8% of the ORP RF). Responses to the NRP of 0.0-0.7-15.4-0.8 ms were slightly longer than those from the ORP (96.8% of the ORP RF) (10.5-20.6 ms).

These results demonstrate that either temporary or permanent deafferentation of single digit induces a marked reorganization of the thalamic representation within minutes of VPM the thalamus. (KRP 93)

566.16 DEAFFERENTATION CHANGES THE DISTRIBUTION AND ORGANIZATION OF THE BURSTING PATTERNS OF NEURONS IN SOMATOSENSORY CORTEX OF AWAKE CATS. B.W. Dykes1, H.H. Webster, A.A. Myasnikov and I. Salimi. Dept. de physiologie and Centre de recherche, Dept de psychiatrie, Hopital Sac-oeur, Universite de Montreal, Montreal, Quebec H3C 3J7.

After identifying specific classes of neurons in the cat somatosensory cortex based on the structure of their spontaneous activity, these same classes were sought in somatosensory cortex that had undergone a large deafferentation by transection of the radial, median and ulnar nerves. Recordings made from several days to two weeks after the surgery showed an increased probability of encountering neurons that exhibited bursts (small cortical receptive fields, RPs) of the cutaneous forepaw representation or a decreased probability of encountering neurons with long bursts. This change suggests that deafferentation leads to less structure in the ongoing activity within deprived cortex. We hypothesize that this results from a reduction of the strength of corticocortical and corticobalamic feedback loops impinging on the deprived area.

(supported by the Medical Research Council of Canada)

566.17 DISTINCTIVE PATTERNS OF BURSTING IN NEURONAL ACTIVITY FROM SOMATOSENSORY CORTEX OF AWAKE CATS. A.A. Myasnikov1, H.H. Webster and B.W. Dykes. Department de physiologie, Université De Montréal, Montréal, Québec H3C 3J7.

Recent studies have shown that differences in the membrane characteristics of cortical neurons allow cortical neurons to be distinguished on the basis of the shape and temporal pattern of their action potentials. These characteristics may allow for the identification of a behaving animals. To examine this possibility in the somatosensory cortex, we obtained extracellular field recordings from neurons in awake, quietly resting cats using tungsten-in-glass microelectrodes. Neurons were characterized by their action potential waveforms, receive field characteristics and other electrophysiologic attributes. Analysis of the spontaneous activity showed some cells to have distinctive bursting patterns. Cells of one class had multiple peaks in their autocorrelograms, many impulses per burst and nearly constant interburst intervals. A second had only one peak in their autocorrelograms, short bursts, and increasingly longer intervals within the burst. Other cells lacked any temporal dependence between spikes. (funded by the Med. Res. Council of Canada)

566.18 NEOCORTICAL AND THALAMIC PLASTICITY FOLLOWING NEONATAL DEAFFERENTATION IN RATS. D.M. Li, J.T. Ross, J. Nisanov, and P.J. Hand. Institute of Neurological Science, University of Pennsylvania, PA 19104.

One critical issue involving activity-dependent neocortical plasticity is the relative contribution of intracortical and subcortical structures to representational changes. Our previous studies showed that neonatal removal of all whiskers except C3 produced a prominent enlargement of 2Dg functional representation of spared C3 (3C) in SI cortex. In this study, we used the same model to investigate the plasticity at the cortical and subcortical level. SC3 preparation resulted in a significant expansion of 2Dg functional representation in both SI cortex (O(3d), 3.35% 8%) and ventral thalamus (O(12.5), 3.4%) but not in the brainstem trigeminal complex. However, we only found a 99.5±17.6% enlargements in barre size as revealed by CO staining. Presumably the striking representational enlargement was only partly due to a structural growth. The use of the active whiskers in the passive whisker stimulation may involve in this additional expansion, we performed GAD immunochemistry in the sc3 model. Preliminary results showed that the pattern of GAD in somatosensory cortex is well organized and homogenized. In contrast, the boundary of each barre in deafferented barre cortex is disorganized and the GAD positive cell density of adjacent barres is significant attenuated as compared with sc3 region. These results suggest the GAD expression may be activity-dependent and its down regulation following deafferentation may reflect a decreased lateral GABAergic inhibition that contributes to the observed neocortical plasticity. [Supported by NIH-2P41RR01638].

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS IV

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Somatotopic organization of the human somatosensory cortex was analyzed with echo planar imaging (EPI) at 1.5 T. All subjects were subjected to the deoxyhemoglobin as an endogenous contrast medium. Scrubbing stimulation at a frequency of 3 Hz was applied to one of three cutaneous areas: toes, fingertips, and tongue tip. Each recording session consisted of resting (40 s), stimulation (30 s), and resting (40 s) periods. Sagittal EPI slices of 8 or 15-mm thickness (data acquisition time, 60 ms per slice; in-plane resolution, 2 x 4 mm) were obtained every 2 s continuously in a single session. A spin echo image of the corresponding sagittal slice was taken just before and after several sessions. Statistical significance of signal changes was assessed with Student's t-test for each voxel. We found focal bands of increased signals (1.5 to 8 %) during stimulation periods, with rise time of 2 to 6 s. These activated bands were identified on the contralateral postcentral gyrus. The cortical responses from the three stimulation sites were anatomically distinct and organized mediolaterally in the order of toes, fingertips, and tongue tip.

567.3 MOTOROTOPIC ORGANIZATION OF HUMAN CORTICAL 20-Hz OSCILLATIONS. R. Salmelin, R. Hari, M. Hamalainen, and M. Kajola. Low Temp. Lab., Helsinki Univ. of Technology, 02150 Espoo, and Neuroimag Ltd., 00510 Helsinki, Finland.

In humans, the spectral distribution of cortical spontaneous rhythms (alpha, mu, tau) is dominated by frequencies around 10 and 20 Hz. The reactivity and source areas of these cortical somatosensory rhythms associated with self-paced left- and right-sided index finger, toe, and mouth movements were studied non-invasively in eight healthy subjects employing a 122-channel whole-head neuro-magnetometer. Following the complete suppression during movements, the rhythms manifested a pronounced increase above the baseline, particularly in the 20-Hz range. Sources of the enhanced 20-Hz activity were found in mesial cortex for toe movements and about 5 cm and 8 cm from Rolandic cortex (for hand and mouth movements, respectively, apparently tracking the representation of the moving body parts in the motor cortex. The reactive 20-Hz rhythms, on the contrary, were increased at about 6 cm from vertex, close to the hand area in the somatosensory cortex, for all tasks. The 10- and 20-Hz somatomotor rhythms seem to have separate spatial distribution and distinct functional roles in motor tasks, with the 20-Hz range manifesting motorotopic organization.

Respiratory related evoked potentials (RREP) recorded from C2-C3 and C2-C4 have been elicited by occlusion of inspiration. The initial peak positive (P1) is believed to represent the sensory cortical response to the activation of the afferents transducing the inspiratory load. It was hypothesized that the P1 peak amplitude is proportional to the inspiratory load magnitude in children. Children were studied semi-awake at rest. They inspired through a mouthpiece and non-rebreathing valve connected to a loading manifold. EEG activity was recorded from C2-C3 and C2-C4. The resistive (R) load magnitude was set to 21.0 cm H2O/sec (4.92KHz bandwidth). Evoked potentials were obtained by interruption of inspiration with the load, R, open, port open. The EEG activity was averaged on-line and stored on computer system. Each trial consisted of 80 load presentations. Each load magnitude and the control no-load were applied 20 times each in an trial. There were 4 trials. The P1 peak amplitude and latency were measured. No P1 peak was observed. The P1 also increased as the R load on loads and occlusion. The mean P1 latency were C2-C3=38.2, C2-C4=38.4 ms and there were no significant differences between R load magnitudes. The P1, were measured with the resistive (R) load magnitudes and for both electrode pairs. Inspiratory occlusion and resistive loads produce mechanical changes to the inspiratory transduced by respiratory mechanoreceptors. These data support the hypothesis that increased in inspiratory load are correlated with increased activation on sensory cortical neurons. Supported by ALAF grant UF #95005907.

567.2 PUTATIVE HUMAN SOMATOSENSORY AREA III (SIII) AND ITS MODULATION BY ATTENTION. J.V. Pardo, J. Lee. Psychiatry PET Unit, Psychiatry Service, VAMC, and the Division of Neuroscience Research, Department of Psychiatry, University of Minnesota, Minneapolis, MN.

PET and MEG have recently helped to define human SI (along the Rolandic Sulcus) and SII (parietal operculum). By analogy to the organization of non-human somatosensory cortices, Caselli has postulated the existence of human SII and SIII. Human SII and SIV are hypothesized to compose a ventrolateral somatosensory associative cortex whose damage causes tactile agnosia.

Ten healthy volunteers participated in a somatosensory processing task while cerebral blood flow was measured with the 11C-[1H]O Dihydroxybutane technique and PET. In the somatosensory attention condition, subjects monitored their finger, lip, or great toe for pauses in a series of taps (3 Hz) from a von Frey hair and maintained passive visual fixation. In the visual attention condition, subjects fixated attentively looking for rare, transient disappearances of the fixation mark. We recorded SII, right contralateral to the stimulatedips or contralateral toe, and lip responses in SII who were closely mapped together and were modulated significantly by attention.

Functional magnetic resonance imaging (fMRI) techniques have recently been developed to identify cortical areas activated during specific tasks. We have further modified these techniques to identify regions in the cortex activated during simple somatosensory and/or motor tasks.

All data were collected from normal subjects. Images were obtained with a 1.5 T MRI scanner. Each protocol typically consisted of alternating sets of 6 images during a task and 6 images at rest or during a control task for a total of 72 images. Typical imaging parameters were: 4mm axial cortical slice, TR=68ms, TE=40ms, bandwidth=4.92KHz, field of view=302mm, 256x128 matrix. flip angle=90°. Somatosensory-related events were presented to the patients during an electrical stimulus applied to the median nerve with a TENS-type stimulator to evoke strong perceptual awareness in the distribution of the nerve, or 2) natural tactile stimuli (e.g., light brush) of the skin. For comparative purposes, scans were also obtained during a sequential motor/sensory task (e.g., thumb to finger opposition with contact). Activated regions were determined based on a pixel by pixel statistical analysis (t-test) of the mean intensity signal difference during the task and control.

Natural tactile stimuli activated large areas of SII and SIII. Electrical stimuli that evoked paradiahic sensory activations disscnt areas of SII. During simple motor tasks, SII, SIII, and SIV were activated. Within activated areas, the mean signal intensity followed the expected somatotopic pattern indicative of cortical activation. These data indicate that fMRI can be used to identify and confirm the functioning of sensory and motor cortical areas active during simple tasks.

Functional magnetic resonance imaging (fMRI) has the potential to achieve greater spatial resolution than PET and SPECT. We tested the ability of fMRI to resolve individual finger representations within the somatosensory cortices (SI and SII) by applying a vibratory stimulus to single digits during a Tridimensional Trains or Stimuli (T) mapping protocol. In each session each vibratory and proprioceptive stimuli were applied to DII, DII, and DIII, 6.5 mm 6.5 mm 6 mm 6.5 mm stimulus-control cycles in each session. Five images/slice were obtained during stimulus or control. T-maps were superimposed on high resolution MR images. The vibratory cortical activation maps for all three digits showed significant activations (t-map clusters containing 9 or more pixels with all p<0.05) in SI and SII. The regions activated by DII and DIII were spatially distinct when measured both by the center of gravity of the peak which exhibited the largest increase in intensity within the activated cluster. In SI, the activated regions for DII and DIII were spatially closest while the activated regions for DII and DIII were more distant. The proprioceptive cortical activations were less localized than the vibratory activations.

This demonstrates that fMRI can distinguish the cortical representation of individual fingers in single subjects. Therefore, the spatial resolution of fMRI is higher than that of PET or SPECT.
567.7 SPATIAL MAPPING OF PAIN AND MOTOR ACTIVATION IN HUMAN CEREBRAL CORTEX WITH FMRI AT 4 TESLA. Michael J. Jaderala, Han Wei, Robert C. Coghlan, Steven D. Wolf and Robert S. Balaban. Neuromagnetobiology Branch, NEPR and Laboratory of Cardiac Energetics, NHLBI, NIH, Bethesda, MD USA.

A high resolution gradient recalled echo FMRI method was developed to visualize neural activity evoked by thermal nociceptive stimuli and motor tasks. Changes in neural activity reflected by blood flow and blood oxygenation level differences (in flow effects and T2 effect, respectively) were obtained by using 2 and 6 mm thick transaxial slices with repetitive 13 sec. scans that provided good contrast and were registered to high resolution anatomical scan. In both cases, activated voxels were discretely organized such that the activity generally traced the gyral borders and overlapped somewhat into the sulci. The appearance of the signal was consistent with tin originating from marginal or central gyral veins of medium caliber and possibly their collaterals. Mictalse acquisitions indicated that the nociceptive signal (from heating the tip of the thumb) occurred over 4-8 mm in the axial dimension and was contiguous between slices. The motor task (repetitive flexion of the last joint of the thumb) yielded a more extensive signal. For example, in 9 successive 5 mm slices starting from the superficial cerebral cortex to the level of the corpus callosum, contiguous activity (associated with the posterior bank of the precentral gyrus/superior sulcus) could be traced through adjacent 3 slices. One slice contained the major locus of activity. In the coronal plane the activity was very discretely distributed and these data suggested that a prominent portion of the signal increase arises from the venous compartment and that the signal provides functionally relevant and anatomically discrete information.

567.8 NEURAL BASIS FOR TACTILE ROUGHNESS PERCEPTION: THE RELATIVE CONTRIBUTIONS OF SLOWLY ADAPTING AND RAPIDLY ADAPTING AFFERENTS. D.T. Blakeslee, S.S. Hsiao, and R.O. Johnson. Krueger Mind/Brain Inst. and Dept. of Neuroscience, Johns Hopkins Univ. Baltimore, MD 21205

Psychophysical and neurophysiological studies were done to assess the relative contributions of slowly adapting (SA) and rapidly adapting (RA) peripheral afferents to tactile roughness perception. The stimuli consisted of 18 embossed surfaces composed of tetragonal dot patterns with constant, 3.5 mm center-to-center spacings, variable diameters (2.0, 100, 500, 2000 and 2500 mm) and variable heights (280, 350, 680 um). Dot diameter and height are shown to have differential effects on the responses of SA and RA afferents. It is postulated that differentially stimulating these afferents will allow us to determine the relative contributions of SA and RA afferents to roughness perception.

Psychophysical reports from 15 subjects show that both dot diameter and dot height have significant effects on roughness perception. Decreases in dot diameter and increases in dot height both cause increases in perceived roughness with dot height having a larger effect at small diameters: narrow dots feel more than 2 times as rough at 680 um than at 280 um, while wide dots feel equally smooth at all dot heights. Neurophysiological recordings from 12 SA and 14 RA afferents from the ulnar and median nerves of 3 Macaque monkeys were made using the same dot patterns. The neural responses, which are plotted as two-dimensional spatial event plots, are analyzed using a measure of spatial variation in firing rates (J.Neurosci. 12:3414-3426, 1992.). In accordance with previous results (see, Physiol. and Pharm., in press), only the SA afferents systematically match the psychophysics. While both SA and RA spatial variation measures are mildly affected by dot diameter, only the SA's are affected by dot height. These results strongly suggest that RA afferents do not contribute to tactile roughness and that SA afferents alone form the neural basis for tactile roughness.

567.9 TRANSFORMATION OF TACTILE SPATIAL FORM WITHIN A CORTICAL COLUMN IN AREA 3b OF THE MACAQUE. J. DiCarlo, S.S. Hsiao, and R.O. Johnson. Krueger Mind/Brain Inst. and Dept. of Neuroscience, Johns Hopkins Univ., Baltimore, MD 21205

Multi-electrode (7 elect., 400 μm spacing) recordings were made in area 3b from both hemispheres of the awake Macaque monkey. The electrodes were positioned such that isolated neurons had receptive field centers on the same spatial location of the monkey's distal finger pad. Typically this allowed simultaneous recording from 3-5 neurons along a perpendicular to the cortical surface, which we assumed to be within a single cortical column. The monkey performed a visual task while embossed letters and oriented bars were repeatedly scanned at a controlled force (30 μm) in 0.5-0.8 mm (electrode) across the distal finger pad. The locations of the penetrations were confirmed using standard histological techniques. Two-hundred and fifty neurons (65 recorded per animal) were studied using the letter and bar stimuli. The neural responses to the embossed letters were used to construct two-dimensional spatial event plots (SEPs). A structural analysis of the SEPs shows neurons recorded in the central layers tend to be more isomorphic (similar in structure to the stimulus letters) and more responsive (higher impulse rates) than neurons in both supra- and infragranular layers. Cross-correlation analysis on 223 simultaneously recorded pairs of neurons suggested monosynaptic excitatory connections between 34% and common input to 16% of the pairs. In general, among pairs exhibiting monosynaptic excitatory connectivity, the SEPs of the "sender" neuron are more isomorphic than those of the "receiver" neuron. The overall pattern of functional connectivity is consistent with anatomical studies; there are monosynaptic connections from the central layers of cortex to supragranular and infragranular layers and monosynaptic connections from supra- to infragranular layers. Together, these results support the hypothesis that local, columnar cortical processing of spatial form proceeds from layer 4 to supra- and infragranular layers and that this processing results in a significant transformation of spatial form.

567.10 SHORT- AND LONG-LATENCY SOMATOSENSORY EVOKED FIELDS REFLECT DIFFERENT ASPECTS OF TACTILE INFORMATION PROCESSING. N. Forsa, R. Salmelin, V. Jousetki and R. Hari. Low Temperature Laboratory, Helsinki University of Technology, 02150 Espoo, Finland.

We recorded whole-head somatosensory evoked fields (SEFs) from 7 healthy subjects to air puff (of dorsum of the middle finger) and electric (median nerve at the wrist) stimuli; the interstimulus interval (ISI) was 3 s. The early (20-60 ms) SEFs to both stimuli originated in the central/perietal somatosensory cortex (SI) and the late (>85 ms) SEFs bilaterally in the second somatosensory corticies (SII). An additional source was active at 70-110 ms in the contralateral parietal postcentral cortex (PCC) in the wall of the postcentral fissure. Only SI responses were markedly smaller in amplitude and longer in latency to airpuffs than to electric stimuli. In an odd-ball paradigm, electric or air puff stimuli were delivered to the thumb and 'deviants' (15%) to the little finger, or vice versa (SI 0.5 s). In SI, the deviants elicited similar responses irrespective of whether they were presented alone or among standards. In contrast, SEFs from SII, and especially those from PCC, were clearly larger to deviants presented without the intervening standards. The early and late SEFs apparently reflect different aspects of tactile information processing. SI and PCC seem to be more integrative and less stimulus-specific in function than the SI cortex.

567.11 VIBROTACTILE SENSITIVITY IN PATIENTS WITH CARPAL TUNNEL SYNDROME (CTS). C.M. Checkoski* and S.J. Balowinski, Institute for Sensory Research and Department of Biomedical Engineering and Neuroscience, Syracuse University, Syracuse, NY 13244

CTS is commonly diagnosed by neurologic examination and electrophysiologic evaluation. However, many investigators have recently advocated the use of vibrotactile testing as a complementary diagnostic tool. The purpose of this study was to determine if the idea that the large-diameter sensory fibers are affected first in nerve compression, possibly resulting in elevated vibrotactile thresholds. More recently, however, it has been shown that vibrotactile thresholds were elevated during coincident pain (Akgarian et al., Soc Neurosci Abstr 1992). The purpose of this study was to assess vibrotactile sensitivity in CTS quantitatively using strictly controlled laboratory techniques. Analysis on 223 simultaneously recorded pairs of neurons suggests monosynaptic excitatory connections between 34% and common input to 16% of the pairs. In general, among pairs exhibiting monosynaptic excitatory connectivity, the SEPs of the "sender" neuron are more isomorphic than those of the "receiver" neuron. The overall pattern of functional connectivity is consistent with anatomical studies; there are monosynaptic connections from the central layers of cortex to supragranular and infragranular layers and monosynaptic connections from supra- to infragranular layers. Together, these results support the hypothesis that local, columnar cortical processing of spatial form proceeds from layer 4 to supra- and infragranular layers and that this processing results in a significant transformation of spatial form.

Human subjects identified either the higher of two vibrotactile stimuli differing in frequency or the rougher of two tactile gratings differing in spatial frequency. Stimuli were presented under computer control by a feedback regulated vibrator or a servo operated surface stimulator previously described. On each trial stimulus pairs were separated by a ~0.5 to 30 second delay interval. For both vibrotactile and textured stimuli, percent correct decreased and reaction times increased as a function of increased delay interval length. Engagement in a distracting task was used to determine whether elevated thresholds correlate with the presence of pain. Detection thresholds were measured on 20 patients (36 hands) clinically diagnosed with CTS. Bursts of vibrotactile stimuli were presented to the affected hand (stimulus frequencies, 1, 10 and 300 Hz; conductor spaces, 0.08 cm² and 2.9 cm²). The subjects also rated the amount of pain that was present at the beginning of each testing session. Thresholds were compared to normative data in the literature and to a within-subject control site, the hypothenar. No elevations in threshold were found on affected areas in 19 hands during all testing sessions when compared to controls. Thus, the testing of vibrotactile thresholds for CTS may not be warranted. In 11 testing sessions elevation thresholds were obtained on affected areas where the subjects reported the presence of pain. These results indicate that elevated thresholds in CTS may actually be the result of the presence of pain. Supported by NIH, HD30098.
567.13

Two rhesus macaques performed a task that manipulated attention across tactile space and between somatosensory modalities. The task involved three concurrent stimuli: two tactile vibrations presented to the hands and an analogous auditory tone. The monkeys were cued in a blockwise fashion to discriminate between target and non-target stimuli at the three stimulus positions at a time. This enabled us to measure neural responses to physically identical stimulus arrays under conditions differing only by cue. An asymmetry between somatic allow us to separate the components of the response.

Psychophysical tests using 80% valid cues verified that the monkeys used the cue to direct their attention.

We surveyed 373 cells in areas 7R and 7b. Of these, 170 were held long enough for us to record replicate blocks under each attentional condition (for a total of 420 trials per cell), and 85 satisfied an additional F-ratio criterion representing task-relatedness and stability of response. Excitatory responses to the transient phases of the tactile stimuli were the most common response pattern, but there were notable exceptions. In SII, a subset of cells was excited by the sustained phases of the stimulus but inhibited by the transients. In 7b, bimodal tactile and visual responses were common, and a few cells showed consistent directional selectivity across modalities. Bilateral tactile receptive fields were found in both areas. In many cases, the response to the first stimulus was followed by a diminished response to the second. Temporal order effects may be related to the phenomenon of tactile masking. (Supported by NS 31060)

567.14

Cells in areas SII and 7R were observed under three different attention conditions: the "no attention" condition (blocks set 1 and 2), the "auditory stimulus" condition (blocks set 3 and 4), and the "auditory and visual stimulus" condition (blocks set 5, 6, and 7). The monkeys were cued to an auditory stimulus, with each treatment presented in replicated blocks of trials. 40% of the cells showed firing rate differences of 50% or greater between left and right targets, and a subset of cells were used for three stimulus presentations at a time. There was no consistency, however, in the directions of these effects. Across the population that we sampled, both spatial and cross-modal attention effects appeared.

Randomization analyses were applied to determine whether the magnitudes of these observed effects were greater than would be expected by chance alone. The paradigm for tactile stimulus presentation consisted of a set of blocks where the first was a blank block, the second was a cue block, and the third was a treatment block. Randomization procedures were used to assign the monkeys to one of the four treatment conditions, with the restriction that each treatment was compared to reference distributions generated by random assignment of treatment stimuli. These analyses showed that the observed attention effects were not significantly greater than would be expected by chance and, furthermore, that there was no significant serial correlation between observations within blocks. The assumption of independence of our observations made by conventional analyses of variance and t-tests is therefore inappropriate.

Analyses of variance using hierarchical error terms corroborated these findings. While a conventional analysis found 75% of the cells to show attention effects significant to p < .05, an analysis that made no assumption of independence within blocks found only 6% to be significant. Time series plots reveal random drifts in activity underlying the serial correlation effect. (Supported by NS 31058)

RESPONSES OF NEURONS IN PRIMARY SOMATOSENSORY CORTEX TO PREHENSION OF OBJECTS OF DEFINED GEOMETRY. E.P. Gardnee*, S. Ghosh, and C.E. Kopp, Dept. of Physiology and Biophysics, NYU Medical Center, New York, NY 10016.

These experiments measure the responses of cortical neurons when monkeys actively grasp and manipulate objects of defined geometry. The monkey is presented with a set of objects of specified shape (large and small spheres, cylinders, cubes and rectangular blocks) which he is trained to grasp and lift. Visual cues delivered on the screen of a video monitor indicate which knob should be grasped. The monkey's hand movements are videotaped using two genlocked cameras, and stored together with extracellular spike records of cortical neurons on a VHS video recorder. Quick freezes are made from VHS compressed video and electrophysiological data on a Macintosh Quadra computer, to allow frame-by-frame correlation of hand position with neuronal firing patterns. These experiments indicate differences in information processing in anterior and posterior portions of S-I cortex. In anterior S-I, where neurons have small receptive fields on single digits, the neuron's firing patterns correlate with hand position across the digit. These neurons appear most strongly activated when the edges of the cylindrical or rectangular knobs contact the receptive field, and are less responsive when the hand moves over the gently curved spherical surfaces. In posterior S-I, where receptive fields cover multiple digits, some neurons appear to differentiate the surface curvature of individual objects. Other neurons are silenced upon hand contact with the knobs, regardless of shape, and resume tonic activity when the hand is removed. We postulate that neurons in posterior S-I may play a role in global appreciation of the entire object, rather than in perception of specific features of single surfaces. (Supported by NIH: NS11852)

TWO TYPES OF VIBRATORY RESPONSIVE PACINIAN-LIKE NEURONS IN MONKEY PRIMARY SOMATOSENSORY CORTEX (SI) STUDIED DURING ACTIVE HAND MOVEMENTS. M.A. Lebedev, L.Nelson Department of Anatomy and Neurobiology, College of Medicine, University of Tennessee, Memphis, 875 Monroe Avenue, Memphis, TN 38163.

Some SI neurons respond to vibratory stimulation of their receptive fields with vibration-entrained responses (Mountcastle et al., J. Neurophysiol. 32:452-469, 1969). Previously, we described the sustained and transient firing of neurons in SI activated by both raised and moving flats and extensions in response to palpation or passive movement of fingers. In a previous study, we evaluated a population of 18 SI neurons (L, 5.6, 20 and 3 from areas 3a, 3b, 1 and 2) and have been considered to be Pacinian-like because each responded better to the highest of the three vibrotactile stimulus frequencies. Two types of Pacinian-like SI neurons were found: (1) those that were strongly vibration-entrained (N=19), and (2) those that were not (N=12). Each neuron was tested for its response to vibration stimuli, with the vibration being increased to a constant level of intensity. Each stimulus was then repeated at three different intensities, and the neuronal response to each intensity was measured. The paradigm was that of a repeated measures design, with each neuron being exposed to different intensities of vibration. The most significant difference in firing was found at the highest intensity, where the neurons fired at the greatest rate. To rule out that the firing rate was due to increased input, the vibration stimulus was repeated at different intensities and the neuronal response was measured. The most significant difference in firing was found at the highest intensity, where the neurons fired at the greatest rate. To rule out that the firing rate was due to increased input, the vibration stimulus was repeated at different intensities and the neuronal response was measured. The most significant difference in firing was found at the highest intensity, where the neurons fired at the greatest rate. To rule out that the firing rate was due to increased input, the vibration stimulus was repeated at different intensities and the neuronal response was measured. The most significant difference in firing was found at the highest intensity, where the neurons fired at the greatest rate.

INTRATHecal TREATMENT WITH ANTISENSE OLIGODEOXYNUCLEOTIDES TO THE NMDA-RECEPTOR SHOW EFFECTS IN NOCICEPTIVE TESTS IN RATS. M. Kuhlbeck, C. Alten, S. Pfeifer, D. O. Boss, C. R. M. H. Gasser, M. M. D. Granger, Control AB, Novum Unit, S-141 57 Huddinge, Sweden.

The NMDA receptor has been shown to be involved in transmission and modulation of nociceptive information in the spinal cord. Molecular cloning has recently revealed the existence of five different receptor subtypes termed NR1 and NR2A-D. Functional NMDA receptors can be reconstituted using the NR1 subunit in combination with any one of the four NR2 subunits. The different combinations differ in expression patterns in the CNS and in their pharmacological properties. We have studied the effect of receptor-specific antisense oligodeoxyribonucleotides (ODDN) to the NR1 subunit in rats.

METHOD: Rats (n=18) were divided into five groups receiving 5 pmol probe 1 (NR1 antisense 2) or probe 2 (NR1 antisense 1) Sallati 1985%. Two injections were made on day one, three and five. On day six, tail flick, hot plate and formalin tests were performed. The behaviour was scored by means of a computer program with five behavioral categories. When there was continuous wave 60 minutes after injection; rest and activity with/without paw protection and active pain behaviour (licking, biting). Number of paw jerks were also registered. After testing the rats were killed and the spinal cord was collected on dry ice for radioligand binding experiments. RESULTS: In the hot plate test the time latency was significantly prolonged in the antisense-treated group compared to controls. In the tail flick test the latency was the same although no significance was obtained. In the formalin test the total number of paw jerks was markedly reduced in the antisense group and active pain behavior was also affected. No motor disturbances were observed in any of the groups. Autoradiography with CGP37653 binding in spinal cord sections from all three groups was undertaken.

CONCLUSION: This study shows that antisense ODN may be a useful tool in understanding the role of different receptors and their subtypes in complex events such as spinal nociceptive transmission.

568.2

ROLE FOR NMDA RECEPTORS IN THE DEVELOPMENT OF MECHANICAL HYPERALGESIA PRODUCED BY CAPSAICIN IN RATS. H.L. Gilchrist and D.A. Simon. Neuroscience Research in Psychiatry, University of Minnesota, Minneapolis, MN 55455.

Intradermal injection of capsaicin (CAP) has been used as a model for cutaneous hyperalgesia in humans. When injected into the skin, CAP produced hyperalgesia to heat and mechanical stimuli. Furthermore, it was shown that hyperalgesia following CAP correlated with an enhanced excitability of dorsal horn neurons. In order to study underlying pharmacological mechanisms of CAP mediated hyperalgesia, a similar model was developed in rat and described previously (Suc. Neurosci. Abstr., 396, 1991). Briefly, rats received one intraplantar injection of CAP into the plantar surface of one hindpaw. CAP (1-30 µg) produced a dose-dependent decrease in withdrawal latency to heat as well as increased the frequency of withdrawal to mechanical stimuli (vibratory and brushing) by filament tests (vibratory and brushing) in quantified by filament tests.

In the present study, we investigated the role of spinal NMDA receptors in the development of hyperalgesia following CAP. A chronic intrathecal (I.T.) catheter was surgically placed at the level of the lumbar enlargement. I.T. pretreatment with the competitive NMDA receptor antagonist AP-5 (2, 4, or 8 µg in 5 µl) significantly attenuated the normally enhanced withdrawal responses evoked by mechanical stimuli without altering hyperalgesia to heat stimuli. This suggests that spinal NMDA receptors are necessary for the development of mechanical hyperalgesia following CAP in rat. It is also concluded that this model, hyperalgesia to heat may involve alternate mechanisms, such as sensitization of peripheral nociceptors. Data will be discussed in terms of the contribution of spinal NMDA as well as non-NMDA receptors to the development of hyperalgesia produced by CAP. Supported by NRSK DA05592 and the Minnesota Medical Foundation.

THALAMIC N-METHYL-D-ASPARTATE (NMDA) RECEPTORS ARE INVOLVED IN THE DEVELOPMENT AND MAINTENANCE OF HYPERALGESIA FOLLOWING UNILATERAL HINDPAW INFLAMMATION. K. Kohlhaas*, and O.F. Gabbott. Dept. of Pharmacology, Univ. of Iowa, Iowa City, 52242.

Effects of intrathalamic injection of an NMDA receptor antagonist, D-2-amino-5-phosphonovaleric acid (D-APV) on the thermal and mechanical hyperalgesia induced by hindlimb intraplantar injection of carrageenan in the rat were studied in the "acute phase" (within 3 hrs) and the "subacute phase" (24 hrs) after carrageenan administration.

Male Sprague-Dawley rats were injected in the left hindpaw with 2mg carrageenan. Noxious mechanical and thermal hyperalgesia within 3 hours of injection. Two consecutive doses spaced 30 min apart of either D-APV (5 nmol) or saline were injected into the hindlimb representation of the ipsilateral thalamus (0.5 µl).

Treatment with D-APV, but not saline, in the contralateral thalamus significantly reduced both the acute mechanical and thermal hyperalgesia induced by carrageenan. There was no effect on the non-inflamed hindpaw. Rats treated with D-APV in the acute phase failed to develop thermal and mechanical hyperalgesia in the subacute phase. In contrast, rats treated with saline or D-APV in the ipsilateral thalamus in the acute phase demonstrated significant thermal and mechanical hyperalgesia in the subacute phase.

Taken together, these results suggest an involvement of thalamic NMDA receptors in the development and maintenance of hyperalgesia associated with inflammation in a model of chronic pain.

568.4

NMDA AND NK1 RECEPTOR ANTAGONISTS ACT ADDITIVELY TO REDUCE BEHAVIORAL HYPERALGESIA IN RATS WITH UNILATERAL INFLAMMATION. K. Ren* and R. Dubner. Neurology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Previous studies suggest that both N-methyl-D-aspartate (NMDA) and tachykinin (NK1) receptors are involved in spinal nociceptive transmission. To assess the interaction between NMDA and NK1 receptor systems on nociceptive responses of rats with complete Freund's adjuvant-induced hindpaw inflammation/hyperalgesia, an isobolographic analysis was performed using competitive antagonist tests against NMDA or NK1 receptors. Thermal hyperalgesia, determined by the ability of a noxious stimulus to elicit a reflexive withdrawal response, was induced by a single injection of complete Freund's adjuvant (1:1 emulsion, 100 µg Mycobacterium) into the hindpaw of rats. The drugs were given intrathecally. Dextroprophan, a non-competitive NMDA receptor antagonist, attenuated hyperalgesia dose-dependently with a maximal ~80% reversal of hyperalgesia. WIN-51,708 and CP-96,345, a combination of Dextroprophan and WIN-51,708 was then given at a fixed ratio. The ED50 value obtained from co-administration of the drugs was found to be not significantly different from the isobolographic line generated by individual ED50 values of the two receptor antagonists. These results suggest that although both NMDA and NK1 receptor systems play a role in inflammation-induced hyperalgesia, the two systems appear to act independently.
568.5
Supraspinal morphine analgesia in the peri-aqueductal gray (PAG) is modulated by mu and delta opioid receptors and by SHT, and SHT, receptors in the rostroventral medulla (RVM). Since NMDA and muscarinic receptors in the RVM have been implicated in nociception, the present study evaluated whether NMDA and mementic (scopolamine, pirenzepine) antagonists in the RVM altered PAG morphine analgesia on the tail-flick and jump tests. PAG morphine (2.5 μg) analgesia was dose-dependently reduced by MK-801 (0.03-3 μg: 50-100%) and AP7 (0.01-1 μg: 30-70%) in the RVM on both tests. RVM injections of MK-801, but not AP7 reduced basal nociception. PAG morphine analgesia was dose-dependently reduced by the muscarinic antagonist, scopolamine (0.5-5 μg: 70%) and less so by the M₁ antagonist, pirenzepine (0.05-5 μg: 35-50%). Both muscarinic antagonists reduced basal latencies, but not nociception thresholds. These data implicate NMDA and muscarinic receptors in the complex modulation of PAG morphine analgesia by the RVM.

568.6
Excitatory Amino Acids (EAAs) are contained in and released from nociceptive primary afferents. Although EAAs are apparently contained in all nociceptiveafferent types, the EAAs receptors that mediate the nociceptive responses produced by activating these afferents have not been determined.
In this experiment, we determined the effects of intrathecal (i.t.) administration of the NMDA and non-NMDA antagonist DNXQ on nociception produced by activation of Aδ or C nociceptors. Administration of APS produced a selective, dose-dependent increase in latency. paw foot withdrawal responses evoked by low nocuous skin heating rates, but did not alter nociceptive responses produced by high skin heating rates in doses that did not alter motor activity. These results indicate that activation of C-nociceptors produces nociception mediated in part by NMDA receptors. In contrast, intrathecal DNXQ increased latencies for both high and low heating rates. These results suggest that EAAs released from both Aδ and C nociceptors act on non-NMDA receptors to produce nociception. Supported by USPHS Grants DA08256 (DOV) and DA03880 (HHP).

568.7
Organic variables have been shown to play a modulatory role in the expression of endogenous pain control mechanisms. This study assessed lifespan changes in the magnitude and neurochemical mediation of cold-water stress-induced analgesia (SSIA) in male and female young and old Swiss-Webster mice. We have previously shown that this swim stressor produces enhanced analgesia on the hotplate test in both male and female mice, and this analgesia is mediated by the NMDA receptor in young adult males, but not in similarly aged females (Mogil et al. Pain. 53, 17-25, 1993). In the present study, male and female young and old mice (approximately 15 months of age) mice were tested for their analgesic response to a single stress exposure in warm water maintained at 33°C. In 32 day-old animals, male and female mice exhibited analgesia following the swim stressor that was antagonized by MK-801 (0.075 mg/kg, ip), and was therefore NMDA mediated, in both sexes. Thus, puppafemales display primarily NMDA-mediated SSIA, whereas we previously reported that sexually mature females do not (Mogil et al., ibid.). In 15-month-old animals, MK-801 did not antagonize SSIA in either sex. Thus, a qualitative difference in SSIA mediation noted across the lifespan is in male mice, as well as females. Analgesic magnitude increased significantly in male mice with aging, but not in females. These findings indicate that ontogenetic stage can contribute significantly to the expression of SSIA, and should be taken into consideration in future studies on SSIA mechanisms. This research was supported by NIH grant NS07629 and an Unrestricted Pain Research Grant from the Bristol-Myers Squibb Company.

PERIPHERAL ADMINISTRATION OF EXCITATORY AMINO ACIDS MODULATE NOCICEPTIVE BEHAVIOR IN RATS. D.L. Jackson, J.D. Richardussen, R.M. Haggrensw, Dept. of Rest. Sciences and Pharmacology, University of Minnesota, MN 55455.
While it has been demonstrated that certain primary afferent neurons in a neonatal rat spinal cord-cord preparation are activated by peripherally administered glutamate (Auil and Hildebrand, Agents Actions 1993; 39:C143-144), relatively little is known about the peripheral actions of EAAs in the intact adult animal. We aimed to examine possible peripheral mechanisms of nociception modulation by EAAs. Male Sprague-Dawley rats were tested for thermal hyperalgesia by placing them in a clear plastic chamber with an infrared heat source aimed through the glass floor of the chamber at the treated hindpaw (Pain 1986; 26:77-88). Paw withdrawal latencies were detected by a photocell and recorded by an observer blinded to treatment allocation. Following the collection of basal latencies, rats received 100 μl ipl injections of L- or D-glutamate (10 nmol), aspirate (100 nmol), or saline vehicle. Post-injection latencies were measured at 15 and 60 minutes. Data were analyzed by ANOVA and Duncan's test and expressed as means±SEM. L-glutamate reduced latencies at 15 minutes relative to the saline control (-10.0±15.6% vs. +5.3±15.9%; p<0.05). The stereoseomer, D-glutamate, had no effect on latencies at this time point (+10.6±13.7%). This is in contrast to the observed increase in latency at both 15 and 60 minutes following the ipl injection of aspirate relative to control (15 min = +4.2±11.4% vs. +4.6±11.9%; p<0.05, and 60 min = +5.0±10.6% vs. 1.8±11.9%; p<0.05). Collectively, these results support the hypothesis that the glutamate and aspartate can differentially modulate nociceptive behavior when injected into normal tissue. This research was funded by K16-DE02027, DE08860, DE10003, and a Howard Hughes Medical Institute Predoctoral Fellowship LDRD.
568.11
PAIN REDUCTION BY INTRATHRAL ADMINISTRATION OF GLYCINE.
Neurosurgery Department, Baylor College of Medicine, Houston, TX 77030.
Glucine, the primary inhibitory neurotransmitter of the spinal cord, is found in
high concentration within segmental interneuron pools. Glucine is released during
excessive spinal afferent stimuli, an effective means of nociceptive pain.
We hypothesized that the pain is attenuated by glucine.
Nociceptive rats were created by unilateral partial ligation of the proximal sciatic
nerve with 4 absorbable chronic sutures placed 1 mm apart. A PE-10 catheter
was introduced into the cisterna magna and directed towards the lumbar enlargement.
Twelve days after PE-10 implantation, rats were selected based on the induction of
nociceptive behavior, monitored by intrathecal glucine, MK-801, and 5,7-DKA, at a concentration of 0.1 µmol for 2 hours and
at a rate of 5-10 µl/h. Pain scores were calculated using the Randall-Selitto
scale of 0-4. The effects of glucine, MK-801, and 5,7-DKA on nociceptive behavior
were measured and compared to sham surgeries. Our results demonstrated that
the force necessary to produce nociceptive behavior could be significantly
lowered by the administration of glucine. This suggests that glucine may be
a potential therapeutic agent in the treatment of chronic pain.

568.12
ROLE OF NMDA RECEPTOR AND NITRIC OXIDE (NO) IN THE FACILITATION BY INTRATHAL (IT) NMDA OF LIMB WITHDRAWALS EVOKED BY GRADED NOCICEPTOR STIMULATION. L. Cantell*, Neurobiology, Physiology & Behavior, Univ. of California, Davis, CA 95616.
Secondary hyperalgesia is thought to be mediated by hyperexcitability of nociceptive spinal neurons via (a) glutamatergic overactivity of the NMDA-ionotropic
NMDA receptors to (c) allow Ca2+ influx to (d) effect persistent cellular changes in
behavioral studies, hyperalgesia is thought to be mediated by hyperexcitability
of nociceptive responses such as wind-up. We investigated if IT NMDA receptors
threshold and threshold responses using a quantitative measure of limb withdrawal response (LWR) magnitude, and if this is prevented by NMDA receptor antagonists (APV, MK801, respectively) or the alternate substitute for NO synthase (L-NAME).
One wk after implanting IT catheters, the ventral lip was fixed to a thermometer to
determine an ascending series of heat pulses (30°C-50°C, 15 sec per pulse).
The normalized area of integrated limb flexor EMG gave a measure of WRT magnitude across
stimulus-response function (SRF). Two paradigms were used: (1) One SRF was generated with a 60°C no drug (control), (b) 3 NT IT NMDA (100 µmol) given IT prior
to each heat stimulus, or (c) 10 µl of IT APV (5 µmol-µl), MK801 (1 µmol) or L-NAME (1 µmol) followed by (d). Two SRFs were generated, the first with no drug (control) and the second 20 min later with (b), (c), (d) each heat stimulus preceded by IT NaCl (0.9%), or (e) APV, MK801 or L-NAME followed by (d).
In the 2-SRF paradigm, NMDA significantly increased WRT magnitude in 40-49°C.
controls, reducing the SRF threshold and slope. This was not prevented by APV,
MK801 or L-NAME. In these cases where NaCl or MK801 = NaCl was given,
the second SRF was shifted toward significantly higher temperatures. Thus, WRTs appear
to be sensitized during the second SRF. This sensitization may confound any effect of
NMDA on the second SRF.
In the 1-SRF paradigm, NMDA significantly reduced the threshold of the SRF
compared to controls. This was prevented in rats pretreated with APV, MK801 and
L-NAME. These data support the idea that the NMDA receptor and NO are involved in
the development of hyperexcitability in spinal neurons mediating the WR.

SPINAL STRYCHNINE INCREASES RESPONSES OF NOCICEPTIVE DORSAL HORN NEURONS TO LOW THRESHOLD INPUT AND LENGTHENS INTRADORSAL DISCHARGE. L. Sekontola* and J. Robertson, Anesthesiology Research Lab, Univ. of Calif. @ San Diego, La Jolla CA 92033-0188.
Hyperesthesia following many noxious injuries is associated with inhibitory interneurons loss. Pharmacological blockade of excitatory receptors in spinal cord
nociceptive dorsal horn neurons.
Excitatory properties of spinal neurons (STN) results in tonic evoked
alldynia. It has been proposed that this is due to loss of "auto-inhibition" of
low threshold (LT) input to wide dynamic range (WDR) cells via an inhibitory
input. This study determined if spinal strychnine (STN) results in excitation
responsiveness of dorsal horn neurons.
Dialysis probe was inserted ventral horn of chloroento-anesthetized cats and
electrocellular recordings made from WDR cells in close proximity to the probe.
Artificial CSF was perfused and baseline responses to a range of mechanical stimuli
measured. The perfusate was exchanged to STN (1 µM) or an NMDA antagonist
(2 mM APV) or STN + a non-NMDA antagonist (1 mM CNQX) and the receptive
field properties measured.
Exposure to STN resulted in a greatly enhanced high frequency response to LT
input (especially hair). The firing pattern was usually one of irregular bursts.
The response to high threshold input increased, but to a lesser degree. The high
threshold response was usually followed by a prolonged afterdischarge (several
minutes). This was less seen less frequently after LT input. Receptive field size also
increased substantially. In most cases, basal firing rates were unaffected.
These results indicate that this enhanced responsiveness was blocked by co
administration of APV and CNQX reduced evoked activity while leaving the
afterdischarge relatively intact.
These results support the hypothesis that removal of tonic glycine inhibition leads
to excessive activity in WDR neurons which is mediated by activity at a local
NMDA receptor. (This study was supported by NS 11255)

568.14
Excitatory amino acids, via activation of the NMDA receptor, are implicated in
the persistence of pathological pain. Recent work in our laboratory indicates that the transplantation of adrenal medullary chromaffin cells into the spinal cord
subarachnoid space can alleviate chronic pain syndromes in animal models. The
purpose of this study was to determine whether adrenal medullary transplants act
via modifying spinal NMDA hyperexcitability. For this study intrathecal catheters
were implanted into the spinal subarachnoid space of rats. Rats also received
either adrenal medullary transplants or controlistrated muscle transplants via
laminectomy at the level of the lumbar enlargement. Abnormal pain responses
to several doses of intrathecally administered NMDA were determined using
behavioral tests for plantar allogeneic and mechanical and thermal hyperalgesia.
Results indicated that NMDA produced allogeneic and hyperalgesia and control
transplanted animals in a dose related fashion. In contrast, the dose response to
NMDA was significantly shifted rightward in animals with adrenal medullary
transplants, and hyperalgesia and allodynia were completely alleviated in the
lower dose ranges of NMDA in these animals. The beneficial effects of the
transplants were not decreased by naloxone, but were partially attenuated
by phenolamine, indicating a limited role for catecholamines released by the
transplanted cells. However, this did not completely account for the effects of the
transplants. In summary, these results suggest that adrenal medullary
subtransplants may intervene in the cascade of hyperalgesia initiated by
the activation of NMDA receptors in pathological pain syndromes. Supported
by NIH grant NS25054.

568.15
Dextromethorphan (DM) is a clinically available oral antitussive and NMDA receptor antagonist with the ability to attenuate neuronal "wind-up" (Dickenson et al., 1991). We have found that pretreatment with DM (6, 20 or 60 mg/kg sc) suppresses formalin-induced nociceptive behaviors in a dose-dependent manner. Nociception turns on the expression of the immediate early genes (IEG) including c-fos and c-fos like genes during inflammation. In 30 minutes post injection. No change in c-fos mRNA was detected. The contralateral S2H, nucleus raphe magnus, periaqueductal gray, thalamic thalamus, or motor cortex. Pretreatment with DM at 60 mg/kg sc 30 minutes prior to formalin resulted in a suppression of c-fos induction. This suggests that c-fos mRNA levels in S2H of animals receiving DM prior to formalin did not differ from controls. These data indicate that DM suppresses formalin nociceptive behavior and one of the biochemical consequences of formalin nociception, i.e., induction of c-fos mRNA. Supported by the VVZ Research Foundation (JKE) and DA01457, DA01724, DA0196 and CA2897.

568.16
Slow temporal summation of second pain is thought to be a psychophysical
correlate of temporal summation of C-afferent-mediated responses of
dorsal horn nociceptive neurons, termed windup. Windup has been shown to be
mediated by N-methyl-D-aspartate (NMDA) receptor activation within the
spinal cord of experimental animals. We thus tested whether a NMDA receptor
antagonist would reduce slow temporal summation of second pain in
man. Oral doses of dextromethorphan (DM), a common cough suppressant
and NMDA receptor antagonist, and their vehicle control were given on
a double blind basis to normal volunteer human subjects who rated intensities
of first and second pain in response to repeated painful stimuli separated
by 30 seconds (mean 5°C) and repeated 32°C heat pulses. Doses of 30 and 45 mg but not 15 mg (in
a single bolus) were effective in attenuating temporal summation of second pain as
compared to vehicle controls (Wilcoxon signed-ranks test, P < 0.03). By
contrast, neither first pain nor second pain evoked by the first stimulus in
a train of stimuli were affected by any of these doses of DM (P > 0.05). These
results further confirm temporal summation of second pain as
a psychophysical correlate of windup and provide evidence that DM
selectively reduces temporal summation of second pain, as has been shown for
windup.
568.17
Repetitive stimulation of somatic nociceptors evokes progressive increases in the excitability of spinal neurones ("wind up"). Some forms of nociceptive stimulation may induce excitatory changes in the last-order potential of somatic reflexes. These changes are believed to be mediated by the activation of NMDA receptors on spinal neurones. In this study we have investigated the excitatory changes induced by nociceptive viscerosomatic reflexes and the role of spinal NMDA receptors in their generation.
Experiments were conducted on decerebrated and spinalised rabbits. Reflex activity was elicited by a lumbar nerve in response to supramaximal electrical stimulation of the ipsilateral second lumbar nerve (somatic reflex) or of the sciatic nerves (viscerosomatic reflex). Changes in excitability of these reflexes during repetitive stimulation at 1Hz ("wind up") and up to 5 minutes after (reflex potentiation) were studied as were the effects of intraventricular administration of the NMDA receptor antagonist ketamine at doses between 1 and 30 mg/kg.
"Wind up" was consistently evoked in somatic reflexes but less so in viscerosomatic reflexes. Potentiation of viscerosomatic reflexes was rarely seen and often these reflexes were depressed by repetitive stimulation of visceral afferents. Ketamine caused a dose-dependent decrease of both somatic and viscerosomatic reflexes and a reduction in the magnitude of "wind up". We conclude that there are important differences in the spinal organization of somatic and viscerosomatic nociceptive reflexes and that NMDA receptors influence the baseline levels of reflex excitability in the spinal cord and as the dynamic components of the reflexes.

568.18
BEHAVIORAL AND ELECTROPHYSIOLOGICAL EFFECTS OF MEMANTINE IN A PRIMATE MODEL OF PERIPHERAL NEUROPATHY. S.M. Carson, R. Rest, K. Gordon, M. Cope, G. W. Moore, and W.D. Willis. Dept. of Anatomy and Neurosciences, Marine Biomedical Inst. UTMB, Galveston, TX 77555
The development of animal models mimicking painful peripheral neuropathies allows investigation of the underlying mechanisms that will be used to improve clinical treatment. NMDA receptor activation is an important mechanism contributing to neuropathic pain. Memantine (MEM), a non-competitive NMDA antagonist, in attenuating behavioral and electrophysiological abnormalities previously documented in a monkey model of peripheral neuropathy.
In an anesthetized monkey (Macaca fascicularis), on L7 spinal nerve was tightly ligated, a sham operation was performed on the contralateral side. Compared to presurgery levels, the animal demonstrated an increased sensitivity to mechanical stimulation (allogynia) with von Frey hairs and brushing with a cotton ball. This was most apparent on days post-surgery. On day 36 post-surgery, MEM was delivered in a bolus infusum (3 mg, 10 mg, subcutaneous (12mg) or orally (30 and 50mg). The first test period of each test day the animal was assessed for withdrawal reflexes toward a range of stimuli (painful and non-painful). The second test period was repeated at hourly intervals. The most effective route in attenuating allodynia in the EXP group was for oral administration; the subcutaneous injection did not have any effect. The response on the control foot were not affected by any route. The results suggest that MEM is effective in a peripheral neuropathy model.

568.19
SYSTEMIC TREATMENT WITH MEMANTINE REDUCES MECHANICAL ALLODYNNIA IN A RAT MODEL OF PERIPHERAL NEUROPATHY. G. Hargens, A. Friedman and L. Hruby. Dept. of Anatomy and Neurosciences, Marine Biomedical Inst. UTMB, Galveston, TX 77555
A recently developed animal model of peripheral neuropathy is characterized by mechanical allodynia which develops within days following surgery and lasts for 3 months following resolution of the injury. The goal of the present study was to determine whether treatment with the non-competitive NMDA antagonist Memantine (MEM) had therapeutic and/or prophylactic effects in relieving mechanical allodynia observed in this animal model.
Acute delivery: In 3 groups of rats (Sprague-Dawley, 125-175g) a dose-response curve was established. Following baseline testing with von Frey hairs on the ventral surface of each foot and performance on a rotarod, animals were anesthetized and the L5 and L6 spinal nerves ligated with 0-5 suture. Animals were retested on days 1, 3, 5, 7, 9, 12, 15, and 17 post-surgery. The pumps delivered MEM at a continuous rate of 4mg/kg for 4 weeks. To determine prophylactic effects, rats were implanted with IP pumps day 2 prior to surgery. At the end of the experiment all rats (n=10) were administered a dose of 0.1 mg/kg MEM for withdrawal response on von Frey hairs and rotarod performance.
Acute IP injections of MEM demonstrated that saline and 0.1mg/kg MEM had no effect on behavior. 5mg/kg MEM significantly attenuated mechanical allodynia at the post-injection with no motor impairment. Animals receiving 10mg/kg MEM effectively attenuated mechanical allodynia at 1, 2, 4, and 8hrs, the animals displayed hypothermia. No effect was observed on the contralateral control paw. Preliminary studies concerning chronic treatment with 4mg/kg via pumps (n=3) demonstrated a therapeutic effect with no abnormal motor signs. However, this dose had no obvious prophylactic effect. Results indicate that NMDA receptors play an important role in the expression and in MEM may be a successful treatment for neuropathic pain. (Supported by NS11255 and NS27910.)

568.20
The sequence of events that leads to neuropathic pain may include activation of the N-methylD-aspartate (NMDA) receptor-ion channel complex since pretreatment with compounds as well as noncompetative NMDA receptor antagonists prevents nerve injury-induced abnormal pain. Earlier studies in our laboratory have shown that spinal adrenergic mediator transplants reduce neuropathic pain over an extended period of time. The effects of adrenalin transplants on spinal NMDA receptor binding was investigated using a new high-affinity glutamate binding site antagonist, CUP-39653. Saturation studies in spinal cord revealed that [125I]CUP-39653 binding affinity in control cerebral cortex but even lower. Neuropathic pain was induced in rats by loss of ligation of the right sciatic nerve (Bennet and Xie, 1990). Two weeks following surgery, either adrenergic medullary or sham transplanted rats were sacrificed in the subarachnoid space above lumbar spinal cord. One week following implantation, membrane preparations were made from spinal lumbar regions L5-L6, the spinal cord split in half and the dorsal central and homogenized septic extract. Animals that received control transplants showed decreased [125I]CUP-39653 specific binding ipsilateral to nerve ligation, compared to the contralateral side and unoperated controls. In contrast, adrenal medullary transplants bilaterally increased [125I]CUP-39653 binding, bringing binding on the nerve-injured side back to near normal control levels. These results suggest that adrenergic medullary transplants reduce neuropathic pain by equilibrating abnormal excitatory amino acid transmission in the spinal cord. Supported by NIH grant NS20504.

569.1
We will state and discuss the proposition that cortical evoked potentials are generated when neurones interact with glial cells across extracellular space. The evidence is as follows. First, glial research by Kuffler, Nichols, Dowling, and dozens of others confirms that the claim that the major evoked potential of the eye, the retinal b-wave, is produced this way. Second, the b-wave of freely-moving rats (stimulated through a light-emitting diode implanted above an eye) approximately doubles in amplitude during slow wave sleep; similar plastic changes take place in the visual cortical evoked potential response. Third, when the rat receives paired flashes, the refractory periods measured for b-wave and for cortical responses are both prolonged, but not identically, b-waves begin when synaptic potentials generated by rods and cones initiate potassium currents within Müller (glial) cell cytoplasm. The evidence that cortical astrocytes similarly optimize [K+]o is still indirect, but nothing uncovered so far seems to rule the possibility out.

SCLERAL DISTRIBUTION OF ERG B-WAVE AND OSCILLATORY POTENTIALS (OPs). P. Lachapelle*, J. Benoit* & C. Casanova*. Dept. of Ophthalmology, McGill University - Montreal Children's Hospital, Montréal, Que., Canada H3C 1P3 and Université de Sherbrooke, Sherbrooke, Que., Canada J1H 5N4.
Previous studies reporting the scleral distribution of the ERG made use of a bipolar recording approach which could have masked the existence of localised ERG dips. We investigated this issue in (n=10) anesthetized, paralyzed and artificially ventilated New Zealand rabbits. Scleral ERGs (1,000Hz OPs and 100,000Hz OPs) were recorded with a 0.5 mm tungsten electrode with reference and ground electrodes positioned in the mouth and neck muscles respectively. The anterior portion of the globe was dominated by a posterior b-wave whose amplitude decreased over the inner cornea. It was gradually replaced by a slow negative wave (inversion at -5-6 mm posterior to the limbus) onto which were superimposed large oscillations. These new ERG components were recorded in bipolar recordings, reaching a maximum at 7-mm posterior to the limbus. FFT analysis performed on this scleral location indicated that: 1- the negative wave is not an inverted b-wave, 2- the large OPs are generated in the large OPs (CUP-39653 some 7-8 mm posterior to the limbus. Our results indicate that the OPs are the most consistent retinal potentials since they are found at all scleral locations while the b-wave appears to be limited to the anterior portion of the eye. Furthermore in showing that maximal OPs are obtained in b-wave free locations suggests that the two retinal generators (b-wave and OPs) may interact in an inhibitory fashion. Funded by MRC MT12153.

RETINA AND PHOTORECEPTORS VI
STIMULATION OF RETINAL DOPAMINE D2 RECEPTORS AFFECTS AMPLITUDES OF THE B BUT NOT A WAVES OF THE RABBIT ELECTRORETINOGRAPHY. L. Bourguet, D. Belliveau, F.D. Jolicoeur* and C. Casanove. Departments of Ophthalmology and Physiology-Biophysics and Departments of Psychiatry and Neurology* Faculty of Medicine, Univ. of Sherbrooke, Sherbrooke, Quebec, Canada J1H 5N4

The two classical sub-types of dopamine receptors, D1 and D2, are present in the retina. We have shown that stimulation of both receptors with the mixed D1 and D2 agonist apomorphine results in marked reductions in amplitudes of both a and b waves of the rabbit ERG. In order to better delineate dopamine receptor responsivity to these stimuli, we have examined the effects of N-acetylcysteine (NPA), a purported selective D2 agonist, on retinal electrophysiological responses. Cells were isolated from anesthetized adult pigmented rabbits. A corneal electrode was inserted near the limbus to record the ERG. Responses were evoked by a diffuse flash (Grass PS2) and averaged 25 times. Three intensity levels were tested. NPA was injected intravenously at various concentrations (0.01-10 μg in 100 μl). Our results indicate that the intravitreal injection of NPA reduced, in a dose related fashion, the amplitude of the ERG b wave (up to 40%) in both scotopic and photopic conditions without significant changes in the implicit time. No effects were seen at the level of the a-wave. These results suggest that the D2 receptor is implicated in modulation of the b-wave, whereas the D1 receptor is involved in the modulation of the a-wave.

EXPRESSSION OF METABOTROPIC GLUTAMATE RECEPTOR mRNAs IN ADULT RAT RETINA. E. Hayworth* and J. H. Brandstatter, Max-Planck-Institut für Hirnforschung, Neuonauten, Alt., Frankfurt, Germany.

Glutamate is the major neurotransmitter in the vertebrate retina and retina is a unique area of neurons and glia characterized by a series of ionotropic and metabotropic glutamate receptors which have been cloned and characterized. While the major glutamatergic neurotransmission in the retina seems to be mediated by ionotropic receptors, the extent of involvement of metabotropic receptors in retinal function is unclear. We have therefore investigated expression of patterns of six metabotropic glutamate receptor (mGluR) subtypes in situ hybridization, using digoxigenin-labeled cRNA probes and then exposed to anti-digoxigenin alkaline phosphatase and staining with substrate. mGluR1 is expressed in all cells in the ganglion cell layer (GCL) and by some cells with their somata in the innermost layer of the inner nuclear layer (INL), most likely amacrine cells. mGluR2: expressed by some cells in the GCL and by some amacrine cells in the INL. mGluR3: not expressed at detectable levels. mGluR4: expressed by cells in the GCL and the INL, similar pattern to that seen for mGluR1. mGluR5: expressed by cells with their somata in the outer third of the INL, possibly horizontal cells. mGluR6: expressed by cells with somata located in the outer half of the INL, consistent with the recent suggestion by Nakajima et al. (1993) that this receptor corresponds to the physiologically and pharmacologically defined APB-receptor that mediates synaptic input from photoreceptors to ON-bipolar cells. Taken together, these results suggest a considerably more widespread expression of the in retina than suggested from physiological experiments. We are currently extending this investigation by examining the expression of the recently cloned mGluR7 and improving the cellular resolution by in situ hybridization of dissociated cells. Supported by a HHF Foundation (HHF) and SFB 269/B4.

GONADOTROPIN OF ACETYLCHOLINESTERASE (AChE) IN THE DEVELOPING OPUSCULAR RETINA. Camarao, L.M.C.; Pariá, A.C. and J.H. Holok*. Depto. Histolgia & Embriologia (ICCH); 1Instituto de Biofisica Carlos Chagas Jr., Universidade Federal do Rio de Janeiro, 21949-900, BRASIL.

We have previously shown that the differentiation of choline containing neurons in the retina was detected around 15 postnatal days (P15). In this work, we follow the pattern of expression of AChE, the hydrolyzing enzyme for acetylcholine, during the development of the retina, applying the Hemagreen method (1985). The onset of AChE activity was seen in the P10 opossum, in cell bodies present in the distal layer of the retina (P15). This activity is detected before the emergence of the inner plexiform layer (IPL) and before the appearance of cholinergic neurons, much earlier than the onset of synthesis of acetylcholine in the IPL (P22). Between P25-P33, the histochemistry reaction becomes more intense, but is still restricted to cell bodies in the GCL. Only after P45 AChE positive bands in the IPL (strata 1, 3 and 4/5) and somata in the inner nuclear layer (INL) could be seen. In P50, when the retina was morphologically mature and the AChE-histochemistry was the same pattern, i.e., cell bodies in the GCL and INL, labeled bands in the IPL and OPL. Since AChE could be detected so early during opossum retinal development, a question arises whether AChE takes part on cellular proliferation and/or differentiation in the retina.

GABA RAISES INTRACELLULAR CALCIUM IN NEURONS OF DEVELOPING RABBIT RETINA. B. Huang* D. Redburn Dept. Neurobiology and Anatomy, Univ. Texas-Houston Med. Sch., Houston, TX 77030.

Previous studies in this laboratory have shown that horizontal cells of the rabbit retina are transiently GABAergic during early post-natal development and that lesioning these horizontal cells or blocking GABA receptors with antagonists interrupts cone synaptogenesis. In order to determine the mechanism by which GABA might mediate these effects, we have used a Ca^2+ fluorescent assay to explore the effects of GABA on calcium flux in developing retinal neurons.

Cells from neonatal rabbit retina were freshly isolated and then loaded with fluo-3 AM. When challenged with 100 μM GABA, intracellular Ca^2+ increased in certain populations of retinal neurons. This GABA-induced Ca^2+ response began to appear in retinal cells of postnatal day 3 and was most prominent on day 5. Both picrotoxin and bicuculline blocked the response, indicating that GABA, receptors were involved. Based on these results, we propose that during postnatal retinal development GABA may exert its trophic action on retinal synaptogenesis through membrane depolarization and a rise in intracellular Ca^2+.

CIRCADIAN RHYTHMS IN THE QUAIL RETINA: MODULATION BY LIGHT AND DOPAMINE

ME. Kelly, NF. Emlong, and RB. Barlow* Institute for Sensory Research, Syracuse Univ., NY 13244

The Japanese quail exhibits a circadian rhythm in retinal sensitivity. 1 Rhythmic shifting of rod-cone dominance with time of day appears to be intensity dependent. Circadian rhythms in dark-adapted eyes are readily detectable for photopic stimuli: rods dominate retinal sensitivity at night while cones dominate during the day. Suprisingly, for scotopic stimuli, rods dominate retinal sensitivity regardless of time of day, thus abolishing circadian rhythms of sensitivity.

How does the circadian clock shift rod-cone dominance during the day but not at night? We hypothesize that dopamine blocks rod signals to increase stimuli during the day and thereby shifts the retina to the cone-dominated state. Retinal dopamine levels are high during the day and low at night in constant dark making dopamine an obvious candidate for modulating retinal sensitivity. Dopamine agonists and antagonists alter the rhythms of retinal sensitivity, and light adaptation can disrupt the normal rod dominance at night. 1,2 Primary retinal neurons, light and dopamine are independent modulators of the ocular clock in the Japanese quail.

 Supported by NIH grant EY 00667.

The area 3b cortex of primates contains hand- and foot-like aggregates of neurons that are dominated by cutaneous inputs from the ulnar, radial, and median nerves to the hand. The ulnar nerve innervates about 43% of the hand surface, and normally provides dominant inputs to about 20% of the area 3b hand cortex. This study evaluated whether ulnar nerve dominance aggregates change in size over the first several minutes to hours after wrist level transection of the radial and median nerves. Acutely after injury, cortical aggregates of the ulnar nerve rapidly expanded from a normal mean area of about 4.9 mm^2 to a mean area of about 7.1 mm^2. Due to this change, ulnar inputs rapidly gain access to about 59% of the area 3b hand cortex, or about 1.5 times the normal cortical surface. These size changes are initiated within minutes after injury. The extent and spatial distribution of these changes provide an image of central substrates that were available for decompensation of ulnar nerve dominance aggregates at the time of injury. Previous evaluations of radial nerve dominance aggregates after acute transection of the ulnar and median nerves show that these aggregates rapidly gain access to a cortical space that is about 2 times the normal cortical space. Thus, dominance aggregates of different nerves undergo rapid size changes of variable extents. It is suggested that this variability is dependent on differences in the patterns of central connections that are rapidly impacted by the different injuries, and on differences in the patterns of central substrates that can be rapidly accessed by the uninjured nerve.

Reorganization of Movement Representations in Primary Motor Cortex of Adult Squirrel Monkeys Following Distal Forelimb Restriction. G.W. Bilimben*, E.J. Plautz, G.A. Gardner, B. Raiszadeh, and R.J. Nudo* Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX 77030.

The consequences of distal forelimb restriction on the functional topography of primary motor cortex (area 4) were examined in normal adult squirrel monkeys. Using intracortical microstimulation techniques, a detailed map of the movement representations of the hand, wrist, and arm contralateral to the preferred hand, and the hand of the nonpreferred hand, were derived (Nudo, et al., J. Neurosci., 12:918, 1992). After a post-operative recovery period the preferred forelimb was placed in a cast that effectively restricted movements of the hand and wrist. Movement maps of the distal forelimb representation were re-derived at 3 month intervals.

In each case, post-restriction maps revealed significant changes in movement representations. The movement show that within 6 months, finger representations decreased while wrist representations increased in total area extent. In contrast, the movement representations of control animals that did not undergo forelimb restriction remained relatively unchanged. These results demonstrate that distal forelimb movement representations are alterable through disuse, and that the changes associated with forelimb restriction are progressive over several months. Taken together with our previous findings that forelimb representations are alterable through increased use, these studies lend further support to the idea that movement representations in primary motor cortex are shaped by experiential factors related to use.

Supported by NS 08386 (GWM) & NS 27974 (BJN). This work was done during the tenure of an Established Investigatorship from the American Heart Association.

The motor cortical maps in adult mammals are reported to reorganize following various manipulations including peripheral denervation (Donoghue et al, 1990), repetitive intracortical microstimulation (ICMS) (Nudo et al 1990a) and local disinhibition by intracortical baclofen infusion (Jacobs and Donoghue 1991).

These studies suggest that differential activities in competing regions within the primary motor cortex (MI) mediate the reorganization of motor representations. The present experiment examined this hypothesis by recording multiple unit activity (MUA) from vibrissal and other regions of MI before and after facial nerve transection.

Three to seven microelectrodes were placed at low threshold depths of the right MI in ketamine-anaesthetized rats. The same microelectrodes were used for ICMS and MUA recording. Multisite MUA, ICMS-evoked movements and electromyograms of left facial, neck and forelimb muscles were recorded before and after transection of the buccal and mandibular branches of the left facial nerve. The MUA at sites recording primary vibrissal movements was greatly reduced, compared with other sites, immediately after the transection and remained so up to several hours. This result suggests that the differential neural activities in the MI might play a role in MUA reorganization. The MUA reduction in vibrissal regions of MI may be due to a decrease in vibrissal (trigeminal) afferent tone resulting from the motor nerve transection.
507.5 CORRELATION DIMENSION AND LYAPUNOV EXPONENT CALCULATIONS FOR NEURAL ACTIVITY RECORDED IN PRIMATES DURING VOLUNTARY TWO-DIMENSIONAL HAND MOVEMENT WITH INSTRUCTED DEGREES OF FREEDOM

Martin Gall1, Al. Dueren2,3, and Michael Aertsen1
1Dept. of Neurobiology, Brown University, Providence, RI 02912
In addition to linear methods, such as Fourier transforms, autocorrelations and crosscorrelations, nonlinear dynamical analysis methods were used to examine multichannel cortical activity in order to characterize the spatio-temporal dynamics of the cortical network during movement performance (Gall et al., 1991). We used the method of estimated local field potentials (LFP) proved to be nondirectional in a planar directional hand movement task using instructed delay, while units showed directional selectivity (Donoghue et al., 1994), this volume and extracellular unit activity were subjected to correlation dimension (CD) and largest Lyapunov exponent (LE) calculations using MTRACHOS and MTrLyAPV software developed by R. M. Rosenstein (Rosenstein et al., 1993; Physica D 65) as well as Chaos Data Analyzer distributed by the American Physics Institute. Both LFP and unit data turned out to be higher than those observed in the past. The high dimension correlation results obtained indicate that no simple set of equations can be derived to model the system. New methods, such as complexity calculations (Rapp et al., J. Neurosci, 1994) have been used to further investigate extracellular spikes and activity.

507.7 THE POTENTIAL FUNCTIONAL ROLE OF REVERBERATING SYNAPSE CHAINS DEVELOPING IN RANDOMLY CONNECTED NEURAL NETWORKS

Martin Aertsen1, Ad Aertsen2,3 and Mucho Abeles4
1Inst. for Neuroinformatics, Rhein. Univers. Bochum, 44780, Germany; 2Center for Brain Research, Weizmann Inst. of Science, Rehovot, Israel; 4Hebrew Univ., Jerusalem, Israel

Over the past few years, several types of synchronized neural activities have been observed in different cortical areas. This review gives rise to a theoretical debate on the potential role of such synchronizations for cortical function. Experimental results on the abundance of certain events and dependence of cortical phenomena on the spatio-temporal spike patterns in the prefrontal cortex of awake behaving monkey ( Abeles et al. 1993) support the hypothesis, that 'synaptic volley' propagate through the cortex in 'reverberating synapse chain' (RSC). Feedback networks with additional feedback connections.

To get insight into the possible functional role of such RSCs, we investigated their development in a model neural network (see also Brennerstock, 1991). An initially randomly connected network of excitatory and inhibitory neurons with poisson-distributed coupling strength was repeatedly stimulated by a single synchronized spike event, adjusted to activate only a small fraction of the neurons in the network. The global dynamics of the resulting activity spread through the network can be described analytically following Amoroso et al. (1970). Concomitantly, the synaptic connectivity changes gradually as a result of interaction with a 'competitive learning rule'. This development leads eventually to the formation of RSC. Moreover, interactions between different RSCs develop, depending on the spatio-temporal structure of the corresponding stimulus. The path through the network defined by the RSC, may be interpreted functionally as a trace of auto- and hetero-associations. Thus, the space-time composition of the RSCs and their interconnections provide a natural implementation of stimulus context memory.

Additional funding was received from the German Ministry of Science and Technology (BMFT, Neurobiology Program), the German Science Foundation (DFG, A102-1) and the Israel Academy of Science.

507.9 THE PROFILE OF VOLTAGE-DEPENDENT CONDUCTANCES IN NEOCORTICAL LAYER 1 NEURONS

J.A. White1, T. Bude2, and A.R. Kay1
1Dept. of Biological Sciences, Univ. of Iowa, Iowa City, IA 52242 U.S.A.

Layer I of the mammalian neocortex contains >90% GABAAergic interneurons and a very low neuronal density. Presumably because of its low density, it has proven to be extremely difficult to record from layer 1 cells. Consequently, nothing is known about the neurons' intrinsic firing properties or the complement of ion channels underlying these properties.

We studied membrane currents in acutely dissociated layer 1 neurons obtained from the rat layer by minimizing layer I from neocortical slices and subjecting the pieces to enzymatic digestion. Inward currents exhibited by layer I neurons included a fast-inactivating, low-threshold Ca2+-current, which, in some neurons was followed by a persistent K+-current. No evidence was found for a persistent Na+-current. TTX-resistant Na+-current, or low-threshold Ca2+-current. Outward currents included a delayed K+-current, an A-current, and a Ca2+-activated K+-current. Further characterization of the Ca2+-current included an inward rectification of TTX-sensitive Ca2+-current at negative potentials.

The profile in layer 1 cells differs from those reported previously in pyramidal or nonpyramidal neurons from lower layers. Unlike nonpyramidal cells, mature layer I cells express an A-current. Unlike pyramidal cells, layer I cells do not exhibit higher dimensional than results of previous relevant calculations in this particular complement of ion channels will be discussed.

Supported by grants from the ONR and NIH

507.10 PHYSIOLOGICAL SUBGROUPS OF NONPYRAMIDAL CELLS IN LAYER II/III OF RAT FRONTAL CORTEX Y. Kawaguchi1, Lab. for Neural Circuits, Bio-Mimetic Control Research Center, RIKEN, Saitama, Japan

Physiological and morphological properties of nonpyramidal cells in layer II/III of frontal cortex of young rats were studied in vitro by whole cell recording and intracellular staining of Nissl. Layer II/III nonpyramidal cells could be divided into four subgroups by their firing patterns in response to depolarizing pulses and patterns of dendritic and axonal arborizations. (1) Fast-spiking (FS) cells had shorter-duration action potentials and constant spike frequencies during an episode of discharges. FS cells had local or horizontal axonal arbors which did not enter layer I. FS cells were strongly activated by GABA-A and parvalbumin cells. (2) Late-spiking (LS) cells exhibited slowly-developing ramp depolarizations near threshold. LS cells were neurogliaform cells. (3) Low-threshold spike (LTS) cells had low-threshold spikes with larger amplitude and longer duration. The main axons of LTS cells ascended, and the collaterals entered into layer I. (4) Although the remaining cells (regular-spiking (RS) nonpyramidal cells) did not have clearly distinguishable electrophysiological properties, RS cells are tentatively classified into two types. (a) RS type 1 (RS-1) cells induced depolarizing fast notches with smaller amplitude by depolarization from hyperpolarized potentials. RS-1 cells had vertically elongated axonal fields, extending from layer I to V, sometimes to layer VI. This type contained bipolar cells. (b) RS type 2 (RS-2) cells extended axonal branches vertically, giving rise to layer I, RS-2 cells also contained a chandelier cell. These suggest that each subgroup may differentially contribute to the laminar and columnar circuitry of cortex.

PYRAMIDAL MOTOR EVOKED POTENTIALS EVOKED BY CORTEX STIMULATION IN RATS. Y.C. Park*, J.W. Chang, J.H. Kim and S.S. Chung, Dept. of Neurosurgery, Kyung Hee University Hospital, Seoul, Korea
Motor evoked potential (MEP) produced by cortical surface stimulation has recently evolved as a new clinical and experimental tool to study excitability of motor pathways. The original concept using MEPs was based on the assumption that synchronized neuronal discharges evoked by electrical stimulation of pyramidal neurons in the motor cortex were conducted along the corticospinal tracts in the spinal cord. It was, however, recently found that MEPs in the spinal cord were mainly produced by activation of reticular systems in the brain stems due to spread of stimulus current applied on the motor cortex, especially in non-patients with intact brain.

The purpose of this study was, therefore, to selectively monitor MEPs evoked by cortical areas in the rat. A small surface electrode with a diameter of 1.5 mm and another electrode protruded 1.5 mm from the surface electrode were used as an anode and cathode, respectively. The evoked responses were recorded on the spinal cord using bipolar electrodes. The potentials monitored were compared with their origin since the potentials were abolished when the pyramidal tract was selectively lesioned at the internal capsule. The intracord recording of the MEPs showed that the amplitude was highest at the ventralmost area of the dorsal column where the corticospinal tract was located. Latencies of these potentials were much longer than the latencies of the non-pyramidal MEPs. Amplitudes, latencies and wave forms of these potentials were studied following intravenous injection of various general anesthetics to examine the effect of these drugs on MEPS.

MULTIPLE MOVEMENTS MAY BE RELIABLY DIFFERENTIATED USING fmri, PROVIDING ORGANIZATIONAL PERSPECTIVES ON BRAIN FUNCTION. T.W. Kier*, A.A. Hertz, P. Jessard, T.P. Pons, B.J. Richmond. Lab. of Neuropsychology, INSERM, Bethesda MD, USA; Nordia, Copenhagen, Denmark; Lab. of Cardiac Energetics, NHLBI/NIH, Bethesda, MD, USA.
We have investigated the differentiability of activations in the human brain during several randomly-interleaved self-paced motor tasks, as revealed in functional magnetic resonance imaging (fMRI). We used a neural network as a distribution-free technique to classify the tasks on the basis of the fMRI signal. This approach directly estimates probabilities of multiple conditions from an fMRI picture (or any set in area x time). It does not make a priori assumptions about the distribution of the signal or the relative signal strength for different conditions. Discriminability is computed as the information content in the image about the classification set.

Different sets of fMRI-amplitude data from four motor tasks were analyzed. The analyses were carried out on 6 spatial scales, from individual voxels to the full picture. In some cases, the data were preprocessed using principal components. In general, information was found to be encoded across many different voxels. However some voxels were found to be completely independent of their neighbors. Hence spatial smoothing of fMRI data (by intentional smoothing approx.) is undesirable.

To determine whether the overall discriminability of a set of conditions was due only to the discriminability of a few of them, we repeated the analyses for subsets of the conditions and compared the information carried out about these subsets that conveyed about the entire condition set. In this way we found areas in the lower part of the frontal lobe where the information in the signal was larger for 4 conditions than for any subset of 2 conditions. Another area at the frontoparietal junction only permits differentiation between pairs of conditions. For these areas, there is no information in the pictures about added conditions. On the basis of these results, we conjecture that the first set of areas could be involved in planning movements and the second in specific movement components.

571.3
Neuromagnetic fields elicited from the left hemisphere of five healthy right-handed subjects were investigated under three different experimental conditions run in random order every 5-8 s: electrical stimulation of the right index finger (task S), voluntary movement of the right index finger (M), and "interference" condition consisting of voluntary movements triggering the S at the very beginning of the electromyogram of the active muscle. The activity of the sources corresponding to the main components of the SEFs and movement-related components was mapped and localized by means of a moving dipole model. The gating effect was measured by S/(M+S-M). In all the subjects recorded the gating effect was observed starting at approx. 30 ms after movement onset and lasting for the whole period of the ongoing movement. The site of the early gating effect (mostcentrally) was found to be more closely located than the later (mostly centroparietal) gating effect. The task SEFs were found to be larger (significantly after 40 ms) than the control SEFs elicited in a basal condition.

The results in terms of the gating, the mechanism (centrifugal and centripetal), and locus and selectivity of the somatosensory gating. The interesting cortical finding about larger task SEFs as compared to the control SEFs is interpreted in terms of specific attentional influences upon the components after 40 ms.
571.5
DOES THE CORTEX PROCESS POSTURAL ADJUSTMENTS ASSOCIATED WITH BALLISTIC MOVEMENTS? E. Palmer*, E. Cadopoli, P. Ashby. Playfair Neurosience Unit, Toronto Western Hospital, Toronto, Canada.

When seated subjects rapidly abduct one arm in response to a tone, EMG activity occurs in the deltoid of that arm, and, almost simultaneously, in the contralateral latisissimus dorsi. The contralateral activity is assumed to be an "associated postural adjustment". When subjects abducted the left arm rapidly, magnetic stimulation over the left motor cortex delayed the onset of the EMG burst in the right latissimus dorsi relative to the initial burst in the left deltoid. When subjects abducted the right arm rapidly, magnetic stimulation over the left motor cortex delayed the onset of the initial EMG burst in the right deltoid relative to the burst in the left latissimus dorsi. In each case, the delay was greatest when the stimulus was given just before the burst was expected to occur. The inhibition of voluntary movements by transcranial stimulation was not associated with a reduction in the excitability of spinal motorneurons. We postulate that both the focal ballistic movement and the associated postural adjustment are preprogrammed, held in memory until the "go" signal and then released through both motor cortices to spinal neurons. 571.6
MOTOR EVOKED POTENTIALS (MEPS) TO PAIRED TRANSCRANIAL MAGNETIC STIMULI SHOW DIFFERENCES DURING REST, ACTIVATION AND POST-EXERCISE FACILITATION. J. Sanfilippo, M. Halil, S. Grill and E.M. Wassermann. Human Motor Control Section, NINUS, Bethesda, MD 20892

A TMS pulse to the motor cortex at an intensity of 1 x threshold inhibits the MEP produced by a second pulse at intervals (ISIs) from about 40 to 150 ms (Valle-Inclan et al., 1993). But maximal inhibition of the MEP occurs when ISIs are in the range of 15-20 ms after 10 sec periods of 20% maximal voluntary contraction. In both subjects activation caused a large increase in the amplitude of the first MEP and a progressive decrease of inhibition at ISIs greater than about 100 ms which was not seen at rest. Post-exercise facilitation caused a significantly smaller increase in the amplitude of the first MEP in both subjects, but complete reversal of the inhibition of the second MEP in one subject and frank facilitation of the second MEP in the other. Post-exercise facilitation has a weaker facilitatory effect on the first MEP, but it can cause facilitation or a greater reduction in inhibition after the MEP than voluntary activation.

571.7
RESPONSES TO TRANSCRANIAL MAGNETIC STIMULATION DURING FATIGUING MAXIMUM VOLUNTARY CONTRACTION W.B. McKay*, S.M. Tael, A.M. Sherwood, M.R. Dimitrijevic, Div Research and Neurology, Human Neurology, Baylor College of Medicine, Houston, Texas

Sustained maximum voluntary contraction (MVC) is a widely used paradigm for the study of fatigue mechanisms. Cortical motor output was measured by surface recorded motor evoked potentials (MEPs) resulting from transcranial magnetic stimulation (TMS) of the motor cortex. TMS at 80% of maximum (2.0 Joules) was delivered over the Cz scalp EEG location. MEPs and M-waves from supramaximal nerve stimulation (SNS) were recorded at 15 second intervals before and during MVC of ankle dorsiflexors in six healthy human subjects. The subjects were asked to maintain MVC of the right ankle dorsiflexors until the force developed decreased to 50% of its initial value. During ankle MVC, MEP activity, M-waves, and muscle activity were monitored. The MEP amplitude to right and left quadriceps, hamstrings, anterior tibia and triceps surae muscles increased compared to pre-fatigue conditions. The changes in the largest increase occurred in the exercised anterior tibial muscle (p < 0.05). Also, MEP amplitudes in the contracted anterior tibial muscle were maintained while its voluntary activity amplitude and median EMG frequency and force of contraction decreased. Anterior tibial muscle M-wave amplitudes did not change but twitch forces decreased during the contraction. The results show that motor cortex output for single TMS delivery does not decrease while voluntary force generation and EMG decrease during sustained MVC.

Controversy in human mapping studies of unilateral movements relates to bilaterality, quantitation, and spatial extent of the activations. We used quantitative measurements of regional cerebral blood flow (rCBF) with [15O]-butanol and positron emission tomography for mapping of simple finger movements using a computerized task, and [15O]-water for mapping of cortical activity related to the number of words produced for a given word category. rCBF at rest was measured using a time-locked approach. Similar results were obtained at rest and during voluntary index flexion movements. A preliminary analysis of a large number of words was presented at the symposium. Significant increases in rCBF were seen in the left premotor cortex (650 ml) and motor cortex (260 ml) in both hemispheres, but larger increases were seen in the left hemisphere. Increases were noted in the supplementary motor cortex, both dorsal and ventral premotor cortex, and the posterior parietal cortex. No increases were observed in the cerebellum or the thalamus. The increases in rCBF were significantly larger in the left hemisphere. The increases were influenced by the number of words produced, with larger increases as the number of words increased. The results indicate that the human motor system is bilaterally activated for a simple finger movement task, with greater involvement of the left hemisphere. The increases were seen in the primary motor cortex, supplementary motor cortex, and the posterior parietal cortex. No increases were observed in the cerebellum or the thalamus. The increases in rCBF were significantly larger in the left hemisphere. The increases were influenced by the number of words produced, with larger increases as the number of words increased. The results indicate that the human motor system is bilaterally activated for a simple finger movement task, with greater involvement of the left hemisphere.

VIBRATORY, MOTOR AND TRANSCRANIAL MAGNETIC STIMULATION IN HUMANS PRODUCE A LOCALIZED CHANGE IN CEREBRAL OXYGENATION DEMONSTRATED WITH NEAR INFRARED SPECTROSCOPY. H. Chou, B. Brantzen, R. Meyer, GID Biometrics, U. Dinagd, A. Vingerling, Dept. of Neurology, Humboldt-University, Berlin, and Ludwig-Maximilians-University, Munich FRG

We examined the potential of Near Infrared Spectroscopy (NIRS) to detect localized changes in concentrations of oxygenated and deoxygenated hemoglobin ([Oxy-Hb],[deoxy-Hb]), [total-Hb]=[Oxy-Hb]+[deoxy-Hb]) with a non-invasive near infrared spectroscopy monitor (NIRS-500, Hamamatsu). The following tests were studied: (1) a sequential motor task, (2) magnetic stimulation, (3) vibratory stimulation and (4) electrical median nerve stimulation. Optodes were positioned according to a modified 10/20 system. In 3 experiments, optode position was assessed by T1-weighted-MRI. (1) In 20 subjects a finger opposition task ipsi- and contra-lateral to optode position over left primary motor cortex was repea-tedly performed in a time-locked fashion to movement onset. A clear rise of [Oxy-Hb] and [total-Hb] was accompanied by a decrease of [deoxy-Hb] detected exhibiting a pro-nounced contralateral predominance. (2) In 5 subjects transcranial magnetic stimulation was applied over the mid-point between the optodes resulting in a contralateral finger movement. Voluntar-y movement of the same finger was performed in the same experiment. Magnetic stimulation-induced movement resulted in smaller changes of NIRS-parameters. (3) A localized response to a vibratory stimulus was elicited over primary somatosensory cortex, whereas (4) electrical stimulation of median nerve did not show a clear response. The experiments show that NIRS is able to detect rather small changes of local cerebral oxygenation, though optode positioning remains a problem. Supported by the DFG VI 387/1-
571.11 SPATIAL AND TEMPORAL DISTURBANCES IN PATIENTS WITH PARALYTIC LESIONS WITH AND WITHOUT IDIOMETOR APRAXIA. R. Hether, F. Weiss, S. Neumann, C. Dode, H. Kuhlmann and H. J. Freund. Department of Neurology, Univ. of Dusseldorf, 4002 Dusseldorf, Germany. Lesions of the parietal cortex lead to severe motor disorders, known as apraxia for left- and hemispheric for right-hemispheric lesions. In a retrospective study, 6 patients with parietal lesions (4 with and 2 without idiometor apraxia) and 6 patients with right parietal lesions were tested for spatial and temporal errors and the presence of a neglect component. Movement trajectories were recorded by a Selspot IIP system and a video camera. During the first set of experiments patients had to produce horizontal, vertical, and circular arm movement components in their personal space, each consisting of 10 movement sequences (SMS) were composed. These SMS had to be produced after reading aloud the instructions ('reading'), after verbal instructions ('instruction'), and after the experimenter had demonstrated the movement ('demonstration'). The 5 SMS and the 1 model of instruction were randomized for each side. For all patients the same sequence was used. In patients with left parietal lesions, significantly more spatial (direction reversions) and sequencing errors (wrong order of movement components) of the movement trajectory were observed in comparison to the right parietal lesioned patients. More omissions or repetitions of movement components revealed aspects of motor neglect or perseveration errors. In the second set of experiments, the patients had to grasp a 10 cm long stylus (lying horizontally in front of them) after eye opening without previous visual feedback. Whether hand inversion (HI) or hand elevation (HE) is used for grasping depends on the angle of the stylus in relation to the sagittal plane resulting in a (HIHE) probability curve. In normals, the HIHE-probability varied within a small range of 20 degrees only. In both parietal groups, especially in the left hemispheric patients with apraxia, this angle range was significantly enlarged to more than 100 degrees in comparison to the controls.

We conclude, that the right parietal cortex is mainly involved in the decision "what to do" and the left parietal cortex in the problem "how to do" a motor task. Thus, normal motor behavior affords an intensive interaction between both parietal cortices.

Our recent studies in the cat (Cullen et al. 1991) have demonstrated that IBM discharges are best correlated, not with the metrics of the movement of the eye in the head but with the movement of the visual axis in space (gaze) during rapid orienting coordinated eye and head movements. To further address whether cal and monkey IBNs carry gaze or eye related signals, we carried out a dynamic analysis of IBM discharge. The activity of IBNs reflects an up-swing segment which encodes a non-linear representation of motor error (Van Gelsenberg et al. 1981) was first tested. For our neurons, discharges head-fast or head-fixed were significantly less correlated with a quasi-linear representation of eye or gaze motor-error, than by simple downstream dynamic models which incorporated eye or gaze velocity and a firing rate bias term. For downstream models, we found that gaze velocity was better at predicting IBM activity than eye velocity. The estimated firing rate based on a model using gaze velocity produced significantly better fits of the actual firing patterns, which was based on a quasi-linear model (> 30% less RMS). Adding a bias term to the gaze and eye velocity models improved the fit of both models. Interestingly, the value of the bias estimated for the gaze model was comparable to that which we determined for head-fixed models, while the estimated value for the eye model was significantly larger. Since the bias term caused the physiological "resting discharge" of the IBM, it seems important to determine why this bias is not present, and why both of these models perform so well. The firing rate of the neurons studied was correlated with the metrics of the eye and/or gaze movements.

572.2 INTERACTION BETWEEN VERTICAL EYE POSITION-RELATED NEURONS IN AND AROUND THE INTERSTITIAL NUCLEUS OF CAJAL ON BOTH SIDES. Y. Iwamoto*, S. Chimoto, E. Nambo, K. Tohvida. Dept. Physiology, Inst. Basic Med. Sci., Univ. of Tsukuba, Tsukuba, 305 Japan. We have recently shown that many neurons in and around the interstitial nucleus of Cajal (INC) that project contralaterally carry vertical eye position signals. In the present study, we recorded activity of vertical eye position-related INC neurons and examined electrophysiologically their aural course and synaptic nature in the alert cat. For 11 downward-on and 5 upward-on neurons, depth profiles of threshold and latency for antidromic activation were studied by tracking in and around the contralateral (c-INC). These neurons were activated from not only c-INC but also a region 1-2 mm dorsal to c-INC. The latency became longer as the stimulation site moved ventrally, showing that the stem axon coursed ventrally toward c-INC. Double or triple low-threshold peaks were observed in 4 downward-on and 2 upward-on neurons when stimuli were applied to c-INC, indicating the existence of branches. Stimulation of the midline region suggested that these neurons project to the commissural and/or efferent pontine commissure. Stimulation of c-INC and the more dorsal region inhibited spike generation of 7 downward-on and 2 upward-on neurons that were not laterally inhibited. The range of connection was from 0.7 to 1.4 msec. Effective stimulation sites seemed to be distributed along the course of fibers from PC. Results suggest that these non-contralaterally projecting neurons project to commissural INC neurons on the contralateral side, most likely from those having an opposite orientation.

572.3 AN EGG-BASED BRAIN-COMPUTER INTERFACE: USE BY INDIVIDUALS WITH ALS. D. J. McFarland*, L. McCane, T. Vaughan, and J. R. Wolpaw. Wadsworth Labs, NY State Dept Health and SUNY, Albany, NY 12201. Humans can learn to control the amplitude of EEG activity recorded over sensorimotor cortex (e.g., the 8-12 Hz mu rhythm) and use it to move a cursor to a target on a video screen (Electroenceph clin Neurophysiol 78:252-259, 1991 and in press). Brain-computer interface (BCI) systems link the synchronization of motor imagery to a new communication channel for those with severe motor disabilities. We are using high-resolution EEG frequency and topographic analysis to improve this technology and are investigating its applicability to individuals with specific motor disabilities.

After initial evaluation of the EEG and its relationships to sensorimotor activity, subjects learn to control cursor movement through 24 channels of EEG are stored for offline analysis aimed at improving the algorithm that converts EEG activity into cursor movement.

In initial studies, individuals with early-stage amyotrophic lateral sclerosis (ALS) were able to learn to control cursor movement. If this control persists as the disease progresses, EEG-based communication could prove of considerable value in the later stages, when useful voluntary movement is largely or totally gone. (Supported by the National Center for Medical Rehabilitation Research (NIH grant HD 30146).)
572.5

The movement field properties and the d-charge dynamics of 206 MRF neurons located lateral to the oculomotor complex have been studied in 2 awake behaving monkeys performing visually guided saccades. At least two major clusters of neurons can be distinguished. One group, the long lead burst neurons, has a build-up of activity which begins 150 msec before saccades, an accelerated burst just before the saccade, this burst declines during the saccade, and the tail of activity may continue for 50 msec after saccade end. The horizontal saccade vector for these cells is primarily contraversive with a vertical component. The movement fields for these cells are large and open-ended. These cells are located in the more ventral and caudal portions of the MRF. A second group of cells is distinguished by a tightly coupled burst of activity which starts 20-30 msec before, peaks just prior to, and declines sharply during visually guided saccades with little post saccadic activity (i.e. clipped cells). These tightly coupled cells can have either large (open-ended) or small (closed) movement fields. While many of these cells have omnidirectional discharges, the optimal saccade vector for these cells is again contraversal with a pronounced vertical component. These cells are located in the more dorsal and rostral portions of the MRF. The correlation of cell type with histologic location suggests at least two physiologically distinct regions of the MRF.

EFFECTS OF REVERSIBLE LESIONS OF THE CENTRAL MESENCEPHALIC RETICULAR FORMATION (cMRF) ON PRIMATE SACCADIC EYE MOVEMENTS. D. M. Waitzman* and V. L. Slisak, Newington VAMC, 555 Willard Avenue, Newington, CT 06111.

Recent studies suggest that the cMRF participates in the generation of saccades, but its exact role remains unclear (Waitzman, Soc. Neurosci. Abstr., 1992). Visually guided saccadic eye movements of one awake rhesus monkey were recorded using a scleral search coil before and after the injection of 2% lidocaine (1 - 5 µl) and muscimol (1 - 3 µg) into the cMRF. Fifteen injections of lidocaine, 5 injections of muscimol, and 4 injections of saline were placed at a series of sites (containing saccade associated, multi-unit activity cells) which were at 1 mm increments along the rostral-caudal axis, 2 mm lateral to the oculomotor complex. Within 2 minutes of injection of either lidocaine or muscimol, contraversive horizontal and vertical saccades were hypometric, while vertical movements were hypometric. The primary position of gaze was shifted 3º down and to the ipsilateral side. The trajectories of vertical and oblique saccades were markedly curved toward the ipsilateral side. Injections 2 mm above or below the cMRF produced no effects on saccades. The effects on saccade trajectory suggest that the cMRF participates in the descending control of the horizontal component of movement, while changes in saccadic accuracy suggest the cMRF participates in the feedback control of saccade amplitude. The shift in the primary position of the eyes in the direction opposite to that of cMRF neurons is used in the maintenance of the primary position of the eyes. Supported by NIH Research Grant EY 09481 and a RAG Grant from the Office of Medical Research, Dept. of Veterans Affairs.

572.7

THE TIMING OF SACCADIC-RELATED RESPONSES OF BRAINSTEM OMNIPAUSE NEURONS IN CAT. M. Parducz* and D. Guirao, Montreal Neurological Institute and McGill Univ., Montreal H3A 2B4, Canada.

Recent evidence (Parducz and Guirao 1994) suggests that omnipause neurons (OPNs) in the superior colliculus project onto brainstem omnipause neurons (OPNs). Both cell types pause for eye saccades in monkey and gaze saccades in cat and it is of interest to determine whether they share other discharge properties. We recorded OPNs during visually-guided horizontal gaze shifts in the head-fixed and head-free cut and quantitatively analysed the temporal relation of their discharge relative to parameters of eye or gaze saccades. L. Cat OPNs ceased firing, on average, 25ms before saccade start. They resumed firing, on average, 6sec before saccade end. Some cells were reactivated after saccade end. Consequently, as already reported, the saccade duration was well correlated with saccade duration (r=0.9) but the slope of this relation was always less than one - a similar relation holds for monkey OPNs (Murao and Wurtz 1993). The slope increased linearly with the associated correlation coefficient, indicating that OPNs whose pauses are temporally well correlated to saccades have equal onset and end times. 2. Monkey OPNs are reactivated sooner for contraversive saccades compared to ipsiversive ones. The timing of the majority of our cat OPNs depended on saccade direction; two-thirds of the cells had significant left-right differences in pause end time. 3. Pause end time was twice as variable as pause onset time; the inverse has been observed for monkey OPNs. 4. OPN tonic discharge rate influenced pause timing: the higher a neuron’s firing rate, the closer to saccade start it stopped discharging. 5. Pause end time did not depend on any saccade parameters. On average, OPNs were reactivated at either ~16deg of gaze error or ~100m/s. In 1 and 2, OPNs and FPs have similar discharge characteristics. This suggests that OPNs are segregated into two lateralized populations of cells each receiving inputs from consular OPNs. However, the timing characteristics of OPNs are also clearly influenced by extra-FP inputs.

572.8

Botulinum neurotoxin A (BoNT) is an useful tool for the study of motoneuron-muscle interactions, since it produces a functional disconnection by blocking the release of acetylcholine at the neuromuscular junction. Are there any retrograde effects on the discharge characteristics of motoneurons when their target muscle is paralyzed with BoNT? To address this question, adult cats were prepared for the chronic recording of eye movements, lateral rectus muscle potentials and abducens motoneuron electrical activity. After control recordings, BoNT was injected into the lateral rectus muscle at either 3 or 0.3 mg/kg. Both doses produced in a few hours the paralysis of abducting eye movements that paralleled the disappearance of muscle field potentials induced by the electrical stimulation of the Vth nerve. The time course of these changes was shorter for the high BoNT dose and the recovery lasted longer. On the contrary, the high dose produced significant alterations in the discharge characteristics of abducens motoneurons. Thus, motoneurons lost their typical tonic-burst firing that accompanies eye fixations and saccades. Instead they showed a sustained low firing rate (15-50 Hz/pulse) and barely existed or cut-off in form that they were firing for the off-direction. Firing modulation for both spontaneous and vestibularly-induced eye movements was extremely weak yielding low sensitivities to both eye position and velocity. The signalizing deficits of motoneurons for off-directed eye movements were deeper than those for the on-direction. Accordingly, the scatterplots of firing rate vs eye position or velocity showed that two rather than one regression line fitted better the data and corresponded to the data partition into on- and off-directions of movement. The low dose of BoNT produced only subtle changes in the firing of some motoneurons despite total muscle paralysis. These data suggest that the firing alterations found result of a direct action of BoNT on motoneurons and not due to the target disconnection.

The synaptically focused population of abucescent interneuronal neurons with medial rectus (MR) motorneurons in the cat oculomotor nucleus have been examined by light and electron microscopy following injections of biocytin into the abucescent and vestibular nuclei, respectively. Both AB and IN synaptic terminals had a spherical shape, were small and uniformly distributed. About 1400 synaptic contacts were made with 6 motoneurones. Single biocytin filled terminals were followed extensively through the CNS, and made single synaptic contacts with distal dendrites, whereas most AB synaptic endings contacted proximal dendrites (98%) or soma (2%). IN synaptic endings were associated with either a postsynaptic density at sites of synaptic contact or axo-somatic synapses were in close apposition of the axon hillock. The abucescent pathway might function as a means of counteracting the effects of other inputs that are related to conjugate horizontal movements. Supported by USPHS Research Grant EY02191.

TRANSNEURAL TRANSPORT OF BIOCYTIN THROUGH ABUCESCENT MOTONEURONES OUTLINES THE INNERVIAL AND VESTIBULAR PATHWAYS IN TELEROST FISH. B. Berger, L. Marchi and P. Labbe. Dept. of Physiological and Biological Sciences, Univ. of Nantes, Inst. of Pharmacology, Nantes, France.

Selective injection of biocytin into the telerostral CNS of a diversity group of teleosts reveals retinal and cerebellar subgroups of abucescent motorneurons with intensely labeled dendrites and terminals in the extreme mediobasal extent of the hindbrain. Labeled immediately doro-medial to each sub-group and in about a 1.2 ratio are interneuronal neurons whose axons ascend dorsally in the medulla, pass cranially through the pons, and reach the midbrain, and then project rostrally in the diencephalic tract of the contra-MLF where they terminate onto other and possibly other motorneurons. In those species with rhythmiically conjugate horizontal scanning eye movements (e.g. goldfish, catfish vs. sculpin, sunfish), the bipartite oculomotor/nucleus interneuronal somata position is observed medially in the hindbrain and this location appears to be independent of either optic axis or location of the eye in the orbit. However, even when the eyes are horizontal in the midline, terminals are predominantly, but not exclusively, adjacent to the vestibular nucleus (e.g. midlenspman), the medially directed dendrites not only reach but also cross the midline. In all cases, labeled dendrites from each motoneuronal population with those of the adjacent interneuronal populations suggesting a similar embryonic origin of all neurones in rhombomeres 5 and 6. Transneural biocytin transport also marks the pathway and location of contralateral vestibular neurones in the descending oculovestibular nucleus included occasionally the axons of vestibular neurones that project to medial rectus motoneurons. Electron microscopy of the oculomotor and abucescent motor nucleus in goldfish reveals numerous axonometric and axodendritic synaptic endings showing membrane specializations characterizing chemical and gap junctions. Therefore, the extensive electrotropic coupling and transneural transport of biocytin prevalent in the lateral eye, the oculomotor and in other CNS regions would fulfill the essential demands of these neuronal subpopulations. Supported by USPHS Grant EY06968.

SIMULATION OF MOTOR UNIT RECRUITMENT IN EXTRAOCULAR MUSCLE. Paul Deutet*, Dept. of Psychology, University of Sheffield, Sheffield S10 2TN, England.

Understanding the recruitment pattern of extracellular motor units is important for constructing distributed models of oculomotor control. Recruitment in the abucescent nucleus was simulated using the adaptive model of motor unit recruitment, the firing rates of oculomotor neurones (e.g. Robinson and Keller, Bibl. Ophth. 82: 7, 1972), and the total active force developed in the lateral rectus muscle (e.g. Miller and Robinson, Comp. Biomed. Res. 17: 43S, 1984). The purpose was to determine the distribution of motor unit strengths that would fit both sets of data over the oculomotor range. The lateral rectus was represented as 100 motor units, initially of identical strength. For a given position of the eye, the force developed by each unit was calculated, and the sum of unit forces with the active force in the entire muscle as measured experimentally. The properties of the active units were then adjusted to reduce the size of any resultant error, in a manner related to gradient descent methods required to train the model. The simulated eye muscle was trained in the fitness for a series of eye positions drawn at random from the oculomotor range until performance stabilized. Flows of motor unit strength against oculomotor neurone threshold revealed an U-shaped pattern, with the strongest units being recruited at both extremes of the oculomotor range, and the weakest units recruited in the middle. The pattern remained qualitatively stable over a range of assumptions about the distribution of oculomotorneurone populations, and the relation between motorneurone firing rate and unit force. One part of the U-shaped pattern is similar to that observed in spinal motor neurones, where stronger units tend to have higher recruitment thresholds, whereas the other part is consistent with evidence from single motor-unit stimulation studies (Wall and Goldberg, Brain Res. 587: 291, 1992) suggesting that in eye muscles the strongest units are recruited first. The pattern as a whole may reflect the functional need for precise control of eye position in the middle of the oculomotor range. support of the grant USPHS Grant EY07446.

The performance of anti-saccades (AS) - saccades directed opposite to a visual target - entails the inhibition of reflexive saccade and the coordinate computation of a goal specified by instruction, i.e. not pointed to the oculo-motor representation of eye position seem mismatched. As a result, 2 flashes at the same retinal localization appear to be at different places. Could this illusory spatial mislocation improve the temporal discrimination of 2 stimuli flashed in rapid succession? Horizontal eye movements were recorded with an Ober eye-observer scanner in 2 human subjects, head fixed in the dark. Subjects were instructed to make a saccade to a 10 ms light (on left), 10 ms rightward from the point of fixation. During the latency period, another 4 ms light spot was flashed twice at 12° to the right of the point of fixation. Flash separation varied from 10 to 100 ms on the same lens the same time. When the same location localization appear to be at different places. The frequency of reporting errors as for eye positions was that of the saccadic onset. The frequency of reporting two flashes at different locations increased in parallel. We suggest that the improvement in temporal discrimination of 2 stimuli flashed in rapid succession of the eye position signal on visual input. (Supported by USHHS grant T32 GM038735 and USPHS grant EY058797).

BILATERAL PROJECTION OF SINGLE MOTOR NEURONS INVOLVED IN VISUOMOTOR CONTROL, A DOUBLE LABELLING STUDY IN THE RAT. P.A. Stringer (SFON: Brain Research Association). Department of Psychology, University of Central Lancaster, Preston PR1 2HE, UK.

Preliminary retrograde double labelling studies have identified oculomotor nucleus motoneurons projecting bilateral axonal collaterals through the retinotopical fields. This study was designed to combine retrograde / anterograde tracers in delineating these projections. Twenty male Wistar rats (230 - 330 g w.) were anesthetized with trinemethanol, and individual extracellular muslces, bilaterally, were injected (0.05 - 0.2 pL) through 50 μm tip diameter glass micropipettes connected to a Linear Flourograph (GF, Gil, Fast Blue (FB), PHA-I, BioIoylated Dextran Amine (BDA) or choleraotoxin - horsenized peroxidase (CTB). Survival times ranged from 48-96 hours, and following perfusion 80 μm sections were appropriately processed. Tryramethenidine diaminobenzidine and Vector VIP were used as chromogens with PHA-I, BDA and CTB. Fluorescent tracers were viewed with a Leica Discope. These studies showed only occasional bilateral innervation of extracellular muslces. A more common configuration would be, for example, for a ventromedially and rostrally located oculomotor neuron, retrogradely labelled only injection to the positions in the left inferior rectus, to also send an axon collateral to terminate in association the contralateral third nerve fascicles retrogradely labelled in turn following an injection of tracer to the right inferior rectus muscle. The results demonstrate that the anatomical bases of muscle linkages carried out at the simplest level of individual neurones. A primitive system overlap and increased in sophistication by the complex interconnections of premotor afferents. thursday am

OCCULOMOTOR: PERFORMANCE AND MODELING OF SACCADES
573.3

How the brain regulates saccadic initiation is not known. For useful neural correlates to be identified, novel behavioral methods are needed that systematically manipulate saccadic production. To manipulate the initiation of saccades, we implemented a countermarching paradigm (Lappe and Erkink, 1966, J Exp Psych, 72:805) in two rhesus monkeys. After fixation of a central spot, a target appeared at 1 of 2 locations. At the same time the fixation spot disappeared, signalling the monkey to generate a saccade to the target. On 25% of the trials the fixation spot reappeared after a delay, signalling the monkey to withhold the saccade. The stop-signal delay ranged from 25-225 ms. With short stop-signal delays monkeys withheld saccades to the target. On longer stop-signal delays monkeys increasingly failed to withhold the saccade. We observed a few trials in which monkeys generated a saccade failing short of the target, and on those trials a return saccade was usually made. The probability of saccade generation as a function of stop-signal delay increased monotonically with stop-signal delay in a sigmoid fashion (best fit logistic equation, r^2 = 0.97). The hypothesis that generation of the saccade is determined by a race between a go and a stop process provides a means of analyzing this inhibition function to estimate the covert latency of response to the stop signal (Logan and Cowan, 1984, Psych Rev, 91:295). For each stop-signal delay the stop-signal response time was estimated as the point on the cumulative distribution of go trial saccade latencies corresponding to the proportion of stop-trial results in which a saccade was generated for that stop-signal delay. Stop-signal response time increased with stop-signal delay from 140 ms at a 25 ms delay to 30 ms at a 225 ms delay. The average stop-signal reaction time for both monkeys was 80 ms. This countermarching paradigm will be useful to study the neural mechanisms that regulate saccade initiation. (Supported by ROI:EY08890 and T32:EY07135)

573.5

Saccades made to a visual target can have a bimodal latency distribution, the first mode of which is termed "express." If more than one target is presented, express saccades are suppressed (Schiller et al. 1987). It has also been reported that saccades occurring during the simultaneous presentation of two targets can be "averaging" and terminate between the targets. In this study, we examined the effect of averaging saccades and exhibit bimodal latency distributions. Two rhesus monkeys with implanted scleral search coils were used. At the start of a trial, a fixation spot was presented. After a randomized amount of time, this spot was extinguished and either one (80% of trials) or two (20%) targets were turned on at 6 deg. The two target condition, separations varied from 0.5 to 5.5 deg of arc. Saccadic latencies and their endpoints in space were analyzed. Whenever a distinct saccade population appeared, these saccades had bimodal latencies. As the proportion of the paired target was increased, the probability of averaging saccades declined and saccadic accuracy improved. Also, as saccades became less "averaging" and more "target directed", the express mode was markedly reduced. This study shows that express saccades can be made when two nearby targets are presented simultaneously, but they tend to land at averaged positions where there is no actual visual stimulus.

573.7

The existence of an express (E) and a regular (R) mode in distributions of saccadic reaction times (SRT) is now widely accepted fact (review, Fischer & Weber, Biol. Brain Sci., 16, 1993). The E-mode is often observed in the gap paradigm, where the offset of an attention attractor precedes target onset. These results led to the notion of "engaged" and "disengaged" attention. Without induced disengaged attention, two modes lead to a reduction of mean regular SRTs (Sadow, J Opt Soc Am., 57, 1967).

We have been interested in the relationship of SRTs to states of attention into a quantitative model. We assume that: (1) The attentional state can be mapped onto one continuous variable, a(t). (2) Aside from conduction delays, the total SRT is determined by a "processing time" which is mapped onto the relaxation of a(t), governed by stochastic dynamics of the form a + f(a) + e(t), down to a threshold. (3) e(t) is a Gaussian white-noise. (2) Two behavioural relevant "signals" act parametrically onto the attentional system: a 'warning' and a "go-signal." Without these signals the dynamics is bistable, reflecting the states of engaged/disengaged attention. To make the system switches spontaneously between the two states, so that they are visited with a certain probability. During the gap interval the system is still bistable, but now the disengaged state is more stable than the engaged state. Thus, the probability of being disengaged increases with time after the warm-up event. The go-signal duration. During the delay monophasic function x(t) crosses the threshold after a time which depends on the state at go signal onset. Simulations show the behavior of gap paradigms, including skewed SRT distributions and the dichotomy of E- and R-saccades as well as the reduction of regular SRTs with increasing gap interval. EYE SACCADES GUIDED BY VISUAL, TACTILE AND PROPRIOCEPTIVE STIMULI IN MAN. O. Blanke, O.-J. Gröther and W.O. Guldin*, Department of Physiology, Freie Universität, 14195 Berlin, Germany.

Horizontal visual saccades (binocular stimulation with light-emitting diodes, distance up to ± 40 degrees horizontal eccentricity) were used to calibrate eye movements recording using a reflective infrared method). In addition to "visual" saccades the subjects performed saccades in the dark directed to the left and right index fingers positioned at a 90° or 180° angle (1970.7-1 per sec). The subjects were also asked without tactile stimulation to look at the index fingers (same position as in the preceding paradigm), whereby a short auditory kick determined the alternation frequency.

At an alternation rate of 0.7-4 per sec the "tactile" and "proprioceptive" saccades were significantly larger than the visually guided saccades in all but one subject, i.e. there was a considerable overshoot, indicating that the difference in the controlling eye position in the dark were operating at a gain below 1. This "error" in saccade amplitude increased with crossed hands. When visual saccades were suddenly changed to tactile or proprioceptive saccades, the increase in saccade amplitude occurred gradually with a time constant between 3 and 5 sec. The same was true when saccades were guided 20 times by two alternating diodes after an initial memory. (Supported in part by a grant from the Bundesministerium für Wissenschaft und Technologie, Germany).

INFLUENCE OF FAST SACCADE GAIN ADAPTATION AND FATIQUE ON SACCADE METRICS IN THE MONKEY. A. Straube, S. Ulster, P. R. Robinson, and A. F. Poach*, Neurologische Klinik, Ludwig-Maximillian University, Munich, Germany, and Department of Biology and Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195, USA.

To provide accurate sacades, the oculomotor system must be able to compensate for changes in its neural elements. Such changes can be simulated by altering saccade gain either temporally decreased or increased the gain of visually-guided saccades by electronically detecting a targeting saccade and then causing the target to step either forward or backward by ±30° on these trials, this paradigm caused either a decrease or increase of saccadic gain to the initial target step by an average of 0.28 and 0.24 to 30% step, respectively in 3 monkeys. The adaptation in vertical or horizontal direction. The time constant for the readaptation towards the normal gain was always smaller than the time constant of the primary adaptation. For 30% backadaptation, the gain decrease was still 18% after 20 hours in the dark.

Associated with the gain change, however, there was also a change in saccade metrics. For both forward and backward adaptation, saccades were slower with longer durations. The percentage decrease in peak velocity was larger for larger saccades. It also varied from monkey to monkey and became less if sacades were adapted with a background. Saccade slowing could not be explained solely by fatigue because the same number of visually-guided sacades without a artificial target step caused smaller changes in duration and peak velocity.

Supported by grants from the Heisenberg Foundation and by NIH grants EY 00745 & EY 0799.

Translation of the stimulus induced rapid adaptation of horizontal saccade amplitude by contrast, rotation of the visual field did not affect a significant adaptation in torsion. Thus, our results do not support the hypothesis that Listing's law serves a visual purpose.

573.9 DYNAMICAL PROPERTIES OF AUDITORY EVOKED SACCADES M.A. Freas and A.J. van Opstal* Department of Medical Physics and Biophysics, University of Nijmegen, P.O. Box 9101, 6500 HB Nijmegen, The Netherlands

We measured saccadic eye movements of human subjects towards visual and auditory targets through the oculomotor range. It was noted that auditory-evoked saccades had trajectories and velocity profiles that were less stereotyped than visually-evoked saccades. This often resulted in curved trajectories for saccades driven towards auditory targets in oblique directions. Close inspection of the velocity profiles showed that the main sequence properties of the horizontal and vertical components of auditory-evoked saccades seem to be at least in part, due to saccadic fixation. There is also evidence that the fact that the auditory system derives azimuth and elevation of a sound from different neural pathways. Therefore, convergence of these pathways in a late stage of the oculomotor pathway may give rise to these effects.

This is in strong contrast to visually-driven saccades, the dynamics of which seem to be vectorially encoded, resulting in approximately straight saccades.

In order to further study these apparent differences, we are currently recording the activity of saccade related burst neurons in the deep layers of the monkey Superior Colliculus during saccades towards auditory and visual targets.

573.10 EFFECTS OF AUDITORY STIMULUS ON HUMAN GAZE SHIFTS TO VISUAL TARGETS. B.D. Cornell and D.P. Munoz* MRC Group in Sensory-Motor Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6

We investigated the effects of presentation of auditory stimuli on gaze shifts (eye-head movements) of visual targets in human subjects. Subjects were instructed to look as fast as possible from a central LED to an eccentric LED, either 40° to the right or left as presented on the computer monitor. Subjects were instructed to either select the same location as the eccentric LED (enhancer), or on the opposite side (distractor), or not at all (rest). The average saccade latencies are also shown.

The experiments were performed in a gap condition in which the central LED was turned off 200ms before onset of the eccentric LED. In this gap condition, subjects fixated the central LED until the onset of the eccentric LED, at which point a target was presented in either gap or enhancement condition. These experiments were also performed in a condition in which the central LED was turned on 200ms after onset of the eccentric LED. In this condition, subjects were able to saccade to the target at a rate of 0.9 Hz, which is comparable to their rate of fixation. The average saccade latencies are shown.

The data suggest that the oculomotor system is modulated by auditory stimuli in a way that is consistent with the hypothesis that the auditory system is involved in the control of gaze shifts to visual targets. Reaction times to acquire the eccentric LED were reduced significantly in all subjects during enhancer trials and increased significantly in all subjects during distractor trials. These experiments were also performed in a condition in which the central LED was turned off 200ms before onset of the eccentric LED. In this gap condition, subjects fixated the central LED until the onset of the eccentric LED, at which point a target was presented in either gap or enhancement condition. These experiments were also performed in a condition in which the central LED was turned on 200ms after onset of the eccentric LED. In this condition, subjects were able to saccade to the target at a rate of 0.9 Hz, which is comparable to their rate of fixation. The average saccade latencies are shown.

ACTIVITY OF PONTINE OPM NEURON S DURING EYE BLINKS.

L. E. Mays* and D. W. Morris. Dept. of Physiological Optics and Vision Science Research Center, University of Alabama at Birmingham, Birmingham, AL 35294.

Pontine OPM Neurons (OPNs) are known to play a crucial role in the generation of saccades and quick phase eye movements. These neurons are located in the nucleus raphe interpositus of the monkey, near the midline and just ventral and rostral to the abducens nucleus. OPNs are tonically active in the awake monkey and cat and cease firing just before and during saccades and quick phases of nystagmus. OPNs have been shown to inhibit saccadic excitation and inhibitory burst cells, and electrochemical stimulation of the OPN region suppresses saccades and quick phases but not slow eye movements. Since blinks are often associated with saccades, it can be difficult to determine whether a cessation of OPN activity is associated with a blink or the eye movements which accompany a blink. In experiments using anesthetized monkeys trained to maintain fixation on a visual target, we have observed that OPN activity may be related to blink frequency and not simply to the eye movements which accompany the blinks. Furthermore, the duration of the pause is positively correlated with the duration of the blink. Analysis of the data obtained using lid coils shows that OPN activity ceases 10 ms before the blink onset and that the pause lasts considerably longer than the downward phase of the movement.

574.8

THE ULTRASTRUCTURE OF EYELID MOTONEURONS IN THE MACAQUE.

P.J. Mays* Departments of Anatomy, Neurology and Ophthalmology, Univ. of Mississippi Med. Ctr., Jackson, MS 39216.

Eyelid movements are primarily controlled by two muscles: the orbicularis oculi, which produces blink down-phases, and the levator palpebrae, which produces blink up-phases and moves the lid away from the eye during opening and closing. Neural control of these movements is mediated by motoneurons which control these two muscles. These motoneurons which control these two muscles have been identified with intraocularly transported WGA-HRP/HRP. The ultrastructure of these identified lid motoneurons and the axon terminals synaptically contacting them provide a basis for determining the pattern of inputs that produce blink and gaze-related limb movements. Levator motoneurons have a relatively low density of synaptic contacts upon the plasma membranes of their somata and proximal dendrites. In addition to their dendritic arbors, these motoneurons possess a high density of synaptic contact sites with the axons of other motoneurons. The synapses of these motoneurons are of the ocular variety: Orbicularis motoneurons have a high density of synaptic contacts on their somatic and dendritic plasma membranes, with terminals often forming continuous lines along some membrane segments. A characteristic feature of these motoneurons is the occasional presence of a subsurface system immediately beneath a synaptic contact. This subsurface system appears to be a dense-cored vesicle.

EFFECTS OF SUPERIOR COLICULAR STIMULATION ON THE BLINK REFLEX IN MONKEYS.

S,M. La*, B Brezen, M. Basco, C. Evinger and JW. Gnad, Departments of Neurology & Behavior and Psychology, SUNY Stony Brook, NY 11794.

In alert Rhesus monkeys, the effects of SC stimulation on reflex blink responses were studied by delivering 100-300 ms trains of electrical pulses beginning 30-50 ms before a 30-50 ms air puff to one eye. Eye and lid position were monitored using the search coil technique. Location within the SC motor map was determined with 10-25 µA biphasic pulses at 250-300 Hz. The threshold current for blink suppression was always higher than for saccades. The most effective sites for blink suppression were in the rostral layers near the rostral pole, where the ratio of thresholds was roughly 1.5. This ratio increased to 3 or greater at superficial and caudal sites.

The gradient of stimulation within the SC correlates well with the gradient of excitatory projections of the SC to the brainstem oculomotor neurons (OPN). Moreover, stimulation of OPN suppresses blinks. Nevertheless, the difference in the threshold for producing blink suppression and saccades suggests that the underlying neuronal circuitry may differ for the two processes.

BRANSTEN LINKAGE BETWEEN THE SUPERIOR COLICULARIS AND BLINKING.

M.A. Bassoe* and C. Evinger. Deps. of Psychology, Neurobiology & Behavior and Ophthalmology; SUNY Stony Brook, NY 11794.

Both clinical and experimental data show that swallowing can dramatically modulate the brainstem blink reflex circuit. Previously, we have demonstrated that the superrior colliculus (SC) is an important mediator of these effects, such that submaximal inhibition of the SC increases the blink. The goal of the current study was to identify the brainstem neurons that mediate the SC modulation of blinking. The hypothalamic oculomotor neurons (OPN) are one candidate because electrical stimulation of the OPN region (La et al., 1994) and stimulation of the rostral SC, a region which provides a large input to the OPN, is the most effective for suppressing blinks with electrical stimulation. However, since blink suppression with SC stimulation is higher than that for evoking saccades or producing fixation (La et al., 1994), it is also possible that a non-ocular group of brainstem neurons mediate SC blink suppression.

By presenting a single, electrical pulse to the SC in urethane anesthetized rats, we determined the latency of suppression of orbital ocular EMG (OOEMG) activity to be 7 ms. Single unit recordings in the brainstem revealed a group of tonically active neurons caudal to the OPN that paused with reflex blinks. Stimulation at the site of these neurons produced a decrease in OOEMG activity within 5 ms. Stimulation at other brainstem sites, however, produced blink suppression at much longer latencies.

Consistent with SC stimulation in monkeys and behavioral studies in humans, the SC appears to modulate reflex blinking through brainstem neurons other than those involved in saccadic eye movements.

GRAVITY-DEPENDENCE OF TORSIONAL OPTOKINETIC GAIN IN RHESES MONKEYS.

D. Straumann*, M. Dieterich, V. Hens, BIM Hess, Neurology Department, University Hospital, CH-8091 Zurich, Switzerland.

In three rhesus monkeys we measured torsional optokinetic nystagmus using the three-dimensional search coil technique. The animals were exposed to 30 degrees of stimulation by an optokinetic sphere, which rotated about the naso-occipital axis at different velocities. Gain (eye-stimulus-velocity coefficient) during the last 5 seconds of stimulation was determined for upright and supine body position. Compared to stimulations in the upright position, we found that torsional gain of optokinetic nystagmus was strongly attenuated in the upright position with angular eye velocity saturating at 5-10 deg/s (see also Schaff et al. 1986 Soc Neurosci Abstr 12: 744). Gain values in supine position varied considerably among the three monkeys, and several investigators have briefly noted that OPNs are less effective for saccades than for torsional vestibulo-ocular reflex. The data can be interpreted that the velocity-storage mechanism active in torsional optokinetic nystagmus is supine position. In upright position, however, the rotation axis of torsional nystagmus does not coincide with the gravity vector. Hence, velocity-storage is inflated and torsional optokinetic gain decreases.

LEAKY NEURAL INTEGRATION OF TORSIONAL VESTIBULAR SIGNALS IN HUMANS.

We investigated the dynamic properties of the human torsional vestibulo-ocular reflex (VOR) during roll head rotations, and compared them with those of the horizontal VOR movements. Differences were related to the contributions of the extracocular plant and the neural integrator. Three subjects underwent position-step stimuli in the roll plane, and the resulting torsional eye movements were recorded using the magnetic search-coil technique. Using optimal parameter estimation techniques, the data were fit to a step-response model of the torsional VOR, which incorporated plant parameters obtained through previous forced-duction experiments. Following the position step, the eye drifted back to is resting position in the torsional plane, demonstrating a time constant of neural integration typically ~2.5 sec. Despite previous evidence of an asymmetry in the ocular-motor plant between torsion and extension, torsional eye movements appear to be well yoked during roll stimulation.

When subjects underwent similar VOR stimulation in the yaw plane, the eye held their new horizontal position for a much longer period of time, always yielding a time constant of neural integration of much greater than 20 sec.

We hypothesize that the incomplete integration of vestibular signals for torsional eye movements reflects different neural properties. In addition, the yoking of binocular torsional eye movements despite possible asymmetries on the plant may demonstrate a larger separation of control of individual muscles than previously thought to hold true.

THREE-DIMENSIONAL CONSTRAINTS ON COORDINATED EYE-HEAD GAZE SHIFTS IN THE MONKEY. D. Gitton* and J.D. Crawford, Montreal Neurological Institute and Department of Neurology and Neurosurgery, McGill University, Montreal, Canada, H3A 2B4.

We have studied the normal orienting behaviour of one head-free Macaca Fascicularis. Dual search coils were implanted in one eye, and temporally screwed onto the skull cap. Eye and head position questionnaires were recorded while the animal looked at visual targets presented randomly throughout the gaze range. With the head fixed, the eye was constrained to a Listing's plane with a torsional standard deviation of ±5°. Listing's plane was no longer maintained with the head free, because VOR slow phases produced torsional changes in eye position. However, opposite torsional components in the rapid eye movement components of the gaze shift prevented accumulated torsion. Both the head and eye-in-space loosely followed a strategy resembling a set of Fick gimbals (Glenn & Vills, J. Neurophysiol, 1992): horizontal rotations occurred about a relatively fixed vertical axis, but vertical rotations occurred about a horizontal axis that tended to rotate with the head. These axis tilts were not as stereotyped as those observed with the head fixed, and thus the ranges of head and eye position-in-space were not so tightly constrained (torsional standard deviations were 4° and 4.5° respectively). However, the ranges showed the curvature characteristic of the Fick gimbals strategy: Up-left & down-right gaze directions were accompanied by clockwise torsional tilt of the eyes & head, and down-left & up-right gazes had counterclockwise tilts (in earth-fixed coordinates). These results agree with human studies (Glenn & Vills, 1992), suggesting that the monkey provides an appropriate experimental model for invasive studies of this behaviour.

575.1
A NEURAL MODEL OF VOLUNTARY MOVEMENT AND PROPRIOCEPTION. D. Bullock*, P. Cleek, S. Grossberg, Boston University, Dept. of Cognitive and Neural Systems, Boston, MA 02215.

A neural model of voluntary movement and motor proprioception is developed within constraints from neuropsychology and motor psychophysics. The model generates trajectories to a desired endpoint in spatial coordinates, while using motor command corollary discharges and muscle spindle error feedback to construct an accurate perception of position. Response of model elements resemble observed cortical and subcortical physiological data while functional characteristics suggest explanations of proprioceptive illusions and load effects. Simulations show the system's ability to execute voluntary movements while reducing oscillations caused by limb dynamics and compensating for external forces such as those caused by loads or obstacles. Further simulations demonstrate how the network can self-organize its sensorimotor transformations through spontaneous co-contractions of synergistic muscles.

Supported in part by the National Science Foundation (IR 80-26577, IR 86-00530) and Office of Naval Research (ONR N00014-92-1-1309, ONR N00014-93-1-1346).

575.2

Recent evidence suggests that motor programs are specified gradually (Hening W., Favilla M., Ghaz T.: Exp. Brain Res. 71, 116-128 (1988)), can be continuously updated, and are part of a closed feedback loop. The implied theoretical challenge is to address the dynamic properties of motor programs. We present a dynamic field theory of motor programs that is based on a neural representation of movement parameters such as movement direction and amplitude. The topology of such parameters is expressed by structuring the neural representations as fields. Motor programs are stable localized solutions in such neural fields. They evolve under two types of external influences: (1) localized input representing the perceptual specification of movement parameters and (2) input representing the pre-structuring of motor plans and thus reflecting the nature of the task space defined by the experimental paradigm. The distance of this pre-shape from the specified motor program in a dynamic sense determines the time needed to generate the correct motor program and therefore affects reaction time in the theory. We compare our model to experimental results of Ghez and colleagues on the gradual build-up of motor programs. We account for the Hick-Hyman law, the dependence of reaction time on the metrics of tasks, on pre-cued information, and discuss effects such as range or bias effects and deprogramming. The longer term goal of integrating such a dynamic description with a dynamic account of coordination (Schöner G., Kelso J.A.S.: Science 239, 1513-1520 (1988)) is sketched.

575.3

Why do humans shift from walking to running when speed increases? We have proposed a dynamic theory of human locomotion in which preferred gaits are attractors that exhibit stable phase relationships, and gait transitions are bifurcations characterized by a loss of stability (Diedrich & Warren, in press). According to this theory, manipulation of the location of the attractors should have an effect on the speed of the transition. As suggested by energy expenditure data, one way to manipulate this is by inclining the treadmill. Six participants walked and ran on a treadmill at grades of 0% and 10% while speed was varied. As expected, the speed at which transitions of the ankle-hip phase relationship were at a minimum shifted downward from 1.63 m/s on a 0% grade to 1.54 m/s on a 10% grade, consistent with movement of the attractor to a lower speed. Similarly, the mean transition speed on the descending and descending trials, shifted downward from 2.19 m/s at 0% to 2.00 m/s at 10%. In sum, changing treadmill inclination led to movement of the attractors and corresponding changes at the walk-run transition. There generally corresponds with those expected on the basis of previous energy expenditure data.

575.4
A NEURAL NETWORK MODEL OF BASAL GANGLIA THALAMOCORTICAL RELATIONS IN NORMAL AND PARKINSONIAN MOVEMENT. J.J. Contreras-Vidal*, G.E. Stelmach, Arizona State University, Laboratory of Motor Control, Tempe, AZ 85287.

Anatomical, neurophysiological, and neurochemical evidence support the notion of segregated parallel basal ganglia-thalamocortical motor channel. We developed a neural network model for the function of this system in simple and complex (sequential and simultaneous) movements in normal and Parkinsonian (PD) behavior. Non-linear differential equations are used to model the membrane potential for each cell type (short-term activation), its physiological action (inhibitory or excitatory), as well as neurotransmitter/neuromodulators (medium-term dynamics: e.g. GABA, enkephalin, substanina P). The model reproduces motor impairment in PD due to dopamine depletion such as akinesis, bradykinesia, and puts between movement components (the figure shows a normal and PD simulation of a two-stroke sequential movement). Specific observations of the effect of subthalamotomy and postero-ventral PD improvement are made. The model also suggests how the motor load is distributed across several brain structures during multi-joint movements. Support by Flins Grant, Contreras-Vidal on leave from Monterrey Institute of Technology (Mexico).
575.5 ACUTE EFFECTS OF LEVODOPA ON WRIST MOVEMENT IN PARKINSON'S DISEASE: KINETIC, VOLUMETRIC EMG MODULATION, AND REFLEX AMPLITUDE MODULATION MTJ Johnson*, A. Mendez, AN Kneiss, P. Silverman, F. Zwischel, A. T. Elger Departments of Neurology, Neuropsychology, and Physiology, University of Minnesota, and Minneapolis Clinic of Neurology, Minneapolis, Minnesota, USA.

Acute changes in motor performance due to levodopa were evaluated by a series of four motor tests unified by their focus on wrist flexion-extension movements. Subjects with idiopathic Parkinson's disease were evaluated with a test battery containing an isometric voluntary contraction in which velocity was to be maximized, visually guided tracking of a sinusoid and a square wave, and an array of stretch reflex modulation during volitional sinusoidal tracking. The maximal amplitude of active flexion and extension movements increased after levodopa (ON), without significant changes in the movement period or amplitude. In the two tracking tasks, the RMS error, peak velocity, or peak movement amplitude did not change after levodopa. Significant and consistent changes did occur in an array of reflex modulation during error-constrained tracking after levodopa. The amplitude of volitional EMG increased after levodopa, concurrently with a reduction in reflex EMG. These changes are consistent with the noted increase in movement velocity. These results show that the effects of levodopa on movement velocity were not translated into increased accuracy. Also, the changes in the long latency reflex gain argue for a central control of this reflex, mediated by structures sensitive to levodopa. Supported by NIH grants R44 NS28633 and T32 NS07361.

Target locations, as perceived by the visual system must be transformed into kinesthetic and motor coordinate frames for the upper limb to perform reaching movements. Recent studies in this laboratory have shown that the perceptually preferred anterior/posterior (AP) axis of kinesthetic coordinate system is trunk-fixed (Butler et al. 1993 - Soc. Neurosci. Abstr. 19, 550) and for the visual system is also likely trunk-fixed (Darling and Williams 1993 - AbS Proceedings of 17th An. Mtg., pp 110). The earth-fixed gravitational axis is preferred by the kinesthetic system at the perceptual level (Darling, manuscript in preparation). The purpose of this investigation was to determine if the visual system prefers the earth-fixed gravitational axis to body-fixed axes at the perceptual level. Ten normal healthy individuals positioned a hand-held lighted wand under four different experimental conditions that were each run under light and dark conditions. The earth-fixed gravitational axis was moved in anatomical positions and moved the wand parallel to the gravitational axis, (2) earth - same as (1) except that subjects head and trunk orientations were varied, (3) head - same as (2) except that subjects positioned the wand parallel to their head-fixed longitudinal axis and (4) same as (2) except that subjects positioned the wand parallel to the trunk-fixed longitudinal axis. Orientations of the head, trunk and wand were recorded optoelectronically. The results clearly showed that subjects were most accurate at positioning the wand parallel to the gravitational axis even when head and trunk orientations were varied. Control experiments showed that kinesesthesia was not used for precise positioning of the hand-held wand. Thus, the visual system prefers the earth-fixed gravitational axis to body-fixed longitudinal axes at the perceptual level and coordinate transformations at this level are simplified because of the parallel axes for the visual and kinesthetic coordinate systems.

575.9 FOCAI INTRASPINAL NMDA IONTOPHORESIS PRODUCES DISTINCT ACTIVATION PATTERNS IN THE FROG, P. Salonit and E. Bizzi. Dept of Brain and Cognitive Science, MIT, Cambridge, MA 02139.

In the spinal frog, microinjection of the lumbar grey produces only a few possible orientations for the convergent force fields recorded in the horizontal plane from the isolated hindlimb muscle. This force field points towards body, rostral flexorward extensor and medial extensor. To determine if this representation activates fibres of passage or of neurons, and as a preliminary step to anatomical studies aimed at identifying such fibres, NMDA (final concentration 250 nM) was iontophoresed at eight sites within microinjection tracks within the same pipette that had been effective. Forces and 11 EMGs were recorded. 38% of sites (32 sites in 7 frogs) did not respond to NMDA. Of the NMDA-responsive sites (average latency 16 sec., range 4-29 sec.), the forces evoked by chemical stimulation had the same direction of orientation as those visually, matching them at 68% of sites. For the EMGs, a close match was seen in only 38% of cases.

However the NMDA-evoked EMG's fell in a few distinct patterns which could be related to the force produced. One pattern (1/17 sites) consisted of a nearly simultaneous onset of a tonic or rhythmic oscillation of all muscle except for RA (rota anterior), VI (vastus internus) and GA (gastrocnemius) which were only weakly activated. With one exception towards body forces, a second pattern (6/17 sites), muscle recruitment occurred progressively over a succession of cycles, with the production at first of rostral flexion and then flexor body forces. RA, VI, and GA were among the most active muscles. Cose sites eliciting the first and second patterns were generally located caudally and rostrally to the 8th root respectively. A third pattern (2/17 sites) produced outward extensor forces. In conclusion, focal intraspinal NMDA iontophoresis may be helpful to localize groups of neurons responsible for the generation of distinct EMG patterns which produce the same set of force orientations previously identified with electrical microstimulation. (Supported by ONR N00014-94-K-0273)

575.6 THE EFFECTS OF GRAVITATIONAL CUES ON THE TRANSFORMATION BETWEEN KINESISTHETIC AND VISUAL INFORMATION TO REACHES TO REMEMBERED TARGET LOCATIONS: A. Butler*, W.G. Darlington, M.A. Frazzetto. Department of Exercise Science, University of Iowa, Iowa City, IA. 52242.

The abilities of human subjects to point to kinesthetically presented targets which are no longer present during a reaching movement was studied under 2 gravitational and 3 reaching conditions: (1) VS/G, VGS - visual self motion; (2) GS/G, GVS - no motion, no gravity; (3) VS/VG, VVS - visually reach with pointer, no gravity. The ability to specify target locations on the basis of kinesthetic information alone has been found to be accurate (Darling and Miller, Exp Brain Res. 1993, Vol 93, pp 534). Reaching with a pointer requires transformation of kinesthetically derived limb coordinates into a visual coordinate system. Availability of gravitational information about target locations was not manipulated in previous studies and is thought to be used in the kinesthetic representation of upper limb orientation. Thus, the main purpose of this experiment was to study the abilities of subject to reach to a remembered kinesthetic target location with or without gravitational information on target location. We presented 10 targets in two planes using a programmable arm. Positions of the arm, hand, fingertip and target object in three-dimensional space were recorded using optoelectronic techniques (WATSMART system, Norhem Digital). Manipulating gravitational information on target location had little influence on directional and distance errors during visually guided reaching with the hand. When using the pointer, there was a substantial increase in distance errors, but not in direction errors. Availability of gravitational information had little influence on a performance when reaching with the pointer. Consistent with the findings of previous work, subjects tended to overlook close targets and underestimated far targets during visually guided reaching to kinesthetic targets. These results suggest that removing gravitational information about kinesthetic target location does not interfere with reproducing a kinesthetically remembered hand location or with transformation of kinesthetic information into a visual coordinate system.

The attraction of motor control to oscillatory components is one of the fundamental features of biological systems. Recently, we reported a systematic phase relationship between tremor and the onset of fast voluntary motor responses in patients with Parkinson's disease (PD) (Staudte, C. et al. Soc. Neurosci. Abstr. 1982:1862). Experiments with control subjects mimicking tremor showed similar results. The aim of this study was to establish a functional model for the attractive effect of the tremor oscillator in the framework of the equilibrium point (EP) hypothesis. According to the EP hypothesis, there is only one central variable that controls the behavior of a muscle, the threshold λ of its tonic stretch reflex (Feldman, AG Biophysics. 1966:11:565-578). Single joint movement models are induced by a shift (virtual trajectory) in control variables λ, of at least one pair of antagonist muscles from an initial value (that depends on the actual phase of the tremor cycle) to a final state. Within the virtual trajectory model, the movement trajectories and the electromyographic patterns of the antagonist muscles can be predicted. Movement patterns of PD tremor patients and control subjects mimicking tremor were recorded under both isometric and kinetic reaction time paradigms and compared to computer simulations. The EP hypothesis proved to reliably predict the observed movement patterns under various conditions. We conclude that attraction of voluntary motor response to intrinsic oscillators is a system inherent phenomenon of motor control and does not depend on the origin of the oscillatory component.

575.10 MOTOR TEMPLATES IN TYPING: F. Viviani and G. Laisard. 1Faculty of Psychology and Educational Sciences, Univ. of Geneva, Geneva, Switzerland and 2Dept. of Cognitive Science, Istituto S. Raffaele, Milan, Italy.

We investigated the performance of professional typists transcribing texts presented visually. The timing of the keystrokes was analyzed as a function of the following factors: 1) the combination of fingers used for typing digrams; 2) the relative frequency of the digrams in the language; 3) the word-context in which digrams are embedded; 4) the total duration of the typing sequence for the word. The mechanical and linguistic factors were found to influence the interstroke intervals. However, over and above these factors, we demonstrated that words (i.e. well-formed lexical items) were typed with sequences of keystrokes whose temporal structure depended idiosyncratically on the words and the typing context. Within the range of variability of the rhythm that is normally observed in transcription, this structure - defined as the set of all ratios between interstroke intervals - remained unchanged (homothetic invariance). The results suggest that these highly complex motor sequences are controlled by global motor plans that include an abstract representation of the timing of the keystrokes. A simple counting mechanism was postulated to explain the findings. We contrasted four variations of the mechanism on the basis of the pattern of temporal variability.

Previous work from this laboratory has described a set of movement primitives encoded in the frog spinal cord. In order to examine the generality of these findings, we are currently exploring movements encoded in the spinal cord of the rat. As a first step in this project, we describe here the pattern of position dependent forces, i.e. the force fields, produced by rat hind limb muscles and the result of combined stimulation of two muscles. In the frog, simultaneous stimulation of two muscles produces a force field which is the vector sum of the force fields of the two muscles stimulated separately. This property of summation holds for the non-redundant case, with the force transducer attached to the ankle, and not for the redundant case, with the force transducer attached to the foot. We found a similar pattern of results in the rat: the force field predicted by summation of the two separate muscle fields was highly correlated with the field produced by the costimulation of the muscles for both the redundant and non-redundant case. This result implies that, at least for the degrees of redundancy in these experiments, the combination of muscles can be approximated as a linear vector sum, potentially simplifying the control of the hindlimb. Supported by NIH NS09043 and AR05710 and ONRNO0014993/1946.

Tonic electrical stimulation to the midbrain periaqueductal gray (PAG) induced naturally sounded vocalization. The stimulation to the pontine call site (PCS) within the ventrolateral pons also induced vocalization. To know whether the PCS is the descending pathway for vocalization from the PAG to the lower brainstem, an anterograde tracer, Phaseolus vulgaris leucoagglutinin, was applied at sites located in the lateral PAG where the electrical stimulation induced vocalization. At the level of the caudal superior colliculus, labelled fibres sparsely distributed and passed laterally through the dorsal part of the midbrain tegmentum where the stimulus threshold for vocalization was higher than the PAG. At the level of the inferior colliculus, they could be traced ipsilaterally to the ventral area along the medial lemniscus and consisted of a narrower bundle around the PCS where the stimulus threshold was the lowest.

At the level of the upperpons, they occupied a broad but thin region in the dorsal portion of the trapezoid body ventral to the medial lemniscus. Further caudally, they appeared to be concentrated in a discrete area ventral to the inferior olive and dorsal to the pyramidal tract, and could be continuously traced to the upper cervical spinal cord.

It was known that the PAG stimulation induced vocalization associated with rage, while the PCS stimulation induced vocalization without rage. The present results suggested that the PCS is the descending pathway specific for vocalization from the PAG to the lower brainstem.

MOTION SICKNESS HELPS PRESERVE SENSORMOTOR COORDINATION IN THE PRESENT AND FUTURE. D.W. Jensen*. Department of Biology, Tomball College, Tomball, TX 77375.

A new hypothesis is proposed for the function of the mechanisms of motion sickness. The hypothesis accounts for data from plasticity of postural control, development of sensory-motor coordination, motion sickness, vomiting, pharmacology, and neurotendy hypothesis. The mechanisms giving rise to the early symptoms of motion sickness impel an individual to remove the sensory conflicts of an offending motion. The early symptoms are a variety of ill feelings and actions that do not interfere greatly with motor control. The sufferer can still remove sensory conflicts, so the brain is not stimulated to undergo long-term adaptive changes that alter sensorimotor coordination. Thus, the early symptoms and their mechanisms serve to resist redefining normal motion while concordantly preserving the existing sensorimotor coordination. Later developing symptoms of vomiting and severe nausea, however, impose motor control problems; in such a state one cannot control much of anything. This extremely ill feeling is the same as what is produced by certain neurotoxins. The state of being poisoned by provocative motion is strongly associated with the motion. When the same kind of sensorimotor-alteration-motion occurs again that association is recalled. Acting on this recall and avoiding that motion preserves the existing sensorimotor coordination in the future.

THE ROLE OF DOPAMINE TERMINALS IN THE NUCLEUS ACCUMBENS IN LOCOMOTION INDUCED BY ACTIVATING THE HIPPOCAMPAL → ACCUMBENS GLUTAMATE PROJECTION.

Earlier electrophysiological evidence has shown that the stimulation of the hippocampal input to the nucleus accumbens evokes short-latency, early-duration, glutamate-mediated excitatory responses in the nucleus accumbens neurons (Yang & Mogenson, 1984). It has also been shown in our recent behavioral studies that injecting glutamate receptor agonists, NMDA or AMPA, into the nucleus accumbens activates the glutamate receptors located on mesolimbic dopaminergic terminals (Wu et al., 1993). This evidence suggests that glutamate in the nucleus accumbens may act on glutamate receptors in mesolimbic dopaminergic terminals and accumbens output neurons. The objective of this study was to investigate the role of the mesolimbic dopamine terminals in the nucleus accumbens in the initiation of locomotion by activating the hippocampal excitatory input to the nucleus accumbens.

Locomotion (measured in an Opto-Varimex-3 activity cage) was significantly increased by unilateral injections of NMDA into the ventral subiculum of the hippocampus. This NMDA-induced locomotion from the hippocampus was abolished after the destruction of the mesolimbic dopaminergic terminals in the accumbens, by injecting 6-OHDA into the ventral tegmental area (VTA). The results suggest that the mesolimbic dopamine terminals are essential in transmitting hippocampal signals to the output neurons within the nucleus accumbens.

ACTIVITY IN VENTROLATERAL THALAMIC AREAS DURING CONDITIONED VOCALIZATIONS IN CAT. G.R. Farley*, Research Division, Boys Town National Research Hospital, Omaha, NE 68131.

Although ventrolateral thalamus has been implicated in motor control tasks, its role during vocal behavior might be questioned. Jurgens and colleagues, based on electrical stimulation and lesion data, indicated that it was part of a core system of brain structures capable of producing vocalizations in the absence of concomitant reinforcing potentiation. In the present study, we recorded single- and multi-unit activity from sites in the ventrolateral thalamic area in awake, behaving cats. A substantial proportion of recording sites showed strong temporal correlations in neural activity with various aspects of the instrumental conditioned vocalization paradigm, including both vocal production and feeding behavior. Activity related to feeding was generally strongest, and most prevalent, typically involving bursts of firing during ingestion of the food reward. However, there were also numerous examples of increased and decreased firing during vocalizations, as well as changes in firing rate immediately following vocalization. There were no obvious changes in firing related to background respiratory activity. However, a number of loci showed bursts of activity apparently related to laryngeal EMG activity not associated with vocalizations. Finally, we also noted apparent long-term fluctuations in background firing rate associated with periods of intense behavioral activity versus periods of behavioral quiescence. These data are consistent with a possible role of this structure in motor control during vocal production. (Supported by NIH grant 5-R01-DC01535-01.)

ESTIMATION OF IDENTIFIED INTERNEURONS FORMING A FUNCTIONAL GROUP CONTROLLING ABDOMINAL POSITIONING IN THE CRAYFISH, P. Boesiger, and J.L. Larimer*. Dept. of Zoology, Univ. of Texas at Austin, Austin, TX 78712.

Several studies have indicated that the command elements controlling abdominal positioning (flexion and extension) in the crayfish can predict the abdominal positioning was observed in isolated nerve cords by recording from motor roots while stimulating single command elements intracellularly. Extracellular recordings of interneurons were made from rostral and caudal connectives or connectives* (1 and 2). When one of these command elements is stimulated it activates a number of previously defined elements and elements increases or inhibits the spontaneous activity of other interneurons. We then compared spontaneous with evoked activity. The largest number of recorded interneurons was 64, the smallest was 4, and the average was 23 (r=15). Some of these command elements are identified cells based on morphology and physiology. Data was gathered from one identified cell on three separate occasions. A comparison of these data revealed that although the number of recorded cells and their firing frequencies were not identical they were surprisingly similar. These data support the functional group hypothesis, and suggest that the number about 23 interneurons controls each abdominal positioning behavior.

Furthermore, these data and previous studies indicate that the interneurons within a group may or may not be tightly coupled to each other, and their recruitment may be based on such factors as stimulus intensity and synaptic efficacy. Counts from other hemiconnectedes were doubled since motor output and nerve cord activity are usually synergically. (Supported by NIH grant NS 54243, to J.L.L.)

SEPARATE PERIPHERAL NERVES INNERVATE THE HEADS OF THE HUMAN LATERAL PTERYGOID MUSCLE. M. A. Aziz and R. J. Conne *

Anatomical, developmental and biomechanical studies of the human lateral pterygoid (Lp) muscle indicate that it is divisible, at least partially, into two heads. Electromyographic (EMG) studies supporting the independent activity of the superior (SLP) and inferior (ILP) heads during the masticatory cycle have been questioned. The precise peripheral nerve pathways to the two heads and the full structural complexity of the masticatory apparatus remains uninvestigated. Therefore, we have greatly dissected the Lp muscle and nerves, and measured the fiber orientations of 7 dissection room specimens. Photographs, drawings, and whole sections through the masticatory space were analyzed. Our results show that: i) the two heads are independently innervated, such that the SLP receives a single branch from the root of the masticatory nerve, while the ILP receives two or more branches from the root of the long buccal a., as well as loops bridging the anterior and posterior mandibular (V3) divisions; ii) the origins of the heads are easily recognizable, but in two cases each head shows further horizontal segmentation; iii) the mean insertion orientations of SLP and ILP fibers are 27° (±9) and 38° (±9) from the Frankfort plane, respectively.

These findings support: i) a claim that the two Lp heads are enclosed in separate fascial compartments; ii) EMG studies indicating their independent functions; iii) the likely segregation of their central control mechanisms. These data are prerequisite to a planned histochomical demonstration of the latter in primates.

Negative phototaxis in the river lamprey (Lampetra fluviatilis) was characterized behaviourally, and the strategies for performing yaw turns away from light were investigated with video recordings, combined with EMG-recordings from the myotomal musculature, in freely behaving animals. In swimming lampreys, illumination from one side evoked a yaw turn away from the light. An increase in light intensity resulted in a significant increase in yawing angle. Strong lateral illumination frequently evoked an escape response, characterized by a decrease in swimming speed, an approximately 180° yaw turn either away from or towards the light, and subsequent locomotion in a direction opposite to the initial one. During yaw turns the locomotor rhythm was maintained and asymmetrical, so that the lateral displacement of the undulatory wave was larger in the direction of the turn, and smaller on the other side. In the EMG-recordings, the intensity and duration of individual muscle units were highly variable also during straight swimming, which presumably reflects variations in the activity of individual motor units between cycles. Stronger turns (> 60°) were correlated with an asymmetrical increase in burst intensity and duration on the ipsilateral side, and a slowing down of the rhythm. During weak turns no consistent changes in the EMG-pattern were seen. Eye illumination of quiescent lampreys, attached with their suckers to the bottom, evoked a strong yaw turn away from light, and locomotion. The initial turn was reflected in the EMG-recording, as a unilateral burst of high intensity and long duration. Burst intensity was positively correlated with the turning angle.

AN ASYMMETRICAL VISUAL INPUT CAN ABOLISH POSTURAL DISTURBANCES EVOKED BY UNILATERAL LABYRINTHOTOMY IN THE LAMPEREY. T.O.Delphinia * Nobel Institute for Neurophysiology, Department of Neurosciences, Karolinska Institute, 171 77 Stockholm, Sweden.

In all classes of vertebrates, removal of the vestibular organ (unilateral labyrinthectomy, UL) results in severe motor disorders. In the lamprey (a lower vertebrate), one of the most pronounced symptoms induced by UL is continuous rotation (rolling) around the longitudinal axis during swimming. The aim of the present study was to abolish this symptom by means of an artificially organized, asymmetrical visual input. Five lampreys, with two eyes surgically removed from their finding that an asymmetrical visual input can strongly influence both the lamprey-driven roll control system (Delphinia et al., Exp. Brain Res. 95, 421-428, 1993). Swinging of the lampreys subjected to UL (control), and the effects produced by different types of asymmetrical input combined with UL were investigated. The animals of the first control group (UL only, n=11) rotated continuously during swimming. This symptom lasted up to 12 weeks after surgery. In the animals of the second group (UL plus bilateral inclusion, n=14) rotation during swimming was observed even longer, for 6-10 weeks. However, if a removal of the labyrinth was accompanied by a removal of the eye on the same side, the animals (n=17) swam normally, without rotation, immediately after surgery. In animals subjected to UL and bilateral inclusion, which were rotated continuously, the rotation terminated immediately with onset of electrical stimulation (10Hz) of the optic nerve ipsilateral to the intact labyrinth (n=5). In the lamprey deprived of the labyrinth and the eye on the same side, input from the remaining eye was able not only to functionally substitute the lost vestibular input, but also to induce adaptive changes in the roll control system: a removal of the remaining eye in 10-30 days after the first surgery did not destabilize the postural control, and the animal driven by only one labyrinth swam normally, without rotation.

MASTICATION FUNCTION IN PATIENTS WITH CORTICAL BRAIN INJURY AND HEMIPLAGIA. N. Kemppainen*, J. Waltimo, M. Kaste, H. Palosuo and 0. Saalonen. Dept. of Prosthetic Dentistry, Univ. of Helsinki, Dept. of Neurology and Dept. of Radiology, Helsinki Univ. Central Hosp., Finland.

The masticatory function of sixteen patients (11 men and 5 women) with severe hemiparesis caused by brain infarction (A. cerebri media) was studied by means of interview, clinical examination and bite force measurements. The location of the infarction was assessed with computer tomography and magnetic resonance imaging to be localized in the facial primary motor cortex. The Rankin Disability Score and the Scandinavian Stroke Group Index showed that the patients had an infarction causing marked invalidity, eg. facial paralysis and a marked loss of hand grip force on the contralesional side of the cortical lesion. However, the patients reported no change in their chewing ability, although four of them reported hoarding of food in the buccal sulcus area of the paralyzed side. The clinical examination revealed no major signs of cranial and motor disorders, and masticatory muscles contracted symmetrically when examined by palpation. Bite force measurements also indicated symmetrical contraction, since we could not detect any difference in the maximal bite force between the healthy and paralyzed side. These results are in agreement with recent laboratory findings in monkeys supporting the importance of bilateral representation and cortical projections in the production and coordination of orofacial functions.
567.1 MULTI-JOINT COORDINATION DURING THE WIPING REFLEX IN FROGS.
M.G. Sirota, R. Dubois and A.O. Feldman.
CéSNN, Université de Montréal H3C 3J7 and Dep. de kinésiologie, Université du Québec à Montréal, Québec, Canada H3C 3P8.

Intact and spinal frogs produce non-rhythmic target-directed hindlimb movements in response to stimulation of the skin (the wiping reflex or WR). Analysis of the WR allows us to study the problems of redundancy in terms of degrees of freedom. We studied the redundancy problem by analyzing interjoint coordinations with kinematic techniques for the WR in response to central body surface stimulation in grass frogs (n = 9). These frogs were spinalized between the 1st and 2nd vertebrae under tricaine anesthesia. WRs were elicited by a series of 3-5 light pricks with a needle. Hindlimb movements were recorded in two dimensions using a light-reflecting markers (8 points on the hindlimb joints and body). Movement duration was effectively increased by cooling the projection. Trajectories of the limb's endpoint and angle-angle diagrams were analyzed. Results show that there are phases of the WR in which a significant excursion in a single ("leading") joint is associated with relatively small excursions in the others. The leading joint can be different for different phases of the WR. However, there are phases in which joint angles change simultaneously. In the later case, the coordination between joints was not fixed and might be changed in repeated movements. It is concluded that target-directed reaching can be accomplished by relatively independent movements in the joints despite motor task constraints.

567.2 ORGANIZATION OF CENTRAL CONTROL SIGNALS ASSOCIATED WITH MULTIPLE DEGREE OF FREEDOM ARM MOVEMENTS. L.E. Sergi* and D.J. Ostry.
McGill University, Montreal, PQ, Canada H3A 1B1

To gain insight into the organization of central control signals associated with motion in one or more degrees of freedom, we examined the behaviour of bi-articular muscles during movements in which they acted as agonists and antagonists, and acted as antagonist to another. As an example, the action of biceps brachii, which acts to flex and supinate the forearm, was studied during a series of flexing pronations, where it acted as an agonist to the flexion movement and an antagonist to the pronation movement. We addressed the following question: Will bi-articular muscles display purely agonist or antagonist activity depending on factors such as movement amplitude or required torque, or will the muscle display antagonist activity. Subjects performed flexions or extensions of a fixed amplitude while simultaneously performing supinations or pronations of increasingly larger amplitude. The activity of eight muscles about the elbow was recorded using surface electrodes while arm position was monitored using OPTOTRAK. Results show that bi-articular muscles display an activity pattern which has both agonist and antagonist components. For example, during a small flexion combined with a large supination, pronator teres, which acts to flex and pronate the forearm, displays phasic activity concurrent with brachiais, a pure agonist. It also displays a burst of activity concurrent with pronator teres, another antagonist. This suggests that central commands for motion in individual degrees of freedom may be specified independently and superimposed.

567.3 EXAMINATIONS OF POSSIBLE EXPLANATIONS FOR TRAJECTORY CURVATURE IN MULTI-JOINT ARM MOVEMENTS. Oto, R.*1, Uno, Y.1, Kojge, Y.2, & Kawato, M.2
Dept. of Psychol., Fac. of Letters, Kyoto Univ. & ATR Human Inf. Processing Res. Labs., Kyoto, Japan.

We discuss the coordinate frame in which visually guided human multi-joint arm movements are planned. In point-to-point planar reaching movements, hand paths tend to be gently curved. Models that rely on intrinsic-dynamic coordinates such as the minimum-torque-change model predict curved paths whereas models that rely on extrinsic-kinematic coordinates such as the minimum-jerk model predict straight paths. To decide between these two coordinate frames, we tested following three possible explanations for observed curvature in extrinsic-kinematic models (Wolpert, et al., 1993): (1) The planned trajectories are straight but imperfect execution of control causes the curvature. (2) Visual misperception causes the curvature. (3) Arm trajectories are controlled using straight virtual trajectories and biomechanics of the arm causes the curvature. In Exp. 1 we examined the movements from the side of the body to the front of the body. We found that if subjects were explicitly instructed to generate straight paths for such movements, these movements were straighter than those generated spontaneously. This result argues against (1). In Exp. 2, subjects generated spontaneously curved trajectories even in the fronto-parallel plane where visual misperception was not expected to be a factor. This result argues against (2). In Exp. 3, EMG signals of 6 related muscles of the same movements as Exp. 1 suggest that subjects can make straighter paths without raising stiffness. This poses a problem for the portion of (3), namely, the virtual trajectory hypothesis that accounts for the performance of straighter trajectories using straight virtual trajectories by raising stiffness. Thus our results support the hypothesis that the CNS plans trajectories using intrinsic-dynamic coordinates. Supported by JSPS Fellowships for Japanese Jun. Scientists.

567.4 LEARNING AND TRAJECTORY PLANNING IN KINEMATIC ALTERATION OF JOINT ANGLES. H. Imamizu*, Y. Uno and M. Kawato
ATR Human Information Processing Research Labs, Kyoto, Japan.

We investigated whether trajectories of the human arm are planned solely in an extrinsic (kinematic) space or in both an intrinsic (dynamical) space and an extrinsic space. We virtually misaligned (1/2) the elbow angle and magnified (5/4) the shoulder angle of normal human subjects while they were aiming at targets. A position marker was attached to the subject's hand and its current altered position was displayed as a cursor on a CRT screen. This linear transformation in joint angles corresponds to nonlinear transformation between the hand plane and the screen, and makes a straight trajectory on the hand plane a curved one on the screen. If trajectories are planned in an intrinsic space then they are invariant in the intrinsic space (the hand plane) and distorted in the extrinsic space (the screen) under the kinematic alteration. On the other hand, if they are planned in the extrinsic space, they are invariant in the extrinsic space and distorted in the intrinsic space. The task for the subjects was to move the cursor to a target within a short time period (900 ms). The aiming error decreased with practice. We compared the trajectories after 320 trials of training to those under no alteration on the screen. There was significant difference between them. This suggests that the trajectories were distorted in the extrinsic space. The result supports the hypothesis that trajectories are planned in the intrinsic space. We also investigated intermanual transfer of the learning effect to obtain evidence of internal representation of intrinsic coordinates (joint angles) in the central nervous system.

567.5 The Three-dimensional Curvature of Unrestrained Straight-ahead Movements. F. E. Pollick*, C. Ishimura
ATR Human Inf. Processing Res. Labs, Kyoto, Japan.

We examined the three-dimensional curvature of unrestrained point-to-point hand movements in the forward direction. Subjects moved the hand from a position above the start point to a forward position above targets of different size and distance. Paths showed curvature resulting from an initial lateral and primarily downward movement that was compensated for in the second half of the movement. The power component of motion was temporally coupled to the forward motion, with the maximum drop occurring at the time of peak forward velocity. The curvature was greatest for movements that aimed for targets at intermediate range and decreased as target distance increased. Analysis of the relationship between velocity and radius of curvature showed that velocity was related to radius of curvature by a power law with an exponent of 0.59, different from the value of 1/3 typically obtained in curvilinear drawing motions. Aspects of the downward motion suggest that it was purposeful in speeding up the movement and offer explanation to the deviation from the typically reported exponent.

567.6 LEARNING AND GENERALIZATION OF LIMB DYNAMICS.
R.L. Sainburg & O. Ghez.

We have recently shown that impaired control over interaction torques in proprioceptive deafferentation can be dramatically reduced when, prior to movements performed without vision, patients were allowed to view their limb in motion. We therefore proposed that visual updating of a model of limb dynamics used to program movement. We now ask whether intact subjects also use feedback to control interjoint dynamics and examine the learning and use of internal limb models.

Subjects were to trace linear hand-path templates presented on a computer screen with rapid, overlapping out-and-back movements. Their arms were supported in the frontal plane by a low inertia one-degree-of-freedom system. An outlier to which weights could be attached enabled the distribution of mass of the forearm-hand segment to be varied. Subjects were trained in a given direction of movement, with a given inertial configuration, by providing them with visual feedback of the screen cursor. Accuracy was then tested during movements in other directions and with different inertial configurations.

After training, subjects made errors in initial direction, movement linearity and interjoint coordination. Simulations showed these errors resulted from the production of torques appropriate to the inertial conditions during training. Such effects also occurred for movement directions that differed from the training direction. Accuracy improved as the magnitude was greatest in the trained direction. We conclude that the normal control of interjoint dynamics is dependent on feedback mechanisms that employ internal models of limb mechanics that can be rapidly recalibrated. However, recalibration through training in a single direction allows only incomplete generalization to untrained directions. (NS22715).

The present study examines the spatial control of distal joint angles when interaction forces produced by the motion of proximal joints are reduced. Cats reached to grasp a piece of beef from the end of a narrow food-well at different inclinations and heights. The coordinates of markers at the shoulder, elbow, MCP and 4th digit were recorded at 100Hz for kinematic and dynamic analysis. Joint torques were partitioned into components due to the effects of segments distal to the joint, intersegmental interactions, gravity and a residual term that includes active muscle contraction and passive visco-elastic resistance.

Paw paths were compared on two linear segments in which the paw was aimed first to a vis point in front of the food-well (lift), and then, within the well, to the frontal plane. During lift, kinematic trajectories were compatible without training, and hand movement and hand muscle activity so distal angles stayed independent of reach height. This indicates that there is a bias for muscle and joint torques to distal joints, to vary independently of movement height. Training to control the contraction required of distal muscles (NS31391).

We have previously shown that direction and extent of hand movement represent independently planned features of reaching movements. The purpose of this study was to compare the time courses of adaptation to experimentally imposed rotations and gain alterations in the virtual workspace. Healthy adult male movements were recorded on a horizontal digitizing tablet. However, vision of the hand and arm was blocked, and virtual targets and hand positions were displayed on a computer screen. We separately applied either a rotation or a change in gain to the screen display of hand path while leaving the virtual targets unchanged. The hand display was used to plan the path taken by the virtual hand was displayed following each movement as knowledge of results.

Adaptation to both types of distortion showed evidence of two distinct processes: a relatively rapid reduction in mean error over trials, and a more gradual reduction in variability of movement error. Adaptation to rotational distortions, and re-adaptation to conditions after rotations, was generally slower than for gain changes. Increased variability was also more pronounced and prolonged during adaptation to rotational distortions.

Differences between directional and extent adaptation support previous findings of independent specification of direction and extent. The learned visuo-motor transformation between target and hand direction is generally robust to short-term adaptation, perhaps because this involves altered specification of which muscles to contract. The target-extent relation is more rapidly recalibrated, perhaps because it involves shifting a scaling factor. (Supported by HD 01018, NS 22715).

We have previously reported that when subjects reach to visual targets without seeing their limb, movements show directional biases that vary with the initial position of the hand. The spatial organization of these biases suggest that planning movement direction the nervous system underestimates the distance of the hand from a bias-free position between midline and the target. Since this is the horizontal workspace of the hand, we hypothesized that these errors reflect their prior experience. We now asked: (1) Can directional bias in a specific location be eliminated by training with visual feedback? (2) Does such training alter the biases in other untrained areas of the workspace? Subjects moved their hand on a digitizing tablet from different central points to 12 radial targets displayed on a computer screen. Subjects were trained to perform accurate movements from initial positions normally associated with clockwise or counterclockwise biases by providing visual feedback of cursor and hand during movement. They were then tested without feedback for movements initiated from the same and other points. Training signified directional biases for movements initiated in the region of training. Movements initiated from other locations, including the previous error-free region, showed new biases that again represented underestimates of the distance of the initial hand position, but from the new trained location. The present findings are compatible with the hypothesis that training in a particular region of the workspace resets subjects' default estimate of their initial hand position. Kinematic planning is richly dependent on learned representations of the hand in the workspace. (NS 22719).

Learning a novel movement pattern requires developing a new dynamic model of limbs and objects ("getting into the ball park" Greene, Prog Theor Biol. 1972). It is proposed that initial learning is enhanced under consistent practice conditions which permit stabilization of the dynamic model and disrupts learning. These hypotheses were tested with similar tasks (SIM): using chopsticks to pick up and transport small, medium or large buttons to a container; or dissimilar tasks (DIS): chopsticks/medium button, card sorting, mirror tracing. Adult subjects (N=36), naive in chopstick use, were assigned to one of 4 practice conditions: Blocked/SIM (15 successive trials on each of 3 tasks randomly ordered), Blocked/DIS, Random/SIM, Random/DIS. Movement time was tested (medium button), immediate and delayed retention tests and 2 transfer tests (new button sizes). Findings confirmed predictions: Blocked/SIM yielded better learning than Random/SIM practice. DIS conditions did not differ in retention but tended to be better than Random/SIM. These results contradict reports (Magni & Hull, Q.J.E.P, 1999) favoring random practice over blocked ("contextual interference effect").

576.11 THE RELATIVE CONTRIBUTIONS OF GEOMETRIC VERSUS BEHAVIORAL CONSTRAINTS IN RESOLVING JOINT-LEVEL, MOTOR-EQUIVALENCE. Rebecca A. Stanley* and Charles F. Wight. Psychology Dept., Columbia, University, New York, NY 10027.

Motor equivalence exists when a task may be performed using various movement patterns. For example, in a pinch task, all arm configurations that suffice to position the hand at a desired location constitute a "motor-equivalence set." Motor equivalence provides flexibility, but also complicates motor planning.

When subjects were asked to select a single movement configuration from those available in the motor equivalence set.

Previous studies have shown that, at the end-point of aimed, arm movements, much of the inexactness associated with joint-level motor equivalence can be accounted for (Soechting and Flanders, 1985; Stains & Wright, 1993). Two factors may contribute to the noisiness of geometric constraints imposed by a fixed linkage system, and behavioral strategies. We evaluate their probable contribution by investigating aimed, arm movements performed with two excess degrees of freedom.

Arm configurations were measured while five subjects made repeated pointing movements from 10 starting points to a target. Five targets were tested on separate days. Movement is permitted in a horizontal plane, using four degrees of rotational freedom: one each at the right wrist, elbow and shoulder, and one at the torso.

We compared the movements sampled at the end-point of movements to a single target with the variability that would exist if all configurations within the motor equivalence set were sampled. Results show that behavioral strategies make a substantial contribution for all subjects, even though individuals' strategies differ dramatically. Effects of particular strategies are explored through simulation modeling.

Results suggest new techniques for evaluating models of joint-level motor equivalence (Rosenbaum et al., in press, Bullock & Greenspan, 1993, Bower & Cruse, 1990) by testing the extent to which they replicate the partitioning of variance between geometric and behavioral strategies observed here.
576.13 UNCONTRAINED SINGLE-JOINT MOVEMENTS IN INDIVIDUALS WITH DOWNS SYNDROME: G. L. Almeida*, L.-M. Hong*, M. D. Corcos, G. L. Costill*, *Rush Medical Center, Chicago, IL 60612, *University of Illinois at Chicago, Chicago, IL 60608 and *Universidade Estadual de Campinas, SP, Brazil.

Three individuals with Down syndrome performed unconstrained single-joint elbow and shoulder flexion movements, in a sagittal plane. First, the subjects were instructed to move one joint (the "focal joint") as fast as possible, while keeping the "non-focal" joint stationary. These movements were performed over three different distances. Second, the subjects were instructed to move a "focal joint" at three different speeds, over one distance.

The movements of the focal joint were accompanied by varying degrees of movements at the non-focal joint. On average, the movements at the non-focal joint were twice as large as those observed in neurologically normal individuals, and they displayed slower movement speed at the focal joint. For the movements performed over three distance, the pattern of muscle activity was typical for "speed insensitive strategy." The duration of the agonist EMG burst scaled with distance while their rate of rise remained constant. Nevertheless, there was more variability related to the antagonist latency. One subject presented a pattern of co-contraction, whereas for the other, the antagonist latency did not scale with distance.

For the movements performed at three different speeds, the pattern of muscle activity was typical of "speed sensitive strategy." The rate of rise of the agonist EMG burst scaled with distance with the antagonist latency being activated early for fast movements.

These findings suggest that, in comparison with neurologically normal individuals, individuals with Down syndrome use similar rules to control the muscle activation. Nevertheless, they seem to have a coordination problem which is reflected in their coupling of the muscle activity burst and in the large range of the movements in the "non-focal joint".

576.15 ANALYSIS OF KINEMATIC AND DYNAMIC PARAMETERS OF HUMAN MOTOR LEARNING: S.J. Staubes* and T.J. Elber, Departments of Neurosurgery and Physiology, and Graduate Program in Neuroscience, University of Minnesota, Minneapolis, MN 55455.

In order to more fully understand the characteristics of human motor learning, human subjects were evaluated using a step-movement task. Subjects were seated in front of a video display and controlled the movement on the display with the right hand using a planar 2-joint manipulandum. A string supporting the elbow constrained movement to the horizontal plane to permit explicit determination of shoulder and elbow joint angles and torques. The task consisted of maintaining the cursor in a central "start box" until one of eight equidistant "target" boxes appeared; the cursor then had to be moved to and held in the target box within a movement time window. After practicing on a normal hand-cursor movement relationship, the gain was changed, forcing the subjects to learn a new relationship between hand and cursor movement. Once the subjects' performance had returned to an acceptable level, the gain was restored to the initial conditions. Initially, subjects' hand paths were nominally straight with characteristic bell-shaped hand velocity profiles and biphase accelerations. Biphase (accelerating) and "decorrelating" torque profiles varied predictably with direction during the normal gain condition. Upon initial presentation with the new gain, movement errors increased, with larger errors in directions involving larger shoulder torques, and smaller errors in directions involving larger elbow torques. Compared to other targets, learning in these directions appeared to be more difficult. The "accelerating" phases of the joint torques followed a stereotyped profile, while the "breaking" phases of the joint torques were prolonged in the early stages of learning, regaining their characteristic form as net performance improved. The correlation of the shoulder/elbow torques with the spatial dependence of the error suggests that the control scheme for reorganization of two-joint movements is more complex than that for single-joint movements.

CIRCUITRY AND PATTERN GENERATION III

Rhythmic motor patterns of the dorsal ventricular nerve of the stomatogastric ganglion were monitored with chronically implanted electrodes in intact crayfish, *Cragon saxonus*, while the activity of the gastric mill and the cardio-pyloric valve was monitored by endoscopic imaging. Feeding experiments of free-moving crayfish demonstrate a decrease in the pyloric activity during presentation and grabbing of food which is followed by a strong increase in the pyloric frequency. After food intake the gastric activity starts vigorously and stays on a high frequency level for long duration (see figure). The activity level increases further depending on the amount of food.

Application of juice from mussels or fish into the stomach induces an amplification of movements of the gastric mill as well as a modification in the opening and closing of the cardio-pyloric valve. Gastric movements often show pyloric modifications which reflect complex gastric-pyloric patterns probably due to changes in the consistency of food. The investigations on the function of the stomatogastric system and neuroanatomical studies of the networks indicate the importance of sensorimotor mechanisms of integration which are involved in initiation and feedback control of the stomach's rhythmic motor-patterns. Supported by HFPSP.

It has been shown (Shadmehr and Mussa-Ivaldi, J. Neurosci., in press) that humans can adapt to virtual dynamic environments. We are interested in finding the neural mechanisms underlying this phenomenon. As a first step, before beginning the recording of single cells from cortical areas, it is necessary to assess how well the data observed in human subjects apply to macaque monkeys. Psychophysical tests were performed in an awake behaving monkey using the following paradigm: The monkey was trained to move a manipulandum in a set of targets sequentially appearing on a computer screen and hold the cursor in the target for at least one second in order to get a reward. In the baseline condition, the manipulandum behaves like a damper in order to help the monkey move smoothly. In the perturbation condition, non-homogeneous viscous field is superimposed on the baseline field. In the latter condition, a dramatic alteration of the trajectory was observed initially, followed by a gradual return to the baseline trajectory. This is consistent with the hypothesis of an underlying kinematic planner cascaded with an execution module canceling out the dynamics of the environment by learning a model of the disturbing field. We ruled out the possibility of co-contracting, which would be an alternative explanation of the data, by looking at the after-effects obtained by restoring the baseline condition. The after-effect appeared as a distortion in the path opposite to that induced by the field. Such after-effects decay rapidly when the monkey is longer exposed to the field. 577.3 NOVEL DEPOLARIZING GLUTAMATERIC CONDUCTANCE EXPRESSED IN CRUSTACEAN STOMATOGASTRIC MOTOR NEURONS IN PRIMARY CULTURE. T.A. Cleland* and A.L. Selverston, Dept. of Biology 0157, Univ. Calif. San Diego, La Jolla, CA 92039-0357.

The stomatogastric ganglion (STG) of the Pacific spiny lobster, Palinurus interruptus, is one of the most well-defined central pattern generators studied at the intercellular and circuit level. In this study, STG neurons were individually isolated in primary culture and tested in two-electrode voltage clamp. Calcium-dependent properties under improved space-clamp conditions and without the complicating effects of other networked cells. Glutamate-induced responses were characterized using two-dimensional phase-portraits. Biophysical and pharmacological characterizations of this glutamatergic conductance are presented.

Supported by NIH grant P01NS25916 to AIS and an NSF Predoctoral Fellowship to TAC.

577.4 MODES OF OSCILLATION AND SETTING RELATIVE PHASE IN SMALL MOTOR PATTERN GENERATING NETWORKS. P.E. Burr* and A.L. Selverston, Biology Department, U.C. San Diego, La Jolla, CA 92039-0357.

We have constructed a simplifying, biologically constrained, network model of the gastric mill CPG which shows that only a few basic mechanisms are sufficient to produce the relatively complex patterns characteristic of the gastric mill. These mechanisms include a cell model with a fast current with an N-shaped I-V curve and slow inward and outward currents with linear steady-state I-V curves; graded synaptic transmission; and "slow" synapses. The cell model captures important characteristic behaviors of gastric mill cells, such as plateau potentials, post-inhibitory rebound, and endogenous oscillation. The reciprocal inhibitory pair is an essential sub-network of the gastric mill network, which enables the cell model to produce a pattern whether or not the individual cells are endogenous oscillators.

An isolated cell has six distinct behaviors: endogenous oscillations; silent; almost an oscillator; plateau potentials; tonically firing, hyperpolarized. Using pairs of two-dimensional phase-portraits, we have studied in detail the modes of oscillation of two cells connected with reciprocal inhibitory synapses, in which the center of the synaptically transfer function, or "threshold", was allowed to be different for the two synapses. Every combination of behaviors in the individual cells can give rise to oscillations, provided the thresholds and weights are correctly adjusted. In the symmetric case, the cells are exactly out of phase, but when asymmetries are allowed many other phase relationships are obtained. In addition, one can get 1 N (N=1,2,3) or even M N phase locking, and chaos from the reciprocal inhibitory pair.

The 8 py motoneurons in the stomatogastric ganglion of the spiny lobster Palinurus interruptus are integral members of the pyloric central pattern generator and innervate 13 intrinsic constrictor muscles on the pylorus. Electrophysiological differences between cells of this class have been acknowledged for many years (Hartline, et al., 1987). Consistent with previous studies we found two distinct physiological phenotypes which can be quickly identified. PY cells do not respond to stimulation of the hepaticorenal duct nerve (Hdnl) or to a bell (10-4 M) applied on the abdomen (DA), are strongly electrically coupled to LE cells (-5 mV into LE cell), are strongly active during pyloric cycling, and can overlap the LP firing phase in a combined preparation. PY cells do respond to 5-HT, respond weakly or not at all to DA, and are not detectably electrically coupled to LP(-5 mV into PY); they are often silent during the ongoing pyloric rhythm and never overlap LP activity in a combined preparation. Four superficial muscles (p2,8,10,12) were used to test for differences in innervation patterns between the PY subtypes. The results showed no segregation of innervation on the muscles by other subtype; each muscle is innervated by at least one neuron of each type. We are currently looking at PT heterogeneity at the level of expression of mRNA for the skater K+ channel family using in situ hybridization. Supported by NIH NS17523 and SPOI NS25915.

577.6 EFFECT OF DOPAMINE ON THE TRANSIENT POTASSIUM CURRENT AND THE HYPERPOLARIZATION-ACTIVATED CURRENT IN PY AND LP NEURONS OF THE PYLOCIRIC MOTOR CIRCUIT. L.M. Congiglio and R.M. Harris-Warrick, Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

The stomatogastric ganglion of the lobster, contains a network of neurons, called the pyloric network, which controls rhythmic movements of the pylorus, part of the lobster foregut. The pyloric motor pattern is altered by the endogenous neuromodulator dopamine. The effect of dopamine on the pyloric pattern is due to both synaptic connections between neurons of the pyloric network and direct effects on the neurons themselves. We show that in two cell types, PY cells and LP cells, dopamine specifically affects the transient potassium current, Ih. In the PY cell type, dopamine decreases Ih by reducing its maximum conductance, shifting its voltage of half-activation in the depolarized direction, and increasing its rate of inactivation. In the LP cell, dopamine also decreases Ih by reducing its maximum conductance and shifting its voltage of half-activation in the depolarized direction. In the LP cell, however, dopamine has no effect in the rate of inactivation of Ih. In addition, in the LP cell dopamine affects a second current, the hyperpolarization activated current Ih. Dopamine effectively increases Ih by shifting its voltage-dependence of activation in the depolarizing direction and increasing its rate of activation.

Understanding the specific effects of dopamine on these neurons is important in understanding how alterations in particular neuronal properties can underlie the alteration of a motor pattern.

577.7 DISTRIBUTED ANINE MODULATION OF GRADED CHEMICAL SYNAPTIC INTERACTIONS BETWEEN NEURONS OF THE PYLOCIRIC MOTOR NETWORK. R.R. Johnson*, L. Peck and R.M. Harris-Warrick, Section of Neurobiology and Behavior, Cornell University and Dept. of Psychology, Ithaca College, Ithaca, NY.

Dopamine (DA), seratonin (5HT) and octopamine (OA) are endogenous neuromodulators in Crustacea, and each evokes a distinct motor pattern from the quiescent pyloric network in the stomatogastric ganglion of the spiny lobster. We examined amine effects on graded chemical synaptic transmission between known synaptically isolated pairs of neurons in the pyloric network to determine if these could contribute to the amine-generated motor patterns. Each amine had a unique and distinct spectrum of transmitter effects on graded chemical synaptic transmission across the pyloric synapses. DA (10-6 M) enhanced some pairs of synaptic interactions and weakened others. 5HT (10-6 M) also enhanced and weakened different pairs of synaptic interactions, but to a lesser degree than DA. OA (10-6 M) strengthened some synaptic interactions and had no effect on others. At some previously described chemical synapses, amine effects were comparable to those reported for octopamine (OA). However, these neuromodulators are required for the functional expression of some chemical synapses within the pyloric network. This completes our survey of the functional role of several neurotransmitters in chemical and electrical synaptic interactions within the pyloric network. Supported by NIH grant NS 17523 and the Human Frontier Science Program.

577.8 FUNCTIONAL ROLE OF ELECTRICAL COUPLING IN CONTROLLING THE LOCAL ACTIVITY OF A MODULATORY PROJECTION NEURON. M.J. Coleman*, P. Menvie* and M.P. Huebna*, 1Department of Physiology and Biophysics, Univ. Alabama at Birmingham, B'ham, AL 35294/Dept. of Neuroscience, Univ. Pennsylvania Medical School, Philadelphia, PA 19104; 2Lab. de Neurobiologie et Physiologie Comparées, CNRS, 33120 Arcachon, France. Intracellular recordings at the entrance to the stomatogastric ganglion (STG) of the crab Cancer borealis show that the STG terminals of modulatory commissural neuron 1 (MCN1) excites the pyloric and gastric mill rhythms in the STG, receives IPSPS from the lateral gastric (LG) neurons, and is weakly-coupled to LG (Nusbaum et al., J Neurosci. 12:2708). The LG inhibition of MCN1 controls the gastric mill rhythm-terminating activity of MCN1 in the STG (Coleman & Huebna, J Neurosci. in press).

Despite the synaptic inhibition from LG to MCN1, LG can also influence MCN1 via the electrical coupling between these two neurons. For example, depolarizing LG to levels sufficient to elicit transmitter release activates MCN1. Slightly stronger LG depolarization first activates and then inhibits MCN1. When the LG-mediated inhibition is eliminated by bath-applying picrotoxin (10-5 M), LG stimulation activates MCN1 and later enables MCN1 to activate its STG targets.

MCN1 stimulates gastric mill rhythms, the MCN1 hyperpolarization is largest at the start of each LG burst. This response in MCN1 then exhibits a depolarizing sag, despite the fact that MCN1 is hyperpolarized due to its underlying membrane potential. This enables MCN1 to escape from inhibition before the end of the LG burst. We are studying whether the electrical coupling between LG and MCN1 contributes to this escape facilitation in MCN1.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

THURSDAY AM
MUSCARINIC MODULATION OF EXCITABILITY AND SYNAPTIC OUTPUT IN A GASTRIC PATTERN-GENERATING NEURON OF THE LOBSTER STOMATO garganglion. R.E. Skinner and A.I. Selverston, Department of Biology, UCSD, La Jolla CA 92039.

In the isolated stomatogastric ganglion of spiny lobsters, the muscarinic agonist, pilocarpine, activates gastric output neurons in the gastric mill CPG. The lateral gastric neuron, LG, an important pattern-generating cell, goes from quiescence to spontaneous spiking and then to firing strong bursts underlaid by plateau potentials.

Even before the onset of spontaneous activity, however, one can detect a large increase in the amplitude of LG's slow afterhyperpolarizing potentials (SAPs) to other gastric neurons. IPSs to PDs are evoked by ortho- and antidromic spikes grow larger, the input-output function for graded synaptic transmission gets steeper, and the threshold for transmitter release is seemingly reduced when concurrent coupling is monitored neurally input resistance during synaptic potentiation, and found a large increase in synaptic conducance. The resting input resistance of LG could also increase, but is not clear is LG conducts all for the all-observed potentiation.

Currently, pilocarpine decreases LG's spike threshold and increases the slope of the spike frequency action potential. Together these changes enhance the role of spike-mediated transmission at low presynaptic depletions. Also induced is a slow, seemingly active, depolarization, which may be the plateau current, and which is a good driver of graded transmission.

A possible interpretation of these results is that munc43 modulates lead to enhanced activation of calcium currents in LG's distal neurites, allowing greater transmitter release. Present experiments seek to identify which conductances are modulated in LG to and to clarify how these changes relate to modifications of excitability and efficacy. Supported by NIH grants NS0152916, NS09322 and PH507220.

We characterize how modulation of an intrinsic conductance (I) alters the responses of a half-center oscillator formed by reciprocally inhibitory connections. We use a combined theoretical/experimental approach employing conventional models and neuronal recordings, to examine the dependence of dynamic clamp (Sharp et al., J.Neurophys., 69-992,1993). A plot of network period vs. synaptic threshold produces an inverted U-shaped relationship (see accompanying abstract). As the maximal I conductance is increased the I conductance is organized as a cycle of activity. In the direction, the period vs. synaptic threshold relationship is shifted in the depolarizing direction. This indicates that these changes cause a frequency increase if a synaptic threshold is increased and a frequency decrease if a synaptic release mechanism is in operation. For a small range of synaptic threshold values, it is also possible for the system to switch between synaptic escape and release modes for these changes. If the maximal conductance is made too small or the activation curve is shifted too far in the hyperpolarizing direction, oscillations cease. This indicates that there is a critical relationship and intrinsic properties in order to generate sustained half-center oscillations. This differs for a detailed understanding of these relationships. Supported by NIMH MH57472 and NSF BNS0090251.

RECIROCALLY INHIBITORY NEURAL NETWORKS: EFFECTS OF VARIATIONS IN SYNAPTIC PRINCIPLES. F.K. Skinner, A.A. Sharp, and E. Marder. C. for Complex Systems and Dept. of Biology, Brandeis University, Waltham MA 02254-9110.

Reciprocally inhibitory circuits are ubiquitous components of oscillatory neural systems. We characterize how modulation of synaptic properties alter the responses of such a two cell system (half-center oscillator) using a combined theoretical/experimental approach. We employ two two-compartment models. This includes: a) model in which includes HH-like spikes. Experimentally, we take advantage of the dynamic clamp technique (Sharp et al., J. Neurophysiol., 69-992,1993) to couple pairs of gastric mill neurons in the stomatogastric ganglion, and to introduce artificial I. As the synaptic threshold is increased, the frequency decreases and then increases. This frequency transition occurs as the system switches from a synaptic escape mechanism to a synaptic conductance mechanism (Skinner et al., J. Computational Neurosci., in press). As the synaptic time constant is increased, the network frequency and oscillator amplitude both decrease. Increasing the maximal synaptic conductance decreases a frequency decrease and an increase in oscillator amplitude. For large synaptic conductances, oscillations can not be initiated for values of the synaptic threshold which fall in the transition between synaptic escape and release mechanisms. This interactive approach allows for a detailed understanding of how interactions between synaptic and intrinsic parameters generate network behavior. Supported by NIMH MH46742 and NSF BNS0090251.

The pyloric network neurons types are distinctly different on the basis of muscle innervation, electrophysiological activity, and synaptic connectivity in the network. We examined whether the individual neuron types also have different morphologies by injecting neurons with the fluorescent dyes Lucifer yellow or fluorescein dextran and reconstructing the neurons with a Eustacic three dimensional neuron tracing system.

In agreement with the results of King and Selverston (1976) and Selverston and Mullenby (1973), the main neurite of the Ventral Terminal (V) neuron splits in the neuropil into two processes, each of which continues to form one of the neuropil axons. In addition, within the neuropil, the LG neuron distinctly has a process that leaves the main neurite at or before the axon initiation zone and then goes around the neuropil. Detailed analysis of the neuropil neuron of the two axonal processes reveals they occupy non-overlapping regions of the neuropil.

The pyloric network has two Pyloric Dilator (PD) neurons that seem to be identical electrophysiologically. However, these neurons appear to have two different morphologies. In one class (n=4), the main process loops over itself as it continues to run in the neuropil. The other PD neurons have less ramifications than the former class (n=7) and have more distant initial branches (av. distance from soma, 133±41nm). In four PD neuron fills, one of each class was present in the ganglion. In a fifth very poor double fill, I could see connective tissue that filled up with PD neuron profiles were present.

These results suggest that at least some the pyloric neuron types have distinct morphologies. Perhaps more interestingly, the distinct volumes occupied by the PD neuron neurite processes could provide for a basis for anatomical segregation of the stomatogastric neuropil.

The two pairs of dorsal dilator muscles are an invertebrate also innervated by the Pyloric Dilator (PD) neurons and have been assayed to express a pyloric motor pattern. We examined the intrinsic constrictions of these muscles in vitro preparations maintained in oxygenated canine saline solution. In 3 of 5 preparations, we observed no or only very small (<0.1mm) pyloric timed contractions. In the other preparations these large (~1mm), long duration (4s) contractions 6 to 8 sec, very different from the PD neuron burst length (~250ms) and cycle period (~1s) present in these preparations. In 10-4M dopamine (DA), all preparations large to (up to 2mm) contractions, with long durations and periods. Large (>0.1mm) pyloric timed activity was often concentric in either the DA or VP.

In two experiments, we observed that the large contractions were phase locked with Gastric Mill (GM) neuronal activity, and that constriction duration covered with GM neuron burst length. In one experiment we stimulated the anterior lateral (aln) nerve, which contains GM neurons axons; elicited, at constant short latency, contractions whose duration was matched with the stimuli duration. In the other, we stimulated the posterior lateral (pln) innervated by the pyloric muscle, the large contractions were much longer than the pyloric period, suggesting that even if pyloric activity is present, the pyloric escape mechanism in either the DA or VP. This idea was tested by applying DA to augment contraction amplitude and stimulating the lateral ventricular (IVN) nerve or aln using parameters (40Hz for 250ms every 1s) mimicking pyloric neuron bursts. Under these conditions the contractions summed, resulting in a sustained contraction.

These results suggest that the dorsal dilator muscles, at least under some conditions, 1) may respond to pyloric input with sustained contraction and 2) can express gastric mill timed and duration motor output.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

The rhythmic pattern produced by the lobster pyloric network maintains relatively constant phasing as cycle frequency is altered by current injection into the pyloric pacemaker. Perfect phase maintenance requires appropriate changes in both pacemaker burst duration and firing delay of follower neurons after injection. Previously I showed that when trains of hyperpolarizing current pulses are injected into isolated pyloric neurons, firing delay of Inferior Cardiac (IC) and Lateral Pyloric (LP) neurons primarily depends on pulse amplitude, whereas Pyloric (PY) neuron firing delay primarily depends on the temporal characteristics of the input current.

Intracellular recordings from LP and IC neurons in the intact network show that injection of current pulses into these cells changes as pyloric frequency is altered. However, this change is small and opposite to the change expected if the cellular properties of these neurons play a role in phase control. Re-analysis of prior experiments with respect to delay after the pacemaker burst, rather than phase, shows these neurons fire with a constant lag after pacemaker activity.

In the intact network, PY neurons do show appropriate changes in firing delay, and thus the firing delay properties described previously likely are relevant to their phasing. This work did not directly address whether PY neuron firing delay depends on pulse length or interpulse interval. Experiments in which these lengths were varied independently showed that inter-pulse interval, not pulse length, mainly determines PY neuron firing delay.

Maintenance of LP and IC neuron phase as pyloric frequency changes thus is largely due to the associated changes in pacemaker burst length. PY neuron phase maintenance, alternatively, is likely associated with PY neuron cellular properties that alter neuron firing delay as pyloric frequency is altered. However, this delay may be primarily determined by the length of the PY neuron burst in the preceding pyloric cycle, not the changing duration of pacemaker inhibition received by the PY neuron.

ASSOCIATION CORTEX AND THALAMOCORTICAL RELATIONS

MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL PROPERTIES OF LAYER 1 NEURONS IN RAT NEOCORTEX. F.M. Zhou* and J.J. Habibz, Neurobiology Research Center, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

The basic morphological properties of layer 1 neurons were described by Ramon y Cajal about 100 years ago. Yet, the electrophysiological properties of these neurons has remained an enigma and their neuronal nature has been questioned. Using an in vitro slice preparation, we have examined the morphological and electrophysiological properties of visually identified layer 1 neurons. Whole cell patch clamp techniques were used in slices from 2-3 week-old rats. Biocyn labeled cells were multipolar with somas 10-20 μm in diameter. Most cell processes were smooth and spread horizontally for 1-2 mm within layer I. Some presumed axonal processes going to layers II-IV were observed. All the layer 1 cells (N=30) tested had electrophysiological properties typical of interneurons. Action potentials evoked by depolarizing current pulses showed minimal or no frequency adaptation. Action potential durations, measured at the base, were short compared to pyramidal neurons recorded under similar conditions (2.5-5 ms at 22°C). In the presence of 20 μM APV and 10 μM CNQX, bicuculline-sensitive spontaneous IPSCs were recorded in the majority of cells. The amplitude of sIPSCs ranged from less than 10 pA to more than 200 pA, at a holding potential -60 mV in symmetrical Cl-, and reversed at 0 mV. Adding 0.5 mM TTX reduced sIPSC frequency and blocked large amplitude sIPSCs. These results suggest that layer 1 neurons have firing properties characteristic of interneurons and receive inhibitory inputs. They appear to have extensive processes which may serve in controlling cortical excitability. (Supported by NS18145 and NS22373)

TWO DISTINCT PATHWAYS FOR ACTIVATING cGMP IN THE CRAB STOMATOGASTRIC NERVOUS SYSTEM. K. L. Schütz, M. F. Guy*, A. J. W. Trammell, and K. Grabaush*, Univ. of Washington, Dept. of Zoology, Seattle, WA 98195 and Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599.

We are investigating pathways of cGMP activation in the crab stomatogastric nervous system (STNS), a collection of motor circuits known to be extensively modulated by both synaptically-delivered transmitters and circulating neurohormones. Using antisera selective for cGMP, we have conducted parallel radioimmunoassay (RIA) and immunocytochemical (ICC) studies to screen for stimuli that activate cGMP synthesis in the STNS. We have found two classes of activators that are effective; nitric oxide (NO) donors and peptide-containing extracts of crab sinus gland.

In RIA studies, three NO donors (SNP, SNAP, and SIN-1) were all found to produce large increases in cGMP levels when applied with the phosphodiesterase inhibitor IBMX. A similar result was obtained with ICC studies; treatments with NO donors and IBMX consistently caused the appearance of cGMP immunoreactivity in a subset of neurons. We used an arginine-to-citrulline conversion assay to screen tissues in the vicinity of the STNS for a nitric oxide synthase (NOS), and found a candidate in crab heart. This tissue contains an arginine-utilizing enzyme with properties that resemble a constitutive NOS, including calcium-dependence, NADPH-dependence and sensitivity to arginine analogs. No such activity was observed in the STNS, the crustacean digestive system. Neurons that contained the cGMP content of the STNS when applied with IBMX. We are currently using cGMP ICC to identify which cells are targeted by the active component of the extract; preliminary results indicate that the peptide extract has a different target specificity than do the NO donors. Based on these results, we suggest that NO and a sinus gland peptide represent two non-overlapping pathways for activating cGMP in the STNS. Supported by an NRSA fellowship to N.S., NIH grants (NS15697 to K.O. and NS 25915 to M.G.) and NSF grant IBN-9245993 to J.T.

578.3 Efferent projections from the rostral thalamic reticular nucleus to the ipsilateral and contralateral thalami: An ANTONERI and POSTERIOR techniques in the monkey. R.D. Burwell, M. Caballero-Bleda, M. Guillery, and D.G. Amaral.1 Department of Neurophysiology, Neural Institute “C. Besta,” 20133 Milano, Italy.

The conventional view that the intralaminar connections are sparse or absent has been recently challenged by anatomical studies from different groups (Bostiglio et al., 1995; Petre and Sorine, 1995; Boultham et al., 1994). These studies, mainly based on anterograde or retrograde tracer experiments, have been performed in the macaque by injecting the thalamic reticular nucleus (TRN), and particularly its rostral part, to contralateral (as well as to ipsilateral) thalamic nuclei. The retrograde transport of biotin- derived amine (BDA) was employed in the present study to investigate the connectivity of the rostral TRN and the medial, ventral, and lateral regions of both hemispheres. The present study was designed to test whether projections from the rostral thalamic nuclei of the contralateral hemisphere provide a mechanism for the interhemispheric transfer of information.

After BDA injections in the medial region of the contralateral TRN, anterogradely labeled fibers were observed in the corresponding regions of the ipsilateral thalamus. The present study demonstrates the thalamic network involved in interhemispheric connectivity and the role of the rostral part of the TRN in reciprocal connections of the thalamus. The present data suggest a reciprocal connectivity through the thalamic network and the role of the rostral TRN in reciprocal connections of the thalamus. The present data demonstrate the importance of the rostral TRN in reciprocal connections of the thalamus and the role of the rostral TRN in reciprocal connections of the thalamus.

578.5 A PHA-L STUDY OF THE PERIRHINAL PROJECTION TO THE THALAMUS IN THE RAT. R.D. Burwell,1 M. Caballero-Bleda, M. Witter,2 and D.G. Amaral.31 The Center for Behavioral Neuroscience, SUNY at Stony Brook, Stony Brook, NY, 11794-3755.2 Anatomy and Neurophysiology, Vrije University, Amsterdam, The Netherlands.

The precise relationship of certain thalamic nuclei with distinct regions of the neocortex has provided one mechanism for defining the cytoarchitectonic boundaries of the cortical mantle. This study was designed to determine whether projections from various locations of the perirhinal cortex might differentiate subdivisions of this region. Using adult male Sprague-Dawley rats as subjects, the anterograde tracer, Fluoro-gold (FG), was injected into the lateral entorhinal cortex. After a survival period of 7 days, brain sections were stained with FG to test for the presence of labeling.

Cross-sectional studies in this region revealed a pattern of labeling that was consistent with the pattern observed in the monkey. The perirhinal cortex is characterized by a dense distribution of FG-labeled neurons that is consistent with the pattern observed in the monkey and consistent with the pattern observed in the monkey.

578.6 INTRINSIC CIRCUITS OF FUNCTIONALLY SPECIALIZED SUBDIVISIONS OF HUMAN CEREBRAL CORTEX. M.F. Krubitzer. Department of Neurology and Behavior, SUNY at Stony Brook, Stony Brook, NY, 11794-2520.

The present study was designed to determine whether connections from various subdivisions of the neocortex might differentiate subdivisions of this region. Using adult male Sprague-Dawley rats as subjects, the anterograde tracer, Fluoro-gold (FG), was injected into the lateral entorhinal cortex. After a survival period of 7 days, brain sections were stained with FG to test for the presence of labeling.

Cross-sectional studies in this region revealed a pattern of labeling that was consistent with the pattern observed in the monkey. The perirhinal cortex is characterized by a dense distribution of FG-labeled neurons that is consistent with the pattern observed in the monkey and consistent with the pattern observed in the monkey.

578.7 EVOLUTION OF THE FRONTAL LOBES: AN MRI STUDY ON APES AND HUMANS. K. Smedes,2 H. Damos,2 and G.W. Van Hoosier3.3 Dept. of Anthropology,1 Neurology2 and Anatomy3, Univ. of Iowa, Iowa City, IA 52240.

How much did the frontal lobes (FL) enlarge during hominoid evolution and which of the subdivisions (dorsal, mesial, orbital) changed the most? We studied 5 living hominoids: chimpanzees, gorillas, orangutans, and a monkey (macaque). Thin cut MRIs were obtained from non-human primate brains and from a human living subject. All were reconstructed in 3-D. Major landmarks were determined and used to generate the coordinates of a dorsal, mesial and orbital region of interest in each hemisphere. The overall size of the hemisphere was compared with CT a second arctan and white matter and subcortical grey structures.

Relative to the rest of the hemisphere, the size of the FL is largest in the chimpanzee, where it is nearly identical (36.3% and 36.9% of the same hemisphere). The area and gyri have the smallest (31.3% and 31.5%) (1). The FL show a trend towards increased size in hominoid evolution, but the 3 sectors did not change much. Across the three species, the rostral and orbital sectors are more, but not, in a relative sense and, as expected, the dorsal sector is largest followed by the mesial and orbital. A noteworthy difference was found in the fourth sector, the frontal lobe, where the human frontotemporal region is largest. The modest marked difference was seen in the anterior third, which contains the white matter, underlying prefrontal cortices.

Support from the National Institute of Health, grant RO1 19632-11. We thank Yerkes Regional Primate Research Center, Bush Gardens Zoo, Houston Zoo, Toledo Zoo, Gladys Porter Zoo and Metro Washington Park Zoo for providing the ape specimens.

578.8 SYNAPTIC PHYSIOLOGY OF THE AMYGDALA-PERIRHINAL PATHWAY STUDIED IN VITRO. J.M. Szego.1 and J.W. Kaftans. Department of Physiology and Center for Neuroscience, Yale University, New Haven, CT 06511.

Although cortical and limbic areas have been suggested to play complementry roles in mammalian memory, little work has been done to study synaptic interactions between these two regions. To address this issue, we have performed experiments in vitro in an in vitro slice preparation which maintains connectivity between perirhinal cortex (PRh) and the lateral nucleus of the amygdala (LA). Here we describe experiments using the optic fiber technique for reliable preparation of these slices and present the results of studies of synaptic plasticity in this system.

Coronal slices 400µm thick were obtained from brain in the range of -2.2 to -3.8 from brain. Stimulation with current pulses of 50-100µA in PRh in 33% of these slices. Current-source density analysis reveals a current sink restricted to layers III-IV of PRh. Injection of the lipophilic tracer DiI also confirmed that a fiber pathway with contralateral labeling in the LA is present in a subfield of the R. LA. These data indicate that there is a component that can follow at 100Hz with a constant latency of 5ms over a range of stimulation intensities of 0.2-2Apep.

To examine use-dependent plasticity, field potentials were recorded in superficial layers of PRh while applying high-frequency stimulation in LA. Preliminary results indicate that these responses can be potentiated. Stimulation applied to superficial layers of adjacent cortical areas can either potentiate or inhibit these responses recorded in a superficial PRh. We are investigating whether there exists cooperativity or associativity between the LA and intracortical inputs to PRh. Future studies will examine whether this plasticity is NMDA-dependent, and if the input from LA can serve as a "reinforcement signal" to consolidate intracortical plasticity in PRh (Supported by NIH and Yale University).

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
758.9

The excitatory axon terminals that furnish intra- and inter-areal connections in monkey prefrontal cortex (PFC) are both arranged in discrete clusters. Although, little is known about the organization of these two types of terminal fields, it seems certain that the distribution of their origins of origin. Single injections (150 μl diam.) into sectioned tissue of areas 9 or 46 of microwave monkey PFC produced two distinct types (intra- and inter-areal) of clusters of immunohistochemically characterized axon terminals. Within areas 9 or 46, labeled terminals formed multiple stripes (45 × 1.4 μm) in layers 1-3 that were similar to the intraregional lattice structure formed labels in the medioapical collateral of layer 2/3 presumed as revealed by the tracer biocytin (Levit et al., 1993). Terminals from the same injection also formed bands (49 × 1.2 mm) at substantially greater distances from injection site. These axon terminals, which were distributed across all cortical layers, arose from labeled axons in the underlying white matter. Similar injection of cholera toxin B (CTB) revealed two analogous types of clusters of retrogradely-labeled pyramidal neurons. Within areas 9 and 46, labeled neurons formed stripes (42 ± 1.2 mm) primarily in layers 2/3, whereas in other PFC regions, clusters of labeled neurons were present in both superficial and deep layers. Anterogradely-labeled CTB axon terminal at both the intra- and interareal cell clusters, revealing the reciprocity of these connections. These findings confirm the discontinuous distribution of both intra- and interareal connections in monkey PFC. They also demonstrate that each point in the intrinsic lattice furnishes divergent output to multiple zones within the lattice as well as to other PFC regions, and they converge input from these same zones. These patterns of reciprocal intra- and interareal connections provide an anatomical substrate for the simultaneous and recurrent activation of specific distributed networks of neurons in monkey PFC.

758.10

Pyramidal neurons in the superficial layers of monkey prefrontal cortex (PFC) furnish horizontally spreading axon branches that form the same type of lattice comprised of multiple stripes (Levit et al., 1993). Because the function of the intra-areal circuitry depends on the input and output of the cells which furnish it, we investigated the dendritic morphology and extrinsic projections of these neurons. Small iontophoretic injections of biotinylated dextran amine (BDA) were made into areas 9 or 46 of monkey PFC. Retrogradely-labeled neurons 1) which were labeled via their axonal collateral projections, and 2) which BDA provided complete filling of dendrites. Typical features of these pyramidal neurons included: location in layers 2/3, an axon which emitted collaterals to the cortical surface at a shallow dendrites extending into layer 1, and basal dendrites which were confined to layers 2/3. The horizontal extent of the dendritic arbor (250-450 μm) was similar to the width of intrinsic neuronal lattice (Levit et al., 1993), suggesting that these neurons sample input from a single stripe. In order to determine the destination of the extrinsic projections of these neurons, dual injections were: 1) cholera toxin B (CTB) in areas 9 or 46, to label neurons with intrinsic axon collaterals within these areas, and 2) Fast Blue (FB) in another area of PFC, to label association-projecting neurons. In locations where the axons overlapped, 40.6% (54/135) of FB-labeled neurons were also labeled with CTB. Thus, neurons which furnish axonal collaterals of the intrinsic lattice also provide association projections. The lamina location of the dendritic arbor of these neurons indicates that they may receive inputs and/or project to other cortical areas. These features suggest that the intrinsic lattice plays an important role in cortical information processing by permitting the simultaneous activation of discrete, spatially segregated groups of neurons, resulting in a specific pattern of output from the PFC to other cortical areas.

758.11
DENDRITIC MORPHOLOGY OF NEURONS WITH DIFFERENT AXONAL PROJECTIONS IN MONKEY PREFRONTAL CORTEX. A.S. Sologyai*, M.L. Popack, and D.A. Lewis.1,2. Deps. of Neuroscience1 and Psychology1, Univ. of Pittsburgh, Pittsburgh, PA 15260.

The dendritic morphology of pyramidal neurons, the major source of excitatory intra- and interareal cortical connections, has been reported to differ depending upon the target of their effector axons. In addition, separate populations of neurons have been shown to furnish associated and collateral projections from a given region of monkey prefrontal cortex (PFC). In this study, injections of the fluorescent tracer Fast Blue (FB) into areas 9 or 46 of cynomolgus monkey PFC were used to identify associative and collateral neurons in these areas. Retrogradely-labeled neurons were then intracellularly injected with Lucifer Yellow in fixed slices (300 μm), converted to an immunoperoxidase label, and reconstructed using the Magnetic Neuron Tracing System. Neurons providing associative projections were pyramidal or modified pyramidal cells located predominantly in layers 2/3, with a smaller number in layers 5/6. Association neurons in the superficial layers shared the following characteristics: an apical dendrite which extended into layer 1, a basilar dendrite which was confined to layers 2-3, and a dendritic arbor with a horizontal spread of 200-400 μm. The laminar location, vertical and horizontal spread of the dendritic tree, and the pattern of dendritic arborization of association neurons is quite similar to that of neurons whose axon collaterals form the lattice-like structure of intraareal connections. These similarities are consistent with other evidence indicating that a subpopulation of PFC neurons furnishes both intra- and interareal connections (Michelzky et al. 94). Collateral neurons were also similar to association neurons in their laminar distribution and soma morphology; quantitative assessments of dendritic arborization and complexity, as well as measures of excitatory input, will be used to directly compare these two non-overlapping cell populations.

758.12

The calcium-binding protein, calretinin (CR), is present in a morphologically distinct population of local circuit neurons in superficial layers of monkey prefrontal cortex (PFC). This morphological cell class has previously been targeted to both pyramidal and non-pyramidal neurons. We examined the ultrastructural features of these neurons in areas 9 and 46 of monkey PFC using preembedding immunogold marker and investigated their association with DA terminals by combining immunogold staining with peroxidase immunoelectron microscopy for tyrosine hydroxylase (TH) and a postembedding approach to study synaptic contacts with cell soma, as well as large and small diameter dendrites. These contacts were primarily of the symmetric type. Many of the small dendritic targets had the morphological characteristics of typical pyramidal neurons; however, they were not immunoreactive for CR. CR immunoreactivity was also observed in small nonpyramidal neurons whose dendrites were distinctly varicose and received abundant synaptic input. In double labeled sections, immunoreactive for CR were frequently observed in adjacent areas of the neuropil. However, appositions between labeled processes were rare, and specific instances of synaptic input were not observed. Although our previous findings demonstrated that DA terminals directly innervate some GABAergic interneurons in the PFC, the present findings suggest that CR-containing interneurons are not included in this target population. However, a more indirect modulatory interaction between CR and TH-containing processes is suggested by their common distribution.
CORTICOCTORTAL CONNECTIONS MEDIATE DIRECTED ATTENTION IN RATS: BEHAVIORAL AND ANATOMICAL EVIDENCE. R.L. Reep*, J Vandevelde, E. Duckworth, M. Stoll and T.V. Corwin. Department of Physiological Sciences, University of Florida, Gainesville, FL 32610; and Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

We investigated the role of corticocortical connections in directed attention by selectively disconnecting areas AGm and FPC, then testing animals for signs of hemispatial neglect. In rats, these two cortical areas are involved in spatial orientation and are highly interconnected via rostrocaudally directed axons traveling both directions in the deep gray matter. Therefore, coronally oriented knife cuts which extend into layer VI but do not erode upon the white matter should selectively transect these axons without interrupting those directed subcortically.

Knife cuts extending into layer VI (N=6) produced neglect, whereas control cuts extending only as deep as layer V (N=4) did not (p<0.02). The deeper knife cuts resulted in appreciably less axonal labeling than normal and a very sparsely labeled region rostral to the cut, whereas control subjects with shallower cuts exhibited labeling which was comparable to normals.

These results suggest that the corticocortical axons linking AGm and FPC play a pivotal role in directed attention.

Considerable progress has been made in recent years in determining the CNS mechanisms which mediate vomiting. However, the neuronal substrates that subserve nausea are completely unknown. The present study used functional neuroimaging techniques to determine if a localized cortical area is activated during nausea. Functional data were obtained using a 37-channel SQUID-based magnetic source imaging (MSI) device (Magnes, Biomagnetic Technologies Inc., San Diego, CA) and were overlaid on neuroanatomical information from high-resolution 3D SPGR MRI. Data were analyzed for the occurrence of transient bursts of neural activity exceeding 6000 fT when data were filtered in the range 8-100Hz). These were used to derive the location of the responsive neural source using the single equivalent dipole model. Data have been obtained from one volunteer in which nausea was produced on two separate days by either oral ingestion of syrup of ipecac or by visual stimulation (induced by head movements during yaw-axis rotation, while wearing vision-reversing goggles). Current dipoles indicative of neuronal activation were localized to a 2-3cm diameter region of cortex in the inferior frontal gyrus, when nausea was produced by either stimulus. Such activity was not observed during baseline controls or during sequences involving swallowing or exaggerated respiratory movements. While preliminary, the data suggest that MS1 may provide a quantitative means of measuring the effects of various pharmacological interventions on nausea and suggest a new CNS target for such intervention.

Supported by grants from NIH (NS20885 to AM).

APOMORPHINE ADMINISTRATION PRODUCES ACUTE DOSE-DEPENDENT RECOVERY FROM NEGLIGENCE FOLLOWING UNILATERAL POSTERIOR PARITIAL CORTEX LESIONS IN RATS. T.V. Corwin*, G.J. Altman, J.K. Bushman, and C. Goetz. Psychology Dept., Northern Illinois University, DeKalb, IL 60115

Previous research from our laboratory (Corwin et al., 1986; King and Corwin, 1990) has indicated that apomorphine (apo) has an acute dose-dependent therapeutic effect on neglect induced by unilateral lesion of the posterior parietal cortex (PPC), the present study examined the effects of apo administration on neglect induced by unilateral destruction of the PPC.

Subjects were 20 Long-Evans hooded male rats. After extensive handling, the subjects received an injection of either the left or right PPC via aspiration. At 48-96 hrs post-surgery, the subjects were tested for the presence of multimodal neglect, determined by the degree of head orientation in response to presentation of visual, tactile, or auditory stimuli. Subjects which met the criterion for severe neglect (defined by a ratio of responsiveness of the neglect side/non-neglect side of <1:3) were randomly assigned to one of four apo dosage groups: vehicle, 0.1, 0.3, or 0.5 mg/kg. Apo or the vehicle was administered i.p. 45-60 min after behavioral testing. Eighteen minutes post-injection, the subjects were retested. All behavioral testing was done with the experimenter "blind" with respect to the dosage administered.

There was a significant reduction in the severity of overall neglect in the 0.3 and 0.5 mg/kg groups (p<.05), but not in the vehicle or 0.1 mg/kg groups. The results indicated that apo produces an acute dose-dependent therapeutic effect on multimodal neglect produced by PPC lesions. As found for the AGm, neglect produced by unilateral PPC removal may be a result of disruption of dopaminergic mechanisms.

**COMPARATIVE NEUROANATOMY: SENSORY SYSTEMS**

SOME MORPHOLOGICAL FEATURES OF A VISUAL THALAMIC NUCLEUS IN A REPTILE. M.B. Fritz*, Dept. of Neurol. Surg., Indiana U. Sch. of Med., Indianapolis, IN 46202-5124.

Nucleus rotundus is a prominent nucleus in the dorsal thalamus of all non-avian vertebrates. In one group of reptiles, Catoblepis crocodilis, this neuronal aggregate contains no cells only and lacks local circuit neurons. The present study investigated some aspects of rotundal cytoarchitecture based on examination of Nissl morphology. Neurons were not uniformly distributed throughout the nucleus but were grouped in clusters commonly ranging from 2 to 5 cells. Somas were round, oval or triangular in shape. The following cortical features were investigated: area, perimeter, and roundness or eccentricity expressed as the ratio of greatest width to greatest length. Preliminary observations, mean ± standard deviation, examined neurons in each of 3 planes: horizontal (N=55), sagittal (N=50), and transverse (N=50). Measurements were as follows: (1.) area (μm²) = 196.88 ± 46.13 – horizontal; 205.58 ± 50.69 – sagittal; and 202.93 ± 39.12 – transverse; (2.) perimeter (μm) = 55.32 ± 7.64 – horizontal; 56.46 ± 7.35 – sagittal; and 54.30 ± 5.70 – transverse; (3.) roundness; 0.675.13 – horizontal; 0.62 ± 0.10 – sagittal; and 0.71 ± 0.11 – transverse. Additional observations will be made to determine whether these morphological features identify subpopulations of relay cells in nucleus rotundus.

A COMPARISON OF THE EIMER'S ORGANS OF THE STAR-NOSED MOLE (CONDYLURA CRISTATA), THE HAIRY TAILED MOLE, (PARASCALOPS BREWERI), AND THE EASTERN MOLE (SCALOPUS AUSTRALIS). K. C. Catania* Neurobiology Unit, Scrips Institution of Oceanography and Dept. of Neurosciences, School of Medicine, Univ. of Calif., San Diego, La Jolla, CA 92030-2011.

Eimer's organ is a tactile sensory structure found on the snouts of moles and some shrews. It consists of a raised dome of epithelium containing a column of cells associated with sensory receptors. Scanning electron microscopy and light microscopy were used to compare the size and distribution of these organs in three North American moles.

Eimer's organs are visible on the skin surface of the hairy tailed mole and the eastern mole. The organ has an ovoid appearance, distribution, and internal structure of the Eimer's organs of the hairy tailed mole are similar to those most commonly found in other species. The structure of the Eimer's organs of the star-nosed mole and the eastern mole diverge from this basic form in seemingly opposite directions. The Eimer's organs of the star-nosed mole are more numerous, smaller, highly organized units with little variability and a consistent pattern of terminal swellings within a cell column, just below a thin keratinized epidermis. By contrast, the Eimer's organs of the eastern mole lie below a thick keratinized epithelium, are larger and more variable in structure, and have no central cell column. These differences may be influenced by the soil type through which each species burrows; saturated mud allowing a more elaborate and delicate sensory apparatus in the case of the star-nosed mole, and dry abrasive soil requiring a thick keratinized epidermis to resist the receptor complex in the case of the eastern mole. Supported in part by NIH grants NS24869 to R. Glenn Northcutt, and 5132-GM08107 (Biological Training Grant).

The organization and fiber connections of the dorsal column nuclei (DCN) of the anurans Rana ridibunda and Xenopus laevis are studied with immunohistochemistry and tract tracing. Primary afferents from cervical, thoracic and lumbar spinal dorsal roots reach the DCN somatotopically arranged. Primary afferents from the cranial nerves V, VII, IX and X innervate the DCN via the descending trigeminal tract. Nonprimary afferents arise bilaterally in cells of the rhombencephalic reticular formation, the mesencephalic reticular formation, the octavolateralis and thalamic nuclei, and project to the spinal cord.

The main efferent projection of the DCN, i.e. the medial lemniscus, is formed by DCN fibers that cross the midline at the level of the nuclei and innervate contralaterally the rhombencephalic reticular formation, the octavolateralis, cerebellum, the principal, magnocellular and mainly the laminar nucleus of the torus semicircularis, the anterodorsal and anteroventral (including the red nucleus) mesencephalic reticular nuclei and areas and in X, laevis the intermediate and deep layers of the tectum. At mesodiencephalic levels the medial lemniscal fibers innervate the posterior tubercle, the ventral thalamus (ventromedial and ventrolateral nuclei), and sparsely the posterior and central nuclei of the doral nucleus. Spinal, extratrigeminal, DCN efferents reach the granular layer of the cerebellum and descending effenter fibers innervate the spinal cord. Histochimical and immunohistochemical observations of the DCN area revealed the presence of GABAergic, glycineergic, as well as parvalbumine (in X, laevis also calbindin), and NADPH diaphorase positive neurons in the DCN. Terminal structures positive for 5-HT, CRMP, SP, NPY and NADPH are present in the DCN.

579.5

The nervus terminalis (NT) was discovered more than a century ago in elasmobranchs. Presumed homologs of this cranial nerve have been investigated in many vertebrate classes. However, only a few data are available on the connectivity of the NT in elasmobranchs. We investigated the projections of the NT by means of biotinylated dextran amine (BDA) injections into the olfactory bulb (OB) and rostral telencephalic areas and corresponding nerve tracts to the OB in the thornback guitarfish, Platyrrhinoidis trierisata.

Injections of BDA into the OB revealed labeled fibers entering the forebrain in the NT, proceeding caudally in a mediopetal position adjacent to the rocessus neuroporicus and penetrating septal and preoptic areas. Labelled cell bodies were not observed only in the lateral part of nuclear mass, which is similar to previous studies in other elasmobranchs, above the optic tectum. Injections into the area where the NT enters the forebrain revealed labeled cells in all of the ganglia along the course of the NT towards the lateral part of the OB. Previous work has shown that the NT carries tonic efferent activity [Bullock and Northcutt Neurosci Lett 44(1984)155-160]. The labelled cells we found in the nucleus preopticus are possibly the source of these efferents.

Supported by a DFG grant to MIH and NIH grants to RGN and THB.

The vestibulolateral cerebellum of the catfish is comprised of two discrete granule cell nuclei; a lateral (ELG) and medial (ECM) eminencia granularia. Previous studies have demonstrated that these two areas receive different nerve fiber input from lateral (mechanosensory and electroreceptive) and auricular nerve respectively. Azores of granule cells in the eminencia form a portion of the cerebellar crest that projects back over the medullary octavolateralis nucleus and modulates the activity of ascending medullary sensory neurons. The purpose of this study is to determine some of the sources of afferent input to the eminencia granularia.

Chromed catfish were anesthetized with MS-222 and a division of the eminencia granularia were labeled with either horseradish peroxidase or biot. After suitable transport times the brains were sectioned and viewed via light or fluorescence microscopy.

The bilateral eminencia granularia are heavily interconnected by commissural fibers that decussate through a deep cerebellar commissural dorsal to the cerebral aqueduct. Additional afferent arises bilaterally from the inferior olivary nuclei from two basal medullary nuclei. In the catfish the nucleus is located in the inferior olive, the other is positioned more rostrally and laterally. In the metacetohelicus both the nucleus praeminentialis and the nucleus of the medial longitudinal fasciculus provide labeled terminals to the EC.

The eminencia granularia is part of a descending central control system that provides gain control and adaptive filtering to the octavolateralis sensory systems. Our results indicate several sources of afferent input to this cerebellar region but no role in evoking networks of the SG.

The eminencia granularia is a part of the sensory system.

COMPARATIVE LOCALIZATION OF NITRIC OXIDE SYNTHASE IN THE VERTEBRATE SPINAL CORD. G. Brüning,*
Department of Anatomy, Free University of Berlin, D-14195 Berlin, Germany.

The localization of nitric oxide synthase was investigated in the spinal cord of mouse, chicken, turtle, frog and goldfish by NADPH diaphorase histochemistry. Specificity of the histochemical detection method was verified by co-localization with an antiserum against nitric oxide synthase purified from porcine cerebrum. In all vertebrate species, the motoneurons were, as a rule, unstained. Strongly stained neurons were concentrated in the dorsal horn. Widespread areas of the dorsal horn were filled by a dense terminal plexus which appeared to be formed chiefly by intrinsic neurons as dorsal root fibers were mostly negative. Internally stained neurons were also scattered in the intermediate grey and the ventral horn. In the mouse, intensely positive neurons were clustered in the preganglionic sympathetic and parasympathetic nuclei. In the corresponding cell columns of nonmammalian species, stained neurons were detected only occasionally. In summary, these results indicate that, despite certain species differences, there is a considerable conservation in the expression of nitric oxide synthase in the spinal cord, suggesting that nitric oxide may influence sensory information processing throughout vertebrate species.

DISTIBUTION OF THE SUPEROXIDE DISMUTASE 1 (SOD1) IN THE MAMMALIAN NERVOUS SYSTEM. C. Pandey*, Z.-S. Xu*, D.W. Cleveland*, and D. Price*, Departments of Pathology, Biological Chemistry, Neurology, and Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

SOD1, an enzyme participating in the free radical scavenger system, protects against oxidative stress. Recent evidence indicates that some cases of familial amyotrophic lateral sclerosis are linked to mutations in SOD1, but it is not clear how these mutations cause degeneration of motor neurons. A first step in understanding these processes is to define the cellular distributions of SOD1 in the nervous system. To this end, we have produced new specific antibodies to be used in Western blot and immunocytochemical studies. In human, monkey, baboon, rat, and mouse, SOD1 immunoreactivity (SOD1-IR) was identified primarily in neurons in the CNS and PNS. In spinal cord, SOD1-IR was present in motor neurons, interneurons, and diffusely in the substantia gelatinosa. Immunoelectron microscopic analysis disclosed that SOD1 was localized predominantly in the perikaryon, axonal and dendritic compartments, and euvacuomous areas of the nucleus, and there was evidence of different levels of SOD1-IR among cell groups. In the hippocampal formation, neurons of the CA3-CA4 sectors were intensively SOD1 immunoreactive, whereas CA1 neurons showed less immunoreactivity. SOD1-IR was also demonstrated in large- and medium-sized pyramidal neurons of roccortex, subsets of neurons in pyriform cortex, amygdala, striatum, and thalamus. These findings indicate that SOD1 is present in many neuronal populations throughout the nervous system and that certain subsets of nerve cells, including motor neurons in spinal cord and brainstem, are enriched in this enzyme.

NITRIC OXIDE SYNTHASE IN THE LOCUS COERULEUS OF THE CHICK: DEVELOPMENT, DISTRIBUTION AND LACK OF CORRELATION WITH TRANSMITTER PHENOTYPES. A. Scholer*, C. Burgard*, and C.S. von Bartheld*, Departments of Physiology & Biophysics (SJ-40), University of Washington, Seattle, WA 98195; Department of Anatomy & Cell Biology, University of Heidelberg, D-69120 Heidelberg, FRG.

The distribution and morphology of nitric oxide synthase (NOS)-containing neurons was investigated in the locus coeruleus complex (LC) of chick embryos. The NADPH-diaphorase technique was used to detect the presence of NOS at the incubation days E8, E12, E14 and 14 days posthatch (P14). The first NOS expression in LC was found at age E12. The number of NOS-positive cells in the locus coeruleus proper (LCP) increased from E12 to E18 (450 to 850) and decreased slightly after hatching (P14). In the locus subcoeruleus (LSC), NOS-containing neurons could be identified as early as E18. The number of NOS-expressing neurons increased from E18 to P14 (70 to 270). To determine which cholinergic neurotransmitter phenotype may be coexpressed with NOS, adjacent sections were immunolabeled for choline acetyltransferase (ChAT), for somatostatin (SOM) and for the low-affinity neurotrophin receptor (P75) as a marker for noradrenergic LC neurons (von Bartheld and Burgard, 1992; J.Comp.Neural. 320:479-500). In addition, NADPH-diaphorase histochemistry was combined with immunocytochemistry of P75, ChAT and SOM in the same sections. NOS is not co-localized with the P75 receptor (noradrenergic cells) or ChAT but with few cholinergic cells (10%) were double-labeled with NOS. In birds, NOS is an excellent marker for a major subpopulation of LC neurons. None of the classical neurotransmitters examined is coexpressed in NOS-positive LC neurons. These results indicate that major differences exist between species, as the rat LC contains only few NOS-positive cells (Xu et al., 1994, Exp. Brain Res. 95:154-158). The role of nitric oxide in developmental and physiological aspects of the LC in the chick brain. Supported by DHG grant Scho 489/1-1 and NIH grants NS 30305 and HD 29177.

DISTRIBUTION OF CATCHEMELIN IMMUNOREACTIVITY IN THE CENTRAL NERVOUS SYSTEM OF THE LIZARD ANolis SAGrei. A. Rehn, P. Ekström and T. Ousthilm*, Dep. of Zoology, Univ. of Lund, Sweden. Adults of the “brown anole”, Anolis sagrei (Lam., Iguanidae, order Squamata) caught in Miami, Florida, USA and juveniles obtained from our own breeding colony were used in this study. Immunohistochemical methods with antibodies against the transmitter dopamine (DA) and the synthetic enzymes, tyrosine hydroxylase (TH), dopamine β-hydroxylase (DBH) and phensylethanolamine-N-methyltransferase (PNMT) were used to locate the distribution of cathecholamine in the anole CNS. Cathecholaminergic neurons were observed in all parts of the brain. In the olfactory bulb, TH and DA immunoreactive (ir) neurons were observed in the glomerular layer and the external plexiform layer. In the telencephalon, THir neurons were seen in the nucleus septalis medialis. In the diencephalon, THir and DAir neurons were present in the periventricular preptic area, the periventricular hypothalamic nucleus and the lateral hypothalamic area. CSF-contacting neurons in the periventricular hypothalamic organ were only DAir. THir neurons were present in the posterior diencephalon. Large groups of cathecholaminergic neurons were found in the mesencephalon. THir and DAir neurons were located in the ventral tegmental area, the substantia nigra and the pretectal regions. ChAT and SOM were seen in different areas of the cerebral aqueduct. In the rhombencephalon, THir, DAir and DBHir neurons were found in the hindbrain, the nucleus of the solitary tract and in the area postrema. THir, DAir and DBHir neurons were observed in the lateral part of the reticular formation. In the spinal cord, THir and DAir CSF-contacting neurons were present in the ventral wall of the central canal. The distribution of cathecholaminergic neurons in A. sagrei is generally similar to that in previously studied reptiles (Anolis carolinensis, Gekko gecko, Varanus exanthematicus, Chameleon Cup, Pseudemys scripta elegans and Python regius). However, a number of interspecific differences were observed. Supported by grants from the Swedish Natural Science Research Council.
COMPARATIVE RESULTS

The aim of the present study was to extend our knowledge of catecholamine systems (CA) in amphibians to the gymnophonans, i.e. the gymnophonans. For that purpose, the distribution of CA neuronal structures in the permanent aquatic gymnophonan Tiphlocyclus compressuscaudatus was studied by immunochemistry for tyrosine hydroxylase (TH). The TH-immunoreactive cells of this species are located in the olfactory bulb, preoptic area, hypothalamus, pretectum, mesencephalic tegmental areas, and the diencephalon and mesencephalon. A large number of TH-immunoreactive (TH) cell groups were found. They are located in the olfactory bulb, preoptic area, hypothalamus, pretectum, mesencephalic tegmental areas, and the diencephalon and mesencephalon. Nevertheless, when the distribution patterns of TH immunoreactivity of representatives of the three amphibian orders (Anura, Urodela and Gymnophiona) are compared with each other, it is obvious that there exists a basic pattern. Moreover, the organization of the CA in Tiphlocyclus resembles the pattern of TH nerve elements in these species, which may indicate evolutionarily conserved patterns of neuronal organization.

The brains of the lizard Anolis carolinensis were either frozen in tissue freezing medium or dehydrated, cleared, and embedded in wax. Following sectioning, 5 - 12 µm, brains were incubated at 4°C for 48 h with a polyclonal rabbit-anti-human glial fibrillary acidic protein antibody (GFA-P). This antibody was raised against amino acids 341 - 367 of the amino terminal domain of human glial fibrillary acidic protein. Receptor staining was accomplished by diaminobenzidine reaction to a biotinylated secondary antibody (goat-anti-rabbit). Most immunoreactive staining was localized in cell nuclei.

The area with the greatest concentration of glial fibrillary acidic protein immunoreactive staining was the anterior dorsal ventricular ridge. This area has also been referred to as the hypopallium and hyperstriatum ventrale. The area of the pallium was seen to be the ventral margins of the lateral ventricles at the level of the optic chiasm and epiphysis. More anteriorly, dense staining was seen in the marginal layer of the dorsal ventricular ridge between the lateral and olfactory ventricles. Staining was also prevalent in the medial cortex, also referred to as the hippocampal cortex or hippocampus par dorsalis.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Neuropeptide Y (NPY), a 36-amino acid peptide, has been shown to be localized in neurons of the cerebral cortex, striatum, and amygdala of mammals. The present study examined its distribution in the forebrain of the painted turtle (Chrysemys picta). We used fluorescence immunohistochemistry to visualize the NPY cells and fibers. Sections were incubated in a polyclonal primary antibody against synthetic NPY made in rabbit (Accurate) and then in a biotinylated anti-rabbit secondary, followed by avidin conjugated to the fluorophore FITC. In the telencephalon, NPY-positive cells were found in the tuberculum olfactorium, in the medial, dorsomedial, dorsal, and lateral cortices, and in the dorsal ventricular ridge. NPY-positive cells were also found in the paleostriatum augmentum (equivalent to the striatum), in area (the septal equivalent of nucleus accumbens), and in the amygdala. Few cells were seen in globus pallidus or in the septal area. NPY-positive fibers were widely distributed throughout the telencephalon, but were especially prominent in the molecular layer of the medial and dorsomedial cortices. In the diencephalon, NPY-positive cells were seen only in the dorsal nucleus of the ventral thalamus, which is equivalent to the thalamic reticular nucleus of mammals. Fibers were present in the hypothalamus, including a dense plexus in the nucleus ventromedialis hypothalami. These results are similar to those seen in mammals, especially in the telencephalon, and together with results of studies of other nonmammals, show continuity in forebrain development during the course of evolution. Supported by NS17883 to ASP.

BRAIN METABOLISM AND BLOOD FLOW: BASIC MECHANISMS II

rCBF was measured twice in six dogs within one week. The first measurement was done while animals were sedated using Pentothal, a short acting barbiturate, 20 mg/kg and in the second Fentanyl was titrated to a maximum of 50 doses. The rCBF was measured using a modified NOVO 10a Cerebograph using two detectors on each side; the remaining detectors were shielded. Animals were sedated, endotracheally intubated & connected to the cerebograph. ECG, heart rate, respiration and tidal volume were monitored. The end tidal CO2 was kept at 35-40 mmHg. Radiolabeled Xenon (Dupon Pharmaceuticals) was mixed with low dissolved oxygen saline (LDO). Following registration of background activity for 0.5 min, a bolus of Xe was in an intracranial vein. Xe clearance was recorded throughout 11 minutes and expired air was monitored to supply the air curve. CBF results were expressed in ml/100g/min as the initial slope index between 30 and 90 sec, as CBF15 and as the fast compartment flow FI. Corrections for hemoglobin and CO2 were not instituted. Hemispheric CBF was treated as the average value of the two detectors on each side & an average for each animal was calculated. ANOVA showed a difference in rCBF between the two measurements as described in ISI, CBF15, and FI. There were no differences in PCO2, hemoglobin levels or the injected Xe

Sympathoexcitatory reticulospinal neurons of RVL are central oxygen detectors rapidly inhibited by ischemia, hypoxia, or NaCN (Sun and Reis, J. Physiol. 476:101, 1994). As a consequence, they increase sympathetic nerve activity and arterial pressure (AP) (Sun and Reis, Am. J. Physiol. 268:R245, 1994). The facts that systemic hypoxia increases rCBF without metabolism, stimulation of RVL (Underwood et al., J. Careb. Blood Flow Metab. 12:844, 1992) replicates this response, and bilateral lesions of RVL reduce, by over 50%, hypoxic vasodilation (Underwood et al., Brain Res. 635:217, 1994) suggests that hypoxic stimulation of RVL neurons may increase rCBF. To test the hypothesis, NaCN was microinjected (150 pm, 5 nl) into RVL of anesthetized rats. CN rapidly (<2 sec), site-specifically, dose-dependently and reversibly increased rCBF (measured by laser-Doppler flowmetry) to 21±6% (+0.01, n=8) and AP to 138±13 mmHg (p<0.05). After spinalization, NaCN only increased rCBF. CN also increased the numbers of cortical rCBF wave complexes (Golanov and Reis, J. Physiol. 268:R245, 1994) and excited neurons in lamina V which discharge during the negative potential of spontaneous activity (Golanov et al., Brain Res. 635:217, 1994). These results suggest that the effects of hypoxic stimulation of RVL neurons on rCBF and the activity of "vasodilator" neurons of the cerebral cortex are real. The results also support the hypothesis that hypoxic cranial vasodilation is, in part, neurogenic resulting from reflexogenic activation of a pool of cortical neurons by oxygen-sensitive neurons in RVL.

The present study examines the possible correlation between cerebrovascular vasodilator agents and generation of cGMP in guinea pig cerebral vessels. Aciotocin (ACTH), substance P (SP), nitroglucceryl (GT) and sodium nitroprusside (SNP) not only decreased concentration-dependent relaxation of basal artery segments, but also significantly increased the generation of cGMP of cerebral vessels. Neuropeptide Y (NPY) increased the generation of cGMP by 7%-45% of control levels (at 10-7-10-4M of NPY; p<0.05). In addition, NPY (10-4M) induced a transient relaxation of the precontracted guinea pig basilar arteries with endothelium. This transient relaxation was blocked by yohimbine (NOLAG 10-4M). α-Tritostol did not alter the production of cGMP. In the presence of α-tritostol NPY (10-7-10-4M) did not significantly elevate the production of cGMP. The rise in cGMP induced by AC, SP and NTG was slightly increased by the addition of NPY (3x10-5M). AC, SP and NTG induced an endothelium-dependent relaxation of the precontracted guinea pig basilar arteries, while SNP and NTG induced an endothelium-independent relaxation. AC, SP and NTG induced concentration-dependent relaxations of basilar artery, respectively. This relaxation elicited by AC or SP, but not NTG, was markedly attenuated by NPY (3x10-5M). This inhibition effect of NPY on vasoconstrictor responses was completely reversed by α-tritostol (10-4M). In conclusion, there is a close correlation between relaxation and cGMP formation induced by AC, SP, NPY, SNP and NTG. The relaxant response to AC, SP and NPY are mediated via the release of endothelium-derived relaxing factor/taurine oxide (EDRF/NO), while SNP and NTG act directly on the guanylyl cyclase. The inhibitory effect of NPY on endothelium mediated relaxation by AC and SP are not mediated via cGMP, but inhibited by α-tritostol.

RESPONSES OF CEREBRAL COLLATERAL VESSELS TO INHIBITION OF ATP-SENSITIVE POTASSIUM CHANNELS. C.A. Mazzocchi, J. Gerdes, M.G. Muhlen, S.C. Robertson* and C.M. Loftus. Div. of Neurosurgery, Unv. of Iowa College of Medicine, Iowa City, IA 52242 and Veterans Affairs Medical Center, Iowa City, IA 52246.

The mechanism of collateral vasooclusion following cerebral arterial occlusion is not completely understood. The canine cerebral vasculature was investigated for the presence of ATP-sensitive potassium channels, and effects of an inhibitor to these channels as they relate to collateral blood flow. In eight mongrel dogs a left sided craniotomy was performed with temperature controlled artificial cerebrospinal fluid (aCSF) superfused over the brain. Normal cerebral artery pressure was measured with a glass microprobe. A branch of the middle cerebral artery (MCA) was cannulated and back pressure measured. Collateral-dependent branch was identified using the "shadow flow" technique. Glibenclamide (10-5M) was added to the aCSF. Regional cerebral blood flow (rCBF) in subcortical cerebrum was measured with radioactive microspheres. Baseline blood flow to ipsilateral normal cerebrum was 98±16 ml/100g min-1 and did not change during glibenclamide. Flow to collateral-dependent tissue was 93±13 ml/100g min-1, and 68±7 ml/100g min-1 following glibenclamide (p<0.05). The attenuation of collateral blood flow was associated with a profound decrease in cannulated MCA branch back pressure. Pressure in the normal MCA branch was unchanged.

When ATP-sensitive potassium channels, which probably participate in compensatory vasooclusion were inhibited, a reduction in rCBF occurred in collateral-dependent tissue, but not in normal cerebrum. This would imply that ATP-sensitive potassium channels are involved in collateral vasodilatation following MCA occlusion, but may not be involved in maintenance of resting basal tone of cerebral arteries.

STIMULUS PARAMETERS INFLUENCE MAGNITUDE AND TIME COURSE OF OPTICAL INTRINSIC RESPONSES IN RODENT BARREL CORTEX. A.J. Blood, T.M. Narayanan, A.W. Toga. Laboratory of Neuro Imaging, UCLA School of Medicine, Los Angeles, CA 90024

Optical imaging of intrinsic signals was performed in primary somatosensory cortex of the rat during single whisker deflections of varying frequencies and durations, as well as during competitive stimulation of forelimb and whisker. A dose-response relationship was observed between whisker stimulation parameters and the intensity and spatial/temporal characteristics of the optically recorded intrinsic signal. When frequency was constant, longer durations of stimulation resulted in larger magnitude responses, as determined by pixel intensity in a statistically defined region of interest. Similarly, when duration was constant, higher frequencies of stimulation resulted in larger magnitude responses. In addition, greater numbers of deflections per trial resulted in higher magnitude responses than relatively smaller numbers of stimuli. Conversely, there were no differences in response magnitude between different combinations of frequency and duration which had in common the same number of stimuli. Temporally, there is evidence that the time between stimulus onset and peak response is influenced by frequency, with higher frequency stimulation resulting in a faster time-to-peak. Registration with certain aspects of vascular anatomy and stereotactic coordinates demonstrated that intrinsic responses were well spatially localized with both types of fiducial points. Electrophysiological recordings demonstrated that optical response regions were coincident with areas of neuronal activity, although the time course of optical responses was slower than that of neuronal firing. Finally, competitive forelimb stimulation caused decreases in whisker response magnitude, and the intensity of forelimb stimulation determined the degree to which the whisker response decreased. Thus, both whisker stimulus parameters and introduction of competitive stimuli are critical variables in determining the magnitude and/or timing of optical intrinsic responses in rat barrel cortex.

FUNCTIONAL NEURAL-VASCULAR CONGRUENCE OVER SOMATOSENSORY CORTEX. S. M. Narayanan*, A.J. Blood and A.W. Toga. Laboratory of Neuro Imaging, Dept of Neurology, UCLA, Los Angeles CA.

We examined the relationship between cerebral blood volume (CBV) and activation of primary somatosensory cortex (S-I) in the rat, using plasma-fluorescence, optical intrinsic signals and single unit recordings. Cortices of urethane-anaesthetised male Sprague-Dawley rats were exposed, and fluorescent Texas Red Dextran dye (MW 70,000) given i.v. Visual deflection or forelimb electroshock were associated with dye-related fluorescence increases over contralateral postero-medial barrel subfield or forelimb S-I. Fluorescence change foci overlay areas of increased cortical layer III cell firing on single unit recordings. Surface boundaries of even the smallest foci overspill the electrolytologic center receptive field. Larger stimuli caused fluorescence foci to enlarge considerably while the receptive field did so only slightly, increasing this spatial discrepancy. Fluorescence change was delayed and prolonged, suggesting that CBV increases at 1-1.5 s, and peaks 2.2-5 s after the onset of 1-2 s stimulation in both regions. Interleaved optical intrinsic studies revealed reflectance decreases between 550-830 nm, with similar timing and location to fluorescence increases after identical stimuli.

Thus, we observed delayed increases in vascular dye-fluorescence (related to CBV) over activated cortex. The striking similarity between optical reflectance and fluorescence suggest that changes in intrinsic cortical reflectance are strongly related to changes in CBV.

581.7

BLOOD FLOW RESPONSES IN THE RAT BARREL CORTEX DURING WHISKER STIMULATION. D. Liu, J. Dowling, M.E. Spence, C. Rovainen, and T. Woolsey*. Dept. of Neuro. and Neurosurg. Surg. of Cell Biol, Dept. of Neuro. and Neurosurg. and Univ. of Medicine, St. Louis, MO 63110.

Arteriovenous transit times (AVTTs) of 0.001% FITC-dextrans were measured by videomicroscopy through a closed cranial window to examine blood flow responses during whisker row and single whisker stimulation. During non-sensory activity during whisking, AVTTs were determined with optical imaging of "intrinsic" responses. Whiskers were stimulated at 4-5 Hz for 1 min. Whisker row stimulation produced a mean AVTT decrease of 24.0% (n=24, SD±11.61, p<0.0001), whereas single whisker stimulation resulted in a mean decrease of 16.5% (n=68, SD±9.0, p<0.0001). Single whisker stimulation produced a significantly smaller decrease (p<0.001) in vessels with different constrictions. Decreases in AVTTs could be detected within 5 seconds of the onset of whisker stimulation. Recovery to baseline values occurred with 5-10 seconds after stimulation ceased. These studies show that targeted measurement of AVTTs can be used for measurements of quantitative localized changes in blood flow in response to natural stimuli.

Supported by NIH Grant NS 27811 and HL 41074, the McDonnell Center for Studies of Higher Brain Function and an award from the Spastic Paralysis Foundation of the Illinois-Eastern Iowa District of the Kiwanis International.

Local cerebral blood flow (LCBF) and local cerebral glucose utilization (LCGU) in response to natural stimulation of the trigeminal (whisker) pathway were determined and its connectivity was studied with optical imaging and fluorescence microscopy. The LCBF and LCGU in the trigeminal (V) pathway were measured autoradiographically with [14C]iodoantipyrine and by 2-deoxyglucose respectively. Stimulation of the V nerve was elicited by: V nerve and tract; V motor root and nucleus; V spinal nuclei and principal nucleus; ventralbasal thalamus and barrel cortex. LCBF and LCGU were measured simultaneously using two methods: LCBF and LCGU in the left barrel cortex. LCGU values of various structures during whisker stimulation were highly correlated (r=0.95) with their corresponding LCBF values. The stimulated regions were indicated by close coupling between LCBF and LCGU during whisker stimulation.

Supported by NIH Grant NS 26004, NS 27811 and HL 41075, the McDonnell Center for Studies of Higher Brain Function and an award from the Spastic Paralysis Foundation of the Illinois-Eastern Iowa District of the Kiwanis International.

581.9

Blood flow increases during stimulation of single whiskers in rodent barrel cortex. The control and precision of the vascular response depends in part on the structure of cerebral vascular units: a terminal field found in efferent and venular draining those capillaries. Vascular units were demonstrated in barrel cortex by dye injection into single arterioles. Adult mice were anaesthetised and perfused with 4% paraformaldehyde in HEPES-saline from the abdominal aorta. The aim of fixation was to prevent further constriction or relaxation or reflow of parenchymal elements. Blood vessels were visualized by steady perfusion at 60cm H2O with 1% Propidol Red in 150mM NaCl. Single generating 7-23 mm arterioles were impaled with glass micropipettes and injected with 0.4% Patent Blue or 2% FITC-albumin. Injected markers emerged in 1-7 mm vessels. Vascular units were defined as the polygon of the injected arteriole and its emerging vessels at the pial surface. Arteriolar domains were approximately the same size as projected layer IV barrels stained for cytochrome oxidase but formed independent maps. Portions of arteriolar domains overlapped, and the distribution of internal capillary 10-500um diameters. The injections of internal arteriolar branches may clarify the structure of finer capillary modules in somatosensory cortex.

Intrinsic cortical responses were examined over the rat barrel cortex during continuous whisker stimulation. Videomicroscopy through a closed cranial window was recorded before and during whisker stimulation of C-row and single whiskers. After 4-5 Hz for 10-50 min. Computer analysis of these recordings and of "live" images revealed "intrinsic" responses localized to the appropriate areas of barrel cortex by local histology. Responses remained localized to these areas up to 10 min, but subsequently appeared to spread. The quality of images constructed from video recordings was comparable, though slightly inferior, to live images. These studies demonstrate that "intrinsic" optical signals persist and remain localized for at least several minutes of continuous whisker stimulation. Video tape recording facilities subsequent analysis of "intrinsic" optical responses.

RED CELL FLUXES CHANGE WITH STIMULATION OF RAT WHISKER BARREL CORTEX. E.P. Liang, B. Gillespie, M.P. Spence, D. Lin, C.M. Reynolds, T.A. Woolver and R.E. Schmidt*. Dept. of Neurosurgery, of Cell Biology and Physiology and of Pathology, Washington University School of Medicine, St. Louis MO 63110.

Fluorescent rhodopsins (IRBCs) were used to measure blood flow changes in cerebral cortex with whisker stimulation. IRBCs (PKH2-GL, fluorescein isothiocyanate, and fluorescein beads) are long lived intravascular markers (t1/2 = 2 hours) permitting changes to be evaluated prior to, during and after controlled whisker stimulation. IRBCs were recorded microscopy through a cranial window over rat whisker-barrel cortex and were counted as they emerged from cortical vessels. "Optical intrinsic" signals were used to target activated barrel cortex; after the experiments vessels and barrel vessels were mapped by histology. Stimulation of a row of whiskers promptly and significantly increased flux draining a periactively active cortex; flux recovered quickly to baseline after stimulus termination. Vessels draining non-actively active barrel cortex have reduced or unchanged fluxes. Vessel diameter did not change. Localized changes in RBC flux were consistent with previous measurements by other methods. In contrast to plasma markers, IRBCs permitted continuous evaluations over long periods and allowed selection and detailed sampling of multiple vessels from images = 1mm2.

COGNITION IV

CORNELL UNIVERSITY

The corpus callosum (CC) can be easily visualized and measured on midsagittal magnetic resonance imaging (MRI) sections. Variations in the size of anatomically defined subregions, such as the genu, body, isthmus and splenium, have been associated with verbal fluency, language lateralization, handedness, sex, and age. In this study these subregions of the CC were measured using Witsett's method. Intrarater and inter-rater reliability estimates ranged from 0.87 to 0.94. We investigated the development of these regions in a group of 32 control children between the ages of 5.7 and 12.5 (18 boys and 14 girls) who had received the Test of Nonverbal Intelligence (TONI), mean score = 106). The area of each region was divided by the area of the total intracranial volume to correct for overall differences in brain size. After this correction, the body of the corpus callosum was the only region that was significantly smaller in girls (F1,59 = 4.62, p < 0.02). The body and the isthmus were the only regions to show a significant increase in size with age (Isthmus: r = 0.42, p < 0.02; Body: r = 0.39, p < 0.03). In girls, the size of the genu showed a trend toward correlation with the TONI score (r = 0.48, p < 0.10). In boys, none of the subregion correlations with the TONI were greater than 0.15. We are currently studying the relation between subregion size and asymmetries in association cortex. ABNORMAL CORTICAL ACTIVATION GENERATED BY SIMPLE AUDITORY STIMULATION AND MUSIC IN CHILDHOOD AUTISM. M. Zilbovicius*, B. Garreau, C. Barthelmy, P. Remy, A. Syrnes, G. Leland and Y. Sannier, SMFI, CELA, Oraey and INSERM U 316, CHU Bretonneau, Tours, France.

Abnormal behavioral and electrophysiological responses to auditory stimuli are typical of childhood autism, and may reflect an abnormal cortical processing of auditory inputs. We investigated a putative abnormal pattern of cortical activation in autistic children using an auditory stimulus (CBF paradigm. Eleven autistic children (mean age 8 ± 3.5 years) were compared to five non-autistic children (mean age 8 ± 3.5 years). CBF was measured under premedication using SPECT and 110mXenon (at rest) and 2) during simple binaural auditory stimulus (70 Hz tones, duration of 200 msec, intensity of 80 dB, frequency of one tone per second) and 3) while listening to music (Schubert piano sonata no 9). No CBF abnormality was observed at rest. The simple auditory stimulus induced a rCBF increase in the left temporo-occipital cortex in controls (+5% ± 3%; p<0.005). Listening to music induced in autistic children a rCBF increase in the right temporo-occipital cortex (+3% ± 4%; p<0.005). Autism showed a rCBF increase in the right temporo-occipital cortex (+5% ± 4%; p<0.005). Comparison between both groups revealed a significant difference in the left temporo-occipital region (p<0.005). Listening to music induced in autistic children a rCBF increase in the right anterior temporal (+5% ± 4%; p<0.001) and in the temporo-occipital region (left: +6% ± 8%; p<0.02; right: +6% ± 12%; p<0.05). Children showed a trend toward activation in the left temporo anterior region (+3% ± 5%; p<0.09). Comparison between both groups revealed a difference in the right anterior temporal region (p<0.05). Thus, autistic children seem to have an abnormal lateralization pattern of cortical activation induced by auditory stimulations, with deficient left cortical processing of short simple auditory stimuli, and increased right cortical processing of music. 582.5 VISUAL RECOGNITION MEMORY IN HUMAN INFANTS. O. Frascati* and S. de Schonen. Developmental Unit, Lab. of Cognitive Neuroscience, C.N.R.S., Marseille, France.

Visual recognition memory was assessed in 3-day-, 2-month-, and 3-month-old infants with a paired-comparison task. Infants were first habituated to a picture of a face using an infant-controlled procedure, and, after a 2-min retention interval, they were presented with the familiar face and a novel face for two retention periods of 16 sec for the youngest group and 20 sec for the oldest groups. Time spent looking at either stimulus during the two retention periods was measured and percent fixation to the novel face was calculated. At the age of 3 days and 3 months, infants looked significantly longer at the novel face (p < .01) whereas at the age of 2 months, infants looked longer at the familiar face (p < .01). These data demonstrate the presence of visual recognition memory for delays of 2 min as early as 3 days of age in human infants. In addition, the change in preferential viewing in 2-month-old infants (performance for familiar instead of novel face) suggests a discontinuity in the development of this memory system. Together with the lack of novelty preference found in amnesic patients (Mckee & Squire, 1992, J. Exp. Psychol.) and in infant monkeys with cerebral temporal lobectomies (Bachevalier et al., 1993, Neuroreport), the findings indicate that, in human neonates, the medial temporal lobe makes a critical contribution to recognition memory. These results are discussed in relation to neuroanatomical data on the maturation of the visual system and medial temporal lobe structures in human and non-human primates.

582.7 AUDITORY EVOKE POTENTIALS AND VERBAL AND SPATIAL ABILITIES IN PREADOLESCENT CHILDREN. J.J. Shurett*, D.W. Shurett, G.L. Clark, C.P. Scheffer, R.L. Chepper, T. Quinlivan, M.L. Voorhees. Departments of Neurology and Pediatrics, SUNY at Buffalo School of Medicine, 100 High Street (D6), Buffalo, NY 14203.

Evidence from both behavioral and electrophysiological studies has supported the notion that there are differences between the sexes in both anatomical/functional brain organization as well as in cognitive abilities, such as visual spatial perception and memory. Our laboratory has been exploring these purported cognitive sex differences using both neuropsychological and electrophysiological techniques. In the present study, we examined the pattern of cerebral activations across a well characterized sample of pre-adolescent males and females in order to further explore possible relationships between cognitive abilities and electrophysiological indices of cortical organization.

Boys and girls (N=15) between 8 and 11 years of age were studied. Children were determined to be prepubertal by the Tanner Scale of Puberal Development. Subjects participated in (a) neuropsychological assessment and (b) electrophysiological testing to obtain auditory evoked potentials (AEPs) to probe stimuli from Frontal, Temporal, Central and Parietal scalp sites during the performance of spatial and verbal tasks.

Subjects were categorized into high, medium, and low spatial abilities groups based on a linear combination of three behavioral measures of visual-spatial skills. Differences in AEP amplitude occurred between the high and medium versus low spatial abilities groups obtained during the performance of spatial tasks. High and medium spatial subjects showed greater amplitude AEPs as compared to the low spatial subjects. These differences were most prevalent in the parietal leads and were not seen during the verbal task. High spatial subjects, regardless of sex, showed this AEP pattern. Supported in part by NIH grant HD25718.

Previously, Kimura and Carlson (1993) reported a correlation between cognitive pattern and dermatoglyphic patterns on tasks involving spatial abilities and sex differences in performance. Specifically, both male and female subjects who had a greater number of loops in the right thumbprint compared to the left thumbprint performed better on cognitive tests usually associated with enhanced performance by males (e.g., spatial processing, math). In contrast, subjects with higher left-hand counts did better on tests frequently associated with superior performance by females (e.g., fluency, perceptual speed). In this preliminary attempt to replicate Kimura and Carlson's findings, young adult male and female subjects performed a variety of paper-and-pencil cognitive tasks and their thumbprints were examined. As expected, based on earlier work, the males, overall, had significantly more thumbprints than did the females. We also found that all subjects performed equivalently on a putative gender-related task (i.e., vocabulary). On three tests of spatial ability, however, there was a dissociation of dermatoglyphic and memory patterns. Specifically, the Children's Digits Test showed no relationship between dermatoglyphic asymmetry and performance. The Full-Memory Test showed a greater relationship between dermatoglyphic asymmetry and performance, whereas the Schaffer Task showed a stronger performance for females with right-handedness. The dermatoglyphic asymmetry was not related to a difference in memory performance. The Full-Memory Test showed a greater relationship between dermatoglyphic asymmetry and female performance, whereas the Schaffer Task showed a stronger performance for females with right-handedness. The results suggest that dermatoglyphic asymmetry may play a role in the development of spatial abilities.

582.10 SEX DIFFERENCES, SPATIAL WORKING MEMORY AND EVENT-RELATED POTENTIALS. J.M. Hoering*, S. Levine, R. You, & C. Edgar. Dept. of Psychol., Univ. of New Mexico, Albuquerque, NM 87131 and Radiology, V.A. Medical Center, Albuquerque, NM 87123.

Research on individual differences in cognitive functioning is beginning to reveal important sex differences in problem-solving strategies. It has been found that males outperform females on certain tasks that require imaginary manipulation of objects, navigating through a route, guiding or intercepting projectiles, and mathematical reasoning tasks. Females do better on tasks in which perceptual speed is important (e.g., identifying matching items). They have greater verbal fluency, are superior in arithmetic calculation, recalling landmarks along a route, and manual tasks that require fine-motor coordination. Here we report a novel sex difference. The task, based on a procedure described by Sternberg (1969), is presented in two phases. Phase 1 requires the subject to memorize an array of letters. The locations occupied by letters in an array in phase 2 is then the subject is shown single letters and is asked to identify whether the letter a) was a member of the memorized array (letter identification), or b) a letter occupied by an letter in the memorized array (location identification). Females take the same amount of time for letter identification as for location identification of a letter that is faster in the location versus letter identification conditions. This suggests that males use different processing mechanisms to solve location versus item-recognition memory tasks. Females appear to use a common processing mechanism for the two tasks.

GENDER DIFFERENCES IN SENSORY INTERHEMISPHERIC TRANSMISSION TIMES. S. Caillé and M. Lavandière*. Groupe de Recherche en Neuropsychologie Expérimentale, Univ. de Montréal, Qué., Canada.

The fibers of the corpus callosum (CC) connect the hemispheres following a rostro-caudal distribution: visual fibers course through the splenium, auditory fibers through the posterior body (isthmus) and somesthetic fibers through the anterior body. The aim of this study was to estimate the interhemispheric transmission time (TTT) in the visual, auditory and somesthetic modalities in right-handed women, given that previous data suggest a gender dimorphism favoring women in the posterior part of the CC (spleminum and isthmus). Sensory ITTs consisting of a tone at threshold, puffs of pure tones were presented to 30 normal dextral subjects (25 males and 25 females) to evaluate, visual, somesthetic and auditory ITT respectively. Results indicated that while somesthetic (13.61 ms) and visual (3.75 ms) ITTs did not differ according to gender, auditory ITTs of men (2.52 ms) and women (0.09 ms) differed significantly. This finding is cautiously interpreted as the consequence of women having a larger isthmus than men. Moreover, it offers an anatomical substrate for the reported weaker lateralization of function in women.

SEX DIFFERENCES IN NUMERICAL DENSITY OF NEURONS IN HUMAN AUDITORY CORTEX. S. F. Winblad1, I. I. Glezer2 and D. L. Kigar3. 1Dept. of Psychology, McMaster Univ., Hamilton, ON, L8N 3Z5; 2Dept. of Neurology, Univ. of Cincinnati, Cincinnati, OH; 3Dept. of Neurology, Sunnybrook & Women's Hospital, Toronto, ON, Canada.

Brain size is approximately 10% larger in men than women. This sex difference could be reflected in some microscopic difference: e.g., in the total number fibers, number or numerical density of neurons, differences have been documented in the gross anatomy of and in the cognitive functions mediated by paraietotemporal regions (Winblad & Kigar, JCN, 1992). The aim of the present study was to assess microscopic features of cytoarchitectonic area T1 (von Economo), auditory association cortex in the parietal temparate within the Sylvian fossa. The brains of 5 women and 4 men were studied (mean age = 54 and 49 yr, respectively), all selected to be of documented normal neurologic and cognitive status and consistently-right-handed. Cortical depth (D), the number of neurons in a column under 1 mm surface area through the depth of the cortex (N_D), the number of neurons per unit volume (N_v) were obtained using direct counting under the light microscope. Counts were made from 25μm Nissl-stained sections from right and left hemispheres. These three measures were also obtained for each of the 6 cortical layers. Results indicated that regardless of hemisphere, D did not differ between sexes, but N_D did by 11% (df = 7, p < .008, two-tailed t-test). There was no overlap between the sexes. This sex difference was observed for layers II and IV only. These findings suggest that sex differences in architecture and, as a consequence, possibly in neurophysiology, are mostly non- pyramidal, granular layers associated with reception and distribution of information to the cortex. Such a sex difference could have consequences for neural function and cognition.

We thank Dr. M. Colombe for his contribution in the early stages of this work. Funded in part by grants NS31984 and MRC (CA) MA-10610.

582.13  
SEXUAL ORIENTATION AND ANATOMY OF THE CORPUS CALLOSUM. A. Scammongela1, S. F. Winblad1, M. Bronkelli2, P. Stachevska3, S. Black4, G. Ouma5, M. Stonier6 and B. Buck6. 1Dept. of Psychiatry, McMaster Univ., Hamilton, ON, L8N 3Z5; 2Dept. of Medical Imaging, Medicine (Neur.) and Rad., Sunnybrook Health Science Centre, Univ. of Toronto.

An increased prevalence of left handedness (defined as not exclusive right-hand-preference) was found in gay men compared to the general population (McCormick & Winblad, Psychoneuroendocrinology, 1991). Left handedness and, by inference, hemispheric functional asymmetry, was found also to be correlated with increased cross-sectional area of the isthmus of the corpus callosum in men (Winblad & Goldsmith, Brain Res., 1991). Based on these and other findings it was hypothesized that the isthmus is larger in gay than heterosexual men even when hand preference was controlled. Eleven gay men, 10 heterosexual men matched for age and educational level, all selected to be in good health and consistently-right-handed, underwent a research MR scanning procedure specifically designed for this study. Callosal measurements were obtained from 4 mm mid-sagittal slices. Area measures of the total corpus callosum, the isthmus and other subregions were obtained. The isthmus was larger in gay men by 13% (p = .05, one-tailed t-test). Similar results were reported for the anterior commissure (Allen & Gorski, PNAS, 1992). The isthmus interconnects right and left parietotemporal regions involved in linguistic and spatial cognitive functions, tasks on which gay and heterosexual men differ (e.g., McCormick & Winblad, 1991). Our findings add to the evidence of a neurobiological factor in the origin of male sexual orientation. Moreover, our results indicate that sexual orientation is linked to functional lateralization of higher cognitive functions and may be part of a larger constellation of cortical and cognitive characteristics.

SEMANTIC INTERHEMISPHERIC INTEGRATION IN THE SPLIT-BRAIN: MORE ILLUSORY THAN REAL. Alan Kinsbourne and Michael S. Gazzaniga*. Center for Neuroscience, University of California, Davis, 95616.

Subcortical semantic transfer is strongly suggested when a callosotomy patient draws pictures that integrate the meaning of words lateralized to the separated hemispheres. In our study patient J.W. drew pictures with the left hand (right hemisphere) or the right hand (left hemisphere), with or without visual feedback of the drawing. Sometimes the presented words were conceptually ambiguous (e.g., "word" and "stool" may be drawn as a toad sitting on a stool, or as a single emergent object -- a mushroom). Results indicated that word integration (e.g., a toad sitting on a stool) occurred mainly when visual feedback was provided; hemispheric control of the ponslare as well as the contralateral response hand was observed; and emergent objects were never drawn when words were lateralized. We conclude that what might first appear as evidence of subcortical semantic integration is in fact each hemisphere drawing its own separate picture with the same response hand on the same piece of paper. Our results support the view that the evidence for interhemispheric semantic integration in the split-brain patient is not compelling. (Supported by NIH/NINDS P01 NS1778).

582.15  
THE RELATIVE VALUE OF SPEECH ARREST, READING AND REPEITION ERRORS TO DETERMINE CEREBRAL DOMINANCE FOR LANGUAGE DURING THE INTRACAROTID SODIUM AMYTAL TEST. J. Cabot, H. Roquis*, A. Toutard. Université du Québec à Montréal & Hôpital Notre-Dame, Montréal, Québec, Canada.

The intracarotid Sodium Amytal (ISA) test is commonly used to establish cerebral dominance for language (CDL) prior to surgery for intractable epilepsy. CDL determined clinically is based on a general analysis of the operative reactions during the ISA test but the respective lateralizing value of speech arrest, reading and repetition errors has not been fully examined. To address this issue, the ISA sessions of 30 (clinical CDL: 25 left (L), 2 right (R) and 3 mixed) right-handed epileptic patients, with a unilateral temporal focus, were examined retrospectively. For each patient, presence of speech arrest and dysphasic errors during reading and repetition of words and phrases were compared for L and R injections. Speech arrest was observed in 28 patients (L: 21; R: 7); L > R only; 3: L = R; 4: The presence of suppression corresponded for all patients but 2 with (mixed dominance) with the established clinical CDL. The analysis of 114 reading errors produced by the patients with a L CDL revealed the expected dissociation between neglect error (R inj.) and phonemic paraphasia (L inj.). However, morphological errors were found after both injections. In contrast, repetition errors were observed only following the dominant injection and were mostly phonemic transformations. Taken together, these results suggest that speech arrest and repetition errors are specific to the injection of the dominant hemisphere. While reading errors are not, under these findings would apply to all epileptics (e.g., left-handers, frontal focus etc.) will also be discussed.

582.16  

We examined hand size in 50 adult volunteers who described themselves as right-handers, and 50 who considered themselves left-handers. Volumetric measurements of the two hands, assessed for each subject by a simple water displacement technique, showed that right-handed individuals have larger right hands than left (mean difference = 3.5 ± 0.4%, p < 0.000001). In contrast, the hands of left-handers are much more nearly symmetrical (mean difference = 0.3 ± 0.5%, p > 0.5). Based on what is known about trophic interactions between neurons and their targets, these findings predict a corresponding asymmetry of the relevant parts of the sensorimotor system in right handers. This implication accords with preliminary studies of the human sensorimotor cortex, which show a lefthand hemispheric asymmetry in the region where hand and upper limb are represented (White et al. Nature 368: 197-198, 1994). Corresponding studies of the spinal cord show a rightward asymmetry at the level of the cervical enlargement (mean difference of the cross-sectional area of the hemisected = 6.3 ± 2.7%, n = 5; see also Nathan et al. Brain 113: 363-324, 1990). Measurements of hand size and neurosonomic asymmetry in infants could address whether these asymmetries arise from differential use or intrinsic factors.

RECOVERY OF A VIBRISSEAE-DEPENDENT BEHAVIORAL RESPONSE FOLLOWING PHOTOTHERMニック INFARCTION OF SOMATO-SENSORY CORTEX IN RATS. A.J. Parent, M.D. Magarey, A. Ferri, P.M. McCabe, W.D. Dietrich, E.J. Gage. Dept of Psychology, University of Miami, Coral Gables, FL 33124

Previous work indicates that rats trained to perform an appetitively motivated vibrissal sensory discrimination task exhibit substantial behavioral deficits following an infarction of the primary somatosensory cortex (S1). These deficits were monitored using a water maze task (goal: a six-sided cylinder, one side open) and the one-way discrimination (control: S1, experimental: non-S1). Sixteen adult male Wistar rats were trained to jump into one of the two open corners of the cylinder for a food reward, and were then tested in a water maze task until they met the criterion for escape behavior. After the training phase, rats were divided into two groups: control (n=7) and experimental (n=7). Following the training phase, the experimental group was subjected to a unilateral photothermal infarction of the S1 cortex, while the control group was subjected to a sham procedure. Post-infarction behavioral testing revealed that animals in each of the infarcted groups required a significantly greater number of days to return to criterion than did sham rats. Nevertheless, each animal eventually recovered to pre-infarct levels of responding. These results indicate that, even after a large infarct, some aspect of behavioral recovery is still possible. The mechanism of behavioral recovery requires neural plasticity in that region. Supported by AHA 93GIA60

MK-801 FAILS TO INDUCE RECOVERY FROM CHRONIC TACTILE PLACING DEFICITS AFTER UNILATERAL LESIONS INCLUDING THE ROSTRAL AND CAUDAL FORELIMB AREAS OF THE RAT SOMATOSENSORY/MOTOR CORTEX. S. Batha* and T.M. Bark, Dept. of Psych., Texas Christian University, Fort Worth, TX 76129

Previous studies have shown that unilateral lesions of the caudal forelimb area (CFL) of the rat somatosensory motor cortex (SMC) produce a transient ipsilateral somatosensory asymmetry on a bilateral-tactile-stimulation test and transient contralateral impairment in tactile-forelimb testing (lasting 14-28 days). Recovery from these deficits is facilitated by a region of the noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist MK-801 beginning 16 hrs after the lesion. The present study investigated whether a similar regimen of MK-801 would attenuate chronic deficits produced by a unilateral lesion including the rostral and caudal forelimb area (RFL) of the rat SMC. Rats received large unilateral lesions of the SMC followed by a regimen of MK-801 (1 mg/kg) beginning 16 hrs after the brain injury. In untreated control rats, no differences in tactile-forelimb placing deficits were observed, and there was no spontaneous recovery. Control rats also showed an ipsilateral asymmetry on the bilateral-tactile stimulation test that partially recovered in the 6 month postoperative observation period. Treatment with MK-801 failed to induce recovery of tactile-forelimb placing deficits but did significantly accelerate the rate of recovery on the bilateral-tactile stimulation test. These data suggest that while MK-801 may be effective in facilitating the rate of recovery from transient deficits, there is no evidence that this agent has the capacity to enhance recovery when no restoration of function is expected. Moreover, the present results indicate that an intact normal forelimb area may be involved in the process of recovery from unilateral CFL lesions because removing this structure (along with the CFL) prevents the occurrence of recovery.
583.4 EFFECTS OF SCOPOLAMINE AND MK-801 ON RECOVERY OF FUNCTION FOLLOWING SENSORIMOTOR CORTEX LESIONS IN THE RAT. B.M. Sapone*, M.R. Huang, S. Bhatnagar, and L.M. Barth, Department of Psych., Texas Christian University, Ft. Worth, TX 76120.

Following brain injury there is an excessive release of glutamate and acetylcholine which may lead to suppression of brain function and to the development of secondary brain injury. Previous research has suggested that agents which antagonize glutamatergic and cholinergic receptors may serve as neuroprotective agents and facilitate behavior that has been lost. Here, we evaluated the efficacy of treatment with MK-801 (a noncompetitive antagonist at the N-methyl-D-aspartate [NMDA] receptor) and scopolamine (an antimuscarinic agent at the muscarinic acetylcholine receptor) following brain injury, very few studies have systematically examined the "window of opportunity" for these drugs. Moreover, the effects of treatments with a combination of neuroprotective drugs are largely undetermined. The present study examined the "window of opportunity" for MK-801 and scopolamine by themselves and in combination. Rats received unilateral lesions of the frontal cortex representation in the somatosensory motor cortex (SOM) and a single injection of either scopolamine (1 mg/kg), MK-801 (1 mg/kg), scopolamine + MK-801, or saline. In addition, to the type of treatment, the timing of the drug injections was varied among groups with some animals receiving their treatments at 15 minutes, 2 hours, or 48 hours after the brain lesion. Behavioral tests included measures of forelimb tactile placing and locomotor placing. The results were that although scopolamine and MK-801 by themselves facilitated the recovery of function on some of these tasks when given at 15 minutes or 2 hours, the combination treatment provided the most consistent beneficial effects regardless of the type of injection or the behavioral test. These data support the idea that activation of both muscarinic and NMDA receptors are involved in the production of secondary brain damage and that combination treatments with antidepressants may provide the most consistent facilitative effects on behavioral recovery.

In five patients with traumatic brain injuries, we investigated somatosensory representation of the central and peripheral surfaces of the body, and the extent of central reorganization or "cortical plasticity." We administered functional magnetic resonance imaging (fMRI) pre- and post-injury. The in vivo functional anatomy of the corticospinal projections was examined by fMRI using a combination of the following techniques: 1) A non-standard "rediffusion" fMRI approach was applied using a high resolution echo-planar BOLD-sensitive sequence; 2) A T2* sensitive sequence with high spatial resolution was used in a single-slice version; 3) A T2-weighted sequence in a high resolution 3D volumetric version was used to identify the cortical landmarks; 4) A conventional T1-weighted spin-echo sequence was used to map the cytoarchitecture of the brain. The supratentorial cortical lesions were confirmed by brain imaging and neurosurgery. The patients were scanned pre- and post-injury and the results were compared. We observed a significant increase in the cortical areas which are involved in the control of the hand after injury. The changes in the cortical representation of the hand were observed in the parietal opercular region and in the frontal cortex. The results suggest that the functional anatomy of the somatosensory cortex in adults is plastic and can be modified by injury and rehabilitation.

COORDINATED SYNAPTIC AND ASTROCYTIC STRUCTURAL CHANGES IN RATS REARED IN COMPLEX ENVIRONMENTS. T.A. Jones*, N. Haerykay, and W.T. Greenough. Dept. Psychology and Neuroscience Program, Beckman Institute, Univ. of Illinois, Urbana, IL 61801.
Rats in a complex environment (EC) have larger neuronal dendritic fields and an increased number of synapses per neuron than do rats in a simple environment (SE). This is in comparison to animals housed individually (IC) or socially (SC) in standard laboratory cages. These neuronal effects are accompanied by hypertrophy and proliferation of astrocytes in the inferior olivary nuclei in layers I, III, and IV of the EC, and these effects were greater in the following months than in the following days of EC, IC, or SE housing. Stereological measures of the volume fraction and surface density of glial processes showed little change in these size categories following exposure to EC. However, there was a specific increase in the region of contact between glial processes and pre- and post-synaptic elements in EC rats, measured as the surface density of glial membrane in direct apposition to these synaptic elements. That is, glial processes become more enwrapping of synapses, an effect which may be indicative of greater involvement in synaptic activity and/or a response to elevated synaptic activity. The increased glia-synapse apposition bears a resemblance to the glial response previously reported in relation to increases in synapse efficacy (Wenzel et al., 1991). Ongoing work is assessing the possibility that structural and positional changes in presynaptic astrocytic processes occur in close temporal coordination with synaptic events. Supported by MH45321 and MH10422.

583.10
Astrocytes demonstrate dynamic experience-dependent growth and hence proliferative response in the visual cortex of rats reared in a complex environment compared to those reared in individual cages (Sirevaag and Greenough, 1991 Brain Res. 542:273-278). To further delineate the effect of experience on the growth and differentiation of astrocytes in the visual cortex, monocularly deprived rats were examined with GFAP.
Eye lid were saturated at P12. Saturated rats were assigned to one of two groups; those with sutures remaining in place until P80 (MD, n=6) and those that had the sutures removed at P75 and were allowed 5 days of light exposure (MD+/L+/n=6). A nonsensur control group P80 (CL, n=6) was used for comparison. Optical dissectors and random systematic sampling techniques were used to estimate the numerical densities (NV) of astrocytes, neurons and total glia. A stereological cytocrit intersection method was used to estimate the surface density (SGFAP) of GFAP immunopositive processes. The numerical densities and (SV) were estimated in layers 2/3, 4, 5, 6.
The NV of astrocytes was not significantly different between the three groups. Group MD had a significant (35%) decrease in the SV in layer 4 as compared to control. The ratio of SV to NV of neurons (SV/NV), an estimate of the amount of GFAP-immunoreactive astrocyte surface area per neuron, was significantly decreased in layer 4 in both monocularly deprived groups compared to control. These results suggest that early experience has a profound effect on the morphological characteristics of astrocytes in the mature brain. Supported by MH45321.

Rats given an optic nerve crush regain visual function despite a 90% loss of retinal ganglion cells. Thus, there is either restoration of information from retina to brain or there is an adaptation in that visual function occurs with less information transfer. The 2-[14C] deoxyglucose technique was used to determine local cerebral glucose use (LCGU) as an assessment of information transfer from retina to brain visual centers. Male and Long Evans rats (F344 x Wistar) were given a mild crush to the right optic nerve and LCGU was assessed 2, 9, or 22 days later. LCGU procedure was determined during stimulation with a flashing strobe-light and rotating bar pattern with or without psychostimuline (300 mg/kg, i.m.), a cholinesterase inhibitor known to activate retinocollicular pathways. Qualitative inspection of LCGU autoradiograms from rats 2 days after crush revealed a marked reduction in LCGU in the left superior colliculus, especially the superficial layer. There was only minimal restoration of LCGU at 9 or 22 days after crush, restoration was greatest in the portion of the superior colliculus adjacent to the brain midline. Quantification of LCGU according to the Sokoloff equation is in progress. These results provide evidence that visual function is restored after optic nerve crush in spite of a marked dysfunction in retinocollicular information transfer. Supported by BFMT 07 98 040.

583.12
Nitric oxide (NO) is a ubiquitous messenger in the brain. This cellular messenger has been shown to modify activity-dependent synaptic efficacy in hippocampal slices (Schuman & Madison, Science 245:1503-1506, 1991; O’Dell et al., Proc. Natl. Acad. Sci. USA 88:11258-11259, 1991). We are interested if NO is also involved in activity-dependent modifications of ocular-specific connections occurred in the visual cortex during the critical period for monocular deprivation. Eight kittens were monocularly deprived for 10 days starting at 44-46 days of age. Four of the kittens also received infusion of N-nitro-L-arginine methyl ester (NAME) into one visual cortex by an osmotic minipump while deprivation. At the end of the monocular deprivation, the ocular dominance of visual cortical cells was evaluated electrophysiologically. Our data showed that the ocular dominance histogram in NAME treated cortex shifted less than un-treated cortex. However, NAME did not completely abolish the effect of monocular deprivation. Preliminary results also showed that the effect of this NOS inhibitor on the ocular dominance shift was found in layers V-L but not in layer VI. Our results suggest that nitric oxide may play a role in modification of eye-specific connections in the visual cortex. However, the activity of nitric oxide synthase is probably not essential for the modification of the connections. Supported by EY 06474 and NS 29343.

583.13
We have recently demonstrated that inhibition of nitric oxide synthase by intramuscular injection of 30-150 mg/kg of the methyl ester (L-NAME) one hour before each training session blocks touch learning in Octopus vulgaris (Proc. Roy. Soc. London, B in press). We used discrimination between ~1 cm black plastic balls, one smooth and one rough as the learning paradigm. The balls could not be discriminated by vision alone but were readily distinguished by touch. We have now extended these studies to visual learning using discrimination between vertical and horizontal white rectangles as the learning paradigm. We have now begun a study of the effects on touch learning of intramuscular application of the NO synthase inhibitor L-NAME 10-9 to 10-5 mg/kg. After a few days this resulted in significant inhibition of touch learning. Since this inhibits heme oxygenase-2, the source of CO in brain tissue, it seems that CO, as well as NO, is necessary for touch learning. Wayne, Bonaventura and Sherm have recently shown that NO, at low concentrations, causes active extension of filopodia in neuronal cultures (Proc. Soc. Neurosci. 1993). We have shown that cytochalasin D, which also blocks filopodial extension, blocks touch learning in Octopus, so our findings suggest that filopodial extension may be essential to touch learning in Octopus. There is also some doubt when using drugs to inhibit learning as to whether the primary effect is on sensory or motor output rather than on the learning process itself. To address this question, we have shown that animals treated with L-NAME can recall a previously learned touch paradigm but cannot learn a reversal of the paradigm. This suggests that the drug acts directly on the learning process.

ABC AN ACTIVITY-REGULATED CYTOSKELETAL PROTEIN IS A BRAIN SPECIFIC IMMEDIATE EARLY GENE THAT ASSOCIATES WITH THE CYTOSKELETON. G.L. Lyford, K. Yamagami, W. Kaufmann, A. Lamanna, and C.A. Dancer* and F.F. Worley Department of Neuroscience, Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD 21205 and JS, Division of Neuroscience, Memory and Aging, University of Arizona, Tucson, AZ 85724.
To define the molecular mechanisms of neuronal plasticity, we have identified novel proteins that are rapidly regulated by neuronal activity. In particular we have isolated a novel gene, Arc, which demonstrates co-localization and interaction with the neuronal cytoskeleton. Arc was isolated by differentiating axonal growth techniques from electrically stimulated hippocampus. The message encodes for a 33KD protein that is homologous to loop 21 and 22 of the structural protein, α-spectrin. Arc mRNAs and protein are rapidly and transiently induced in response to activity. Arc mRNA induction is not blocked by pretreatment with cycloheximide. Basal arc mRNA expression shows developmental regulation with levels rising at mid-late gestation and peaking at P16. Immunohistochemistry demonstrates Arc expression is restricted to neurons with protein detected in both cell soma and dendrites. Confocal images show that Arc co-localizes with the actin cytoskeleton in the sub-membranous cell cortex. In situ hybridization after seizure shows signal in both the cellular and membrane layers of the dentate. It is likely that arc mRNA is induced not only in the cell soma but also in the dendritic tree of the granule cells. Biochemical data corroborate the evidence from sequence homology and protein localization that arc is a cytoskeletal-associated protein. At the 90% arc mRNA induction from brain that greater than 90% of Arc immunoreactivity resides in the cytoskeletal pellet which is resistant to 10M HC1 and 1% Triton x-100 washes. We have further demonstrated that Arc co-localizes with actin cytoskeleton in the sub-membranous cell cortex. Together these findings suggest that arc is a cytoskeletal-associated protein which may play a role in dendritic structural changes underlying neuronal plasticity. This work is supported by EY03974 and AG09019.

We address the problem of fast reorganizational plasticity using a protocol of simultaneous, paired peripheral tactile stimulation (PPTS), motivated by the potential of Hebb that temporal coincidence of external events are required to evoke plastic change in the reorganization in the hindbrain representation of somatosensory cortex of adult rats, a few hours of PPTS induced a dramatic reorganization that included: 1) enlargement of receptive fields (RFs) that were comprised to the RFs of the stimulated sites. Quantitative analysis of response parameters confirmed the findings: 2) RF overlap was significantly between RFs representing stimulated skin fields 3) Cortical representational areas of the stimulated skin fields were several fold enlarged and were shifted by a siphid the hindbrain representational borders. 4) Response durations were elongated due to enhancement of late response components. 5) Computer-based reconstruction of somatosensory maps revealed distortions that were selectively related to the stimulated skin sites, but the overall topography was mostly preserved. 6) All effects were fully reversible after 6 to 8 hours after termination of PPTS. 7) Response amplitudes and latencies were not affected. The implications of residual plasticity for short term plasticity in representational maps of adults are now investigated in computer simulations based on self-organizing maps. These modifications of synaptic coupling without involving anatomical changes.

GENEERATION OF A SUBTRACTED cDNA LIBRARY FROM THE CEREBRAL CORTEXES OF AN ENVIRONMENTALLY ENRICHED RAT AND A STANDARD ENVIRONMENT RAT. S. J. Brooks, D. T. Ribeiro, M. C. Diamond, and J. J. Martinez J. Jr., Department of Integrative Biology and Department of Psychology, University of California, Berkeley, CA 94720

Environmental enrichment in rats, when compared to rats housed in a standard environment, induces a number of anatomical and structural changes in the cerebral cortex including: an increase in dendritic branching (Holloway 1966, Brain Res., 2:393-396), an increase in dendritic spine counts (Globus et al. 1973, J. of Comp. Physiol., Psychol., 82:175-181), an increase in glial cell counts (Altman et al., 1974, Neurosci. 2: 411-416), and an increase in the area of cortical RNA to unique rat RNA sequences (Uphouse et al., 1973, Dev. Psychobiology 2: 171-178). Together these results suggest that changes in gene expression underlie the enrichment-induced changes in the cerebral cortex. In an effort to identify some of the up-regulated genes, we performed a cDNA library subtraction using a ten-fold excess of standard cortex cDNA. We have begun characterization of the subtracted cDNA library and to date have isolated two genes, which are differentially expressed. Preliminary analysis indicates that these genes are differentially expressed. Further analysis will include sequencing the genes and In situ hybridization with the genes in the brains of both enriched and standard environment animals. Supported by Rennie Fund to Joe J. Martinez Jr.

The nigrostriatal dopaminergic system has been implicated in the behavioral neglect and recovery seen following unilateral ablation of the of the medial agranular area of prefrontal cortex (AAGm). In this study, immediate early gene (IEG) protein products was used to examine alterations in striatal neuronal response at 5 days (neglect group) and 21 days (recovered group) after unilateral AAGm ablation. Basal and dopamine agonist-induced (5 mg/kg d-amphetamine) c-fos levels in the striatum were examined. Adjacent brain sections were reacted with antisera to ZIF268 or Jun B, and the amount of immunoreactivity in the CPu was determined through image analysis. At 5 days postlesion, basal and AMPH-induced ZIF-immunoreactive (IR) nuclei in the ipsilateral CPu were fewer in number (25-30%, p<0.03) and smaller in size (6%, p<0.03) compared to those in contralateral CPUs. For Jun-IR nuclei at 5 days postlesion, no hemispheric asysemblies in basal levels were evident, while AMPH-induced levels were reduced by 25% in the ipsilateral CPus (p<0.03). This reduction was due to both a decrease in the number of nuclei (10%) of Jun-IR nuclei. For both Fos and Jun, hemispheric asysemblies were primarily restricted to dorsolateral CPUs, the region receiving dense afferents from AGm. In contrast to the 5-day findings, all hemispheric asysemblies were significantly diminished or not evident in recovered rats (21+ days).

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Unilateral removal of the medial agranular region of prefrontal cortex (AGm) results in behavioral neglect of contralateral stimuli followed by recovery in about 3 weeks. The present study used autoradiography to examine regional alterations in striatal NMDA receptors at 5 days (neglect group) and 21+ days (recovery group) after unilateral AGm ablation. Time-dependent asymmetries in [HGLU binding in the ipsilateral caudate-putamen (CPu) were decreased by 2% at 5 days postsurgery and increased by 9% at 21+ days postsurgery (p<.05). These effects were restricted to the dorsolateral CPu, the region receiving dense afferents from AGm. Contralateral lateral striatal asymmetry binding. These results are unlikely to be due to changes in CPu neuronal density following partial deafferentation since no lesion effects on [HThiC-253 binding were evident in adjacent brain sections. These findings indicate that a partial loss of corticostriatal afferents leads to an initial reduction followed by an upregulation of striatal NMDA receptor binding, perhaps as a compensatory response to the loss of GLU input. These NMDA receptor changes may be partly responsible for the behavioral neglect and recovery and for the time-dependent alterations of striatal immediate early gene expression seen following unilateral AGm ablation (see Marshall and Vargo, this volume).

584.6 NONCOMPETITIVE NMDA ANALYTIC AND ANTIDOPAMINANE DRUGS FACILITATE BEHAVIORAL RECOVERY FOLLOWING ELECTROLYTIC LESIONS OF THE RAT CORTEX. M.R. Hantsce, D. Smith, and M. Mark. Dept. of Psych., Texas Christian University, Ft. Worth, TX. 76129.

Following brain injury due to ischemia, hypoxia or fluid percussion trauma there is an extensive release of glutamate that opens a sequence of events leading to secondary cell death proximal and distal to the initial site of damage (i.e. excitotoxicity). These events are mediated by N-methyl-D-aspartate (NMDA) receptor activation. The ability of NMDA receptor activation to mediate excitotoxicity may be attenuated by neuropeptide drugs that either prevent or limit the activation of the N-methyl-D-aspartate (NMDA) receptor by glutamate or prevent the breakdown of the cell membrane by free radical scavengers). These neuropeptide drugs may facilitate behavioral recovery by limiting the extent of secondary brain damage. The present experiment investigated the possibility that neuropeptide drugs facilitate behavioral recovery following electrolytic lesions of the cortex. Three drugs were studied: MK-801 (a noncompetitive NMDA antagonist working at the PCP binding site); magnesium chloride (MgCl2; a voltage dependent noncompetitive NMDA antagonist); and N-tetra-hexyl-phenyliprione (PB; an antioxidant and free radical scavenger). Rats received the anesthetic sensorimotor cortex (SMC) and a regimen of MK-801 (1 mg/kg), MgCl2 1 mmol/kg), PBM (100 mg/kg) or saline beginning 15 min after the lesion. The rats were tested on a locomotor placing task. Saline treated animals showed the expected severe impairment in placing the contralateral forelimb during locomotion on the grid floor. In contrast, rats receiving, MK-801, MgCl2 or PBM showed a reduction in the magnitude of the initial deficit as well as an acceleration of recovery. These results suggest that neuropeptide drugs identified in models of ischemia and traumatic brain injury have the expected behavioral effects in an electrolytic lesion model. Moreover, they suggest a process similar to that of excitotoxicity may occur following electrolytic brain lesions causing transneuronal degeneration in areas distant from the lesion site.

There are several reports of dendritic reorganization following neural injury in adult rats. We have found that prefrontal, cingulate, and motor cortex lesions all lead to a chronic increase in dendritic arbor in parietal cortex ipsilateral to the lesion. Jones & Schallert (1992) also found increased dendritic growth in the normal hemisphere of rats with unilateral motor cortex lesions, and they correlated this with behavioral asymmetry. In contrast, we found that large unilateral strokes result in chronic changes of dendritic arbor ipsilateral to the lesion and no change in the normal hemisphere, in spite of a large behavioral asymmetry. The presence or absence of dendritic growth following these lesions may be due to differences in dendritic reactivity, to differences in motor behavior, or to differences in dendritic reorganization. We therefore made unilateral motor cortex lesions of varying sizes and at different ages throughout the lifespan and measured behavioral asymmetry. Animals were sacrificed at different postoperative intervals for GFAP, bFGF, vimentin, synaptophysin, and OX-42 immunohistochemistry, or Golgi-Cox analysis.

Dendritic change was related to age, the magnitude of the astrocyctic reaction, and lesion size, but we found no relationship between behavioral change and dendritic growth in the normal hemisphere.

584.8 TACTILE STIMULATION ENHANCES RECOVERY AND DENDRITIC GROWTH IN RATS WITH NEONATAL FRONTAL LESIONS. Bryan Kolb*, Grazyna Gorny and Robbin Gibb. Dept. of Psychology, University of Lethbridge, Lethbridge, Canada, T1K 3M4.

Rats were given medial frontal lesions or sham operations on postnatal day 4. Beginning on day 5 the animals were given 15 min of tactile stimulation with a small paintbrush three times a day until weaning at day 21. At 60 days the animals were trained in the Morris water task and the Whishaw reaching task. The behavioral results showed large behavioral deficits in lesion animals relative to normal control rats. These deficits were significantly attenuated by the stroking. At the end of testing the brains were processed for a modified Golgi-Cox stain or immunohistochemistry. Frontal lesions reduced brain weight and decreased dendritic reactivity, but there was no significant correlation. The tactile stimulation significantly reversed these effects, with the effects being larger in female than male rats. Spine density was decreased by tactile stimulation in both normal and operated rats. GFAP, OX-42, and synaptophysin immunohistochemistry is in progress. Overall, the results suggest that tactile stimulation during infancy may modulate the effects of perinatal cortical injury and may affect synaptic development in the normal brain.

It has been proposed that the cholinergic system plays a critical role in learning and memory (Deutsch, 1971, Science 174:788-794; Bartos et al., 1985, Ann NY Acad Sci 444:332-358). In support of this hypothesis are data demonstrating that cortical cholinergic hypofunction correlates with cognitive deficits in humans (Perry et al., 1978 Br Med J 1:149-151; Wolk et al., 1982 J Neurosci 2:427-439). In the present study, injections of choline into the basal forebrain have been used to further explore the relationship between cholinergic and behavioral function. Bilateral injections of coenzyme (3 ul AU/0.4 ul saline) or vehicle (0.4 ul saline) were made in the nucleus basalis magnocellularis (NBM) of male Long-Evans rats (n=12/group). Four weeks post-lesion, behavioral assessments were made for one-half of the rats in each group. Five weeks post-lesion, the rats were sacrificed, and ChAT activity was measured in several brain regions. The second half of the rats were tested behaviorally 11 weeks post-lesion and sacrificed twelve weeks post-lesion. Five weeks post-lesion, there was a significant decrease in cortical ChAT activity and passive avoidance cross-over latency and a deficit in the acquisition rate of a water maze task. Twelve weeks after cochlicine infusion, ChAT activity in the motor cortex of the lesioned side was not significantly different than vehicle-infused rats, although a significant decrease was seen in the passive avoidance cross-over latency. These data suggest an association between time-dependent changes and recovery of a water maze learning task. In contrast, the passive avoidance task had an equivalent deficit at both timepoints. In summary, these data show task-specific behavioral recovery associated with time-dependent recovery in a specific regional cholinergic marker.

584.10 BEHAVIORAL EFFECTS OF BILATERAL CORTEX LESIONS ON REACTION-TIME PERFORMANCE IN THE RAT. C. Bauer, P. Gulin, A. Nicollin and M. Amatric*. Cellular and Functional Neurobiology Laboratory, ENRES, 13402 Marselle cx 9 (France).

There is substantial evidence that suppression of cortical projections enhance striatal dopaminergic activity. Cortical ablation however does not result in obvious motor deficits on spontaneous behaviors. The effect of a bilateral cortical lesion upon reaction-time was thus studied in a conditioned motor task known to be sensitive to striatal dopaminergic activity. Rats were trained to depress and hold a lever until the presentation of a visual conditioned stimulus (CS) and then to release it with a reaction time (RT) of less than 500 ms for food reinforcement. Cortical lesions were performed by thermocoagulation of fronto-parietal areas. Such lesions are known to induce a progressive degeneration of the cortical layers. The animals were tested daily from day seven to thirty-five post-lesion. A dramatic short-lasting increase in the number of delayed responses (over 500 ms), recovering after 20 days, could be observed in the reaction-time task. This effect was classically considered as a motor impairment. In contrast, a significant increase in number of anticipated responses (premature release of the lever before the CS) was observed throughout the 35 days of testing. These results show that an extensive lesion of the fronto-parietal cortical areas induced a mixed effect with different time recovery. The long-lasting effect on anticipated responses could be related to the effects produced by a dopaminergic hyperactivity in the striatum. The short-lasting effect on delayed responses is suggested to result from damage of the direct motor pathways following extensive cortical lesions that are rapidly compensated by other mechanisms.
584.11 THE CONTRIBUTION OF TASK-SPECIFIC EXPERIENCE TO THE AMPLITUDE-INDUCED FACILITATION OF RECOVERY IN RATS WITH CORTICAL DAMAGE. T.D. Schmahmann, L.L. Bowerman, and T.M. Barth, Dept. of Psych., Texas Christian University, Ft. Worth, TX 76129.

In an early study it was shown that amphetamine facilitates the recovery of beam-walking after brain injury. However, no motor cortex damage (MCD) was only if the animals receive task-specific practice while under the influence of the drug. More recently it has been suggested that amphetamine and practice have independent effects on recovery of beam-walking. The present study evaluated the effects of amphetamine and practice on the recovery of tactile forepaw placing after unilateral MCD lesions. The behavior was chosen because amphetamine facilitates recovery from placing deficits even though the animals do not show placebo reactions during the time of drug intoxication. If task specific experience has a role in the facilitation of recovery it does not require the execution of the motor response while under the influence of the drug. 1) training with amphetamine (2 mg/kg) was given to six groups to effect recovery. Four groups were used: drug + practice (dp), drug - no practice (dp), saline + practice (sp), saline + no practice (sn). The dp group showed the fastest rate of recovery. Statistical analyses showed that there were main effects for drug and practice but no significant drug x practice interaction. These data suggest amphetamine and practice have independent effects on recovery of tactile placing. Two groups were selected to isolate the type of experience necessary to facilitate recovery of forepaw placing. Unilateral MCD damaged rats were given amphetamine and assigned to one of four different groups: practice on the contralateral side only, practice on the ipsilateral side only, hanting and no practice. The results were that rats receiving either ipsilateral or contralateral experience during the period of drug action recovered significantly faster than animals receiving no practice. These data suggest that task specific somatotopic stabilization on contralateral or ipsilateral control and motor experience on the task facilitate recovery of tactile placing.

Recent experiments revealed rapid reorganization of the cortical representations of the primary somatosensory area in young adult rats following intracortical (ICM) and intrathalamic (ITM) microstimulation (R1Casoni et al. 1992a; 1992b; 1993a; 1993b; 1994a; 1994b). While there is a substantial body of information on the reorganization at a cortical level, little is known about the nature of subcortical plasticity. The present study investigated the contribution of the thalamic ventral posterolateral nucleus (VPL) to the cortical reorganization elicited by ICMS and of the reorganization of the somatotopic representation in this thalamic nucleus induced by direct intrathalamic microstimulation (ITMS). The experiments were performed in adult rats weighing 180-220 g. Unilateral VPL neurons within the hindpaw representation in SP and in VPL were recorded with glass microelectrodes. Microstimulation was applied at a local cortical (ICMS) or thalamic (ITMS) site for 5-7 seconds. All experiments were recorded with the 18 Hz stimulation frequency. The data showed that ICMS and ITMS induced significant changes of VPL activity in the thalamus. While ICMS induced an increase of VPL discharge rates with no significant spatial changes in the skin representation, ITMS elicited changes in the somatosensory map at the VPL site. However, the changes are small compared to those described for ICMS, suggesting that this type of fast plasticity is a predominantly cortical phenomenon.

Suggested by Coordenadoria de Apoio ao Avanço de Recursos (CAPES-Brazil).

A fundamental issue in quantitative neuropathology is the extent to which processing of sensory information affects the complexity of dendritic trees. To study this, the basilar dendrites of supragranular pyramidal neurons in the human superior temporal and occipital association cortex (prefrontal, area 10) were compared with those in primary and secondary visual cortex. Neurons obtained from the left hemisphere of 5 neuropathologically normal subjects were fixed with a modified rapid Golgi technique. Quantification of 100 neurons (10 neurons per tissue block) was performed using the Neurolucida system (Microbrightfield, Inc.) according to accepted criteria (Jacobs & Scheibel, 1993, J. Comp. Neurol., 327, 83-96). Dependent measures were total dendritic length (DML), mean dendritic length (MDL), dendritic spine density (DS2), dendritic surface area (DSD), and total dendritic volume (TDV). A distinction was also made between proximal (1st, 2nd, and 3rd order) and the more distal portion of the dendritic tree (3rd order and above). The results indicated that in the prefrontal cortex, neurones in area 10 consistently exhibited higher TDL (19.8%), DSC (19.9%), and DS2 (11.6%) values than those in area 18. However, the overall distribution was similar between both cortical areas for TDL, DSC, and DS2, but distal segment MDL was an average of 7.6% greater than proximal segment MDL, which is consistent with Jacobs et al. (1993). J. Comp. Neurol., 217, 97-111). An order by order analysis of the dendritic envelope revealed that differences between the two cortical areas were most pronounced in 4th order dendritic segments. Significant age-related decreases in TDL, MDL, and DS2 were also noted. This finding of greater dendritic scropl in area 10 over area 18 provides tentative support in humans for the notion that dendritic system complexity reflects the computational demands placed on those systems. (Supported by grants from the National Science Foundation to DW and NS25742 to DFC.)

584.14 LEARNING INDUCED PLASTICITY OF CORTICAL MAPS - LACK OF CHANGES IN REPRESENTATIONS OF ADJACENT, UNSTAINED SENSORY RECEPTORS. M. Koonsnatt and S. Snulcik, Dept. of Neurophysiology, Neuroklinika, Naujoji Val. 34, LT-02133, VILNIUS, LITHUANIA.

Sensory training is known to produce an enlargement of cortical representations of receptors activated during the training (Jenkins et al. 1990; Rencane et al., 1992; Weisberger et al., 1993). Increase of cortical representations of trained receptors was accompanied by a decrease in extent of adjacent representations of receptors not involved in training. We have previously demonstrated that short lasting classical conditioning involving stimulation of vibrissa resulted in enlargement of vibrissal cortical representation. In the present experiment we examined if the enlargement of the trained row B of whiskers representation takes place at the expense of neighboring, untrained rows. During training stimulation of row B was paired with electrical irritation of the tail. Four pairings per minute were repeated for 10 min, a day for 3 days (altogether 130 pairings). A day after completion, 2-deoxyglucose mapping was performed, in which cortical representation of the trained row B and control row B on the other side of the snout were visualized. As we have shown previously, representation of the trained row B was enlarged by 45%, expanding into territories of row C and A. In another group of animals we examined if cortical representation of rows A and C bordering the trained row B, are narrower than usually. Analysis of 2DG autoradiograms revealed that labeling induced by stimulation of rows A and C is not decreased either in area or in intensity compared to control. The cortex corresponding to the trained row B representation (asundimented during 2DG mapping) showed higher labeling than on the control side. The results indicate that training-induced expansion of row B representation is a dynamic phenomenon, where regions of cortex are activated by a new input without loosing normal reactivity to the old one.

The purpose of this study was to determine whether peripheral nerve grafts in the CNS can promote axonal regeneration resulting in behavioral recovery. Fourteen rats received bilateral knife-cut lesions of the fibria-fornix. Eight of the animals also received a sciatic nerve transplant placed between the septum and hippocampus. Four animals served as normal controls. Beginning 2 weeks after the transplant procedure, all animals were tested on a delayed-response alternation task and the Morris water maze. Testing continued for 2 months. Both experimental groups were significantly impaired on the spatial tests compared to the normal group throughout testing. Moreover, preliminary analysis of the results indicate that the sciatic nerve transplants had no facilitating effects on spatial performance.

Correlations between cholinergic innervation and behavior are currently being conducted.

RHEB, A RAS HOMOLOG ENRICHED IN BRAIN, INTERACTS WITH RAFI SERINE/THREONINE KINASE IN AN ACTIVITY-REGULATED MANNER. W. M. Yee1, A. Lanahan1, and P.F. Worley1. Department of Neuroscience, Sch. of Medicine, Baltimore, MD 21202.

It has been postulated that production of specific gene products in response to neuronal stimulation is required for the establishment and maintenance of neuronal plasticity. In our efforts to characterize activity-regulated gene products associated with neuronal plasticity and long-term potentiation (LTP), we have isolated and characterized Rheb, a novel Ras homolog enriched in brain that is induced by LTP and seizure stimuli and is regulated as an immediate early gene. Rheb is also induced by NGF, EGF, and FGF in neuronal cell lines and is enriched in the granule cell layer of the hippocampus following neurotransmitter stimulation. Rheb shares a high level of homology with human H-Ras and yeast RAS1 in conserved domains required for GTP-binding and hydrolysis, and appears to be a functionally close relative of human H-Ras as determined by Rheb's ability to transform mammalian cells.

In order to characterize Rheb's physiological role in neurons following neuronal stimulation, we have utilized the yeast two-hybrid system of identifying protein-protein interactions to isolate upstream and downstream interactors of Rheb. We report here that Rheb interacts with Raf1, a serine/threonine kinase required for the oncogenic activity of human H-Ras. Using an in vitro co-precipitation assay, we have confirmed that Rheb interacts with Raf1 kinase isolated from the hippocampus and cortex of postnatal day 21 rats. In addition, we have experimental evidence suggesting that the interaction between Rheb and Raf1 may be regulated by neuronal activity. This line of evidence suggests that Rheb may be acting as an activity-regulated "molecular switch" that activates Raf1 serine/threonine kinase following depolarizing stimuli or neurotransmitter binding.

VARIABILITY OF POPULATION SPIKE AMPLITUDE IN LONG-TERM POTENTIATION IN BEHAVING RATS. S.J. Jones1, D. Moore2, and M.E. Corcoran3, 4. Dept. of Psychology, University of Victoria, POB 3050, Victoria, B.C., Canada, V8W 3P6.

Although long-term potentiation (LTP) has been postulated to be a mechanism of learning and memory, relatively few investigations of LTP have been performed in awake rats carrying chronic electrodes, and, of those, large variation in the amount of LTP has been observed across laboratories. To study factors influencing LTP, we measured the amplitude of the population spike (PS) evoked in the dentate hilus by stimulation of the medial thigh over the posterior paw in awake rats that had undergone hippocampal recording. In Experiment 1, LTP was induced in 1 group with high chemodenervation infusions of acSF, in another group with chemodenervation but no infusions, and in a third group with electrodes. The electrode group received greater gain than the chemodenervation group. Experiment 2 tested the effects of behavioral state on LTP. Data from 1 group were collected only when rats were immobile; data from group 2 were collected irrespective of ongoing behavior, and rats were in Experiment 3 tested the possibility that the saline injection may have suppressed LTP at 60 min after test, to mimic conditions of drug administration. No LTP was observed in either group at 60 min post-injection, whereas significant LTP was observed 24 hr post-injection. In Experiment 4, only group 2 exhibited significant LTP whereas both groups showed no LTP at 24 hr. In Experiment 4, 1 series of tetanic stimulations was applied each day for 9 days. Significant LTP was observed only after session 2 and asymptoted after session 6.

We conclude that the magnitude of LTP is affected by the presence of the chemodenervation and by prior injections and that induction of LTP is more reliable with multiple sessions of tetanization. (Supported by NISER)

Fleeting changes of neuronal activity produce a lasting reorganization of synaptic connections in developing and mature mammalian nervous system. Activity-dependent interactions also contribute to a formation of abnormal synaptic connections in the mature nervous system. Expression of the immediate early gene, c-fos, has been postulated to link fleeting changes of neuronal activity to lasting modifications of neuronal function and structure in the mammalian nervous system. To test this hypothesis, we examined behavioral and electrophysiologic indices of kindling development and kindling-induced sprouting of hippocampal granule cell axons in wild type (+/+), heterozygous (+/-), and homozygous (-/-) mice null mutant of c-fos. Defects of both electrophysiologic and behavioral features of kindling development were evident in null mutants. Kindling-induction of granule cell axon sprouting measured by Timm staining was significantly attenuated in null mutants compared to +/+ mice with intermediate values evident in +/- mice. We conclude that c-fos is necessary for both normal development of kindling and complete expression of kindling-induced synaptic reorganization of granule cell axons. We suggest that the null mutation of c-fos produces this phenotype by altering seizure-induced transcriptional activation of target genes.

A NOVEL PROTEIN REGULATED BY SYNAPTIC ACTIVITY IN VISUAL CORTEX AND HIPPOCAMPUS. P. R. Brahman4, A. Lanahan5, and P.F. Worley1.

1Dept. of Neuroscience and Neurology, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21202.

A novel activity-regulated developmental immediate-early gene (Ar62) was cloned by differential screening of a rat hippocampal cDNA library. Ar62 encodes a brain-specific 6.5 kb RNA with a 186 amino acid active reading frame that is not homologous to known proteins. Sequence analysis predicts that Ar62 has multiple phosphorylation sites, but no glycosylation sites. Antisera raised against a bacterial fusion protein containing the 186 amino acid open reading frame recognizes a single 28 kd band in HEK 293 cells transiently transfected with an expression construct containing the open reading frame and a 28 kd doublet in rat hippocampus. This 28 kd doublet is rapidly induced in hippocampal follower seizure with a maximal induction at 4 hours. Fractionation of hippocampal tissue shows that Ar62 is primarily cytosolic, but not nuclear, and also is associated with the membrane fraction. Northern blot analysis shows that Ar62 is induced in hippocampus within 30 minutes following seizure and is super-induced by pre-treating with cycloheximide. In situ hybridization studies show that Ar62 is strikingly inducible in visual cortex. Exposing dark-reared rat pups to light dramatically increases Ar62 mRNA in visual cortex, and unilateral intracocular injection of TTX reduces basal expression of Ar62 in the contralateral visual cortex. A role for Ar62 in synaptogenesis is suggested by the redistribution of Ar62 message in cortex during a critical period of exophytic synaptogenesis in the second post-natal week in rats. The distribution of Ar62 changes from a diffuse cortical distribution in day 10 rats to a specific localization in cortical layers II and V in day 14 rats. In addition, Ar62 is strongly induced in dentate gyrus in an NMDA-dependent manner following a high frequency LTD stimulus. Ar62 is a novel protein regulated by synaptic activity in cortex and may be involved in cortical synaptogenesis. Supported by EY08547.

DEHYDROEPiANDROSTERONE SULFATE INCREASES PS IN DENTATE GRYUS LTP IN INACT RATS. A. Yoo1, J.Harris2, and B.Bubryowa3. Dept. of Physiology, McGill University, Montreal, Quebec, Canada H3A1L1.

Dehydroepiandrosterone Sulfate (DHEAS), a neurosteroid secreted by both the adrenal cortex and the glisa, has been shown to behave as a non-competitive antagonist of the GABA receptor which exerts a inhibitory effects on LTP development when activated. Thus, it could be hypothesized that DHEAS would enhance LTP formation. Experiments were performed in intact anesthetized rats (1,5mg/kg). Electrodes were stereotaxically positioned in the perforant path (bifocal for stimulation) and in the dentate gyrus (monofocal for recording). DHEAS (20 mg/kg) was injected in the femoral vein, dissolved in Nutralipid 10% which served as control injection. Our data showed that after hormonal treatment primary tetanic stimulation (8 trains of impulses, total duration of 1 sec, train rate of 0.03 Hz, frequency of 350 Hz and pulse duration of 500 microsec each half wave), the amplitudes of the population spike (PS) increased approximately 2 fold over the ones from control experiments. In contrast, slopes of EPSP were shifted towards shorter durations with the hormone. The results, consistent with the work of Heyer et al.(1993) in CA1 area of rat hippocampus, suggest that hormonal compounds could differentially affect selected neuronal loci.

REWARD-SCHEDULE EFFECTS AND GRANULE CELL NEUROGENESIS IN THE DENTATE GYRUS OF THE RAT
G.L. Eppig* , A. Avoli† , J.A. Gage . Dept. of Psychology & Inst. for Neuroscience, University of Texas, Austin, TX 78712
Granule cell neurogenesis in the rat dentate gyrus has been shown to continue well into adulthood, although peak neurogenesis occurs at the end of the first postnatal week. We recently examined the effect of a number of kinds of learning on granule cell neurogenesis in 11-12-day-old pups (Eppig & Avoli, Soc. Neurol. Neurosci., Abst., 1993). No significant training effect was found, but there was a significant effect due to handling. The experiment has now been replicated with 17-18-day-old pups. The pups were trained for 5 sessions (3 session per day). 30 trials per session. There were 3 groups defined by reinforcement schedule: continuous reinforcement, partial reinforcer, or reinforcer in a pattern of single alternation (PSA). A hippocampal stimulation training, but was put through all other specific aspects of handling in the training situation. A fifth group was an unhandled control: no handling and no training. At the end of each of the 2 training days, pups from all groups were injected intraperitoneally with Methyl-β-HTHThymidine (activity 2Ci/mmol, SmCign w/v) in order to label newly forming cells. Coronal brain sections were coated with Kodak NTB-2 emulsion, exposed, developed, and then counterstained with cresyl violet. Computer-assisted counts revealed no significant differences among all five groups including no handling effect. At 17 days of age, rat pups can learn PSA only at an 8-second ITI. To test the possibility that neurogenesis of granule cells in the dentate gyrus is influenced only at long ITIs, the first 11-17 day-old experimental groups are being replicated with longer ITIs. Data are also being collected on the effects of postnatal handling administered by artificial rearing from days 4 - 9. Supported by NIAAA grant AA07052.

585.10
Growth-associated protein-43 (GAP-43) is a nervous system-specific phosphoprotein whose expression is correlated with axon growth during regeneration and development. We are interested in the involvement of GAP-43 in axon elongation and branching in the developing nervous system. Using a model of selective ablation of the dentate gyrus (DG) of the hippocampus, and subsequent growth and reorganization of the denervated areas by other afferents projecting to the DG. Preliminary data suggest that the sprouting response induced by electrolytic and aspiration methods may be qualitatively and quantitatively different. While under nebulized anesthesia (50 mg/kg), the right EC is lesioned (aspiration or electrolytic) in male Sprague-Dawley rats. The animals survive for 2, 6, 15, or 30 days before sacrificing. The brain is removed, embedded, sectioned, and then immunoreacted with GAP-43 or GFAP antibodies. Following electrolytic lesions of the EC, the inner molecular layer of the DG expands to a greater width than following aspiration lesions as evidenced by GAP-43 immunoreactivity of brain sections. In addition, astrocytes are more immunoreactive with GFAP antibodies indicating a more robust gliosis following electrolytic lesions than after aspiration lesions. We are currently investigating other differences between the two types of lesions in generating a sprouting response in DG. We postulate that in DG, the various types of nerve cells discharged during the electrolytic lesion may recruit anionic pathways and the ECM utilizes a variety of mechanisms to reorganize the DG.}

SYSTEMIC ADMINISTRATION OF NALOXONE AFFECTS EPSP-SPIKE COUPLING IN LONG-TERM POTENTIATION OF THE LATERAL PERFORANT PATH. R.D. Kirkby*, C.B. Bramham, and J.M. Sarvey. Department of Pharmacology, Uniformed Services University, Bethesda, MD 20814
Previous research suggests that activation of opioid receptors is necessary for the induction of long-term potentiation of field responses evoked in the dentate gyrus by electrical stimulation of the lateral perforant path, the terminals of which may release both glutamate and opioid peptides. To further assess the role of opioid receptors in long-term potentiation in this pathway, we systematically administered naloxone (10 mg/kg; i.p.) 60 min prior to tetanic stimulation of the lateral perforant path in urethane-anesthetized adult rats. Tetanic stimulation consisted of 10 trains (60s intertrain interval) of 8 pulses (200 Hz; 400 Hz).
Contrary to expectation, naloxone- and saline-treated rats demonstrated similar increases in the initial slope of the excitatory postsynaptic potential (EPSP) recorded in the hilus. On the other hand, the magnitude of the population spike as a function of the slope of the EPSP after tetanus was somewhat smaller in rats treated with naloxone. The findings may shed light on the participation of opioid receptors in synaptic plasticity in the lateral perforant path. Supported by NIH NS32885.

585.12
We present a kinetic model of associative Long-Term Potentiation (LTP) in the hippocampus. We used an extension of a previous work on simulation of LTP (M.Ayala and G.F.Ayala, Neur. Comp. 5, 103 (1993)) to implement the two populations of synapses activated by a weak (W) and/or a strong (S) afferent pathways to the same hippocampal dentate region. The model was fine tuned with good agreement with experimental data on the associative properties of LTP and its modifications when using different protocols of stimulation. The model suggests a possible interpretation of the experiments in terms of molecular processes and a possible key role of retrograde messengers in the induction of associative LTP. In particular, the model suggests that the associative properties of LTP could be explained in terms of the modulating effects by the retrograde messengers on the coupling mechanisms between the W and S pathways. Two possible modes of coupling the two pathways have been tested with this model: one pre- and one post-synaptic, and both are in good qualitative agreement with experimental data.

585.13
We propose a kinetic model that suggests an interpretation of experiments in terms of the molecular processes that control the induction and maintenance of Long-Term Potentiation (LTP) and Long-Term Depression (LTD). The model suggests that LTD and LTP could be maintained by two similar but distinct autocatalytic processes activated by the same class of retrograde messengers. In particular, we propose that these two processes could interfere with the normal synaptic transmission mechanisms, increasing (LTP) or decreasing (LTD) the amount of neurotransmitter released at each stimulus. We present simulations of the effects of application of inhibitory retrograde signal production such as L-NAME and ZnPP, and application of Nitric Oxide scavengers, such as Hemoglobin. Simulations' results suggest an explanation of the experimental findings that retrograde messengers are infiiuent to maintain LTP or LTD, whereas an appropriate level of retrograde signal is needed to induce or maintain LTD and/or LTD during tetanic stimulation.

585.14
We have previously demonstrated changes in the hippocampal immunoreactivity for mAChRs and PCKy after spatial learning (Van der Zee et al., J. Neurosci., 1995). In the present study we determined whether 500 msec trace eyeblink conditioning induces changes in mAChR- and PCKy in the hippocampus. Young adult (3 months) female NZW rabbits were trace conditioned (3x2) and behaviorally naive animals (n=8) served as controls. 24 Hrs after a rabbit reached the 80% criterion or after the 15th day of training, the animals were transectedally perfused with 2.5% paraformaldehyde + 0.025% glutaraldehyde. Free-floating sections were immunostained for mAChR- and PCKy. In the hippocampus, only moderate levels for mAChR- and PCKy were observed for mAChR- and PCKy in control animals were determined to be the same in naive and trace-avoided animals. One animal only reached 40% CR's showed similar changes for mAChR- and PCKy, whereas the conditioning animals showed a variable effect for mAChR- and PCKy. These results demonstrate protein-selective changes in the hippocampal principal cells in trace eyeblink conditioned rabbits which may underlie the accompanying behavioral and electrophysiological changes. (Supported by the Netherlands Organization for Scientific Research (NWO) to E.A. and by NYU R01 MH47340 and R01 AG058796)

Neurofilaments (NF) are cytoskeletal proteins which play a fundamental role in neuronal morphology and axonal transport. Enhanced neuronal connections are formed during learning. However, it was previously reported in relation to learning and memory in the brain. In the present study we determined whether the immunoreactivity (ir) for the low subunit NF changes in the hippocampus during acquisition of trace eyeblink conditioning. A hippocampus-dependent task. Young (3 months) female NZW rabbits were trace conditioned (n=8), Pseudoconditioned (n=8) and behaviorally naive animals (n=6) served as controls. 34 hrs after the rabbits reached the 80% criterion, or was trained for 15 days, the animals were transcardially perfused with 2.5% paraformaldehyde. Free-floating cryostat sections were immunolabeled with a phosphoprotein-dependent (88kD. Sigma. NR4) or a phosphoprotein-dependent (NDK. Chemicon. MAB1615) anti-NF antibody. No gross changes in staining-intensity were found for either antibody in the principal cells or interneurons between the different groups. However, trace conditioned rabbits showed a twofold increase in fiber density for NR4 in the stratum oriens, and approximately a 50% decrease in the number of fiber crossings for MAB1615 was found in the stratum radiatum as compared to pseudoconditioned and naive animals. The increase for NR4-ir most likely results from an increase in NF-contents in CA1 output fibers. The decrease in the MAB1615-positive fibers most likely indicates an increase in dephosphorylation allowing the assembly of NFs formed from the low-subunit, and enabling the neurons to reshape their axons. These results indicate region-selective changes in the hippocampus of trace eyelink conditioned rabbits which may underlie learning and memory processes. (Supported by the Netherlands Organization for Scientific Research (NWO) to E.A.V.d.Z. and by NIH ROI M014730 and ROI AI00798)

585.17 BRIEF TETANIC STIMULATION CAUSES SELECTIVE TRANSIENT INHIBITORY SUPPRESSION IN THE DENTATE GYRUS N. W. Migram* and J. Ferbinteanu University of Toronto, Scarborough Campus, 1265 Military Trail, Scarborough, Canada, M1C 1A4.

Several studies have reported that repeated activation of hippocampal afferents leads to a loss of recurrent inhibition. These findings suggest that inhibition is susceptible to use dependent breakdown. To further understand the conditions necessary for such an inhibition, we have investigated the effect of brief stimulus trains to the perforant path on both paired pulse inhibition and facilitation in the dentate gyrus with urethane anesthetized male hooded rats. An afferent pulse procedure with a reference pulse, a variable intensity conditioning pulse (C-pulse) and a test pulse (T-pulse) was used. The interval between the C and T pulse was set at 25 msec and the intensity of the T pulse was held constant. Under the control condition, there was paired pulse facilitation with a low intensity C pulse, while a high intensity C pulse caused paired pulse inhibition. Trains with 5 pulses were applied at frequencies of 2 Hz 200 Hz, 15 seconds before delivery of the T pulses. The paired pulse facilitation, a loss of both paired pulse facilitation and inhibition. Increasing the number of pulses to 17 at a 2 Hz frequency had no incremental effect on paired pulse suppression, but attenuated the loss of paired pulse facilitation. There was evidence that the inhibitory loss was transient, since it was reduced when the delay between the trains and the T pulse was set at 1 minute. Work currently in progress is examining whether this use dependent inhibitory loss is enhanced by treatments which induce epileptic seizures.

Neurobiological signals, such as the EEG, are usually nonstationary over time. One way to account for the temporal nonstationarity of a signal is to use time-frequency analysis to reveal its time-frequency relations. In this report, the short-time Fourier Transform (STFT), an extension of the Fourier Transform, has been used to analyze the EEG recorded from entorhinal cortex (EC) and dentate gyrus (DG). The resulting 2-dimensional time-frequency spectrum image was obtained via a 2A sliding window with a 1.9s overlap. Thirty second samples of EEG (sampled at 256 Hz) were extracted simultaneously from the EC and the DG of behaving rats. During the middle 10s of each 30s epoch, a low intensity train of electrical pulses at one of 5 frequencies (2.610, 14,181Hz) was applied to the pyriform cortex (PC), which projects to the EC. The EC projects, in turn, to the DG. Although there was no or little visually apparent change in the EEG produced by the stimulation, the time-frequency spectrum image showed clear peaks at the stimulation frequency and its harmonics. The time-frequency form of the coherence function was calculated based on the STFT (15 EEG epochs) to study the connectivity between the EC and the DG. Coherence was high for the theta frequency, which fluctuated around 7-9 Hz during the 30s sampling period, and was also enhanced during stimulation at the stimulation frequency and its harmonics. The STFT was also used in signal synthesis (or extraction). The portion of the time-frequency image at the stimulation frequency and its harmonics (1-2Hz) were extracted and an inverse Fourier transform was performed on the extracted signal. The effect of the stimulation train, originally embedded in the raw EEG, showed up clearly in the reconstructed signal. Our results indicated that the STFT is an effective technique for signal processing of the nonstationary EEG.

Aged rats can be potentiated to the same degree as young ones by proper path stimulation, but they lose their potentiated response in the dentate gyrus more rapidly (Barnes, J. Comp. Physiol. Psychol., 1979, 93: 74; de Toledo-Morrell et al., Neurobiol. Aging, 1988, 9: 581). We showed earlier that the induction of LTD in the dentate gyrus of young rats is followed by a selective increase in the number of axospinous synapses with multiple, completely partitioned transmission zones (Geinisman et al., Hippocampus, 1993, 3: 455). To determine whether structural synaptic plasticity induced by LTD in aged animals is similar to that observed in young adults, aged (27-31 mo.) F344 rats were implanted with stimulating electrodes in the medial perforant path and recording electrodes in the hilus of the ipsilateral dentate gyrus. Potentiated rats were stimulated (with fifteen 20 ms bursts at 1 Hz) delivered at 0.5 Hz on each of 4 consecutive days and sacrificed 1 h after the fourth stimulation. Aged animals did not differ significantly from young controls in terms of the extent of potentialization. The number of synapses per neuron was differentially estimated for various synaptic subtypes in the middle (MML) and inner (IML) molecular layer of the dentate gyrus using the unbiased dissector technique. Only axospinous synapses with multiple, completely partitioned transmission zones were significantly increased in numbers in the MML, but not in the IML of potentiated aged rats relative to their stimulated (at a frequency of 0.2 Hz) or implanted controls. The magnitude of this change was practically the same in old and young responsive controls. This finding suggests that the observed structural synaptic modification may account for the equivalent extent of potentiation in rats of different chronological ages. Supported by Grants AG08794 from NIA and BNS-8912372 from NSF.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
586.1

Following complex motor learning, rats exhibit an increase in the number of synapses/neuron in the cerebellar cortex. This experiment examined which synapse types are altered. Female rats, approximately 8 months of age, were randomly assigned to an Acrobatic motor learning Condition (AC), a Forced Walking Exercise Condition (FW), or an Inactive Condition (IC). AC animals were trained for 30 consecutive days on a motor learning task which consisted of a series of obstacle laden pathways requiring a significant amount of motor coordination to complete. The WX animals were housed with running wheels attached to their home cages to which they had unlimited access and the IC animals were housed alone. The rats were shifted to a daily handling schedule equivalent to that experienced by the other groups. The density of synapses was obtained using the physical disector on serial electron micrograph montages taken within the molecular layer of the cerebellar cortex and synapses were classified as to their pre and post synaptic origins. Purkinje cell density was obtained using the physical disector on serial 1 μm sections of the cerebellar cortex and data were expressed as synapse/Purkinje cell. Results indicate that the AC animals have a greater number of parallel fiber to Purkinje cell synapses in comparison to controls. Detailed assessment of other synapse subtypes is in progress. Supported by AG 10154, NSF BNS 88 21219 and NSERC.

586.2

Following complex motor learning, rats exhibited increased numbers of synapses/neuron in the cerebellar cortex. Here we present preliminary findings examining the structural plasticity of the parallel fiber following motor skill acquisition. Female rats were randomly assigned to an Acrobatic motor learning Condition (AC), a Forced Walking Exercise Condition (FW), or an Inactive Condition (IC). AC animals were trained for 30 consecutive days on a complex motor learning task which consisted of a series of obstacle laden pathways requiring a significant amount of motor coordination to complete. The WX animals were housed with running wheels attached to their home cages to which they had unlimited access and the IC animals received the same handling schedule as the AC and FW rats. The intervariocyst distance along Golgi impregnated parallel fibers did not significantly differ among the three groups suggesting that few new pre synaptic varicosities had developed. The second experiment utilized the same behavioral paradigm and examined the number of single varicosities forming multiple synaptic contacts (double synapses) using unbiased stereological measures from serial electron micrographs. AC rats had significantly more double synapses/Purkinje cell than WX or IC rats. The increase in synapses in the cerebellar cortex following motor skill acquisition appears to involve a reorganization of parallel fiber varicosities. Supported by AG 10154, NSF BNS 88 21219 and NSERC.

586.3

Following training on a complex motor learning task, structural changes have been observed in the rat motor cortex (across adjacent posteriors). Previous research has also shown Fos to be expressed during learning. In this study, the expression of Fos was examined during the acquisition and maintenance phases of training on a complex motor learning task. Female rats were randomly assigned to an Acrobatic motor learning Condition (AC), a Forced Walking Exercise (FW) or an Inactive Condition (IC). AC animals were trained for 30 days on an elevated runway equal in length to the acrobatic course which required a substantial amount of motor skill to traverse. Each AC animal was pair matched with a WX animal which was forced to travel a flat elevated runway equal in length to the acrobatic course. The WX animals received no motor training or activity but were handled daily. Five animals from each condition were sacrificed after 1, 2, 5, 10 and 20 days of the experimental manipulation. Four 100 μm coronal sections containing motor cortex (1.6 mm to -1.4 mm from Bregma) were taken from one hemisphere of each animal and immunohistochemically stained for Fos. Sections were analyzed for the percent area stained for Fos. Using the disector method, the number of Fos positive cells was counted and expressed as a percentage of the total number of neurons in each condition. The results indicate that the AC animals have a greater percentage of Fos positive cells during the acquisition phase (days 1, 2 and 5) versus the maintenance phase (days 10 and 20) of training. Fos expression was not significantly changed as a function of time in the WX and IC animals. Supported by AG 10154, MH 40631, NSF BNS 88 21219 and NSERC.

586.4

Following training on a complex motor learning task, changes have been observed in synapse number in the rat cerebellar cortex. In this study, the number of synapses per neuron was examined in Layer II/III of the motor cortex following training on a complex motor learning task. Female rats were randomly assigned to an Acrobatic motor learning Condition (AC), a Forced Walking Exercise (FW) or an Inactive Condition (IC). AC animals were trained for 30 days on an elevated runway equal in length to the acrobatic course. Each AC animal was pair matched with a WX animal which was forced to travel a flat elevated runway equal in length to the acrobatic course. The WX animals received no motor training or activity but were handled daily. Five animals from each condition were sacrificed after 1, 2, 5, 10 and 20 days of the experimental manipulation. Ten 200 μm coronal sections were taken through one hemisphere (1.6 mm to -1.4 mm from Bregma) from each animal. Blocks of tissue containing the motor cortex were removed and embedded for electron microscopy. The physical disector was used to obtain neuronal density from 80 serial 1 μm sections through Layer II/III of the motor cortex. Synaptic density was measured using the physical disector on 16 serial electron micrographs taken within Layer II/III. The number of synapses/neuron in each animal was estimated from these two measures. The AC animals had significantly greater number of synapses/neuron than the WX and IC animals. Supported by AG 10154, MH 40631 NSF BNS 88 21219 and NSERC.

VISUALLY-INDUCED PLASTICITY IN THE AUDITORY SPACE MAP OF ADULT BARN OWLS. M. S. Brainard* and E. J. Knudsen. Dep. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305-5401.

The optic tectum (superior colliculus) contains mutually aligned neural maps of visual and auditory space. Prior experiments have demonstrated that during development and the topography of the auditory map is calibrated by visual experience: in owls reared with prismatic spectacles that optically shift the visual field along the along the horizon, the map of auditory space in the tectum gradually shifts to become aligned with the optically displaced visual map. In this study, we examined the capacity of the auditory space map in adult prism-challenged owls to recover normal topography following restoration of normal visual experience.

Owls were reared from shortly after eyelid opening (16-19 days) with prismatic spectacles that displaced the visual field by 2 degrees to the left or the right. After owls reached adulthood, the tectal auditory space map was assessed for changes induced by exposure to dichotically presented stimuli of varying interaural time difference. For owls in which visual experience had been restored and the tectal auditory space map, prisms were removed at ages ranging from 300 to 2000 days, and subsequent changes in the auditory map were assessed.

In all groups, regardless of the age at which normal vision was restored, the tectal map of auditory space recovered essentially normal topography. This recovery occurred rapidly, over periods ranging from 10-30 days. The results indicate that substantial visually-induced plasticity in the tectal representation of auditory space is maintained in adult owls. This finding contrasts with the plasticity observed in the visual and somatosensory domains which have suggested a loss of plasticity in the tectal map of auditory space and in sound localization behavior beyond a critical period in development.

The effects of soiled bedding on synaptic morphology in the accessory olfactory bulb (AOB) were examined in adult male rats. Forty-day-old male rats were isolated. One group was exposed to bedding soiled by male and female rats (EC). Another group was only male soiled bedding (SC). The last was exposed to clean bedding (FC) for 2 months, the animals were sacrificed for electron microscopy. The size and the numerical density of synapses were measured in the granule cell layer and the granule cell layer. In the granule layer, the length of the synaptic contact zone was significantly greater in the EC than in the SC and the IC, while there was no statistically significant difference in the density of synapses among the three groups. Two types of synapses were classified in the granule cell layer (1) perforated synapse and (2) nonperforated synapses. For perforated synapses, the length of the synaptic contact zone was significantly greater than normal owls, regardless of the sex of the rat. For nonperforated synapses, there was no statistically significant difference in the length of the synaptic contact zone among the three groups. In the density of both perforated and nonperforated synapses, there was no statistically significant difference among the three groups. These results demonstrated that exposure to bedding soiled by female rats, which contains female odour substances (pheromones) can induce structural changes of the synapses in the AOB of male adult rats.

THE AT-14 mRNA IS ENRICHED IN SEVERAL AVIAN SONG CONTROL NUCLEI AND ENCODES AN RCS/NEUROGRANIN-RELATED PROTEIN S.M. Siegert* J.M. George, H. Jin and D.P. Clayton* Dept. of Cell & Structural Biology, University of Illinois, Urbana, IL 61801

Differential CDNA hybridization experiments led to the identification of a brain-specific, forebrain-enriched RNA (HAT-14) that is especially abundant in song control nuclei HVC and IMAN of canaries and zebra finches. The sequence of the HAT-14 cDNA predicts a 73 amino acid protein that contains a domain found in the GAP-43 and RCS/neurogranin proteins, which it is believed to encode protein kinase C-regulated calmodulin binding. Further analysis of the sequence reveals the first 50 amino acids are 84% identical between rat RCS and HAT14. The identity drops to 25% in the remaining C-terminal portion, with lack of conservation of the residues identified as "collagen-like" in the rat sequence. Antibodies raised against predicted HAT-14 peptide sequences react with neurons in the songbird telencephalon. In sharp contrast to RCS/neurogranin (which is not expressed outside the telencephalon), high levels of HAT14 expression are also observed in cerebellar Purkinje cells in the songbird. Supported by NIH Grant NS-25742.

DEVELOPMENTAL REGULATION OF GAP43 MRNA IN AVIAN SONG CONTROL NUCLEI. H. Jin, H. S. Simpson, S. Siegert, C. Mello, M. Iuculano, K.L. Neukirch, J.M. George and D.P. Clayton* Dept. of Cell and Structural Biology, University of Illinois, Urbana, IL 61801

GAP-43 is an axonal protein whose expression increases during neurite outgrowth, and which undergoes phosphorylation by Protein Kinase C during long-term potentiation. The mRNA for GAP-43 is proposed to be involved in both neural development and adult plasticity. The avian song control system stands as one of the best models of regulated neural plasticity. To determine whether GAP-43 may regulate plasticity in the song system, we cloned the cDNA homolog of the GAP-43 cDNA. We used this cDNA to measure in situ hybridization the expression of GAP-43 mRNA in the adult canary brain, and in the zebra finch brain during the critical period for song system development. These studies have emerged. First, GAP-43 is not notably abundant (compared to surrounding telencephalon) in the principal song nuclei HVC and RA in adult songbirds, but is relatively upregulated in nucleus N18TG2. Second, GAP-43 mRNA levels remain relatively stable throughout zebra finch development (15-110 days of age) in most song nuclei, with one exception: RNA levels are increased in nucleus RA when the bird is first learning to sing (before day 60) then fall to the low levels observed in adults. These results suggest GAP43 gene regulation does not play a significant role in the initial establishment of connections within the song control circuit, although the gene is expressed constitutively and thus the protein itself may serve a function. In RA, downregulation of the gene may be correlated with stabilization of the motor control pathways for song production.

Gonadal steroids influence performance on a variety of spatial tasks in both humans and rodents. In estrogen modifies the structure and response properties of neurons in the hippocampus, an area believed to be involved in processing spatial information. The present study examined the effects of estrogen on spatial performance and various measures of hippocampal physiology. Ovariectomized rats with and without hormone replacement (estradiol-progesterone regimen) were used to mimic the natural cycle and control rats at various stages of the estrous cycle were tested in the Morris water maze and spontaneously firing neurons in the CA1 region of the hippocampus was then assessed in vivo at the same stage of the estrous cycle as at behavioral testing. A gradient of effect of hormones was observed for swim task performance and potentiation following primed burst stimulation: High levels of circulating estrogen related to poorer swim task performance and to higher levels of primed burst potentiation. Thus, a significant negative correlation between spatial memory and magnitude of synaptic plasticity emerged. We are presently examining the effects of fluctuations in estrogen on sleep and other behavioral measures in female rats. Possible actions of circulating estrogen on hippocampal function include: 1) neuromodulatory effects, via hippocampal afferents 2) direct, activational effects on hippocampal function and 3) regulation of number and/or function of synapses. Supported by AG00540 (DLX), AG07648 (PEG) and NS31830 (TFC).

586.10

We investigated whether the TH gene is expressed in the SN and whether it contributes to the motor symptoms of SN-P. TH mRNA was observed in the nigrostriatal system, the periventricular tegmentum, substantia nigra, and the red nucleus. We used the TH gene as a probe to examine the neuronal phenotype of SN-P in the rat. Sustained rotational behavior was observed following injection of the TH reporter gene construct into the SN-P nigrostriatal system. We have demonstrated that the TH reporter gene construct can be useful for identifying and targeting TH expressing neurons within SN-P. The gene transfer strategy used in this study may provide the basis for understanding the cellular mechanisms underlying the motor symptoms of SN-P.

NIGROSTRIATAL PROJECTION AFTER UNILATERAL 6-HYDROXYDOPAMINE INJECTION INTO THE STRIATUM IN NEONATAL RATS. Y. Ichitan1, M. Takagami and T. Konishi,1 Inst. of Psychology, Univ. of Tsukuba, Tsukuba, Ibaraki 305, Japan.

In order to investigate the reorganization of nigrostriatal dopaminergic neuron system after a lesion of this system, we examined the effects of neonatal 6-hydroxydopamine (6-OHDA) injection unilaterally into the striatum on the subsequent development of contralateral projections from the intact side of substantia nigra (SN). After treatment of dopamine levels was (20mg/kg, s.c.), rats received unilateral injection of 6-OHDA (10mg/5pl) into the striatum on the day 2 after birth. At the age of 4 weeks to 5 months, cholera toxin B subunit (CTB, 1%) was injected (0.4pl) into the striatum in order to label the CTB-immunoreactive cell bodies in the SN contralateral to the injection regardless of the age of animals. Results suggest that unilateral lesion of the neonatal nigrostriatal system did not have marked effects on the formation of interhemispheric connections of this system.

DEVELOPMENTAL CHANGES IN THE VESTIBULO-OCULAR PATHWAYS DURING METAMORPHOSIS IN FLATFISH. J.K. Jansen* and P.S. Eger. Dept. of Physiology and Institute of Biology, University of Oslo, N-0316 Oslo, Norway.

During the first two months after hatching, flounders go through a very unusual metamorphosis. They tilt their bodies progressively to one side while the one eye migrates in the medio-lateral direction across the dorsal midline to settle next to the other eye, on the opposite side of the head. During this process the vestibulo-ocular pathways are presumably reorganized to compensate for the right-left disalignment of visual and vestibular frames of reference. In the present study we have examined the vestibular nuclear complex with anterograde and retrograd neuronal tract tracing techniques (HRP and dextranamine) before and after the period of eye migration in larvae and juvenile turbot.

We find: 1. that the vestibular complex consists of spatially segregated groups of neurons selecting distinct pathways to reach their targets in rostral eye motor nuclei and in the spinal cord. 2. All groups can be recognized in premetamorphic larvae as well as in juveniles. 3. The number of projection neurons increase comparably in the vestibulo-ocular and the vestibulo-spinal components of the vestibular complex. 4. Some of the projection neurons change their terminal fields in the rostral eye motor nucleus from pre-metamorphic unilateral terminal fields in the larva to bilateral termination after the period of eye migration in juveniles.

We conclude that the vestibular complex is basically similar in flounders and other teleosts. The reorganization of terminal fields in vestibulo-ocular pathway during metamorphosis may be part of the plasticity required to compensate for the eye migration.

MAP KINASE KINASE (MEK-1) IS ENRICHED IN RADIAL CELL PROCESSES IN ZEBRA FINCH BRAIN. J.M. George*, H. Jin, W.S. Woods, and D.F. Clayton. Dept. of Cell and Structural Biol., Univ. of Illinois, Urbana, IL 61801.

A differential screening strategy previously led to the identification of cDNA clones representing RNAs enriched in parts of the songbird telencephalon (Mol. Br. Res. 12:323, 1992). The sequence of one of these clones (HAT-5) predicts a protein 95% identical to the recently cloned mammalian MEK-1 protein (Crews et al., Science 258:478, 1992), which functions as an activator of MAP Kinase/ERK-1 and -2, as part of the signal transduction pathway for various growth factors. By Northern analysis, the HAT-5 RNA is most abundant in the songbird neocortex (Zebra finch, canary), but is noticeably enriched in the brain. Expression in brain is minimal in newly hatched finches, moderate at 7 days of age, and much higher still in adults. An antibody raised against residues 38-50 of the MEK-1 peptide reacts with a band of ~48 kD on immunoblots of brain extracts. By immunocytochemistry, the antibody stains cellular processes that appear to arise from the vestibular lining, the tegmental plate at the tips of the ventricles. In Nissl-counterstained sections, the processes are occasionally associated with small elongated cells. Processes with these features have previously been identified as elements of radial cells, which serve both as neuronal precursors and as substrates for migration of young neuroblasts in the adult avian brain. The enrichment of MEK-1 in radial cell processes suggests the radial cells may respond to signals generated deep within brain tissue, far from their soma in the vestibular lining. FUNCTIONAL DESENSITIZATION OF NMDA RECEPTORS IN AN ANIMAL MODEL OF CHRONIC UP-REGULATION OF GLUTAMATE RELEASE. P. Marinii, M. Di Luca, A. Caputo, L. Pastore, M. Camgo, G. Bonamico, M. Raineri, J. Perez-Portela and F. Cuello. Institute of Pharmacological Sciences, University of Milano, 20133 Milano and Institute of Pharmacology and Pharmacognosy, University of Genova, 16148 Genova, Italy.

Rat exposed in utero to methylazoxymethanol (MAM) at embryonic day 15 show a profound disorganization in the CA region of the hippocampus. These animals show cognitive deficits and impairments in LTP induction (Ramakers et al., 1993). At a molecular level, in the presynaptic compartment increased phosphorylation of B-SUGAR-43 is present with a parallel and persistent increase in the membrane-associated PKC. As a consequence, increased basal glutamate release (352±23 pmol/log protein control; 575±50 pmol of protein-MAM-treated) has been observed in hippocampal synaptosomes of MAM-treated rats, whereas basal release of GABA is unaltered.

The functional state of NMDA receptors was evaluated in hippocampal plasma membranes by 3H-MK801 binding under nonequilibrium conditions, with a mathematical model allowing for the study of simultaneous modulation of the receptor by two agonists, Glycine and Glutamate, according to Marvizon and Baudy, 1993. The data show that in MAM-treated rats the allotropic interaction between Glycine and Glutamate sites shows a 10 fold difference with respect to controls, without changes in the number of binding sites as measured by [3H]-CGP38653 binding.

It is known that phosphorylation processes can influence the function of NMDA receptor. In these animals in vivo PKC dependent phosphorylation of the post-synaptic substrate neurogranin is markedly altered, suggesting that alterations of plasticity mechanisms involve pre- and post-synaptic parameters. Marvizon J.C. and Baudy M. Analyt.Biomed. 213-31, 1993. Ramakers G.M.J. et al., Neurosci. 54:49-60, 1993.

586.16

Previous studies of differential gene expression in songbird brain led to the identification of a brain-specific novel protein, HAT-3 (George et al., 1993). This sequence predicts a 143 amino acid protein which contains a repeating amphiphatic motif of 11 amino acids. Antibodies raised against the predicted C-terminus detected a single band (~17 kD) on immunoblots of both songbird and rat brain synaptosomal extracts, and stained zebra finch brain sections in a pattern consistent with synaptic localization.

With the ultimate goal of analyzing the function of the novel protein, we have used these antibodies to stain cultured hippocampal neurons from rat brain. Before synaptic contacts are present (e.g. 1-3 days in vitro [DIV]), HAT-3 is present in the cell body but appears diffuse and in low levels in processes. The antibodies yield a punctate staining pattern in more mature neurons (e.g. 7 DIV or older) that have established synaptic contacts. In double staining experiments, the protein is colocalized at the light microscopic level with the well-characterized synaptic vesicle protein synapsin I. Double staining with MAP2 revealed that HAT-3 puncta were concentrated around the soma and along dendrites. These results suggest that, while initially diffuse, in later stages of development HAT-3 protein becomes concentrated at regions of synaptic contact, and is localized presynaptically. Supported by NS17112 (GB), NS07189 (GW), HD07333 (AS), NS05742 (DC).

Closed head injury has been associated with cognitive and behavioral deficits in humans. In this study, we examined the effects of such injury on the circadian system. Wistar rats were implanted with biotelemetry transmitters, and circadian temperature and activity rhythms were recorded under constant darkness (DD) conditions for 10 days. Pentobarbital-anesthetized rats were then mounted in a stereotaxic apparatus and injected using a 25-gm weight drop device. Behavioral and core temperature rhythms were altered by closed head injury. Both cold light and pentobarbital anesthesia reduced the amplitude of these rhythms. These results suggest that closed head injury alters circadian rhythmicity. Colony environments and potential head injury might be secondary to the effects of such damage on the circadian system.
LOCAL SYNAPTIC CIRCUITS IN THE RAT SUPRACHIASMATIC NUCLEUS.

Previous anatomical studies have indicated that a large fraction of neurons and presynaptic terminals in the suprachiasmatic nucleus (SCN) contain GABA. Furthermore, electrical stimulation of regions outside the SCN has been found to produce GABAergic synaptic potentials in SCN neurons, but it is unclear whether such evoked potentials arise from the stimulation of GABAergic neurons within the SCN, or of fibers originating in other areas. To test whether SCN neurons from local lateral geniculate nucleus (LGN) neurons, we applied brief pulses of glutamate (10 mM, 0.2 s) to the SCN during whole-cell voltage-clamp recording in thin (150 μm) hypothalamic slices. Such glutamate pulses would be expected to stimulate projection fibers rather than fibers of passage. Whole-cell voltage-clamp recordings in SCN from 12 to 18 day-old Lewis rats revealed spontaneous outward currents in all neurons (n = 33), with amplitudes ranging from 20 to 200 pA at holding potentials near 0 mV, and a frequency of occurrence ranging from 0.03 to 10 Hz. Bicuculline (10 μM) blocked these events in 9 of 9 neurons, indicating that they were GABA-mediated inhibitory postsynaptic currents (IPSCs). Pressure ejection of glutamate-containing bath solution onto the SCN resulted in clear increases in the rate of IPSCs in 6 of 18 neurons. Spontaneous inward currents, which were presumably presynaptic postsynaptic currents (PPSCs), were seen in fewer neurons (n = 11 of 15), possibly due to their lower rate of occurrence (about 0.1 Hz, on average). Glutamate microinjection did not evoked IPSCs reliably in any of 12 cells. These results suggest local synaptic circuits within the SCN exist, and are predominantly inhibitory.

LOCALIZATION OF PRETECTAL NEURONS IN THE RAT WITH EXTENSIVE PROJECTIONS TO THE SUPRACHIASMATIC NUCLEUS (SCN) AND INTERGENICULATE LEAFLET (IGL).

A characteristic anatomical feature of the two most important components of the mammalian circadian timing system: the SCN and the IGL, is that they are bilaterally innervated from the retina. Parts of the olfactory and posterior pretectal nuclei have been shown to be bilaterally innervated from the retina as well, and we therefore aimed to explore whether these two nuclei were anatomically related to the circadian system. We examined retrograde neuronal labeling with Fluoro-Gold, Phaseolus vulgaris-leucoagglutinin (PVAL), and biocytin. Injections were given in the IGL and SCN of adult male rats. Only if PVAL was injected in the medial part of the pretectum it was possible to get the IGL and pretectal nuclei labeled. PVAL and biocytin filled fibers were observed to course laterally and rostrally into the optic tract, and, within the optic tract and chiasm, the biocytin filled fibers penetrate medially and descend rostrally into the SCN. Along this pathway, the projection gave rise to a large number of branches, across the superior, middle, and inferior IGL, and the entire IGL and the SCN. The presence of labeled neurons scattered in both the posterior and olfactory pretectal nuclei was observed in both experiments. Most neurons were found in the medial part of the posterior pretectal nucleus and in the dorsal-medial part of the olfactory pretectal nucleus ipsilateral to the injection, confirming the anterograde tracing studies. These neocellular tracts tracing reveal the presence of a novel pathway linking the pretectum, the SCN and the IGL, indicating that the projecting pretectal neurons and their efferent projections are potentially involved in phase-shifting mechanisms.

OVOGENY OF THE MOTOR CIRCUIT SYSTEM IN CRAYFISH.
J. Hernández-Falcón A. de la O-Martínez and P. Fuentes-Pardo, Depto. Fisiología, Facultad de Medicina, UNAM, AP 70-250, México, 04510, D. F., MEXICO.

The ontogeny of motor circuits of the crayfish (Procambarus clarkii) was studied using specimens kept under controlled conditions of light and temperature (17°C). The motor activity of animals aged between 10 to 100 days after hatching was recorded. During 10 days the movements of unrestrained crayfish were monitored by means of a video camera coupled to a digital recorder. The recordings were obtained under free-running in darkness (DD), free-running in light (LD) and LL 12:12 (LD). From each recording in order to obtain a measure of periodogram parameters (amplitude, : ratio and night/day ratio) were measured; was calculated by means of a computer program. From each periodogram the mean of 10 days the mean of 6 periods was calculated by means of a computer program. The mean of the mean of 6 periods was 25.9 h in both LL and LD. The lowest mean of the mean of 6 periods was 22 h in LL, 23.9 h in DD, and 20 h in LD. The crayfish in LD was more irregular than the locomotor patterns. However, the ability to be synchronized by LD photoperiods is better in the younger than in the older crayfish. The results indicate that the circadian organization appears very early in the development. They suggest also a progressive increment in the number, kind, and position of division of the oscillator during the ontogenetic development.

DIFFERENTIAL INNERVATION OF THE HAMSTER SUPRACHIASMATIC NUCLEUS (SCN) AND INTERGENICULATE LEAFLET (IGL) BY RAPHÉ NUCLEI. E.L. Meyer* and L.P. Morin, Dept. Psychiatry and Neurobiology, Stony Brook University, NY 11794.

The SCN and IGL, components of the circadian system, receive serotonergic (5-HT) innervation from the dorsal (DR) or median (MR) midbrain raphe. In the rat, the data are inconsistent as to which nuclei projects to SCN or IGL. To study DR and MR pathways to the hamster circadian system we have not performed. Retrograde (Fluoro-Gold, cholera toxin, Fast Blue) and anterograde (Phaseolus vulgaris leucoagglutinin; PHA-L) tracing techniques were used to show raphe neurons and their projections. Retrograde tracers were injected into the SCN or IGL of male golden hamsters and locations of labeled cells in DR and MR were shown. PHA-L was also injected into the DR or MR and the projections to the SCN and IGL were mapped.

The autoradiograms show the DR, but not projections to the IGL. Retrograde labeling placed in the SCN labels cells in the MR, but not DR. In contrast, placement of PHA-L in either the DR or MR labels fibers in the IGL. Retrograde analysis is in progress. The results are consistent with data (unpublished) showing that, but not DR, lesions destroy 5-HT projections to the SCN, DR, but not MR, lesion show 5-HT fibers to the IGL. The anterograde labelled MR fibras to the IGL may not contain 5-HT. This issue is being evaluated. Supported by NSF21168.

THE SUPRACHIASMATIC NUCLEUS AND INTERGENICULATE LEAFLET OF ARVICACHUS NILOTICUS, A DIURNAL MURID RODENT.
L. Smale*, Dept. Psychology, Michigan State University, East Lansing, MI, 48824.

Little is currently known about how the neural substrates controlling circadian rhythms differ in diurnal compared to nocturnal species. Numerous studies have been carried out on rodent models. Arvicanthus niloticus, a murid rodent recently imported from Kenya, exhibits a diurnal pattern of precisely timed wheel-running activity and may represent an ideal diurnal mammal for studies of the neural control of circadian rhythms. Arvicanthus niloticus is a murid rodent that has been adapted to nocturnal activity, and has been used for many years as a model of circadian rhythms. The use of this species as a model of circadian rhythms has not been widely utilized. In this study, we will use immunohistochemistry to examine the distribution of peptides in the SCN and IGL of 8 adult A. niloticus (2 females and 6 males); in this initial study animals were not pre-treated with colchicine. In A. niloticus, as in other mammals, distinctly different subdivisions of the SCN contained VIP and VP immunoreactive (IR) cell bodies. Within the SCN, we did not observe cell bodies containing npy, naitkalin or substance-P. Immunoreactive NPY-IR, ENK-IR and VIP-IR fibers were present within the IGL. The IGL contained a substantial number of VIP-IR cells, as well as SP-IR and ENK-IR terminals. Overall, the IGL and SCN of A. niloticus resembled, in many respects, those previously described in rats.

EFFECT OF SKELTON PHOTOTOPÆRES UPON THE CARDIAC MOTOR ACTIVITY RHYTHM DURING ONTOGENY IN CRAYFISH.

During the development of the crayfish Procambarus clarkii, the synchronization of the circadian activity rhythm (CAR) to complete photoperiods (CP) is not clear (1) probably due to a masking effect of light. We tried to rule out this effect, studying the influence of the syetehetical skeleton photoperiods (SSP) upon the CAR at different stages of development, Procambarus clarkii juvenile instars between 10 up to 150 days after hatching were individually housed in activity recording cages under constant darkness and temperature conditions. Each crayfish was free running during 15 days. Afterwards, it was changed to the following CP: 12:12, 8:16 and 20:4. After 15 days of SSP stimulation they were left free running again. The results suggest that only animals older up to 60 days are able to synchronize to SSP adjusting its maximal phase to the longest scotophase.

588.1

The aim of the present work was to study the effects of lesions in the intergeniculate leaflet (IGL) or the deep ponte / lamina intercalaris region (DP) on the diurnal profile of N-acetylserotonin (NAS) and on the nocturnal pineal inhibition process induced by acute light exposure. Male adult albino rats (n=2/12, 12h:12l-dark cycle, lights on at 0600h), intact or previously lesioned, were killed along the 24 hours or during the night immediately after 1 or 15 minutes of exposure to 500 lux white lights. The pineal glands were collected and frozen (-70°C) until NAS was assayed by HPLC-ED. The 24-hour experiment shows that there is no phase shifting on the diurnal NAS curve of groups of rats with large bilateral IGL lesion compared to the controls. On the other hand there is a significant reduction in the amplitude of pineal NAS content observed in every nocturnal point of the curve (p<0.05). The pineal glands of IGL-lesioned rats do not respond to bright (1 min.) retinal photostimulation keeping its NAS content equal to the lesioned dark killed rats (p<0.05). On the other hand, 15 min. of photostimulation bring the pineal NAS content of the IGL group to nearly zero evenly to the control animals. In experiments done at 2400 h, DP lesion does not modify the content of NAS in the pineal gland of rats killed in the dark. However, the pineal photo-inhibition process induced by 1 min, of light exposure is impaired since the lesioned group has its NAS content reduced much less than the intact animals. These results suggest that: 1) the nocturnal photostimulation input of the pineal gland is partially dependent on central and direct neural projections, probably from the IGL region; 2) The IGL exerts a tonic excitatory control on the nocturnal pineal NAS production, probably via its indirect projections controlling the hypothalamo-spinal cord-sympathetic pineal system.

INTRACELLULAR CA\textsuperscript{2+} DYNAMICS IN DISCONNECTED CELLS OF THE CHICK PINEAL GLAND. T. D’Souza & S. F. Dryer*. Program in Neuroscience, Florida State University, Tallahassee, FL 32306.

The regulation of intracellular free Ca\textsuperscript{2+} concentration was examined in disconnected chick pineal cells using the fura-2 technique. Approximately 10% of cells examined exhibited spontaneous Ca\textsuperscript{2+} oscillations. Membrane depolarization evoked large increases in intracellular calcium which were dependent upon external Ca\textsuperscript{2+} ions. Application of thapsigargin (2 \muM) evoked increases in intracellular free Ca\textsuperscript{2+} in the absence of external Ca\textsuperscript{2+}, indicating the presence of internal stores. Application of 100 \muM caffeine (100 nM), forskolin (200 nM) evoked sustained increases in intracellular Ca\textsuperscript{2+}. The responses to forskolin could be observed in Ca\textsuperscript{2+} free external saline suggesting mobilization of internal stores. These results suggest new mechanisms for the regulation of melatonin synthesis and secretion, and possible sites of action for the intrinsic circadian oscillator. Supported by AFOSR F49620.

588.3

ML-1 receptor binding sites have been localized within a number of circadian and visual areas of the mammalian and avian CNS. We have localized and characterized [Z2(-2)-I]-iodomelatonin ([Z2(-2)-I]ME) binding sites in guinea-pig brain. Specific [Z2(-2)-I]MEEL binding, defined using melatonin (1µM), was identified in coronal sections of guinea-pig brain by receptor autoradiography at the level of the arcuate, suprachiasmatic and lateral geniculate nucleus, superior colliculus (SC) and nucleus accumbens. In SC and hypothalamic membranes, high-affinity, specific, saturable and reversible binding was observed. In the SC, [Z2(-2)-I]MEEL is bound to a single population of high-affinity binding sites (Kd 14.16±6.13 pm, Bmax 662±46fmol/g tissue), while in hypothalamic both high and low affinity sites were identified (Kd 33.5±6.5 pm, Bmax 19.1±10.7fmol/g tissue; Kd 6.6±2.8 pm, Bmax 153±47fmol/g tissue), which appear to represent two affinity states of the ML-1 receptor. In hypothalamic, melatonin agonists inhibited binding with a rank order of potency (5-CIT: [Z2(-2)-iodomelatonin]: 1-iodo-C-tryptophan: 1-iodo-Cl-tryptophan: 0.25µM) > NQZ-C-7-(methylthio)-tryptophan which (1.8±0.2 mg/ml > 6-chloromelatonin (1.1±0.6 mg/ml) > N-acetyl-1-iodomelatonin (1.4±0.7 mg/ml) > 5-HT (>100µM), 5-methoxytryptamine-N-acetyltryptamine (0.2 mg/ml), which has higher affinity for N-acetylserotonin-preferring (ML-2) receptors (Dubocovich et al., JUPHR, 1994), was only weakly active (<1µM). The rank order of potencies in SC membranes was identical (correlation coefficient 0.998).

In conclusion, [Z2(-2)-I]MEEL binding sites, with the characteristics of ML-1 receptors, were localized in guinea-pig SC and hypothalamic areas, in which this receptor may regulate visual and circadian information, respectively.

588.4
NON G-PROTEIN COUPLED HIGH AFFINITY MELATONIN RECEPTORS ARE PRESENT IN THE SHEEP BRAIN. Barret, P. L., Lawson, W., MacLean, A., Hazledin, D., Williams, L. M. and Morgan P.J. Rowell Research Institute Buckholt, N.T, Australia, Commonwealth Scientific and Industrial Research Organization (CSIRO) / NCI. All Melatonin receptors have been localised to both neuronal and non-neuronal sites by in vitro autoradiography using the radioligand [3H]-iodomelatonin. In general these receptors are characterised as members of the G-protein class, as they are membrane-bound, of pico-molar affinity which is modulated by guanine nucleotides. In human cerebral and pinealocytes, melatonin receptors to inhibit forskolin-stimulated adenylyl cyclase through a coupling to two independent inhibitory G-proteins. Recent evidence suggests that unique G-like G-proteins, which is both a cloned cholinergic subtype and recognised by olsubt4 C-terminally directed antibodies mediate this response. In contrast sheep neuronal tissue has markedly different characteristics. Homogenate binding assays reveal that the hippocampal binding site has high affinity (Kd = 56 pm), yet binding is not affected by GTPyS, choloria or pertussis toxins, each of which modulate the affinity of the PT melatonin receptor. Native polyacylamide gel electrophoresis resides the PT receptor as a complex which migrates with a molecular mass of ~515kDa. Under the same conditions the hippocampal receptor migrates with a molecular mass of ~360kDa. This assay also provides a visual demonstration of the lack of GTPyS sensitivity of the hippocampal receptor. With this technique we also show that the melatonin receptor present in the cerebral cortex and pre-optic area has a similar mass to the hippocampal receptor and are not affected by GTPyS. This suggests that these receptors are not G-protein coupled and therefore belong to different class of receptor.

Sleep-inducing properties of low doses of melatonin examined in young healthy volunteers. The hormone (0.3 or 1.0 mg, p.o.) or placebo was administered at 1800 or 2000 h; the lower dose elevated serum melatonin to concentrations comparable to those normally occurring nocturnally in adults (80-120 pg/ml). Effects of the treatment on performance and mood were monitored all day prior to evening treatment and until 0900 the next morning. The volunteers' subjective evaluation of the hypnotic effect showed that they could distinguish between the treated and placebo group, especially after treatment at 2000 h. Beginning 2 hours after treatment, sleep latency was measured by a switch release or by a polysomnographic system. Either dose given at either time point decreased both sleep latency and the sensitive index of melatonin's effect, sleep stage 2 latency. These observations indicate that raising blood melatonin levels to those normally occurring nocturnally promotes sleep onset in humans.

The pineal melatonin rhythm in a variety of rodents is suppressed by exposure to 60 Hz magnetic fields (MF) and may alter the clock mechanism involved in the photoperiodic control of reproduction (U Cell Biol 31: 394, 1993). To determine if MF disrupts photoperiodic regulation of sexual maturation, males in long (14L:2D) or short (12L:12D) days were exposed each day to a 1 Gauss MF (15 min, beginning 2 h before lights on) for 2 days, with 18 days of development. At 25 days of age, the MF exposure continued for 4 days. Males were housed singly and maintained on a 10-10 hr light-dark schedule. The numbers of the hamsters were measured in circadian rhythm, and the melatonin activity was determined by radioimmunoassay.

588.8 MELATONIN DURATION AND REPRODUCTIVE RESPONSES IN MALE SYRIAN HAMSTERS. J.B. Powesky*, A.E. Jetton and R.A. Mascola, Departments of Psychology and Biology, Univ. of Massachusetts, Amherst, MA 01003-7710.

Syrian hamsters are long day breeders, exposure to short days causes inhibition of the reproductive system. This response requires the nightly secretion of melatonin which serves as a hormonal indicator of night length. Traditional views suggested that day length shorter than 12.5 hr were equally effective in generating reproductive inhibition, independent of the actual day length used and its associated melatonin duration. In the experiments presented here we determined if variations in melatonin duration or photoperiod history would affect the rate of reproductive inhibition following melatonin treatment. Forty-five male Syrian hamsters were exposed to long days (16L:8D) for two months and then assigned to one of four groups; three remained in 16L and were pseudoexcised (PDNX); the fourth was shifted to a short day (7L:17D) and was sham pseudoexcised (SH-PDNX). These PDNX groups received nightly infusions for nine weeks containing either vehicle (VEH) or melatonin (MEL, 50 mg/hr) for 8.5 hr or 12.0 hr. The SH-PDNX group was not infused. At three week intervals, testis weight were measured and blood withdrawn for assays of follicle stimulating hormone (FSH) and prolactin (PRL). Both MEL durations caused significant testicular regression but this occurred more rapidly with the longer MEL duration (p<0.05). In a second experiment, MEL duration was held constant but groups were exposed to differing long days prior to MEL treatments. Forty-eight males were divided into two groups - one exposed to 16L:4D, the other to 14L:10D for six weeks. All hamsters were then PDNX and switched to 16L:8D. Within each condition, one-half the males were infused for 9.5 hrs each night for nine weeks with either MEL or VEH; their reproductive condition was assessed as in the first experiment. MEL infusions caused significant reproductive inhibition (p<0.05) but this was only moderately influenced by photoperiod conditions prior to MEL treatment. Results derived from serum assays of FSH and PRL will be reported. Supported by HD30372, HD70673 and MH44132.

588.9 MELATONIN INDUCES OUTWARD CURRENTS IN A SUBPOPULATION OF RAT SUPRACHIASMATIC NUCLEUS (SCN) NEURONS. Z. C. Jiang and C.N. Allen, Center for Research on Occupational and Environmental Toxicology and Dept. of Physiology, Oregon Health Sciences University, Portland, OR 97201.

Several lines of evidence support a role for melatonin in entrainment of circadian rhythms via direct actions on SCN neurons. However, the cellular mechanisms of melatonin's actions remain largely unknown. We used whole-cell recording techniques and brain slices to examine the membrane responses induced by melatonin. Young adult male rats were housed on a 12:12 h light-dark cycle and their locomotor activity and body temperature monitored for 2.4 weeks before the experiments. Full entrainment was observed in the light-dark schedule was always achieved in less than a week. Animals were killed 3.5 h (CT3-5) after lights off and recordings were made during the next 1-0 h (CT3-5). Melatonin (0.1-33 nM) induced an outward current (3.40 pA, at -60 mV), in 4 of 20, 8 of 27 and 5 of 18 cells tested between CT6-CT9, CT9-CT12 and CT12-CT15, respectively. The current was associated with an increase in membrane conductance. The response concentration-dependent with a threshold of about 100 nM and a maximum effect at 30-300 nM. The melatonin-activated currents were blocked by 1 mM Ba2+, partially blocked by 3 mM Cs, but not affected by TTX and/or a combination of CNQX and APV. The current amplitude was reduced and, in a few cases, reversed by a hyperpolarization over -100 mV. These data suggest that melatonin activates a potassium current thus causes inhibition in a subpopulation of SCN neurons. Study supported by grant AG10794.

Department of Animal Sciences, University of Nebraska, Lincoln, NE 68588.

Ovine parabasilis (oPT) cells containing melatonin receptors, and parabasal (oP) cells lacking such binding sites, were studied for the intracellular transduction of melatonin signal. oPT cells, which are involved in the level of CREB activation, measured as P-CREB immunoreactivity (P-CREBir). Gel shifts identified two specific CRE oligonucleotide-protein complexes in oPT nuclear extracts. These were displaced by control and different CRE oligonucleotides and both bands were supershifted using anti-CREB and anti-P-CREB antisera. Immunocytochemistry results were quantitated using digitized image-analysis to measure oPT nuclei containing CREB or P-CREBir. The CREB was increased in the nuclear optical density. Increased PCREBir in response to forskolin stimulation was time and dose dependent. This change in staining was not detectable using the anti-CREB antibody, hence increased PCREBir is due to rapid phosphorylation rather than de novo CREB synthesis. The time course for forskolin stimulated P-CREBir was consistent with nuclear translation of protein kinase A. In oPT but not oP cells, CREB phosphorylation was inhibited by melatonin in a time and dose dependent manner, with the dose also being dependent on the forskolin concentration used. The IC50 for melatonin was around 10nM. Melatonin is therefore thought to regulate expression of cAMP-responsive gene expression through exerting an inhibitory effect, via the cAMP/PAK pathway, on the level of activation of the transcription factor CREB. Funded by SAFRD and Welcome trust.

Pineal calcifications increase with advancing age in man and in many other mammals. Melatonin biosynthesis decreases with advancing age, and has several calcium dependent steps, suggests the possibility of pineal cell dysfunction related to the aging process may accelerate biomineralization in the pineal gland. Pineals from a range of aged men (14, 47, 62 and 82 years) were metallographically embedded, polished, and studied by scanning EM and transmission EM for age related differences. The data show: 1) Concentratically aligned crescent shaped lamellae increase in number and decrease in width, with advancing age. This suggests remodelling age. 2) There is an increase in the calcium: phosphorus ratio (1.27-1.41 in 14 to 62 year age), with advancing age (1.49-1.62 in 82 years) in all lamellae. CIP lamellar increases may parallel cell dysfunction and dysfunction. 3) The architecture of the deposits show an age progression from a) round smooth-stage, through a round beaded stage and into acrocelli (i.e. arteriol) stage. This suggests mineralization and growth by method other than simple apposition. These results suggest a biomimeralization followed by a remodeling that changes throughout the organism's life span and may relate to the decline of melatonin biosynthesis.

Aerobic exercise training (ET) modifies the behavioral responses to acute stress. The effects of ET on the response to stress are less clear. The purpose of this study was to examine the effectiveness of ET in attenuating the behavioral and hormonal responses to a stressor, namely, 20 min of restraint stress (CUS). 16 Flinders Sensitive Line (FSL) and 16 Flinders Resistant Line (FRL) rats were used in this investigation due to their respective sensitivity and resistance and subjected to 3 weeks of ET (25 m.min⁻¹ and 7% grade, 30 min per day) or remained sedentary (SED). Animals were then subjected to 1 wk of CUS. Open field mobility (OFM) and sucrose preference (SPC) were evaluated prior to and after CUS. After CUS, blood was collected for measurement of plasma corticosterone (CORT). Following CUS the number of squares entered during OFM was reduced (p<0.05) in sedentary animals (both FSL and FRL); however, the number of squares entered during OFM was unchanged in FSL-ET and FRL-ET. The number of rears during OFM was reduced (p<0.05) in all animals following CUS. Following CUS, SC consumption was reduced (p<0.05) in all groups except FRL-ET. Plasma CORT was greater in FSL-SED than FRL-ET following CUS. In comparison, plasma CORT values in FSL-SED and FSL-ET were similar to normal resting values. These results indicate that ET is effective in attenuating some, but not all, of the behavioral responses to CUS. Furthermore, FSL animals did not benefit as much from ET as FRL animals. Resistance to the behavioral effects of stress by ET was associated with lower CORT levels in FRL animals.

EFFECTS OF MILD INTERMITTENT TAIL SHOCK ON COLONIC MOTOR ACTIVITY. N.S. Morrow* and T. Garrick. Center for Ultra Research and Education, Dept. of Veteran Affairs, Palo Alto Medical Center, Los Altos, CA 94324.

Changes in the motor activity during tail shock were examined in rats chronically implanted with 2 force transducers into the colon. Baseline colonic contractions were monitored in home cages for 3 days. Meal-stimulated changes in colonic activity were then examined in 2 testing periods. Following a scheduled feeding trial, rats were randomly divided into 3 groups (n=6 each) for testing. All rats were loosely restrained in a Plexiglas tube, and 2 electrodes taped to the tail. One group of rats was administered unpredictable, intermittent tail shocks, 1.5 sec VI-1, 4 shocks/5 min. A second group was exposed to the tail shock chamber but was not shocked. The third group of rats received tail shocks for 1 h and then 24 h later were re-exposed to the tail shock chamber but were not shocked. Fecal output was recorded throughout the experiment. The number of feces evacuated decreased significantly (p<0.05) when compared to basal values. Tail shock increased the number of feces evacuated (p<0.05) and affected fecal consistency in a variable manner. Exposure to the shock chamber, alone, did not significantly alter the colonic contractility pattern or fecal output from basal values. These results indicate that alterations in colonic motor activity can be induced by exposure to environmental stressors and may be a contributing factor in stress-induced bowel dysfunction.

Prenatal stress and neonatal handling are known to have long-lasting effects on emotionality. The hippocampus mediates, at least part of, these effects. In some cases of stress exposure, the hippocampus effects are beneficial, whereas in some cases more detrimental effects may be seen. In this study we investigated the effect of prenatal stress and of neonatal handling on spatial ability and learning, behaviors regulated by the hippocampus. From GD 14 to 21 pups were exposed to shock, or no shock, for 45 min 3 times/day. From PN 1-10, half of the pups were handled daily by placing them in a cage at 37°C for 3 min. At approximately 23 and 63 days rats were tested in a Morris Water Maze (MWM). Prenatal stress and handling on a MWM, nor did handling. A sex difference in latency to find the platform, was observed in adult animals, males performing better than females. These results were confirmed in prepubertal animals. No age difference was also observed, with older animals learning to reach the platform twice as fast as prepubertal animals. Our previous results show that the prenatal stress treatment was effective in reducing the number of squares entered during a 20 min of restraint stress (CUS). These animals were then subjected to a social defeat experience for 5 days with submissive behavior and ultrasound vocalizations monitored. Changes in the amplitudes of cardiac and ultrasonic rhythms following social stress and light shift and entrainment effects following drinking were observed.

THE IMMEDIATE EFFECTS OF PHYSICAL EXERCISE ON PASSIVE-AVOIDANCE MEMORY AND ANXIETY IN RATS. J.E. BRVAT, Tracey Smith, Leslie R. Hicks and Michael J. Lewis. Neurobehavior Lab, Dept of Psych, Howard University, Washington, D.C. 20059

Participation in physical exercise is currently fashionable. Although many people report psychological benefits following exercise, the present research was designed to investigate the effect of physical exercise on passive-avoidance behavior and anxiety in rats. The subjects were 32 female, 250 g Sprague-Dawley rats divided into four groups of eight. All rats were given 20 min daily training sessions of an eight-trial, two-choice, passive-avoidance task. Following training, behavior was assessed in the active-avoidance and forced-choice tasks. Group A was exposed to a 10 day running regimen, Group B served as a control group. Group C received 10 days of running training, followed by a 10 day running regimen, Group D served as a control group. The exercise program was designed to increase VO2max by 30%. Passive-avoidance behavior was assessed by the latency to enter zone A, and forced-choice behavior by the latency to respond to zone A. The results were analyzed by 2 x 2 x 2 x 2 ANOVA. The analysis revealed significant main effects of running and non-running on active-avoidance performance, and a significant interaction of training and non-training on forced-choice responses. It was concluded that exercise training had positive effects on anxiety and passive-avoidance memory in rats. This finding is consistent with previous studies. Further studies are needed to determine the underlying mechanism of this effect.

EFFECTS OF INDUCED POSITIVE AND NEGATIVE STRESSORS ON IMMUNE FUNCTIONING IN CHRONIC DEPRESSION AND CONTROLS. A. V. Raymond, J. Griffiths, S. Zalcman & H. Anisman. Royal Ottawa Hospital, Ottawa, Ontario, Canada KIZ.TK4.

Stressful events encountered by humans have been reported to influence immune functioning. Depending on severity, stressors may influence natural killer (NK) cytotoxicity, circulating lymphocyte subsets (e.g., NK cells), as well as cell proliferation in response to mitogens. In the present investigation, a brief mild laboratory stressor (cognitive challenge) increased NK cell numbers in controls and in dysthymic, low grade depressive patients. The extent of the increase was directly related to plasma norepinephrine levels, and may reflect effects on cell trafficking. Likewise, a more meaningful stressor (having subjects complete the day-to-day (CS) task, leading to subsequent stressors) resulted in an increase of NK cell numbers in both dysthymic and control subjects. Cell proliferation in response to mitogens was reduced in patients who experienced these stressors.

These effects were less marked when patients discussed uplifts, or in control subjects who discussed their hassles. Finally, control subjects who had undergone a stressor perceived as being more severe (final academic examination) exhibited NK cell alterations, as well as variations of several other lymphocyte subsets (e.g., CD4, CD3 and CD-19). The data discussed in terms of the relationship between stress and depression and the impact of stressors on immune functioning.

EXAGGERATED ACOUSTIC STARTLE IN GULF WAR VETERANS WITH PTSD. C. A. Morgan III, C. Griffiths, S. Southwick, and D. S. Charney. Department of Psychiatry, Yale University School of Medicine, West Haven VAMC, West Haven CT 06516.

Exaggerated startle is reputed to be one of the cardinal symptoms of Post Traumatic Stress Disorder (PTSD). Objective studies have given conflicting results as to whether or not startle is increased in PTSD. However these studies were conducted on subjects with chronic PTSD (Vietnam and Israeli combat veterans). The present study investigated the acoustically startle response of eight Gulf War veterans with acute PTSD and 15 healthy age matched controls. The eyelid component of the startle reflex was measured in response to six blocks of pulses (40 ms) white noise bursts of varying intensities (90, 96, 102, 108, 114, 120 dB). No war related or stressful cues were presented to subjects prior to or during testing. Startle amplitude was significantly greater and habituation significantly reduced in the PTSD subjects compared to controls. Because other studies in the literature, as well as our own laboratory, which have investigated the acoustically startle response in chronic PTSD, have failed to find exaggerated startle or reduced habituation of startle at baseline (i.e., absence of stress), it is likely that the present results reflect an acute elevation of startle in this group. The higher amplitude and decreased habituation of startle in the PTSD subjects may reflect a sensitization of the fear/alarms response created by the recent stress of combat trauma consistent with preclinical studies of shock sensitization and startle.

589.10

The purpose of the present study was to characterize the disruptive effects of chronic stress on the acquisition and terminal accuracy of a simple alternation task in rats. All rats lived in individual cages that were exposed to a 12:12 light/dark cycle. During the preshock period, two levers were available and any leverpress resulted in the delivery of a food pellet. Subsequently, rats in group A/E were trained to (Alvoid)/Eiscape signaled footshocks. After learning to escape, food was only available for alternating leverpresses. Alternation was also required in groups Y and C. In group Y, signals and shocks were yoked to those delivered to rats in group A/E; rats in group C were not shocked. This resulted in no difference between groups during acquisition, terminal accuracy (percent correct alternation) was significantly higher in group C than in the A/E or Y groups. This result is from a significantly higher mean number of correct presses (food pellets) for Group C than for either shock group. Since mean number of incorrect presses was significantly higher for group A/E than for group C or Y, the requirement to A/E footshock may have interfered with the accuracy of alternation.

DIFFERENTIAL EFFECTS OF ACUTE STRESS EXPOSURE ON RADIAL ARM MAZE PERFORMANCE. M.J. Stillman, R. Schug-Hale, A. Levy, H.E. Modrow, and H.B. Lieberman. Military Performance and Neuroendocrine Division, United States Army Research Institute of Environmental Medicine, Natick, MA 01760-5007, GEO-CENTERS, INC., Newton Centre, MA 02195, and HIB, Ness Ziona, ISRAEL.

This study examined radial arm maze (RAM) performance following exposure to two stress conditions and a normothemic-free moving control condition. Male Fischer 344 rats were trained on the win-shift RAM procedure for 7 days by which time they achieved asymptotic performance. The next day, rats were exposed to 15 min of restraint in either 37°C water (normothermic-restraint) or in 20°C water (cold-restraint). Rats were removed from restraint and were allowed 40 min in a dry cage prior to being tested in the RAM. Performance was measured using the following dependent variables: time per choice, the total number of choices, the percent error, and the number of correct out of the first eight choices (number correct). NOVA indicated significant effect of stress on number correct (p<.05) as well as the other variables. Performance decrements were observed in both stress conditions relative to the normothemic-free moving condition, with the normothemic-restrained rats displaying less impairment than the cold-restrained rats. From the data it was concluded that stress exposure, when compared to control conditions, had a significant effect on radial arm maze performance. Further studies are needed to determine the underlying mechanism of this effect.

589.12

In an attempt to characterize the pain tolerance response to naloxone administration following exposure to controllable stress, forty healthy male subjects were exposed to bursts of 95 dB noise while attempting to solve a visual-spatial task under either control (CS) or uncontrollable stress (UCS). No difference in pain tolerance was noted among groups during acquisition, terminal accuracy (percent correct alternation) was significantly higher in group C than in the A/E or Y groups. This result is from a significantly higher mean number of correct presses (food pellets) for Group C than for either shock group. Since mean number of incorrect presses was significantly higher for group A/E than for group C or Y, the requirement to A/E footshock may have interfered with the accuracy of alternation.

PERSISTENT HIGH CORTISOL RESPONSES TO REPEATED PSYCHOLOGICAL STRESS IN A SUBGROUP OF HEALTHY MALES. C. Kirchbaum, J. Frittnier, A.A. Stone, I. Fedenor, J. Gaab, D. Lintz, N. Schonmer and D.H. Hellhammer*. Center for Psychology and Psychosomatics, University of Trier, 54286 Trier, Germany.

The present study tested the hypothesis that some subjects may not readily show habituation of adrenocortical stress responses to repeated psychological stress. 20 healthy males were exposed five times to the same, brief psychosocial stressor (public speaking and mental arithmetic in front of an audience) with one stress session per day. Salivary cortisol levels were assessed as an index of adrenocortical stress responses. For the total group, cortisol levels were significantly elevated on each of the five days. The mean response decreased from day 1 to day 2, however, no further attenuation could be observed on the remaining days. Consequently, we evaluated a subsample of subjects who showed completely different response kinetics. In the first group (n=13), termed "low responders", cortisol levels were elevated on day 1 only. Days 2-5 cortisol levels were unaltered. In contrast, subject in the second group ("high responders") displayed large increases to each of the five experimental treatments. This group had no significant response decrement from day 1 to days 2-4 and only a marginal response difference between day 1 and day 5. Discriminant analysis revealed that a combination of scores on a symptom checklist significantly discriminated between high and low responders. Using this discriminant function, all 20 subjects were correctly classified to the two groups. These results are discussed with a focus on the possible impact of adrenocortical stress response types on health and disease.

STRESS: NEUROTRANSMITTER STUDIES

To clarify information processing for novel stress in rat medial frontal cortex (mPFC), we developed newly system to monitor glutamate (GLU) and lactate with a high time-resolution (less than 1 min) by using in vivo brain microdialysis. The dialysate was mixed directly with an enzyme solution (containing GLU- and lactate-dehydrogenase and NAD+) in a Teflon-coated cartridge. The fluorescent of produced NADH in the mixture was measured continually by a fluorometer equipped with a flow cell. The basal level of mPFC GLU release was 60 pg/min and decreased 2-3pg/min a week. The basal lactate release was 90 pg/min and decreased 1-2 pg/min a week. These basal release rates were suppressed partially by the 2nd trial 1 hour later in a manner of habituation (GR; TP: 32.9 (+/-3.8%); LR: TP: 34.5; 7.1%; 100dB: 33.9-9.2%; IMB; 45.5-6.2% vs. the initial responses, all at least p<0.05 by paired t-test (n=4-5)), consistent with dishabituation to a novel stimulus or "bellowzer" habituation by several repetitions. GR and LR both showed the decreasing response by TP in septum. The mPFC GR release was appeared under reserpinein (0.5 mg/kg, sc) while these of LR were completely not. These results suggested that there are two different systems for stress processing compared in rat mPFC.

We obtained a chemical map of learned helplessness (LH) in the rat involving serotonin (5-HT), dopamine (DA) and GABA in medial prefrontal cortex, GABA and norepinephrine (NE) in hippocampus, and 5HT in septum. In hypothalamus, other investigators have reported decreased 5-HT uptake by sodium and K-stimulated release by tissue slices of LH rats, as well as decreased paroxentine and unchanged 5-HT-adrenergic receptor binding. We have now applied in vivo microdialysis to measuring DA, NE and 5-HT simultaneously in hypothalamus and caudate of conscious, freely moving rats in a LH paradigm. Rats received 100 trials of inescapable tailshock stress, and after testing, LH, microdialysis probes were implanted into either caudate or lateral hypothalamus. One day later, perfusion was maintained with Ringer's solution until a stable baseline was obtained, then switched to Ringer's with high K+. No differences were found in caudate in DA or 5-HT among any of the three experimental groups (LH, NH - stressed, non-stressed, or blank control). In hypothal,

*Adrenergic, no differences were seen for DA or 5-HT. NE in hypothalamus, significantly higher levels of basal NE were observed for LH rats, compared to NH and TC, while the NH rats had significantly higher K-stimulated NE release than LH or TC. For all the stressed rats, there was a significant positive correlation between shuttlebox escape latency and basal NE release. These data suggest that the caudate may not be involved in the in vivo biogenic amine neurotransmission of LH, and that in the lateral hypothalamus, NE mechanisms predominate in this animal model of depression.
590.5 EFFECT OF BETA-1 ADRENERGIC BLOCKADE ON c-FOS RESPONSE TO STRESS IN MOUSE BRAIN. Y. Zhang* and E.A. Stone. Dept. Psychiatry, New York University School of Medicine, New York, NY 10016

We have previously shown that beta-blocker-reversible c-fos expression can be used as a marker for postsynaptic noradrenergic activity at beta-receptors in the brain. The present study utilizes this method to determine in which regions of the brain beta-1 receptors are activated during stress. Male Swiss Webster mice were injected with the selective beta-1 blocker, beta-blocker-reversible c-fos immunohistochemistry using a fos-specific antibody by standard procedure. Noninjected-nonstressed and betaxolol-injected-stressed mice showed little c-fos immunoactivity in the forebrain. c-IMPO stress caused widespread c-fos expression in the forebrain and brainstem. Betaxolol treatment prior to stress significantly reduced c-fos in most forebrain structures but not in the brainstem. These results suggest that stress activates beta-1 receptors primarily throughout the forebrain. Supported in part by grants AFOSR F49620-92-J-0084, MH52655 and MH08618.

590.6 EFFECT OF PROPRANOLOL ON STRESS-INDUCED CHANGES IN PASSIVE AVOIDANCE AND OPEN FIELD EMERGENCE TESTS. I.S. Manavalan*, M. Najimi, E.A. Stone and D. Quartermain. Depts. Psychiatry & Neurology, New York University School of Medicine, New York, NY 10016

The present study examined the effect of propranolol on the ability of stress to elicit behavioral inhibition in Harlan Hsd:Nrd4 mice. Mice were given propranolol prior to immobilization or tube-restraint stress and then were tested for either passive avoidance performance or time to emerge into an open field. In contrast to previous findings by others, propranolol was found to markedly potentiate stress-induced increases in latency in these tests. These unexpected results were not due to peculiarities of the behavior measured, the stressors used or the dosage of the drug administered. As propranolol has blocking actions at beta adrenergic and serotoninergic receptors, the results raise the possibility that, under some conditions, the response of the noradrenergic and/or serotoninergic systems to stress may have anxiolytic or anti-stress effects. Supported in part by grants AFOSR F49620-92-J-0084, MH52655 and MH08618.

Recent experiments with rats in semi-naturalistic environments have indicated that chronic subordination stress impairs risk assessment, i.e., reduces the likelihood that the animal will engage in species typical behaviors to alter the location and source of possible danger. The present study was undertaken to determine if acute stress disrupts risk assessment in mice measured in terms of latency to emerge from a dark cage into a novel, potentially dangerous environment. Groups of male Swiss Webster mice (N=12) were either to immobilization, tube-restraint, unavoidable footshock or exposure to a dominant aggressive mouse. All stressors were administered to individual mice for a duration of 1 hr. Risk assessment behavior was examined 30 min following stress termination. Mice were placed in a small dark enclosed entry chamber which was attached to a large brightly lit open field which could be entered through a small door at the end of the chamber. Latency to emerge (max. 5 min) was determined. Immediately after, animals were observed in the open field for a 5 min period during which time locomotor activity was measured and rearing, grooming and defecation frequencies were recorded. Results showed: 1. Mean entry latency for all stress groups was significantly faster than that of a non-stressed control group. 2. All stressed groups showed significantly less locomotor activity and rearing and significantly more episodes of grooming than non-stressed mice during a 5 min period in the open field. These data indicate that acute stress can disrupt defensive behavior by impairing the animal's ability to respond to potentially threatening stimuli. Supported in part by grants AFOSR F49620-92-J-0084, MH52655 and MH08618.

590.8 THE ROLE OF NORADELINE IN THE MEDIAL PREFRONTAL CORTEX IN THE ELEVATION OF HEART RATE INDUCED BY TAIL PINCH IN THE RAT. D. Fung* and J. Stewart. Center for Studies in Behavioral Neurobiology. Dept. Psychology, Concordia University, Montreal, Canada, H3G 1M8

The noradrenaline (NA)-containing projections to the medial prefrontal cortex (MFC) are activated in response to stress. The functional role of MFC NA release in the stress-induced activation of the autonomic nervous system (ANS), however, remains undefined. This study examined the effects of microinjections of Nα-blocking drugs into the MFC on a response mediated by ANS activation, the increase in heart rate (HR) induced by tail pinch. Male rats anesthetised with urethane (1.5 g/kg) received 2-10 s tail pinches separated by 5 minutes prior to and after infusions of 10 nmol of the beta adrenergic agonist isoproterenol (ISO) unilaterally into the right MFC. Tail pinch elevated HR, which returned to basal levels in the succeeding 5 minutes. Injection of ISO into the MFC increased baseline HR, and potentiated the increases in heart rate induced by tail pinch. The alpha adrenergic agonist phenylpropanolamine (20 nmol) was without effect on either baseline HR or tail pinch induced increases in HR. These results suggest that NA released in the MFC, via stimulation of beta adrenergic receptors, plays a facilitating role in the stress-induced activation of the ANS. Studies are in progress to examine the function of the dopaminergic projection to the MFC in stress responses mediated by the ANS.

590.9 EFFECTS OF CHLORZAPAXIDE ON FOOTSHOCK-INDUCED OVERFLOW OF CEREBRAL NOREPINEPHRINE. Artur H. Swierget*, Zhongyou Wei, Yashik Li and Adrian J. Dunn. Department of Pharmacology, Louisiana State Univ. Med. Ctr., Shreveport, LA 71130-3935

Synaptic release of central catecholamines is increased during stress. The effects of benzdiazepines on the stress-related release of catecholamines has been evaluated. We have used microdialysis to examine the effect of chlorzepaxide (CDP) pretreatment on the footshock-induced release of norepinephrine (NE). Freezly moving rats were implanted with microdialysis probes in the hypothalamus and the medial prefrontal cortex (PFCM). Footshock (50 x 0.1-0.2 mA shocks over 20 min) significantly increased microdialysate concentrations of NE in the first sample collected. The subsequent two samples showed small elevations that were not statistically significant. In both the hypothalamus and the PFCM samples, NE was significantly augmented over the prefootshock baseline. CDP administration (5 mg/kg ip) had no statistically significant effects on the basal dialysate concentrations of NE, although there was a tendency towards a reduction. CDP administered before the footshock significantly attenuated the dialysate concentrations of NE.

These results suggest that footshock increases the synaptic release of NE in the cortex and hypothalamus, and that this response is attenuated by CDP. The experimental design used cannot determine whether systemic CDP alters the input to LC noradrenergic neurons, or whether benzdiazepines exert a direct effect on the noradrenergic neurons.

Supported by grants from the Air Force of Scientific Research.
SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

590.11 FLUOXETINE TREATMENT ATTENUATES STRESS-INDUCED NORADRENAL (NE) EFFLUX IN THE HIPPOCAMPUS M.E. Page* and E.D. Abercrombie. Center for Molecular & Behavioral Neurosciences, Rutgers University, New Brunswick, NJ 08902

The noradrenergic locus coeruleus (LC) has long been implicated in various aspects of the regulation of behavioral state. This system is responsive to a wide variety of stimuli, especially novel or threatening and stress. Noradrenergic (NE) turnover increases in LC target regions in response to stress. It has been previously shown that presentation of acute stressors increases the synthesis and release of NE in the hippocampus (Abel et al., 1988). Despite its thought to contribute to a number of mental health problems including depression, anxiety and panic disorder. Chronic treatment with antidepressants alleviates many of the symptoms of depression and anxiety shows to alter LC function. However the mechanism of the therapeutic action of these drugs is unclear. It has been demonstrated that serotonin selectively attenuates LC responses evoked by local application of glutamate or nociceptive stimuli. The effect of acute treatment (2 days: 10 mg/kg/day) with the antidepressant fluoxetine, a selective 5-HT reuptake inhibitor, on hippocampal NE and DOPAC efflux was examined using in vivo microdialysis. Because there is no significant DA innervation of the hippocampus, DOPAC levels in this region are thought to reflect NE synthesis. Basal levels of NE and DOPAC did not differ between vehicle controls and 2-day fluoxetine-treated animals. Application of a clump to the rat's tail for 30 min, evoked an 80% increase in NE in vehicle control animals (n=3) and a 33% increase in animals which received FLU for 2 days (n=5). Taelpich evoked an 89% increase in extracellular DOPAC levels in vehicle animals compared to a 33% increase in FLU animals. Experiments are presently underway to determine the effects of chronic (14 day) administration of FLU on stress-induced NE efflux. One function of fluoxetine may be to modulate stress-induced responses of the LC-NE system. This work supported by NIMH DA08986.

Results from a variety of experimental paradigms have pointed to a cholinergic involvement in the stress response. Recently, analytical techniques have become available to measure ACh release in vivo during exposure to various stressors. In these experiments designed to monitor ACh output every 15 min in the dorsal hippocampus (HIPP), amygdala (AMY), nucleus accumbens and prefrontal cortex (PFC) before, during and after a 15 min session of intermittent tail shock (1/min, 1 mA, 1 sec duration) in rats. In response to the stressor, ACh release was significantly increased in the PFC (180%; p<.01), HIPP (170%; p<.01) and AMY (144%; p<.05) but not in the NAcs. In each site tested behavioral and/or maximal release occurred in the 15 min sample following release from restraint at which point ACh levels reached significance in the NAc (130%; p<.05). These data demonstrate an enhancement of cholinergic activity during application of the stressor in three ACh projection systems (HIPP, AMY, PFC).

590.13 CHRONIC COLD STRESS ENHANCES THE RESPONSE OF LOCUS COERULEUS NEURONS TO STIMULATION OF NUCLEUS PARAGIGANTOCELULARIS M. Mame* and A.A. Grau. Dept. of Neuroscience & Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260

We have previously demonstrated that chronic cold stress increases the footshock-evoked response of locus coeruleus (LC) neurons in the anesthetized rat. Using in vivo extracellular single-unit recordings, we now demonstrate that this stress-related enhancement of evoked activity also occurs in response to direct electrical stimulation of the nucleus paragigantocellularis (nPGi), the major glomerular afferent to the LC. Twenty-four hours after termination of chronic cold stress (5°C for 17-22 days), LC neurons from cold-stressed rats displayed a significant elevation in basal firing rate (mean = 2.7 Hz for Cold Stress vs. 1.8 Hz for Controls); these basal rates were significantly higher than we have previously reported and may be related to the implantation of the stimulation electrode into nPGi. There were no differences in the threshold for activation of LC cells by nPGi stimulation (Cold Stress = 190 ± 9 μA; Control = 155 ± 4 μA in extracellular current) or in their response latencies (Cold Stress = 0.013 ms vs. Control = 0.014 ms). However, the incidence of spike activation by nPGi stimulation was greater in LC cells from the cold stressed rats (Cold Stress = 40 responses vs. Control = 34 responses; 30 stimulations at 150% of threshold), as was the incidence of burst firing (Cold Stress = 8 bursts/30 stimulations vs. Control = 4 bursts/30 stimulations). In addition, the duration of postactivation spike suppression was shorter for LC cells from cold stressed rats (Cold Stress = 600 ms vs. Control = 780 ms). We are currently investigating whether these stress-induced changes in the LC response to glutamatergic excitation from nPGi are due to changes in their sensitivity to glutamate or to a change in some other system which modulates this response.

590.15 ALtered EXPRESSION OF mRNAs ENCODING GABA A RECEPTOR SUBUNITS α1 AND α2 FOLLOWING RESTRAINT OF JUVENILE AND ADULT RATS. Roberts, Alice A; Pleger, Glorieta L; Jones, Amy W; and Kellnace, Carol K. Dept. of Psychology, Univ. of Rochester, New York, 14627.

The GABA A receptor, a multimeric protein complex located on neuronal cell membranes, mediates inhibition in cortical circuits by altering GABA-gated chloride permeability. Cortical GABA A receptors of male rats functionally respond to acute stressors in young adult (P70-90) but not at juvenile (P35) or adolecent (P35-42) ages. Likewise, young adult males exhibit altered behavioral and GABA A responsive responses based on prior experience, whereas juvenile do not. We have found modest increases (30-40%) in cortical mRNAs encoding α1 and α2 GABA A subunits immediately after two-hour restraint of young adult, but not juvenile, brains. The present study tracks expression of GABA A subunit mRNAs in young adult and juvenile brains taken at 0, 2, 4, and 6 hours following two-hour restraint; levels in cortex, hippocampus, and cerebellum, are determined by RNAase Protection Assay. Our initial results (n = 6) suggest that the impact of experience on cortical GABA Aα subunit expression may develop across adolescence in parallel with functional responsiveness of cortical GABA A receptors to acute stressors. Since juveniles lack experience-dependent behavioral responses, it may be that altered GABA Aα subunit expression underlies inhibitory synaptic plasticity critical for specific behavioral adaptation to challenging environmental stimuli.

Exposure to toxic stressors such as noxious tailshock (IS) lead to a variety of behavioral alterations not produced by controllable stressors. While noxious stressors that induce effects
because IS leads to an intense activation of the dorsal raphe nucleus (DRN), a consequent downregulation of inhibitory somatodendric 5-HT1A autoreceptors, and hyper-excitability of the 5-HT1A receptors.

The present experiments tested these possibilities by inhibiting DRN activity either before IS exposure or before behavioral testing 24 hr later. By the above arguments, one should block the behavioral effects of IS. Male Sprague-Dawley rats were either exposed to 100 unignited 1 mA tailshocks or were loosely restrained for an equal time period. Testing occurred 24 hr after shock or restraint and involved fear conditioning and shuttlebox escape testing. The 5-HT1A agonist 8-OH-DPAT was infused into the region of the DRN (1 ug in 1 ul) either before the IS treatment or prior to testing. These results differ from those reported for systemic administrations of 8-OH-DPAT. However, doses of systemic 8-OH-DPAT may facilitate rather than inhibit 5-HT activity through action at post-synaptic receptors. Therefore, different doses of 8-OH-DPAT were systemically administered before testing. A dose of 0.1 mg/kg blocked the enhanced escape deficit produced by IS, 0.1 mg/kg attenuated this effect of IS, and 1.0 mg/kg had no effect on escape performance. Conditioned fear, however, was blocked by all doses of 8-OH-DPAT. Support provided by NIH MH 50479.

THE EFFECTS OF SOCIAL STRESS ON SEROTONERGIC INDICES IN PREFRONTAL CORTEX OF ADULT MALE CYMOLOUS MONKEYS. MB Rochelot*, JR Kaplan, SR Mannik, JF Mann, Dept. of Comparative Med., Bowman Gray Sch. of Med., Wake Forest Univ. Winston-Salem, NC 27117 and Departments of Psychology and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15213.

The effects of social stress and maternal status on monoamine concentrations in the prefrontal cortex were examined in adult male cynomolgus monkeys (Macaca fuscata). Seventy-five animals were housed in five-member social groups for 28 months. Social groups either remained intact at the time of testing or had their group membership (no-stress condition) or had their group membership reorganized at monthly intervals during months 1-14 (post-stress condition) or during months 15-28 (recent-stress condition). At necropsy, brain samples were collected and stored at -70°C until analyzed. Frontal pole cortical and CSF monoamines (serotonin [5-HT], dopamine, noradrenaline and metabolites [5-hydroxyindoleacetic acid [5-HIAA], homocysteic acid, 3-methoxy-4-hydroxyphenylglycol [MHPG]) were assayed using high-performance liquid chromatography with electrochemical detection.

Animals exposed to past social stress had significantly lower 5-HT (p < 0.02) and 5-HIAA (p < 0.01) concentrations in the prefrontal cortex compared to animals in the no-stress condition. Prefrontal cortical 5-HIAA and 5-HT concentrations in the recent-stress condition were intermediate between the concentrations in the no- and post-stress conditions. These data suggest that past exposure to chronic social stress may be associated with an enduring and perhaps progressive reduction in serotonergic function in the prefrontal cortex. Such an effect may underlie the behavioral sequelae of stress such as post-traumatic stress disorder.
HORMONAL CONTROL OF REPRODUCTIVE BEHAVIOR: PARENTAL/AGGRESSIVE

EXCITOTOXIC LESIONS OF THE VENTRAL BED NUCLEUS OF THE STRIA TERMINALIS DISRUPT MATERNAL BEHAVIOR IN RATS.
M. Numan, M. Jung, J. Psychology, Boston College, Chestnut Hill, MA 02167.
Lesions of the medial preoptic area (MPOA) severely disrupt maternal behavior in rats, but these lesions also damage the ventral part of the bed nucleus of the stria terminalis (VBNST). Other work has shown that Fos expression increases in both the MPOA and the VBNST of lactating maternal females rats. Finally, anatomical work has suggested that these lesion may be VBNST efferents to the brainstem, rather than MPOA efferents, which are important for maternal behavior.

The present work directly tests the importance of the VBNST. Pregnant rats with pretreatment received one of the following: bilateral injections (3 ug/ul) of the excitotoxin, N-methyl-D-aspartic acid (NMDA) directly into either the VBNST or the doratal BST, or bilateral injections of the inactive, I-aminoacid, into the VBNST. Only animals that received NMDA injections into the VBNST showed severe deficits in maternal behavior.

These results suggest that VBNST efferents are important for maternal behavior. Additional work is iontophoretically applying PHA-L to the VBNST in order to examine its major projection routes and termination sites.

Supported by NSF Grant 19831315.

95.1.7
THE DISTRIBUTION OF PROLACTIN BINDING SITES IN THE BRAIN OF BROODING SALAMANDERS.
L.P. Mangurian*, K.I. MacArthur, R.L. Sejnowski, and D.C. Forester. Department of Biological Sciences, Towson State University, Towson, MD 21204.
Prolactin (PRL) influences reproductive behaviors and has been shown to stimulate maternal behavior in rats and doves. The reproductive behavior of amphibia, such as the water drive prior to oviposition, is also influenced by PRL. Desmognathus fuscus females exhibit a brooding behavior. This study was designed to investigate the possibility that prolactin may influence brooding behavior by examining their brain potential prolactin sensitive areas. The localization of PRL target areas was carried out using in vitro autoradiography. Frozen brain sections were incubated with 125I ovine PRL and then autoradiographed. Only the olfactory bulb (300 fold) regions were found.

Supported by TSU Faculty Research Grant (LPM) and TSU Student Research Grants (KJM and RLS).

95.1.9
QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF D1 AND D2 DOPAMINE RECEPTORS IN RAT BRAIN ACROSS PREGNANCY.
Previous work has suggested that dopamine may be a neurotransmitter involved in some aspects of maternal behavior (Phys & Behav 48:211). In addition, treatment of females with pharmacological doses of dopamine, a hormone important in late pregnancy, increased the level of dopamine binding in the striatum (Brain Res 46:249, 1988). We hypothesized that the naturally occurring physiological and endocrine events of pregnancy may alter the level of the D1 and D2 dopamine receptors in a regional specific manner. Using quantitative autoradiography (D1 receptors: 1.0 mg/mL-C-3H-SCH-23390; D2 receptors: 1.0 mg/mL-D-2-spiroperidol), brains from pregnant females (day 1 to 21), non-pregnant females, and males were examined. As predicted from previous work, even in pregnant females, in most brain regions D1 receptors were present in greater density than D2 receptors. The highest levels of D1 and D2 binding were in striatum, nucleus accumbens, and olfactory tubercle. Moderate to low levels of D1 binding were found in zona incerta, thalamus and hypothalamus, and low levels of D2 binding were found in olfactory bulb and hypothalamus. In some brain regions, pregnancy did not alter the D1 or D2 receptor levels; in other brain regions receptor binding was significantly different in females on day 2 compared to day 21 of pregnancy. For example, D2 females had substantially lower levels of D1 receptor in lateral and medial striatum than 2 day pregnant females. Preliminary results also show that late pregnant females had modestly lower levels of D2 receptors in anterior striatum, nucleus accumbens and olfactory tubercle. These results may provide clues to the brain regions that are most important for dopamine mediation of maternal behavior in rats. Supported by HD 22963 to JBM.

95.1.6
CHOLECYSTOKININ (CCK) AND THE REGULATION OF MATERNAL BEHAVIOR.
Recent work in our laboratory has established that concurrent intracerebroventricular (icv) infusions of CCK-8 with -endorphin prevents the disruptive effects of -endorphin on the maintenance of maternal behavior in lactating rats (Felicio et al., 1991). CCK has also been shown to stimulate the onset of maternal behavior in virgin rats; Linden et al. (1985) found that chronic pretreatment with CCK-8 (300 pg) for 12 h stimulated maternal behavior within 2 hours of exposure to pups. The goal of the present series of experiments was to further examine the role of CCK in the induction of maternal behavior and characterize CCK's involvement in ongoing maternal behavior. In a set of studies evaluating the role of CCK in the onset of maternal behavior, we were unable to stimulate maternal behavior in virgin Sprague-Dawley rats treated chronically with CCK-8 (300 pg) or in steroid-primed, ovariectomized, virgin rats given icv infusions of CCK-8. Moreover, chronic infusions of CCK-8 into the lateral ventricle of primigravid rats late in pregnancy also failed to stimulate maternal behavior. In contrast to the apparent lack of involvement of CCK in the onset of maternal behavior, ongoing maternal behavior appears to be regulated in part by CCK. When lactating rats were infused icv on day 5 postpartum with either 25 or 126 pg of progesterone, a nonspecific CCK antagonist, lactating rats displayed longer latencies to first crouch over their young, an effect similar to the inhibitory response found after central infusions of -endorphin (Mann et al., 1991,1992). Together, these data suggest to us that CCK-8 is more strongly involved in the regulation of ongoing maternal behavior than in the induction of maternal behavior in the rat. Further studies are needed to determine sites and modes of CCK action. Supported by PHS Grants DA04291 and HD19789 (RSB).

95.1.8
FOS IMMUNOREACTIVITY IN THE HYPOTHALAMUS ASSOCIATED WITH PARENTAL BEHAVIOR IN THE PRAIRIE VOLE, M. OCHROGASTER. B. Kirkpatrick*, D. Litman, T.W. Kim. Maryland Psychiatric Research Center, Department of Psychiatry, University of Maryland School of Medicine, Baltimore, MD 21228.
A number of studies have implicated the paraventricular nucleus of the hypothalamus (PVN) in the onset of maternal behavior in rats. However, we found no increase in Fos immunoactivity associated with maternal or female parental behavior in the PVN in the prairie vole, a species in which both males and females spontaneously exhibit parental behavior prior to sexual maturity.

To clarify the role of hypothalamic Fos in paternal behavior, we examined cellular activation in areas of the hypothalamus other than the PVN, following exposure to a pup in male prairie voles. Fos immunoactivity was quantified in suprachiasmatic, ventromedial, dorsomedial, and premammary nuclei, and the anterior and posterior hypothalamic areas. Compared to controls exposed to a novel olfactory stimulus, males exposed to pups showed an increase in several discrete areas. These results suggest hypothalamic areas other than the PVN may be involved in the control of paternal behavior in this species.

95.1.10
EFFECTS OF FOOD RESTRICTION ON MONOAMINE CONCENTRATIONS IN HYPOTHALAMIC NUCLEI OF THE CHICKEN BRAIN. L. Moors,* Y. Gu and F. Vandesande* Lab. of Neuroendocrinology, Zoological Institute, Naamsestraat 59, 3000 Leuven, Belgium, Europe.
Intensive selection for increased muscle growth in meat-type chickens has led to a decrease in the reproductive performance. Excessive food restriction has become the standard industrial procedure to improve the reproductive efficiency of the meat-type parent stocks. The neural control of both the feeding and the reproductive behavior seems to happen through identical neurotransmitters, catecholamines and serotonin. In order to determine whether food restriction alters in some way the concentration of monoamines in hypothalamic nuclei assumed to be involved in the control of reproduction, - ad libitum fed and food restricted female meat-type chickens were killed at the ages of 4, 10, 16 and 22 weeks. A quantitative determination of the concentration of biogenic amines was performed in ten different micropunctured hypothalamic brain areas. The amines: L-DOPA, dopamine, norepinephrine (NE), epinephrine and serotonin and their major metabolites were separated on a C-18 HPLC column and determined by electrochemical detection. In most hypothalamic areas studied and for most neurotransmitters determined no concentration difference, resulting from food restriction, was found. However, food restriction did affect the amount of certain biogenic amines in a few hypothalamic nuclei. The most striking difference occurs in the median eminence, where the concentration of NE is largely increased in food restricted animals. These quantitative data provide an excellent basis for further research on the possible role of catecholamines and indolamines in the altered feeding and reproductive behavior in the meat-type chicken.
EPILEPSY: MECHANISMS OF EXCESSIVE DISCHARGE

592.1

NPY, SS, AND GAD MOLAR MOLECULAR LAYER SPROUTING IN HUMAN EPILEPTIC HIPPOCAMPI. G.W. Mathern, T.L. Babb, J.L. Leite, J.K. Preoty, and J. Engel, Jr. UCLA School of Medicine, Los Angeles, CA 90024-1766.

Patients with Hippocampal Scarring (HS, n=18), Mass Lesions (Mass, n=9), or autopsies were compared for differences in: 1) percentage of hilar neurons immunoreactive (IR) for NPY, somatostatin (SS), and GAD, and 2) patterns of fascia dentata (FD) IR-sprouting, and FD densities of FD IR-sprouting. Results were: 1) NPY-IR hilar neurons decreased in an equal proportion to all hilar neurons (p=0.47), SS-IR neurons were significantly decreased in HS in excess of hilar n=0.03), and GAD-IR neurons were not significantly different (p=0.26). 2) Outer molecular NPY-IR decreased in HS compared to Mass (p=0.0002), but was unchanged in SS-IR (p=0.09), and inner molecular layer with GAD-IR (p=0.007). 3) The patterns of IR-sprouting between HS and Mass were significantly different (p=0.001). This supports the notion that peptide hilar counts and molecular layer synaptic reorganization differ among peptides and between patients with HS and Mass pathogenic mechanisms. Supported by NS 20808 and KO8-NS 01603.

592.2

Although status epilepticus (SE)-induced brain damage is well-documented in animal models, human cases of neuronal damage caused strictly by SE have been difficult to document because of systemic factors or a history of pre-existing epilepsy. It has been hypothesized that excessive release of neurotransmitter glutamate is responsible for the SE-induced neuronal necrosis. We report 3 patients who died 12-27 d after the onset of focal motor SE, in whom hypotension, hypoxemia and hypoglycemia do not complicate the interpretation of results. Two of the 3 patients had no prior seizures and no known cause of their SE. The third patient, who had leptome ningeal carcinomatosis, had 1 seizure 2 months before the onset of SE. The duration of SE was 2.5 h-3 d. EEGs showed unilateral temporal lobe sharp-wave discharges in 1 and independent temporal lobe sharp-wave discharges bilaterally in the other 2. There was widespread neuronal loss in the hippocampus (CA1-3 and hilus), amygdala, piriform cortex, dorsomedial thalamic nucleus and cerebellum (Furkine ecells), with scattered neuronal loss in the cerebral cortex. In 2 of the 3 cases the damage was unilateral and occurred on the side in which seizure discharges were most prominent. The regional distribution of the damage in these 3 cases was similar to that found in animal models of limbic SE: it occurred primarily in limbic structures with high densities of glutamate receptors. (Supported by the Dept. of Veterans Affairs.)

592.3

In order to investigate the prevalence of neuronal synchronization in specific pathways of the human hippocampal formation and amygdala, EEG spikes, single and multiple cell action potentials were recorded in patients with surgically implanted intracranial depth electrodes required for diagnostic studies. MRI guidance was used to place electrodes bilaterally in amygdala, anterior and medial hippocampus, entorhinal cortex, and parahippocampal gyrus. Bundles of 9 microwires were used for extracellular recording. In one group of patients interictal EEG spikes were monitored continuously for 6 to 10 and bipolar spike density maps were obtained at each recording site using EEG spike detection software. Spike frequency distributions (spikes/min) were plotted over the entire period and crosscorrelations between recording sites were computed. Although correlations varied widely, a direct relationship was found between spike rate and the probability of a significant positive correlation between specific anatomical pathways, including the periforn, longitudinal association, and retrohippocampal pathways. In a second group of patients, microelectrode recordings 5 to 30 min in duration were obtained from a total of 255 cells and subjected to crosscorrelation analysis between 2 to 8 simultaneously recorded cells. Or 93 possible within-bundle unit correlations, 49% were significant, and of 516 possible between-bundle correlations dependent upon anatomical connections, 25% were significant. Both showed a greater proportion of significant correlations in the temporal lobe where seizures originated. Supported by NS 20808.

592.4

Synchronized neuronal burst discharge is hypothesized to initiate ictal events. If so, inter-ictal neuronal synchrony in epileptogenic structures may include a higher percentage of burst action potentials (burst APs). We therefore sought to examine the relative contributions of isolated and burst APs to synchronous interactions both ipsilateral and contralateral to seizure onset in patients with complex partial seizures. Spontaneous inter-ictal single cell activity was recorded from the hippocampus, amygdala, and other temporal lobe structures of patients undergoing chronic depth electrode implantation to localize seizure onset. When cross-correlation histograms between pairs of simultaneously recorded cells contained a significant central peak, implying a synchronous interaction between those cells (r=0.75 ipsilateral, r=0.93 contralateral), the proportion of burst APs contributing to that peak was calculated for each cell. Bursts APs showed a strong trend towards a proportionally greater contribution to synchronous interactions contralateral to the side of seizure onset. The correlation between the likelihood of a neuron to discharge bursts and the contribution of burst APs to synchronous interactions involving that cell was stronger in the contralateral hemisphere (r=0.72) than the ipsilateral (r=0.72). Our results suggest that in the inter-ictal state, regions that commonly initiate seizures are less likely to contain synchronously bursting neurons. Supported by NS 20808.

592.5

Modulation of neuronal discharge by the cardiac cycle is relatively common in the mammalian nervous systems. Cardiac cells in amygdala is markedly higher ipsilateral to seizure onset, suggesting an interaction of these cells with epileptogenesis. We examined 314 single units from patients with epilepsy undergoing depth recordings of mesial temporal EEG. Bilateral recordings were performed in amygdala, hippocampus, anterior and posterior perihippocampal cortex, and entorhinal cortex. From 3 to 20 spike trains were recorded simultaneously from each patient, permitting direct evaluation of the nature and number of cell interactions. Spike trains were characterized on the basis of cross- and auto-correlograms, with inhibitory and excitatory phenomena recorded as the proportion of possible interactions. Cardiac-modulated cells were more likely to participate in spike trains and were strongly coupled with inhibitory interactions. In amygdala, this relationship was strikingly dependent on the side of seizure onset. Cardiac-related amygdala cells on the contralateral side participated in inhibitory interactions, and were likely to "drive" cells in other structures. On the ipsilateral side, cardiac dependency was associated only with a bursting pattern of discharge. This difference may result from a loss of region inhibitory connections to cardiac-dependent cells. Supported by NS 20808.

592.6

Paced-pulse stimulation of the perforant pathway has been used to animal models of epilepsy to examine the status of inhibitory processes in the dentate granule cells, relative facilitation of the granule by observed following experimental treatments which destroy inhibitory interneurons in the dentate hilus1. We report the intraoperative use of the paired-pulse paradigm in eighteen patients undergoing synchronous for medically intractable seizures. During the resection surgery, after the lateral leucocortex, monophasic depth electrodes were placedcephalad through the dentate gyrus. Four contact strip electrodes were also placed on the hippocampal alveus surface and on the entorhinal cortex. Stimulation to the perforant path was performed utilizing single pulse paired pulses with interpulse intervals of 20, 40, 60-100 and 200 msec. In the initial 10 patients, PSs were recorded without modulation spike. Technical improvements have allowed us to record clear population spikes in six of the last 8 patients. Inhibition was observed in the pairing of the PSP or spike amplitude selected at each IPI to that measured after a single pulse. In an on-going study, these measures are compared to pathological studies of the excised hippocampus, other in-vivo and in-silico electrophysiological studies, and the test predicted in part by an American Heart Assoc. Fellowship and NIH Grant NS06169)

592.7

DISTRIBUTION OF CALCIUM-BINDING PROTEINS PARVALBUMIN, CALBINDIN D-28K, CALRETININ, AND PERINEURONAL NETS IN THE HUMAN EPILEPTIC HIPPOCAMPUS. C. Eckedo*, I. Slivkina*, M. R. Cela*, C. E. Crawford, and J. D. White. Dept. of Neurosurgery, University of Bonn Medical Center, 53105 Bonn, Germany. 2 Dept. of Histology and General Embryology, University of Fribourg, 1705 Fribourg, Switzerland. Neural vascular changes during epileptic seizures has been associated with an increase in intracellular free calcium concentration. Hippocampal neurons which contain the calcium-binding proteins (CalpBPs) parvalbumin (PV), calbindin D-28K (CB) and calretinin (CR) are, therefore, reasonable candidates for studies on the morphological and neurochemical alterations in human temporal lobe epilepsy (TLE). PV+ and CB+ neurons (PV-Lo) neurons are also covered with different extracellular matrix molecules forming the perineuronal nets (PNs) and are surrounded by astroglial processes. PNs may protect these neurons from an excess of extracellular glutamate during seizures.

We studied the distribution of PV-Lo, CB-Lo, and CR-Lo neurons in hippocampus (HC) specimens obtained from patients with TLE. Autopsy brains were used as controls. The immunohistochemical staining pattern were correlated with the following histopathological changes: (1) HC without histological alterations; (2) HC with focal lesions or tumors; (3) HC with Ammonshorn sclerosis (AS); (4) HC with both, focal lesions/tumors and AS. In general, the neuronal loss observed in TLE patients was associated with a decrease in CB+ neurons. However, among the surviving neurons, many PV+ and CB-Lo neurons were covered with PNs. In some patients, CR-Lo showed an increase in neurileptol staining in the dentate gyrus and CA3 region, as well as "de-novo" granule cell staining in some of the CR-Lo neurons were covered with PNs. We conclude that neurons expressing PV and CB, which were surrounded by PNs, were less vulnerable to degeneration in TLE. In addition, CR may serve as an interesting marker for activated and reorganizing neuronal systems in human TLE.

Supported by the German BMFT Helmholtz-fellowship for I.B.

MORPHOLOGY OF GRANULAR NEURONS IN THE HUMAN HIPPOCAMPUS. G. von Campe, P. Baard* D. Spencer, N. C. de Leraovere, Yale University School of Medicine, Section of Neuropsychology, New Haven, CT 06519.

Examination of hippocampi removed from patients with medically intractable temporal lobe epilepsy (TLE) has shown considerable neuronal reorganization within the seizure focus. Granule cells and their mossy fiber axons contain the opioid peptide dynorphin, which in normal hippocampi is not expressed in the molecular layer. In patients with mesial temporal sclerosis, a dense band of staining is observed in the inner molecular layer, suggesting collateral sprouts from granule cells into the molecular layer. To directly examine the presence of such collaterals from granule cells we studied the morphology of individual cells by using an intracellular injection technique. Fluorescent microspheres (4%) fixed with formalin were sliced into 100 μm thick sections on a Vibriostat. Individual neurons were then visualised and photographed (20x for 5-15 minutes) with Lucifer Yellow (3-5% aqueous solution) under UV illumination. Selected filled cells were then photoinjected with UV irradiation in the presence of diamobenzidine (DAB) to produce a peroxidase-like reaction. In patients with mesial temporal sclerosis at least two morphological types of granule cells were found. One type was a single branched apical dendrite and a single axon-like process extending from the opposite end toward the hilus. The other type of granule cell has a more rounded cell body with two to several apical dendrites and a single basal axon. In several neurons, fiber-like processes were observed to arise from the basal to lateral region of the cell body, and after a short course toward the hilus, they curved back up and entered the molecular layer. Such processes may be the morphological basis of the dynorphin immunoreactivity observed in the inner molecular layer of hippocampus from patients with temporal lobe epilepsy. Supported by NS06208.

592.11

Glutamate is the principal neurotransmitter identified within the intrinsic circuitry of the hippocampal formation. It is hypothesized that glutamate plays a central role in excitotoxicity associated with temporal lobe epilepsy. In this report we have addressed the organization of the AMPA receptor subunits within this hippocampal circuitry by immunocytochemical localization of the AMPA selective subunits GluR1 and GluR2/3 in relation to patterns of cell loss in patients with temporal lobe epilepsy.

Hippocampal tissue was resected during surgery from patients with medically intractable temporal lobe epilepsy. Representative sections of tissue were placed in 4% paraformaldehyde with 0.2% picric acid. Serial sections were cut either on the vibratome or freezing microtome and stored in a cryoprotectant solution. Tissue was processed immunocytochemically using antibodies generated against the GluR1 subunit and the GluR2/3 subunits.

The localization of these subunits is distinct in the hippocampus. The GluR1 subunit is restricted to fibers of the molecular layer of the dentate gyrus, whereas GluR2/3 subunits' distribution is widespread. Surviving pyramidal cells in all CA subfields stain positively for GluR2/3. In addition, immunoreactive neurons are also present throughout the dentate gyrus. Knowledge of the distribution of selective glutamate receptor subunits can elucidate the effects of cortical injury that may proceed in temporal lobe epilepsy. Supported by NIH grant NS21323.

592.8

GABA-A ALPHA AND BETA RECEPTORS AND GABAA AXON SPROUTING IN HUMAN HIPPOCAMPAL EPILEPSY. T.L. Babb*, G.W. Mathern, J.P. Lete, and J.K. Frickhinger. UCLA School of Medicine, Los Angeles, CA 90024-1769.

Resected human hippocampi (HC) with Hippocampal Sclerosis (HS; n=6) or little HC cell damage (n=4), a large mass lesion and a HC mass lesion (n=2) were compared for GABAergic (GAD-ICC) vs control (FD) (MD) axon sprouting and "matching" changes in post-synaptic GABA-A receptor subtypes. Neuronal and axonal changes in the FD-M were weakly correlated with cell losses in the HP (p=0.07) and FD (p=0.07; i.e. reactive synaptogenesis). The densities of FD-ML receptor subtypes for GABA-A alpha (p=0.28) and beta (p=0.85) did not correlate with neuron loss (i.e. HS). There was a trend for the GABA-A receptor subtypes to have similar densities in the FD-ML (p=0.08) suggesting that both beta types were similarly affected in epileptic FD. Finally, the GABA axon patterns in the FD-ML scored semi-quantitatively, showed varying densities and distributions across the inner through outer molecular layers, and these did not predict GABA-A alpha (p=0.15) or beta (p=0.70) densities, suggesting that in epilepsy there may be heterogeneous remodelling of receptor subtype patterns to aberrant presynaptic terminals. Supported by NS 20808, NIH-FIC, CNPq (Brazil) and K08-NS 061605.

592.10

ANALYSIS OF HUMAN EPILEPSY-ASSOCIATED GENE EXPRESSION BY MESSANGER RNA DIFFERENTIAL DISPLAY. H. Xie, M. L. Brines, J. K. Kim*, N. C. de Leraovere. Sections of Neuropsychology, Neuropathology, and Neuroendocrine Program, Yale University School of Medicine, New Haven, CT 06519.

Human diseases (including temporal lobe epilepsy; TLE) are usually associated with alterations in gene expression. These changes in gene regulation may be the consequence or the cause of the underlying disease. Detailed study of the alterations in patterns of gene expression could provide insight into the etiology of the disease. The objective of this study is to identify genes which are differentially expressed in one subgroup of epilepsy characterized by mesial temporal sclerosis and associated hippocampal reorganization (MTLE), compared to another subgroup characterized by extrahippocampal temporal or neocortical lesions (ExH group). We used mRNA differential display methodology, which involves the reverse transcription of mRNA into cDNA and the use of PCR with random primers to amplify the cDNA signals. We applied the differential display methodology to two pairs of hippocampal specimens obtained from patients operated to control TLE. More than eighty different primer pairs were used for the PCR differential display, which statistically should cover almost all mRNA species. Fifty-two uniquely amplified bands were identified and the corresponding DNA fragment extracted from the dried sequencing gels. Five of the 52 bands have been closed and sequenced to date. Four of them have no matches in the database GenBank, which indicates that those sequences may represent novel mRNA species yet to be characterized. The fifth cDNA fragment is 320 bases long, with a 70% homology (in a 150 bp overlap region) to the innervate transposase gene mariner. Our preliminary PCR, Northern, and Southern blot data indicate that this 320-base sequence is represented in the normal human genome. However, the level of expression in normal humans is reduced compared to epilepsy patients. Further characterization of this gene is in progress. We conclude that mRNA differential display is highly efficient in identification of disease specific genes and in the analysis of gene expression alterations in human epilepsy brain tissue. Supported by NS 27081.

592.12

HIPPOCAMPAL NMDA RECEPTOR NR1 SUBUNIT EXPRESSION IN EPILEPTIC HUMAN HIPPOCAMPUS. I. Nunn*, G. Tooco, V. Comar, R. Kakagi, H. Liiders, and M. Bandeir. Section of Epilepsy Surgery, The Cleveland Clinic, Cleveland, OH, and Neurosciences Program, USC, Los Angeles, CA.

NMDA receptors, subtype of glutamate receptors, have been shown to play an important role in the genesis of seizures. The NR1 subunit of the NMDA receptor is associated with increased neuronal excitability in temporal lobe epilepsy (TLE). We examined the changes in the prevalence of the NR1 subunit mRNA of the NMDA receptor in frontal and temporal lobes of patients with temporal lobe resections in patients with intractable TLE (n=12). In situ hybridizations using a labeled oligonucleotide recognizing the NR1 subunit mRNA of the NMDA receptor were used to generate autoradiograms. Optical density measurements were performed in different hippocampal subfields. Our results show significant increase in NR1 subunit expression in both control and astroglial type immunoreactivity was observed across the hippocampal formations from patients suffering from intractable TLE as compared to control hippocampal tissue obtained at autopsy. The increased expression of NMDA receptor subunit mRNA in hippocampal tissue was apparent in contrast with a previous report showing a decrease in total NMDA receptor/channel binding. This may represent a preferential expression of certain subtypes of NMDA receptors that may explain the apparent variability and participate in the genesis of seizures in patients with TLE. Supported by grant NIH 510377 from NSF (MB).

592.13 IMMUNOHISTOCHEMICAL DISTRIBUTION OF NMDA-RECEPTOR (R1), AMPA-RECEPTOR (R2), AND KAINATE (R5/7) RECEPTOR SUBUNITS IN HUMAN EPILEPTIC HIPPOCAMPUS. L. Blinicka, C. Eischiish, H.C. Wold, O.D. Wiessing. Dept. of Neuropathology, University of Bonn Medical Center, Sigmund-Freud Str. 25, 53105 Bonn, Germany.

Glutamate receptors and receptor-mediated excitotoxicity have recently been associated with the pathogenesis of human temporal lobe epilepsy (TLE). Using monoclonal antibodies, which selectively recognize the N-methyl-D-aspartate (NMDA) R1-receptor, the alpha-amino-3-hydroxy-5-methyl-4-oxo-pyridine (AMPA) R2-receptor and the kainate R5/7-receptor subunits (kindly provided by J.H. Morrison), we have examined the immunohistological distribution of these glutamate receptor isoforms in the hippocampal formation (HC) of patients with intractable TLE. Normal human HC-specimens revealed at autopsy were used as controls. Histopathologically, the specimens were classified into 4 categories: (1) HC without histological alterations; (2) HC with focal lesions, e.g. ganglioglioma, low-grade glioma, dysplasmoepithelial neoplasms, hamartoma or vascular malformations; (21%); (2) HC with Ammonshorn sclerosis (AS); 54%; (4) HC with both focal lesions and AS (15%). Glutamate analysis of the regional and cellular distribution of NMDA R1, AMPA GluR2, and kainate GluR5/7 immunoreactivity showed that the vast majority of neuronal cell bodies and dendrites of the granule and pyramidal cell layers exhibited immunoreactivity for all three proteins. We found no evidence for compensatory upregulation or selective loss of receptor expression in the HC of patients with chronic TLE. A decrease in or loss of immunoreactivity was closely correlated with the overall neuronal loss. So far, there was only one patient with a substantia nigra in HC R1 staining in the polymorphic layer of the dentate gyrus and in the stratum lucidum of CA3. However, this data may indicate that the glutamate receptor subunits are not directly involved in the pathogenesis of human TLE.

Supported by the German BMT-Helmholtz fellowship for I.B.

The transfer of genetic information into hippocampal cells in primary culture, slice preparations and test animals is yielding significant new information about the physiology and pathology associated with the hippocampus. In addition, gene transfer into the hippocampus provides hope for gene therapy in diseases affecting the hippocampus, including some forms of epilepsy.

We have recently developed an adenoviral-associated virus (AAV) vector containing the Lac Z gene, encoding a bacterial ?-galactosidase, under control of a cytomegalovirus immediate Early promoter. This vector and appropriate controls were injected into the hippocampal tissue derived from human patients undergoing temporal lobectomies for medically intractable seizures. Five hundred microliters contained in artificial CSF 3°C for 5 hours, and then 30 ?m thick slices were generated from the larger slices and X-gal staining was performed to ascertain the presence of the bacterial ?-galactosidase. In those slices exposed to the AAV vector with the Lac Z gene, significant ?-galactosidase activity was observed in cells surrounding the injection track. No staining was seen in controls. The implications for gene transfer transfer into the human hippocampus and other CNS locations are addressed.

Rasmussen's encephalitis is a childhood disease of intractable focal seizures and characteristic inflammatory histopathology in the affected brain hemisphere. Two rabbits injected with a bacterial fusion protein expressing neuronal receptor subunit, GluR3, were observed to develop seizures and early histopathological changes similar to those observed in Rasmussen's encephalitis. To test the hypothesis that NMDA GluR3 may be associated with Rasmussen's encephalitis, the sera from affected patients and age and sex matched controls were examined for immunoreactivity towards GluR3 subunits using Western blot analysis and transfected cells. Rasmussen patients with active disease were found to have circulating IgG antibodies to GluR3. In a therapeutic trial of one patient, removal of circulating GluR3 antibodies by plasmapheresis correlated with a reduced rate of seizure and improved cognitive function. Our results suggest that Rasmussen's encephalitis consists of an autoimmune component which includes autoantibodies towards glutamate receptors of the CNS. Supported by NIH grants NS030990, NS28709, NS17771, NS24448, EY08362 and M01-RR-30.

Paraneoplastic (PN) cerebral degeneration is a remote complication of disseminated systemic cancer. This disease is characterized by loss of Purkinje neurons, variable loss of granule cells, and occasional peripheral lymphocytic infiltrates. High titer anticerebellar antibodies are often present. We have examined a series of 16 patients with Type 1 or Type 2 PN disease for autoimmune reactivity to glutamate receptor (GluR) subunits using both Western blot and immunohistochemical analyses. We identified one patient with the Type 1 paraneoplastic disease whose serum exhibited immunoreactivity to GluR5. Unexpectedly, immunohistochemical analyses of mouse brain sections with serum from the same patient exhibited highly specific regional staining of the lateral septum, bed nucleus of the stria terminals, centromedial habenula, and dentate gyrus of R1,3,4,5 subunits in the cerebellum. Staining of this pattern persisted to dilutions of 1:20,000. This pattern of expression is strongly suggestive of an immunohistochemical phenomenon for GluR1,2,3,4,5 (Rogers, et al. JNS 11:2713, 1991). These results suggest that this patient may harbor autoantibodies to more than one GluR subunit. This is the first peptide of GluR1,2,3,4,5 subunits can occur in PD disease, and that this differs from the anti-GluR3 immunoreactivity observed in Rasmussen's encephalitis (see abstract by Rogers et al). Any of these GluR subunits may serve as autoantigens in neurodegenerative disease.

592.18 NEURONAL GLUTAMATE RECEPTOR ANTIBODIES — POTENTIAL EXCITOTOXINS? L.C. Gahing, R.E. Twyman, M.J. Eichen, S.N. Rutweks, L. Jackson, J.R. Baringer* and S.W. Rogers. Programs in Neuroscience and Human Molecular Biology & Genetics, Univ. of Utah School of Medicine and VA-GRECC, Salt Lake City, UT 84112.

Two rabbits injected with bacterially prepared protein of neuronal glutamate receptor subunit GluR3, developed autoantibodies and pathology similar to those observed in Rasmussen's encephalitis (see abstract Rogers et al). Our initial studies have focused on rabbit immune serum and the mechanism of antibody action. Rats injected with at least two epitopes exist in the region of aminocid 245-457 of GluR3 near the presumed extracellular glutamate binding site. Immunohistochemical examination on mouse brain reveals the presence of GluR3 expression consistent with in-situ hybridization studies. These antibodies also identify a small subset of morphologically similar cells in live mouse (E14) cortical neurons in culture. Whole cell electrophysiological studies of these neurons indicate that GluR3 expressed in our model system are non-NMDA sodium currents and that these neurons also have kainic acid inducible currents. Antibody evoked currents were blocked by CNQX and currents were not elicited by other sera. Single cell RT-PCR analysis of these neurons identifies the presence of GluR3 and additional GluR subunits. These results indicate that antibodies to GluR3 have antigen properties on unique properties that include neurotoxicity in conditions such as epilepsy, neurodegenerative diseases and paraneoplastic syndromes.

CHANGES IN HIPPOCAMPAL GLUTAMATE/AMPA RECEPTORS IN EPILEPTIC HUMAN HIPPOCAMPUS

Y. Comait, G. Toecz, J. Njam, R. Kasagi, H. Leolis, and M. Baudry
Section of Epilepsy Surgery, Cleveland Clinic, Cleveland, OH 44195, and Neuroscience Program, USC, Los Angeles, CA 90089

Changes in glutamate receptor properties in the limbic system have been proposed to participate in the increased neuronal excitability observed in human temporal lobe epilepsy (TLE). We examined the changes in binding properties of hippocampal glutamate/AMPA receptors using quantitative ligand binding autoradiography in frozen-sectioned sections obtained from temporal lobe resection in patients with intractable TLE. As observed in rat hippocampal sections, preincubation of human hippocampal sections (n=12) at 15°C resulted in a large decrease in [3H]-AMPA binding as compared to sections preincubated at 0°C. Preincubation at 15°C in the presence of calcium (2 mM) resulted in a large increase in binding as compared to sections that were not treated with calcium. Sectioning from epileptic patients exhibited an increase in binding following preincubation at 35°C in the absence of calcium and no change after preincubation in the presence of calcium as compared to control tissue obtained at autopsy. Our results indicate that TLE is associated with a decrease in synaptic receptors and an increase in non-synaptic (possibly cytoplasmic) AMPA receptors.

Thus, the changes in AMPA receptor binding are more complex than previously reported, and the increase in functional AMPA receptors with calcium at physiological temperature, may contribute to the hyperexcitability in epileptic human hippocampus.

593.1

POTENTIATION OF AUDIogenic SEIZURES BY TMPp AND PTZ IN NAIVE ADULT FISCHER-344 AND SPRAGUE-DAWLEY RATS

G.D. Ritchie*, J. Rossi III, M.S. Buring, C. Ademujohn, J. Smith, T. Morton and M. Langley, Naval Medical Research Institute Detachment (Toxicology) and Geo-Centers, Inc., Wright-Patterson AFB, OH 45433-7803.

Trimethylpropane phosphate (TMPp) and pentyltetrazol (PTZ), two potent convulsants thought to antagonize the GABA, inhibition system, potentiated audiogenic seizures in naive adult Fischer-344 and Sprague-Dawley rats. Doses of TMPp (0.0125-0.05 mg/kg ip) insufficient to produce observable behavioral convulsions or EEG response nevertheless potentiated wild running fits or wild running fits followed by tonic seizures 30 min. after the initial administration. PTZ doses (0.15-0.20 mg/kg ip) sufficient to effect observable behavioral response and EEG paroxysms reliably potentiated wild running fits followed by severe tonic-clonic seizures in 80% of animals tested. Time to initial seizure response following onset of the audiogenic stimulus was linearly dose dependent. In some animals a single TMPp administration potentiated an audiogenic seizure response when animals were acoustically stimulated up to three months later. PTZ (0.0-25.0 mg/kg ip) potentiated audiogenic seizures in naive adult Sprague-Dawley rats 30 min. following the initial dose. This result was unexpected, and may reflect the use of a mixed frequency (8,000 Hz predominant frequency, 110 dB for 60 sec.) audogenic stimulus as opposed to the traditionally used bell or pure tone. The results are discussed in terms of possible neurological mechanisms of action.

593.2

DIFFERENTIAL SUSCEPTIBILITY OF BALB/c, SWISS-WEISTER AND DBA/2 MICE TO INTRAHIPPOCAMPAL a-ACETYLENIC GABA. R. Urbanska*, G. Ceresaol, and R. Schwartz, Maryland Psych. Research Center, Baltimore, MD 21228.

Intrahippocampal application of the 'indirect' excitotoxin a-acetylenic gamma-aminobutyric acid (GABA) (240 nmol) caused a unilateral increase in seizures in rats (Exp. Neurol. 124:186, 1993). Unilateral GABA injections were made into the hippocampus of 3-week-old and adult Balb/c, Swiss-Webster and DBA/2 mice. Animals were killed 3 days later, and their brains were analyzed by light microscopy. Mortality, behavioral convulsions and hippocampal neurotoxicity differed substantially among strains (DBA/2 > Swiss > Balb/c). 360 nmol GABA had virtually no effect in Balb/c mice and led to seizure-related death in 30% of Swiss mice. In contrast, 90 nmol GABA caused 50% mortality in DBA/2 mice. Convulsions developed by 3-5 hrs post injection and often progressed to status epilepticus and tonic death. Hippocampal necrosis was seen in all (and only in) animals which had status epilepticus. Neuronal damage occurred bilaterally in area CA1 and often also in area CA3. Granule and hilar cells degenerated mostly ipsilaterally to the GAG infusion. In DBA/2 mice treated with 90 nmol GABA, the anticonvulsant valproic acid (2 x 350 mg/kg) and the NMDA antagonist CPP (40316 (20 mg/kg) totally abolished seizures and nerve cell death. In mice, therefore, GAG-induced hippocampal neurodegeneration seems to be seizure-related and mediated via NMDA receptors.

593.3

ENHANCED KAINATE SENSITIVITY IN THE HAN-WISTAR RAT. B.W. Cohen*, C. Cepeda, C.A. Crawford, I.E. Margulies, L.B. Watson and M.S. Levine, Mental Retardation Res. Center, UCLA School of Medicine, Los Angeles, CA 90024.

We are studying a mutant Han-Wistar (HW) rat strain which displays a pattern of hippocampal degeneration (CA3 pyramidal cells) and mossy fiber sprouting similar to rat models of epilepsy (i.e., kainate-injected, kindling). We first studied the sensitivity of 40 day old mutants and littermate controls (n=20 pairs) to kainate injections (7-9mg/kg). Bipolar electrodes were implanted in the dorsal hippocampus and EEG recordings were made 3-5 days later. Prior to kainate injections, both mutants and controls did not show any abnormal paroxysmal discharges. After injection, behavioral and electrographic seizures occurred earlier (15-30 mins) and were more intense in the mutant. The mutants' seizures resembled the tonic-clonic type, while the controls exhibited short duration, high amplitude, paroxysmal discharges. Kainate injection was lethal to 50% (10/20) of the mutants but only 5% (1/20) of the controls. Another set of kainate-injected pairs (n=3) was analyzed by immunohistochemistry for the presence of c-fos, a gene regulating protein which becomes elevated in epileptic cells. Mutant hippocampus, which showed no differences c-fos expression prior to kainate treatment, exhibited a 30-40% increase in c-fos compared with controls. To determine a molecular basis of sensitivity, we examined the expression of non-NMDA glutamate receptor mRNA by in situ hybridization. We sampled all regions of the mutant hippocampus, suggesting an enhanced kainate sensitivity in the mutant. We propose that this strain, because of its kainate sensitivity, can be used to understand the complex relationship between cell degeneration and hippocampal reorganization in epilepsy.

593.4

PROCONVULSIVE ACTION OF PERIPHERAL-TYPE (OR MITOCHONDRIAL) BENZODIAZEPINE RECEPTORS IN ET AND 'NEURONAL' MUTANT MICE. Y. Nakamoto*, M. Yoshii, S. Watabe and T. Shitanai.

Dept. of Neurophysiology, Tokyo Institute of Psychiatry, Tokyo 156 and Tokyo R & D Center, Daiichi Pharmaceutical Co. Ltd., Tokyo 134, Japan.

We have recently reported that Ro 5-4864, a specific agonist for the peripheral-type (or mitochondrial) benzodiazepine receptor (PBR), can efficiently induce seizures in E1 mice, an animal model of epilepsy (Nakamoto et al., Soc. Neurosci. Abstr. 16, 380, 1992). To further characterize the proconvulsive action of PBR, we have examined the 'neuronal' mutant mouse, which develops a selective degeneration of cerebellar Purkinje cells with abnormal mitochondria. Ro 5-4864 at a dosage of 20 mg/kg or higher (i.p.) induced seizures consistently in nervous mice, whereas in their controls (heterozygous littermates) seizures could be induced at a lower dosage of 10 mg/kg. In binding assay for [3H]Ro 5-4864 in brain homogenates, the binding of [3H]Ro 5-4864 was reduced more than 50% in cerebella of nervous mice when compared with controls. In contrast, no significant changes in [3H]Ro 5-4864 binding were observed in forebrains between nervous and control mice. There was no apparent alteration in receptor affinity for [3H]Ro 5-4864. The results suggest that PBRs in the cerebellum could contribute to seizures as those in the forebrain.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

Parenteral administration of drugs can cause different rates of absorption. The glutamate agonist kainic acid (KA) is usually administered systemically by either the intraperitoneal (ip) or subcutaneous (sc) route to produce acute tonic limbic seizures in rats and is used as a model for temporal lobe epilepsy. In the present study, KA was systemically administered by ip, sc or intramuscular (im) routes for comparison. Fisher 344 rats were anaesthetized with a neutral pH by the ip, sc, or im route. Behavior was monitored for 30 minutes before and 240 minutes after injection of KA. The number of animals demonstrating behavioral seizures, number of animals exhibiting status epilepticus, behavioral seizure scores, latency to first seizure and latency to status epilepticus were compared for the three parenteral injection routes. Results showed trends for rats with sc injections to have shorter latencies to first seizure and to status epilepticus, for im injected rats to have the longest and ip injected rats intermediate latencies. There was also a trend for ip and im injected rats to have higher seizure scores than sc injected rats. However, there were no statistically significant differences between the three routes of parenteral administration on any of the seizure parameters measured. Seizure response variability due to route of administration will be discussed. Supported by the Department of Veterans Affairs.

THALAMIC-TRIGGERED SEIZURES. G.A. Cotrell*, H. Granasekaram and W.M. Burnham. Blooorview Epilepsy Laboratory, Dept. Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

Past research has shown that the midbrain and hindbrain can produce convulsive seizures when subjected to high levels of stimulation. The present experiment was designed to investigate convulsive behavior patterns elicited from the thalamus. Male Long-Evans rats were implanted with single bipolar electrodes using standard stereotaxic techniques. High-intensity electrical stimulation was administered to 14 thalamic nuclei, at 3 anterior-posterior planes. The posterior nuclei of the thalamus produced a generalized convulsion which was tonic or tonic-clonic, depending on the intensity of the stimulation. These convulsions resembled maximal electroshock seizures. Stimulation of the anterior and middle nuclei of the thalamus produced bilateral forelimb clonus, sometimes preceded by contralateral forelimb clonus. These seizures were never tonic, even at high stimulation levels. The data suggest that the thalamus is capable of producing convergent patterns, one purely clonic and the other tonic-clonic.

This research was supported by the Blooorview Epilepsy Program Grant and the Medical Research Council of Canada.

CITRULLINE INCREASE DURING TEMPORAL LOBEE SEIZURES SUPPORTS THE ROLE OF NITRIC OXIDE FORMATION IN EPILEPSY: AN IN-VIVO MICRORADIOISY STUDY. M.H. Shone, C.L. Wilson, N.P. Maina, E.H. Holgate, J.D. Roberts, J. Fried*. Deps. of Neurology, Anatomy, Psychiatry, Neurosurgery, and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Seizure initiation and spread involving glutamate (GLU) activation of the NMDA receptor may be mediated by Ca2+/calmodulin-dependent conversion of nitric oxide (NO) and citrulline (CIT) from arginine by nitric oxide synthase (NOS). Using in vivo microdialysis, Sorkin (Neuroreport, 1993, 4: 479-482) has shown an NMDA-evoked increase in the levels of CIT and GLU which is blocked by the NOS inhibitor L-NAME. Our hypothesis is that NO is involved in the cascade of events underlying seizure genesis in human epilepsy. Due to its gaseous nature, NO can diffuse to surrounding presynaptic terminals, increasing levels of cGMP and release of transmitter resulting in seizure genesis and propagation. In patients with intractable complex partial epilepsy who require diagnostic studies prior to temporal lobectomy, intracranial probes containing microelectrodes and microdialysis membranes were used to record EEG, single unit activity, and amino acid levels in the hippocampal formation, amygdala and entorhinal cortex. We have observed up to 5-fold increases in glutamate and citrulline during 3 out of 4 complex partial seizures in two patients, and a significant correlation in levels of glutamate with citrulline (r=0.71, p<0.001) both icatally and interictally. These increases provide evidence from the human temporal lobe in support of a role for NO in seizure genesis. Supported by NS 02808.

After global ischemia, rats tend to develop sound-triggered seizures which resemble those seen in genetically epilepsy-prone rats (Reid et al., FASEB J. 8:A660, 1994). We sought to maximize the fraction of post-ischemic seizures induced by the developed audiogenic seizures through an evaluation of 5 possible predictors of post-ischemic seizures in 60 rats. All rats received 7 minutes of chest compression under ketamine anesthesia at a skull temperature of 35°C. Resuscitated rats were tested for sound-induced seizures 24 hours later. The predictors evaluated were blood glucose, skull temperature, time to first spontaneous respiration, time to first EEG activity, and peak blood pressure during reperfusion. Receiver operating characteristic curves indicated that the best single predictor was the amplitude of isoelectric EEG; this had an accuracy value of 0.79. Combinations of predictors did not significantly improve this value, in part because we tried to hold all parameters constant so that the range of measured values was narrow. Supported in part by Alliant Community Trust Fund 9210.

Hippocampal CA1 region is known to be susceptible to global ischemia. The time-dependent change in this region of the post-ischemic seizure prone rats following chest compression was studied in 8 seizure prone rats and 2 controls. Rats were anesthetized and perfused fix 4 h, 48 h, 7 day, and 6 weeks following a 7 min global ischemia. Brains were removed, fixed for 3 more days, before being vibratom-sectioned at 40 μm for light microscopy or microdissected for electron microscopy processing. Decreased width of the stratum pyramidale and a concomitant increase in glial cell was observed in 7 day and 6 week samples. The early perivascular edema showed resolution through glial capping from day 7. Gradual neuronal death and glial migration as well as the presence of neurofilament-rich glia around the micro-vessels were verified by electron microscopy. These results confirmed selective vulnerability of the CA1 pyramidale cells and suggest that gliosis is an important sequela of this global ischemia model. Supported in part by Alliant Community Trust Fund 9210.

In this study we examined dynamic changes of monosynaptically evoked field potential in dentate gyrus (DG) by paired perforant path stimulus (25ms apart) for analysis of local GABA function during low-frequency (2Hz) DG kindling stimulus train using unanesthetized freely moving rats. We also observed extracellular field recording associating with afterdischarge (AD) triggering. During the kindling stimulus train, in all cases AD was triggered prior to occurrence of disinhibition of paired-pulse depression. Furthermore the triggered AD shapes changed with a population spike like component when the disinhibition occurred. By the kindling development, the paired-pulse depression was rather enhanced in the early period of stimulus train and latency until the disinhibition was prolonged. We consider that these findings suggest a possibility that collapse of local GABA mediated inhibition might contribute to seizure propagation rather than its initiation.

Following the recent theoretical prediction that chaotic physical systems might be readily controllable, there has been rapid and successful application of this technique to mechanical systems, electrical circuits, and even systems in cardiac tissue. One of the hallmarks of the human epileptic brain during periods of time in between seizures is the presence of aperiodic bursts of local synchronized neuronal activity known as interictal spikes. The high potassium in vitro hippocampal brain slice preparation exhibits population burst-firing activity that is in many ways analogous to the interictal spike. We sought to determine whether such neuronal bursting activity was amenable to control. Transverse slices 400 μm thick were prepared from the hippocampus of 125-150 gm female Sprague-Dawley rats with a tissue chopper, and placed in an interface type perfusion chamber at 32-35°C. Experiments consisted of combinations of slow control, periodic pacing, and the inverse of chaos control which we term anti-control. Ninety-one experimental trials were performed on 22 slices from 9 rats. Good control of this neuronal circuit was achieved in 14/52 chaos control trials, 8/19 trials using periodic pulses, and in 5/21 attempts at anti-control. This is the second attempt at achieving control of a chaotic biological system, and the first attempt in brain. Chaos control has the advantage over override periodic pacing in terms of its ability to identify and track the system's activity over time. In addition, the control of chaos during this experiment is possible by "anti-control". The anti-control method used here employs a minimum number of stimuli needed to prevent periodic behavior. Such techniques may be applicable to human epileptic foci.

Spike and wave high voltage spikes (HVS) pattern (7.8 Hz) in rodents is an animal model for petit mal epilepsy. These nonconvulsive generalized seizures originate in the thalamus and become bilaterally synchronous in the cerebral cortex through the neural interplay between thalamo-cortical and interictal networks. In this study, microdialysis probes were placed unilaterally to perfuse CNQX (0.01-1.0mM) and high-calcium ACSF (2.4-30.0mM) into the ventral basal (VAVL) and reticular (VTN) thalamic nuclei to alter seizure activity in awake nonanesthetized freely-moving rats. This form of drug administration greatly reduces repeated handling, which can affect seizure rate, while enabling the infusion of dialysates into discrete brain regions. EEG was recorded, after 1 hour of drug washout, for 2 hours with epidural screw electrodes.

High-voltage concentrations did not change overall HVS duration but seizures were limited to the time of calcium perfusion and greatly reduced during normal ACSF perfusion. Calcium infusion outside of the VAVL, VTN did not exhibit this effect. CNQX perfusion: 0.01mM created a 2 Hz delta, 0.1mM amplitude spiking pattern ipsilateral to the probe while not affecting the contralateral HVS pattern. 0.1mM induced a 2 Hz, 0.2mM ipsilateral spiking pattern, while suppressing the contralateral HSV or created ipsilateral 1 mV spiking without affecting the contralateral HSV or decreases ipsilateral HVS. 1.0mM suppressed HVS bilaterally but not completely contralateral to infusion. In most cases HVS durations and amplitudes recovered after 24 hours of ACSF infusion.

These experiments further underline the importance of calcium and the AMPA glutamatergic system in the thalamic oscillations underlying petit mal epilepsy.

Department of Anatomy, California State University, Fullerton, CA 92634. 1. The kainate-treated rat, an animal model of temporal-lobe epilepsy, undergoes an initial period of status epilepticus that can ultimately result in a permanent epileptic state. The aim of the present experiments was to determine the initial effects of kainate-induced seizures on evoked field potentials from dentate granule cells in freely-behaving rats. Chronic in vivo recordings were performed during a 2 day period prior and 1 day after kainate treatment. Rats (n=3) were given pentylenetetrazol (PTZ; 2 mg/kg per hr) for 4-8 hr, and class IV seizures were elicited for ≥ 3 hr. Prior to kainate treatment, single stimuli of the perforant path (at maximal intensity) evoked a positive field-potential PSP that lasted for 15-20 ms with one to two superimposed population spikes. Paired-pulse stimulation of the perforant path (interpulse interval = 20 ms; stimulus intensity that produced a half-maximal population spike) showed attenuation or little change of the field PSP and population spikes to the second stimulus. One day after kainate-induced status epilepticus, however, single stimuli evoked prolonged field PSPs (duration = 63-75 ms) with multiple population spikes. Paired-pulse stimulation led to facilitation of the field PSP and population spike to the second stimulus. The prolongation of the field PSP and the paired-pulse facilitation suggests that recurrent inhibition was depressed in the dentate gyrus of the kainate treated rat. Although further experiments are necessary, these results suggest that relative rapid changes in dentate electrophysiology, apparently including recurrent inhibition, occur following a period of kainate-induced status epilepticus. Supported by NIH grants NS16683 and NS28893.

594.10 MEMBRANE PROPERTIES OF CA3 HIPPOCAMPAL REGION IN THE GENETICALLY EPILEPSY PRONE RATS. Suntaneta Verma-Abuji, M. Steven Evans, and Teresa L. Fenecke, Department of Surgery, Division of Neurosurgery, and Department of Pharmacology, Southern Illinois University School of Medicine, Springfield, Illinois, 62294-9200.

Genetically epilepsy-prone rats (EPR) exhibit a generalized increase in seizure susceptibility. Several factors indicating an increased excitability in CA3 region of the EPRs have previously been reported. These included an increased input resistance, reduction in spike frequency adaptation, less current required to elicit an orthodromic EPSP and marked facilitation with repetitive stimulation in CA3 region. We now have recorded membrane properties from 15 neurons in the CA3 region of Sprague Dawley (SD) rats and five neurons in the EPRs CA3 region. The resting membrane potential and action potential amplitude were not different between the two. A significant difference was seen in the spike frequency adaptation in the GEPR neurons. In SD neurons a suprathreshold stimulus of 800 μs elicits a burst of action potentials followed by a prolonged hyperpolarization lasting 600 to 750 ms. No action potentials were observed following the burst in these neurons. In GEPR neurons there was a significant increase in the number of spikes in the burst. This increased firing in the burst was not followed by a hyperpolarization, and action potentials were elicited throughout the 800 ms depolarizing stimulus. This suggests an abnormality in the calcium or calcium dependent potassium conductance.

Exposing immature rats to hypoxia evokes epileptiform activity which is dependent upon both age and oxygen concentration (Ann. Neurol. 20:629-637). Although perinatal hypoxia leads to increased long term seizure susceptibility, morphological damage has not been demonstrated (Epilepsia 33:971-980; Life Sci. 31:1597-1604). We have attempted to identify hypoxic conditions which will produce short-term hippocampal damage in order to study the possible functional abnormalities resulting from such trauma.

Rats representing 3 age groups (P8-P12, P15-P17, and P20-P27) were exposed to either 15 minutes of anoxia or 3 successive 5 minute single 60 minute treatments. Silver degeneration and Nissl staining revealed no difference between treated and control animals at 1, 4, or 7 days following treatment. Fifteen minute hypoxic exposures (or P8-P12 or P9-P11) did not significantly affect CA1 field potentials or intrinsic properties, but may have altered fast IPSP conductance in hippocampal slices prepared 1, 4, or 7 days after the third treatment.

The immediate posthypoxic period in the hippocampus is characterized by a combination of hypoxia and ischemia. We found that, whereas neither hypoxia nor unilateral carotid ligation alone produced neuropathology, the combination of the two reliably produced neuronal damage (see also Ann. Neurol. 13:131-144). In P8-P12 rats, unilateral carotid ligation followed by 60 minutes of hypoxia induced light terminal degeneration in the terminal field of the mossy fiber (the stratum lucidum in CA3) as well as apparent transcellular cell damage in the pyramidal cell region. Supported by NIH, NINDS grant NS 15117.

594.12 CORTICAL MICROGLIA ARE EPILEPTOGENIC IN VITRO. K.M. Jacobs*, M.J. Gurnick, and D.A. Prince. Dept. Neurology & Neurological Sciences, Stanford University Medical Center, Stanford, CA 94305.

Cortical microglia, thought to be the result of abnormal neuronal migration, are commonly found in the brains of epileptic patients. Clinical data suggest that seizures in some form of malformation of cortical development (MCD) are linked to the presence of bilateral structural abnormality, although mechanisms underlying epileptogenesis in the maldeveloped cortex are unknown. We used a method preparing experimental microglia in rats described by Dvorak and Feit (1977), in which an intracerebral injection of Trypan blue in the 4th ventricle stained the microglia. In initial experiments, Trypan blue microglia were found in the cerebral cortex only in rats treated with a combination of hypoxia and ischemia. We found that, whereas neither hypoxia nor unilateral carotid ligation alone produced neuropathology, the combination of the two reliably produced neuronal damage (see also Ann. Neurol. 13:131-144). In P8-P12 rats, unilateral carotid ligation followed by 60 minutes of hypoxia induced light terminal degeneration in the terminal field of the mossy fibers (the stratum lucidum in CA3) as well as apparent transcellular cell damage in the pyramidal cell region. Supported by NIH grants NS04677, NS12151 and NS07288.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994

It is still a question of much debate whether single epileptic seizures can cause cell loss. A critical implication that epilepsy in general is a progressive disorder, experimental evidence is not conclusive on this point. Recently, it has been shown electrically-induced afterdischarges of less than 2 minutes may induce structural impairments in neurons (Soc. Neurosci. Abst. 1992, 18:553). Here we evaluated whether spontaneous seizures could lead to structural changes. Chronic spontaneous recurrent seizures were induced with pilocarpine (320 mg/kg, i.p.). Animals were sacrificed from 1 h to 6 h after single or multiple seizures. A Golgi-like sensitivity and silver-staining procedure (J.Comp.Neural. 1990, 298:654-673) was used to reveal injured neurons. Silver-stained dark neurons were never found in control animals or in epileptic animals that had no behavioral seizures in the 8 h prior to sacrifice. After spontaneous seizures (injured) dark neurons were mostly interneurons and were present in hippocampus (CA I stratum radiatum), amygdala, piriform cortex and other limbic structures. Animals with multiple seizures had a higher number of dark cells than animals with single seizures. Our findings suggest that even single generalized spontaneous tonic-clonic seizures can induce long-lasting morphological changes. Our results favor the idea that epilepsy is a progressive disorder in which 1 seizure begets the next. Supported by: FAPESP, CNPq and FINEP, L.C. is a CNPq fellow.

AXONAL ARBORIZATIONS OF BICYTIN FILLED CA1 PYRAMIDAL CELLS FROM HYPEREXCITABLE SLICES OF KAINATE TREATED RATS. Y. Perez, F. Morin, J. Jatras, C. Beaulieu and J-C. Lacaille. Center for Research in Neurobiology and Department of Physiology and Pathology, University of Montreal, Montréal, QC, Canada H3T 3J7.

Following hippocampal kainic acid (KA) lesions, CA1 pyramidal cells become hyperexcitable. To examine if sprouting of CA1 pyramidal cells contribute to this epileptiform activity, the axonal arborizations of intracellularly-marked pyramidal cells have been compared in control and hyperexcitable slices of KA treated rats. Hippocampal slices were obtained from Sprague-Dawley rats 2-4 weeks after bilateral intraventricular injection of KA (0.65 µg). Hyperexcitable slices were identified using cholera toxin B subunit (CTB) retrograde labeling. CA1 cells were impaled in control (uninjured) or hyperexcitable slices with microelectrodes containing bicytin (1%) in 1M K-acetate. Synaptic responses were recorded at 100 Hz. Axons from pyramidal cells that could be followed from the soma to the axon were drawn with a camera lucida. In cells from CA1 of control slices, axon branches on average once (mean branch points 0.9 ± 1.0) before entering the alveus and then coursing toward the fimbria or subiculum. In CA1 cells from KA lesioned CA1 pyramidal cells develop more extensive local axon collaterals and this sprouting may contribute to the epileptiform activity.

(Supported by the MRC, FRSQ, FCAR and the Savoy Foundation)

Long-term changes in animal behavior and hippocampal tissue were investigated on the male Wistar rats in which limbic seizures were induced at the age of 5 weeks by subcutaneous injection of kainic acid in order to clarify any plastic changes following seizures. The rats were injected with 50 µg/100 µl of kainic acid at 3-5 weekly intervals until 1-3 hours by diazepam, neuronal loss was observed in the CA1 pyramidal layer of the dorsal hippocampus. Morris water maze learning with a hidden platform) and passive avoidance learning were impaired within two weeks after the seizure. However, the rats learned these tasks well when tested 1-2 months later. A small number of neurons survived in the lesioned pyramidal layer and extended their dendritic branching obliquely and tortuously. Synaptophysin/SV2P immunostaining and cholineresterase histochemistry were not changed in the lesioned CA1, suggesting that some synapses and axon fibers were well maintained. Astrocytes proliferated there and some of them immunoreacted on anti-GABA and anti-glutamate decarboxylase (GAD) antibodies. On the other hand, when the seizures continued over 5 hours without diazepam, the lesion was more extensive and permanent. Neuronal loss was observed in CA1 and the subiculum and the hippocampus was atrophied. The rats did not recover from the impaired water maze learning.

Injection of 75 µg aminoxyacetic acid (AOAA) into the rat entorhinal cortex (EC) produces acute behavioral seizures and selective neuronal loss in layer III of the region (Neurosci. Lett., 147:185, 1992). Since the EC provides a major efferent input to the hippocampus, we examined the hippocampus of rats receiving an entorhinal AOAA injection using Nissl staining and heat shock protein (HSP) immunohistochemistry. BSEP expression has been considered a specific marker of excitation-induced neuronal stress. Rats were sacrificed after 15 or 24 hours, or 5 days. After 5 days, neurodegeneration and gliosis were readily observed in Nissl-stained sections in the subiculum and CA1 field of the ventral hippocampus ipsilateral to the injection site. WSP immunoreactivity (-) were detected slightly after 15 hours following the injection, mainly in the subiculum, CA1 and in the hilus. Rats of HSP-1 neurons remained similar at 24 hours and 5 days after AOAA treatment. These results indicate that injection of AOAA into the EC produces a long-lasting degeneration of postynaptic neurons in the rat hippocampus. AOAA injection into the EC in rats may therefore provide a novel model for temporal lobe epilepsy. Supported in part by USPHS grant NS16102.

THE DENSITY OF DENTATE GRANULE CELL SPROUTING IN HEAT-INDUCED SEIZURES IN THE RAT IS RELATED TO THE NUMBERS OF SEIZURES SURVIVING THE FIRST 14 DAYS. J.H. Kang, B.D. Korfine, and J.C. Lendale*. Section of Neuropsychology, Yale Univ. School of Medicine, New Haven, CT. 06510.

The sprouting of mossy fiber collaterals into the inner molecular layer (IML) of the dentate gyrus has been observed in patients with temporal lobe epilepsy (TLE) (Brain Res, 189, 493-587). Patients that show this phenomenon are often found to have a history of febrile seizures. The relationship of the degree of sprouting to seizure history remains speculative in humans because of the difficulty of obtaining accurate information on the subject. Rat pups experiencing heat-induced seizures also show sprouting. These seizures are ionic-toxic seizures (lasting 30 sec to 5 min) and not status epilepticus, thus resembling seizures in TLE patients. The relationship of the degree of sprouting to the duration of seizures was evaluated in this experimental model. Variable numbers of seizures (1, 6, 12, 24) were induced in different experimental groups of rat pups beginning at 22 days of age. Seizure induction was by exposure of a rat for 4 minutes to water at 45°C. Consequent seizures were induced every fourth day in the multiple seizure groups. The core body temperature of the rats rose from approximately 38°C to 44°C on exposure. Sprouting was observed by the Timm stain. No sprouting was found in the IML of the dentate in the one seizure group. In the six seizure group Timm staining positive particles were limited to the tips and angle of the dentate blades in the IML. Sprouting into the IML was seen in the 12 seizure group, sprouting being strongest at the tips and angle of the blade than in the six seizure group. In the 24 seizure group there was considerably increased sprouting which extended in the IML throughout the entire of the dentate gyrus, with most intense stain at the tips and dentate blade angle. These results support the hypothesis that sprouting is the result of the seizures, and more seizures produce more sprouting. Supported by NS 06038.

CORTICAL CONOTOXIN BINDING DIFFERENTIATES EOSPHAGAL AND NON-EOSPHAGAL MICE. S.K. Jensen, A.F. Burowolls, F. Matsuo, and M.J. Litzinger. Laboratory of Applied Neurology, Department of Pediatrics and *Neurology, University of Utah, Salt Lake City, UT 84132.

Espelin et al. (Epilepsia, 1994) have suggested that N-type presynaptic voltage sensitive calcium channels (VSCC) are differentially expressed in epileptic (DBA/2J) and non-epileptic (C57/B1) mice. Binding with the presynaptic calcium channel probe α-conotoxin, believed to mark N-type voltage sensitive calcium channel (VSCC), was demonstrated in the cerebellum but no differences in synapse formation between these two mouse types. Whole brain α-conotoxin binding was measured by the eye opening postnatal day (PND) 6 C57/B1 mouse brain to have fewer binding sites than its epileptic counterpart DBA/2J mouse. Postnatal day (PND) 16 C57 mouse have significantly more binding sites than the DBA mouse.

The purpose of this study was to show that the majority of binding in the whole brain studies came from cortical VSCC development. Regional dissections were performed as previously described (Litzinger et al., J. Child Neurology, 1994). Preliminary data indicates that the cortex is responsible for the developmental binding differences seen in the whole brain preparations from these two different mouse types. Cerebellar and diencephal-brainstem binding remains relatively unchanged. This data suggests that pre-synaptic VSCC's in the cortex are potentially involved to the seizure susceptibility described by Espelin. For discussion of functional differences see Burrows and Litzinger, this section.

Induction of seizure activity utilizing a variety of techniques including electroconvulsive shock (ECS) and amygdaloid kindling has consistently been reported to produce alterations in thyrotropin releasing hormone (TRH) concentration and increases in prepro-TRH mRNA expression in discrete brain regions. Studies in our laboratory have shown that induction of seizures by kainic acid administration, which activates limbic pathways preferentially, has a more pronounced and prolonged effect on limbic TRH concentrations. To further elucidate the neurochemical basis of the effects of seizure activity on TRH neuronal systems, we have utilized hybridization methods to study systemic kainic acid administration on the expression of prepro-TRH mRNA in limbic brain regions. Male Sprague Dawley rats (180-200g) received a single intraperitoneal injection of either kainic acid, 12mg/kg, in 0.9% NaCl, or vehicle. Separate groups of rats (n=4) were sacrificed by decapitation at 6, 24, 48, and 72 hours, and 14 days post-seizure. Rat brains were dissected at 10cm and processed for in situ hybridization using a [35S]-labeled riboprobe to detect TRH preprohormone mRNA. Significant increases in preproTRH mRNA at 6 and 24 hours were observed in the hippocampus, amygdala, piriform cortex, entorhinal cortex, and the reticular thalamic nucleus following a single stage 5 seizure. In the hippocampus, prepro-TRH mRNA grains were most dense in the dentate gyrus region. After reaching a peak within 24 hours, message levels in these areas gradually declined and reached baselines by 14 days. These findings provide further support for a role of TRH neuronal systems in seizure modulation.

595.11

Employing Northern blot analysis, we examined in the rat the postnatal development of c-fos mRNA expression induced by systemic administration of pentylene trinitrate (PTZ)(50mg/kg) induced after a hour a high level of c-fos mRNA in the neocortex at 23 and 49 days, but not at 8 and 14 days, postpartum as compared with the saline-injected control animals. The induction increased gradually from day 23 to 49, and declined dramatically from day 23 to 49. In contrast, c-fos mRNA was nearly undetectable in the hippocampus of both groups throughout day 8 to 49. Induction of the proto-oncogene c-fos is considered to be a marker of neuronal activity. The present results thus indicate that neocortical neuronal circuits responsive to the drug may alter remarkably between day 23 and 49.

LONG TERM UP-REGULATION OF OXYTOCIN MESSENGER RNA EXPRESSION IN RAT PVN FOLLOWING KAINIC ACID INDUCED SEIZURES. Q.Sun, S.Peter*, C.D. Applegate, D.Pautom, Departments of Neurobiology and Anatomy, University of Rochester, Rochester, NY 14642.

The paraventricular nucleus of hypothalamus (PVN) is the neuroendocrine center for stress-related responses. It is known that the CRF neurons of the PVN have an important role in regulating stress responses of the CNS. Vasopressin and oxytocin (OX) neurons of PVN are traditionally associated with the regulation of CNS responses to disturbances of cardiovascular. However, these neurons might also be involved in CNS responses to other stressful stimuli. Our laboratory had previously shown that the Fos antibody was expressed in OX neurons of PVN in both electrical and kainic acid induced seizures, indicating these neurons were activated by the stress stimulation induced by seizures. To further characterize the involvement of OX in response to seizures, OX mRNA in rat PVN was examined with quantitative in situ hybridization in kainic acid induced seizure. No OX mRNA was observed in PVN seizure animals more than 20% higher than that of control animals at all time points of survival. The level of OX mRNA occurred as early as 1.5 hour following the first stage 5 seizure and remained elevated as long as 4 weeks. These results demonstrate that OX neurons of PVN respond to seizure by up-regulating their mRNA expression. They also demonstrate that this response represents a long term effect of seizures on magnocellular PVN neurons. Supported by NIH grant NS 18626.

NEUROANATOMICAL CONCORDANCE OF ABNORMAL TYROSINE HYDROXYLASE AND c-fos mRNA EXPRESSION DURING FOCAL MYOCYCLIC EPISODES IN THE MOUSE MUTANT TOTTERING (tptg). L.J. Hess* and M.L. Williams, Departments of Neurosceience & Anatomy, The Pennsylvania State University College of Medicine, Hershey Medical Center, Hershey, PA 17033.

Tottering (tg) is a labile autosomal recessive mutation in the mouse that results in a trait of neurobehaviours including spike and wave discharges, ataxia and focal myoclonus. The spike and wave discharges and ataxia have been extensively characterized, however the myoclonus expressed by these mice has been difficult to study because these seizures have no obvious electrical correlates. We have previously identified the myoclonus as a subcortical phenomenon occurring in thalamo-pontine neurons using the expression of the immediate early gene (IEG) c-jun to chart the progression of abnormal nervous system activity. In situ hybridization revealed myoclonus-induced c-fos mRNA expression only in the cerebral cortex and brainstem nuclei and faintly in motor cortex with the highest levels of expression in the cerebellum. We have refined these results and have found that c-jun expression in the cerebellum occurs in the more medial aspects of the cerebellum and is not induced in Crus I or Crus II. Thus, these seizures appear to delimit functionally distinct regions of the cerebellum. We have also previously observed a substantial reduction in basal c-fos expression in brain stem and compared the time course of expression of tyrosine hydroxylase (TH) in the Purkinje cells of these mutants (Neuron, 6:125). Interestingly, TH expression is also restricted to the medial regions of the cerebellum. In fact, in situ hybridization on back to back sections of the cerebellum revealed that c-jun induction during a myoclonic episode occurs in granule cells adjacent to Purkinje cells abnormally expressing TH. These results suggest that not only is the cerebellum important in the generation and maintenance of myoclonus, but it appears that very specific cerebellar regions are affected by the mutation. Additionally, these results suggest that c-jun may directly contribute to the phenotypic expression of the mutant mutation. Supported by a Klingenstein Fellowship.
595.15 GABA<sub>A</sub> RECEPTOR FUNCTION IN THE THALAMUS AND CORTEX IS ALTERED IN RATS WITH EXPERIMENTAL ABSENCE-LIKE SEIZURES. G. Czerneck, M. A. Ivey and P. K. Reuter. Div. Neurol. Childrens Hospital of Los Angeles, Dept. Neurol. Univ. Southern California, School of Medicine, Los Angeles, CA 90027

Both clinical and experimental absence seizures are exacerbated by GABA<sub>A</sub> agonists. We investigated GABA<sub>A</sub> receptor activity during the course of absence-like seizures induced by 4-hydroxybutyric acid (GHB) in rats using receptor autoradiography in brain sections obtained at different time intervals during GHB-induced seizure activity. The 3H-flunitrazepam and [35S]TPPS<sub>3</sub> binding in the parietal cortex was increased, and in the temporal cortex, both binding sites were decreased and increased, respectively. The 3H-flunitrazepam binding was also increased in the thalamus (approx. 25-35%) and cortex (approx. 10-15%) associated with a brief loss of ALP-induced increase in [35S]TPPS<sub>3</sub> binding observed which returned to baseline levels 10 min after the onset of seizures. 3H-flunitrazepam binding rose in midline thalamic structures (by 10%) and cortex (by 15%) throughout GHB-induced absence seizures. There was a selective loss of ALP-induced enhancement of [35S]TPPS<sub>3</sub> binding in cortex, but not thalamus during the course of seizure activity. These results suggest that GABA<sub>A</sub> receptor activity is modulated in a subtle fashion during experimental absence seizures induced by GHB. Whether this is the cause or effect of the experimental absence seizures is not clear.

Sprouting of the mossy fibers into the supragranular region of the dentate gyrus is a well-known regenerative process after epileptic injury. No consensus has been achieved so far about whether new circuitries form as a result of sprouting are excitatory or inhibitory in nature. This study investigated an uncharacterized target for sprouted mossy fibers using a combination of immunofluorescent and Timm stainings. Two months after the injection of mossy fiber sprouting by kainic acid injection, rats were perfused transcardially with 4% paraformaldehyde. Immunolabeled parvalbumin and calbindin were first immunostained for parvalbumin (PV) or calbindin D-28k (CaBP) using FITC-labeled antibodies. Then they were stained using Timm sulfide-silver histochemical method. Analysis of parvalbumin-positive and calbindin-positive neurons and processes was made using the confocal laser scanning microscope revealing that the Timm-positive mossy fibers were in close contacts with the PV- and CaBP-immunopositive neurons within the granule cell layer, through which the sprouted mossy fibers were spreading in the kainic acid injected rats. These results suggest that the PV- and CaBP-containing cells are the targets for the sprouted mossy fibers. Therefore if PV is present in the inhibitory nonpyramidal cells and CaBP in the granule cells sprouting results in formation of both inhibitory and excitatory circuitry. However, it should be noted that we cannot rule out the possibility that the CaBP-positive neurons which were found to be surrounded by mossy fibers in the granule cell layer are not CaBP-containing nonpyramidal cells, and thus inhibitory in nature.
596.3 ANTECEDENT TONE PRESENTATION SIGNIFICANTLY DELAYS RATE OF AMYGDALA KINDLING T.D. Hernandez*, I.A. Warner, P.J. Kahler and A.E. Klugs, Department of Psychology, University of Colorado, Boulder, CO 80309

The degree to which external stimuli contribute to seizure occurrence is an important issue. Can external events elicit the aberrant neuronal activity that precipitates a seizure? Alternatively, can certain external events cue the organism to an impending seizure and result in a compensatory response that is in effect "anti-convulsant"? While several studies have addressed these issues (Hu & Yamaguchi, 1963; Finet et al., 1973; Wyler & Hevner, 1979; Jarowsky et al., 1980; Mostolosky & Myloobdsky, 1982; Myloobdsky et al., 1983; Freeman R.B. Kindling, 1986) the results have been inconsistent. Consequently, we conducted the present study in an attempt to clarify these issues. Twenty-seven male Long-Evans hooded rats were chronically implanted with electrodes in the right amygdala and randomly assigned to one of two groups. The Tone group was presented with a 2-second tone beginning immediately prior to and overlapping with the daily kindling stimulus, while the No Tone group was kindled without the tone. Presentation of the tone significantly delayed the rate of amygandal kindling. All animals in the No Tone group reached a Stage 5 kindled seizure by the 12th daily stimulation, while all animals in the Tone group responded with a Stage 5 seizure by the 22nd daily stimulation. These data indicate that the antecedent presentation of a mild auditory cue has a profound inhibitory effect on the rate of kindling.

596.5 HYPO- or HYPERTHYROIDISM DOES NOT AFFECT AMYGDALA KINDLING-INDUCED THYROTROPIN-RELEASING HORMONE (TRH) mRNA INCREASES IN LIMBIC STRUCTURES. S.L. Kim* and J.B. Rosen, Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.

Our laboratory has demonstrated that TRH mRNA is dramatically increased following amygdala kindling in limbic structures including dentate gyrus, and pyriform, entorhinal and perirhinal cortices, but not in the paraventricular nucleus of the hypothalamus(PVN). The regulatory mechanisms of kindling-induced TRH mRNA expression are not known. Since thyroid hormone regulates TRH mRNA in the PVN, we investigated whether kindling-induced TRH mRNA elevations in limbic regions are also regulated by thyroid hormones. Rats were treated with 0.05% propylthiouracil (PTU) (equivalent to ~30 mg/kg/day) or 4 ug/ml triiodothyronine(T3) (equivalent to ~500 mcg/kg/day) in drinking water for 10 days before kindling and throughout the kindling protocol. Rats were sacrificed 4 hours after a fully kindled seizure. The efficacy of oral treatment of PTU and T3 was confirmed by Northern blotting hybridization of pituitary thyroid-stimulating hormone(TSH) mRNA. TSH mRNA was significantly increased by PTU and decreased by T3, but unaffected by kindling. In addition, in situ hybridization showed that PTU increased and T3 decreased TRH mRNA in the PVN while kindling had no effect on TRH mRNA in the PVN. In contrast, kindling significantly increased TRH mRNA in dentate gyrus, pyriform, entorhinal and perirhinal cortices regardless of PTU or T3 treatment. The findings demonstrate that unlike its effects on hypothalamic TRH mRNA, thyroid hormone manipulation does not alter baseline TRH mRNA expression in extrahypothalamic areas and does not affect TRH mRNA expression following amygdala kindling. These data suggest that hypothalamic TRH mRNA and seizure-induced TRH mRNA in limbic structures are regulated by different transcriptional mechanisms.

596.6 EXTENDED KINDLING RESULTS IN SPATIAL LEARNING DEFICITS IN THE RAT. J.Th. Rick*, S. Cammeule, C.J. Reid, M.P. Murphy, M. Michaela, J. Farbintaneu, and N.W. Milgram, University of Toronto, Scarborough Campus, 1265 Military Trail, Division of Life Sciences, Scarborough, ON, Canada M1C 1A4.

Kindling is a model of epilepsy in which repeated electrical stimulation of various forebrain structures leads to the progressive development of motor seizures. Impaired spatial cognitive functioning, sometimes seen in epileptic patients, has not been observed in kindled animals except when tested shortly after a seizure. Previous kindling studies have reported no long-term deficits in spatial learning, but stimulation was terminated after fewer than 10 class 5 seizures (Baceline Scale). Moreover, more seizures may be required before cognitive deficits arise. In the present study, a total of 12 male Long-Evans hooded rats were stimulated 1-3 times daily through electrodes implanted either in the amygdala (N=5) or perforant path (N=7) until they became spontaneously epileptic or received 300 stimulations. Twelve additional animals with matched electrode placements served as controls. Kindled rats experienced up to 290 class 4 or greater seizures and 5 of these subjects experienced spontaneous motor seizures. Ten days after the termination of kindling, the rats were given 10 trials per day for 3 days in the Morris water maze. Kindled rats required more trials to reach the learning criterion (3 consecutive trials with escape latencies under 20 s) than controls (p<0.0003). The number of major seizures (class 4 and up) was a significant predictor of poor performance (p<0.003). These results suggest that extended kindling can lead to a persistent spatial memory deficit in the rat.

The hippocampus has long been known to play an important role in spatial learning, that interference with hippocampal functioning can produce deficits in tasks that involve spatial learning. Leung (1989) reported that kindling of hippocampal field CA1 disrupts performance in the radial arm maze and that this disruption was caused primarily by hippocampal afterdischarges (ADs) in the absence of behavioral seizures. We asked whether CA1 kindling would disrupt spatial learning in the Morris water maze.

We used two procedures: (1) seizures were kindled with stimulation of CA1 prior to training in the maze (acquisition); and (2) seizures were kindled following maze training, and then retesting in the maze occurred after kindling (retention). In both cases, experimental rats received one daily CA1 stimulation until 3 consecutive generalized seizures were evoked, or until a predetermined number of ADs was reached without eliciting generalized seizures (p<0.05). The rats were tested (or retested) in the maze 24 hours after the last seizure or last AD.

We found that CA1 kindling failed to disrupt maze performance during either acquisition or retention for both rats kindled partially and fully kindled groups, which demonstrated acquisition and retention performance comparable to that in nonkindled controls. These findings are inconsistent with previous results suggesting that memory deficits occur during or after hippocampal kindling and may indicate that deficits are task-specific. (Supported by NSERC)

A single topical dose of Penicillin (Pm) induces a dose dependent "massed" amygdaloid kindling. Interictal spikes (1-3 cps) appear in 1 or 2 minutes after Pm administration and last for several hours. 20 Wistar male rats were anesthetized when used. A calcium-electrode was stereotaxically implanted into the medial amygdala, and a bipolar electrode was placed in the right amygdala. For cortical recording and mapping, a 16 epidural monopolar electrode (stainless steel) array was implanted covering the whole dorsal cortex (frontal, Rolandic, temporo-parietal and visual). Mapping of restricted cortical areas was performed with a moveable 4x4 electrode matrix covering 16 mm².

After a 40 min control recording, each rat was given a dose of Penicillin ranging from 50 to 200 IIU/1 ml which were microinjected in the base-lateral amygdaloid nucleus. Naloxone was IP delivered (0.5-1.0 mg/kg) after the injections. A/P Activity in the NAc and Se was compared before and after naloxone (10 µg/kg). Amygdaloid Penicillin bsp spikes with a variable latency and progressive enhanced frequency and amplitude were observed during a period of 35 min. After a plateaus (1-3 Hz), a frequency decrease was observed. Spiking frequency and amplitude diminished in about 45 min. (200 IUJ). Some animals displayed brief (5 to 10 sec) focal or generalized seizures during this period. Naloxone increased the interictal spike frequency and amplitude. Finally, both massed and massed inhibited Pm spiking when delivered after Pm. When delivered before Pm, the enkephalins depressed the interictal Pm spiking or avoided the Pm effect.

We conclude that enkephalins elicits focal discharges and that this inhibition is blocked by Naloxone.

SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 20, 1994
596.9 THE TIMING OF PERMANENT ALTERATIONS IN SEIZURE SUSCEPTIBILITY DURING KINDLING. J.L. Burdeett* and C.D. Applegate. Comprehensive Epilepsy Program, Dept. of Neurology, Univ. of Rochester School of Medicine, Rochester, NY 14642.

When does kindled seizure development become permanent? It is well known that kindling is permanent after stage 5, but are permanent changes induced at earlier stages. Specifically, does each successive afterdischarge induce permanent alterations through the kindling process or does the process become permanent only after some threshold is reached. We designed an experiment to choose between these two possibilities.

Adult Sprague Dawley rats were kindled from the septal nucleus. Different groups of animals received 6, 9, 12, 15, or 21 stimulations, respectively. Then the animals were stimulated for 4 weeks and the histology, activities and seizures were again stimulated until they reached stage 5 seizures.

If each afterdischarge induces a permanent increase of seizure susceptibility, then the bimodal pattern of development should affect subsequent kindling development. We would predict that: (1) the total number of trials to reach stage 5 should be the same for each group, and (2) the number of post-lusists trials should be invariant related to the number of trials for each group.

The outcome was inconsistent with these predictions, suggesting a lack of permanent alteration of seizure susceptibility during early kindling trials. We conclude that there is a threshold for permanent changes during kindled seizures development. Our data are most consistent with this threshold occurring during the transition from stage 2 to stage 3.

Supported by NID grant NS20351.

596.10 LATERAL OLFACTORY TRACT IS THE OPTIMAL SITE FOR KINDLING T.J. Neto(e), W. Freeman(a), F. Margalh(+) and M.B. Diogo(-). (+) MC-B -Neuroscience. (-) School of Optometry, University of California at Berkeley, Berkeley, CA 94720.

In the late 1960s Graham Goddard discovered the phenomena of kindling, and that stimulating the amygdala produced kindling the fastest. For years this result was not easily replicated. Recently we have discovered that stimulation in the deep layers of the pyriform cortex (PC) caused kindling to occur even more rapidly. This lead us to look at the lateral olfactory tract (LOT) as a stimulus site. We have found that when kindling here requires fewer seizure sessions to bring an animal to stage 5 kindling than stimulating in the amygdala. The olfactory bulb (OB) was found to have the background excitation for the PC through the LOT. Stimulation of the LOT is more efficient than directly stimulating the PC in two ways: 1) the stimulus in the LOT projects broadly to the PC stimulating a large portion of the PC directly and not just a small area around the electrode; 2) the stimulus in the LOT stimulates the OB antidromically as well, thus altering the dynamics of the limbic system very efficiently. The other change we have made from the standard kindling model is the stimulus duration and intensity. The stimulus is much milder (0.1-0.2 ms duration, 60 Hz, 10-15 V) and impedance has been matched to the LOT so that the largest evoked potential in the OB and PC are observed. However, the stimulus requires a longer train (60-10 sec) to elicit a seizure.

596.11 THE KINDLED STATE, BRAIN DAMAGE AND SEIZURE SUSCEPTIBILITY. Craig D. Appleget* and Gary M. Samoriski. Comprehensive Epilepsy Program and Dept. of Neurology, University of Rochester School of Medicine, Rochester, NY 14642.

Several studies suggest that the kindled, kindling-induced increase in seizure susceptibility is not static, but continues to evolve over time. Our studies support this interpretation, and further indicate that impairment of the body's ability to chronically indwelling electrodes significantly contribute to increased seizure susceptibility. Male, C57BL mice were stereotaxically implanted with electrodes into the olfactory bulb and following a 4 week recovery were kindled to a criterion of 6 consecutive stage 5 seizures. Seizure threshold to fluorode (HFE) was tested and 20 days following the last seizure. Both implanted mice tested at the same post-surgical intervals and unimplanted mice served as controls. Kindling significantly lowered HFE thresholds to generalized seizures and 30 days post-kindling in comparison with both control groups. Seizure expression differed at these timepoints, however. Only in the control group was the number of seizures significantly lower at 2 days, whereas b10 extended tonic seizures at 30 days post-kindling. Electrode implantation did not significantly alter HFE thresholds at either time point, but significantly altered seizure expression such that 7/7 exhibited tonic seizures at 30 days, but 0/7 at 2 days. Data suggest that damage caused by implantation of chronically indwelling electrodes significantly lowers the threshold for tonic seizure expression.

596.12 DIFFERENTIAL CHANGES IN THE ACTIVITIES OF MULTIPLE PROTEIN KINASE C SUBSPECIES IN THE HIPPOCAMPAL-KINDLED RAT. Kazutoshi Akiyama*, Mitsuhiro Ono and Kimiyo Tsuzuki and Shigehito Kukudo.*

1Department of Neuropsychiatry and 2Third Department of Anatomy, Okayama University Medical School, 2-5-1 Shikata-cho, Okayama, 700, JAPAN.

In previous studies we demonstrated that the membrane-associated protein kinase C (PKC) activities in the right and left hippocampus (HIP) of rats kindled (from the left HIP) significantly increased 4 weeks and 4 months after the last seizure compared with those in matched control rats (Daigen et al, Brain Res 545:131-136, 1991; Kohara et al, Brain Res 595:195-201, 1992). In the study, we investigated the long-lasting effect of HIPP-kindling on the membrane-associated activities of PKC subspecies in the bilateral HIP in 4 weeks and 4 weeks after the last kindling and the kindling had been induced by the kindling-associated activities of PKC subspecies were found to be subject to differential regulation. The activity of the α-subspecies was unchanged, whereas the reciprocal activities of the γ-subspecies were changed, respectively in the left- and right-subspecies. In the left-subspecies increased significantly, compared with the controls, one week (21%, P<0.0001), for the p-subspecies, and 23%, P<0.001 for the γ-subspecies) and 4 weeks (18%, P=0.001 for the p-subspecies, and 19%, P=0.001 for the γ-subspecies) after the last seizure. There were no significant differences in cytosolic PKC activity between the control and kindled groups for any subspecies, except for the γ-subspecies in the right-subspecies 4 weeks after the last seizure. These results suggest that activation of the PKC p- and γ-subspecies may play an important role in the enduring seizure susceptibility associated with kindling.

596.13 ACETAZOLAMIDE, A CARBONIC ANHYDRASE INHIBITOR, ACTS AS A PROCONVULSANT IN KINDLED RATS. L.J. Burdeett* and M.J. Lotharius.

Dept of Neurology, Graduate Hospital, Philadelphia, PA 19146.

Seizure activity alters extracellular pH which has been shown to influence NMDA and GABA-A-mediated currents. Acetazolamide inhibits the reversible hydration of CO2 by carbonic anhydrase, resulting in more pronounced synaptic transmission. The possibility that pH modulation of synaptic transmission may be affected by repetitive seizure activity (kindling model) was tested by comparing input/output (I/O) and paired pulse depression (20 and 200 ms interpulse intervals) functions recorded from the dentate gyrus of kindled rats before and after acetazolamide (10-20 mg/kg, p.o). Rats were kindled daily by perforant path stimulation (200-800 μAmps, 0.1 ms, 5 Hz, 9 sec) until 5 consecutive generalized seizures were obtained. Acetazolamide had no influence on the kindling-induced potentiation of I/O functions or of GABA-A-mediated early paired pulse depression. A dose-dependent decrease was observed, however, in late paired pulse depression. Rats were kindled for 5 Hz train duration required to elicit an afterdischarge (AD) also was significantly reduced by acetazolamide. We previously have shown that a failure of late inhibition precedes AD initiation, suggesting that the proconvulsant action of acetazolamide in kindled rats may result from the depression of late inhibition. Indirect support of a proconvulsant mechanism for NMDA also has been provided in earlier studies. Together with evidence that NMDA currents are increased at alkaline pH, these findings suggest that kindling may enhance the sensitivity of NMDA-mediated currents to alkaline shifts in the extracellular space, leading to a decrease in late inhibition and enhanced seizure susceptibility. DOWN-REGULATION OF AMYLOID PROTEIN PRECURSOR BY ANTISENSE OLIGONUCLEOTIDES REDUCES NEURONAL ADHESION TO LAMININ, E. Coccini1,2, L.C. Bartlett, P.F. Bartlett, D. Bailey, K. Beversluis1, and C.L. Masters.1 1Dept. Pathology, University of Melbourne, Vic., 3052, Australia. 2 Walter & Eliza Hall Institute for Medical Research, Parkville, Vic., 3052, Australia. 3 Center for Molecular Biology, University of Heidelberg, D-69120, Germany.

The Amyloid Protein Precursor (APP) is known as the source of βA4 amyloid, which forms plaques in brains of Alzheimer’s disease patients. APP forms a complex stabilized by alternatively spliced membrane bound and secreted glycoproteins and is a member of a large APP superfamily. APP isoforms are widely expressed, and in the brain products lacking exon 7 (the KPI domain) and containing exon 15 are most prevalent. The normal function of APP and its role in neurite extension and synaptogenesis is not yet clear. We are investigating the function of APP in neurons using phospholipase A2 antisense oligonucleotides. We find by cell adhesion assay that, after 24-48 hours, P2 mouse dissociated DRG neuronal cultures exposed to antisense APP oligonucleotides are less adherent to laminin (P<0.001) than cultures which are exposed to non-Antisense oligonucleotides of matched base composition. This change in adherence is not observed on other substrates (poly-L-lysine, fibrinogen, and matrigel). An effect on neuronal survival, neurite outgrowth, or neurite branching is not observed but this may be due to a lag time of APP down-regulation by the antisense oligonucleotides. Although neuritic networks are formed 16 hours after plating, the maximal effect on reduction in adhesion is after 48 hours, coincident with the patchy expression of APP on the surface of neurons. These data are consistent with a role for APP as a mediator of medium-term adhesion of neurons to extracellular matrix, and provide support for the specificity of an interaction of APP with laminin.

AMYLOID β PROTEIN PePTIDE (25-35) STIMULATES THE ACCUMULATION OF ALZHEIMER AMYLOID PROTEIN PRECURSOR VIA TAU PROTEIN KinASE I IN CULTURED HIPPOCAMPUS NEURON. A. Takashima1, H. Yamaguchi2, K. Ishigaku1, K. Nishimori1, T. Hoshino1, and K. Ohiri1.1 Research Institute of Life Sciences, 11 Minaminomiya, Machida-shi, Tokyo 194, 2 College of Medical Care and Technology, Gunma University, 3-39-15 Showa, Gunma, Japan.

Pathological changes of Alzheimer’s disease (AD) are characterized by cerebral cortical atrophy as a result of degeneration and loss of neurons. Typical histological lesions include numerous senile plaques composed of deposits of β-amyloid (Aβ) and neurofibrillary tangles consisting predominantly of ubiquitin and highly phosphorylated tau proteins. The exogenous application of synthesized amyloid β protein (Aβ) induced the neurotoxicity in the cultured hippocampal neurons. We recently found that some proteins induced by Aβ treatment leads to a programmed cell death in cultured hippocampal and that tau protein kinase I (TPKI) played a role in the Aβ induced neuronal death. Now we tried to identify the protein which was altered by Aβ treatment in the cultured hippocampal neurons. The level of amyloid protein precursor (APP) in cytoplasm increased by 10 folds of control level in response to exogenous application of Aβ peptide (25-35). The pretreatment of TPKI antisense oligonucleotide inhibited the Aβ induced APP accumulation and neuronal death. These results were interpreted as that TPKI regulated the increased APP accumulation in cytoplasm due to Aβ treatment, and that the increased APP accumulation in cultured hippocampus neuron might contribute to a process of Aβ induced neuronal death.

ECTO-PROTEIN KINASE IN BRAIN NEUROPS: A TARGET FOR ALZHEIMER’S β-AMYLOID PePTIDES. J. V. Hogan1, A. Patel2, J. A. Shimokawa1, H. A. Yang1, and J. A. Redin1.1 Shering-Plough Research, 2 Celltech, Bristol-Myers Squibb, Princeton, NJ 08543, USA.

Ecto-protein kinase (ectoPK) can serve as a direct target for neuroprotective agents that operate extracellularly. To study the effect of amyloid peptides on this activity, we have used primary neuronal cultures prepared from the telencephalon of 7-day chick embryos. The endogenous substrates of ectoPK on these neurons were identified as proteins with MW of 116K, 105K, 67K, 17K, 13K and 12K. The surface phosphorylation of the 12K and 13K proteins is catalyzed by an ectoPK with the specificity of PKC, and is maximal during de-novo neurite outgrowth. The β-amyloid peptide 1-40, when used at neurotoxic concentrations, inhibited the phosphorylation of the 12K and 13K surface proteins (over 80% inhibition of the phosphorylation of the 13K protein by 0.5µM β-amyloid peptide 1-40). At the same concentration, the β-amyloid peptide 1-26, which does not have neurotoxic effects, did not inhibit this phosphorylation. On the other hand, the neurotrophic β-amyloid peptide 25-35 selectively inhibited the phosphorylation of the 12K and 13K proteins by ecto-PK at the same concentration range (0.1-25µM) in which it produces neurodegeneration in cultured neurons. At nanomolar, non-neurotoxic concentrations, β-amyloid 25-35 stimulated this activity. Thus, the direct regulation of extracellular- PKC can mediate both the neurotrophic and neurodegenerative actions of β-amyloid peptides. Supported by HD20788
